Figure 13 An idealistic view of the events attributed to therapeutic granulocyte and monocyte apheresis with the Adacolumn in patients with inflammatory bowel disease. Scanning photomicrographs of leucocytes adsorbed onto a granulocyte and monocyte apheresis (GMA) carrier and the basic events, which follow on the surface of the carriers during GMA in clinical setting (see Figure 4 as well). Normal, non-activated and non-adherent neutrophils and monocytes/macrophages express extensive surface microvilli. The villi bear various receptors like tumour necrosis factor (TNF) receptors, and L selectin, which are shed upon adsorption of the cells to the carriers. Further as seen, adsorbed leucocytes undergo extensive release reaction. Up to now, interleukin-1 receptor antagonist (IL-1ra), hepatocyte growth factor (HGF), IL-10 and soluble TNF receptors have been measured. During GMA, the blood, which returns to patients via the column outflow line may be likened to a biologic cocktail containing a large number of soluble substances released by the adherent leucocytes. The adsorptive nature of GMA is thought to be the most intriguing feature of this non-pharmacological treatment intervention. M: Monocyte; N: Neutrophil; P: Platelet; IBD: Inflammatory bowel disease.

to minimize the number of patients who need such intervention. Centuries ago, bloodletting was a major medical practice to cure disease because of lack of today's medicines, while today, GMA therapy reflects advance in our knowledge of immune behaviour in IBD and a desire to treat without drugs.

Abstract

Patients with inflammatory bowel disease (IBD) are at increased risk for developing colorectal cancer (CRC), although the overall incidence of IBD-associated CRC has been diminishing in recent decades in western countries. As demonstrated in previous studies, the risk of CRC in IBD increases with longer duration, extent of colitis, a familial history of CRC, coexistent primary sclerosing cholangitis, and the degree of inflammation. The pathogenesis of CRC in IBD is poorly understood. Similar to sporadic CRC, IBD-associated CRC is a consequence of sequential episodes of genomic alteration. Multiple inter-related pathways, including immune response by mucosal inflammatory mediators, oxidative stress, and intestinal microbiota, are also involved in the pathogenesis of IBD-associated CRC. Continuing colonic inflammation appears to be a factor in the development of CRC; therefore, anti-inflammatory agents such as 5-aminosalicylate compounds and immune modulators have been considered as potential chemopreventive agents. Colonoscopic surveillance is widely accepted as being effective in reducing the risk of IBD-associated CRC, although no clear evidence has confirmed that

surveillance colonoscopy prolongs survival in patients with extensive colitis. The traditional recommendation has been quadrantic random biopsies throughout the entire colon; however, several guidelines now have endorsed chromoendoscopy with a target biopsy because of increasing diagnostic yields and reduced workloads for endoscopists and pathologists. New technologies such as narrow band imaging, confocal endomicroscopy, and autofluorescence imaging have not yet been confirmed as surveillance strategies in IBD.

INTRODUCTION

Inflammatory bowel disease (IBD) is widely accepted as one of the important risk factors leading to colorectal cancer (CRC). IBD ranks as the third highest risk condition for CRC, behind only familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer syndrome (HNPCC)^[1]. In fact, CRC accounts for one sixth of ulcerative colitis-related deaths^[2].

Recently, a large nationwide Japanese study reported poorer survival for patients with ulcerative colitis (UC)-

Table 1 Summary of cumulative risk of colorectal cancer in patients with inflammatory bowel disease in recent population-based studies and meta-analysis

| Study | Country (n) | Population (n) | Observed period | Incidence of colorectal cancer |
|---------------------------------------|--|---|-----------------|---|
| Eaden <i>et al</i> ^[5] | United States (4), United Kingdom (7), Scandinavia (3), other (5) | UC (meta-analysis of 19 studies) | 1925-1999 | Cumulative incidence 1.6% by 10 yr of disease 8.3% by 20 yr of disease 18.4% by 30 yr of disease |
| Winther <i>et al</i> ^[6] | Copenhagen County, Denmark | 1161 UC | 1962-1987 | Cumulative probability 0.4% by 10 yr of disease 1.1% by 20 yr of disease 2.1% by 30 yr of disease |
| Lakatos <i>et al</i> ^[14] | Veszprem, Hungary | 723 UC | 1974-2004 | Cumulative risk 0.6% by 10 yr of disease 5.4% by 20 yr of disease 7.5% by 30 yr of disease |
| Rutter <i>et al</i> ^[84] | London, United Kingdom | 600 long standing extensive UC | 1971-2000 | Cumulative incidence 0% by 10 yr of disease 2.5% by 20 yr of disease 7.6% by 30 yr of disease 10.8% by 40 yr of disease |
| Söderlund <i>et al</i> ^[8] | Sweden | 7607 UC | 1954-1989 | Cumulative risk 1.5% by 10 yr of disease 3.8% by 20 yr of disease 7.6% by 30 yr of disease |
| Canavan <i>et al</i> ^[9] | United States (3), Denmark (3), United Kingdom (2), Sweden (2), Canada (1), Israel (1) | 11545 CD (meta-analysis of 12 studies) | 1972-2004 | Cumulative risk 2.9% by 10 yr of disease 5.6% by 20 yr of disease 8.3% by 30 yr of disease |
| Kim <i>et al</i> ^[7] | South Korea | 7061 UC | 1970-2005 | Cumulative risk 0.7% by 10 yr of disease 7.9% by 20 yr of disease 33.2% by 30 yr of disease |

CD: Crohn's disease; UC: Ulcerative colitis.

associated CRC than with sporadic CRC in the advanced stage. In addition, UC-associated CRC tended to be of higher histologic grade, such as mucinous or signet ring cell type, and had a greater multiplicity in number when compared to sporadic CRC^[3]. This finding is similar to results reported in the large-scale nationwide population-based Danish study^[4], where the overall mortality rate ratio for UC-associated CRC patients compared with sporadic CRC patients was 1.24 (95%CI: 1.02-1.51) in the first year and 1.17 (95%CI: 1.01-1.36) after 5 years of follow-up. Therefore, identifying the at-risk patients and carrying out appropriate preventions such as chemoprevention or surveillance for these patients is of great importance in managing the CRC risk in IBD.

This review discusses the established risk factors, pathogenesis, and prevention and diagnosis of colon carcinogenesis in patients with IBD.

RISK FACTORS

The most important and well-recognized risk factors identified for IBD-associated CRC are disease duration and extent. The meta-analysis by Eaden *et al*^[5], which included 116 studies from a wide array of centers and geographic sites, was one of several milestones in establishing the incidence and cumulative risk of UC-associated CRC. This global meta-analysis reported that the

incidence, which measures risk over time, was 0.3% per year, or 3 cases of CRC per 1000 patient-years of follow up. Based on long term follow up in a subset of studies included in the meta-analysis, the cumulative risk of CRC in patients with left-sided disease or pancolitis was estimated at 1.6% at 10 years, 8.3% at 20 years, and 18.4% at 30 years after the development of UC. However, the more recently published population studies demonstrated contradictory results (Table 1). A Danish population-based cohort study reported that the cumulative probability of CRC was 0.4% at 10 years, 1.1% at 20 years, and 2.1% at 30 years after the development of UC^[6]. However, these results must be interpreted with caution because they reported high rates of proctocolectomy. Apart from this, several large studies from Hungary, the United Kingdom, and Sweden reported the cumulative risk of CRC in UC as 0.6%-1.5% at 10 years, 2.5%-5.4% at 20 years, and 7.5%-10.8% at 30 years; these studies suggest a low incidence rate of CRC. Recently, a nationwide Korean study involving 7061 patients with UC reported an estimated cumulative risk of ulcerative colitis-associated CRC of 0.7% at 10 years, 7.9% at 20 years, and 33.2% at 30 years^[7]. These results were comparable to Eaden's meta-analysis^[5].

This discrepancy between Western and Asian studies is thought to arise for several reasons. The incidence of ulcerative colitis seems to have reached a plateau in

Western countries; thus, colitic cancer development may also be at a steady state or else decreasing^[8]. However, in Asian countries, ulcerative colitis is still increasing; therefore, the occurrence of colitis cancer is also anticipated to increase. A meta-analysis of 12 published articles by Canavan *et al*^[9] reported that the cumulative risk for patients with Crohn's disease (CD) was 2.9% at 10 years, 5.6% at 20 years, and 8.3% at 30 years after the CD diagnosis. This study showed that cumulative risk of developing CRC, once diagnosed with CD, is comparable to the risk associated with UC^[9].

The extent of colitis is an important risk factor, along with duration, for the development of CRC. The meta-analysis by Eaden *et al*^[5] reported that an overall prevalence of 3.7% for CRC among patients with UC in all 116 studies, but when restricted to the 35 studies that stratified their analyses by extent of UC, the prevalence of CRC among patients with extensive involvement rose to 5.4%^[5,10]. A recent Danish population-based cohort study involving 1515 patients diagnosed with UC also reported that the risk of CRC in patients diagnosed with UC was highest among patients with extensive colitis (standardized incidence ratio, 1.85; 95%CI: 0.60-4.32). Several studies have shown a general consensus indicating little or no increased risk of CRC in patients with proctitis or proctosigmoiditis, whereas the risk is intermediate in those with left-sided colitis and highest with pan-colitis^[5,7,8,11-14].

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease that is strongly associated with IBD. An increased risk of CRC has been observed in patients with IBD complicated by PSC. A meta-analysis by Molodecky *et al*^[15] reported that the pooled proportion of IBD in PSC cases was 68% (58%-77%). Among IBD subtypes, PSC was more common in UC than CD (80% *vs* 10% of cases)^[16]. The association with IBD was stronger with more extensive colonic involvement: in patients with pancolitis, the prevalence of PSC was about 6%, in contrast to 1% in those with only distal colitis^[17]. A meta-analysis of 11 studies involving 16844 patients with UC by Soetikno *et al*^[18] reported that, overall, 21% of the patients with both UC and PSC developed colorectal neoplasms, compared with 4% of patients without PSC. The OR of developing dysplasia or cancer in patients with PSC was thus 4.8 (95%CI: 3.6-6.4), and this increased risk was present even when the risk of CRC alone was considered (OR = 4.3; 95%CI: 2.8-6.5).

Familial history of sporadic CRC increases the risk of CRC by at least two-fold when compared to patients with IBD without familial history for CRC^[19,20]. A population-based cohort study of patients with IBD reported that a family history of CRC was associated with a more than 2-fold risk of IBD-associated CRC (adjusted RR = 2.5; 95%CI: 1.4-4.4); furthermore, patients with a 1st-degree relative diagnosed with CRC before 50 years of age also had a higher risk (RR = 9.2; 95%CI: 3.7-23)^[20].

Chronic inflammation is believed to promote carcinogenesis^[21]. Several lines of evidence indicate that chronic inflammation is a key risk factor for CRC in patients with

IBD^[22]. However, few studies have directly investigated whether the level of inflammation correlates with CRC risk in patients with IBD^[21]. A retrospective case-control study^[23] reported a significant correlation between the colonoscopic and histologic inflammation scores and the risk of colorectal neoplasia. However, multivariate analysis revealed that only the histologic inflammation score remained a significant risk factor. Another retrospective cohort study of 418 patients undergoing colonoscopic surveillance for UC showed similar results, where each unit increase in inflammation score conferred a 3.8-fold increase in the risk for high-grade dysplasia or CRC over time, based on use of a 4-point scale to classify histologic inflammation from a previous retrospective case control study^[23,24]. On the other hand, Velayos *et al*^[25] reported that the history of pseudopolyps increased the risk of CRC in UC by 2.5-fold (95%CI: 1.4-4.6), as a marker of more severe inflammation in the past.

PATHOGENESIS

The pathogenesis of CRC in IBD is poorly understood. Both genetic and environmental factors contribute to this pathogenesis, and the factors responsible for neoplastic changes in IBD can be summarized as follows: genetic instability; epigenetic alteration; immune response by mucosal inflammatory mediators; oxidative stress; and intestinal microbiota^[21,26,27].

Many of the genetic alterations associated with development of sporadic CRC also play roles in colitis-associated CRC^[27,28]. Colon carcinogenesis in IBD is thought to be similar to the adenoma-carcinoma sequence found in sporadic CRC. However, unlike sporadic CRC, which develops from dysplasia in 1 or 2 foci of the colon, cancer arising in colitis mucosa usually develops from multifocal dysplasia, indicating a "field change effect"^[1,21]. Aneuploidy, a marker of genomic instability, is demonstrated at 20%-50% in dysplastic lesion and 50%-90% of cancers and is detected in long-standing UC^[1,27,29,30]. Because aneuploidy is often more widespread than dysplasia in IBD, substantial genomic alterations must occur in colonic mucosa without disturbing morphology^[1,21].

The two major types of genomic instability found in CRCs are chromosomal instability (CIN) and microsatellite instability (MSI)^[31]. CIN and MSI in colitis-associated CRC appeared with the same frequency (85% CIN, 15% MSI) as seen in sporadic CRC, but they differed in the timing and frequency from the pattern seen with sporadic CRC (Figure 1)^[10,21,27,32]. For example, loss of adenomatous polyposis coli (*APC*) function, considered to be a very common initiating event in sporadic colorectal carcinogenesis, is less frequent and usually occurs later in the colitis-associated dysplasia-carcinoma sequence^[32-34]. Loss of *P53* function is an important step in the progression of colitis-associated cancer. In contrast to sporadic CRC, *P53* mutation in patients with IBD occurs early and is often detected in mucosa that is nondysplastic^[26,27,35]. MSI, due to defective DNA mismatch repair, has been

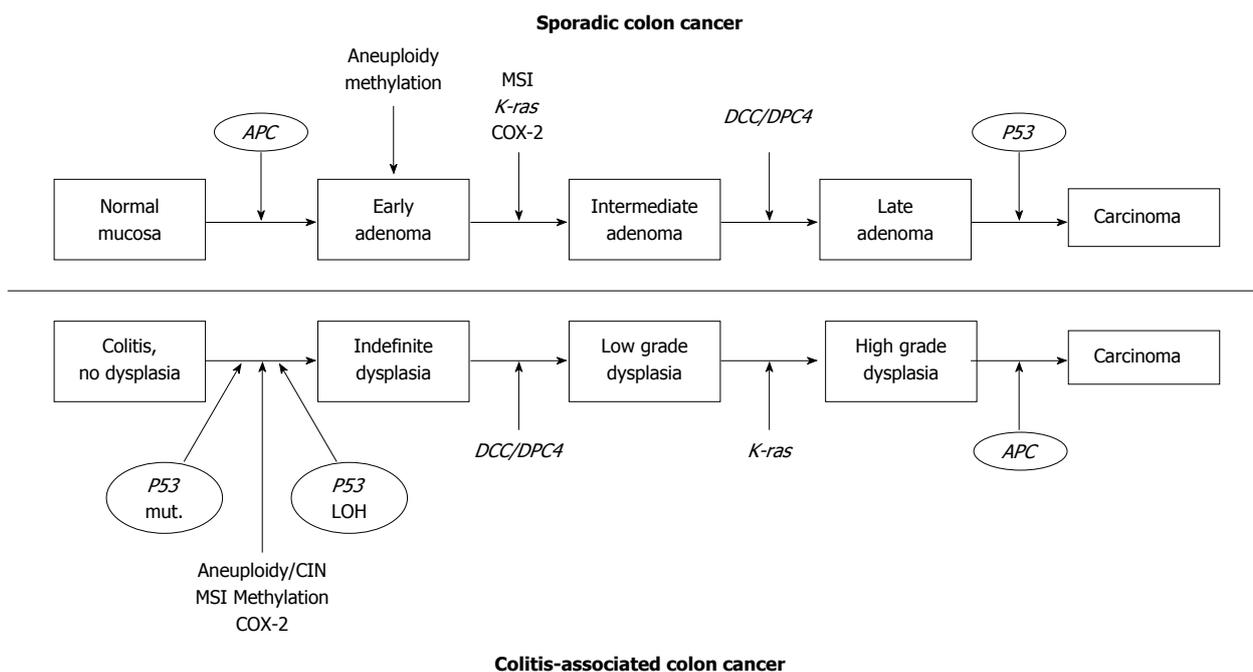

Figure 1 Molecular pathogenesis of sporadic colon cancer and colon cancer associated with inflammatory bowel disease. Many of the genetic alterations associated with development of sporadic colon cancer also play a role in colitis associated colon cancer. However, the frequency and sequence of these events differ between the cancers. Modified from Ref [21]. APC: Adenomatous polyposis coli; MSI: Microsatellite instability; KAS: Kirsten Rat Sarcoma Viral Oncogene Homolog; COX-2: Cyclooxygenase-2; DCC: Deleted in colorectal carcinoma; DPC4: Deleted in pancreatic carcinoma 4; CIN: Chromosomal instability.

reported to occur at variable frequencies in IBD associated CRC^[28,36-38]. The MSI-high (MSI-H) phenotype is observed in approximately 10% to 15% of sporadic CRC^[36].

The CpG island hypermethylation is a key epigenetic mechanism of gene silencing of tumor suppressor genes, including certain DNA repair genes where it acts through hypermethylation of their promoters^[28,32]. Promoter hypermethylation of the mismatch repair gene *bMLH1* is strongly associated with MSI. Among neoplastic samples from patients with colitis, *bMLH1* hypermethylation was observed in 6 of 13 (46%) patients with high levels of MSI, 1 of 6 (16%) with low levels of MSI, and 4 of 27 (15%) without MSI, so it might cause MSI or contribute to its development^[28,32,38]. Likewise, p16INK4a, a cell cycle inhibitor that is also implicated in sporadic colon cancer, is commonly hypermethylated in UC tissues, even in the absence of dysplasia^[28,39].

Other key elements in the pathogenesis of CRC in IBD are related to chronic inflammation, such as the induction cyclooxygenase (COX)-2, inflammatory cytokines, and chemokines. Some evidence indicates that NSAIDs decrease the risk of CRC in IBD patients by 40%-50%^[26,40]. NSAIDs exert their effects through their action on COX enzymes. Among three isoforms of COX enzyme, COX-2 is induced by inflammation and triggered by inflammatory stimuli such as IL-1, IFN- γ , and TNF- α ^[26]. Previous studies have shown that COX-2 expression is elevated in nearly 50% of adenomas and 85% of adenocarcinomas^[41,42]. Agoff *et al*^[43] reported that COX-2 messenger RNA and COX-2 protein over-expression occurred early in UC-associated neoplasia.

TNF- α is released by activated macrophages and T cells; it binds to the receptor TNF-receptor (TNF-R) and has been reported to promote inflammation and colitis-associated cancer^[21]. Several studies have assessed the relationship between the polymorphism of TNF- α -308 G>A and susceptibility to IBD and CRC^[26]. Recently, a meta-analysis study suggested that the polymorphism of TNF- α -308 G>A participates in modifying the susceptibility to UC and CD in Europeans and Asians^[44]. However, the increased risk of CRC in IBD patients should be clarified as the combined effects of polymorphisms in TNF- α and other cytokines and the interaction with environmental factors^[44].

Oxidative stress also contributes to pathogenesis of the colon carcinogenesis by attacking proteins and nucleic acids, resulting in denaturation and a variety of alterations including base modifications, double-base lesions, and strand breaks^[21,45,46]. Oxidative stress develops in response to inflammatory reactions in particular because the inflammatory cells, activated neutrophils, and macrophages produce large amounts of reactive oxygen and nitrogen species (RONS)^[21,26,28]. Inflamed tissues from patients with active UC or CD demonstrate increased expression of nitric oxide synthase (NOS) and RONS^[47-49]. RONS can interact with key genes involved in carcinogenic pathways such as *P53* and DNA mismatch repair genes^[28]. A previous study showed higher levels of *P53* mutation frequencies of both G:C to A:T transitions at the CpG site of codon 248 and C:G to T:A transitions at codon 247 in the inflamed tissue than in the noninflamed tissue of the colon, as well as in colon tissue from normal adult con-

trols^[47]. Another study reported that noncytotoxic levels of hydrogen peroxide dramatically reduced the activities of the mismatch repair system^[45].

Although intestinal microbiota have been considered as contributors to development of colorectal neoplasia in IBD, the mechanism of intestinal microbiota-induced carcinogenesis remains largely unclear^[26,27,50]. Several different rodent models of IBD have suggested that commensal or specific bacteria contribute to the development of colitis-associated cancer. For example, the IL-10 knock-out mice showed IBD (primarily colon and rectum) induced by *Enterococcus faecalis*, as well as rectal dysplasia and adenocarcinoma^[51]. Under specific pathogen free conditions, all IL-10 gene knock-out mice also developed colitis after 3 mo of age, and CRC observed in 25% and 60% of the mice after 3 and 6 mo, respectively^[52]. Modification of enteric flora in IL-10 knockout mice by probiotic lactobacilli was associated with a reduced prevalence of colon cancer and mucosal inflammatory activity^[53].

CHEMOPREVENTION

Chemoprevention has been shown to reduce the risk of adenoma and CRC in the general population without IBD^[54]. Pinczowski *et al.*^[55] first reported a chemopreventive effect of sulfasalazine in IBD, and several agents with chemopreventive potential have since been identified, including 5-aminosalicylate (5-ASA) compounds, immunomodulators, ursodeoxycholic acid (UDCA), and folic acid^[56]. However, prospective randomized controlled trials on chemoprevention are lacking in patients with IBD because of insurmountable obstacles such as ethical problems; consequently, data on chemoprevention in patients with IBD are not clearly definitive and refer to either retrospective case-control or cohort studies^[27,56].

Chronic inflammation has been accepted as one of the causative factors of IBD-associated CRC. The 5-ASA compounds are used as maintenance therapy in patients with UC because they have been shown to reduce inflammation in patients with UC. A meta-analysis of nine studies (three cohort and six case-control studies) that included 1932 UC patients reported that use of 5-ASA in UC was associated with a reduced risk of CRC, and the benefit occurred with regular use and use of at least 1.2 g of mesalamine equivalents per day^[57]. However, subsequent to this meta-analysis, more studies reporting negative results have emerged^[58,60]. A population based case control study showed that among patients with IBD (364 CRC cases, 1172 controls), exposure to 5-ASA therapy of any dose or duration during the 12 mo before CRC diagnosis was not associated with a reduced risk of CRC (OR = 0.97; 95%CI: 0.77-1.23)^[58]. Recently, Bernstein *et al.*^[59] used the Manitoba IBD epidemiology database to show that 5-ASA was not chemoprophylactic in IBD for CRC in either a population-based case control or a cohort analysis. Although the chemopreventive role of 5-ASA compounds has biological plausibility, the chemopreventive effects of 5-ASA in IBD remain conflicting.

Immunomodulators also have anti-inflammatory properties and are used as maintenance therapy in IBD patients. Only limited evidence exists for a chemopreventive role for immunomodulators in IBD. A recent population-based study using a database linked to a nationwide pathology network from the Netherlands demonstrated a significant chemopreventive effect of thiopurine in patients with IBD (the adjusted hazard ratio: 0.10; 95%CI: 0.01-0.75). However, the majority of studies have not shown a chemopreventive effect for immunomodulators^[25,58,61,62]. An 8-year follow up study reported no significant differences in rates of progression to advanced neoplasia or to any neoplasia between azathiopurine/6-MP user and never-user patients with UC^[62]. Another retrospective cohort study also failed to demonstrate any preventive effect of azathiopurine/6-MP^[24].

The chemopreventive role of UDCA therapy is well-supported from studies of patients with concomitant with IBD and PSC. The colonic concentration of additional bile acids has been implicated as a carcinogen, as this is cytotoxic to colonic epithelial cells and induces hyperproliferation^[56]. Therefore, studies have suggested that treatment with UDCA may reduce the risk of CRC in IBD^[63]. A post hoc analysis of a randomized, placebo-controlled trial of patients with UC and PSC suggested a significant chemoprotective effect for UDCA in these patients, with a 74% reduction seen in the risk for dysplasia or cancer in those assigned to the UDCA group^[64]. Tung *et al.*^[65] reported that UDCA use was strongly associated with a decreased prevalence of colonic dysplasia (OR: 0.18; 95%CI: 0.05-0.61). However, a retrospective analysis of data from a randomized controlled trial using a high dose UDCA (28-30 mg/kg body weight) showed that long-term use of high-dose UDCA was associated with an increased risk of colorectal neoplasia in patients with UC and PSC^[66]. The chemoprotective effect of using UDCA for patients with UC but without PSC has not been explored.

Low folate intake has been associated with an increased risk for developing CRC and colon adenoma in sporadic CRC^[27,56]. Folate deficiency is associated with alteration of the normal DNA methylation process, imbalance of steady-state levels of DNA precursors, and changes in chromosome and chromatin^[67]. Patients with IBD are at risk of folate deficiency because sulfapyridine, a moiety of sulfasalazine used in IBD therapy, can lead to an impairment of folate absorption^[68,69]. A meta-analysis showed that both sulfasalazine and folate supplementation have a protective effect in CRC development in patients with longstanding UC^[70]. However, recent studies failed to find a chemopreventive effect of folic acid supplementation^[56,60,71].

DIAGNOSIS AND SURVEILLANCE

One key element to decrease the risk of CRC in IBD may be the early diagnosis by colonoscopic surveillance and treatment of precancerous lesions^[10]. However, ran-

Table 2 Summary of the screening and surveillance recommendation from international guidelines for patients with inflammatory bowel disease

| | ECCO 2008 | BSG 2010 | AGA 2010 | ACG 2010 |
|---------------------------|---|---|---|-------------|
| 1 st screening | 8-10 yr | 10 yr | Max 8 yr | 8-10 yr |
| Surveillance interval | Extensive: 2 yearly to 20 yr then annually Left sided: 2 yearly starting at 15 yr PSC: 1 yr | By risk: low 5 yr Intermediate 3 yr High 1 yr | 1-3 yr More often at high risk <i>e.g.</i> , PSC | 1-2 yr |
| Random biopsy | Recommended | Recommended | Recommended | Recommended |
| Chromoendoscopy | Superior to white light endoscopy | ≥ 33 if no chromo | ≥ 33 | ≥ 33 |

domized controlled trials have not been performed to verify that surveillance colonoscopy is effective. A previous Japanese study reported that close surveillance results in the detection of 48% of the cancers, 61% of which are early cancers^[1,72]. A recent Cochrane analysis concluded that, for patients undergoing surveillance, cancers tend to be detected at an earlier stage and hence have a better prognosis, even if lead-time bias may contribute to the apparent benefit of surveillance^[1,73,74]. Indirect evidence appears to support an effectiveness of surveillance in reducing the risk of death from IBD-associated CRC and that surveillance may be acceptably cost-effective, although no clear evidence was shown that surveillance colonoscopy prolonged survival in patients with extensive colitis^[73,75].

Currently, several guidelines are available for recommending a specific surveillance program in IBD patients^[76-79]. Almost all the guidelines agree on the following: (1) that a screening colonoscopy should be performed on patients during clinical remission of the disease in order to avoid confusion of inflammatory changes with dysplasia; (2) that surveillance colonoscopy should be started 8-10 years after the onset of symptoms for patients with left sided or extensive colitis; (3) that regular surveillance schedules need to be followed after the initial colonoscopy; and (4) that two to four random biopsy specimens should be taken with a jumbo forceps every 10 cm along the entire colon, with additional samples being taken in suspicious areas. Some distinctions are also made, such as the surveillance interval. These are summarized in Table 2.

The success of surveillance colonoscopy will depend on improvement of the diagnostic yield of dysplasia or early colon cancer. As stated previously, many current guidelines recommend quadrantic random biopsies every 10 cm throughout the entire colon^[63,80]. However, a random biopsy only samples 0.03% of the mucosal surface and has a detection rate of < 2 per 1000 biopsies^[80,81]. A retrospective analysis estimated that 33 and 64 biopsy specimens are required to detect dysplasia with 90% and 95% probabilities, respectively^[78,82]. This has served as the basis for the surveillance practice recommendation, and current guidelines for dysplasia surveillance recommend a minimum of 33 biopsies^[10,78]. However, this biopsy protocol has failed to clearly demonstrate any significant

gain in mortality rates and cost effectiveness^[83-85]. Recent data have shown that most gastroenterologists do not follow the biopsy protocol. A previous study from the Netherlands showed that only 27% of gastroenterologists obeyed the recommended number of 33 random biopsies^[86]. Another study showed that more than 50% of the gastroenterologists surveyed obtained fewer than 10 colonic mucosal biopsies per endoscopic surveillance examination^[87,88].

The random biopsy protocol is now increasingly criticized, and increased focus is being placed on target biopsies supported by chromoendoscopy or other newer endoscopic techniques^[10,63,89]. Chromoendoscopy involves the topical application of a dye onto colonic mucosa to improve detection of subtle colonic lesions, characterization, or diagnosis that are not visible with white light endoscopy^[63,78,88]. Previous studies have demonstrated that the use of chromoendoscopy increases the detection rate of dysplasia by approximately 2 to 3 fold and gives a per lesion increase of 4 to 5 fold^[83,90,91]. Comparable diagnostic yields have been obtained with both methylene blue and indigo carmine^[90,92]. Although chromoendoscopy has a demerit of being more time consuming than white light endoscopy, recent guidelines have endorsed chromoendoscopy with target biopsies^[76,77,80,88]. Moreover, recent back-to-back colonoscopy studies have showed that withdrawal times were similar, at 10 min for colonoscopy with random biopsy and 11 min for chromoendoscopy with target biopsy. In addition, a targeted biopsy protocol with pancolonial chromoendoscopy required fewer biopsies to detect dysplastic lesions^[90].

Narrow band imaging (NBI) is another available technique that can provide clear imaging of the microvascular structure. However, NBI was not any more efficacious than conventional colonoscopy in detecting patients with neoplasia in tandem study and multicenter randomized studies^[88,93-95]. Confocal laser endomicroscopy and fluorescence endoscopy are other promising techniques, but only limited data are available. Confocal laser endomicroscopy visualizes the histology of the mucosa and it has been proposed as an addition to chromoscopic detection of lesions to help target biopsy^[80,88]. A recent study showed that endomicroscopy targeted biopsies increased the diagnostic yield of intraepithelial neoplasias by 2.5-fold when compared to chromoendoscopy guided

biopsies alone^[96]. Kiesslich *et al.*^[83] demonstrated that the combined use of chromoscopy and endomicroscopy detected 4.75-fold more neoplasias than could be detected with conventional colonoscopy and 50% fewer biopsy specimens were required.

Fluorescence endoscopy assesses intraepithelial neoplasia after topical or systemic sensitization with 5-aminolevulinic acid (5-ALA), which is converted intracellularly into the sensitizer protoporphyrin IX and accumulates selectively in neoplastic tissue^[88,97]. In a previous study of 37 patients with UC, fluorescence endoscopy after 5-ALA sensitization showed excellent sensitivity, ranging from 87% to 100% after local sensitization, and negative predictive values of non-fluorescent mucosa for exclusion of dysplasia were also very high^[97]. A recent back-to-back study that used autofluorescence imaging, where short-wavelength light provided the excitation of endogenous tissue fluorophores, showed lower neoplasia miss rates for autofluorescence imaging than for white light endoscopy^[98].

CONCLUSION

Recent data about IBD-associated CRC have indicated several new trends. The overall incidence of CRC has been at a steady state or diminishing in western countries in recent decades. However, an anticipated increase in the occurrence of IBD-associated CRC has appeared in Asian countries as a consequence of the increasing incidence of IBD. Studies on the pathogenesis of IBD-associated CRC are now focused on genetic alteration. Interest is rising with regard to the role of several factors, such as oxidative stress, immune responses, and bacterial flora, in colon carcinogenesis in patients with IBD. Prospective randomized controlled trials on chemoprevention in patients with IBD are lacking and data on chemoprevention on patients with IBD are not clearly definitive; however, anti-inflammatory agents such as the 5-aminosalicylate compounds and immune modulators have been considered as potential chemopreventive agents. Several guidelines for surveillance strategy have also recently endorsed the use of a target biopsy that incorporates chromoendoscopy or some new technologies instead of multiple random biopsies. However, the effectiveness of new technologies like narrow band imaging, confocal endomicroscopy, and autofluorescence imaging remain to be proven.

Abstract

Crohn's disease (CD) and ulcerative colitis (UC) are the two main forms of inflammatory bowel disease (IBD) with both overlapping and distinct clinical, pathological and biomolecular features. It has been suggested that pediatric IBD is a distinct disease entity, with probably different disease subtypes. The aim of this study is to review and summarize the evolution of the current concept of pediatric IBD. The results of this review reinforce the idea that pediatric CD and UC may be further classified in various clinicopathologic entities. For clinicians and pathologists convenience, practical algorithms for the distinction of the various subphenotypes of pediatric IBD are also provided.

INTRODUCTION

Inflammatory bowel disease (IBD) represents a group of idiopathic, chronic, inflammatory intestinal conditions in which complex interactions among genetic, immune, and environmental factors are involved. Crohn's disease (CD) and ulcerative colitis (UC) are the two most common forms of IBD with both overlapping and distinct clinical, pathological and biomolecular features. Traditionally, UC is defined as a disease involving the colonic mucosa in a diffuse, continuous manner, always affecting the rectum. In contrast, CD may involve any part of the gastrointestinal tract and frequently shows discontinuous or segmental involvement. However, IBD may be better considered as a syndrome of complex disorders with a significant heterogeneity in disease presentation and course^[1-5]. It has also been suggested that pediatric IBD is characterized by distinct phenotypic differences including disease type, disease location, disease behaviour, gender preponderance and genetically attributable risk, compared to adult-onset IBD^[6-11]. The incidence of IBD in childhood is rising worldwide^[12,13]. Rates are highest in North America and Europe, with rapid increases noted in developing nations adopting a Westernized lifestyle.

Childhood and adolescent IBD accounts for nearly 30% of total cases^[14-17]. Pediatric IBD demonstrates a pattern with CD predominating over UC. In particular, the incidence of CD has risen markedly, while a rather stable incidence of pediatric onset UC has been reported^[18]. A recent study based on the Swedish population found that the incidence of CD was 9.2 per 100000 per person years. The incidence of UC in children over the same time period was 2.8 per 100000 per person years^[19]. Similar rates have been reported by other studies^[20-24].

Recent population based studies have demonstrated a significant male excess in incidence of pediatric CD^[25]. Pediatric CD more often involves the ileocolonic/colonic regions, whereas adult CD does not demonstrate a high proportion of colonic disease^[7]. Furthermore, a variety of phenotypic characteristics have been described in pediatric UC thanks to increasing diagnostic accuracy^[26,27]. Reflecting these trends, IBD classification has been changed from the Vienna statement^[28], through the Montreal classification^[29] to the recent pediatric Paris classification^[30].

Although the precise etiology of IBD remains elusive, both animal and human studies point towards a strong genetic susceptibility. Genome wide association studies (GWAS) identified over 160 susceptibility loci/genes that are significantly associated with IBD^[31-33]. However, newer genomics technologies are now beginning to complement GWAS findings and add to our understanding of the molecular genetic universe of IBD. Genetic studies have provided detailed appreciation of the molecular architecture of IBD, and, in particular, the areas of overlap between CD and UC (such as Th17 pathways) and the pathways which are disease-specific. Moreover, the genes implicated in childhood-onset and adult-onset IBD often overlap, suggesting similar contributory genetic predisposition and pathophysiological pathways. For CD, gene discoveries have focused on defective processing of intracellular bacteria, autophagy, and innate immunity. For UC, the focus has been on barrier function.

A further addition to the complexity of understanding disease mechanisms is that a susceptibility allele often requires other genetic and non-genetic cues to manifest the disease^[34]. The variable concordance rate in monozygotic twins of 27%-50% in CD compared with 15%-19% in UC suggests that non-genetic factors may have an even more important role in UC than in CD^[35,36].

In the present review, we summarize current knowledge concerning the correlation between clinicopathologic features and genetic profiles of pediatric IBD in order to offer practical algorithms for the categorization of the vast majority in this group of lesions.

PARIS CLASSIFICATION

The issue of subclassification of IBD by phenotype has

been reviewed in recent years. The World Congress of Gastroenterology in Vienna, in 1998, considered age of onset (A), disease location (L), and disease behaviour (B) as predominant phenotypic elements^[28]. The Montreal revision of the Vienna classification did not change the three predominant parameters of age at diagnosis, location, and behaviour, but modification within each of these categories was made^[29]. However, the criteria of Montreal Classification has inherent limitations with respect to classification of pediatric IBD. In the pediatric Paris classification^[30] growth failure in the patient at any time was added as G1 *vs* G0 (never growth failure) to classic phenotypic elements (age at diagnosis, disease location, and disease behaviour). The comparisons between the Montreal and Paris classifications for CD and UC are shown in Tables 1 and 2, respectively.

IBD UNCLASSIFIED AND “INDETERMINATE” COLITIS

The term “indeterminate colitis” was originally coined for IBD resections with features of both UC and CD, usually in the setting of severe acute or “fulminant” colitis^[67]. Over the years the term has been adopted by clinicians to describe patients in whom a diagnosis of UC or CD cannot be made based on standard clinical testing, including colonoscopy, imaging, laboratory tests and biopsy^[38]. However, this term has been used incorrectly with considerable confusion among clinicians and pathologists. Recently, it has been recommended that the term “indeterminate colitis” be reserved only for patients for whom a surgical specimen is available and the term “colonic IBD type unclassified” (IBD-U) for patients with no surgical specimen available and for whom endoscopy is inconclusive and histological changes do not fit with either CD or UC^[29]. It remains controversial whether IBD-U constitutes a problem of classification or an IBD subtype distinct from CD and UC. Some authors believe that IBD-U is not a third form of IBD with specific diagnostic criteria, being a provisional diagnosis of exclusion used until a diagnosis of UC or CD is made with certainty^[39,40]. Instead, other authors consider IBD-U as a distinct phenotype of IBD for the following reasons: (1) A recent meta-analysis showed that IBD-U is more common in children accounting for 12.7% of all cases of IBD *vs* 6% in adults^[41]; (2) Children with IBD-U have a disease that rapidly progresses to pancolitis^[42,43]; (3) Although many patients with IBD-U will be reclassified as having CD or UC on long-term follow-up evaluation, a significant proportion of them will still carry the diagnosis of indeterminate colitis^[44]; (4) Epidemiologic data have shown that clinical course and prognosis of IBD-U could be worse compared with UC, especially concerning outcome of surgery with greater risk of pouchitis^[45]; and (5) As will be discussed in the next section, IBD-U is diagnosed in a large subgroup of patients at a very

early age (0-2 years, infantile IBD)^[30-46].

AGE OF ONSET

An important modification recommended by the Paris classification^[30] includes age at onset as A1a (0 to < 10 years) and A1b (10 to < 17 years). In both the Montreal^[29] and Paris^[30] Classification systems, A2 and A3 account for age of diagnosis at 17-40 years, and > 40 years, respectively.

Although rare, IBD may occur before the age of 2 years. Therefore, the Paris classification^[30] suggested the possibility of distinguishing a separate group of children diagnosed with IBD at a very early age (0-2 years, infantile IBD). This subgroup is characterized by a high rate of consanguinity, more severe disease course, association with primary immunodeficiency and resistance to immunosuppressive treatment^[45,46]. Abscess formation, anal fissures and enterocutaneous or rectovaginal fistulae complicate the disease and frequently require partial or total colectomy^[30,47].

The suspicion of a monogenetic cause of these early onset forms was recently confirmed by the discovery of mutations in the genes coding for one of the two IL10 receptors causing impaired IL10 signalling^[48-52].

The region encoding IL10 was originally identified by a German GWAS in UC, and the association docu-

mented with non-coding variants upstream of the IL10 gene^[53]. Subsequently, an international GWAS meta-analysis showed that this region is associated with CD^[54]. Through a genetic-linkage analysis and candidate-gene sequencing on samples from two unrelated consanguineous families with children affected by early-onset IBD, Glocker *et al*^[55] identified three distinct homozygous mutations in genes IL10RA and ILRB. These genes encode the IL10R1 and IL10R2 proteins, respectively, which form a heterotetramer to make up the IL10 receptor. Functional experiments have shown that the *IL10RA* and *ILRB* gene mutations abrogate IL10 signalling and lead to severe intestinal inflammation. Loss of function mutation in IL10 and IL10R was also identified in 66 patients with very early onset IBD. In this study, it has been found that in 5 patients with IL10R deficiency, the allogeneic hematopoietic stem cell transplantation induced sustained clinical remission with a median follow-up time of 2 years^[49]. Recently, Moran *et al*^[50] have identified a novel homozygous, splice-site point mutation in IL10RA in an infantile-onset IBD Caucasian female. The patient was also affected by significant arthritis and folliculitis. The mutation caused a premature stop codon (P206X) and IL10 insensitivity. Moreover, 188 children with early-onset IBD and 188 healthy subjects have been studied. In the discovery cohort, five IL10RA polymorphisms associated with UC have been found^[50]. These studies

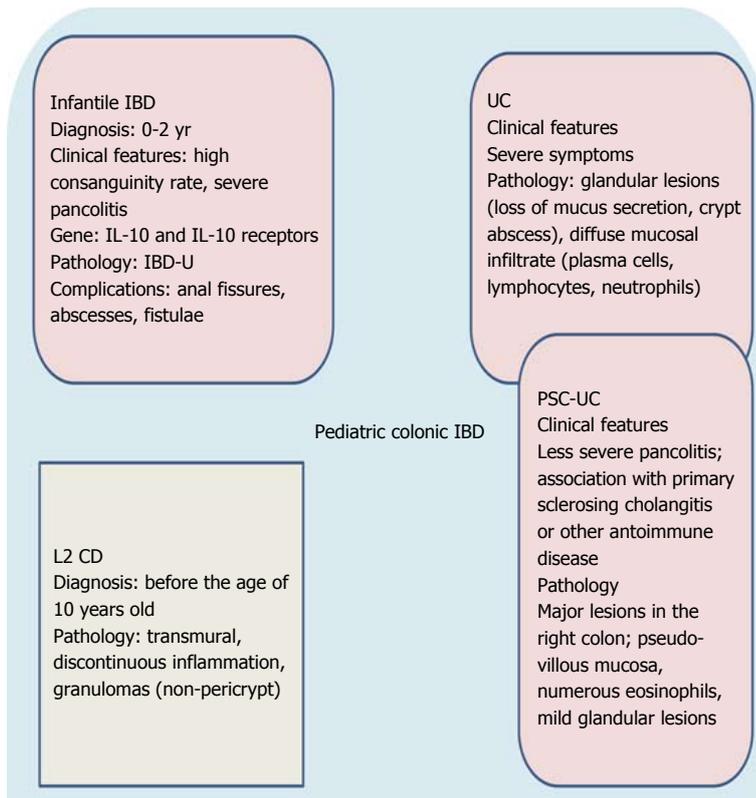

Figure 1 Distinct clinicopathological and biomolecular features of the pediatric colonic inflammatory bowel disease. IBD: Inflammatory bowel disease; CD: Crohn's disease; UC: Ulcerative colitis.

show the role of immune pathways in early onset IBD pathogenesis. Indeed, IL10 is an anti-inflammatory cytokine secreted by a variety of cell types and is critical for maintaining immune homeostasis in the gastrointestinal (GI) tract. IL10 restricts excessive immune response^[56]. In particular, IL10 limits the secretion of proinflammatory cytokines, such as tumour necrosis factor α (TNF- α) and IL12^[57]. Moreover, the assembly of IL10R1 results in the activation of the receptor-associated Janus tyrosine kinases, JAK1 and Tyk2, leading to the phosphorylation of STAT3 (signal transducer and activator of transcription 3) and the induction of STAT3-dependent genes^[58]. A severe enterocolitis has been found in mice that are deficient in either IL10 or IL10R2. These data underline the pivotal role of IL10 in the mediation of signalling that controls inflammation in the gut.

Other monogenic primary immunodeficiencies showing IBD-like gastrointestinal pathology include Wiskott-Aldrich syndrome^[47], chronic granulomatous disease^[47], XIAP deficiency^[55,59], X-linked (IPEX) syndrome^[60] and nuclear factor κ B essential modulator (NEMO) deficiency^[61]. It is also noteworthy that a large subgroup of these patients have IBD-U^[30,42]. Therefore, we think that IBD-U is an IBD subtype distinct from CD and UC as it constitutes a histopathological substrate of a clinicopathologic entity with characteristic epidemiological (< 2 years old), clinical (severe clinical course with pancolitis), and genetic features (*i.e.*, mutation in interleukin-10 receptor and interleukin gene or other primary immuno-

deficiencies). It is, therefore, plausible that infantile IBD (< 2 years) may be incorporated into future modifications of the Paris classification. Figure 1 summarizes the main clinicopathologic characteristics of infantile IBD.

CD

Disease location

According to the Paris classification^[30], CD location is categorized as follows: (L1) involvement of the terminal ileum only, with limited or no cecal disease; (L2) colonic involvement only; (L3) involvement of both the terminal ileum and colon; (L4) isolated upper gastrointestinal disease. L4 is further separated into esophagogastrroduodenal disease (L4A), jejuna/proximal ileal disease (L4B), or both L4A and L4B. Adolescents more often present with ileal disease (L1), whereas children have a tendency to present with isolated colonic disease (L2). Pediatric patients with L2 disease are less likely to have esophagogastrroduodenal involvement or stricturing disease behaviour than patients with L1 and L3 disease^[62]. These data support the existence of discrete subtypes of CD, which are, in part, defined by the predominant anatomical location of disease^[7] and summarized in Table 3 and Figure 2.

Paneth cells are protagonist in the L1CD

Histologic, immunologic and biomolecular evidence strongly suggests a key role for Paneth cells in L1 CD. Histologically, Paneth cells are abundant in the small

IBD: Inflammatory bowel disease; CD: Crohn's disease; UC: Ulcerative colitis.

intestine and are occasionally found in the cecum and proximal ascending colon^[63]. In parallel, L1 (distal 1/3 ileum ± limited cecal disease) CD location corresponds to the normal distribution of Paneth cells.

From an immunological viewpoint, Paneth cells, by virtue of their vast repertoire of effector molecules, are multifunctional cells. They produce antimicrobial proteins such as alpha-defensins HD5 and HD6, lysozyme, secretory phospholipase A2 and the lectin Reg IIIγ^[64]. Wehkamp *et al.*^[65] showed that ileal (L1) but not isolated colonic (L2) CD is associated with a diminished synthesis of Paneth cell defensins. Wehkamp and Stange^[66], therefore, proposed the term “Paneth's disease” to describe a complex disease in which Paneth cells might explain the poor antimicrobial capability of (L1) CD. Paneth cells have also been shown to contain TNF-α transcripts. With ultrastructural immunogold methods, Beil *et al.*^[67] showed TNF-α in mature and immature secretory granules of Paneth cells. One of the major biological roles of TNF-α is in the host defence to bacterial, viral and parasitic infections, and Paneth cells are considered to be the major source of TNF-α in the normal bowel^[67]. Clinical and molecular studies implicate TNF-α as a key mediator in the initiation and propagation of CD^[68]. This is evidenced by an increased amount of TNF in inflammatory cells infiltrating ileal tissue (eosinophils, mast cells, neutrophils, macrophages, fibroblasts) and a marked clinical response of TNF-α antagonists in patients with active CD^[69]. Therefore, abnormal production of TNF-α protein by Paneth cell may be involved in the pathogenesis of L1 CD^[69].

From a histopathological viewpoint, Paneth cell depletion occurs in the most heavily inflamed areas of the ileal mucosa^[70]. Recently, Günther *et al.*^[71] showed a significant decrease in the number of Paneth cells and a high number of dying cells with shrunken eosinophilic cytoplasm at the crypt base in histological samples from terminal ileum of patients with active CD. Paneth cells showed ultrastruc-

tural signs of non-apoptotic cell death, such as organelle swelling, vacuole formation and the lack of blebbing. The data of Günther *et al.*^[71] suggest that necroptosis (a form of non-apoptotic cell death) of Paneth cells might be involved in the pathogenesis of CD.

Recently, VanDussen *et al.*^[72] have studied the correlation between Paneth cell phenotype (based on lysozyme-positive secretory granule morphology) and NOD2 and ATG16L1 genotype. They observed an inverse correlation between abnormal Paneth cells (with disordered, diminished, diffuse, or excluded granule phenotypes) and the presence of granulomas^[72]. The cumulative number of NOD2 and ATG16L1 risk alleles had an additive effect on the proportion of abnormal Paneth cells. Moreover, high proportions of abnormal Paneth cells were associated with shorter time to disease recurrence after surgery. VanDussen *et al.*^[72] suggest stratifying CD based on Paneth cell phenotypes rather than the presence of granulomas. In fact, granulomas could be sparse and more likely to be undersampled, especially in biopsy specimens, whereas Paneth cell phenotypes are more easily analyzed within limited samples. Therefore, these authors concluded that histologic analysis of Paneth cell phenotypes can be used to divide patients with CD into subgroups with distinct pathognomonic and clinical features^[49]. However, further correlative histopathologic and biomolecular studies are necessary to clarify the role of necroptosis and/or granule changes of Paneth cells in L1 CD characterized by abundant or few granulomas (so-called granuloma-rich or granuloma-poor CD).

Biomolecular studies of antimicrobial function in Paneth cells

Defective antimicrobial function in Paneth cells has been described by a variety of mechanisms including mutations in the innate immune receptor NOD 2, defensins, Toll-like receptors (TLRs), the autophagy protein ATG16L1, *IRGM* gene.

NOD2 gene

With the pivotal study of Hugot *et al.*^[73], who discovered the very first and also strongest susceptibility gene for CD in NOD2/CARD15, “IBD gene hunting” was opened. NOD2 is an intracytoplasmic member of the family of intracellular NLR (NOD like receptors) able to recognize pathogen associated molecular patterns (PAMPs) and to modulate an inflammatory response through enhanced NF- κ B activation^[74,75]. NOD2 is highly expressed in cells of the phagocyte system and is involved in the production of defensins in response to gut microbiota. Three single nucleotide polymorphisms (SNPs) within the NOD2/CARD15 gene (R702W, G908R, and 1007fsinsC) have been established as independent risk factors for CD in Caucasians^[76,77] and they represent 82% of the mutations in NOD2^[78]. Interestingly, the NOD2/CARD15 mutations are absent or very rare in Asians, Arabs, Africans, and African Americans^[79]. NOD2/CARD15 variants have been associated to more severe CD, a greater need for surgery and a younger age at onset^[80]. In children, a correlation with ileal (L1) localization^[81-87], stricturing behavior^[82,83,87], early surgery^[83], growth delay^[83,84] and higher disease activity^[83,88] has been found. However, these results have not been confirmed by other studies^[89-91]. The precise mechanistic relationship between NOD2/CARD15 and CD remains controversial. Interestingly, a study by Zelinkova *et al.*^[92] suggested that NOD2 mutations may result in perpetuation of mucosal inflammation through insufficient pathogen elimination.

The important role of NOD2 in the pathogenesis of CD has been underlined by recent studies on microRNAs (miRNAs)^[93]. miRNAs are short non-coding RNAs that have emerged as key modulators of various cellular processes at the post-transcriptional level^[94-96]. There are recent reports on their role in the regulation of intestinal permeability as the loss of intestinal miRNAs impairs the epithelial barrier function, and causes acute inflammation^[97]. Some Authors showed that miRNA-122 regulates intestinal permeability tight junctions (TJ) by targeting occluding mRNA degradation^[98-102]. Moreover, Chen *et al.*^[102] found that NOD2 is a functional target of miRNA-122.

Other mechanisms have been proposed for NOD2/CARD15 mutations in recent years, ranging from abnormal Paneth cell function with reduced defensin secretion, altered modulation of Toll-like receptor signaling and a reduced ability to trigger autophagy^[103]. Several studies have shown the role of defensins in the pathogenesis of CD^[104-107]. In particular, ileal (L1) and ileal colonic (L3) CD is characterized by a specific decrease in small intestinal Paneth cell human α -defensin HD-5 and -6^[106-108]. In a group of pediatric CD, Perminow *et al.*^[109] studied the role of HD5 and TCF-4, a Wnt-signaling transcription factor which controls Paneth cell defensin expression. They showed a low intestinal expression of HD5 and TCF4 mRNA in ileal CD, confirming the important role of antimicrobial host defense in pediatric patients.

Toll-like receptors (TLRs) have an important role in the pathogenesis of CD. They are crucial components of innate immunity and cell surface molecules that also detect normal and pathogenic microbial agents and can trigger antimicrobial host defense responses. TLRs are abundantly expressed on the surface of monocytes, macrophages, and dendritic and epithelial cells^[110]. In IBD mucosa, dendritic cells are activated and there are increased levels of TLR2 and TLR4. These TLRs mediate the recognition of bacterial lipoproteins and LPS, respectively. An association has been described between the TLR4 D299G SNP and IBD, in UC as well as CD patients^[111]. This SNP is associated with impaired LPS signaling and increased susceptibility to gram-negative infections, thus supporting the role of gram-negative bacteria in the pathogenesis of IBD. Polymorphisms have been described in IBD with regard to the TLR9 gene, but their functional significance is still unclear^[112].

Genes of the autophagy: A key role in IBD

The autophagy 16-like 1 (*ATG16L1*), immunity-related guanosine triphosphate M (IRGM), and leucine-rich repeat kinase 2 (*LRRK2*) genes, which regulate autophagy, have been associated with CD in GWAS^[113,114].

Autophagy describes the sequestration of intracellular material such as obsolete organelles or large unfolded protein within membranes, and their trafficking to fuse with lysosome with a subsequent degradation of the contents. Autophagy is now recognized as playing a key role in innate immunity against intracellular microorganisms.

ATG16L1 is essential for all forms of autophagy as it has a role in the clearance of intracellular bacteria^[115]. It interacts with two other autophagy proteins, *ATG5* and *ATG12*, to form a complex essential for the process of autophagy^[116]. The association at *ATG16L1* with CD seems to be entirely accounted for by the *T300A* coding variant which maps to a highly conserved part of the gene adjacent to the coiled-coil domain. *ATG16L1* mutations cause a deficiency of the correspondent protein and disrupt the recruitment of the *ATG12-ATG5*. Therefore, autophagosome formation and degradation of proteins with a long half-life are severely impaired in *ATG16L1*-deficient cells^[117,118]. The decreased autophagy impairs immune tolerance by autoantigen presentation on major histocompatibility complex class II molecules and causes immune inflammation^[119].

ATG16L1 gene mutations could also impair the mechanisms that involve autophagy and apoptosis as there is an acceleration in the rate of epithelial cell apoptosis and an inhibition of inflammatory cell apoptosis in CD and UC^[120,121]. Several studies have been performed on the role of *ATG16L1* gene in the pathogenesis of IBD.

The *T300A* allele was correlated with the incidence of CD in three populations from Germany, Hungary and the Netherlands^[122]. In contrast, no correlation between *T300A* allele and UC was detected. However, the results of other studies on the association of *T300A*

allele with predisposition to CD and UC, are inconsistent^[122], also in child-onset IBD cases^[123]. Recently, a meta-analysis performed on twenty-five studies of CD, 14 of which involved cases of UC^[124] showed that the T300A allele confers a susceptibility to CD and to UC. However, ATG6L1 was associated with the risk of child-onset CD, but not with child-onset UC probably because there are few studies on pediatric UC. Recently, a functional link between NOD2/CARD15, ATG16L1 and autophagy has been provided^[125-128].

IRGM gene

In the Wellcome Trust Case-Control Consortium (WTCCC) GWA scan, a highly significant association between variant flanking IRGM and susceptibility to CD has been shown. The *IRGM* gene is located on chromosome 5q33.1, and is required during the initiation phase of autophagy, when it localizes to bacteria-containing autophagic vacuoles. IRGM and autophagy are involved in clearance of intracellular organisms such as *M. tuberculosis*^[129,130] and the CD-associated IRGM variant is predicted to affect autophagic control of *Salmonella typhimurium*^[131].

The IRGM risk alleles for CD are non-coding and appear to affect mRNA transcription or stability. Over the last 5 years three distinct mechanisms have been identified which might explain the impact on IRGM expression. Cooney *et al.*^[131] discovered a large copy number variant upstream of IRGM which correlated with tissue-specific expression effects. Prescott *et al.*^[132] reported a disruption of a transcription factor binding site in the IRGM promoter. Most recently, Brest *et al.*^[133] found that a synonymous coding variant of IRGM alters the binding domain of miRNA196, a family of miRNAs, hence affecting mRNA stability and gene translation. In this study, it has been shown that microRNA196 is overexpressed in CD patients and that it downregulates an IRGM protective variant but not the risk-associated allele.

Lapaquette *et al.*^[134] found that the reduced *IRGM* gene expression correlated with impaired clearance by macrophages of CD-associated adherent-invasive *Escherichia coli*. A recent Italian study^[135] reported the association between CD and two risk SNPs (rs1000113 and rs4958847) for IRGM, irrespective of age, but not in UC. In addition, a trend to B3 (penetrating) disease behavior in patients with IRGM SNPs was suggested^[135]. Moon *et al.*^[136] showed that IRGM SNP rs10065172 was significantly associated with CD susceptibility. They also reported a protective role of SNP rs72553867.

By suppressive subtractive hybridization (SSH) technique, Sim *et al.*^[137] studied the differential expression gene profiles in ileal biopsies from CD children. Twenty-eight genes previously reported in association with adult CD, and 47 new genes were identified. It is significant that some adult CD genes have also been found in early-onset CD. Indeed, it underlines that, in some cases, there is a common genetic pathway between pediatric and

adult CD cases. Several genes reported in the study are involved in microbial pathogenesis, antigen presentation, inflammation, regulation of epithelial barrier function, vesicular transport or cell differentiation and proliferation. Recent studies have found that IL33 expression is enhanced in the inflamed colonic mucosa of IBD, especially in UC^[138,139], and the IL33/IL1RL1 signalling axis has been implicated in the IBD pathogenesis^[140]. Recently, new genes have been identified by GWAS in IBD^[141-150]. In particular, in 2008, Kugathasan *et al.*^[141] performed the first GWAS in a cohort with pediatric disease onset, identifying two new loci on 20q13 and 21q22. This paper reported the associations with two intronic SNPs (rs2315008 and rs4809330) at the 20q13 locus. These two SNPs map to the zinc finger CCCH-type with G patch domain (ZGPAT) gene which is located in a region containing eight potential candidate genes for CD. Moreover, an association, at the 21q22 region, of CD with the intergenic SNP rs2836878 has been shown that implicated the nearby PSMG1 gene^[141].

A follow-up scan on an extended cohort of 3426 childhood-onset IBD (European/North America collaboration) identified five more new loci associated with pediatric IBD^[147]. These loci included 16p11 near the cytokine gene IL27, 22q12, 10q22, 2q37 and 19q13.11. The results of this study showed that IL27 is a promising candidate gene for pediatric CD. Recently, Latiano *et al.*^[149] have studied a large Italian cohort of adult and early-onset IBD to verify the role of new genes involved in the immune response and inflammation (PTGER4, HLA-BTNL2, TNFSF15, NKX2-3, ZNF365, IFNG, PTPN2, and PSMG1).

Role of colonic epithelial cells producing β -defensins in colonic (L2) CD location.

Since Paneth cells are rare in the colon, the contribution of α -defensins to antimicrobial defence in the large intestine is only limited. In contrast, β -defensins HDB1-3 are secreted by columnar and goblet cells in the colon^[151,152]. A deficiency of β -defensin HDBD2 has been shown by molecular biology in L2 (colonic) CD and confirmed on the protein level by immunohistochemistry^[104]. This observed colonic defect of the antimicrobial barrier caused by a diminished expression of β -defensins may allow luminal microbes to attach to and invade the mucosa triggering the inflammation^[153].

CD behaviour

The Montreal classification^[29] describes three behaviours for CD: nonstricturing nonpenetrating disease (B1), stricturing disease (B2), penetrating/fistulizing disease (B3). In addition, the Paris classification^[30] proposes a new classification B2B3 to identify patients with both B2 and B3 phenotypes (either at the same or different times). Disease locations are the most important factor identified in determining the risk of developing either a structuring or penetrating complication (more complications with ileal, less with colonic disease)^[154]. To date,

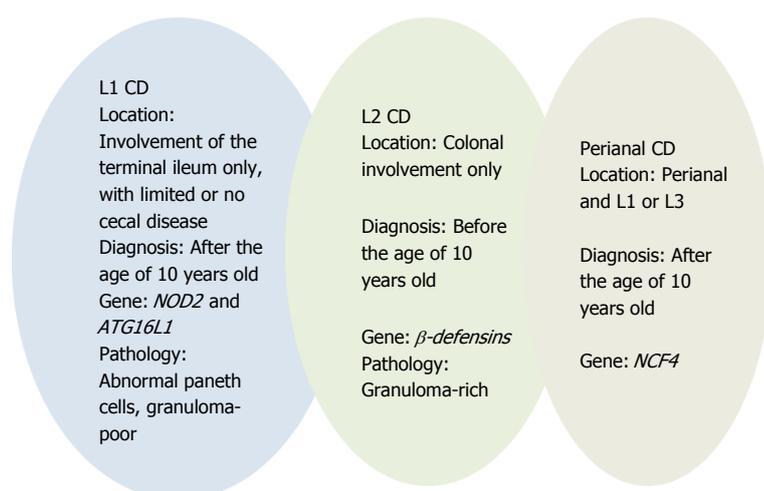

Figure 2 Subtypes of Crohn's disease. CD: Crohn's disease.

there have been few pediatric studies that have evaluated the association between CD behavior and genotype with prolonged follow-up. In a study by Shaoul *et al.*^[155], pediatric CD at the end of follow-up (mean 4.9 years) was classified as inflammatory (78%), stricturing (17%) and penetrating (7%). Moreover, a role for *NOD2* in CD behavior (as opposed to location) was not supported in this study. *NOD2* genotype was clearly associated with ileal involvement (L1), but not as an independent risk factor for stricturing, penetrating disease or a need for surgery^[155]. A recent study showed that L1 CD and stricturing disease behavior are more common in children diagnosed after 10 years of age than in younger patients^[39].

Approximately 10% of newly diagnosed pediatric patients shows perianal CD at time of diagnosis^[156]. The Vienna classification did not distinguish luminal and perianal fistulising disease into different categories^[28]. Subsequent evidence suggested that perianal and luminal fistulae often occur completely independently of each other. According to the Montreal and Paris classifications^[29,30], a separate perianal modifier was added that can coexist with any disease behaviour. Perianal CD is defined as inflammation at or near the anus, including tags, fissures, fistulae, abscesses, or stenosis. A recent study by Eglinton *et al.*^[157] suggests specific associations with perianal CD patients compared with patients without perianal involvement. These associations include younger age at diagnosis, male gender, ileal (L1 or L3) location, and complicated disease behaviour (B2 + B3). In addition, an association with the *NCF4* gene was demonstrated^[157]. Taken together, literature data suggest that perianal CD represents a distinct disease phenotype, summarized in Figure 2.

UC

UC is classically defined as a chronic inflammation characterized by a continuous involvement of the colonic mucosa without granulomas on biopsy, affecting the rectum and a variable extent of the colon in continuity,

and characterized by a relapsing, remittent course^[158]. However, several studies suggest that pediatric UC may present with atypical phenotypes, such as macroscopic rectal sparing, macroscopic skip lesions in the colon, periappendiceal inflammation, backwash ileitis, limited upper gastrointestinal inflammation, and extensive colitis with less severe and less diffuse architectural abnormalities^[159,160]. Thus, diagnosis of UC in pediatric patients may be particularly difficult. The recent Paris classification^[30], which examined this issue, adds a new category (E4) for pancolitis (inflammation extending proximal to the hepatic flexure) (Table 2). Moreover, a disease behavior classification of S0 or S1 was adopted, with the latter denoting the presence of severe disease at any time in patient history (Table 2). The classification of UC based on anatomical extent has clinical relevance, as it affects the choice of therapy and the mode of delivery of drugs. For example, oral therapy is the first choice for UC extending above the splenic flexure^[161].

Primary sclerosing cholangitis (PSC) is a cholestatic liver disease of unknown etiology, commonly associated with IBD and characterized by inflammation, fibrosis, and stenoses of the biliary tree leading to liver cirrhosis^[162]. In most patients (80%-90%) the IBD can be classified as UC. Several features of UC in PSC differ from those of a general UC population (increased frequency of pancolitis, "backwash ileitis", rectal sparing and colorectal carcinoma), and these observations have led to the hypothesis that UC in PSC may represent a specific phenotypic entity (PSC-UC)^[163]. There are a few studies on PSC-UC in pediatric patients. Ordonez *et al.*^[164] studied twenty-eight consecutive children with UC associated with PSC, celiac disease, or autoimmune hepatitis comparing them with a matched control group of 27 children with isolated UC. At diagnosis, pancolitis was seen in 18/28 UC associated with autoimmunity patients compared with 8/27 in UC. Pathological findings were also different from isolated UC: (1) major lesions predominantly located in the right colon; (2) pseudo-villous appearance of the mucosa, and strong infiltration

with eosinophils; and (3) mild glandular lesions. Evolution in UC associated with autoimmune disease was less aggressive, requiring less corticosteroids/immunomodulators^[164]. In conclusion, clinical, histological, and molecular analyses reveal marked differences between pediatric patients with isolated UC and those with associated autoimmune phenomena, supporting the hypothesis of a distinct autoimmune presentation of UC (Figure 1).

Goblet cells as protagonist in the UC

Mucus produced by goblet cells forms a key component of the mucosal barrier. Gel-forming mucins of intestinal mucus are arranged into a bilayer with a firm inner layer devoid of bacteria and a looser outer layer with MUC2 being major constituent of both^[165]. The mucus layer has a crucial role in intestinal homeostasis, as decreased levels of goblet cells, leading to reduced mucin secretion, are a hallmark of human UC^[166]. The thickness of the mucus layer in the healthy colon is between 100 and 300 μm , increasing from the ascending colon to the rectum, whereas in UC, this mucus layer is thinner, more variable and in part denuded^[167-169]. Taken together, several lines of evidence strongly suggest a key role for goblet cells in UC.

Molecular biology of UC

GWAS and candidate gene association studies identified several UC susceptibility loci, including 7 that overlap with CD (*e.g.*, IL23 pathway genes, NKX2-3 and IL10)^[170]. In a recent study, three new UC specific loci (*HNF4A*, *CDH1* and *LAMB1*) has been found that are involved in the regulation of barrier function^[171].

An association was seen at rs6017342 SNP which maps within a recombination hotspot on chromosome 20q13 in which the 3' untranslated region (UTR) of the *HNF4A* gene is located. This gene encodes the transcription factor hepatocyte nuclear factor 4 α which regulates the expression of multiple components within the adherens junction, the tight junction and desmosome^[172].

Cell-cell junctions have an important role on epithelial organization and barrier function. Moreover, in the embryonic age, the *HNF4A* gene participates in the development of mammalian gastrointestinal tract^[173]. *CDH1* gene which encodes E-cadherin has been located on chromosome 16q22. E-cadherin is a transmembrane glycoprotein, a key component of the adherens junction and mediates intercellular adhesion in the intestinal epithelium^[171]. It also participates in processes of epithelial restitution and repair following the damage of mucosa. Indeed, there is a significant reduced expression of *CDH1* in areas of active UC^[174]. Interestingly, two *CDH1* variants associated with UC^[171] have also been associated with colorectal cancer^[175], a possible complication of UC. The recent hypothesis is that *HNF4A* and E-cadherin co-participate to maintain the integrity of the epithelial intestinal barrier. *LAMB1* gene is located on chromosome 7q31^[171] and encodes the laminin β 1 subunit, which is detected in laminins-1, -2 and -10. In

UC, the expression of laminins in the intestinal basement membrane is downregulated^[171].

In 2011, Anderson *et al*^[176] identified 29 additional UC risk loci from a meta-analysis and *IL1R2*, *IL8RA/B*, *IL7R*, *IL12B*, *DAP*, *PRDM1*, *JAK2*, *IRF5*, *GNA12* and *LSP1* were proposed as new important candidate genes in UC pathogenesis. Several genes were associated with cytokines and cytokine receptors, key regulators of cytokine-mediated signalling pathways, innate and adaptive immune response, macrophage activation and regulation of apoptosis. Interestingly, an association with *DAP* gene (death-associated protein) has been found. The expression of *DAP* kinase increases with inflammation in UC^[177] and is a negative regulator of autophagy^[178]. Therefore, the association with *DAP* suggests a possible link between autophagy and UC.

PRDM1, *IRF5* and *NKX2-3* genes could have a key role for transcriptional regulation in UC pathogenesis. *GNA12* which plays a fundamental role in the tight junction assembly in epithelial cells has been identified at the 7p22 locus^[179]. It is the most likely UC candidate gene from those described in the meta-analysis of Anderson *et al*^[176]. Barrier integrity is important in UC pathogenesis given previous associations to *HNF4A*, *CDH1* and *LAMB1* genes^[171]. Further studies are, however, need to verify the role of the genes in pediatric UC. The salient histopathological and biomolecular features of pediatric IBD are shown in Table 3.

CONCLUSION

In conclusion, our review reinforce the idea that pediatric UC and CD may be further classified into various clinicopathologic entities, based on genotype-phenotype correlation reported in recent literature. Therapy for complex genetic diseases such as IBD is difficult. For example, treatment with ant-TNF- α monoclonal antibodies does not induce remission in the majority of CD cases. It is becoming increasingly apparent that novel strategies to define and stratify IBD patients, that are based on serum, DNA and histopathology, will be needed to progress towards improved diagnostics, prognostics and therapeutics.

Abstract

While the etiological underpinnings of inflammatory bowel disease (IBD) are highly complex, it has been noted that both clinical and pathophysiological similarities exist between IBD and both asthma and non-pulmonary allergic phenomena. In this review, several key points on common biomarkers, pathophysiology, clinical manifestations and nutritional and probiotic interventions for both IBD and non-pulmonary allergic diseases are discussed.

Histamine and mast cell activity show common behaviors in both IBD and in certain allergic disorders. IgE also represents a key immunoglobulin involved in both IBD and in certain allergic pathologies, though these links require further study. Probiotics remain a critically important intervention for both IBD subtypes as well as multiple allergic phenomena. Linked clinical phenomena, especially sinonasal disease and IBD, are discussed. In addition, nutritional interventions remain an underutilized and promising therapy for modification of both allergic disorders and IBD. Recommending new mothers breastfeed their infants, and increasing the duration of breastfeeding may also help prevent both IBD and allergic diseases, but requires more investigation. While much remains to be discovered, it is clear that non-pulmonary allergic phenomena are connected to IBD in a myriad number of ways and that the discovery of common immunological pathways may usher in an era of vastly improved treatments for patients.

Key words: Inflammatory bowel disease; Ulcerative colitis; Crohn's disease; Food intolerance; Food allergies; Biomarkers; Pathophysiology; Nutrition; Probiotics

Core tip: There are multiple clinical, pathophysiological and therapeutic commonalities between nonpulmonary allergic disease and inflammatory bowel disease (IBD). In particular, in terms of pathophysiology, histamine expression is upregulated in both IBD and allergic diseases. Ulcerative colitis, in particular, shows upregulation of the Th2 pathway which is seen in a large number of allergic phenomena including sinonasal disease. Both probiotics and nutritional interventions are promising therapies for both IBD and allergic disease (especially food intolerance, food allergies, and eczema) but these require more investigation. Recommending mothers breastfeed their infants, and for a longer duration also shows potential promise in prevention of both IBD and food allergies, but also requires further study.

INTRODUCTION

Inflammatory bowel disease (IBD) is comprised of two major disorders, ulcerative colitis and Crohn's disease (CD). The exact pathophysiology of IBD remains unclear; however immune dysregulation plays a substantial role, with likely significant involvement of the Th1 and Th17 pathways in Crohn's and the Th2 pathway in ulcerative colitis. Intriguingly, some clinical manifestations of allergic disorders and IBD overlap, as well as expression of selected cytokines and immune responses. In particular, both disorders feature histamine release and IgE overexpression. Certain probiotics have been found to be useful in both disorders. There have been some studies that have shown a correlation between sinonasal allergic disease and IBD. Moreover, some food allergies and intolerances have been linked to IBD. Finally, sulfasalazines are often used to treat patients with IBD; such therapy can require desensitization for an individual patient to successfully use. It is evident that allergic disorders and IBD share common etiological characteristics and also share potential common treatment pathways.

HISTAMINE AND OTHER BIOMARKERS ASSOCIATED WITH IBD AND ALLERGY

Role of histamine and mast cells

In 1978, Dvorak *et al*^[1], followed by Levo and Livni^[2], found ultrasonographic and morphological evidence of degranulation of mast-cells in the submucosa of ileal specimens from patients with CD. They found release of mediators including histamine, platelet activation factor, and eosinophil chemotactic factor, all of which may play a role in the pathophysiology of CD. Subsequently, Dvorak *et al*^[1], using transmission electron microscopic studies discovered a markedly increased number of mast cells that were located in the edematous submucosa and between smooth muscle cells in the ileum of subjects with CD. In addition, evidence of degranulation of mast-cells, basophils and eosinophils in the affected area of ileum was also observed^[1]. Similarly, an increased number of mast-cells with intense degranulation was found in the active stage of ulcerative colitis (UC)^[3]. Moreover, it was also demonstrated that the median number of mast-cells in normal colonic tissue was significantly greater in patients with UC than controls (patients examined for colonic adenomas) or those with CD (1500 per milligram of tissue *vs* 1250 per milligram of tissue, $P < 0.05$)^[4]. Furthermore, median mast-cell counts obtained from inflamed colonic tissue were significantly ($P < 0.01$) greater than the number of mast-cells in non-inflamed tissue in patients with

IBD (2000 per milligram of tissue *vs* 1500 per milligram of tissue in UC and 1700 per milligram of tissue *vs* 1250 per milligram of tissue in CD)^[4]. On the other hand, King *et al*^[5] showed an increased mean number of mast cells (19.5) at the demarcation line between active and inactive areas of colonic inflammation in 12 of 20 (60%) UC patients. Finally, a Japanese group determined that patients with IBD or collagenous colitis had a greater number of mast cells in the upper part of the lamina propria of the colon than healthy controls and that patients with IBD had a higher number of mast cells in the lower part of the lamina propria of the colon as compared to those with collagenous colitis and healthy controls^[6].

Knuston *et al*^[7] observed that patients with CD of the distal ileum had a significantly greater mean histamine secretion rate within the small intestine than did healthy controls (152 ng/cm *vs* 71 ng/cm small intestine per hour, $P < 0.01$), and that histamine secretion was related to disease activity (active disease defined as CDAI > 150 : 193 ng/cm per hour *vs* inactive disease defined as CDAI < 150 : 105 ng/cm per hour). Further study also suggested that histamine secretion was significantly increased in inflamed colonic mucosa in patients with both CD and UC when compared to their non-inflamed colonic mucosa or colonic mucosa in healthy controls^[8]. A more recent study showed that urinary excretion of *N*-methylhistamine was significantly increased in patients with active IBD when compared to inactive IBD or non-IBD controls and such urinary histamine excretion strongly correlated with endoscopic activity of CD measured by the CD Endoscopic Index of Severity ($r^2 = 0.70$, $P < 0.0001$)^[9]. Greater expression of tumor necrosis factor- α (TNF- α) by mast cells was also found in the submucosa and muscularis propria of the ileum in patients with CD when compared to controls; significantly greater numbers of TNF- α -labeled mast cells were noted in the muscularis propria both in uninflamed (1.7-fold, $P < 0.05$) and in inflamed ileum (4.6-fold, $P < 0.002$)^[10]. In addition, TNF- α expression was found to be greater in the submucosa in inflamed *vs* uninflamed ileum in CD patients (1.6-fold, $P < 0.01$), while it was lower in the lamina propria in inflamed *vs* uninflamed ileum in CD patients (0.4-fold, $P < 0.05$)^[10]. This is noteworthy as TNF- α has been shown to be an important factor in the inflammatory cascade leading to the inflammatory response in the murine model for IBD^[11].

IgE

IgE as a biomarker of disease activity in IBD: It has been suggested that IgE may mediate an allergic response in patients with IBD. Evidence supporting this hypothesis includes the presence of peripheral and tissue eosinophilia in IBD patients^[12,13], increased numbers of mast cells or cells containing IgE in rectal mucosa of patients with IBD^[14,15], concomitant atopic disease in patients with IBD^[16,17] and a good response to disodium cromoglycate in IBD patients^[18-20].

Several studies have assessed IgE levels in patients with IBD. Pepys *et al*^[21] suggested that some patients with IBD (25% of UC patients and 31% of CD patients) may

have elevated serum IgE levels. These data were further supported by Levo *et al.*^[22], who claimed that patients with IBD have significantly increased mean serum level of IgE when compared to healthy controls (358 IU/mL *vs* 103 IU/mL, $P < 0.05$). On the other hand, several studies report normal serum IgE levels in IBD patients^[23-26]. Becker *et al.*^[25] determined that specific serum IgE levels to food allergens such as egg white, whole milk, β -lactoglobulin and wheat were undetectable in IBD patients and thus suggested that the allergic hypothesis of IBD should be rejected. However, a prior study by Mee *et al.*^[26] observed a significantly higher frequency of positive reactions to food allergens using the skin prick test in IBD patients when compared to healthy controls.

Role of IgE in desensitization to therapies for IBD:

Desensitization to sulfasalazine (SASP) has been found to be effective in patients who experienced hypersensitivity reactions to SASP^[27-30]. This is achieved by administration of successively larger doses of SASP, thereby allowing the presence of specific IgE in a controlled fashion without causing massive histamine release from mast cells^[29]. In the largest published study, reporting on 47 patients with IBD, desensitization was successful in 85% of patients with IBD, and there was no recurrence of hypersensitivity reactions in 82.5% of those who were successfully desensitized^[29]. In addition, among the successfully desensitized patients, 100% of UC patients and 78% of CD patients remained in long-term remission on SASP alone or in combination with intermittent prednisone^[29]. Caution is advised in attempting desensitization in patients with agranulocytosis, toxic epidermal necrolysis, or fibrosing alveolitis^[30]. The risks of these severe reactions may outweigh the benefit of continuing to take SASP containing medications.

PROBIOTICS

At a workshop held at Yale University in 2007, recommendations were made with regards to the use of probiotics in clinical settings for a variety of indications, including IBD^[31]. For IBD, the recommendations included a class “A” recommendation (defined as one made on “strong, positive, well-conducted controlled” studies) for the use of VSL#3 for the prevention and maintenance of remission in pouchitis^[31]. In addition, some probiotics were given a class “C” recommendation (one “based on some positive studies”) for IBD^[31]. These included VSL#3 for the induction of remission of pouchitis, and for inducing remission and maintenance of remission in ulcerative colitis^[31]. The probiotic *Lactobacillus* GG (LGG) was noted to be beneficial in both IBD and allergic diseases; LGG has a “C” class recommendation in the treatment of CD, and a class “A” designation treatment of atopic eczema^[31]. Probiotics may also help with cow milk allergy^[31]. See Tables 1-3 for other disease indications and probiotic regimens, with additional recommendations from the workshop in 2007.

Lactobacillus also has specific bacteriocidal effects, including against *Lactococcus*, *Streptococcus*, *Staphylococcus*, *Listeria* and *Mycobacteria*^[32]. The bacterium uses two different pathways to neutralize competing bacteria. First, it uses a

An “A” recommendation is based on strong, positive, well-conducted, controlled studies in the primary literature, not abstract form; A “B” recommendation is based on positive, controlled studies but the presence of some negative studies; A “C” recommendation is based on some positive studies. IBD: Inflammatory bowel disease; LGG: *Lactobacillus* GG; *S. boulardii*: *Saccharomyces boulardii*.

small molecule to inhibit growth of competitor bacteria, likely a short chain fatty acid, and also uses hydrogen peroxide to alter the bacterial microenvironment from an aerobic one to an anaerobic one^[32]. In addition, *Lactobacillus* also has immunomodulatory abilities. First, the bacillus increases transepithelial resistance, and it also upregulates the key toll-like receptors TLR2 and TLR9. These toll-like receptors recognize foreign hostile viral and bacterial antigens and their activation causes a large expansion of cytokine expression and amplifies the immune response against hostile antigens^[32].

ATOPY, NASAL DISEASE AND URTICARIA IN IBD

Prior studies have described a relationship between IBD

Table 2 Results of random controlled trials which reported efficacy of probiotics in patients with inflammatory bowel disease

and allergy. It is unclear whether this association is manifested as atopy (consisting of atopic dermatitis, allergic rhinitis, asthma, and food allergy) or nasal disease. The association was hypothesized because patients with allergy have an abnormal IgE antibody response to common environmental antigens and earlier findings of peripheral and tissue eosinophilia in patients with IBD had suggested an IgE mediated response. Furthermore, because some allergic symptoms were associated with other systemic inflammatory disorders, it was felt that patients with colitis might also have an increased likelihood of developing atopic illnesses.

A review of prior studies has shown that these results may be equivocal and may only be pertinent in relation to food allergies and possibly sinonasal disease. One study showed that in children with atopic eczema, food allergy is associated with increased intestinal inflammation, as manifested by elevated levels of fecal eosinophil cationic protein, TNF- α and α 1 antitrypsin^[33]. Similarly, in another study, while there was no correlation observed between

frequency of personal history of atopy, serum IgE levels and prick test response between IBD patients and controls, it was observed that IBD patients had a higher frequency of positive prick test when tested against food allergens^[26]. There also seemed to be a positive relationship between IBD and chronic sinonasal disease, since the prevalence of chronic sinonasal disease was elevated in patients with IBD, specifically in patients with CD and especially in those also with obstructive bowel complications^[34]. Interestingly, nearly 70% of these patients had some degree of sinonasal disease; see Figure 1 for a graph depicting the prevalence of sinonasal disease in patients with IBD.

Other atopic features (asthma, hay fever and allergic rhinitis) were investigated in patients with UC and CD with the results indicating that atopic features were twice as common in patients with UC, but no different between patients with CD and controls, suggesting that hypersensitivity may play a part in UC but not in CD^[17].

In contrast, other studies found no association be-

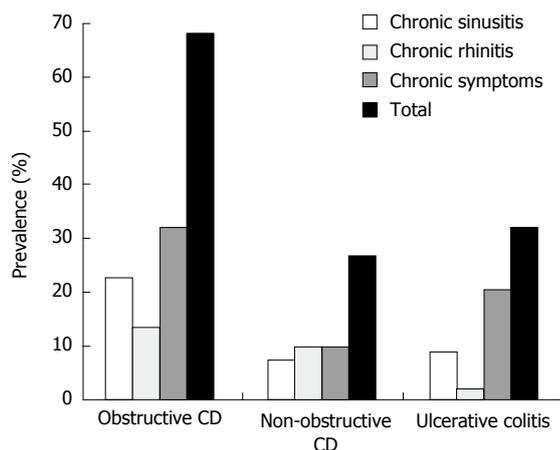

Figure 1 Prevalence of sinonasal disease in inflammatory bowel disease patients. Reproduced with permission from reference Book *et al*^[34]. CD: Crohn's disease.

tween controls and IBD patients in terms of atopic symptoms. Personal history analyses for atopic symptoms (asthma, allergic rhinitis, eczema, urticaria, and allergic symptoms) were assessed in another study where the prevalence of atopy with skin-prick tests (using five allergens - mixed grass pollens, dog hair, cat fur, *Dermatophagoides pteromyssinus* and *Aspergillus fumigatus*) and serum IgE concentrations among 122 patients with IBD and 103 age-matched controls was examined^[35]. The authors showed no statistical difference in the percentage of patients with positive skin tests between controls and IBD patients and also no difference between the subgroups of IBD patients (CD, ulcerative colitis, and ulcerative proctitis)^[35].

Another study assessed skin test reactivity in IBD patients. In this study, two different populations were examined, one in the United States and another in Czechoslovakia, and patients were classified as having CD or UC by clinical, pathological and radiological criteria; those who had been treated with immunosuppressives were taken off these medications for three weeks. The authors found no evidence of skin test energy (assessed by using multiple antigens - candida, mumps, PPD, streptokinase-streptodornase, and trichophyton) when all patients were compared to controls^[36].

Despite initial studies that suggested an association between IBD and IgE mediated allergic reactions, direct evidence is still lacking and the role of IgE mediated reactions remains unclear.

NUTRITION AND IBD

Epidemiology of food intolerance and IBD

IBD is characterized by chronic inflammation of the gastrointestinal tract. The etiology of IBD is complex and probably multi-factorial. Nutrition is an important modulator of IBD^[37]. In particular, it is felt that relationships between food antigens and immune pathways may alter the course of IBD^[38]. Gut bacteria and the inflammatory response are altered by the ingestion of differing foods^[39].

Most patients with IBD are intolerant to selected (or

specific) food items. Food intolerance has been evaluated in multiple studies. In a survey administered to 132 patients (along with 70 controls) with IBD, food intolerance was reported by 66% of patients with CD, and 64% of UC patients^[40]. The most common symptoms included diarrhea and abdominal pain^[40]. In a study that evaluated the antibody response to cow's milk antigen, it was found that IgG and IgM antibodies to beta-lactoglobulin were significantly elevated in patients with UC and CD when compared with normal subjects^[41]. Elevation of IgG further correlated with involvement of the ileum, increase in inflammatory markers, and was higher in untreated patients; interestingly there was no change in IgM levels after sulfasalazine or steroid therapy^[41]. Another study reported on a questionnaire examining dietary habits, the amount of food consumed, and whether patients had problems with specific foods^[42]. A total of 122 foods were evaluated. Intolerance to chocolate, dairy products, fats and artificial sweeteners were seen in both UC and CD, and patients with CD seemed to have a greater range of problems with specific foods^[42]. From 80%-100% of bacteria in the colonic flora of CD patients are bound by immunoglobulin whereas, in controls only 20% are bound; when enteral feeds are given the percentage bound in CD significantly decreases^[43,44].

The prevalence of food reactions was studied in 375 adult patients attending a gastroenterology outpatient clinic: 32% complained of food allergies as being the source of their abdominal complaints and in 14.4% laboratory testing was consistent with intestinal food allergy^[45]. Laboratory testing included counts of eosinophils, the presence of specific IgE against food antigens, increased total IgE, specific clinical signs of atopy, and cromoglycate sensitivity^[45]. Confirmation of the diagnosis of food allergy was found in 3.2%^[45]. This was confirmed through elimination diet and subsequent rechallenge or allergen provocation testing during EGD^[45].

Breastfeeding may have a protective effect against developing IBD^[37,46]. Of thirteen reported case-control studies, 3/13 (23.1%) found that patients with IBD were less likely to have been breast fed as compared to controls^[37]. In another study of 308 matched patients, the patients with CD were found to have had an average breast-feeding duration of 4.6 mo as compared to controls who had an average duration of 5.8 mo^[47]. Postulated mechanisms have been suggested to include a protective effect of immunoglobulins and antibacterial proteins in breast milk^[37]. In addition, breast milk may accelerate maturation of the GI tract in infants, and may also delay the introduction of cow's milk, a potentially allergenic food^[37]. Another population based case-control study examined three cohorts of patients: one with 638 CD patients, one with 653 UC patients, and 600 controls^[46]. Specific factors associated with a lower odds ratio of CD and UC included breast-feeding (CD: OR = 0.55; 95%CI: 0.41-0.74; UC: OR = 0.71; 95%CI: 0.52-0.96), and having a vegetable garden during infancy, childhood or adolescence (CD: OR = 0.52; 95%CI: 0.36-0.76; UC: OR = 0.65; 95%CI: 0.45-0.94)^[46]. In addition, those living in the countryside had a lower odds ratio of having CD (OR = 0.64; 95%CI: 0.46-0.89).

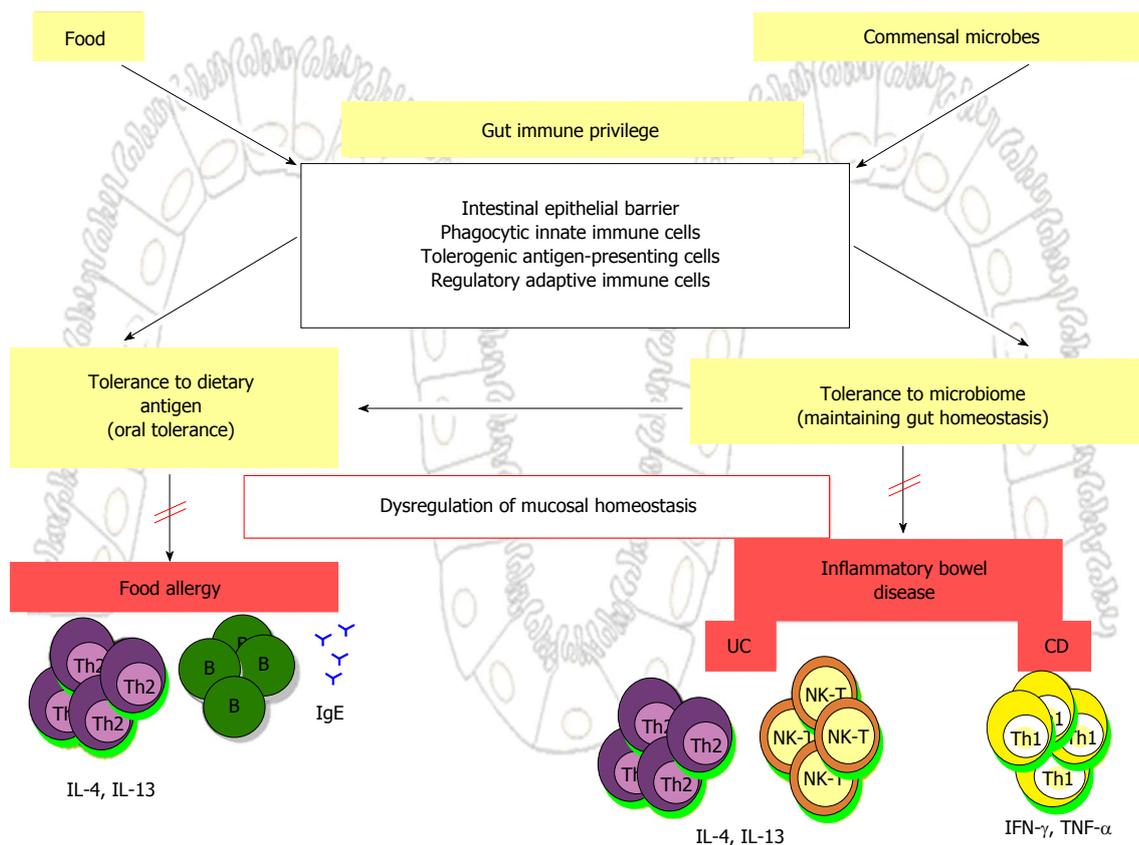

Figure 2 Immune privilege in the gut consists of tolerance to dietary antigens and to commensal microbes^[49]. Reproduced with permission from reference Iweala *et al*^[49]. CD: Crohn's disease; UC: Ulcerative colitis; TNF- α : Tumor necrosis factor- α ; IL: Interleukin; IFN: Interferon.

The duration of breastfeeding was also significant in decreasing both IBD and UC, with those having 0-2 mo of exposure having no protection, as compared with those having 3 or more mo^[46].

Relation between pathophysiology of food insensitivity and IBD

While 20%-30% of the general population have undesirable reactions to food, only 10%-25% of these are actual food allergies^[48]. The gastrointestinal mucosa is however predisposed to develop allergic reactions, since the tissue in the GI tract is exposed to various food and bacterial allergens in addition to containing all cells required to develop allergic reactions, such as eosinophils, mast cells, and lymphocytes^[48].

Proteins in food usually act as the primary foreign antigens that trigger most allergic reactions in the gastrointestinal tract^[49]. The border between intra and extraluminal sites in the intestine plays a vital role in preventing inappropriate inflammation or allergic disease in the gut^[49,50]. The gut barrier works in at least five different ways to prevent such diseases. These include (Figure 2): (1) a physical barrier preventing foreign or microbial invasion; (2) the presence of specialized immune cells, including macrophages, to phagocytize microbes and other proinflammatory or allergic antigens; (3) release of IgA, which sequesters microbes away from the gut in the intraluminal space; (4) promotion of antigen presenting cells which upregulate immune tolerance; and (5) expansion of regu-

latory T cells which dampens the immune response^[49]. Chronic inflammation in the gut may act in an ongoing fashion with increasing inflammation leading to additional damage to the physical barrier of the gut, leading in turn to more proinflammatory antigens which can then pass into the extraluminal space^[51].

A disruption of one of these five regulatory barriers may contribute to inflammation and/or allergic responses. Mast cells and eosinophils also play a critical role in modulating intestinal allergic reactions and have also been found to be stimulated in IBD and eosinophilic gastroenteritis^[52].

In addition, the main inflammatory mechanisms of IBD and of the pathophysiology of intestinal allergic phenomena are related concepts. In particular, the Th2-like response seen in ulcerative colitis is driven by NK-T cells activated by glycolipid and CD1 on epithelial cells, which facilitates their production of proinflammatory cytokines including IL-13 and IL-5^[53]. Interestingly, this process does not result in the production of IL-4. Upregulation and maladaptive Th2 responses have been implicated in chronic rhinosinusitis^[54]. In addition, *Staphylococcus aureus* (*S. aureus*), a common colonizer of the nasal tract, has been shown to upregulate IL-5 and IL-13 in nasopharyngeal lymphocytes^[54].

Additionally, there is also maladaptive activity of T regulatory T cells (Tregs) both in IBD and in food intolerance^[49]. Adoptive transfer of Tregs has been shown to prevent intolerance to the food antigen OVA^[55]. In addition it has been found that TLR4 signaling is critical for

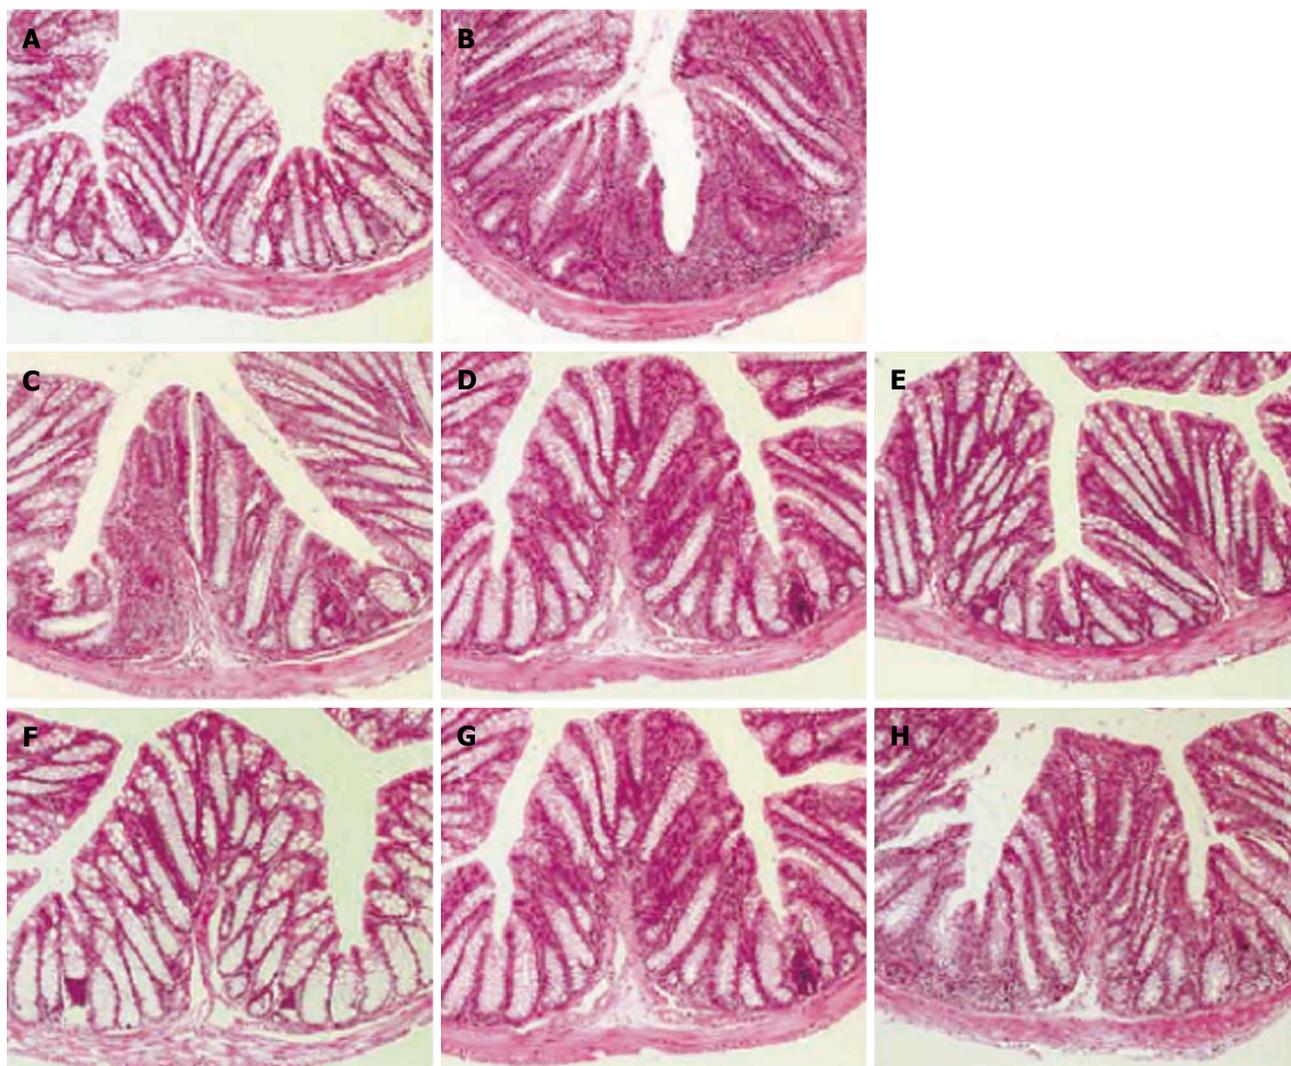

Figure 3 Histologic analysis of the colon in C57BL/6 mice. A: Normal architecture of the colonic mucosa from mice treated with 50% ethanol alone; B: Erosions of the epithelium, distortion of crypts, loss of goblet cells, and massive mononuclear cell infiltration in lamina propria in mice after administration of trinitrobenzene (TNBS); C-E: TNBS-induced colitis is dose-dependently improved by curcumin. Mice were treated with 0.5% (C), 2.0% (D), or 5.0% (E) curcumin just after administration of TNBS; F-H: Mice were treated with 2% curcumin in preventive mode (F), early therapeutic mode (G), or late therapeutic mode (H) (original magnification $\times 50$). Reproduced with permission from reference Sugimoto *et al*^[66].

Treg suppression of responses to food antigens (regulating food tolerance) and also to commensal bacteria (in prevention of colitis)^[49].

Common treatments for food insensitivity and IBD

Alterations in diet have been used as a treatment for IBD. The use of enteral feeding has been shown to be beneficial, with a majority of studies showing a remission rate of over 60%^[56]. Liquid feeding is thought to be helpful because it leads to more rapid transit time for feeds, induces partial bowel rest, as well as alters the fecal flora present^[57]. Tube feeding with an enteral elemental liquid formula cannot be used long-term however, as most patients do not tolerate this, and IBD typically relapses after discontinuation of the diet^[57]. However, the use of polymeric drinks may be better tolerated and shows similar effectiveness in this population^[57].

The use of elimination diets has also been studied. These typically involve the use of a food diary, with elimi-

nation of symptom provoking foods, or the use of a basic diet with reintroduction of potentially problematic foods one food type at a time^[58]. This approach was shown to be beneficial in inducing remission in six of nine studies^[58]. Referral to a nutritionist may be of significant benefit^[58].

Other potential therapies in the treatment of IBD include the use of polyunsaturated fatty acids (PUFA). These acids, including omega-3 fatty acids, decrease inflammation as their derivatives, including eicosapentaenoic acid, and leukotriene derivatives, downregulate neutrophil trafficking and thereby decrease edema formation^[59-61]. Twelve studies with n-3 PUFA, mostly from fish oil, showed benefit in IBD patients, with a decreased need for steroids, diminished disease activity and a lower relapse rate^[59].

Several herbal preparations are considered useful by some in the treatment of inflammatory disorders. *Lonicera japonica* is a Korean traditional treatment, and has been shown to decrease histamine release from mast

cells and inhibit inflammatory pathways, including the NF- κ B and AP-1 pathways^[62-64]. Lonicera may be an attractive agent for future clinical trials in both IBD and allergic disease^[62]. In addition, curcumin and green tea polyphenols have been shown to be potent antioxidants and have anti-inflammatory activity in mice^[65-67]. In one study, 35.5% of mice treated with trinitrobenzene (TNBS) died after developing an ulcerative colitis-like disease; however, no mice died in a group preventively given a 2% curcumin solution^[66]. In addition, mice given doses of curcumin after TNBS-induced colitis demonstrated histologic improvement of colonic mucosa^[66] (Figure 3).

DIFFERENCES BETWEEN EOSINOPHILIC COLITIS AND IBD

Eosinophilic gastrointestinal disorder (EGID) is marked by GI inflammation and intense infiltration of the GI tract with eosinophils seen in the absence of other identified systemic disorders such as malignancy, collagen-vascular disease, IBD, parasitic disease, and medication induced eosinophilia^[68]. In 50%-70% of patients with EGID, there is a family history of allergic disorders or a personal history of atopy^[48]. Symptoms vary between children and adults: in children, the common symptoms are vomiting and abdominal pain, while in adults common symptoms include food impaction, difficulty swallowing, chest pain and heartburn^[68]. Symptoms mimic both irritable bowel syndrome and IBD. Histologically, EGID can be distinguished from GERD; more than 15-20 eosinophils per high power field are seen on biopsy in EGID as opposed to less than 5 in GERD^[48,68]. Both elimination and elemental diets have shown promise in the treatment of patients with EGID^[48,68].

CONCLUSION

While the immunological underpinnings of both IBD and allergic disease are complex and multifaceted, the degree of overlap between the two disorders is striking. Further studies are warranted to try to help better understand their complex basis and commonality, and there is much to be gained by studying treatments that benefit patients with these illnesses.

bowel disease

Core tip: This review of the literature on small bowel carcinoma associated with Crohn's disease specifically addresses the incidence, risk factors, and protective factors which have been identified. It also reviews the clinical presentation, the current modalities of diagnosis, the pathology, treatment, and surveillance. Finally, the prognosis and future direction are addressed. Our experience with small bowel adenocarcinoma in Crohn's disease is reported. Readers will be provided with a better understanding of this rare and often poorly recognized complication of Crohn's disease.

Small bowel adenocarcinoma and Crohn's disease: Any further ahead than 50 years ago? *World J Gastroenterol* 2014; 20(33): 11486-11495 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i33/11486.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i33.11486>

Abstract

This review of the literature on small bowel carcinoma associated with Crohn's disease specifically addresses the incidence, risk factors, and protective factors which have been identified. It also reviews the clinical presentation, the current modalities of diagnosis, the pathology, treatment, and surveillance. Finally, the prognosis and future direction are addressed. Our experience with small bowel adenocarcinoma in Crohn's disease is reported. Readers will be provided with a better understanding of this rare and often poorly recognized complication of Crohn's disease.

INTRODUCTION

Over the past several decades it has become increasingly recognized that small bowel adenocarcinoma is an undeniable complication of Crohn's disease of the small intestine. The exact magnitude of this risk is virtually impossible to determine. The first case of small bowel carcinoma in Crohn's disease was reported by Ginzburg in 1956. Since then, there have been countless published case reports as well as numerous retrospective reviews and cohort studies which have attempted to define the occurrence of small bowel carcinoma in Crohn's disease.

This review of the literature on small bowel carcinoma associated with Crohn's disease specifically addresses the incidence, risk factors, and protective factors which have been identified. It will also review the clinical pre-

sentation, the current modalities of diagnosis, the pathology, treatment, and surveillance. Finally, the prognosis and future direction will be addressed. Our experience with small bowel adenocarcinoma in Crohn's disease is reported. Readers will be provided with a better understanding of this rare and often poorly recognized complication of Crohn's disease.

INCIDENCE

The relative risk of developing carcinoma of the small bowel in patients with Crohn's disease has been estimated to range from 6 to 320^[11]. Jess *et al*^[2] studied a population-based cohort of 374 patients with Crohn's disease in order to determine the long term risk of intestinal and extra-intestinal malignancies. The risk of small bowel adenocarcinoma was increased by more than 60 fold as compared to the general population. On the basis of 5000 cases of Crohn's disease reported in the world literature, Amman^[3] calculated an association with carcinoma of 0.08%, which, he emphasized, was lower than the incidence of carcinoma of the small bowel in the absence of Crohn's disease, which he estimated at 0.098% in 137124 autopsies. However, the incidence in Crohn's disease may be higher than reported as the associated carcinoma may have been missed due to inadequate histopathologic study. These observational series serve to underline the possible fallacies of mass statistics collected from the literature.

Our review of the literature revealed 220 reported cases of adenocarcinoma associated with small bowel Crohn's disease. Since we do not have the number of patients who suffered from Crohn's disease of the small bowel from which those patients were extracted, the actual incidence of carcinoma associated with Crohn's cannot be calculated. These numbers were obtained through a Medline search from the years 1975 to 2013. Some of the reports were reviews and hence there may be some duplication of cases in the series reported.

There is nevertheless a general consensus that the risk of developing small bowel adenocarcinoma is greater in patients with Crohn's disease than in the general population. The exact magnitude of the increased risk is difficult to determine because information derived from population-based studies, case-controlled studies, physician surveys, and case reports have been combined.

Many reports have documented that adenocarcinoma of the small bowel is a complication of Crohn's disease and this has been well reviewed by Kerber^[4] and Frank^[5]. Sometimes the patients who develop an adenocarcinoma are those with small bowel-limited Crohn's disease but most often there is a combination of those with both small and large bowel Crohn's disease. Patients with longstanding small bowel Crohn's disease are thought to have an increased risk of small bowel carcinoma^[6-9].

In a meta-analysis by von Roon *et al*^[10], the relative risk of developing small bowel carcinoma in the 9642 patients was 28.37. The incidence rate of small bowel carcinoma

in 12740 patients was 1.55 per 100000 patient years. In the review by Von Roon, the mean duration of Crohn's disease before the onset of carcinoma was 9 years (range 0.8-41). The relative risk of developing small bowel carcinoma compared to the background population was higher in North America (RR = 41.23), the United Kingdom (RR = 40) and Scandinavia (RR = 21.3).

Shaukat *et al*^[11] studied all cases of small bowel carcinoma in persons 67 years and older in the Surveillance Epidemiology and End Results catchment area. They identified 923 cases of small bowel carcinoma and 142273 controls and found a strong association between Crohn's disease and small bowel carcinoma [odds ratio (OR) = 12.02]. The prevalence of Crohn's disease in patients with small bowel carcinoma was low (1.6%) so the absolute risk remains low.

RISK AND PROTECTIVE FACTORS

Numerous risk factors for developing small bowel carcinoma in Crohn's disease have been postulated in the literature. Many purported risk factors surfaced as a result of observed trends across case reports such as previous stricturoplasty^[12-15] and excluded/bypassed bowel segments^[16-18]. Approximately 30% of reported small bowel carcinomas in Crohn's disease occurred in patients who had bypassed loops^[19]. This complication stresses the need to encourage resection rather than bypass. Lashner^[20] reported a case control study of carcinoma of the small bowel in Crohn's disease in which each case was matched to 4 randomly selected controls from an inflammatory bowel disease registry. The following factors were significantly associated with small bowel carcinoma in Crohn's disease: (1) occupation, with three cases having had exposure to halogenated aromatic compounds and aliphatic amines, asbestos, and cutting oil solvents and abrasives; and (2) 6-mercaptopurine use (OR = 10.8).

Several studies reported that the risk of developing small bowel carcinoma was according to the anatomic location of the Crohn's disease (Table 1). For example, the odds ratio of developing small bowel carcinoma was found to be much higher in 363 patients whose disease was confined to the small bowel (RR = 158.5) than in the 507 patients with ileocolic Crohn's disease (RR = 83.8)^[10].

Table 1 displays a review of the studied risk factors for small bowel carcinoma in Crohn's disease in the literature, highlighting which authors agree and disagree with a purported risk factor. Clinicians should perhaps be more vigilant for small bowel carcinoma in patients with inflammation restricted to the small bowel versus ileocolic inflammation.

Protective factors against development of small bowel carcinoma in Crohn's disease have been less frequently studied, but available information is cited in Table 2. In a study of 29 patients with Crohn's disease and small bowel carcinoma Piton *et al*^[21] found that small bowel resection and prolonged use of salicylates may protect against small bowel carcinoma in Crohn's disease patients.

Table 1 Risk factors for small bowel cancer in Crohn's disease

CLINICAL PRESENTATION

Obstruction is the most common presenting manifestation in small bowel carcinoma in Crohn's disease with symptoms of nausea, vomiting and abdominal pain. Other possible presentations are hemorrhage, fistula, or perforation^[22-24]. Unfortunately, all of these symptoms are hard to differentiate from those of a Crohn's exacerbation, which partly explains the challenge of detecting small bowel carcinoma in this patient population and results in the majority of diagnoses being made at the time of operation or postoperatively. In fact, only a small minority (< 5%) is diagnosed preoperatively^[22]. Furthermore, Collier *et al*^[19] described that over 50% of small bowel carcinomas in resected Crohn's disease segments were unsuspected or incidentally found by the pathologist.

Table 2 Protective factors for small bowel cancer in Crohn's disease

| | | Protective factor against small bowel cancer? | |
|---|----------------|--|--|
| | | Yes | No |
| 1 | Diet | ¹ Negri <i>et al</i> ^[25] | ² Chow <i>et al</i> ^[77] |
| 2 | 5-ASA | Piton <i>et al</i> ^[21] Solem <i>et al</i> ^[26] | |

¹Coffee, fish, vegetables, fruit; ²Fruits and vegetables. 5-ASA: 5-aminosalicylic acid.

Two important clinical indicators of malignancy are recrudescence symptoms after long periods of relative quiescence and small bowel obstruction that is refractory to medical therapy^[23]. Therefore, it is prudent to consider a surgical assessment of patients with longstanding symptomatic Crohn's disease who fail to respond to conservative management.

The usual age of diagnosis of small bowel carcinoma in Crohn's disease patients is 45 to 55 years^[4,6,7,22,23]. This is in contrast to small bowel carcinoma *de novo* which is usually diagnosed between 60 and 69 years of age^[25]. Crohn's disease will often predate the carcinoma diagnosis by 20 to 25 years^[4,22-24,26].

Palascak-Juif *et al*^[27] studied 20 patients with Crohn's disease-associated small bowel carcinoma recruited from French university hospitals and compared them to 40 patients with small bowel carcinoma *de novo* recruited from a population-based registry. Small bowel carcinoma occurred after a median time of 15 years of Crohn's disease and was located within the inflamed areas of the ileum (19) or jejunum (1), whereas in patients with small bowel carcinoma *de novo* it was distributed all along the small intestine. The median age of diagnosis of small bowel carcinoma was 47 years (range 33-72 years) in patients with Crohn's disease and 68 years (range 41-95 years) in those with small bowel carcinoma *de novo*. The cumulative risk of small bowel carcinoma was 0.2% and 2.2% after 10 and 25 years of small bowel Crohn's disease, respectively. The diagnosis was made preoperatively in 1 of 20 patients with Crohn's disease and 22 of 40 patients with small bowel carcinoma *de novo*. Signet ring cells were found in 35% of Crohn's disease cancers but not in patients with small bowel carcinoma *de novo*. Relative survival at 2 and 5 years was not significantly different between these two categories of patients (54% *vs* 37% and 35% *vs* 30%; with and without Crohn's disease, respectively).

In a retrospective review from 1993 to 2009, Widmar *et al*^[23] identified 29 patients with small bowel carcinoma (22 ileal and 5 jejunal) in Crohn's disease. There were no carcinomas in excluded intestinal loops. The median age of onset of Crohn's disease symptoms was 25 years and the median age at cancer diagnosis was 55.4 years, for a mean interval of 25.3 years. Widmar found that 75% of carcinomas arose in the terminal ileum, a location that

only accounts for 13% of sporadic small bowel adenocarcinomas^[28]. Patients with Crohn's disease developed adenocarcinoma at an average age of 48 years versus 65 in the general population, with a male to female ratio of 3 to 1.

Solem *et al*^[26] described the clinical features, outcomes, and risk factors of small bowel carcinoma in Crohn's disease. Nine cases (4 males) were identified. The patients presented with abdominal pain (89%), obstruction (89%), and weight loss (78%). The carcinoma was located in the ileum in 8 patients (89%) and in the jejunum in 1 patient (11%). All cases but one had advanced disease with either lymph node involvement or metastases. The mortality rates at 1 and 2 years were 42% and 61%, respectively.

Floch *et al*^[29] reviewed 47 previously reported small bowel carcinomas in Crohn's disease. The average age of the Crohn's carcinomas was 46.5 years while that for the *de novo* group was 55 years. The sexual ratios were 2.46:1 and 2:1 males to females for the respective groups. The *de novo* carcinomas had a slight predilection for the duodenum (4.7%) while the latter group had a heavy predilection for the ileum (70.8%) and contained no duodenal carcinomas. The prognosis of the Crohn's group appeared to be much worse than that of the *de novo* group with five year survivals of 3.7 and 20%-22%, respectively. Late diagnosis in the enteritis group was felt to be the major reason for this.

Hoffman *et al*^[7] also reviewed the literature and found 49 cases and added two of their own. The Crohn's associated carcinomas differed from carcinoma not associated with Crohn's in that (1) mean age of carcinoma discovery was less (46 years *vs* 64 years); (2) more carcinomas arose in the ileum (76% *vs* 27%); (3) diagnosis and cure were less successful; and (4) they occurred more frequently.

The review by Fresko *et al*^[30] of 59 reported cases of carcinoma of the small bowel in Crohn's disease, to which they added three of their own cases, revealed that (1) carcinoma develops at a younger age than in carcinoma *de novo*; (2) there is no difference in incidence of carcinoma in the first, second and third decades after onset of symptoms of Crohn's disease; (3) 73% of neoplasms arose in the ileum; (4) in all but one case it developed in inflamed segments of bowel; and (5) in 31% of cases carcinoma developed in a bypassed segment of bowel. They concluded that Crohn's carcinoma is a complication of Crohn's disease and not a chance co-existence of the two diseases in the patient.

DIAGNOSIS

The clinical diagnosis of small bowel carcinoma in Crohn's disease patients based on symptoms and physical examination is quite difficult, if not impossible. Indeed, many patients with carcinoma of the small bowel are not suspected of having a malignancy even at time of operation^[5,6,31-33]. Most cases of small bowel carcinoma have been in segments involved with Crohn's disease. These malignancies were indistinguishable radiologically from

longstanding Crohn's disease. In two of the patients described by Kerber^[4] and Frank^[5], there was "shouldering", destruction, and a mass.

In general, imaging techniques may miss small lesions and may not be able to differentiate areas of small bowel carcinomas from those of severe Crohn's disease. Routine computed tomography (CT) exposes patients to radiation, and although magnetic resonance (MR) imaging does not, it is time consuming and costly^[34]. Buckley *et al.*^[35] found CT staging of small bowel carcinoma to be 47% accurate but errors occurred in patients with Crohn's disease. Enteroclysis is invasive and requires special training^[36]. The usefulness of FDG-PET is limited by the background chronic inflammation of Crohn's^[37].

Video capsule endoscopy is challenged by issues of visualization (*i.e.*, limited field of vision, non-continuous image capture, lesions hidden in folds), inadequate preparation, and the stenosing nature of Crohn's disease^[36] that may prohibit a capsule from passing. Furthermore, lesion localization can be difficult and it does not allow for tissue sampling^[38].

Enteroscopic techniques do allow direct visualization and tissue sampling but are invasive, labor intensive, and may be limited by the length and tortuosity of the small bowel. Intraoperative endoscopy is now reserved for lesions which are not accessible by balloon enteroscopy^[39].

Despite their disadvantages, there are published cases demonstrating the utility of some of the techniques listed above. Placé and colleagues^[40] observed two different patterns using MR-enterography: the first was a long, circumferential, asymmetric, and heterogeneous thickening of the ileum with a visible nodule on free induction echo stimulated acquisition images, and the other was a mass of the terminal ileum showing restricted diffusion on diffusion weighted MR imaging. Soyer *et al.*^[41] evaluated 7 patients with small bowel carcinoma, and on CT enterography the carcinoma was visible in five patients. Four different patterns were individualized including small bowel mass (2 patients), long stenosis with heterogeneous submucosal layer (2 patients), short and severe stenosis with proximal small bowel dilatation (2 patients), and sacculated small bowel loop with irregular and asymmetric circumferential thickening (1 patient). Stratification, fat stranding, and comb signs were present in 2, 2, and 1 patient(s), respectively. Nevertheless, adenocarcinoma may be completely indistinguishable from benign fibrotic or acute inflammatory strictures.

A case reported by Kodaira *et al.*^[42] highlighted the unique successful combination of PET/CT and double balloon enteroscopy for the diagnosis of small bowel carcinoma in a Crohn's disease patient. Van Weyenberg *et al.*^[43] found both MR enteroclysis and video capsule endoscopy useful but they believe that MR enteroclysis is the better option. Ultimately, a combination of methods is likely the present day solution.

On the basis of their study of patients in whom adenocarcinoma of the small bowel developed as a complication of Crohn's disease, Kerber^[4] and Frank^[5] concluded: (1) the development of adenocarcinoma is more likely

to be seen in patients with longstanding disease; (2) classical radiographic appearance of carcinoma may not be seen; (3) a progressive change in radiographic appearance over time with the development of masses, fistulas, strictures and obstruction should raise the suspicion of co-existing carcinoma; (4) malignancy should be considered when there is a longstanding quiescent disease activity followed by a recrudescence of symptoms with concurrent radiographic changes; and (5) fistulas may be associated with carcinoma in two ways: a mass produced by carcinoma or carcinoma arising in chronic fistulas from Crohn's disease. Contrary to prior recommendations, they suggest that obtaining radiographic examinations to document changing patterns of disease displays an important role in the management of patients with Crohn's disease and may lead to earlier detection of complicating carcinoma thus improving prognosis in such patients.

PATHOLOGY

In contrast to *de novo* small bowel carcinomas which are most often in the duodenum (55%)^[28], 75% of Crohn's related small bowel carcinomas are ileal^[22,28]. Miller *et al.*^[44] noted that all small bowel carcinomas associated with Crohn's disease were ileal in location. Watanabe *et al.*^[45] published a summary of small bowel carcinoma within Crohn's disease up until 1991 documenting only adenocarcinomas and signet ring cell carcinomas (Table 3). Petras *et al.*^[46] reported four patients with small intestinal carcinoma: three with poorly differentiated or signet ring cell type carcinomas and one with mucinous type. All four patients had high grade dysplasia in the mucosa immediately adjacent to the carcinoma, supporting the dysplasia-carcinoma sequence believed to occur in Crohn's disease as with ulcerative colitis^[47,48]. A wider variety of malignancies have been reported and are noted in Table 3, including sarcomas, lymphomas, and carcinoids.

TREATMENT

The treatment of choice is wide resection of the small bowel segment harboring the carcinoma as well as resection of the corresponding mesentery and lymph nodes^[22]. Pancreaticoduodenectomy for lesions of the second or third portion of the duodenum and right colectomy for carcinoma of the distal ileum would be required^[49].

Evidence regarding the value of adjuvant chemotherapy for small bowel carcinoma is sparse and consists mostly of small retrospective reviews. Most available data is from experience in managing ampullary adenocarcinoma. Fishman *et al.*^[50] reported response rates upwards of 30% in the palliative setting: 33% with Gemcitabine, 50% with 5-FU or Capecitabine, and 42% with Platinum- or Irinotecan-based therapy.

PROGNOSIS

The prognosis of Crohn's associated small bowel carcinoma varies among reported studies but has been noted

Table 3 Histopathology of small bowel cancers in Crohn's disease

| Histology | Watanabe <i>et al</i> ^[45] | Update since 1991 |
|-----------------------|---|---|
| Adenocarcinoma | 61 cases reported up until 1991 as quoted by Watanabe | Barwood <i>et al</i> ^[14] Chan <i>et al</i> ^[78] Chen <i>et al</i> ^[64] Christodoulou <i>et al</i> ^[79] Dossett <i>et al</i> ^[22] Feldstein <i>et al</i> ^[49] Fell <i>et al</i> ^[80] Fielding <i>et al</i> ^[9] Gillen <i>et al</i> ^[81] Gusakova <i>et al</i> ^[82] Jaskowiak <i>et al</i> ^[15] Jess <i>et al</i> ^[73] Kamiya <i>et al</i> ^[69] Katsanos <i>et al</i> ^[83] Kersting <i>et al</i> ^[65] Koga <i>et al</i> ^[84] Kronberger <i>et al</i> ^[85] Lindgren <i>et al</i> ^[86] Mellemjaker <i>et al</i> ^[71] Menon <i>et al</i> ^[12] Michelassi <i>et al</i> ^[55] Palascak-Juif <i>et al</i> ^[27] Partridge <i>et al</i> ^[13] Ribeiro <i>et al</i> ^[11] Richards <i>et al</i> ^[54] Rubio <i>et al</i> ^[87] Sammartino <i>et al</i> ^[88] Sigel <i>et al</i> ^[48] Solem <i>et al</i> ^[26] |
| Sarcoma | | Gollop <i>et al</i> ^[89] (leiomyosarcoma) Jess <i>et al</i> ^[73] (leiomyosarcoma) Fielding <i>et al</i> ^[9] (reticulum-cell sarcoma) |
| Local lymphoma | | Jess <i>et al</i> ^[73] |
| Carcinoid | | Chen <i>et al</i> ^[64] Kvist <i>et al</i> ^[20] Mellemkjaer <i>et al</i> ^[71] Savoca <i>et al</i> ^[62] |
| Poorly differentiated | | Petras <i>et al</i> ^[46] Savoca <i>et al</i> ^[62] Simpson <i>et al</i> ^[47] |
| Signet ring | 8 cases reported up until 1991 as quoted by Watanabe | |

to be poorer than the *de novo* small bowel carcinomas^[24]. Most small bowel carcinomas in Crohn's disease present at a younger age and are more diffusely and distally located than *de novo* carcinomas, usually making them undiagnosable at a curable stage. Indeed, two-thirds of cases present with intestinal obstruction. Greenstein^[51] reported two year disease survival for small bowel carcinoma in Crohn's disease as 9% compared with 15%-25% for *de novo* carcinomas. Mortality for carcinoma in excluded bowel has been reported to be as high as 100%^[51]. One report of carcinomas developing in small bowel Crohn's strictures found only 9 such cases^[52]. All patients had Crohn's disease for more than ten years. The average age of patients was 48 years compared to 65 years for *de novo* carcinomas. In patients with Crohn's disease, carcinoma affects the ileum twice as commonly as the jejunum and four times

as commonly as the duodenum. Fifty-nine percent of all carcinomas complicating Crohn's disease were discovered incidentally during pathologic examination of resected specimens. If small bowel alone is considered this figure rises to 70%.

Small bowel carcinomas associated with Crohn's disease tends to be poorly differentiated and are associated with a poor prognosis^[4,5,19,33,53]. Two year survival rates have been found to be as low as 27%^[22]. In a report by Richards^[54] with three ileal carcinomas, survival ranged from 8 to 44 mo.

Michelassi *et al*^[55] reported 14 cases of intestinal carcinoma complicating Crohn's disease, 7 occurring in the small intestine and 7 in the large bowel. Two thirds of patients were male. The average age at time of diagnosis of Crohn's disease and carcinoma was 28 and 48 years respectively. In five patients with small bowel carcinoma the diagnosis was made at laparotomy. In the remaining cases only careful histologic examination revealed the carcinoma. Six small bowel carcinomas were located in the ileum. Two small bowel carcinomas were multi-focal and had surrounding mucosal dysplasia. No patient with regional or distal metastases survived five years in comparison with an 83% five year actuarial survival rate in patients with carcinoma confined to the intestinal wall. Mean survival was 6 mo for patients with small bowel carcinoma.

Hawker *et al*^[53] reported the clinical and pathological details of three cases diagnosed between 1968-1980 with a review of 58 patients from the literature. Of the 61 cases, 41 carcinomas occurred in the ileum, 18 in the jejunum, 1 in the duodenum and ileum, and 1 in the ileum and colon. Eighteen occurred in bypassed intestinal loops. The prognosis was poor: 44 patients (72%) died with a mean interval of only 7.9 mo from the diagnosis of their malignancy.

Widmar *et al*^[23] reported significant differences in the two year survival for node negative versus node positive carcinomas (79.3% *vs* 49%) and for localized versus metastatic disease (92.3% *vs* 33.3%). Overall, 36 mo survival was 69.3% compared to 40% among those without excluded loops. Sixteen patients had long periods of quiescent disease before the diagnosis (7-45 years) and 16 required operation for bowel obstruction that was refractory to medical management.

OUR EXPERIENCE

From 1990 to 2013, 10 patients with underlying Crohn's disease and small bowel adenocarcinoma were treated at our institution. In our series, there were twice as many males as females. The median age of Crohn's diagnosis was 28 years and the median age of small bowel adenocarcinoma diagnosis was 57 years; this interval is consistent with the literature. In none of the 10 patients was the diagnosis known pre-operatively. Nine patients presented with a clinical picture of obstruction that did not respond to steroid treatment and required operation. Of the nine, two were found to have metastatic disease secondary to small bowel adenocarcinoma

at the time of operation, while the diagnosis for the remaining seven was made on final pathology examination. The tenth patient in our series had refractory Crohn's disease and was incidentally found to have terminal ileal adenocarcinoma on final pathology.

An equal number of patients had Crohn's disease isolated to their small bowel as concomitant small and large bowel disease. None of our patients had bypassed loops of small bowel. In fact, only three patients had had previous operations for Crohn's disease. All but one of our patients had terminal ileal adenocarcinomas; the exception was one jejunal carcinoma. Moreover, all patients had either stricturing and/or fistulizing Crohn's disease. Four of our 10 patients had been treated with 5-ASA, a reported protective factor. All patients had a history of remote immunomodulator use but none were on maintenance immunomodulators at the time of presentation; if they were receiving medical therapy, it was solely high dose steroids. This is consistent with the conclusions made by Kerber^[4] and Frank^[5] concerning the development of a small bowel adenocarcinoma after a period of quiescent Crohn's disease. As reported by others, the prognosis for small bowel adenocarcinoma in our series was also quite poor: the carcinoma-related mortality in our series is 70%.

SURVEILLANCE

It has become increasingly recognized that the risk of developing carcinoma of the colon in patients with colonic Crohn's disease is comparable to those with chronic ulcerative colitis. Hence, regular colonoscopic surveillance in search of dysplastic changes is in order. However, no similar surveillance for patients with small bowel Crohn's disease is possible.

Greenstein^[24] suggests that surveillance should consist of regular abdominal examinations and that the recurrence of obstructive symptoms as well as the development of new symptoms should not be ignored especially after long quiescent periods.

CEA levels, found to be elevated in up to 38% of patients with active Crohn's disease^[56,57], have not been found to be useful in monitoring for small bowel carcinoma^[19,58].

LIMITATIONS

Each of the studies included in this descriptive view has its own limitations. A descriptive review such as ours could not possibly be exhaustive if it had strict inclusion/exclusion criteria. Thus we chose to include data and observations from all available studies despite their limitations.

It is difficult to draw conclusions regarding the cumulative incidence of small bowel carcinoma in Crohn's disease from studies with such a low frequency of event as small bowel carcinoma. Compared to current data, incidence values from older studies may actually be overestimated, as 5-ASA formulations (possibly protective against small bowel carcinoma) were released in the

late 70's and 80's, late in the observation period of most cohorts^[59]. Furthermore, the majority of reports did not have small bowel carcinoma as a primary outcome. Analysis did not routinely address incidence and discussions were sometimes not exclusive to the small bowel (e.g., "intestinal"^[60], "upper digestive tract"^[61], or discussing risk factors for small bowel and colorectal carcinomas together^[62]). Studies rarely controlled for immunosuppressive agents, tobacco or alcohol^[63], and those that did examine such exposures did not provide quantitative data^[64]. Finally, multiple biases inherent of retrospective and single-centre studies exist in the available literature. For example, a high incidence of small bowel carcinoma in Crohn's disease may reflect a bias in tertiary hospitals^[65] or a surveillance bias due to close monitoring of Crohn's disease patients^[66], and reported risk factors may be a result of recall bias^[67]. These limitations are inherent to the challenging problem of a rare disease that is difficult to diagnose.

CONCLUSION

In this review, we highlighted the available current evidence and the gaps of knowledge, technology, and clinical guidelines required for improving care of Crohn's disease patients at risk of this devastating problem. Although the association of carcinoma in Crohn's disease and the need to screen Crohn's disease of the colon is well established, carcinoma associated with Crohn's disease of the small bowel is difficult to diagnose and indeed is often not identified until operation for what is believed to be an exacerbation or non-response to medical therapy. Sadly, the diagnosis is often made after careful examination of the resection specimen by the pathologist. Over the decades there has been a lack of significant improvement in prognosis. There is a need to elucidate screening modalities to facilitate earlier diagnosis and treatment.

Abstract

Ulcerative colitis (UC) is a condition at increased risk for colorectal carcinoma (CRC) development. Nowadays, screening and follow-up programs are routinely performed worldwide to promote the early detection of CRCs in subjects with well known risk factors (extent, duration and severity of the disorder). The diffusion of these procedures is presumably the main reason for the marked reduction of cancer incidence and mortality in the course of UC. In addition, chemoprevention has been widely investigated and developed in many medical fields, and aspirin has shown a preventive effect against CRC, while mesalazine has been strongly invoked as a potential chemopreventive agent in UC. However, available studies show some limitations due to the obvious ethical implications of drug withdrawal in UC in order to design a control group. The estrogen

receptors (ER) alpha/beta balance seems to have a relevant influence on colorectal carcinogenesis and ER beta appears to parallel apoptosis, and hence an anti-carcinogenic effect. Phytoestrogens are compounds acting as ER beta agonists and have shown a promising chemopreventive effect on sporadic as well as genetically inherited CRC. There is evidence suggesting a role for ERs in UC-related carcinogenesis. In this perspective, since these substances can be considered as dietary supplements and are completely free from side effects, phytoestrogens could be an interesting option for CRC prevention, even when the disease is a consequence of long-term chronic inflammation, as in the course of UC. Further studies of their effects are warranted in both the basic research and clinical fields.

Key words: Ulcerative colitis; Epithelial dysplasia; Colorectal cancer; Estrogen receptors; Chemoprevention; Phytoestrogens; Dietary supplementation; Inflammatory bowel disease

Core tip: The present work outlines the main data regarding a possible involvement of estrogen receptors in colorectal carcinogenesis, paying particular attention to cancer arising in the course of ulcerative colitis. A protective role for beta receptors has been suggested by many studies. The challenge for the future could be to devise chemopreventive strategies against colorectal carcinoma employing estrogen receptor beta agonists, such as phytoestrogens.

ULCERATIVE COLITIS: FROM INFLAMMATION TO CANCER

Ulcerative colitis (UC) is associated with an increased risk of colorectal cancer (CRC), which has been related to the long-standing chronic inflammation^[1]. However, the magnitude of the risk is difficult to estimate, as many factors may bias study results^[2] (*i.e.*, patient selection, number of patients, completeness of case recruitment and ascertainment and duration of follow-up)^[2,3].

Castañó-Milla *et al.*^[4] reported an overall incidence rate of CRC in UC of 1.67/1000 per year of disease (PYD) and incidence rates per decade were estimated at 1.01/1000, 3.75/1000 and 5.85/1000 PYD for the first, second and third decades, respectively. In a meta-analysis of prospective population-based studies, Jess *et al.*^[5] found that an average of 1.6% of patients with UC were diagnosed with CRC during the first 14 years of follow-up, and the estimated standardized incidence ratio (SIR) was 2.39 (2.1-2.7). Recent time-trend studies also demonstrate a decreasing risk of CRC in UC patients^[6]. In a recent meta-analysis^[4] the incidence rate was found to have decreased from 4.29/1000 PYD in studies published in the 1950s to 1.09/1000 PYD in the studies published between 2000 and 2011.

As known, reported risk factors for CRC include extensive disease^[7,8], young age at diagnosis^[9], a family history of CRC^[10], co-existing primary sclerosing cholangitis (PSC)^[11] and persistent inflammation of the colon^[12,13].

The pathophysiology of colitis-associated cancer suggests the action of numerous positive and negative regulators^[14]. Positive regulators are pro-carcinogenic cytokines such as tumor necrosis factor alpha (TNF alpha), that is over-expressed in a murine model of carcinoma arising on colitis^[15], interleukin (IL)-6^[16] and IL-21^[17] and chemokines such as CCL2, whose expression is enhanced by TNF alpha, causing the recruitment of macrophages and monocytes^[18]. Negative regulators include IL-10^[19,20], transforming growth factor beta (TGF beta)^[21] and MyD88, a Toll-like receptor adaptor, that has been found to significantly reduce tumor number and size in the Ap^{c^{min/+}} mouse model of intestinal tumorigenesis^[22,23].

The progression from UC to CRC is a multistep process in which the accumulation of genetic mutations leads to the sequential evolution to low-grade dysplasia (LGD), high-grade dysplasia (HGD) and finally to cancer^[24]. The p53 tumor suppressor gene appears to be a key factor in the initial steps of UC-associated colorectal carcinogenesis, being the most frequent single founding mutation in UC associated CRC^[25]. p53 is overexpressed in 33%-67% of patients with dysplasia and in 83%-95% of patients with UC-associated CRC^[26,27]. Other genes that undergo mutation in the following stages of carcinogenesis are kRAS, DCC, cyclin D, COX, iNOS, APC

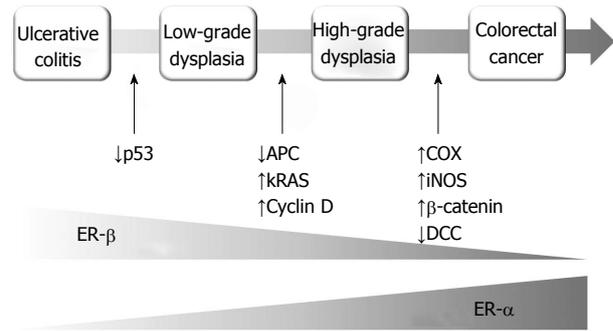

Figure 1 progressive steps of ulcerative colitis-related carcinogenesis, genetic pathways and estrogen receptors alpha and beta patterns.

and beta-catenin (Figure 1), in a sequence that is substantially different from the classical adenoma-carcinoma pathway^[28,29].

The essential morphological features of dysplasia, are (1) nuclear alterations such as increased nuclear to cytoplasmic ratios and hyperchromasia; (2) depletion of goblet cells; and (3) abnormal architectural patterns corresponding to dysregulated cellular proliferation, such as glandular crowding, a villous architecture and diminished surface maturation. HGD differs from LGD in that there are additional alterations, *i.e.*, impaired cellular polarity including loss of nuclear parallelism, stratification of nuclei patterns such as a cribriform architecture. In most cases, the nuclei in HGD show severe cytological aberrations such as irregular nuclear membranes, abnormally prominent nucleoli or atypical mitotic figures^[30]. The progression of such alterations is accompanied by both a progressive increase of epithelial proliferation and a reduction of apoptosis. This phenomenon starts as alterations of glandular architecture (*i.e.*, shortening, loss of parallelism, ramification and branching) which anticipate the dysplasia onset^[31].

The potential risk of malignant degeneration of UC to CRC has made it necessary to institute surveillance protocols to achieve early recognition and treatment of dysplastic lesions. The current evidence-based consensus for endoscopy in inflammatory bowel disease^[32] suggests that surveillance should start when the risk starts to increase, *i.e.*, after 8-10 years from the onset of disease^[7]. This first colonoscopy also aims to reassess the extent of disease, since this parameter has an impact on the risk of CRC. After this first colonoscopy, patients with high risk features (stricture or dysplasia detected within the past 5 years, PSC, extensive colitis with severe active inflammation, or a family history of CRC in a first degree relative aged less than 50 years) should undergo surveillance colonoscopy annually. Conversely, patients with intermediate risk factors should have surveillance colonoscopy scheduled every 2 to 3 years and those without risk factors every 5 years. Biopsy sampling is fundamental: the American Gastroenterological Association recommends extensive sampling, of a minimum of 33 specimens^[33], while, according to the British Society of Gastroenterology^[34], two to four random biopsies every

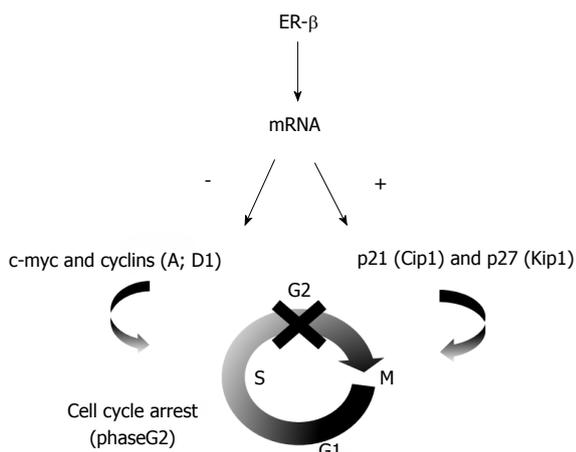

Figure 2 Estrogen receptors beta and interactions with genes involved in the regulation of cell cycle. Estrogen receptors (ER) beta has an antagonist inhibitory function, mediated by the down-regulation of proto-oncogenes c-myc and cyclins (as indicated by minus sign next to the arrow on the left side) and up-regulation of oncosuppressants p21 and p27 (as indicated by plus sign next to the arrow on the right side). In the lowest part of the figure is indicated the cell cycle phases and the site of its interaction with ER beta induced mediators (G2 phase).

10 centimetres should be taken.

Compliance to surveillance protocols, as well as a correct clinical overview of UC and the adequate pharmacological management of the disease, have led to a decreasing CRC incidence and mortality in UC^[35,36]. In 1971, de Dombal^[37] reported a 5% cumulative risk of CRC in a population from Leeds with extensive UC after 10 years and 41.8% after 25 years. Thirty years later, the cumulative risks reported by Lakatos *et al.*^[38] had dropped dramatically: 0.6% after 10 years, 5.4% after 20 years and 7.5% after 30 years of disease duration. These data testify to the exceptional impact of surveillance in the natural history of UC^[39], but we must consider that it is not the only prevention strategy: other routes, such as chemoprevention, may have a remarkable effect.

ESTROGEN RECEPTORS

Modern medicine and oncology have been profoundly affected by the discovery of the estrogen receptors (ERs), a potential marker that plays a pivotal role in the pathogenesis, prognosis and therapy of various cancers, such as breast, prostate and colon. Estrogens can regulate the growth, differentiation, and function of various target tissues both within and outside the reproductive system^[40,41]. The most relevant event after the initial discovery of these receptors^[42] was the identification of two subtypes, ER alpha and ER beta, that are expressed at different levels in each organ of the human body^[43]. Variations in the phenotype of knock-out mice lacking ER alpha or ER beta suggested that these receptors have different biological activities^[44]. Moreover, *in vitro* and *in vivo* studies in ER beta knock-out mice demonstrated that ER beta is a modulator of ER activity, as it is able to reverse the effects of ER alpha and to inhibit estradiol-dependent

proliferation^[45,46]. These experiments demonstrated that ER alpha is a positive regulator of cellular growth, while ER beta has an antagonist inhibitory function, mediated by the down-regulation of proto-oncogenes (c-myc and cyclins) and up-regulation of oncosuppressants (p21 and p27), resulting in cell cycle arrest^[47] (Figure 2). Experiments showing that in various cancers ER alpha is over-expressed and ER beta is down-regulated confirmed *in vitro* studies and demonstrated that cell proliferation is the result of a balance of ER alpha and ER beta^[48,49].

ESTROGEN RECEPTORS AND COLORECTAL CANCER

The hypothesis of a possible link between CRC and ERs was advanced after the publication of epidemiological studies showing that females have a lower rate of colonic adenomas and cancers than males before menopause and that the differences progressively lessen after menopause^[50]. Similarly, both observational and interventional data have shown that hormone replacement therapy decreases colonic adenoma and cancer risks^[51,52]: in the last 40 years, a reduction of deaths from large bowel carcinoma has been observed in the United States. This reduction was significantly higher in women (30%) as compared to men (7%). In the same study, a link was observed between oral contraceptive use and a reduction of colorectal cancer, whereas there was a higher than expected frequency of colorectal tumors among non users^[53].

After the demonstration by our group that ERs are expressed in the colonic mucosa^[54], Konstantinopoulos *et al.*^[55] demonstrated that ER beta is highly expressed in normal colonic mucosa in humans, while it is significantly reduced in CRC; this reduction is more pronounced in the case of poorly differentiated tumors. Since the majority of CRCs are derived from adenomatous polyps (a precancerous condition) our group recently evaluated the expression of ER alpha and ER beta in the colonic tissue of 25 patients with adenomatous polyps of the colon and in 25 normal subjects^[56]. ERs expression was then correlated to proliferation and apoptosis. Our data confirmed that ER beta is the prevalent estrogen receptor in normal mucosa and shows a significantly reduced expression in adenomatous polyps (Figure 3). In a successive study, we confirmed that ER beta plays a primary role in the regulation of colonic mucosa proliferation in patients affected by Familial Adenomatous Polyposis (FAP)^[57], an inherited disease characterized by an early inclination to develop hundreds of polyps and consequently CRC. Furthermore, ERs can even influence the prognosis of CRC, as it has been demonstrated that patients affected by CRCs with a minimal ERs expression had poor prognosis and short survival^[58].

All these data confirm that sex steroid hormones are involved in CRC development and suggest that ER beta could play an important role in the early phase of the carcinogenic process and hence could be a target in the primary prevention of CRC^[59].

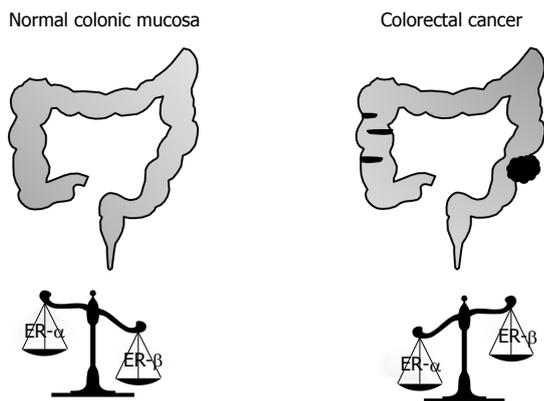

Figure 3 Alpha and beta estrogen receptors balance in normal and neoplastic colon.

ESTROGEN RECEPTORS EXPRESSION IN THE PROGRESSIVE STAGES OF ULCERATIVE COLITIS-RELATED CARCINOGENESIS

ER beta has been suggested to exert anti-inflammatory and anti-tumorigenic effects in the colon, providing a translational potential to prevent and/or treat inflammatory bowel disease (IBD) and its progression to colitis-associated CRC^[60,61]. Most studies in this field used a consolidated animal model which accurately mimics the carcinogenic model related to chronic bowel inflammation in mice (*i.e.*, Azoxymethane/Dextran Sodium Sulfate - AOM/DSS)^[62,63].

Saleiro *et al.*^[64] demonstrated that ER beta-deficient mice developed more severe colitis compared to wild type mice, as evidenced by a significantly higher disease activity index after DSS treatment, as well as the inflammation score and grade of dysplasia. ER beta-deficient colons presented a greater number and size of polyps, and were characterized by a significant increase in IL-6, IL-17, TNF alpha and interferon-gamma mRNA levels as compared to wild type mice organs. Furthermore, higher protein expression levels of nuclear factor-kappa B, inducible nitric oxide synthase (iNOS), beta catenin, proliferating cell nuclear antigen, mucin-1, and significantly lower caveolin-1 and mucin-2 protein levels, were shown in ER beta knock-out mice compared to wild type. These data suggest a possible anti-inflammatory and anti-neoplastic mechanism of action of ER beta in UC-arisen CRC. These results suggest that ER beta may be protective in the AOM/DSS-induced CRC model in mice, supporting a preventive and/or therapeutic potential for the use of ER beta-selective agonists in IBD.

Fujii *et al.*^[65] performed a study to clarify whether methylation analysis of the ER gene in non-neoplastic epithelium can contribute to the prediction of an increased neoplasia risk in UC patients. The study was based on the assumption that the ER gene shows an age-related methylation in the colorectal epithelium and this phenomenon is frequently found in sporadic colorectal

neoplasia, suggesting that it may predispose to colorectal neoplasia. The results suggested that the analysis of ER gene hypermethylation may be a potentially useful marker for identifying individuals at increased risk of neoplasia among those with long-standing and extensive UC. The same group confirmed that the quantitative analysis of ER gene methylation in non-neoplastic epithelium is a marker for identifying individuals at increased risk of neoplasia in long-standing and extensive UC^[66].

A preliminary report by our group^[67] assessed the pattern of ER-alpha/beta expression in relation to epithelial apoptosis and cell proliferation in long-lasting UC. We did not observe significant variations in ERs and their ratio in UC compared to UC-low degree dysplasia. However, there was a statistically significant progressive increase in apoptosis in UC and in UC-dysplasia that, despite Ki-67 expression, revealed a more marked significant increase at the same stages. This result, despite the small sample and the inclusion of only low-grade dysplasia, suggested that a possible ER-beta overseer of apoptosis/proliferation is operative until the investigated stage of carcinogenesis (Figure 1). In fact, in LGD we observed a high increase in cell proliferation with invariable levels of ER beta, accompanied by mild increased apoptosis, that was presumably unable to completely counter Ki-67 over-expression. Further, we investigated ER beta, ER alpha expression and their ratio in normal mucosa, in UC and in UC-low and high grade dysplasia and CRC. ERs did not show significant changes until LGD, while in HGD and UC-carcinoma there was a dramatic loss of ER beta expression and the ER beta/ER alpha ratio. Apoptosis and the TUNEL/Ki-67 ratio demonstrated a statistically significant progressive decrease from LGD to UC-carcinoma^[68].

IS THERE A ROLE FOR CHEMOPREVENTION?

The main risk factors for colorectal cancer are not suitable targets for therapeutic intervention, but primary chemoprevention is an intriguing therapeutic option. The question whether mesalazine could exert a chemopreventive effect has been raised and various studies have investigated this aspect.

The mechanisms by which aspirin or non-steroidal anti-inflammatory drugs (NSAIDs) act in the chemoprevention of CRC in non-IBD patients have not been entirely elucidated. However, data on the chemopreventive effect of aspirin and NSAIDs and CRC are supported by a series of independent lines of evidence. Indeed, several epidemiological studies have shown an inverse correlation between aspirin intake and the risk of CRC^[69-71]. Furthermore, studies on secondary chemoprevention reported that aspirin intake was associated with a decreased risk of adenoma recurrence^[72,73]. Aspirin and NSAIDs seem to act by inducing apoptosis in the colonic epithelium through the inhibition of cyclooxygenase (COX) activity and arachidonic acid accumulation^[74]. Recent evidence suggests that COX inhibition can also change the activity

of mitogen-activated protein kinases and NF κ B^[75,76].

The analogies between acetyl-salicylic acid and mesalazine (5-amino-salicylic acid), and the results obtained by using acetyl-salicylic acid as a chemopreventive agent in patients with sporadic colorectal cancer have prompted the study of potential chemopreventive effects of mesalazine in inflammatory bowel disease. The results of both epidemiological and experimental studies have shown that long-term 5-amino-salicylic acid treatments appear to have a chemopreventive effect. We can cite two studies, by Eaden and Lashner, in which the relative risk of CRC was estimated to be 0.18 and 0.88, respectively^[77,78]. In a group of patients affected by UC and PSC, the risk was 0.88^[79]. The evidence for this effect is provided by retrospective and case-control studies, however, whose results do not reach the highest grades for evidence-based recommendations. Indeed, not all clinical studies reported favorable results regarding CRC in IBD patients. Negative results were mainly reported in studies that elicited positive results with other drugs such as folate or ursodiol^[80]. The peculiarities of the cohorts enrolled in these studies (disease refractory to conventional therapy, consideration for treatment with experimental therapy, consultation for surgery) may account for the negative outcome.

Positive results are supported by a series of experimental studies demonstrating the multiplicity of actions of 5-amino-salicylic acid, although data regarding the chemopreventive effect of 5-amino-salicylic acid may not be rigorous enough to meet the criteria for the highest evidence-based medicine recommendations. A final consideration is that suitable evidence may not be rationally gained in this case, because discontinuation of 5-amino-salicylic acid treatment would be unethical in patients with UC^[81].

FUTURE PERSPECTIVES OF CHEMOPREVENTION BY BETA RECEPTOR AGONISTS

The data summarized in the previous sections suggest the hypothesis that the loss of ER beta expression could be a marker of colonic mucosa at increased risk for colonic neoplasia and that the induction of ER beta with ER beta-selective phytoestrogens could exert a chemopreventive effect against CRC.

Observational data also suggest that phytoestrogen intake may be associated with a decreased incidence of advanced lesions in both men and women^[82-84]. The mechanism of the putative protective effect of estrogens and phytoestrogens on colonic neoplasia is not fully understood, but it seems to be markedly different from the one underlying the detrimental effect of estrogens in breast cancer. In the breast, it is well established that the detrimental effect is due to estrogen binding to the proliferative ER alpha, since a similar effect is not found in women with ER-negative breast cancers^[85].

Barone *et al.*^[86] have shown that the ER beta/ER alpha ratio was lower in the normal small intestinal mucosa of APC^{min/+} mice than in syngenic APC wild type and this phenomenon was associated with a decreased apoptotic activity. The ER beta/ER alpha ratio and apoptosis were normalized by supplementation with a combination of silymarin and insoluble fibers. The combination also markedly decreased the number and size of intestinal tumors in APC^{min/+} mice^[86]. Silymarin displays a full ER beta agonist activity^[87,88] and lignans also exert phytoestrogenic activity^[89]. Another study by our group^[90] was a randomized, double blind placebo-controlled trial in patients undergoing surveillance colonoscopy for previous sporadic colonic adenomas. Sixty eligible patients were randomized to receive a placebo or active dietary intervention with phytoestrogen supplements twice a day, for sixty days before surveillance colonoscopy. The phytoestrogen administration group showed a significant increase in ER beta protein and a general trend to an increase in ER beta, ER beta/ER alpha, TUNEL/Ki-67 ratio. Moreover, a significant increase of ER-beta protein, mRNA and labeling index (*i.e.*, the percentage of ER-beta positive cells at immunohistochemistry) and a decrease of ER-alpha protein, as well as an increase in ER beta/ER beta protein were observed in phytoestrogen versus placebo group in patients without recurrent polyps. Therefore, the role of ER beta on the control of apoptosis, as well as its amenability to dietary intervention, were supported by this study.

Finally, 90-d supplementation with phytoestrogens was efficacious in reducing polyp number and size in recurrent duodenal adenomas of patients with FAP with an ileal pouch-anal anastomosis^[91].

CONCLUSION

UC is a condition that increases affected patients' risk for CRC development. Nowadays, specific screening and follow-up programs, based on epidemiological and clinical parameters, are routinely performed to promote the early detection of CRC onset. This practice has induced a marked reduction of the cancer incidence and mortality in subjects with UC.

Chemoprevention is an interesting topic which has been widely investigated and developed in many medical fields^[92]. Aspirin has shown a preventive effect on CRC onset, and mesalazine has been strongly invoked as a potential chemopreventive agent against carcinoma arising in UC^[93].

The ER alpha/beta balance seems to have a relevant influence on colorectal carcinogenesis and ER beta appears to parallel apoptosis, thus exerting an anti-carcinogenic effect^[94]. In preliminary studies phytoestrogens, which are able to act as ER beta agonists, have shown promising chemopreventive effects on sporadic as well as genetically inherited CRC. In view of the strong evidence of a role for ERs in UC-related carcinogenesis, and taking into account the fact that phytoestrogens can

be considered as dietary supplements and are completely free from side effects, they offer interesting prospects for CRC prevention even when the disease is the long term consequence of chronic inflammation.

In conclusion, ERs have a role in the development of all different types of CRC^[95] (sporadic, genetic and post-inflammatory). Their targeted use is, therefore, a fascinating field for both basic and clinical investigations in order to elucidate the underlying pathophysiological, prognostic and therapeutic aspects.

Abstract

It has been presumed that aberrant immune response to intestinal microorganisms in genetically predisposed individuals may play a major role in the pathogenesis of the inflammatory bowel disease, and there is a good deal of evidence supporting this hypothesis. Commensal enteric bacteria probably play a central role in pathogenesis, providing continuous antigenic stimulation that causes chronic intestinal injury. A strong biologic rationale supports the use of probiotics and prebiotics for inflammatory bowel disease therapy. Many probiotic strains exhibit anti-inflammatory properties through their effects on different immune cells, pro-inflammatory cytokine secretion depression, and the induction of anti-inflammatory cytokines. There is very strong evidence supporting the use of multispecies probiotic VSL#3 for the prevention or recurrence of post-operative pouchitis in patients. For treatment of active ulcerative colitis, as well as for maintenance therapy, the clinical evidence of efficacy is strongest for VSL#3 and *Escherichia coli* Nissle 1917. Moreover, some prebiotics, such as germinated barley foodstuff, *Psyllium* or oligofructose-enriched inulin, might provide some benefit in patients with active ulcerative colitis or ulcerative

colitis in remission. The results of clinical trials in the treatment of active Crohn's disease or the maintenance of its remission with probiotics and prebiotics are disappointing and do not support their use in this disease. The only exception is weak evidence of advantageous use of *Saccharomyces boulardii* concomitantly with medical therapy in maintenance treatment.

Key words: Gut; Microbiota; Inflammatory bowel disease; Probiotic; Prebiotic

Core tip: Intestinal microbiota seems to play an important role in the pathogenesis of inflammatory bowel disease. There is very strong evidence supporting the use of certain probiotics and prebiotics in the therapy of ulcerative colitis and pouchitis, whereas their beneficial role in Crohn's disease has not yet been proven. This article describes the role of gut microbiota in the pathogenesis of inflammatory bowel disease and delineates the possible mechanisms of certain probiotics and prebiotics in disease treatment and maintenance of remission.

REVIEW OF THE FACTS ON GUT MICROBIOTA IN INFLAMMATORY BOWEL DISEASE

A variety of factors, which may be environmental, genetic, immunological, and microbial in nature, contribute to

the development of inflammatory bowel disease (IBD)^[1]. Although the exact etiology of IBD remains unclear, it is believed to be the result of complex aberrant immune responses to as yet undetermined environmental factors (most likely intestinal microorganisms) in the gastrointestinal tract of genetically susceptible hosts^[2].

The human gut normally hosts roughly 10^{14} bacterial organisms of up to 1000 different species; this bacterial community can add up to 1-2 kg^[1]. In total, the number of intestinal bacteria is approximately ten times the number of cells constituting the human body, with the collective bacterial genome, also referred to as the microbiome, containing 100-fold more genes than the entire human genome^[3,4]. More than 99% of the gut microbiota is composed of species within 4 bacterial divisions: *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, and *Actinobacteria*^[5,6]. Greater variations exist below the phylum level, and certain butyrate-producing bacteria, including *Faecalibacterium prausnitzii*, *Roseburia intestinalis*, and *Bacteroides uniformis*, have been identified as key members of adult gut microbiota^[7]. The predominant species in the proximal small intestine are aerobic and Gram-positive. In the distal small bowel, Gram-negative species begin to outnumber Gram-positive bacteria^[8]. Distally to the ileocecal valve, bacterial concentrations increase sharply^[8], and the most densely populated region of the gastrointestinal tract is the colon, with up to 10^{12} bacteria per gram of intestinal content and a population consisting predominantly of the *Bacteroides*, *Bifidobacteria*, *Fusobacteria*, *Clostridia*, and *Peptostreptococci* groups^[1]. The majority of intestinal bacteria belong to the phyla *Bacteroidetes* (64% of attached colonic species) or *Firmicutes* (23% of normal species)^[1,5]. *Enterobacteriaceae* such as *Escherichia coli* are relatively minor components of the *Proteobacteria* division (8% of all bacteria)^[5].

There is plenty of evidence supporting the hypothesis of the involvement of intestinal microbiota in IBD pathogenesis. Crohn's disease (CD) and ulcerative colitis (UC) tend to occur in the colon and distal ileum, which contain the highest intestinal bacterial concentrations^[5]. A pathogenic role of luminal constituents is suggested by the prevention and treatment of Crohn's disease by the diversion of fecal stream and reactivation of inflammation within one week following reinfusion of ileostomy contents^[9]. In patients with CD, diversion of the fecal stream proximally to the inflamed mucosa results in reduction of inflammation and induction of healing in the excluded parts of the gut, while relapse occurs with restoration of fecal stream and re-exposure to luminal contents^[9,10]. Similarly, ulcerative colitis patients who undergo ileal pouch-anastomosis surgery develop mucosal inflammation after bacterial colonization of the pouch^[11]. A recent meta-analysis by Khan *et al.*^[12] has shown the significant beneficial effects of antibiotics over placebo for induction of remission in both CD and UC. Antibiotic treatment also appears to provide clinical benefits in patients with CD and inflammation of the ileal pouch^[13]. Furthermore, there are many studies on animal models supporting the role of gut microbiota in the development

of IBD. In experimental animal models of IBD, genetically-engineered animals developed spontaneous colitis under standard laboratory conditions, but remained colitis-free when they were raised in a sterile, germ-free environment, thus indicating that bacterial exposure and colonization are essential for the development of colitis^[13-16]. Additionally, it has been shown that animal models with chemically induced colitis do not develop intestinal inflammation if they are pretreated with antibiotics^[17].

The majority of genes found to be associated with an increased risk for the development of IBD are those encoding proteins that act to preserve the mucosal barrier and/or regulate the host immune system. A major breakthrough in understanding the linkage between genetic predisposition and IBD development was the discovery of the NOD2/CARD15 gene, which encodes a protein belonging to the family of pattern-recognition receptors responsible for microbial recognition, induction of antimicrobial genes, and control of the host adaptive immune response^[18]. The genetic defects found in IBD CD patients might make these individuals particularly susceptible to infection by intracellular bacteria such as *Mycobacterium avium paratuberculosis*, *Listeria monocytogenes*, and adherent-invasive *Escherichia coli*^[19]. Mutations in genes for toll-like receptors, as well as for the CARD4/NOD1 receptor, may also be associated with increased susceptibility for IBD^[20-23].

Patients with CD have increased intestinal permeability, which could reflect mucosal barrier defects that promote bacterial translocation through the intestinal mucosa^[24]. The intestinal mucus barrier is significantly altered in UC patients, particularly in terms of mucus composition and phospholipid concentration^[25]. Altered function of defensins, antimicrobial peptides with bactericidal activities, might also be involved in IBD^[1,24].

Despite much evidence that intestinal microorganisms are required for the triggering and perpetuation of inflammation in IBD, it still remains enigmatic whether a single specific microorganism or a group of microbial agents sharing distinctive characteristics could be responsible, or if it is actually the aberrant immune response to the dysbiosis of the commensal intestinal microbiota that plays the most major role.

Mycobacterium avium paratuberculosis used to be a particularly strong candidate as the single etiologic agent in CD in the past, since it has been shown to cause granulomatous enterocolitis in cattle that closely resembles CD in humans^[26]. However, a two-year trial of combined antibiotic therapy with clarithromycin, rifabutin, and clofazimine (drugs efficient against *Mycobacteria*) did not reveal any difference in disease activity in CD patients with or without antibiotic treatment^[27]. Increased numbers of invasive mucosa-associated or even intramucosal *Escherichia coli* (*E. coli*) have been reported in patients with CD and UC; a new potentially pathogenic group called adherent-invasive *E. coli* (AIEC)^[20,22,28-30]. AIEC are able to adhere to and invade intestinal epithelial cells with a macropinocytosis-like process. They are capable of surviving and

replicating within macrophages, and are known to induce the release of large amounts of pro-inflammatory cytokines, such as TNF- α , by the infected host cell^[23].

Although microbial pathogens have been postulated to cause Crohn's disease and ulcerative colitis since their original descriptions, it is now generally accepted that commensal enteric bacteria, either incidentally or specifically, play an important or even central role in the pathogenesis of inflammatory bowel disease, and provide the constant antigenic stimulation that continuously activates pathogenic T cells to cause chronic intestinal injury^[1,5]. Four broad mechanisms have been proposed to drive pathogenic immunologic responses to luminal microbial antigens: microbial pathogens inducing intestinal inflammation, dysbiosis of commensal microbiota with a decreased ratio of protective/aggressive commensal bacterial species, host genetic defects in containing commensal microbiota, and defective host immunoregulation. These mechanisms increase exposure of bacterial antigens to mucosal T cells or alter host immune responses to commensal bacteria^[5].

In normal hosts, commensal bacteria activate a sequential program of homeostatic responses by epithelial cells, macrophages, dendritic cells, and T and B lymphocytes that permit coexistence with microbes and their products^[5,31,32]. In IBD, genetically predisposed individuals appear to lose the normal tolerance to commensal bacteria, leading to a chronically active inflammation process in which the microbiota provide constant stimulus for the host immune system, causing perpetuation of the disease^[17]. Tissue damage might result from an immunologic misperception of indigenous flora as dangerous organisms or from the failure of normal regulatory constraints on mucosal immune responsiveness to intestinal bacteria^[33]. There is growing evidence that the interplay between intestinal microbes and the mucosa of susceptible individuals triggers a cascade of reactions that starts with the interaction of microbes with specific receptors on intestinal epithelial cells, dendritic cells, and other antigen-presenting cells, followed by the interaction of these activated cells with lymphocytes, resulting in their differentiation into different subsets, driving either Th1 or Th2 inflammatory responses with the production of a wide range of inflammatory mediators, and consequently leading to mucosal damage^[34]. CD is regarded to be a Th1 immune reaction driven state, whereas UC is a Th2 immune state. Bacterial recognition is dependent on transmembrane pattern recognition receptors of intestinal epithelial cells, including toll-like receptors (TLR) and the intracellular NOD-like receptor family^[5,31,35,36]. Ligation of these bacterial receptors stimulates central signaling cascades that include the nuclear factor-kappaB (NF κ B) pathway, one of the key pathways in mucosal homeostasis that is shown to be elevated in the chronic inflammation tissue of the IBD^[5,37].

Composition of gut microbiota in patients with IBD has been extensively studied over the last decade. Although methodologies and results may differ, some gen-

eralizations are possible^[38]. Numerous studies revealed that fecal microbiota has a different composition in IBD patients compared to healthy controls, and some differences between microbial populations in CD and UC were found. Similar findings were described for mucosa-associated microbiota, a bacterial population present on the mucosal surface that is in direct interaction with intestinal epithelial and immune system cells^[39-42]. Moreover, differences were observed between active and non-active stages of the disease as well as between inflamed and non-inflamed regions of the intestine^[41,43,44]. When studying intestinal flora in IBD, it is important to keep in mind certain facts. Firstly, only up to 30% of the total microflora can be identified using conventional bacteriological techniques^[38], however using molecular techniques has greatly improved the detection rate, though significant numbers of bacteria can still be left undetected^[38,45]. Secondly, many strains found in IBD do not belong to major phylogenetic groups represented in healthy individuals^[38,46]. Furthermore, a distinction should be made between mucosal flora and fecal flora. The composition of these two domains is unique, which seems to be important in IBD^[38,47].

Concentrations of mucosal bacteria are high in patients with bowel inflammation, especially those with CD, whereas they are low in healthy controls. Bacterial invasion of mucosa was evident in up to 83% of biopsies from IBD patients, while no bacteria were detected in tissue samples from controls^[45,48]. Functional alterations are most evident in adherent, invasive *Escherichia coli* that colonize the ileum of Crohn's disease patients^[49]. Fluorescent in situ hybridization studies demonstrate dramatically increased mucosa-associated bacteria in active Crohn's disease, and to a lesser extent in ulcerative colitis^[48]. The fecal microbiota differs from the mucosa-associated microbiota^[6], with the latter probably being more relevant for intestinal immunomodulation^[48].

Reduced microbial diversity in inflammatory bowel disease has been previously reported^[50-52]. Ott *et al*^[50] demonstrated that mucosal inflammation in IBD was associated with a loss of normal anaerobic bacteria; the reduction in diversity in IBD was due to a significant loss of *Bacteroides*, *Eubacterium*, and *Lactobacillus* species. The reduction in mucosa-associated *Bifidobacteria* and increase in *E. coli* and *Clostridia* in patients with IBD supports the hypothesis that an imbalance between potentially beneficial and pathogenic bacteria may contribute to its pathogenesis^[50,53-55]. Manichanh *et al*^[52] used a metagenomic approach to demonstrate the reduced complexity of the bacterial phylum *Firmicutes*, in particular *Clostridium leptum*, in CD patients compared to healthy controls. In general, fewer *Bacteroidetes* and *Firmicutes* were found^[56,57], including *Faecalibacterium prausnitzii* and bacterial species with a large butyrate-generating and anti-inflammatory capacity^[39,42,57,58], as well as a reduced diversity within this phylum^[59]. The counts of other short chain fatty acid (SCFA) producing bacteria such as *Bifidobacteria* are also reduced and consequently concentrations of SCFA in the intes-

tine decrease^[60-62]. Other studies have shown, however, that the number of mucosa-associated bacteria increased with the increase of *Enterobacteriaceae*, including adherent-invasive *E. coli*^[43,62-64].

A comprehensive study of 190 resected tissue samples by Frank *et al* showed decreased numbers of the phyla *Firmicutes* and *Bacteroidetes* with concomitant increases in *Proteobacteria* and *Actinobacteria*^[59]. In a study of adult patients, Gophna *et al* compared the tissue-associated intestinal microbiota in biopsy samples from patients with CD and UC, as well as from healthy controls. Their findings showed a significant increase of *Proteobacteria* and *Bacteroidetes* in CD patients and a decrease in *Clostridia* in this group. Comparison between the ulcerative colitis and healthy control groups displayed no significant differences. Based on the finding that the microbiota was of similar composition in samples from inflamed and non-inflamed tissues within the same individual, they concluded that imbalance in microbiota in CD is probably not sufficient to cause inflammation^[64].

Nwosu *et al*^[65] investigated correlation of age dependency and IBD. Their findings demonstrated an apparent opposite age-related trend for *Bacteroides* and *Escherichia* between UC and CD, suggesting an immunological effect of *Bacteroides* on promoting CD at early age while later having a protective role, suggesting that these differences reflect underlying immunological disorders for CD and UC.

Up to 95% of patients with active colitis may harbor sulfate reducing bacteria (SRB)^[55,66,67]. Fecal samples of patients with UC have been shown to have greater than normal levels of SRB and it has been suggested that SRB may play an important role in UC pathogenesis. Theoretically, the impairment of butyrate metabolism within colonocytes may lead to increased villous atrophy, which is one of the features of active inflammation of colonic mucosa^[54].

Pediatric populations are useful for research into gut microbiota in IBD, as most pediatric patients are treatment-naïve or newly diagnosed. Although most research has been performed on adults, microbiota of pediatric IBD has been increasingly investigated over the last few years. The first larger pediatric microbiota investigation in IBD patients by Conte *et al*^[29] showed a higher number of mucosa-associated facultative-anaerobic and aerobic bacteria in the ileum, cecum, and rectum of children with IBD than in controls, with the highest numbers found in patients with indeterminate colitis and Crohn's disease. They also found a good deal of individual variability in the concentrations of mucosa-associated bacteria within the different groups of patients examined, although the highest heterogeneity of species was found in the ileal mucosa of patients with Crohn's disease.

Microbial dysbiosis was also demonstrated using fecal samples in 19 children with newly diagnosed Crohn's disease. This study showed significantly lower concentrations of *Firmicutes*, mainly due to changes in detection within the *Clostridia* class, and higher concentrations of *Proteobacteria* and *Bacteroidetes*, whereas the concentration

of *Actinobacteria* was similar in CD patients and controls. Furthermore, Kaakoush *et al*^[68] concluded that the ratio of *Bacteroidetes* to *Firmicutes* increased with the PDAI activity index of the patients.

Lionetti *et al*^[69] suggested that a possible mechanism of action of enteral nutrition in inducing disease remission in pediatric patients with Crohn's disease is the modification capacity of the gut microbiota. This was supported by the findings that in 8 out of 9 pediatric Crohn's patients, enteral nutrition alone induced disease remission. In all children with CD, analysis of gel band distribution revealed profound modification of the fecal microflora after exclusive enteral nutrition therapy, whereas in healthy controls no modification of microflora was detected and a bacterial profile analysis remained stable during the 3-mo observation period.

Horizontal distribution of the fecal microbiota in adolescents with IBD was investigated by Gosiewski *et al*^[70], who demonstrated that distribution of the microbiota in the colon is layered. Their results demonstrated that the quantitative composition of the bacterial microbiota changed in the consecutive fecal fractions and tissue samples of patients with CD and UC, whereas in the control group there were no differences in microbiota composition in consecutive fecal and tissue samples. The largest differences in the total proportion of bacteria were visible in the *Bifidobacterium* genus, whose number declined with consecutive fractions, whereas in controls it remained high in all fractions. Also, in patients with CD, the percentage of bacteria from the *Streptococcus* genus and *Enterobacteriaceae* in subsequent fractions increased in comparison to the control group, and in patients with UC similar findings were described for *Lactobacilli*. Investigation of the *Bacteroides spp.* showed that their percentage dropped in the consecutive fecal fractions in CD, similarly to the control group, whereas in patients with UC it increased. Only in the UC group was the bacterial flora attached to the mucous layer found to exert degrading action on the protective mucin^[70]. Mucus layer thickness in adolescents with IBD was studied in a group by Fyderek *et al*^[71]. They demonstrated that the mucus layer in the inflamed sites was significantly thinner as compared to controls and to non-inflamed sites in IBD patients. Furthermore, they reported that *Streptococcus spp.* were predominant in the inflamed mucosa in CD patients, and *Lactobacilli spp.* were predominant in UC patients.

In a study of 15 treatment-naïve pediatric patients with CD and 26 healthy controls, Kellermayer *et al*^[72] investigated mucosal microbiota with high-throughput methodologies. Using distance-based redundancy analysis, they showed that there was significant separation between the CD-associated colonic mucosal microbiota and the microbiota of controls. They also showed that patients with granulomatous CD had a higher number of genera and species, significantly differentiating the colonic mucosal microbiota from controls and patients without granulomas. The most prominent genera distinguishing granulomatous CD from non-granulomatous were *Rumi-*

nococcus, *Roseburia*, *Eggerthella* (all three decreased), and *Porphyromonas* (increased). There was a trend for the genera *Faecalibacterium* to be decreased in the transverse colonic mucosa of granulomatous patients with CD compared with non-granulomatous disease^[72].

A Scottish group by Hansen *et al* has been intensively investigating pediatric gut microbiota in IBD patients over the last few years. They have reported differences in colonic mucosal bacteria between pediatric UC patients and controls. Contrary to findings from previous studies, they reported a reduction in *Bacteroidetes* and an increase in *Firmicutes*^[73]. They also described a reduction in bacterial diversity and an increased concentration of *Faecalibacterium prausnitzii* in de-novo pediatric CD patients, a finding contradicting the current protective role model of *F. prausnitzii* in CD^[74]. In the latest study by this group, microaerophilic microbiota of pediatric IBD onset has been researched. *Campylobacter* appears to be commonly isolated from pediatric colonic biopsies, but does not seem to be strongly associated with IBD. As a common commensal in pediatric gut microbiota, *Sutterella wadsworthensis* has also been reported^[75].

Despite many discoveries in the last two decades, it remains unknown whether the intestinal microbiota triggers and maintains the chronicity of inflammatory response in IBD, or is altered as a secondary response to intestinal inflammation^[76].

PROBIOTICS AND PREBIOTICS

Probiotics are specific live microorganisms which, when ingested in sufficient amounts, can promote health in the host^[77]. In order to qualify as probiotic, microorganisms must fulfill a number of criteria^[78]. They should be strictly specified at the genus, species, and strain levels, and specific strains should be registered and disposed in an international culture collection. Thus, generalizations concerning the efficacy of a whole species or even genus might be misleading. Probiotics should be extremely safe; their safety is supported by the fact that many strains are of human origin and have a long history of safe use. Many probiotics and their applications have been granted GRAS (generally regarded as safe) status. Although this classification should not be generalized, it does not warrant permanent surveillance for potential risks, such as invasiveness and potential for transfer of antibiotic resistance to other microorganisms^[79,80]. Because the effects of probiotic microorganisms are generally dependent on their viability, their stability during processing and storage, as well as their ability to survive intestinal transit through the stomach and proximal small bowel to finally adhere to mucosa and colonize the intestine, should be demonstrated^[78]. The final, but perhaps one of the most important, criteria for specific microorganism to be qualified as probiotic is a scientifically proven effect on the promotion of health or prevention and treatment of a specific disease^[78].

Prebiotics are non-digestible food ingredients that

selectively stimulate favorable bacterial growth and/or promote activity of a limited number of health-promoting bacteria, hence benefiting the host^[81,82]. However, prebiotics can also be applied to enhance the survival and action of ingested probiotic bacteria. When probiotics and prebiotics are combined in one product to achieve synergistic effects they are usually called synbiotics. The vast majority of prebiotic substances are carbohydrates that are indigestible for human digestive enzymes but can be fermented by beneficial bacterial genera in the colon and serve as a substrate for their metabolism. Some of them can be found in natural foods, such as human milk oligosaccharides in mother's milk, while others are added to food. Good examples of prebiotics are fructo-oligosaccharides (FOS), inulin, galacto-oligosaccharides (GOS), soybean oligosaccharides, and complex polysaccharides that constitute dietary fiber^[81].

Probiotics or prebiotics may achieve their therapeutic effect in IBD through many different mechanisms. They influence the composition of intestinal microbiota and alter the metabolic properties of the microbiome^[76]. By increasing the production of short-chain fatty acids, they may lower the pH of the colonic environment and thus inhibit the growth of potentially pathogenic microorganisms. Butyrate plays a trophic role as a nutrient for colonocytes and enhances repair of injured gut epithelium in IBD. Moreover, evidence shows that butyrate acts directly as an anti-inflammatory agent by inactivating the intracellular transcriptional factor NF κ B pathway, consequently attenuating synthesis of inflammatory cytokines^[8]. A large number of probiotic strains are able to produce antibacterial substances, such as hydrogen peroxide, hydrogen sulfide, lactic acid, and specific bacteriocins^[83], as well as displace deleterious microbes from the luminal-mucosal interface by competing for binding sites on the epithelial cell surface or mucus layer^[84,85].

Probiotics communicate with epithelial cells and different sets of cells implicated in both innate and acquired immune response via pattern-recognition receptors^[3]. They can enhance gut barrier function and reduce intestinal permeability for intestinal microorganisms and other antigens^[86]. For example, several strains of *Lactobacilli* can up-regulate MUC3 gene expression, resulting in increased mucus production by intestinal goblet cells^[87,88]. Several probiotic strains can induce the production and secretion of different anti-microbial peptides by epithelial cells, such as defensins, lysozyme, lactoferrin, or phospholipase, and directly decrease permeability of the epithelial layer by enhancing tight junctions and reducing epithelial cell apoptosis^[85,89,90].

Each probiotic strain may have distinct immunoregulatory properties, thus probiotics can indirectly or directly modulate intestinal immune response. In very simplified terms, probiotics can be classified into two groups with regards to their influence on the immune system: one exhibiting immunostimulating activities and the other anti-inflammatory properties^[91]. Numerous studies have revealed the mechanisms by which probiotics down-reg-

ulate the inflammatory immune response, including those with proven clinical efficacy in the therapy of IBD. Some probiotic strains may induce maturation of intestinal dendritic cells, an important part of antigen presenting and immune regulation, and extend their survival^[92]. Several probiotics act through strengthening the regulatory T cell (Treg) response. Tregs are antigen-specific T cells which prevent autoimmunity and preserve tolerance towards harmless antigens, including intestinal commensal microbiota^[84]. They can control excessive NF κ B pathway activation, decrease production of pro-inflammatory cytokines (*e.g.*, TNF α , INF γ , and IL-8), and induce the production and secretion of anti-inflammatory cytokines such as IL-10 and TGF β ^[3,91,93,94].

It is possible that there are further mechanisms of probiotic action that have not yet been demonstrated. Regarding the fact that pathogenesis of each type of IBD differs and that mechanisms of action of probiotics are strain-specific and very different, we might expect that different probiotics would be effective for each type and phase of the disease.

Over the last two decades, several interventional clinical studies comparing the efficacy of probiotic therapy against placebo or standard therapy with drugs have been published. The use of different study designs (*e.g.*, concomitant use of other forms of therapy) and various probiotic strains and doses, with only a few studies resembling one another in such a manner to be able to uniformly compare the results, makes it very difficult to derive any firm conclusions.

TREATMENT OF ACTIVE ULCERATIVE COLITIS

Clinical studies on the efficacy of probiotics for the induction of remission in ulcerative colitis gave encouraging, albeit conflicting, results. Bennet and Brinkman first reported a successful induction of long-lasting remission by a single enema of the fecal microbiota of a healthy donor in a patient with active UC^[95]. Borody *et al*^[96] published six cases of patients with UC resistant to medical therapy with steroids and immunomodulators who underwent transplantation of fecal microbiota from healthy donors by repeated enemas after 7-10 d of pre-therapy with vancomycin, metronidazole, rifampicin, and bowel lavage with polyethylene glycol. Complete reversal of UC was achieved in all patients, and they were all able to stop anti-inflammatory therapy after 6 wk. After 1 to 13 years of follow-up, all patients remained in complete clinical, endoscopic, and histologic remission without any adjunctive therapy.

Several studies investigated the efficacy of multispecies probiotic VSL#3 containing four strains of *Lactobacilli* (*L. casei*, *L. plantarum*, *L. acidophilus*, and *L. delbrueckii* subsp. *bulgaricus*), three strains of *Bifidobacteria* (*B. longum*, *B. breve*, and *B. infantis*) and one strain of *Streptococcus* (*S. salivarius* subsp. *thermophilus*). Tursi *et al*^[97] compared the efficacy and safety of low-dose balsalazide (2.25 g/d)

plus 3 g/d VSL#3 (group A, *n* = 30), with medium-dose balsalazide alone (group B, *n* = 30), and with mesalazine (group C, *n* = 30) in the 8-wk treatment of mild to moderate active ulcerative colitis. Efficacy was assessed by assessment of symptoms, endoscopic appearance, and histological evaluation. Balsalazide/VSL#3 was significantly superior to balsalazide alone and to mesalazine in obtaining remission (85.71% *vs* 80.77% *vs* 72.73%, respectively; *P* < 0.02). The balsalazide/VSL#3 combination was faster in obtaining remission than balsalazide alone or mesalazine (4, 7.5, and 13 d, respectively), and was also better in improving all parameters evaluated. Moreover, balsalazide with or without VSL#3 was better tolerated than mesalazine. The authors concluded that balsalazide/VSL#3 might be a very good choice in the treatment of active mild-to-moderate active ulcerative colitis. Bibiloni *et al*^[98] studied the efficacy and safety of VSL#3 for induction of remission in an open-label study in 34 ambulatory patients with mild to moderate active UC. Among 32 patients who completed 6-wk treatment with VSL#3 3.6×10^9 CFU/d, remission (defined as UCDAI < or = 2) was achieved in 53% and response (decrease in UCDAI > or = 3, but final score > or = 3) in 24%. In 9% of patients there was no response, in another 9% worsening of the condition was observed, and in 5% there was no final endoscopic assessment. The investigators reported no biochemical or clinical adverse events related to VSL#3. In addition, they confirmed the presence of VSL#3 species by DNA sequencing of 16S rRNA in biopsies collected from patients in remission. A small open-label pilot study on 18 pediatric patients between the ages of 3-17 years with mild to moderate acute UC using VSL#3 for 8 wk was performed by Huynh *et al*^[99]. The simple clinical colitis activity index (SCCAI) was used to assess disease activity. Remission (defined as SCCAI \leq 3) was achieved in 56% and response (decrease in SCCAI \geq 2, but final score \leq 5) in 6%, with no change or worsening reported in 39% of patients. Five patients were withdrawn due to lack of improvement and only 13 patients completed 8 wk of VSL#3 treatment. VSL#3 was well tolerated, and no biochemical or clinical adverse effects attributed to VSL#3 were identified.

Tursi *et al*^[100] compared the efficacy of VSL#3 in a dosage of 3.6×10^9 CFU (*n* = 65) with placebo (*n* = 66) in achieving remission in UC patients on concomitant therapy with aminosalicylates and/or immunosuppressants. After 8 wk of treatment, the decrease in UCDAI of 50% or more was significantly higher in the VSL#3 group (63.1%) than in the placebo group (40.8%) (*P* = 0.010). A decrease of three points or more in the UCDAI score was achieved in 60.5% in the VSL#3 group *vs* 41.4% in the placebo group (*P* = 0.017). They also found a significant difference in rectal bleeding (*P* = 0.014) but not in stool frequency, physician's rate of disease activity, or endoscopic score. Remission was slightly higher in the VSL#3 group than in the placebo group (47.7% *vs* 32.4%; *P* = 0.069).

In a randomized, multicenter, double-blind, controlled

trial, Sood *et al.*¹⁰¹¹ compared the efficacy of VSL#3 applied twice daily in a dosage of 3.6×10^9 CFU ($n = 77$) to placebo ($n = 70$) for induction of remission of mild to moderate UC. The primary endpoint was a 50% decrease in the ulcerative colitis disease activity index (UCDAI) at 6 wk. The secondary endpoints included remission by 12 wk and reduction in total individual UCDAI parameters from baseline at 12 wk. At week 6, the percentage of patients with an improvement in UCDAI score that was greater than 50% was significantly higher in the group given VSL#3 (32.5%) than the group given placebo (10%) ($P = 0.001$). At week 12, 42.9% patients given VSL#3 achieved remission, compared with only 15.7% patients given placebo ($P < 0.001$). Furthermore, significantly more patients given VSL#3 (51.9%) achieved a decrease in their UCDAI that was greater than 3 points, compared with those given placebo (18.6%) ($P < 0.001$). The VSL#3 group had significantly greater decreases in UCDAI scores and individual symptoms at weeks 6 and 12 compared with the placebo group.

Miele *et al.*¹⁰²² performed a 1-year prospective, placebo-controlled, double-blind pediatric study to assess the efficacy of VSL#3 on the induction and maintenance of remission in children with active UC. A total of 29 consecutive patients (mean age: 9.8 years; range: 1.7-16.1 years) with newly diagnosed UC were randomized to receive either a weight-based dose of VSL#3 ($n = 14$) or placebo ($n = 15$) in conjunction with concomitant steroid induction and mesalamine maintenance treatment. The Lichtiger colitis activity index and a physician's global assessment were used to measure disease activity. At baseline (within 6 mo, 12 mo, or at the time of relapse), all patients were assessed endoscopically and histologically. All 29 patients responded to the induction therapy. Remission was achieved in 92.8% children treated with VSL#3 and standard therapy compared to only 36.4% treated with placebo and standard therapy ($P < 0.001$). Moreover, only 21.4% patients treated with VSL#3 relapsed within 1 year of follow-up compared to 73.3% patients from the placebo group ($P = 0.014$). At 6 mo, 12 mo, or at time of relapse, endoscopic and histological scores were significantly lower in the VSL#3 group than in the placebo group ($P < 0.05$). There were no biochemical or clinical adverse events related to VSL#3. This study demonstrated the efficacy of VSL#3 both in the induction and maintenance of remission in pediatric UC patients.

In a small open-label study by Tsuda *et al.*¹⁰³¹, the effectiveness of another multispecies probiotic preparation BIO-THREE (containing *Streptococcus faecalis*, *Clostridium butyricum*, and *Bacillus mesentericus*) was tested for treatment of mild to moderate distal UC refractory to conventional therapies. Twenty patients were treated for 4 wk. Clinical symptoms and endoscopic findings were evaluated, and UCDAI scores calculated before and after treatment. In addition, fecal microbiota was analyzed by the terminal restriction fragment length polymorphism (T-RFLP) method. Remission (UCDAI score ≤ 2) was observed

in 45% and response (decrease in UCDAI ≥ 3 , but final score ≥ 3) in 10%, however in 40% there was no response and in 5% they found worsening (UCDAI > 3) of the disease. T-RFLP analysis indicated an increase in *Bifidobacteria*.

In a single-center, randomized, double-dummy study, Rembacken *et al.*¹⁰⁴⁴ examined whether the addition of a non-pathogenic strain of *E. coli* Nissle 1917 to standard medical therapy increased the chance of remission of active ulcerative colitis and whether this probiotic strain was as effective as mesalazine in preventing relapse. Of a total of 116 patients, 59 were randomized to the mesalazine group and 57 to the *E. coli* group. All patients received concomitant standard medical therapy with tapering steroids together with a 1-wk course of oral gentamicin. After remission, patients were maintained on either mesalazine or *E. coli*, and followed-up for 1 year. The investigators found no significant differences between the mesalazine and *E. coli* groups in percentage of patients that achieved remission, mean time to remission, percentage of patients who relapsed, and mean duration of remission. Although the addition of *E. coli* to standard therapy did not increase the induction rate of remission, the results suggested that treatment with this probiotic might have an equivalent effect to mesalazine in maintaining remission of ulcerative colitis.

Kato *et al.*¹⁰⁵¹ conducted a randomized placebo-controlled trial using *Bifidobacteria*-fermented milk (BFM) (containing *Bifidobacterium breve* strain Yakult, *B. bifidum*, and *Lactobacillus acidophilus*) supplementation as a dietary adjunct in treating active ulcerative colitis. Twenty patients with mild to moderate active UC randomly received 100 mL/d of BFM or placebo for 12 wk with conventional treatment. The clinical activity index was significantly lower in the BFM than in the placebo group, and the endoscopic activity index and histological score were significantly reduced in the BFM, but not the placebo group, after treatment. They also observed an increase in fecal butyrate, propionate, and short-chain fatty acid concentrations in the BFM, but not the placebo group. Therefore, the authors concluded that supplementation with this *Bifidobacteria*-fermented milk product is safer and more effective than conventional treatment of active UC alone.

Ishikawa *et al.*¹⁰⁶¹ compared a group of patients with BFM supplementation 100 mL/d ($n = 11$) and a control group ($n = 10$), both receiving standard medical treatment of ulcerative colitis. Colonoscopies, general blood markers, and examinations of intestinal flora, including the analysis of fecal organic acids, were performed at the initiation of the study and after one year. Exacerbation of symptoms was observed in 3 out of 11 subjects in the BFM group and in 9 out of 10 in the control group. Statistical analysis of the cumulative exacerbation rates showed a significant reduction in exacerbations for the BFM group ($P = 0.0184$). A significant reduction in the relative proportion of *B. vulgatus* in *Bacteroidaceae* and butyrate concentration was observed after supplementation

with BFM in comparison with before.

Recently, Oliva *et al*^[107] published a prospective, randomized, placebo-controlled study comparing the effectiveness of *Lactobacillus reuteri* ATCC 55730 enema and placebo in children with active distal UC. A total of 40 patients (median age 7.2 years; range 6-18 years) were enrolled. They received an enema solution containing 10¹⁰ CFU of *L. reuteri* or placebo for 8 wk, in addition to oral mesalazine. Clinical, endoscopic, and histological scores, as well as rectal mucosal expression levels of pro- and anti-inflammatory cytokines, were evaluated at the beginning and at the end of the trial. Mayo score (including clinical and endoscopic features) as well as histological score decreased significantly in the *L. reuteri* group ($P < 0.01$), but not in the placebo group. Moreover, the evaluation of cytokine mucosal expression levels revealed that IL-10 significantly increased ($P < 0.01$), whereas IL-1 β , TNF α , and IL-8 significantly decreased ($P < 0.01$) only in the *L. reuteri* group.

In a small non-controlled pilot study, Guslandi *et al*^[108] treated 25 patients with mild to moderate clinical flare-up of ulcerative colitis with *Saccharomyces boulardii* 250 mg three times a day for 4 wk during maintenance treatment with mesalazine. Of the 24 patients who completed the study, 17 attained clinical and endoscopic remission.

Furrie *et al*^[109] explored the efficacy of a synbiotic combining a probiotic strain of *Bifidobacterium longum* and a prebiotic (Synergy 1), a preferential inulin-oligofructose growth substrate for this probiotic strain. Treatment was used in a double-blinded randomized controlled trial in 18 patients with active UC for a period of one month. Although the subsequent sigmoidoscopy score decrease in the synbiotic group was not statistically significant compared with placebo ($P = 0.06$), they found that biopsies in the test group had reduced inflammation, and increased regeneration of epithelial tissue and mRNA levels for beta defensins 2, 3 and 4 (which are strongly up-regulated in active UC), tumor necrosis factor alpha and interleukin-1 alpha were also significantly reduced in the test group after treatment ($P = 0.016, 0.038, 0.008, 0.018$ and 0.023 , respectively).

In another study by Ishikawa *et al*^[110], the investigators examined the effects of a live *Bifidobacterium breve* strain Yakult and GOS as synbiotic in active UC. Forty-one patients with mild to moderate UC were assigned to two groups; one was treated with the synbiotic (1 g of the probiotic powder (10⁹ CFU/g) three times a day and 5.5 g of GOS once a day) and the other was not (control group). After one-year treatment with the synbiotic, the clinical status of the UC patients as assessed by colonoscopy significantly improved, and the amount of myeloperoxidase in the lavage, a marker of inflammation, decreased. The synbiotic also significantly reduced the fecal counts of *Bacteroidaceae* and fecal pH.

Several reviews and meta-analyses have been performed over recent years concerning the induction of remission in ulcerative colitis by probiotics. In a Cochrane Collaboration review from 2007, the authors as-

sessed the efficacy of probiotics compared to placebo or standard medical treatment with 5-aminosalicylates, sulfasalazine, or corticosteroids^[111]. Only 4 randomized controlled trials met the criteria, and a formal meta-analysis could not be performed because of heterogeneity in methodology, probiotic strains, and outcomes. The authors concluded that combining conventional therapy with probiotics did not improve overall remission rates in patients with mild to moderate UC. However, they found limited evidence that the addition of probiotics might provide modest benefits in terms of disease activity. The negativistic opinion shared in this early review can be at least partially attributed to the low number of high quality studies published at the time. In a meta-analysis later performed by Sang *et al*^[112] and published in 2010, both the induction of remission and maintenance were compared between probiotic and non-probiotic treatment in ulcerative colitis. Thirteen randomized controlled studies met the selection criteria. Seven studies evaluated the remission rate, 8 the recurrence rate, and 2 both remission and recurrence rates. The remission rate for probiotics compared with non-probiotics therapy was 1.35 (95%CI: 0.98-1.85), while when compared with the placebo it was 2.00 (95%CI: 1.35-2.96). Although these differences were not statistically significant, the authors concluded that these results were probably subject to heterogeneous bias. Regarding maintenance of remission, the recurrence rate of ulcerative colitis in patients who received probiotics was 0.69 (95%CI: 2.47-1.01) and 0.25 (95%CI: 0.12-0.51) in patients with mild to moderate UC compared with the non-probiotic group. The group who received *Bifidobacterium bifidum* treatment had a recurrence rate of 0.25 (95%CI: 0.12-0.50) compared with the non-probiotics group. The authors concluded that probiotic treatment was more effective than placebo in maintaining remission in ulcerative colitis.

In contrast with these reviews, a meta-analysis performed by Zigra *et al*^[113] showed a significant benefit of probiotic use for UC remission induction with pooled relative risk 2.27 (95%CI: 1.00-5.14, $P = 0.049$).

In a more recent review by Jonkers *et al*^[56], only subgroup-specific meta-analyses per probiotic were performed. The only probiotic with several published randomized controlled studies for induction of remission in adult patients with UC was VSL#3. The calculated pooled RR for VSL#3 was 1.69 (95%CI: 1.17-2.43), indicating a significant benefit of VSL#3 over control in inducing remission in active UC.

Interestingly, in the 2011 recommendations for probiotic use from the 3rd Yale Workshop, both VSL#3 and *Escherichia coli* Nissle 1017 were rated B, meaning that recommendation of their use for induction of remission in UC is based on positive controlled studies, but with the presence of some negative studies that did not support the primary outcome^[114].

In conclusion, the results of several clinical studies suggest that the addition of specific probiotics to conventional therapy in active UC may be beneficial. The

strongest evidence exists for multispecies preparation VSL#3, with several studies both in adults and children supporting its efficacy.

MAINTENANCE OF REMISSION IN ULCERATIVE COLITIS

There have been several published studies in which efficacy of the probiotic strain of *Escherichia coli* Nissle 1917 was compared to either placebo or standard therapy for maintenance therapy in UC. In a double-blind, double-dummy study by Kruis *et al.*¹¹⁵, 120 patients with inactive ulcerative colitis were randomized to mesalazine 500 mg three times daily or to an oral preparation of *E. coli* Nissle treatment for 12 wk to compare their efficacy in preventing a relapse of the disease. Study objectives were to assess the equivalence of the two therapeutic modalities by comparing the clinical activity index (CAI), relapse rates, relapse-free times, and global assessment. The start and end CAI scores demonstrated no significant difference ($P = 0.12$) between the two treatment groups. Relapse rates were 11.3% under mesalazine and 16.0% under *E. coli* (N.S.), and the relapse-free time was similar for mesalazine and *E. coli* (103 +/- 4 d and 106 +/- 5 d, respectively). Global assessment was also similar for both groups. Tolerability of the treatment was excellent in both groups. Conclusions of this study were that probiotic treatment with *E. coli* Nissle 1917 offered another option for maintenance therapy of ulcerative colitis. Subsequently, the same group performed another, albeit larger, double-blind, double dummy trial to confirm the equivalent efficacy of *Escherichia coli* Nissle 1917 and mesalazine in the maintenance of remission in UC¹¹⁶. Patients received either the probiotic drug 200 mg once daily ($n = 162$) or mesalazine 500 mg three times daily ($n = 165$) for 12 mo, and were assessed by clinical and endoscopic activity indices (Rachmilewitz) as well as by histology. The per-protocol analysis revealed relapses in 40/110 (36.4%) patients in the *E. coli* group and 38/112 (33.9%) in the mesalazine group (significant equivalence $P = 0.003$). Subgroup analyses showed no differences between the treatment groups in terms of duration and localization of disease or pretrial treatment. Safety profile and tolerability were very good for both groups. By the end of this second study the authors concluded that *E. coli* Nissle 1917 showed the same equivalent efficacy and safety as mesalazine in maintaining remission in patients with ulcerative colitis.

In another trial by Rembacken *et al.*¹⁰⁴, both the capacity of induction and maintenance of remission by *E. coli* Nissle 1917 were evaluated. In this single-center, randomized, double-dummy study, patients were maintained on either mesalazine ($n = 59$) or *E. coli* ($n = 57$) and followed up for a maximum of 12 mo. A comparable percentage of patients relapsed in the mesalazine (73%) and *E. coli* groups (67%), and the mean duration of remission was practically similar in both (206 and 221 d, respectively). Again, the authors came to the conclusion

that treatment with non-pathogenic *E. coli* was as equivalently efficient as mesalazine in maintaining remission of ulcerative colitis.

Zocco *et al.*¹¹⁷ studied the efficacy of a probiotic strain of *Lactobacillus rhamnosus* GG for maintenance therapy in UC. They randomized patients into three groups: *Lactobacillus* GG 18×10^9 CFU/d ($n = 65$), mesalazine 2400 mg/d ($n = 60$), or a combination of *Lactobacillus* GG and mesalazine ($n = 62$). Overall analysis of UCDAI scores and endoscopy and histology results showed no difference in relapse rate at 6 and 12 mo among the three groups. However, treatment with *Lactobacillus* GG alone or in combination seemed to be more effective than standard treatment with mesalazine in prolonging relapse-free time ($P < 0.05$).

A non-controlled trial using multispecies preparation VSL#3 in 20 UC patients in remission, intolerant, or allergic to 5-aminosalicylates for 12 mo was performed by Venturi *et al.*¹¹⁸. They reported that 15 out of 20 patients remained in remission during the study, 4 relapsed, and one was lost to follow-up. They suggested that VSL#3 might be useful in maintaining remission in UC patients intolerant to standard therapy.

In the previously mentioned pediatric study by Miele *et al.*¹⁰², the investigators observed that only 21.4% of patients treated with VSL#3 (compared to 73.3% patients from the placebo group) relapsed within 1 year of follow-up ($P = 0.014$). They also found significantly lower endoscopic and histological scores in the VSL#3 group than in the placebo group ($P < 0.05$). The results of this study confirmed the efficacy of VSL#3 in the maintenance of remission in pediatric UC patients.

Cui *et al.*¹¹⁹ randomized 30 patients with UC in remission achieved by treatment with sulfasalazine and glucocorticoids into two groups: one that received bifid triple viable capsule (BIFICO) (1.26 g/d) for 8 wk and the other an identical placebo group. The patients were evaluated clinically, endoscopically, and histologically after 2 mo of treatment or in the event of UC relapse. Only three patients (20%) in the BIFICO group relapsed during the 2-mo follow-up period compared with 14 (93.3%) in the placebo group ($P < 0.01$). Moreover, the microbiological and immunological analyses revealed that the concentration of fecal *Lactobacilli* and *Bifidobacteria* was significantly increased only in the BIFICO-treated group ($P < 0.01$). The expression of pro-inflammatory NF κ B p65 and DNA binding activity of NF κ B were significantly attenuated, and the mRNA expression of anti-inflammatory cytokines was elevated in the treatment group in comparison with the control group ($P < 0.05$). The authors concluded that oral administration of probiotic preparation BIFICO was effective in preventing flare-ups of chronic UC.

Shanahan *et al.*¹²⁰ performed a double-blind, placebo-controlled study on 157 patients to compare the efficacy of *Lactobacillus salivarius* subspecies *salivarius* UCC118, *Bifidobacterium infantis* 35624 (1×10^9 CFU/d), or placebo for maintenance UC therapy. They found no difference

in relapse time between probiotics and placebo.

Wildt *et al.*^[121] performed a small double-blind placebo-controlled study using probiotic preparation Probio-Tec-AB-25 (containing the two probiotic strains *Lactobacillus acidophilus* La-5 and *Bifidobacterium animalis* subspecies *lactis* BB-12) or placebo in patients with left-sided UC in remission for 52 wk. 25% of patients on probiotics and 8% of those on placebo maintained remission after 1 year of treatment ($P = 0.37$). The median time to relapse was 125 d in the probiotic group and 104 d in the placebo group ($P = 0.683$). The authors concluded that no significant clinical benefit of Probio-Tec-AB-25 in comparison with placebo for maintaining remission in UC was demonstrated.

In the recent Cochrane Collaboration review of probiotic efficacy and safety for the maintenance of remission in UC by Naidoo *et al.*^[122], only 4 studies met the inclusion criteria. Three of those trials compared probiotics to mesalazine, and one to placebo. The pooled analysis was performed and revealed no statistically significant differences in the efficacy of probiotics over mesalazine. Relapse was reported in 40.1% of patients treated with probiotics and in 34.1% of those on mesalazine therapy. No statistical difference in the incidence of adverse events between the two groups was demonstrated. In only one placebo-controlled study was the relapse rate between probiotic and placebo groups considered non-significant. The authors concluded that, given the relatively small number of patients included in the clinical studies, the evidence was insufficient to make conclusions about the efficacy of probiotics for the maintenance of remission in UC.

A subgroup probiotic-specific meta-analysis by Jonkers *et al.*^[56] revealed that pooled relative risk for *E. coli* Nissle compared to mesalazine was 1.08 (95% CI 0.86-1.37), indicating that this strain of *E. coli* was not inferior to mesalazine in preventing relapses.

The American Recommendations for probiotic use from 2011 state very strong “A” recommendations for the use of the two specific probiotics *Escherichia coli* Nissle 1917 and multispecies mixture VSL#3 for the maintenance of remission in UC^[114].

In conclusion, specific probiotics such as *Escherichia coli* Nissle 1917 and multispecies mixture VSL#3 are probably as efficient as standard maintenance therapy with mesalazine, and can therefore be used instead of mesalazine in patients intolerant or allergic to 5-aminosalicylates, or as adjunctive therapy to standard therapy, to potentially increase the duration of remission.

TREATMENT AND PREVENTION OF POUCHITIS

In some patients with UC in whom the disease does not respond to medical therapy or who develop dysplasia or cancer, proctocolectomy with the construction of ileal pouch-anal anastomosis (IPAA) is required. Inflammation of this ileal reservoir (pouch), referred to as pouchitis, develops in between 15% and 50% of such patients.

Although the exact etiology of pouchitis is not clear, host genetic factors, fecal stasis, mucosal ischemia, and bacterial dysbiosis in the pouch seem to be involved^[56,87]. Most patients develop pouchitis in the first year after the procedure. Antibiotic therapy is generally successful; however, discontinuation of antibiotics is often followed by recurrence of the disease. Treatment and prevention of pouchitis with probiotics has thus been studied extensively, and only a few studies addressing the use of probiotics for the treatment of active pouchitis were published.

Kuisma *et al.*^[123] performed a double-blind placebo-controlled trial to investigate the efficacy of *Lactobacillus rhamnosus* GG supplementation as primary therapy for ileal pouch inflammation. Twenty patients with a previous history of pouchitis and endoscopic evidence of inflammation were randomized to *Lactobacillus* GG $0.5-1 \times 10^{10}$ CFU twice daily or placebo for 3 mo. Clinical efficacy was assessed by a change in the pouchitis disease activity index (PDAI). In addition, quantitative bacterial cultures of fecal samples and biopsies taken from the pouch were performed before and after probiotic supplementation. No differences were observed between the groups with regard to the mean pouchitis disease activity index. *Lactobacillus* GG supplementation changed the pouch intestinal microbiota by increasing the ratio of total fecal *Lactobacilli* to total fecal anaerobes ($P = 0.03$) and enhancing the frequency of *Lactobacilli*-positive cultures in the pouch. The authors concluded that although probiotic supplementation with *Lactobacillus* GG changed pouch microbiota, it was clinically ineffective as primary therapy for active pouchitis.

In an open-label study, Laake *et al.*^[124] treated 51 UC patients with IPAA, 6 UC patients with ileorectal anastomosis without pouch, and 10 patients with IPPA because of familial adenomatous polyposis with a fermented milk product culture, containing probiotic strains *Lactobacillus acidophilus* La-5 and *Bifidobacterium animalis* subspecies *lactis* BB-12, in a dosage of 5×10^{10} CFU/d for 4 wk. Stool samples were cultured for examination of *Lactobacilli*, *Bifidobacteriae*, fungi, and pH before, during, and after intervention. In addition, before, during, and after intervention, symptom assessment and endoscopic evaluation was performed. Symptoms, such as involuntary defecation, leakage, abdominal cramps, fecal number and consistency, mucus, and urge to evacuate stools were significantly decreased during intervention in the UC/IPAA group. The median endoscopic score of inflammation also significantly decreased. The number of *Lactobacilli* and *Bifidobacteriae* significantly increased during intervention and remained significantly increased one week after intervention.

Gionchetti *et al.*^[125] evaluated the efficacy of high-dose VSL#3 in the treatment of mild active pouchitis in an open-label non-controlled study. Twenty-three patients with mild pouchitis were treated with VSL#3 (3.6×10^9 CFU/d) for four weeks. Symptomatic, endoscopic, and histologic evaluations were undertaken before and after treatment according to PDAI. Remission was defined as

a combination of a PDAI clinical score of ≤ 2 , an endoscopic score of ≤ 1 , and a total PDAI score of ≤ 4 . Patients in remission after initial treatment were treated with a maintenance dose of VSL#3 (1.8×10^9 CFU/d) for an additional six months. Sixteen out of 23 patients (69%) were in remission after treatment. The median total PDAI scores before and after therapy were 10 (range, 9-12) and 4 (range, 2-11), respectively ($P < 0.01$). The median Inflammatory Bowel Disease Questionnaire score also significantly improved ($P < 0.001$). All 16 patients who went into remission maintained remission during maintenance treatment. The authors conclude that high doses of the probiotic VSL#3 were effective in the treatment of mild pouchitis. As pouchitis is a recurrent state, many studies evaluated the potential of probiotics in preventing exacerbations. The most profoundly studied probiotic for this indication was multispecies preparation VSL#3. In a randomized, double-blind, placebo-controlled trial, the same group evaluated the efficacy of VSL#3 in the remission maintenance of chronic pouchitis compared with placebo^[126]. Forty patients in clinical and endoscopic remission achieved by antibiotic therapy were randomized to receive either VSL#3 3×10^{12} CFU/d or placebo for 9 mo. Patients were assessed clinically every month, and endoscopically and histologically every 2 mo or in the event of relapse. In addition, bacterial stool cultures from fecal samples were performed before and after antibiotic treatment and each month during maintenance treatment. Only 3 patients (15%) in the VSL#3 group had relapses within the 9-mo follow-up period, in comparison with 20 (100%) in the placebo group ($P < 0.001$). In the VSL#3-treated group (but not in the control group), fecal concentrations of *Lactobacilli*, *Bifidobacteria*, and *S. thermophilus* increased significantly from baseline levels during treatment ($P < 0.01$). Therefore, the authors concluded that oral administration of VSL#3 is effective in preventing flare-ups of chronic pouchitis.

In another double-blind, placebo-controlled study, Gionchetti *et al*^[127] evaluated the effectiveness of VSL#3 therapy in preventing the onset of pouchitis immediately and during the first year after ileal pouch-anal anastomosis. For this purpose, 40 patients who underwent IPAA for UC were randomized to receive either VSL#3 9×10^{11} CFU/d ($n = 20$) or placebo ($n = 20$) immediately after ileostomy closure for 1 year. The patients were assessed clinically, endoscopically, and histologically every few months, and health-related quality of life was assessed using the Inflammatory Bowel Disease Questionnaire (IBDQ). Only 2 (10%) patients from the VSL#3 group, compared to 8 (40%) from the placebo group, had an episode of acute pouchitis (log-rank test, $Z = 2.273$; $P < 0.05$). As expected, treatment with VSL#3 (but not placebo) produced a significant improvement in IBDQ score.

In a study by Mimura *et al*^[128], the researchers evaluated the effectiveness of a single daily high dose probiotic preparation of VSL#3 in maintaining antibiotic-induced remission. All patients included in this study had pouchi-

tis at least twice in the previous year or required treatment with continuous antibiotics. After remission was induced within four weeks of combined metronidazole and ciprofloxacin therapy, the patients were randomized to receive either VSL#3 (9×10^{11} CFU) ($n = 20$) or placebo ($n = 16$) once daily for one year or until relapse. Symptomatic, endoscopic, and histological evaluations were made before and 2 and 12 mo after randomization or at the time of relapse. Remission was maintained for one year in 17 patients (85%) on VSL#3, but in only one (6%) on placebo ($P < 0.0001$). The IBDQ score remained high in the VSL#3 group but deteriorated in the placebo group ($P = 0.0005$). Therefore, the authors concluded that the once daily high dose probiotic VSL#3 was effective in maintaining antibiotic introduced remission in patients with recurrent or refractory pouchitis.

In an open-label trial by Pronio *et al*^[129], 31 patients at different periods after surgery without signs or symptoms of pouchitis were randomized to VSL#3 9×10^{11} CFU/d or no treatment for 12 mo. Pouchitis activity was evaluated by PDAI, with different immunologic parameters being studied in peripheral-blood mononuclear cells and mucosal biopsies to reveal the mechanisms of probiotic action. During the study period, none of the patients from the probiotic group and only one from the placebo group developed active pouchitis. Because of the extremely low relapse-rate, even in the non-treated group, it was impossible to derive any firm conclusions regarding the efficacy of probiotic treatment from this study. However, a significant reduction in PDAI score was observed in VSL#3 treated patients.

In contrast with these studies, Shen *et al*^[130] reported much more disappointing results. In an open-label uncontrolled trial, they gave VSL#3 9×10^{11} CFU/d for 8 mo to 31 patients after being treated for pouchitis with ciprofloxacin for 2 wk. Baseline PDAI scores were calculated and patient symptoms were reassessed at week 3 of VSL#3 therapy and at the end of the 8-mo trial. Some, but not all, patients underwent repeat pouch endoscopy at the end of the trial. At the 8-mo follow-up, only 6 patients were still on VSL#3 therapy while all others had discontinued the therapy due to either recurrence of symptoms ($n = 23$) or development of adverse effects ($n = 2$). All six patients who completed the 8-mo course had repeat clinical and endoscopic evaluation. Their mean PDAI scores were not statistically different to those before probiotic intervention ($P = 0.27$). However, this trial had several methodological drawbacks. The patients were pre-treated with only one antibiotic and the success of this therapy of acute pouchitis was not regularly evaluated by endoscopy. Therefore, it remains unclear whether all patients were really in remission before the start of maintenance therapy with VSL#3.

In an open-label study by Gosselink *et al*^[131], 39 patients given a fermented milk product containing *Lactobacillus rhamnosus* GG in a dosage of $1-2 \times 10^{10}$ CFU immediately after IPAA operation were compared to 78 patients without any maintenance treatment. The first

episodes of pouchitis were observed significantly less frequently in the *Lactobacillus* GG group than in the untreated group (cumulative risk at 3 years: 7% vs 29%, $P = 0.011$). Therefore, the authors concluded that daily intake of the fermented product containing *Lactobacillus* GG provided significant clinical benefits without side effects, and recommended its use for the primary prevention of pouchitis.

In the Cochrane Collaboration review by Holubar *et al.*^[132] published in 2010, different modalities for the treatment and prevention of pouchitis after ileal pouch-anal anastomosis for UC, including different antibiotics, probiotics, glutamine, butyrate, and budesonide, were meta-analyzed and reviewed. They concluded that *Lactobacillus* GG was not superior in effectiveness compared to placebo for the treatment of acute pouchitis, while VSL#3 was more effective than placebo in the maintenance therapy of chronic pouchitis (97% vs 3%, $P < 0.0001$). The number needed to treat with VSL#3 to prevent one additional relapse was 2. Similarly, in a strain-specific meta-analysis performed by Jonkers *et al.*^[56], the authors calculated the pooled relative risk for prevention of relapses of pouchitis for VSL#3 compared to placebo as 0.17 (95%CI: 0.09-0.33). As a result of these conclusions, the multispecies probiotic preparation VSL#3 was granted the A level recommendation for the primary prevention and maintenance of remission of pouchitis after IPAA according to the American Recommendations for probiotic use from 2011^[115]. Furthermore, they suggested that there was some evidence (C level) supporting its use even for the therapy of active pouchitis.

Finally, clinical guidelines for the management of pouchitis from 2009 suggest the use of VSL#3 in patients with recurrence of pouchitis following antibiotic treatment or having several recurrences despite antibiotic therapy^[133]. However, they do not suggest probiotics for the treatment of acute pouchitis.

TREATMENT OF ACTIVE CROHN'S DISEASE

Clinical studies investigating the treatment of active Crohn's disease with probiotics were scarce. Gupta *et al.*^[134] reported a very small open-label pilot study of four children with mildly to moderately active Crohn's disease who were treated with entero-coated tablets containing *Lactobacillus rhamnosus* GG (10^{10} CFU) twice daily for 6 mo. Clinical activity was monitored by pediatric Crohn's disease activity index (PCDAI) and changes in intestinal permeability were measured by a double sugar permeability test. A significant improvement in clinical activity was observed 1 wk after starting *Lactobacillus* GG. Median PCDAI scores at 4 wk were 73% lower than baseline. Intestinal permeability improved in an almost parallel fashion. The authors concluded that the findings of this pilot study showed that *Lactobacillus* GG might improve clinical status and gut barrier function in children with mildly to moderately active Crohn's disease. Schultz *et*

al.^[135] performed a small randomized, placebo-controlled trial to determine the efficacy of *Lactobacillus rhamnosus* GG in the induction or maintenance of medically-induced remission. Eleven patients with moderate to active Crohn's disease were enrolled to receive either *Lactobacillus* GG (2×10^9 CFU/d) or placebo for six months. In all patients, a tapering steroid regimen was applied for the induction of remission, and all received antibiotics the week before probiotic/placebo intervention was initiated. The primary end point was sustained remission; defined as freedom from relapse after 6 mo. Only 5 patients finished the study, with 2 patients in each group in sustained remission. The median time to relapse was 16 +/- 4 wk in the probiotic and 12 +/- 4.3 wk in the placebo group ($P = 0.5$). In contrast with the results of Gupta *et al.*^[134], this study did not demonstrate any benefit of *Lactobacillus* GG in inducing or maintaining medically-induced remission in CD.

Although Butterworth *et al.*^[136] in the Cochrane Collaboration review concluded that there was insufficient evidence to make any conclusions about the efficacy of probiotics in inducing remission in CD because of a lack of well-designed clinical studies, the two studies using synbiotics that were not included in this review revealed very promising results^[137,138]. Fujimori *et al.*^[137] performed an open-label uncontrolled trial using a synbiotic for the therapy of active refractory Crohn's disease. Ten active CD patients who had failed to achieve remission via an initial therapeutic regimen of aminosalicylates and prednisolone were given synbiotic therapy consisting of two probiotic preparations that both contained *Bifidobacterium breve* 3×10^{10} CFU, *Lactobacillus casei* 3×10^{10} CFU, and *Bifidobacterium longum* 1.5×10^{10} CFU, as well as a prebiotic comprised of 3.3-9.9 g of psyllium (*Plantago ovata*). Patients were free to adjust their intake of probiotics or prebiotics throughout the trial. For the assessment of disease activity, Crohn's disease activity index (CDAI), International Organization for the Study of Inflammatory Bowel Disease (IOIBD) score, and blood sample variables were evaluated and compared before and after the trial. The duration of the trial was 13.0 +/- 4.5 mo. Of the ten included patients, 6 had a complete response, one had a partial response, and three were non-responders. Two patients discontinued treatment and four decreased their corticosteroid therapy. Both CDAI and IOIBD scores were significantly reduced after therapy (255-136, $P = 0.009$; 3.5-2.1, $P = 0.03$, respectively), however the laboratory markers of inflammation did not change. With the exception of some abdominal bloating disappearing with discontinuation of psyllium ingestion, there were no adverse events. The authors concluded that a combination of high-dose probiotics and prebiotics could be safely and effectively used as a co-therapy for the treatment of active CD.

Recently, Steed *et al.*^[138] conducted a randomized, double-blind, placebo-controlled trial including 35 patients with active CD using a synbiotic therapy comprised of probiotic *Bifidobacterium longum* 4×10^{11} CFU and prebiot-

ic Synergy 1 (oligofructose and inulin) 12g daily. Patients were requested to continue on stable doses of conventional medication they were receiving at initiation of the trial. The patients' clinical status was scored by CDAI and endoscopies with biopsies were performed at the start, and at 3 and 6 mo of therapeutic intervention. Six patients from the synbiotic group and 5 from the placebo group were lost from follow-up. Upon comparing pre- and post-treatment CDAI, there was a significant clinical improvement in the synbiotic group (start 219 ± 74.6 , finish 147 ± 74 ; $P = 0.020$) but not in the placebo group (start 249 ± 79.4 , finish 233 ± 155 ; $P = 0.81$). Similarly, there was a significant improvement in mean histological scores in the synbiotic group (start 6 ± 5 , finish 3 ± 4 ; $P = 0.018$) but not in the placebo group (start 6 ± 5 , finish 5 ± 6 ; $P = 0.75$). A significant reduction of pro-inflammatory TNF- α and an increase of mucosal *Bifidobacteria* was also observed in the synbiotic group.

MAINTENANCE OF REMISSION IN CROHN'S DISEASE

Only a few high-quality studies have been performed to assess the efficacy of probiotics for the maintenance of remission achieved with standard medical therapy or surgical resection in Crohn's disease. Currently, the use of probiotics for the maintenance of remission in Crohn's disease is not recommended.

In a trial by Guslandi *et al.*¹³⁹¹, 32 patients with Crohn's disease in clinical remission (CDAI < 150) were randomized to treatment with either mesalamine 1 g three times daily or mesalamine 1 g two times daily plus probiotic yeast *Saccharomyces boulardii* 1 g daily for six months. Clinical relapses were observed in 37.5% of patients receiving mesalamine alone but in only 6.25% of patients combining mesalamine with the probiotic ($P = 0.04$). The authors hence concluded that *Saccharomyces boulardii* might be useful in the maintenance treatment of Crohn's disease.

Bousvaros *et al.*¹⁴⁰¹ conducted a randomized, placebo-controlled trial of the probiotic *Lactobacillus rhamnosus* GG (LGG) to see whether the addition of LGG to standard therapy prolonged remission in children with CD. Seventy-five children and adolescents from 5 to 21 years old with CD in remission were randomized to receive either LGG ($n = 39$) or placebo ($n = 36$), and followed for up to 2 years. Concomitant medications, including aminosalicylates, 6-mercaptopurine, azathioprine, and low-dose alternate day corticosteroids were allowed. The percentage of patients that relapsed did not significantly differ between the LGG and the placebo group (31% *vs* 17%; $P = 0.18$), neither did the median time to relapse (9.8 mo *vs* 11.0 mo; $P = 0.24$). In conclusion, LGG did not prove to be effective for maintaining remission in children with CD when given as an adjunct to standard therapy. The ineffectiveness of probiotic strain *Lactobacillus rhamnosus* GG for maintenance therapy in CD was also supported by a study by Prantera *et al.*¹⁴¹¹, who performed a randomized placebo-controlled study in patients operated for

Crohn's disease in whom all of the diseased gut had been removed. The patients received 1.2×10^9 CFU of *Lactobacillus* GG or placebo for one year. Ileocolonoscopy was performed at the end of the trial or at the onset of symptoms. Clinical recurrence was ascertained in 16.6% in the LGG group and in 10.5% in the placebo group. Sixty percent of patients in clinical remission on LGG had endoscopic recurrence compared with 35.3% on placebo ($P = 0.297$). There were no significant differences in the severity of the lesions between the two groups. Marteau *et al.*¹⁴²¹ studied the potential of *Lactobacillus johnsonii* LA1 for prevention of recurrence in operated CD patients. This was a randomized, double-blind, placebo-controlled study. Patients were randomized to receive *Lactobacillus johnsonii* LA1 4×10^9 CFU/d ($n = 48$) or placebo ($n = 50$) for six months. No other treatment was allowed. There were 4 clinical recurrences in the probiotic group and 3 in the placebo group. In patients with symptomatic remission, endoscopic recurrence was observed in 64% in the placebo group compared to 49% in the probiotic group ($P = 0.15$). Endoscopic score distribution did not differ significantly between the two groups. A similar double-blind placebo-controlled study was performed by Van Gossum *et al.*¹⁴³¹, who randomized 70 patients who had undergone elective ileocecal resection for CD to daily treatment with either *Lactobacillus johnsonii* LA1 10^{10} CFU ($n = 34$) or placebo ($n = 36$) for 12 wk. The primary objective of this study was to assess the effect of probiotics on the endoscopic recurrence rate at 12 wk. Clinical relapse rate was 15% in the probiotic group and 13.5% in the placebo group ($P = 0.79$). The mean endoscopic score at 3 mo was not significantly different between the two groups ($P = 0.48$), nor was the percentage of patients with severe endoscopic recurrence ($P = 0.33$). According to the results of these studies, it seems that, like LGG, *Lactobacillus johnsonii* LA1 has no effect on remission in CD.

With the intention of preventing postoperative recurrence of CD, another two double-blind placebo-controlled trials were performed. Chermesh *et al.*¹⁴⁴¹ investigated the use of a synbiotic cocktail of 4 probiotics and 4 prebiotics (Synbiotic 2000), and Madsen *et al.*¹⁴⁵¹ used multispecies probiotic VSL#3, which proved to be efficient in the therapy of ulcerative colitis and pouchitis.

In the 2006 Cochrane Collaboration review regarding probiotics for maintenance of remission in CD by Rolfe *et al.*¹⁴⁶¹, the authors identified 7 eligible studies. They found no statistically significant benefits of *E. coli* Nissle for reducing the risk of relapse compared to placebo, or for *Lactobacillus rhamnosus* GG after surgical or medically-induced remission. There was no statistically significant benefit of probiotics for reducing the risk of relapse compared to medical maintenance therapy employing aminosalicylates or azathioprine. Moreover, they found more adverse events in *Lactobacillus* GG treated patients. However, a small study using *Saccharomyces boulardii* demonstrated a difference in favor of its use combined with medical maintenance therapy in comparison with standard medical therapy alone, although the difference was

not statistically significant. They concluded that there is no evidence to suggest the use of probiotics for the maintenance of remission in CD. In the second Cochrane Collaboration review analyzing different interventions for the prevention of post-operative recurrence of Crohn's disease, the authors came to the same conclusion that probiotics were not superior to placebo^[147].

Similarly, a meta-analysis performed by Rahimi *et al.*^[148] also failed to demonstrate the efficacy of probiotics in maintaining remission and preventing clinical and endoscopic recurrence in CD. Moreover, in a meta-analysis performed by Shen *et al.*^[149], researchers came to the conclusion that not only were *Lactobacilli* inefficacious, but also that administration of *Lactobacillus* GG might increase the relapse rate.

PREBIOTICS AND IBD

Compared to probiotics, there is considerably less clinical evidence regarding the use of prebiotics for IBD therapy.

In an early trial by Hallert *et al.*^[150], the ingestion efficiency of *Psyllium* (*Plantago ovata*, ispaghula husk) for 4 mo compared to placebo was studied for relieving gastrointestinal symptoms in patients with UC in remission. Regarding the symptom's score, ispaghula was consistently superior to placebo ($P < 0.001$) and was associated with a significantly higher rate of improvement (69% vs 24%; $P < 0.001$). Based on these results, the authors suggested that ispaghula could be helpful in the management of gastrointestinal symptoms in UC.

A Spanish group performed a multicenter open-label, randomized clinical trial to assess the efficacy and safety of *Plantago ovata* seeds as compared with mesalamine in maintaining remission in UC^[151]. A total of 105 patients with UC in remission were randomized into three groups treated with *Plantago ovata* (10 g twice daily), mesalamine (500 mg twice daily), or *Plantago ovata* plus mesalamine at the same doses for 12 mo. Three patients, all from the *Plantago ovata* group, were withdrawn because of adverse events (i.e., constipation and/or flatulence). After 12 mo, the treatment failure rate was 40% in the *Plantago ovata* group, 35% in the mesalamine group, and 30% in the *Plantago ovata* plus mesalamine group. The probability of continued remission was similar ($P = 0.67$). A significant increase in fecal butyrate levels was observed in the groups using *Plantago ovata* ($P = 0.018$). The authors concluded that *Plantago ovata* seeds might be as effective as mesalamine for maintenance therapy in UC patients in remission. Furthermore, Casellas *et al.*^[152] conducted a prospective, randomized, placebo-controlled pilot trial comparing the effect of oligofructose-enriched inulin 12 g/d ($n = 10$) and maltodextrin used as placebo ($n = 9$) for 2 wk in patients with mild to moderately active UC. Concomitant treatment with mesalazine (3 g/d) was allowed. A significant reduction of fecal calprotectin, a marker of intestinal inflammation, was observed in the group receiving oligofructose-enriched inulin (day 0: 4377 +/- 659 $\mu\text{g/g}$; day 7: 1033 +/- 393 $\mu\text{g/g}$, $P < 0.05$) but not

in the placebo group (day 0: 5834 +/- 1563 $\mu\text{g/g}$; day 7: 4084 +/- 1395 $\mu\text{g/g}$, n.s.).

Hafer *et al.*^[153] investigated the clinical and histological efficacy of lactulose in patients with both UC and CD. In a pilot study, 14 UC and 17 CD patients, most of whom were in a clinically active state, were randomized either to receive 10 g lactulose daily or placebo, adjuvant to standard therapy for 4 mo. No significant improvement of clinical activity index, endoscopic score, or immunohistochemical parameters was observed in CD or UC patients receiving lactulose in comparison to the control group.

Several clinical trials were performed in Japan using germinated barley foodstuff (GBF), which mainly consists of dietary fiber and glutamine-rich protein, for the therapy of UC. Kanauchi *et al.*^[154] investigated the efficacy of long-term administration of GBF in the treatment of active UC in a multi-center open trial. Twenty-one patients with mild to moderate UC received 20-30 g of GBF while baseline treatment with 5-aminosalicylates and/or steroids was continued. After 24 wk of treatment, the GBF group showed a significant decrease in clinical activity index compared with the control group ($P < 0.05$). No side effects related to GBF were observed. The same group published results of another study in which GBS was used for maintenance therapy in UC^[155]. Patients were randomized into two groups: GBF 20 mg/d ($n = 22$) and control ($n = 37$). Response to treatment was assessed by monitoring the clinical activity index (CAI) and endoscopic score. Significantly better CAI values and a significantly lower recurrence rate were observed in the GBF group at 3, 6, and 12 mo compared with the controls. No side effects related to GBF were observed. According to the results of both studies, GBF could reduce the clinical activity of active UC, and appeared to be effective as a maintenance therapy in patients with UC.

Moreover, a small open-label trial was performed by Lindsay *et al.*^[156] in which they treated 10 patients with active ileocolonic Crohn's disease with 15 g of FOS for three weeks. FOS induced a significant reduction in the disease activity index from 9.8 ± 3.1 to 6.9 ± 3.4 ($P < 0.01$). They also observed a significant increase in fecal *Bifidobacteria* concentration, in the percentage of IL-10 positive, and TLR2 and TLR4 expressing dendritic cells in mucosal biopsies.

In contrast to previous findings, the results from a randomized double-blind placebo-controlled trial performed by Benjamin *et al.*^[157] did not confirm the efficacy of FOS for therapy of active CD. In this study patients were randomized to 15 g/d FOS ($n = 54$) or placebo ($n = 49$) for 4 wk. More patients receiving FOS (26% vs 8%; $P = 0.018$) withdrew before the 4-wk end point and there was no significant difference in the number of patients achieving a clinical response between the FOS and placebo groups (22% vs 39%; $P = 0.067$).

Considering all the above facts regarding the use of prebiotics, there is very little evidence to support their use in IBD therapy. However, supplementation with germinated barley foodstuff, *Psyllium* (*Plantago ovata*, ispaghula

husk), or oligofructose-enriched inulin might provide some benefit in patients with active UC or UC in remission, but more high-quality clinical studies are needed to confirm their effectiveness.

CONCLUSION

Probiotics and prebiotics definitely have great potential for future therapeutic approaches in inflammatory bowel disease. However, further research is required to identify specific probiotic strains or their combinations and prebiotic substances that will be most efficient for therapies of different types and stages of activity of intestinal inflammation.

Abstract

Inflammatory bowel disease (IBD) is a chronic, relapsing intestinal inflammatory disorder with unidentified causes. Both environmental factors and genetic aspects are believed to be crucial to the pathogenesis of IBD. The incidence and prevalence of IBD have recently been increasing throughout Asia, presumably secondary to environmental changes. This increasing trend in IBD epidemiology necessitates specific health care planning and education in Asia. To this end, we must gain a precise understanding of the distinctive clinical and therapeutic characteristics of Asian patients with IBD. The phenotypes of IBD reportedly differ considerably between Asians and Caucasians. Thus, use of the same management strategies for these different populations may not be appropriate. Moreover, investigation of the Asian-specific clinical aspects of IBD offers the possibility of identifying causative factors in the pathogenesis of IBD in this geographical area. Accordingly, this review summarizes current knowledge of the phenotypic manifestations and management practices of patients with IBD, with a special focus on a comparison

of Eastern and Western perspectives.

Key words: Crohn's disease; Ulcerative colitis; Inflammatory bowel disease; Clinical characteristics; Treatment; Asia

Core tip: Over the past two decades, the incidence and prevalence of inflammatory bowel disease (IBD) have changed with a trend toward increasing across Asia, especially East Asia. This increasing trend in IBD epidemiology necessitates specific health care planning and education in Asia. To this end, we must gain a precise understanding of the distinctive clinical and therapeutic characteristics of Asian patients with IBD, compared to Caucasians patients with IBD. Accordingly, this review summarizes current knowledge of the phenotypic manifestations and management practices of patients with IBD, with a special focus on a comparison of Eastern and Western perspectives.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic, idiopathic inflammatory disorder of the gastrointestinal tract without identifiable causes. It comprises primarily Crohn's disease (CD) and ulcerative colitis (UC). IBD was traditionally regarded as being prevalent in mainly Western countries. Over the past two decades, however, the incidence pat-

Table 1 Clinical characteristics of inflammatory bowel disease in Asian and Western countries

| Differences | Asian characteristics |
|------------------------------|---|
| Peak age at disease onset | Smaller second peak |
| Sex distribution of CD | Male predominance |
| Cigarette smoking in CD | Lower prevalence |
| CD distribution and behavior | Ileocolonic predominance Similar behavior |
| UC distribution and behavior | Similar distribution Milder disease course |
| Familial aggregation in IBD | Lower prevalence |
| Extraintestinal disease | Lower prevalence |
| Medical treatments | Lower use of thiopurine and anti-TNF therapy |
| Surgical treatments | Comparable in CD Lower in UC |
| UC-associated CRC | Comparable cumulative risk |

CD: Crohn's disease; UC: Ulcerative colitis; anti-TNF therapy: anti-Tumor necrosis factor therapy; CRC: Colorectal cancer.

tern of IBD has changed. The incidence in the West has remained relatively stable, while that in Asia has increased markedly^[1]. This recent change in the incidence and prevalence of IBD is attributed to environmental changes.

The growing incidence of IBD in Asia has important implications for those who formulate health care policy plans; these individuals should provide specific health care planning, services, and education while balancing the health needs and social burdens of a given country. However, it also has important implications for clinicians and researchers. According to the published literature, the IBD phenotypes differ considerably between Asians and Caucasians. Nevertheless, most strategies for the prevention and treatment of IBD flare-up in Asia have followed Western guidelines. Gradual accumulation of data on IBD in Asians will facilitate the formulation of Asian-specific practice guidelines; however, direct comparisons of the clinical characteristics of IBD in Asian and Western countries are few. Formulation of appropriate strategies for Asian patients with IBD must begin with an accurate understanding of the different clinical characteristics of the two populations. These include clinical manifestations and therapeutic aspects, as well as epidemiology. To this end, this review summarizes and compares current knowledge of the phenotypic manifestations and management of patients with IBD in Eastern and Western countries. Furthermore, investigation of the Asian-specific clinical aspects of IBD offers the possibility of identifying causative factors in the pathogenesis of IBD, which will also be covered in this review.

DIFFERENCES IN CD BETWEEN THE EAST AND WEST

Clinical characteristics of CD

Peak age of disease onset: Early studies from Western countries reported that CD was characteristically associated with a bimodal age distribution pattern, peaking at

the ages of 20 to 39 years and showing a second smaller peak at the ages of 50 to 79 years^[2-4]. Various peak ages of CD onset have been reported in Asia. A Korean study reported a smaller second peak in the incidence of CD^[5]. There was also a trend toward a second peak in the Hong Kong population^[6]. A recent prospective, population-based study from the Asia-Pacific region also indicated a smaller second peak in the incidence of CD, albeit at a younger age (40-44 years) than that in Western countries^[7]. However, this bimodal presentation has not been uniformly identified in other Asian studies^[8,9]. The reason for the bimodal distribution remains unclear, but some environmental factors are known to be associated with this phenomenon. One hypothesis is that it may be due to certain age-specific environmental factors, such as passive smoking in childhood and active smoking in adulthood. It may also be caused by the different sensitivities of different age groups to certain infectious factors^[10]. We speculate that Asian people with genetic susceptibilities could develop CD at the early peak ages of 20-39 years; however, the later second peak might be smaller than that in the West because environmental factors are less prevalent in Asia. Accordingly, it is expected that the second peak in the incidence of CD in Asia will increase as the region becomes increasingly westernized over time (Table 1).

Male predominance in Asians

European and North American studies have consistently revealed that the incidence of CD in females is equal to or greater than that in males^[2,4,11,12]. In striking contrast, a male predominance in Asian patients with CD has been reported. In all recent studies from Korea, China, and Japan, the male-to-female ratios ranged from 1.67:1 to 2.9:1^[9,13,14]. A recent prospective, population-based study from the Asia-Pacific region also demonstrated a male predominance^[7]. Interestingly, a recent European study indicated a slight male predominance (60%) in adult Eastern European patients with CD^[15]. Smoking, vaccination, or other factors (*e.g.*, geographic, ethnic, and social) might account for this sex difference^[10]. Some Western researchers have suggested that the smoking rates, exposure of social life, or Westernized lifestyles were more prevalent in males than in females in Asia and that males might have more opportunities to receive medical services, including endoscopy, than females in Asia. However, if male predominance is in fact present in Asia, it is possible that changes in susceptible genes in sex chromosomes or changes in sex hormones might be involved in the pathogenesis of CD.

Cigarette smoking

Smoking represents one of the most consistently observed environmental risk factors for CD. Studies in Western countries have shown that smoking is a strong risk factor for the development of CD, but that it protects against the development of UC^[16-20].

Based on recent prospective, population-based cohort

studies, the proportion of current or ex-smokers among Asian patients with CD (11.8%-28.0%)^[7,21] is substantially lower than that among Western (57%) and Eastern European patients (62%)^[15]. A study comparing patients between Melbourne and Hong Kong also reported that fewer patients were current or ex-smokers in Hong Kong (8%) than in Melbourne (50%)^[22].

Western patients with CD who smoke have a worse disease course and are more likely to relapse after medically and surgically induced remission^[23-25]. In terms of flare-up rates and therapeutic needs, disease severity is similar in patients who have never smoked and those who have stopped smoking, and both have a better course than continuing smokers^[23]. Progression to stricturing or penetrating disease and subsequent surgery rates are reduced by smoking cessation^[26]. However, smoking may not have the same effect in CD in different ethnic groups or geographic regions as in Western populations. For example, studies among Israeli Jews showed that smoking is not associated with the risk of CD^[27-29]. More studies on Asian patients with CD are warranted to determine the impact of smoking on the development and progression of disease and its association with the disease phenotype in this population. Our hypothesis is that the lower rate of cigarette smoking among Asians may be one of the factors related to their better prognosis, as indicated by the lower rate of surgery in Asian than in Western patients with CD.

Familial aggregation

Previous studies have suggested that patients with IBD have less family clustering in East Asia. Studies from Asia have collectively reported that familial aggregation rates range from 0.0% to 3.0%^[6,30-35], which is clearly lower than that in the Western population (13.4%)^[36]. However, familial aggregation rates appear to be higher in West Asia, ranging from 12.9% to 19.0%^[1,37]. Recent studies from Korea have suggested that the familial aggregation rate of IBD may increase with time, in parallel with the increase in the prevalence of IBD within the country^[1,5,31]. Data on the familial clustering rates in other Asian countries must be validated by a longitudinal prospective cohort study. Moreover, it should be tested whether patients with family history of IBD would have a worse disease outcome than those without. Our own study showed no difference in clinical characteristics and outcomes between them^[38]. We speculate that both environmental and genetic factors contribute to the low familial aggregation rates among Asian patients with CD. It might be valuable to elucidate the Asian-specific pathogenesis and establish prevention methods by investigating Asia-specific lifestyles or environmental factors, including breast feeding, tonsillectomy, childhood vaccination, infectious disease, or dietary intake of fiber and sugar.

Disease location

In the West, CD has been found to occur in the ileum, colon, and both the ileum and colon in equal proportions

of patients^[15,39]. However, a number of studies from the West have reported isolated colonic disease to be the most common type of CD^[11,40,41]. A study comparing patients in China and the US also reported that American white patients have more colorectal involvement^[32]. However, ileocolonic disease appears to be the most common type of CD in Asia^[5,7,21,33,34,42,43]. CD confined to the small bowel is also common in Asia. Western guidelines suggest a follow-up colonoscopy to assess mucosal healing or recurrence after biologic therapy or surgery. However, routine ileocolonoscopy for therapeutic monitoring or after surgery might be less useful in Asian patients. Instead, radiological evaluation might play a role in such cases because isolated ileal or ileocolonic disease is not entirely visible by ileocolonoscopy.

Upper gastrointestinal tract involvement, which is significantly associated with disease prognosis such as changes in behavior^[44] or the need for early surgery or hospitalization^[45], has been rarely reported in Asia. This might be due to the lack of consensus regarding the performance of routine gastroduodenoscopy in patients with newly diagnosed CD in real practice. A study from China found that 23.5% of patients had upper gastrointestinal tract involvement at the time of diagnosis^[14], but other studies^[3,7,11,46,47] from both the Asia-Pacific region and the West have reported lower proportions. In a recent Korean study, jejunal involvement was observed in 14.1% of patients with CD at the time of diagnosis^[48]. This markedly different result compared to China might be an overestimation. Thus, further larger studies are needed to determine the proportion of upper gastrointestinal involvement in patients with CD in Asia.

Disease behavior and course

Studies from the West have shown that the rates of inflammation, stricture, penetration, and perianal fistulas in CD at the time of diagnosis are 62%-81%, 5%-27%, 8%-14%, and 10%-27%, respectively^[11,44,47,49,50]. Similarly, Asian studies have reported inflammatory disease in 40% to 69%, stricturing disease in 20%-29%, and penetrating disease in 10%-31% of patients with CD^[13,21,33,34,45,51,52]. Interestingly, several studies documenting the disease behavior at the time of diagnosis have reported higher proportions of perianal fistula at the time of diagnosis in Hong Kong (33.3%)^[33], Korea (36.7%)^[34], and China (58.8%)^[14] than in the West. Perianal fistula is known to be a poor prognostic factor in patients with CD^[44,47]. In general, however, the prognosis of Asian patients with CD patients is reportedly better than that of Western patients with CD. Whether the presence of perianal fistula is actually a poor prognostic factor of CD remains to be determined and warrants further study. Actually, perianal fistula is described as independent from the penetrating type in the Montreal classification.

The evolution from inflammatory behavior to a more complicated disease behavior (stricturing or penetrating) is well demonstrated in the Western literature^[46,47,53], and has also been shown in Asian studies from Hong Kong^[33]

and Korea^[54].

Based on long-term follow-up studies from Japan, it appears that Japanese patients with CD have a long-term prognosis similar to that of their Western counterparts regarding cumulative operation rates^[43]. However, compared with Western patients with CD^[55], a recent study from Korea showed a better prognosis with respect to the incidence of surgery^[13,34]. This can be partly explained by the conservative attitude regarding bowel surgery among Korean physicians and patients or the smaller numbers of patients with a severe phenotype because of the short history of CD in the Asian region, including Korea.

Extraintestinal manifestations

Extraintestinal manifestations (EIM) have been reported in Asian patients with CD with widely variable rates: 19.0%-58.8% in China^[14,52,56] and 25.0% in Hong Kong^[6]. Among EIM, a high rate of ankylosing spondylitis (9%) among patients with CD has been reported^[6]. A study comparing patients between the US and China reported that American white patients developed more EIM (40% *vs* 20%; OR = 2.63; *P* = 0.013)^[32], especially chronic arthralgia (32% *vs* 4%; OR = 13.07; *P* < 0.001). However, it is difficult to directly compare the prevalence of EIM between Asian and Western patients with CD because most Asian reports were hospital-based (not population-based) retrospective studies or prospective cohort studies involving small numbers of patients (*n* = 17, 58.8%)^[14]. Moreover, they were performed under different diagnostic criteria for EIM. Generally, the prevalence of EIM in Asia is accepted to be similar or slightly lower than that in the West (19%-25% *vs* 21%-41%, respectively)^[57-60]. Less frequent EIM may be associated with the relatively better prognosis among Asian patients than in Western patients because EIM, especially ankylosing spondylitis, is known to be associated with a poorer prognosis in patients with IBD.

TREATMENT OF CD: COMPARISON BETWEEN THE EAST AND WEST

Medical treatments

Conventional therapy: The use of corticosteroids for CD is variable in studies from Asia. In one study, Asian specialists used corticosteroids as the first-line treatment in 50% of patients with mild CD and 84% of patients with moderate CD^[61]. Moreover, they used corticosteroids as a maintenance therapy in approximately 25% of patients with CD^[61], which might appear to be inappropriately high because corticosteroids have more side effects than placebo or low-dose 5-aminosalicylic acids (5-ASA)^[62]. In a recent prospective European study, 54%-55% of patients with CD received corticosteroid therapy as an initial treatment during the first 3 mo of disease in Eastern and Western European centers, but did not during the maintenance phase^[15].

Among patients with CD, the overall response rates to corticosteroids in Asia were similar to or better than

those in the West. The short-term response rates at 1 mo were > 80% in both Asia and the West (Figure 1A), and 56.6% and 32.0% of patients, respectively, were corticosteroid-free without the need for surgery at 1 year (Figure 1B)^[63,64].

The use of thiopurines in Asia also varies among countries. A Korean single-center study reported that thiopurines were used in 63% of patients with CD^[34]. A separate Korean study showed that 42% of patients received thiopurines and that the cumulative thiopurine requirement was 9.1% at 1 year, 32.2% at 5 years, and 51.6% at 10 years^[65]. Another cross-sectional study from Hong Kong noted that thiopurines were used in 63.6% of patients^[22]. The authors of this study stated that the use of thiopurines was significantly less frequent in Hong Kong patients than in Melbourne patients (63.6% *vs* 82.1%, respectively, *P* < 0.001). A single-center review from East China found that 61 of 227 (26.9%) patients had indications for immunomodulator use. However, such agents were prescribed to only 34.0% of the patients, and of these 34.0%, 38.0% received a subtherapeutic dose with no attempt to increase the dose^[66]. A recent prospective, population-based study from the Asia-Pacific region reported that only 35% of patients with CD received immunomodulator therapy^[7]. Taken together, these results indicate that Asian physicians have a tendency to inappropriately use large amounts of corticosteroids and insufficient amounts of thiopurines. It is important to educate physicians regarding these medications.

There appears to be a higher rate of adverse events, particularly leukopenia, in Asians than in Caucasians when taking thiopurines. Up to 40%-56% of Asian patients may reach the criterion for leucopenia, namely a white blood cell count of < 4000/mm³^[67,68]. The cumulative incidence of myelotoxicity in the Western population was reported to be about 7%^[69]. In Asia, however, thiopurine methyltransferase genotyping itself may not be as helpful in identifying patients who are expected to develop myelotoxicity as in Western countries^[70], and the metabolites of thiopurines are not widely measured in real practice in many Asian countries. In Korea, therefore, physicians usually start a thiopurine at a smaller dose (*e.g.*, 25 or 50 mg of azathioprine) and gradually increase the dose with regular evaluations of the white blood cell count instead of determining the metabolite concentration. Alternatively, they may maintain lower doses of thiopurines than recommended in the Western guidelines^[71].

Biologics: In a recent prospective, population-based cohort study from Europe, the rates of biologics use as an initial treatment during the first 3 mo of disease were reportedly 7% and 2% in Western and Eastern European centers, respectively^[15]. This approach was interpreted as top-down therapy or rapid accelerating therapy. However, the economic burden or the reimbursement system can be obstacles to the use of biologics in the very early phase after diagnosis of CD in many Asian countries. An

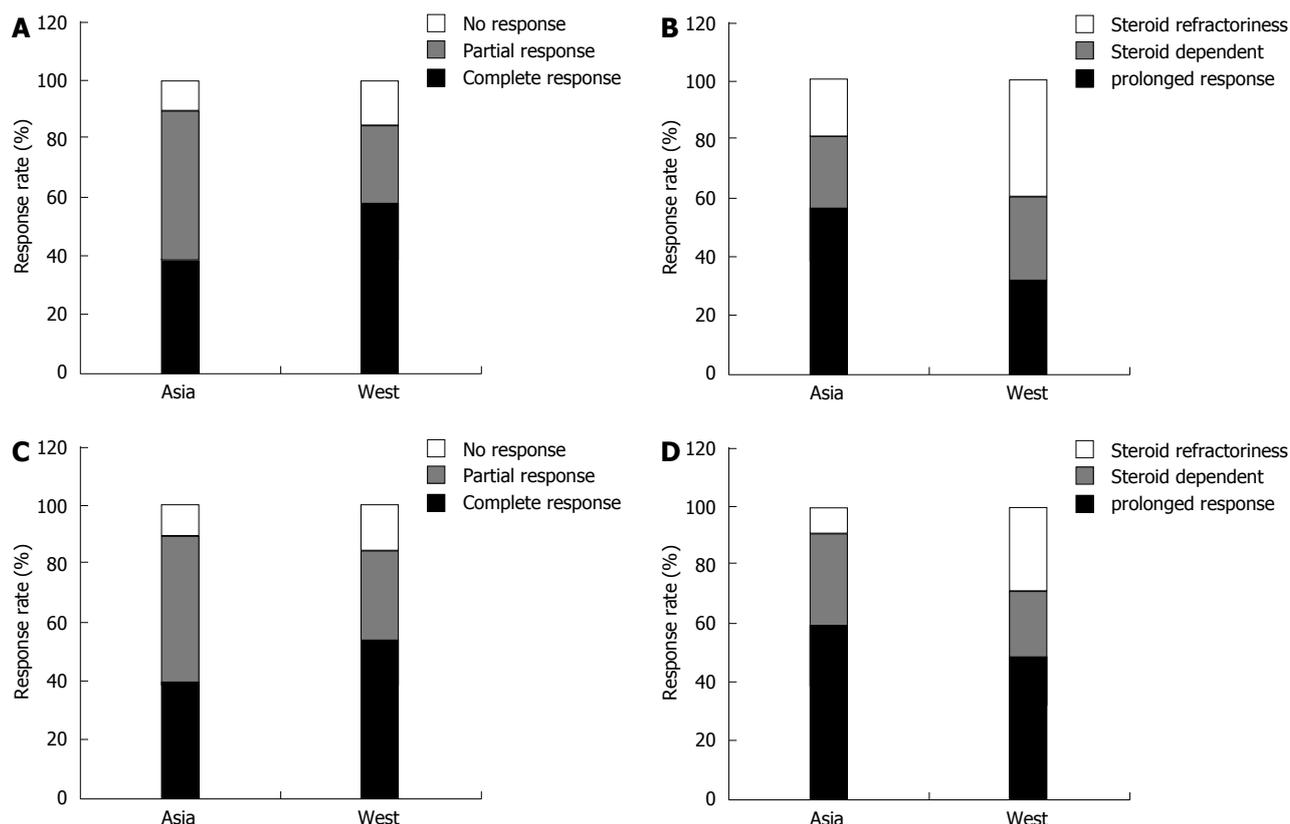

Figure 1 Comparison of the response to corticosteroids between Asia and the West^[63,64,112]. A: Crohn's disease, 1 mo; B: Crohn's disease, 1 year; C: Ulcerative colitis, 1 mo; D: Ulcerative colitis, 1 year.

Asian survey of IBD management practices in different countries found that no IBD specialists would consider anti-tumor necrosis factor (anti-TNF) agents as the first choice for the treatment of CD. Moreover, only 20% considered anti-TNF agents as the second choice^[61]. In a cross-sectional study comparing the management of CD between Melbourne and Hong Kong, a significantly higher number of patients in Melbourne had been on anti-TNF agents than in Hong Kong (40% *vs* 11%)^[22]. A retrospective study from Korea reported that 8.6% of patients with CD used infliximab^[34].

The response rates to infliximab in Asia are similar to or higher than those in the West. Although it is difficult to directly compare the results of responses to infliximab in Asia and the West because of their different designs, the response rates at 2 wk after beginning induction therapy were 72% and 62% in Korea (unpublished retrospective data) and the West^[72], respectively. Moreover, the response rates at 30 and 54 wk after beginning maintenance therapy were 91.7% *vs* 50.0% and 74.7% *vs* 39.0% in Korea (unpublished retrospective data) and the West^[72], respectively. A similar pattern was reported in patients with fistulizing CD between Korea and Western countries. In Asia, anti-TNF agents are used less frequently because of the limited, strict indications under insurance coverage rules, and because of the social economic burden. Moreover, many Asian physicians have not accepted the latest treatment trends, such as rapid accelerated step-up or top-down therapeutic approaches. Again, it is nec-

essary to educate Asian physicians regarding the adequate use of the latest medical treatments for IBD.

Complementary and alternative medicines: There are diverse rates of use of complementary and alternative medicines (CAMs) across Asia. One study from China reported that 90% of patients used concomitant traditional Chinese medications^[73]. Moreover, various proportions of Western patients with IBD use CAM, ranging from 23% to 49% in recent studies^[74-77]. In seven randomized controlled trials of patients with CD, *Artemisia absinthium* (wormwood) and *Tripterygium wilfordii* were superior to placebo in terms of inducing remission and preventing clinical recurrence of postoperative CD, respectively^[78]. In two systematic reviews, omega-3 fatty acids did not appear to be effective for the maintenance of CD remission^[79,80]. Effective anti-inflammatory moieties have yet to be defined.

Another problem is the indiscriminate use of various CAMs without sufficient evidence in patients with IBD. More studies are needed to determine the efficacy and safety of CAM in such patients. In addition, the development of new CAMs from natural products would be helpful in situations in which few drugs are available for patients with IBD.

Surgical treatments

The cumulative operation rates for CD in Japanese studies are comparable to those of Western cohorts, ranging

from 25.9% to 44.4% at 5 years and 46.3% to 80.1% at 10 years, respectively^[43,81]. The surgical resection rate for patients with CD in Hong Kong (29% at 10 years)^[6] is similar to that in a population-based study from Norway, which reported a 10-year cumulative surgical rate of 37.9%^[55]. In a cross-sectional study, there was also no significant difference in the proportion of patients with CD who underwent surgery in Melbourne compared with in Hong Kong (55.1% *vs* 46.0%, respectively, $P = 0.065$)^[22]. Similarly, the cumulative probability of intestinal resection in Korea was reported to be 15.5% after 1 year, 25.0% after 5 years, and 32.8% after 10-15 years. Asian patients with CD are currently considered to have a similar or slightly lower rate of surgery than that among their Western counterparts^[34]. The lack of long-term follow-up studies in Asia makes it difficult to draw a concrete conclusion regarding the cumulative surgical resection rates between Asia and the West.

DIFFERENCES IN UC BETWEEN THE EAST AND WEST

Clinical characteristics of UC

Age and sex: The median age at the time of diagnosis of UC among patients in Asia is similar to or slightly older than that among patients in the West (35-44 years in Asia^[5,9,51,82-85] and 30-40 years in the West^[39,86,87]). In a cross-sectional study, patients with UC in Hong Kong were diagnosed at an older age than Caucasians in Melbourne (median age, 38 years *vs* 30 years, respectively). The authors suggested that this may be partly explained by a delay in diagnosis in Hong Kong^[22]. Another possible explanation would be a weaker influence of genetic factors in Asian patients, which delays disease occurrence (Table 1).

The majority of studies from the West have shown an equal sex distribution for UC, although some reported a male predominance^[86,88]. A growing number of studies in Asia have shown an equal sex distribution^[5,84,85,87,89] or slight male predominance^[9,35,52,82,90]. Collectively, the age and sex distributions of patients with UC are not largely different between the East and West.

Family history: Studies in Asia have reported a family history in 0.0%-3.4% of patients with UC^[35,82,85]. This figure is lower than the 10%-25% reported in Western countries^[37]. A recent population-based cohort study conducted in the Asia-Pacific area showed a family history in 3% of patients in Asia and in 17% of patients in Australia ($P < 0.001$)^[7]. Interestingly, in Korea, an increase in the prevalence of a positive family history from 1.3% in 2001 to 2.7% in 2005^[5] paralleled the increased incidence of IBD. This suggests that the low prevalence of a family history may be a reflection of the low population prevalence and will probably change with time.

In terms of genetic associations, a previous Japanese genome-wide association study (GWAS) and a recent Korean GWAS showed considerable overlap of genetic

associations for UC between Asia and the West. Despite the overlap of genetic associations of Asian and Western patients with UC, as can be seen by the lower proportion of patients with a family history of UC in Asia compared with the West, we realize that UC is one of the principal forms of IBD with complex manifestations, and genetic factors that account for only a portion of the overall disease development. This indicates a need to better explore gene-environment interactions or Asia-specific environmental factors of etiological importance in the development of IBD.

Disease extent: In UC, the extent of disease is classified into three types: proctitis, left-sided colitis, and extensive colitis. In Western population-based studies, these three types comprise 30%-60% of cases, 16%-40% of cases, and 18%-35% of cases, respectively^[91-93]. In Asian population-based studies, they comprise 25.0%-43.7%, 31.0%-31.4%, and 24.9%-39.0%, respectively^[5,42]. Most hospital-based studies in Asia have shown a trend toward a lower proportion of proctitis (8.5%-38.4%), higher proportion of left-sided colitis (29.7%-70.2%), and similar proportion of extensive colitis (21.3%-42.4%) compared with population-based studies^[35,52,84,85,94], indicating that more severe cases were recruited into the hospital-based studies.

In terms of age and disease extent, several studies have reported that the extent of UC at diagnosis differs significantly according to age at diagnosis^[83,95]. In one Korean study, proctitis was more common in elderly patients (28.9% in the young group *vs* 33.8% in the elderly group) and extensive colitis was more common in younger patients (35.1% in the young group *vs* 22.5% in the elderly group), suggesting a poorer clinical outcome in younger patients ($P < 0.05$)^[83].

In a recent comparative epidemiological study of IBD across Asia and the Pacific, the extent of UC was classified as proctitis in 37%, left-sided colitis in 32%, and extensive colitis in 31%. These results are not significantly different from those in a study from Australia, which classified UC as proctitis in 32%, left-sided colitis in 27%, and extensive colitis in 41% (all $P > 0.05$)^[7]. A recent population-based cohort study from the West and East Europe showed that the ratios of disease extent for UC from Western and Eastern European centers were proctitis in 20% and 22%, left-sided colitis in 41% and 46%, and extensive colitis in 38% and 32%, respectively^[15]. Collectively, a slightly higher proportion of extensive colitis is observed in Western countries than in Asia, suggesting a more favorable prognosis of UC in Asia.

Disease course: Although definitions of clinical relapse and measurements of disease severity vary among studies, most suggest that Asian patients with UC have a milder disease course than do patients from Western countries^[82,90,96]. In Asian studies, most patients with UC had a chronic relapsing disease course rather than continuous active disease^[84,97], similar to Western data^[98]. In a Malay-

sian study, the rate of maintaining remission was reported as 64.3% of patients with UC at 10 years after diagnosis, the rate of a chronic relapsing disease course as 25%, and the rate of chronic persistent disease with low or high activity as 3% after 10 years^[97]. In a Norwegian study, the rate of maintaining remission was reported to be 55% of patients with UC at 10 years after diagnosis, which are slightly lower than the Malaysian data^[98], and the rate of a chronic relapsing disease course to be 37%. In a Korean study, the cumulative relapse rate at 10 years after diagnosis (88.4%) was similar to that of a Western study (83%). However, the cumulative probabilities of colectomy (2.0% after 1 year, 2.8% after 3 years, and 3.3% after 5-15 years)^[96] were lower than those in a Western study (3.5% after 1 year, 7.6% after 5 years, and 9.8% after 10 years)^[98].

Based on the larger numbers of patients with a remission status, lower numbers of patients with a chronic relapsing or persistent active disease course, and lower cumulative operation rates, Asian patients with UC appear to have a milder disease course than that of Western patients with UC. However, the above-mentioned lower cumulative surgical rates may also be associated with diversity in management strategies or different levels of acceptance of colectomy by physicians and/or patients between Asia and the West in addition to disease severity.

Incidence of colorectal cancer

The overall prevalence of colorectal cancer (CRC) associated with UC is reportedly 3%-5% in the West^[99] and 0.0% to 2.2% in Asia^[35,52,85,90,96,100-103]. In a previous meta-analysis from the West, the cumulative risk of CRC associated with UC was reportedly 1.6%, 8.3%, and 18.4% at 10, 20, and 30 years, respectively^[104]. In Asian studies, the cumulative risk of CRC in patients with UC was reportedly 0.70% to 1.15% at 10 years, 3.56%-7.90% at 20 years, and 14.4%-33.2% at 30 years^[100,103], which is comparable with Western cohorts. However, considering the hospital-based design of most Asian studies, the actual corresponding risks might be lower than estimated.

Recently, however, a Western report showed that the risk of CRC decreased from 1979 to 2008 (RR = 1.34 in 1979-1988 to 0.57 in 1999-2008) and that the overall risk of CRC among patients with UC was comparable with that of the general population (RR = 1.07; 95%CI: 0.95-1.21). These findings suggest that a diagnosis of UC no longer seems to increase patients' risk of CRC. However, subgroups of patients with UC, including those diagnosed with UC in childhood or as adolescents, those with a long duration of disease, and those with concomitant primary sclerosing cholangitis, remain at increased risk^[105].

Current evidence indicates that the risk of CRC in Asian patients with UC is slightly lower than that in Western patients. There is a chance that the prevalence of CRC will increase with the rising incidence and increasing proportion of patients with a longer follow-up in Asian countries. A very recent single-center study in Korea showed a substantial increase in CRC among patients with long-standing UC, which is comparable to Western data (unpublished data). Long-term prospective follow-

up studies are warranted to estimate the actual risk of CRC in Asian patients with UC.

Extraintestinal manifestations

Although there are limited numbers of long-term prospective cohort studies and variations in the definition of EIM in Asian studies, the prevalence of EIM in UC seems to be lower in Asian than in Western countries^[58,59,73]. The most commonly involved sites of EIM differ between Asia and the West. The most commonly involved site of EIM is the joints in Asian patients with UC (2.0%-19.5%). Next, eye and skin involvement accounts for 0.0%-4.2% and 0.0%-4.2%, respectively^[35,52,82,90,97]. In contrast, eye involvement (iritis/uveitis) in females (3.8%) and primary sclerosing cholangitis (PSC) in males (3.0%) were the most commonly involved sites in a Western population-based study^[58].

PSC associated with UC is less prevalent in Asia (0.0%-1.7%)^[52,84,96,97,106] than in the West (1.6-7.0%)^[59,107]. Because PSC is associated with a risk of CRC in patients with UC, a diagnosis of PSC should not be neglected in real practice despite the low prevalence of PSC in Asia.

TREATMENT OF UC: COMPARISON BETWEEN THE EAST AND WEST

Medical treatments

Conventional therapy: In a recent population-based cohort study in the Asia-Pacific area that compared UC treatments in the first year between Asia and Australia^[7], treatment with antibiotics (22% *vs* 14%, $P = 0.15$) and immunomodulators (thiopurine or methotrexate) (18% *vs* 9%, $P = 0.05$) did not differ between Asia and Australia. Mesalazine (79% *vs* 62%, $P = 0.012$) and corticosteroids (62% *vs* 28%, $P < 0.0001$) were more commonly prescribed for IBD at the time of diagnosis in Australia than in Asia. Topical therapy (mesalazine or corticosteroids) for UC was also more frequently prescribed in Australia than in Asia (55% *vs* 28%, $P = 0.04$).

In a recent population-based European study, 69 (44%) patients with left-sided colitis and 19 (23%) with extensive colitis in Western Europe received more frequently receive combination therapy with oral and topical 5-ASA compared with 21 (42%) and 6 (22%), respectively, in Eastern Europe^[15]. In this study, 26%-33% of patients with UC received corticosteroid therapy as initial treatment during the first 3 mo of disease in Eastern and Western European centers.

In an Asian survey of management practices for IBD in different countries^[61], 83%, 75%, and 61% of respondents preferred 5-ASA, a combination of topical and oral 5-ASA, and corticosteroids, respectively, as induction treatment of mild-to-moderate UC. Almost all respondents agreed that maintenance therapy should be recommended for patients with IBD in remission, with most recommending the use of 5-ASA to maintain remission in UC (91%). However, they also replied that thiopurines and corticosteroids were needed to maintain the remis-

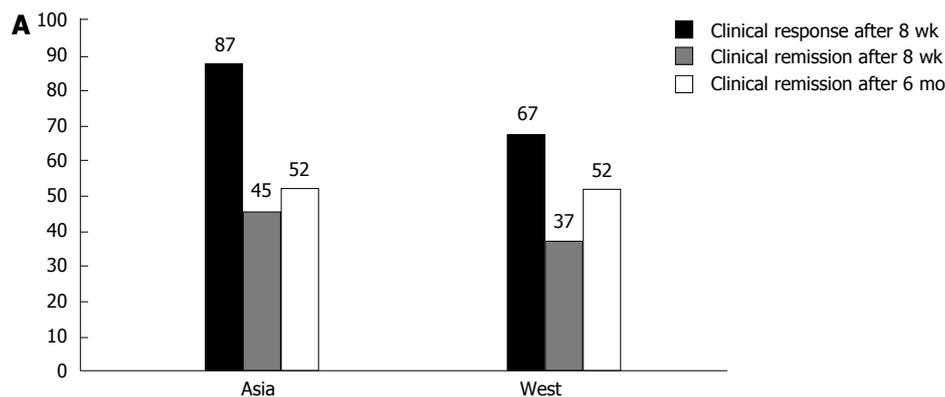

Figure 2 Comparison of the response to infliximab in patients with ulcerative colitis between Asia and the West^[113-115].

sion in approximately 30% and 13% of patients with UC, respectively.

In one cross-sectional study, there was less use of corticosteroids (15.3% *vs* 46.5%, $P < 0.001$) and thiopurines (19.7% *vs* 55.3%, $P < 0.001$) for UC in Hong Kong than in Melbourne, which also reflects differences in practice according to region^[22]. The authors suggested that Asian physicians prefer to manage UC with less intense medical treatments despite more extensive UC and that they use less thiopurines for maintenance therapy compared with the physicians in Melbourne. Again, it is important to educate Asian physicians in terms of following the adequate use of medical treatments according to the practice guidelines for IBD.

Among the UC patients who receive 5-ASA or sulfasalazine therapy, 49.6%^[108] and 72.0% to 75.0%^[109,110] experienced disease relapse in Asia and the West, respectively. The cumulative relapse rate was 21.5% after 1 year, 36.5% after 2 years, 46.9% after 3 years, and 59.8% after 5 years during maintenance therapy with 5-ASA/sulfasalazine, and both the disease extent at diagnosis and anemia were major predictive factors for clinical relapse after 5-ASA/sulfasalazine therapy for Korean patients with mild to moderate UC^[108].

The overall response rates of Asian patients with UC to corticosteroids are similar to or better than those of patients in the West. Short-term response rates at 1 mo were more than 89.2% and 84.0% in Asia and the West (Figure 1C), and 59.4% and 49.0% showed a prolonged response at 1 year, respectively (Figure 1D)^[64,111]

Biologics

A significant difference in the use of anti-TNF inhibitors between Hong Kong and Melbourne has been shown (2/203 *vs* 12/159, $P = 0.001$)^[22]. An Asian survey of IBD management practices in different countries found that < 15% of Asian physicians would use anti-TNF therapy in the management of UC^[61]. In many countries in Asia, the use of biologic agents is self-financed, making the high cost an obstacle to their wider use. However, a short-term population-based study showed that treatment with biological therapy in the first year after diagnosis (2.0% *vs* 0.0%, $P = 0.21$) did not dif-

fer between Asia and Australia^[7]. Long-term follow-up studies are needed to show the chronological trends in the use of anti-TNF therapy in Asia. Emerging studies suggest that anti-TNF therapies are effective and safe in Asian patients with UC. The rates of clinical response and remission to infliximab were 87% and 45% in patients with UC at week 8^[112], which is slightly higher than the rate of clinical response in the West (69.4%-64.5% at week 8)^[113] (Figure 2). Data on long-term efficacy were obtained from 85 of 134 Korean patients who were followed up for more than 6 mo after the first dose of infliximab, and 44 of them (52%) were in remission, which is compatible with UC data in the West^[114]. An another recent Korea study reported that 66.3% of patients demonstrated a clinical response at week 8, 32.6% of whom were determined to be in clinical remission^[115]; this is similar to the response rates in previous Western reports. Collectively, a similar or slightly higher response rate of infliximab in patients with UC is observed in Asia than in Western countries. In the future, it is expected that other anti-TNF agents, such as adalimumab and golimumab, will be used more widely in addition to infliximab in patients with UC in Asian countries.

Complementary and alternative medicines

In 14 randomized controlled trials of patients with UC, aloe vera gel, *Triticum aestivum* (wheat grass juice), *Andropogon paniculata* extract (HMPL-004), and topical Xilei San were superior to placebo in inducing remission or response, and curcumin was superior to placebo in maintaining remission. *Boswellia serrata* gum resin and *Plantago ovata* seeds were as effective as mesalazine, whereas *Oenothera biennis* (evening primrose oil) was not effective and had relapse rates similar to those of omega-3 fatty acids in the treatment of UC^[78]. Larger controlled studies with stricter endpoints and better-defined patient groups are required to obtain more conclusive findings regarding the use of CAM in IBD.

CONCLUSION

Over the past two decades, the incidence and prevalence of IBD have changed with a trend toward increasing

across Asia, especially East Asia. A younger second peak age of disease onset has been shown in Asian populations with CD compared to in Western populations. There is a predominance of male sex and ileocolonic involvement among Asian patients with CD. In patients with UC, the age and sex distribution are not different between Asia and the West. The proportion of current or ex-smokers among Asian patients with CD is lower than that among Western patients. The familial aggregation rates of patients with CD and UC are lower in Asia, but appear to be higher in the West. The disease extent in Asian patients with UC is not significantly different from, and may be slightly less severe than, that in Western populations. Asian patients with UC seem to have a milder disease course than do patients in Western countries. PSC associated with UC is less prevalent in Asia than in the West. Cumulative surgical resection rates in patients with CD do not appear to be different between Asia and the West despite the lack of large-scale, long-term follow-up studies in Asia. Whereas the cumulative surgical resection rates in Asian patients with UC are lower than those in Western patients, the cumulative risk of CRC associated with UC among Asian patients with UC is reportedly comparable with that among Western patients. The use of thiopurine or biologics in patients with IBD remains less frequent in Asia than in the West. There appears to be a higher rate of adverse events, particularly myelotoxicity, in Asians than in Caucasians prescribed thiopurines. The treatment responses for corticosteroids, thiopurines, and biologics of Asian patients with IBD are slightly better than or comparable to those of Western patients.

Several recent prospective, population-based cohort studies were conducted in Asia. Long-term follow-up results from these cohort studies are warranted to help clinicians and researchers further objectively compare the disease prognosis between Asian and Western countries, provide specific health care planning and education, and offer the possibility of identifying causative factors in a population with a rapidly increasing incidence in Asia.

Abstract

Although a considerable number of studies support a substantial increase in incidence, severity, and health-care costs for *Clostridium difficile* infection (CDI) in inflammatory bowel disease (IBD), only few evaluate its impact on IBD outcome. Medline and several other electronic databases from January 1993 to October 2013 were searched in order to identify potentially relevant literature. Most of the studies showed that IBD patients with CDI present a greater proportion of worse outcomes than those without CDI. These patients have longer length of hospital stay, higher rates of colectomies, and increased mortality. Patients with ulcerative colitis are more susceptible to CDI and have more severe outcomes than those with Crohn's disease. However, studies reported variable results in both short-

and long-term outcomes. Contrasting results were also found between studies using nationwide data and those reporting from single-center, or between some North-American and European studies. An important limitation of all studies analyzed was their retrospective design. Due to contrasting data often provided by retrospective studies, further prospective multi-center studies are necessary to evaluate CDI impact on IBD outcome. Until then, a rapid diagnosis and adequate therapy of infection are of paramount importance to improve IBD patients' outcome. The aim of this article is to provide up to date information regarding CDI impact on outcome in IBD patients.

Key words: *Clostridium difficile* infection; Ulcerative colitis; Crohn's disease; Outcome

Core tip: This review summarizes the impact of *Clostridium difficile* infection (CDI) on inflammatory bowel disease (IBD) outcome. Most of the studies showed that IBD patients with CDI have more of the whole range of short- and long-term worst outcomes than those without CDI. Patients with ulcerative colitis have more severe outcomes than those with Crohn's disease. A prompt diagnosis and adequate treatment of CDI are of paramount importance to improve IBD patients' outcome.

Impact of *Clostridium difficile* infection on inflammatory bowel disease outcome: A review. *World J Gastroenterol* 2014; 20(33): 11736-11742 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i33/11736.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i33.11736>

INTRODUCTION

Over the past 15 years, both incidence and severity of

Clostridium difficile (*C. difficile*) infection (CDI) have increased dramatically worldwide^[1,2]. In addition to broad-spectrum antibiotic therapy^[3,4], other potential risk factors such as advanced age, prolonged hospitalization, immunosuppression, multiple co-morbidities, the use of proton pump inhibitors, and the occurrence of a hypervirulent strain of *C. difficile* known as NAP1 (North American pulsed-field type 1) in some North-American and European areas, have been identified^[5-10].

Referring to the same period, several studies clearly demonstrated a significant increase in CDI incidence in patients with inflammatory bowel diseases (IBD)^[11-17]. Both ulcerative colitis (UC) and Crohn's disease (CD) present high-risk for CDI, although patients with UC are more susceptible than those with CD^[11,12,15,16]. Overall, IBD patients with CDI show more of the whole range of short- and long-term worst outcomes than those without CDI or with CDI alone^[11-13,16-19]. However, studies report variable results concerning mortality and colectomy rates, length of hospital stay, and healthcare costs for IBD patients with CDI^[11,13,14,16,18-21].

This review aims to summarize available literature regarding CDI impact on both short- and long-term outcome in adult IBD patients.

RESEARCH

A systematic literature search was performed on Medline/PubMed, EMBASE, Scopus, Science Direct, CINAHL, and Web of Science (ISI Web of Knowledge) databases from January 1993 to October 2013 using various combinations of the following key words: "inflammatory bowel disease", "ulcerative colitis", "Crohn's disease" and "*Clostridium difficile* infection", "*Clostridium difficile*-associated diarrhea", "pseudomembranous colitis". We included only English written studies carried out on adults, from all geographic regions. A manual search of references from the identified studies was also undertaken to identify any additional studies that may have been missed in the computed-assisted literature search. As our objective was to assess the impact of CDI on IBD patients' outcome, only studies reporting outcome of IBD patients co-infected with CDI were taken into analysis. The following data were extracted from each study included: length of hospital stay, colectomy rate, mortality, and healthcare costs. In addition, given the increased need for surgical intervention in UC patients with CDI, a short review of *Clostridium difficile* enteritis and pouchitis has also been made.

SHORT-TERM OUTCOMES

Length of hospital stay

Studies report different results concerning the length of hospital stay in IBD patients with CDI: some report similar stays^[12,19], some shorter ones^[14], while others (Table 1)^[11,13,16,17,21] refer to longer stays than in patients without CDI or with CDI alone. Jodorkovsky *et al.*^[19] reported

a similar mean length of hospital stay in days for IBD (UC) patients with superimposed CDI and those without CDI (11.7 *vs* 11.0, $P = 0.70$), while Bossuyt *et al.*^[14] found significantly shorter stays in IBD patients with CDI (mean 15.2 d) as compared to non-IBD patients co-infected with *C. difficile* (mean 27.7 d) ($P < 0.001$). By contrast, other studies reported longer length of hospitalization in IBD patients with CDI than in those with IBD alone^[11,13,16,17,21]. Thus, Issa *et al.*^[11], in a retrospective, observational study evaluating IBD patients followed in the Inflammatory Bowel Disease Center, Medical College of Wisconsin, Milwaukee, United States, found a mean length of hospital stay of 13.5 d for their UC patients admitted with CDI as compared to 6 d for those without CDI. From the same center, in a study using nationwide data (including over 2000 IBD patients with CDI, over 44000 with CDI alone, and more than 77000 with IBD alone) was found a 3-d longer hospital stay in IBD patients with CDI. Nguyen *et al.*^[16] using the Nationwide Inpatient Sample (NIS) reported a 65% increase in the number of days for CD and 46% for UC patients with CDI as compared to non-IBD patients. A recent study using Hospital Episodes Statistics (HES) which covers all in-patient activity delivered by NHS hospitals in England, reported a 27.9 d longer hospital stay in patients with IBD complicated by hospital-acquired CDI than in those with IBD alone^[17], much higher than in the above two mentioned North-American studies using similar national datasets^[13,16], the difference being partially accounted for by data collection methods. From Canada, a retrospective population-based cohort study of 181 UC patients with CDI and 1835 without CDI hospitalized in Ontario, between 2002-2008, reported a significantly increased mean length of hospital stay in UC patients co-infected with *C. difficile* (11 d *vs* 6 d, $P = 0.0001$)^[21].

Colectomy rate

Contrasting results have also been reported regarding colectomy rate in IBD patients with superimposed CDI. Analysis of the NIS HCUP (Healthcare Cost and Utilization Project) data containing more than 90% of United States community hospital discharges^[22], showed a six fold (OR = 6.6; 95%CI: 4.7-9.3) increase in colectomy rate in IBD patients with concomitant CDI in comparison with CDI patients without underlying IBD^[13]. It should be underlined that this analysis also includes IBD patients admitted for elective surgery, a fact which contributed to such a high colectomy rate^[23]. However, other studies too reported higher colectomy rates in IBD patients with CDI than in CDI-free IBD population or in patients with CDI alone^[11,17-19]. One case-control study reported a 23.4% emergent colectomy rate in patients with both CDI and IBD (UC) as compared to 13.5% (OR = 2.09, 95%CI: 0.72-6.1; $P = 0.17$) in those with IBD alone^[19]. Another study reported a rate of urgent colectomy as high as 45% in hospitalized patients with IBD colitis and co-existing CDI in 2004, which decreased to 25% in 2005, probably due to changes in the treatment

Table 1 Main short-term outcomes in inflammatory bowel disease patients with *Clostridium difficile* infection as compared to those with inflammatory bowel disease alone or *Clostridium difficile* infection alone

| Jodorkovsky <i>et al</i> ^[19] United States | Dig Dis Sci 2010 | In-patients; 2004/06-2005/06 | Similar mean LOS for IBD patients with CDI and those without CDI (11.7 d <i>vs</i> 11.0 d; $P = 0.70$); similar use of cyclosporine therapy (48% <i>vs</i> 47%); higher emergent colectomy rate (23% <i>vs</i> 13.4%, $P = 0.17$) |
| Bossuyt <i>et al</i> ^[14] Belgium | J Crohns Colitis 2009 | In-patients; 2000-2008 | LOS shorter as compared to non-IBD patients (15.2 d <i>vs</i> 27.7 d, $P = 0.001$); one patient with UC+ CDI had a semi-urgent colectomy; no mortality in IBD patients, 2 deaths in non-IBD patients |
| Ricciardi <i>et al</i> ^[15] United States | Dis Colon Rectum 2009 | Case-control analysis of NIS database, out-/in- patients; 1993-2003 | Increased case fatality in UC+CDI patients but not in those with CD+CDI; operative mortality for UC+CDI patients reached 25.7% |
| Ben-Horin <i>et al</i> ^[26] Israel and some European countries | Clin Gastroenterol Hepatol 2009 | Multi-center, in-patients; 2000-2008 | Low colectomy rate (6%) in IBD patients with CDI |
| Ananthakrishnan <i>et al</i> ^[13] United States | Gut 2008 | Case-control analysis of NIS database, out-/in- patients; 2003 | Four-fold higher mortality rate (OR = 4.7, 95%CI: 2.9-7.9) compared with IBD alone and twice higher than in those with CDI alone (OR = 2.21, 95%CI: 1.4-3.4); 3-d longer compared with IBD alone; six-fold greater risk of bowel surgery than those with CDI alone (OR = 6.6, 95%CI: 4.7-9.3); 11406 higher hospital adjusted charges |
| Nguyen <i>et al</i> ^[16] United States | Am J Gastroenterol 2008 | Case-control analysis of NIS database, out-/in- patients; 1998-2004 | Increased mortality in UC (OR = 3.79, 95%CI: 2.84-5.06) but not in CD patients (OR = 1.66, 95%CI: 0.75-3.66); increased LOS with 65% for CD and 46% for UC, and increased hospital charges compared with non-IBD patients |
| Rodemann <i>et al</i> ^[12] United States | Clin Gastroenterol Hepatol 2007 | In-patients, 1998-2004 | LOS similar to non-IBD patients |
| Issa <i>et al</i> ^[11] United States | Clin Gastroenterol Hepatol 2007 | Observational study, out-/ in-patients; 2004-2005 | Increased LOS (13 d <i>vs</i> 6 d); the colectomy rate in UC+CDI decreased from 45% in 2004 to 25% in 2005 |

C. *difficile*: *Clostridium difficile*; CDI: *Clostridium difficile* infection; CD: Crohn's disease; IBD: Inflammatory bowel disease; LOS: Length of hospital stay; NIS: National Inpatient Sample; OR: Odds ratio; UC: Ulcerative colitis.

regimen (use the vancomycin as a primary antibiotic, and a rapid decrease in steroid dosing)^[11]. Using data from NIS, Ananthakrishnan *et al*^[18] reported a significant increase in total colectomy odds from 1998 (OR 1.39, 95% CI: 0.81-2.37) to 2007 (OR = 2.51, 95%CI: 1.90-3.34) ($P = 0.03$) in IBD patients with CDI compared to IBD patients without CDI. Jen *et al*^[17] using HES data for 2002/03 to 2007/08 found that IBD patients with CDI were exposed to a risk of undergoing gastrointestinal surgery or emergency colectomy 1.2 to 3 times higher than those with IBD alone.

In contradiction with previously mentioned studies, others communicated low rates of urgent colectomy in

IBD patients with CDI. Thus, according to two recent studies from Cleveland Clinic's Digestive Disease Institute, United States, CDI in UC patients had no negative impact on colectomy risk within 3 mo of CDI diagnosis. In one study^[20] including 78 patients (39 patients with UC and CDI, 39 with UC alone), 25 underwent colectomy, 12 of whom (48%) were among those with UC and CDI, and 13 (50.9%) with UC alone ($P = 0.81$). Also, in the second study^[24], including 146 patients (45 with UC and CDI, 101 with UC without CDI), within 3 mo of index admission there was no significant difference concerning colectomy risk between UC patients with CDI and those without CDI; however, on long-term follow-up (one

Table 2 Long-term outcomes in inflammatory bowel disease patients with *Clostridium difficile* infection compared to those with inflammatory bowel disease alone

|---|---------------------------------|---|--|
| Murthy <i>et al</i> ^[21] Canada | Aliment Pharmacol Ther 2012 | In-patients; 2002-2008 | UC patients with CDI was associated with increased adjusted 5-yr risk of mortality, but not of colectomy, as compared with UC without CDI |
| Navaneethan <i>et al</i> ^[24] United States | J Crohns Colitis 2012 | Out-/in-patients; 2002-2007 | One year following CDI: increased rates of ERV (37.8% <i>vs</i> 4%, $P = 0.001$) and colectomy (35.6% <i>vs</i> 9.9%, $P = 0.001$); escalation in medical therapy in 58.8% as compared to the prior year (12.9%) ($P = 0.0001$) |
| Jodorkovsky <i>et al</i> ^[19] United States | Dig Dis Sci 2010 | In-patients; 2004-2005 | One year following CDI: UC patients with CDI had increased rate of ERV (8 <i>vs</i> 1, $P = 0.012$), higher number of UC-related hospitalizations (58 <i>vs</i> 27, $P = 0.001$), and two-fold higher rates of colectomy (44.6% <i>vs</i> 25%, $P = 0.04$) compared to UC alone |
| Chiplunker <i>et al</i> ^[27] United States | Gastroenterology 2009 | Case-control, in-patients; 2005-2006 | One year following CDI: over half required an escalation in their IBD medical therapy, 46% had more hospitalisations, colectomy occurred in 10.3% , and no mortality |

CDI: *Clostridium difficile* infection; ERV: Emergency room visits; IBD: Inflammatory bowel disease; OR: Odds ratio; UC: Ulcerative colitis.

year), UC patients with CDI showed a significantly higher rate of colectomy than those without CDI. Kaneko *et al*^[25] in a retrospective study from Yokohama City University Medical Center, Japan, reported that CDI did not have an impact on colectomy rate in their hospitalized UC patients with active disease, the difference in colectomy rate between UC+CDI patients (33.6%) and those without CDI (23.1%) being statistically insignificant (OR = 1.03, 95%CI: 0.41-2.63; $P = 0.94$). Two European studies^[14,26] also reported low rates of colectomy (5% and 6%, respectively) in IBD patients co-infected with *C. difficile*. Recently, Murthy *et al*^[21] found a similar rate of colectomy between UC patients with and without CDI (12% *vs* 9.8%, $P = 0.30$).

The different colectomy rates between single-center studies and those using nationwide data could be partially accounted for by differences in healthcare practice and threshold for surgery, response to CDI medical therapy, and data collection methods used^[23].

Mortality rates are higher in IBD patients with CDI than in those without CDI or with CDI alone^[13,16,17,21]. Among IBD patients, mortality is higher in UC than in CD^[16]. All studies analysing nationwide databases reported high rates of mortality in IBD patients with CDI^[13,16,17,21]. Nguyen *et al*^[16] analyzed NIS discharge records from 1998 to 2004 and found that CDI was associated with a nearly four fold increase in mortality among hospitalized patients with UC (OR 3.79, 95% CI: 2.84-5.06) unlike those with CD (OR = 1.66, 95%CI: 0.75-3.66) as compared to non-IBD patients. Similarly, Ananthakrishnan *et al*^[13], using also data from NIS, found that IBD patients with superimposed CDI had a four fold increase in mortality compared to patients hospitalized with IBD alone (OR = 4.7; 95%CI: 2.9-7.9) and twice higher than those with CDI alone (OR = 2.2, 95%CI: 1.4-3.4). In contrast to Nguyen *et al*^[16] study, where mortality was higher only in UC, this study reported an increased mortality rate in both UC and CD patients. Jen *et al*^[17] using HES data, reported that for the studied period (2002-2008), IBD patients with CDI were

approximately six times more likely to die in hospital than those admitted for IBD alone (adjusted OR = 6.32, 95%CI: 5.67-7.04), and suggested that such high mortality rate may be partially due to increased number of all emergency gastrointestinal surgery and colectomy rates during admissions. Murthy *et al*^[21] also reported a higher mortality rate in hospitalized UC patients co-infected with *C. difficile* than in uninfected UC patients (3.3% *vs* 0.38%, $P = 0.0001$).

Nevertheless, other studies showed a mortality rate for IBD patients with CDI similar to or not statistically higher than what was reported for non-infected IBD patients^[14,18]. Thus, Bossuyt *et al*^[14] registered no deaths among their patients with UC and CDI, while Ananthakrishnan *et al*^[18] found a non-significant increase in the relative mortality risk in IBD patients with superimposed CDI from 1998 (OR = 2.38, 95%CI: 1.52-3.72) to 2007 (OR = 3.38, 95%CI: 2.66-4.29; $P = 0.15$).

LONG-TERM OUTCOMES

Few studies reported on long-term outcomes after an initial episode of CDI in IBD patients (Table 2)^[19,21,24,27]. In a retrospective study including 47 patients with UC and CDI and 52 with UC without CDI, Jodorkovsky *et al*^[19] reported that, over the year following the initial infection episode, a significant increase in the number of visits to the emergency room (8 *vs* 1, $P = 0.012$) was registered, as well as a higher number of UC-related hospitalizations (58 *vs* 27, $P = 0.001$) and a two-fold increase in colectomy rate (44% *vs* 25%, OR = 2.38, 95%CI: 1.01-5.6; $P = 0.04$) as compared to UC patients without CDI. Murthy *et al*^[21], in a retrospective cohort study of UC patients with and without CDI, found that CDI was associated with higher adjusted 5-year risk of mortality [adjusted hazard ratio (aHR) = 2.40, 95%CI: 1.37-4.20], but not of colectomy (aHR = 1.18, 95%CI: 0.90-1.54). In another retrospective study^[24], UC patients with CDI had significantly more UC-related emergency room visits (37 *vs* 4, $P < 0.001$) and a higher rate of colectomy (35.6% *vs* 9%, $P < 0.001$)

than those with UC alone in the year following initial infection. In addition, 55.8% of patients with UC and CDI had an escalation in medical therapy in the year after index infection admission as compared to 12.9% in the previous year ($P < 0.0001$). In a multivariate analysis for risk factors of colectomy, severe disease on endoscopy (OR = 16.7, 95%CI: 4.1-67.9; $P < 0.001$) and CDI (OR = 10.0, 95%CI: 2.7-36.3; $P < 0.001$) were found to be independently associated with colectomy within 1 year. Chiplunker *et al*^[27] in a retrospective, case-control study on 81 patients with IBD comparing disease progression 1 year before and 1 year after the initial infection with *C. difficile*, found that 46% of patients had more hospitalizations and over a half of them (53%) required an escalation in medical therapy during the year following CDI. No deaths occurred during the 1 year follow-up.

Healthcare costs are higher in IBD patients with CDI than in those with IBD alone due to longer hospital stay, higher number of IBD-related hospitalizations, increased need for surgery, and hospital care charges^[13,16]. Nguyen *et al*^[16] found a mean cost increased by 46% and 63% for UC and CD patients, respectively, while Ananthakrishnan *et al*^[13] reported higher increased hospital adjusted expenses of US\$ 11406.

DISCUSSION

The majority of published studies (90%) found by searching Medline and other databases aim to assess CDI incidence in IBD patients, while only 10% of them report on outcome following infection. All studies reporting on outcome in IBD patients with concomitant CDI were retrospective, small single-center cohort studies or large nationwide database studies mostly conducted in North America and Europe. Apart from being retrospective, available studies on outcome have several other limitations such as incomplete information on disease severity, absence of reference to *C. difficile* diagnosis, antibiotic and immunomodulatory therapy. It should be underlined that most of analyzed studies relate to hospitalized IBD patients in the early 2000s, when enzyme immunoassay of stool for *C. difficile* toxins A and B has dominated the laboratory diagnosis of CDI, despite its low sensitivity.

Though few in number, studies reporting outcomes associated with CDI in IBD patients most often show that CDI has a negative impact both on short- and long-term IBD outcomes, increasing the need for surgery, morbidity and mortality rates, as well as healthcare costs^[11,13,16-18,21,24,27]. Both major forms of IBD are under increasing risk for CDI, although patients with UC are most susceptible to infection and have more severe outcomes^[15,16,19]. Short-term outcomes, defined as those measured within 30-90 d of index admission, include length of hospital stay, colectomy and mortality rates. Long-term outcomes, measured at least 1 year following index admission, include emergency room visits, UC-related hospitalizations, escalation in medical therapy, colectomy and mortality rates.

Studies report conflicting results on the length of hospital stay in IBD patients with concomitant CDI: some found similar stays^[12,19], others shorter ones^[14], while most of them reported longer hospitalization periods than in IBD patients without CDI or with CDI alone^[11,13,16,17,21]. Similar or shorter hospitalization periods were reported by single-center studies^[12,14,19], while longer stays were found in studies using nationwide databases^[13,16,17,21]. Discrepancies between studies may be explained by disease severity and response to medical therapy in IBD patients included in the analyses.

Contrasting results have also been reported with regard to colectomy rates in IBD patients with CDI^[11,13,14,17-21,24-26]. Thus, some studies analyzing nationwide data (US NIS HCUP, UK HES) reported high colectomy rates^[13,18], while other single-center ones^[20,24,25] found CDI to have no negative impact on colectomy rate in UC patients. There are discrepancies in what concerns colectomy rates even between studies using nationwide data in North America^[13,18] and Europe^[17], probably due to differences in data collection methods and threshold for surgery^[23]. In addition, studies analyzing nationwide data for colectomy also include IBD patients admitted for elective surgery, a fact which can contribute to high colectomy rates^[23]. Lower risks for colectomy, as reported by single-center North-American^[20] and European^[14,26] studies, may be partially explained by CDI prompt response to medical therapy, followed by clinical remission of IBD flare, thus preventing surgery^[20].

Variable results regarding mortality rate in IBD patients with concomitant CDI are also to be noted^[13,14,16-18,21]. High mortality rates reported by some studies using nationwide data^[13,16,17] may be accounting for by to the increased use of colectomy in IBD patients with CDI^[20], and also by the inclusion of all hospitalized patients who presumably have more severe disease than those from cohort studies^[17,23].

Few studies reported long-term outcomes after an initial CDI episode in IBD (UC) patients. Two^[19,24] reported an increased number of visits to the emergency room and in UC-related hospitalizations, and higher colectomy rate than in patients with UC alone in the year following initial infection. UC patients with CDI had an escalation in medical therapy 1 year after index admission as compared to the previous year^[24,27]. Another study including UC hospitalized patients with and without CDI, found that those with associated CDI had a higher adjusted 5-year risk of mortality, but not of colectomy^[21].

We may add that only one study aimed to identify predictive factors for severe outcomes (colectomy, death) associated with CDI in IBD patients^[28]. Ananthakrishnan *et al*^[28] in a retrospective study using multi-institutional electronic medical record database from two large referral hospitals over the period 1998-2010, reported a 4.4% colectomy and 15.2% mortality rates during 180-d follow-up of 294 IBD patients with CDI (mostly with UC), and found that among several demographic variables and laboratory parameters, only serum albumin below 3

g/dL, hemoglobin below 9 g/dL, and serum creatinine above 1.5 mg/dL were independent predictors of severe outcomes^[28].

CDI IN IBD PATIENTS FOLLOWING SURGICAL INTERVENTION

Clostridium difficile enteritis usually occurs in IBD patients who have undergone colonic surgery, mainly proctocolectomy^[29-31]. *C. difficile* enteritis is generally rare, although the number of cases reported in literature has recently increased^[32]. The predisposition of IBD patients with previous colonic surgery to *C. difficile* enteritis may be accounted for by the colonization of the neo-terminal ileum with colonic-type bacterial flora^[33], and phenotypic changes in the epithelium of pelvic ileoanal pouches^[34]. *C. difficile* enteritis diagnosis and treatment are similar to that for colonic CDI. If some studies reported increased mortality among patients with *C. difficile* enteritis^[35], other ones found low or even no mortality^[29].

Clostridium difficile pouchitis has been reported in IBD patients with ileal pouch anal anastomosis (IPAA)^[36-38]. Shen *et al*^[36] found that 18.3% of their 115 patients with IPAA had CDI. Morphologic changes in the pouch epithelium secondary to prolonged exposures to fecal stream may favor CDI^[34]. In addition, frequent antibiotic treatment for acute or chronic pouchitis is another risk factor for CDI in such patients^[36]. Recently, Tyler *et al*^[39] reported that genetic polymorphisms, particularly the NOD2insC risk allele, are associated with increased risk of developing pouch inflammation among patients with UC and IPAA. Treatment with vancomycin, tinidazole, or rifaximin has been used with benefit in many patients^[37,38].

CONCLUSION

IBD patients with CDI are under a higher risk of worse outcomes than those without CDI. Because the available data are often conflicting and obtained from retrospective studies, further prospective multi-center studies are required to evaluate the impact of CDI on IBD outcomes. Until then, to improve patient outcome, clinicians should have a high index of suspicion for CDI in all IBD patients presenting with a disease flare in order to rapidly establish diagnosis and prompt treatment of infection.

Abstract

Important advances during the last decade have been made in understanding the complex etiopathogenesis of Crohn's disease (CD). While many gaps in our knowledge still exist, it has been suggested that the etiology of CD is multifactorial including genetic, environmental and infectious factors. The most widely accepted theory states that CD is caused by an aggressive immune response to infectious agents in genetically predisposed individuals. The rise of genome-wide association studies allowed the identification of loci and genetic variants in several components of host innate and adaptive immune responses to microorganisms in the gut, highlighting an implication of intestinal microbiota in CD etiology. Moreover, numerous independent studies reported a dysbiosis, *i.e.*, a modification of intestinal microbiota composition, with an imbalance between the abundance of beneficial and harmful bacteria. Although microorganisms including viruses, yeasts, fungi

and bacteria have been postulated as potential CD pathogens, based on epidemiological, clinicopathological, genetic and experimental evidence, their precise role in this disease is not clearly defined. This review summarizes the current knowledge of the infectious agents associated with an increased risk of developing CD. Therapeutic approaches to modulate the intestinal dysbiosis and to target the putative CD-associated pathogens, as well as their potential mechanisms of action are also discussed.

Key words: Crohn's disease; Intestinal microbiota; Dysbiosis; Adherent-invasive *Escherichia coli*; Probiotics; Antibiotics; Fecal microbiota transplantation

Core tip: Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract of which the etiopathogenesis is not fully understood. Increasing evidence has shown that the etiology of CD is multifactorial involving genetic, environmental and infectious factors. A dysbiosis with an increase in the abundance of putative pathogenic bacteria and a decrease in that of potentially beneficial bacteria has been observed in CD patients, revealing the involvement of intestinal microbiota in such disease. This review aims to summarize the current knowledge of the infectious etiology of CD and to discuss therapeutic approaches to modulate intestinal dysbiosis and to target CD-associated pathogens.

INTRODUCTION

The etiopathogenesis of Crohn's disease (CD), a type of inflammatory bowel diseases (IBD), is complex and con-

sists, according to clinical and epidemiological studies, of three interacting elements: environmental factors, genetic susceptibility and infectious agents. While many gaps in our knowledge still exist, the most widely accepted theory holds that the disorder is caused by an aggressive immune response to microorganisms of the intestinal microbiota in genetically predisposed individuals.

The early identification of nucleotide-binding oligomerization domain-containing protein 2 (NOD2), an intracellular sensor of pathogen/microbe-associated molecular patterns, as a susceptibility gene for CD^[1,2] has highlighted the role of innate immunity in the disease. This has been substantiated by genome-wide association studies (GWAS) with the identification of genetic association between CD susceptibility and variants in genes involved in autophagy, ATG16L1 (autophagy-related 16-like 1) and IRGM (Immune-Related GTPase M)^[3-6]. To date, 70 independent loci or genetic variants linked to various components of innate and adaptive immunity have been identified by GWAS as CD susceptibility factors^[4-12]. Arguments in favor of the involvement of environmental factors in CD etiology, which are based on the observation of the irregular distribution of CD cases worldwide, have been raised. Since the appearance of IBD in the middle of the 20th century, the CD incidence and prevalence have shown a continually growing profile in industrialized countries or “Western” countries, such as North Europe and North America, suggesting an involvement of lifestyle^[13]. Another epidemiological study also showed that “Western” diet, rich in fat and sugar and poor in fibers, is associated with an increased risk of developing CD^[14]. This is recently reported that active smoking is associated with an increased risk of developing CD and that smoking cessation leads to a reduced progression of the disease comparatively to patients who still smoke^[15]. Other environmental factors, such as antibiotic use, social status, microbial exposure early in life and during life have been also associated with CD^[16]. Whether these factors, along with genetic susceptibility, lead directly to CD, or whether they allow the conditions needed for infectious agents to thrive, is not clear.

Numerous epidemiological studies, clinicopathological data, genetic and experimental evidence increasingly support an implication of microorganisms in CD pathogenesis. Three non-mutually exclusive theories are currently explored to explain the infectious etiology of CD: (1) a “dysbiosis”, *i.e.* a modification of intestinal microbiota composition with an imbalance between beneficial and harmful bacteria; (2) an excessive bacterial translocation caused by a disrupted intestinal barrier function and defective immune responses; and (3) persistence of a pathogen. This review summarizes our current knowledge of various organisms that have been postulated as infectious agents in CD, and discusses how this may be relevant to the pathogenesis of CD and the new therapeutic approaches.

INTESTINAL MICROBIOTA AND CD

Human intestinal microbiota

The human gastrointestinal (GI) tract contains 10¹⁴ microorganisms of more than 500-1000 different species, forming intestinal microbiota^[17]. The density of intestinal microbiota varies along the GI tract, going from 10² colony forming units (CFU) per gram in stomach to 10¹² CFU per gram in colon^[18].

The intestinal microbial composition can vary greatly between individuals, and an epidemiological study comparing the fecal microbiota between African and European children showed that its composition is determined in part by hygiene, geography and diet^[19]. Higher similarity in fecal bacterial species was reported within twins than in genetically unrelated couples sharing environment and dietary habits^[20]. The gut microbiota composition of siblings also showed increased similarity compared to that of spouses, who were living in the same environment and had similar eating habits^[21].

Given the complexity of the human intestinal microbiota, the characterization of its composition using conventional culture methods and morphological and biochemical-based traditional techniques is limited. Development of new biomolecular techniques, using high-throughput sequencing, allows circumventing these difficulties. Two approaches are currently available. The first is based on sequencing of the 16S ribosomal RNA coding gene (16S rDNA), which is conserved between all phylogenetic bacterial groups^[22]. The second one, namely the metagenomic approach, is based on a complete sequencing of bacterial genome. The evolution of high-throughput technologies with next-generation sequencing allows producing thousands or millions of sequences at once, reducing drastically the costs and facilitating access to full metagenomic sequencing. Dominant bacterial populations in the human intestinal microbiota (> 90%) belong to two phyla: the Firmicutes and the Bacteroidetes; the remainders belong to rarer phyla such as Proteobacteria (containing genera such as *Escherichia* and *Helicobacter*) and Actinobacteria as well as viruses, protists, and fungi^[23-26]. Interestingly, mucosa-associated microbiota is different from the fecal microbiota^[27]. The composition of the fecal microbiota may temporally vary following exposure to different types of foods, medications, or physical environments, and also from changes in transit time, as microbial composition in the lumen varies from caecum to rectum^[24].

Intestinal dysbiosis and CD

An imbalance of the intestinal microbiota, *i.e.* a modification of its composition, with decreased complexity of commensal bacterial profiles and higher numbers of mucosa-associated bacteria, has been reported in CD patients.

Using a 16S rDNA-based profiling technique, Ott

and colleagues showed that the diversity of mucosa-associated microbiota in specimens from patients with active CD undergoing surgery was markedly reduced compared with mucosal specimens from control individuals without inflammation^[28]. Metagenomic studies have shown a decrease in the abundance of several species of the Firmicutes and the Bacteroidetes phyla in CD patients compared with control subjects^[29,32]. The decrease in the abundance of Bacteroidetes could contribute to inflammation since some bacteria belonging to this phyla such as *Bacteroides fragilis* have been shown to exhibit protective effects in a mouse model of colitis induced by *Helicobacter hepaticus*, a murine commensal bacterium with pathogenic properties^[33]. Among Firmicutes, a decrease of the amount of *Faecalibacterium prausnitzii* (*F. prausnitzii*) has been observed in CD patients compared with control subjects^[34]. In mouse models of intestinal inflammation, administration of *F. prausnitzii* resulted in anti-inflammatory effects^[34]. Therefore, the decreased abundance of *F. prausnitzii* could contribute to intestinal inflammation in CD. It has been consistently reported that CD patients have relatively increased amount of Enterobacteriaceae, particularly *Escherichia coli* (*E. coli*) species, compared with control subjects, with a more pronounced difference was observed for mucosa-associated microbiota than fecal samples^[35-43]. An increase in the abundance of some mucolytic bacteria, such as *Ruminococcus gnavus* and *Ruminococcus torques*, in CD patients was also observed^[44].

ROLE OF BACTERIA IN THE PATHOGENESIS OF CD

The intestinal mucosal surface is in a continuous contact with the intestinal microbiota. Given the enormous numbers of enteric bacteria and the persistent threat of opportunistic invasion, it is crucial that the host maintains homeostasis at the luminal surface of the intestinal-microbial interface. This is mediated by a perfect integrity of the intestinal barrier and a functional immunotolerance to the intestinal microbiota and luminal antigens.

Excessive bacterial translocation caused by intestinal epithelial barrier dysfunction

The intestinal barrier allows the absorption of water, ions and nutrients without leaving the microorganisms to penetrate across the mucosal surface. The first line of defence between the intestinal lumen and inner milieu, the physical barrier, is made up of a layer of columnar epithelial cells. More than 80% of these cells are enterocytes, and the rest are enteroendocrine, goblet, and Paneth cells^[45]. Epithelial cells are connected *via* the intercellular junctional complexes including tight junctions, adherent junctions, desmosomes and gap junctions^[46].

Many studies have shown an increased intestinal permeability in CD patients during active phases and a decreased permeability in remission phases^[47-51]. Electron microscopy analyses of biopsies from CD patients in active phases revealed a reduced number of tight junctions

compared with control subjects^[52]. A deregulation of tight junction proteins has been reported in CD patients, with an up-regulation of claudin-2 and a down-regulation of claudin-5 and 8^[52]. The alteration of intestinal permeability observed during active phases of CD could explain the chronic inflammation, given the probably resulting transit of bacteria and other luminal antigens through the mucosa, which are able to activate the sub-mucosal innate immune system.

The intestinal epithelial surface is covered by a mucus layer that prevents the contact between the epithelial layer and microorganisms and the diffusion of unwanted substances, as well as protects the physical barrier from shear stress. The main component of the mucus layer is mucins secreted by goblet cells, which are heavily glycosylated proteins^[53]. The outer loose mucus layer contains a limited number of intestinal microbes; whereas the inner adherent mucus layer contains very few microbes, forming a protected zone adjacent to the epithelial surface^[54]. It is likely that the antimicrobial proteins, which are secreted by epithelial cells and are retained in the mucus layer, contribute to the maintenance of low bacterial numbers in the inner mucus layer^[55]. These “bodyguards” are members of several distinct protein families such as defensins, cathelicidins, and C-type lectins, and they promote bacterial killing by targeting the integrity of bacterial cell walls^[56]. Mice lacking the mucin MUC2 are unable to maintain this relative “bacteria-free” zone and suffer from intestinal inflammation^[54]. It has been shown that mucin gene expression, mucus composition and secretion are altered by intestinal microbiota and host-derived inflammatory mediators^[53].

Dysfunction of immunotolerance and innate immune response to bacteria

Maintenance of immunotolerance and innate immune responses, which allows the control of inflammatory responses in intestinal epithelium, is mediated by several mechanisms: (1) secretion of IgA; (2) bacterial clearance *via* the production of antimicrobial peptides; or (3) a functional autophagic process. Changes in these processes have been observed in CD, which could contribute to abnormal immune responses.

Defective secretory IgA production in CD: The IgA immunoglobulins are secreted by B lymphocytes localized in the intestinal lamina propria^[57]. The secretory IgA is transcytosed across the epithelium and retained in the mucus layer, where it acts to entrap the luminal antigens and bacteria. Bacteria present in the lumen or penetrating the intestinal epithelium are detected by dendritic cells that will alert B cells in the Peyer's patches, which will, in turn, produce IgA specific for intestinal bacteria^[57]. Mice that lack activation-induced cytidine deaminase (AID), which results in defective IgA production in the intestine, exhibit an expansion of mucosa-associated bacteria such as segmented filamentous bacteria (SFB)^[58]. This suggests that secreted IgA also regulates the composition and

density of bacterial communities^[58]. In IBD patients, a serologic shift from an IgA-dominant to an IgG-dominant response in the intestine, which may act as another local defense line, has been reported^[59]. IgG is likely to have an inflammatory effect because in response to flagellin, a common bacterial antigen, the neonatal receptor for IgG FcRn, expressed in hematopoietic cells, promotes inflammation in the presence of anti-flagellin IgG in mice^[60].

Defective bacterial killing through secretion of antimicrobial peptides: The intestinal epithelia secrete antimicrobial molecules whose function is to kill commensal or pathogenic bacteria. Among these molecules are peptides named defensins. Most defensins function by binding to the microbial cell membrane, and, once embedded, forming pore-like membrane defects that allow efflux of essential ions and nutrients^[61,62]. Two classes of defensins have been described in human, α and β -defensins. The α -defensin peptides are mainly secreted by Paneth cells and neutrophils, while β -defensins are more generally secreted by epithelial cells^[61]. The biosynthesis of defensins is triggered by the activation of receptors involved in recognition of extracellular and intracellular bacterial components like Toll-like receptors (TLR) and NOD receptors, respectively, leading to a rapid killing of bacteria in contact with the intestinal epithelium^[63]. Changes in intestinal microbiota were observed in mice that express the human α -defensin 5 and also in mice that do not produce functional α -defensins^[64], suggesting that defensins also regulate the composition and density of bacterial communities. A decrease in α -defensin expression in Paneth cells has been reported in patients with ileal CD, particularly those carrying mutations in *NOD2* gene^[65], indicating the link between infectious etiology and host genetic susceptibility. Reduced expression of β -defensins has been observed in patients with colonic CD^[65]. Other antimicrobial proteins including lysozyme and RegIII γ are secreted by Paneth cells upon exposure to bacteria or bacterial antigens^[66], thereby contributing to host defense against mucosal penetration of both symbiotic and pathogenic bacteria. Mice with a genetic ablation of Paneth cells exhibit increased translocation of bacteria into the host tissues, indicating that Paneth cells contribute to maintaining luminal compartmentalization of intestinal bacteria^[67]. The abnormal synthesis of antimicrobial proteins in CD patients could result in increased intestinal barrier permeability to bacteria that could consequently lead to chronic inflammation.

Defective bacterial clearance by autophagy: Autophagy is a homeostatic process that involves degradation of dysfunctional cellular components through the lysosomal machinery. The newly discovered specialized role of autophagy expands autophagic functions as an immune defense mechanism against intracellular pathogens (also referred to as xenophagy)^[67,68]. GWAS have revealed CD-associated risk variants in several autophagy genes, such as *ATG16L1*, *IRGM*, *ULK1* (Unc-51 like

autophagy activating kinase 1), *PTPN2* (protein tyrosine phosphatase nonreceptor type 2) and *LRRK2* (leucine-rich repeat kinase 2)^[68]. This raised autophagy as one of the most attractive molecular pathways in the field of CD. Further efforts have been made to investigate a functional implication of autophagy in CD pathogenesis^[68,69]. A link between autophagy and the innate immune receptor NOD2 has been established, the latter recruits and interacts with *ATG16L1* at site of bacterial entry in the plasma membrane^[70-72]. These studies have also shown that in epithelial cells, macrophages and dendritic cells, one of the *ATG16L1* or *NOD2* risk variants could result in impaired intracellular pathogenic bacterial clearance owing to a defect in xenophagy response. CD patients homozygous for the *ATG16L1* risk allele exhibited structural aberrances in Paneth cells similar to those observed in mice with hypomorphic *ATG16L1* expression, *i.e.* decreased granule number and lack of lysosomes in the ileal mucus layer^[73]. This indicates that defects in intestinal barrier function in CD could involve dysfunction of Paneth cells related to *ATG16L1* mutation. Interestingly, the CD-associated c.313C>T polymorphism located within the *IRGM* mRNA region results in loss of binding of microRNA-196^[74]. This consequently leads to aberrance of regulation of *IRGM* expression by microRNA-196 and defects in autophagy-mediated control of intracellular replication of the CD-associated adherent-invasive *E. coli*^[74]. Together, these studies suggest that a defect in the autophagy machinery in CD patients could lead to an uncontrolled bacterial proliferation inside host cells and consequently cause chronic inflammation.

INFECTIOUS AGENTS AND CD

Numerous epidemiological, clinicopathological, genetic and experimental evidence has suggested an intervention of infectious agents in CD etiology. Firstly, the preferential location of the lesions in CD are situated in the terminal ileum and colon^[75], where the largest population of bacteria is found^[18]. Secondly, the use of antibiotics in CD treatment has been proven to be sometimes effective^[76]. Thirdly, higher numbers of mucosa-associated and internalized bacteria in biopsies from CD patients compared to control subjects was also reported^[57]. These observations, together with the identification of CD-associated polymorphisms in genes encoding innate immune receptors involved in the recognition of bacterial components or proteins participating in the clearance of pathogenic bacteria by autophagy highly support the hypothesis of an involvement of infectious agents in CD etiology. Those who have been suspected to modify the risk of developing CD include viruses, eukaryotes and bacteria.

Implication of virus in CD

Investigations of viral agents in CD patients have been accomplished with the use of PCR and RT-PCR, and allowed to identify the Epstein Barr virus (EBV) in

15% of patients^[77]. No enterovirus has been detected in the gut of CD patients^[77]. Interestingly, Cadwell *et al*^[78] showed that the abnormalities of Paneth cells in hypomorphic ATG16L1^{IM} mice are dependent on a contact with a particular murine norovirus strain CR6, since mice raised in a germ-free condition or mice infected with a non-persistent norovirus strain exhibited normal Paneth cell morphology. In humans, several clinical studies have shown that norovirus infection can aggravate IBD symptoms^[79,80]. Although there is no direct evidence showing that viral infection could be a causative factor of CD, the study by Cadwell *et al*^[78] suggests that the combination of host genetic susceptibility and the presence of viral factors could lead to CD occurrence.

Bacteriophages are other viral agents that have been suspected to play a role in CD pathogenesis. Indeed, it has been shown that bacteriophages may result in dysbiosis by triggering a destabilization of microbial communities^[81]. A study analyzing the bacteriophage population in CD patients reported that each patient is colonized by one dominant phage family^[82]. In addition, the amount of bacteriophages is significantly increased in CD patients compared with control subjects, and is decreased in ulcerated areas compared with non-ulcerated areas^[82].

Implication of yeast in CD: *Candida albicans*

In 2006, the presence of anti-*Saccharomyces cerevisiae* antibodies (ASCA), involved in the recognition of a mannose residue on the surface of the non-pathogenic yeast *Saccharomyces cerevisiae*^[83], was shown in the serum of 39%-70% of CD patients *vs* 0%-5% of control subjects^[84]. A study proposed that the fungal pathogen *Candida albicans* could act as an intestinal pathogen by triggering the production of ASCA, given that it expresses the ASCA epitope on many surface molecules^[85]. The presence of ASCA in CD patients could reflect a decrease of immunotolerance towards specific antigens of this endogenous yeast. It has been observed that CD patients and their unaffected relatives display a greater colonization of the gastrointestinal tract by *Candida albicans* with respective values of 44 and 38% than the general population with 22%^[86]. In addition, *Candida albicans* colonizes and aggravates gut inflammation in mice^[87]. Although its role in CD etiopathogenesis has not yet been elucidated, the hypothesis of an involvement of *Candida albicans* needs to be taken into consideration.

Implication of pathogenic bacteria in CD

***Mycobacterium avium* subspecies *paratuberculosis*:** *Mycobacterium avium* subspecies *paratuberculosis* (MAP) is the causative agent of the Johne's disease, a chronic granulomatous ileitis most common in ruminants, but can also affect many other species including primates. Given that this pathology shares some facets with CD, MAP could be an agent implicated in the complex etiology of CD^[88,89]. Research groups aiming to identify MAP in CD patients by isolation methods or by amplification of specific DNA sequences have reported contradictory re-

sults; while some show the presence of this bacterium in the blood and intestinal biopsies from CD patients^[90-94], some do not^[95-98]. Furthermore, serologic analyses have highlighted the presence of antibodies against MAP in 90% of CD patients^[99]. Administration of antibiotics with strong activity against mycobacteria has resulted in remission in approximately 66%-75% of patients with active CD as reported by three independent studies^[100-102]. Although these antibiotics are also active against other bacterial groups and their effect needs to be confirmed, these studies highlight the potential role of MAP in CD etiology.

***Yersinia*:** Yersiniosis, an infectious disease caused by the psychrotrophic bacterium *Yersinia*, displays the common facets of CD, including the presence of granulomas and ulcerations along the epithelium^[103]. Another study has shown the penetration of *Yersinia enterocolitica* across the epithelium *via* Peyer's patches^[104]. A *Yersinia enterocolitica* oral infection induces the secretion of pro-inflammatory cytokines in mice^[105]. The presence of *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* strains in the gut of CD patients has been shown^[106,107]. It was also reported that two cases of patients displaying terminal ileitis involving *Yersinia paratuberculosis* were diagnosed with CD thereafter^[108,109]. These observations support the hypothesis of the involvement of *Yersinia* in CD pathogenesis, but further studies are required to determine their precise role.

***Listeria*:** Numerous studies have been conducted to investigate the role of *Listeria* in CD etiology^[110,111]. Immunohistochemical^[112] and molecular^[111,113] analyses have shown the presence of *Listeria monocytogenes* in CD lesions. *Listeria monocytogenes* has been shown to disrupt and cross the intestinal barrier by entering nonphagocytic cells, escaping from the internalization vacuole, allowing bacteria to move in the cell and to spread from cell to cell^[114]. A study reported that NOD2-deficient mice display an increased susceptibility to oral infection by *Listeria monocytogenes*, with a down-regulation of genes coding cryptids, the murine homologs to human α -defensins, in Paneth cells^[115]. These elements are in favor of the hypothesis that *Listeria* is involved in CD etiology, but additional studies are required to ascertain its causative role.

***Helicobacter*:** Bacteria belonging to the *Helicobacter* family have been suspected to play a role in CD pathogenesis. An association between the *Helicobacter pylori* strain and the human gastric mucosal system was highlighted since *Helicobacter pylori* provokes mucosal ulcerations^[116]. Numerous species of *Helicobacter* have been identified in the human gut^[117,118], suggesting that they can cause pathology by colonizing the intestinal mucosa. *In vivo* studies have shown that *Helicobacter hepaticus*, a benign murine commensal bacterium closed to the human *Helicobacter pylori* strain, was able to induce considerable intestinal inflammation in immunocompromised mouse models [mice deficient in T-cell receptor alpha, T-cell receptor

beta or interleukine (IL)-10] by triggering similar immune responses to those observed in CD^[119,120]. These experimental data suggest that *Helicobacter* could initiate disease in individuals being genetically susceptible to CD.

E. COLI AND CD

The involvement of *E. coli* in CD etiopathogenesis has been argued for long time. According to serologic studies, the antibodies raised against the outer membrane porin C of *E. coli* (anti-OmpC) have been found in 37%-55% of CD patients^[121,122]. Numerous studies have shown the presence of *E. coli*-specific antigens in biopsies from CD patients, particularly in the ulcer areas, along the fissures and within the granulomas and *lamina propria*^[37,112,123,124]. These reports are in accordance with numerous independent studies showing increased abundance of *E. coli* in the mucosa-associated microbiota of CD patients with dysbiosis compared with control subjects^[37-43]. Specifically, we have shown that *E. coli* abnormally colonize acute and chronic ileal lesions of CD patients comparatively to control subjects^[35,36].

Pathogenic traits of CD-associated *E. coli*

Adhesion and invasion of epithelial cells: Phenotypic characterization of the *E. coli* strains isolated from CD patients has evidenced their capacity to adhere to eukaryotic cells *in vitro*. It has been shown that 53%-62% of CD patients carry *E. coli* strains that display adhesion properties to buccal cells *vs* only 5%-6% of control subjects^[125,126]. Another study reported that 84.6% of CD patients and 78.9% of patients with disease recurrence carry *E. coli* strains capable of adhering to human intestinal epithelial Caco-2 cells, *vs* only 33.3% of control individuals^[35]. Finally, several independent studies have shown the presence of *E. coli* strains internalized in the intestinal mucosa of CD patients and their capacity to invade intestinal epithelial cells (IECs)^[36,39,41,42,127]. Our group has more particularly studied the *E. coli* reference strain LF82, isolated from a chronic ileal lesion of a CD patient^[35,36], and shown that LF82 is able to adhere to and to invade IECs^[128].

Survival and proliferation in host cells: Increasing evidence has shown the capability of the CD-associated *E. coli* strains to invade, survive and replicate in IECs and macrophages. The first study showed by electron microscopy that the *E. coli* strain LF82 can trigger, in the same way as other enteropathogens such as *Shigella*, the lysis of endocytic vacuoles to be released in the cytoplasm, where the environment is more favorable for bacterial replication^[129]. It has been later reported that CD-associated *E. coli* are able to survive and replicate in macrophages without inducing cell death^[130,131]. The mechanism underlying these pathogenic properties of CD-associated *E. coli* has been then investigated. Given the association of polymorphisms in autophagy genes *ATG16L1* and *IRGM* with an increased risk of developing CD, it has been proposed that defects in autophagic process could allow

the CD-associated *E. coli* to survive and replicate within host cells. Our group has shown that the *E. coli* strain LF82 replicates more importantly in autophagy-deficient murine fibroblasts than in wild-type fibroblasts, and in human epithelial cells and macrophages with siRNA-mediated *ATG16L1* expression silencing^[132]. Increased intracellular replication of the LF82 strain was also observed in human cells expressing the *ATG16L1* risk variant^[132]. As discussed earlier, the CD-associated C313T mutation in *IRGM* gene results in loss of tight regulation of *IRGM* protein and therefore autophagy, leading to an increased persistence of the LF82 bacteria in host cells^[174]. These studies suggest that impaired capacity of autophagy to handle and clear bacteria could be a mechanism underlying the increased risk of CD patients *via* increased numbers of pro-inflammatory bacteria.

Disruption of the intestinal barrier function: Several pathogenic bacteria are capable of disrupting the intestinal barrier to cross the mucosal surface by modulating expression and/or organization of proteins involved in establishment and maintenance of epithelial cell junctions. It has been shown that the CD-associated *E. coli* strains induce disorganization of F-actin and displacement of ZO-1 and E-cadherin from the apical junctional complex in human intestinal Caco-2 cell monolayer, leading to a drop in the trans-epithelial resistance and consequently increased epithelial permeability^[127]. Likewise, the LF82 strain induces a redistribution of ZO-1 in Madin-Darby canine kidney-1 cell monolayer, causing a severe disruption of the epithelial barrier^[133]. These data suggest that the CD-associated *E. coli* could play a causative role in CD etiopathogenesis by inducing disruption of intestinal barrier function.

Inducing pro-inflammatory cytokine/chemokine production:

Several *in vitro* and *in vivo* studies have reported that the CD-associated *E. coli* can induce pro-inflammatory responses in host cells. Infection of macrophages with the LF82 strain induces the secretion of high level of TNF- α ^[127,130], and this is essential for the intramacrophagic replication of the bacteria^[130]. This indicates that the CD-associated *E. coli* could induce production of TNF- α to create an amplification loop of replication and of inflammation. Increased production of IL-8 in LF82-infected IECs has been also reported^[127,134,135]. In a transgenic CEABAC10 mouse model expressing human Carcinoembryonic antigen-related cell adhesion molecules (CEACAMs), the CD-associated *E. coli* strain LF82 can induce a severe colitis accompanied with an increase in production of the pro-inflammatory cytokines IL-1 β , IL-6, and IL-17 and a decrease in that of the anti-inflammatory cytokine IL-10^[136]. These *in vitro* and *in vivo* data support the hypothesis of the involvement of CD-associated *E. coli* in the etiopathogenesis of this chronic inflammatory disease.

Adherent-invasive *E. coli*: A new pathovar

Pathovar definition: Analysis of virulence factors and

clinical manifestations engendered by different *E. coli* strains has allowed distinguishing six pathovars: enterotoxigenic *E. coli*, enterohemorrhagic *E. coli*, enteroaggregative *E. coli*, diffusely adherent *E. coli*, enteropathogenic *E. coli* and enteroinvasive *E. coli* (EIEC)^[137]. CD-associated *E. coli* strains share some virulence features with already established *E. coli* pathovars such as the ability to induce macrophage cell death, but the factors involved in the adhesion and invasion properties of the known pathovars are not present in the CD-associated *E. coli* strains^[35,129]. Thus, a new pathovar was defined to classify these strains, and called adherent-invasive *E. coli* (AIEC)^[129]. The criteria of this pathovar group include abilities to adhere to and to invade IECs, to survive and replicate in large vacuoles within macrophages without inducing cell death, and to induce secretion of high levels of the pro-inflammatory cytokine TNF- α by infected macrophages. The ability to trigger increased intestinal permeability also constitutes one of the pathogenic characteristics of AIEC^[127]. Finally, AIEC have been shown to form biofilm and to induce granulomas formation *in vitro*^[138-140]. The *E. coli* LF82 strain displays all of these characteristics, and is therefore considered as the AIEC reference strain.

AIEC prevalence in CD patients: Evidence has shown a high prevalence of ileal mucosa-associated AIEC in CD, since AIEC have been identified in the neoterminal ileum of 36.4%-51.9% of CD patients *vs* only 6.2%-16.7% of controls^[36,141]. Comparative genomic analyses of AIEC strains isolated from different patients have shown that only one specific strain was not found in all of the patients, nevertheless, some genotypes of particular strains seem to be more frequently associated with ileal lesions of CD^[40,142].

Virulence factors of AIEC: Genetic determinants of virulence of the AIEC reference strain LF82 are not known and are not similar to those of other invasive *E. coli* strains. Thus, they have been searched by random mutagenesis (insertion of the transposon *Tn5phoA*) and by comparison of the genome of LF82 with that of other pathogens^[143,144]. These studies have permitted the identification of the lipoprotein NlpI which appears to be involved in adhesion and invasion capacities of LF82, since the insertion of the *Tn5phoA* transposon in the NlpI-encoding gene leads to a loss of invasion capacity of LF82 and the LF82- Δ *nlpI* isogenic mutant showed a decreased adhesion and invasion capacity in Intestine-407 epithelial cells^[145]. Likewise, the analysis of the *Tn5phoA* insertion mutant library and the construction of isogenic mutants led to the identification of flagella and the membrane proteins YfgL, OmpC and OmpA as factors involved in adhesion and invasion properties of the reference strain LF82^[146-149]. Another study showed that type 1 pili are a crucial virulence factor that allows AIEC to adhere to IECs *via* the receptor CEACAM6^[150]. They are composed of a major subunit with repetition

of FimA protein, minor subunits FimG and FimF, and one adhesin called FimH present at the end of the pilus^[151]. Our group recently showed that point mutations in FimH confer AIEC bacteria a higher ability to adhere to CEACAM6-expressing human IECs^[152]. The replacement of FimH-coding gene having an AIEC-associated mutation in the LF82 strain by a gene coding FimH of the commensal non-pathogenic *E. coli* K12 MG1655 strain decreased the ability of the bacteria to colonize the gut and to induce intestinal inflammation in CEABAC10 transgenic mice^[152]. This suggests that selection of amino acid mutations in FimH is a mechanism of AIEC virulence evolution, which could increase the risk of CD development in a genetically susceptible host. Recently, we have identified long polar fimbriae (LPF) as a key factor for AIEC to target microfold cells (or M cells) on the surface of Peyer's patches, and that the prevalence of the AIEC strains harboring the *lpf* operon was markedly higher in CD patients compared with controls^[153]. This operon has also been identified in other enteropathogenic bacteria such as *Salmonella* Typhimurium and been shown to be involved in specific adherence of the bacteria to M cells on Peyer's patches^[154]. Interestingly, bile salts, of which the composition has been reported to be modified in CD patients^[155], induce LPF expression favoring the colonization of the epithelium by AIEC^[156]. These data could explain the presence of early lesions in the Peyer's patches of CD patients.

THERAPEUTIC APPROACHES

TARGETING INFECTIOUS AGENTS TO TREAT CD

Current CD treatment strategies aim to control inflammation, relieve symptoms and correct nutritional deficiencies. The treatment depends on the location and severity of disease, complications and response to previous treatment. At this time, treatment can help control the disease, but there is no cure. Established therapies for CD include anti-inflammatory agents [*e.g.*, aminosalicylates (5-ASA), omega 3 fatty acids], immunosuppressive drugs (*e.g.*, corticosteroids, azathioprine and 6-mercaptopurine) and antibiotics. An increasing number of novel and alternative therapeutic approaches are in progress^[157]. New biologic therapies include the targeting of pro-inflammatory cytokines, enhancement or infusion of anti-inflammatory cytokines, blocking intravascular adhesion molecules, and modifying T-cell functions^[157]. Given the increasing evidence supporting the infectious etiology of CD, therapeutic approaches to manipulate gut microbiota have been attempted by using antibiotics, probiotics, prebiotics and possibly defensins. Although these approaches are widely used, their benefits are variable and certainly not permanent. One important reason for this is the fact that the etiology of CD is complex and multifactorial, and does not include only infectious factors. Therefore, manipulation of the gut microbiota is beneficial, but, on its

own, is insufficient to cure the disease.

Antibiotics

The beneficial effect of broad-spectrum antibiotics in the treatment of a moderate form of CD has been reported, although it lacked a large-scale clinical trial^[158]. A controlled clinical trial conducted in American and Canadian centers reported that metronidazole, an antibiotic active against strictly anaerobic bacteria, is more effective in CD patients than a placebo at both a low dose (10 mg/kg per day) and a high dose (20 mg/kg per day)^[159]. A therapy based on ciprofloxacin has been shown to be effective in CD treatment and is also effective in combination with conventional treatments in patients with resistant CD^[160,161]. Combination of ciprofloxacin and metronidazole has been tested in treatment of acute phase of the disease and appeared to be effective^[162]. Numerous clinical trials have been performed to test the potential benefit of antibiotics during different clinical manifestations of CD. Papi and colleagues showed that administration of antibiotics (metronidazole and ornidazole) is effective in preventing post-operative recurrence of CD, which is inevitable since the surgery is not curative^[163]. The efficiency of antibiotics in the treatment of perianal fistulas, a complication of CD, was tested, but did not allow obtaining extended closure of fistulas^[164]. The authors of this study suggest the use of antibiotics as a second-line therapy for fistula healing following the use of anti-TNF- α antibodies, which are known to be effective. Pre-operative administration of antibiotics seems to reduce the risk of surgery^[165]. Although antibiotic treatment is effective in some cases, it has some side effects including non-specific effects against microbiota, the possibility of inducing an antibiotic resistance and the risk of *Clostridium difficile* superinfection. Those antibiotics have been therefore recommended as a second-line treatment for CD.

Probiotics

Given that intestinal dysbiosis has been postulated to cause CD in genetically predisposed individuals, therapeutic strategies based on the use of probiotics have been developed to modulate the imbalance of intestinal microbiota observed in CD patients.

Potential action mechanisms of probiotics include competitive interactions with enteropathogens, production of antimicrobial metabolites, influences on the epithelium, and immune modulation^[166]. The use of the probiotic yeast strain *Saccharomyces boulardii* has been shown to be effective in prevention and treatment of antibiotic-associated and *Clostridium difficile* infection-associated diarrhea, as well as traveler's diarrhea^[167]. Several probiotic strains have been tested in CD treatment. Treatment of CD patients with the probiotic *E. coli* strain Nissle 1917 leads to a remission more rapidly than untreated patients, without affecting the number of patients entering remission^[168]. One study, although involving only a few subjects, 32 patients, reported the maintenance of remission

in CD patients treated with the probiotic strain *Saccharomyces boulardii* comparatively to patients treated with mesalamine^[169], of which the effect in maintaining remission has been raised^[170,171]. However, a recent randomized, placebo-controlled trial reported no significant effect of the yeast *Saccharomyces boulardii* in preventing relapse following a medically-induced remission^[172]. Clinical trials have been carried out to evaluate the potential efficacy of the probiotic strain *Lactobacillus GG* in the prevention of post-operative recurrence in CD patients^[173] and on the average time of relapse after a medically induced remission period^[174]. The first reported contradictory effects with rates of clinical and endoscopic recurrence of 16.6% and 60%, respectively, in the *Lactobacillus*-treated group *vs* 10.5% and 35.3% in the placebo group. The second showed a shorter average time of relapse of 9.8 mo in patients treated with the probiotic *vs* 11 mo in the placebo group. Another strain of *Lactobacillus*, *Lactobacillus johnsonii*, was tested in CD patients during two double-blind trials, and both reported no significant effect of this strain in preventing clinical recurrence of the disease following a surgically-induced remission in probiotic-treated patients comparatively to the placebo group^[175,176]. Although probiotics may be the most physiologic and non-toxic way to prevent and treat CD, it may be transient and has a limited and debatable usefulness at present.

Fecal microbiota transplantation

Given the potential role played by intestinal microbiota in CD pathogenesis, another therapeutic approach has been considered for CD treatment: fecal microbiota transplantation. The transfer of fecal microbiota from a healthy individual to the gut of a patient, enabling the re-establishment of a normal microbial community, has been shown to be effective in the treatment of ulcerative colitis^[177], another form of IBD, or infection with *Clostridium difficile*^[178]. *Clostridium difficile* infection has become a major public health problem, occurring after antibiotic treatment or ingestion of spores in the environment. In patients with a recalcitrant infection, fecal microbiota transplantation has been shown to be effective, with an efficiency rate of 90%^[179,180]. Only few case reports and case series of fecal microbiota transplantation for the management of CD have been published. The first case was a 31-year-old man diagnosed with terminal ileal CD who remained symptom-free for 4 mo after the transplantation^[181]. Among the other cases reported, the use of fecal microbiota transplants leads to CD resolution, *i.e.* to a complete cessation of symptoms or to the absence of active disease confirmed by endoscopic and histologic analyses, but in most cases, it does not^[182]. A recent study reported the effectiveness of fecal microbiota transplantation in a case of severe fistulizing CD with a sustained clinical remission for more than 9 mo after the treatment^[183]. Fecal microbiota transplants have also been used to manage *Clostridium difficile* infections in CD patients, and it appears to be effective in most of patients with a reduction or a complete resolution of the

infection-associated diarrhea^[182]. More clinical trials with better standardized protocols are required to confirm the beneficial effect of fecal microbiota transplantation in treatment of this complex disease.

CONCLUSION

Since the first description of CD in 1932, numerous research groups worldwide have attempted to unravel the complex and multifactorial etiology of the disease to develop a curative therapy. In addition to the identification of genetic and environmental risk factors in CD, increasing lines of evidence have supported a role for infectious agents in CD etiopathogenesis. These include the disruption of the intestinal barrier function associated with excessive bacterial translocation, an intestinal dysbiosis, defects in the secretion of IgA entrapping antigens and bacteria in the intestinal lumen and inefficacy of autophagy-mediated clearance of intracellular bacteria. These defects, which have been reported in CD patients, can lead to the emergence of infectious agents (viruses, eukaryotes or bacteria) that could induce chronic inflammatory characteristic of CD. Advances in the knowledge of infectious etiology of CD enable to develop different therapies based on the clearance of CD-associated pathogens, the modification of the imbalanced intestinal microbiota and re-establishment of a "healthy" microbiota with the use of antibiotics, probiotics and fecal microbiota transplantation. However, these therapies on their own are insufficient to provide a cure for CD. Therefore, successful CD therapies are likely to require multiple pathway-integrated treatments depending on the stage of the disease and each patient subset.

Abstract

In the intestine a balance between proinflammatory and repair signals of the immune system is essential for the maintenance of intestinal homeostasis. The innate immunity ensures a primary host response to microbial invasion, which induces an inflammatory process to localize the infection and prevent systemic dissemination of pathogens. The key elements of this process are the germline encoded pattern recognition receptors including Toll-like receptors (TLRs). If pathogens cannot be eliminated, they may elicit chronic inflammation, which may be partly mediated *via* TLRs. Additionally, chronic inflammation has long been suggested to trigger tissue tumorous transformation. Inflammation, the seventh hallmark of cancer, may affect all phases of tumor development, and evade the immune system. Inflammation acts as a cellular stressor and may trigger DNA damage or genetic instability. Furthermore, chronic inflammation can provoke genetic mutations and epigenetic mechanisms that promote malignant cell transformation. Colorectal cancers in inflammatory bowel disease patients are considered typical examples of inflammation-related cancers. Although data regarding

the role of TLRs in the pathomechanism of cancer-associated colitis are rather conflicting, functionally these molecules can be classified as "largely antitumorigenic" and "largely pro-tumorigenic" with the caveat that the underlying signaling pathways are mainly context (*i.e.*, organ-, tissue-, cell-) and ligand-dependent.

Key words: Inflammation; Tissue repair; Immunoregulation; Colitis-associated cancer; Toll-like receptor; Inflammatory bowel disease; Carcinogenesis

Core tip: Colorectal cancers arising in inflammatory bowel disease patients are considered typical examples of inflammation-associated cancers. The exact role of Toll-like receptor (TLR)-signaling in colitis-associated cancer initiation and development is conflicting. Here we aimed to summarize recent data on the contribution of TLR-mediated immune responses to inflammation-related colonic carcinogenesis.

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC), the main clinical phenotypes of idiopathic, relapsing-remitting inflammatory bowel disease (IBD) are systemic disorders affecting the GI-tract with frequent extraintestinal manifestations and other associated autoimmune conditions. IBD is considered a polygenic autoimmune disorder with a complex multifactor etiology. Generally, IBD arises in

susceptible individuals in whom upon an environmental trigger a sustained disturbed, deleterious mucosal immune reaction is provoked towards commensal microbiota^[1].

A balance between proinflammatory and repair signals of the immune system is essential for the maintenance of intestinal homeostasis. The interplay of genes regulating immune functions is strongly affected by the environment, especially gut resident microbiota. On the basis of genetic alterations in CD, impaired sensing and handling of intracellular bacteria by the innate immunity seem to be one of the most relevant pathophysiologic features^[1].

The innate immunity ensures a primary host response to microbial invasion, which induces an inflammatory process to localize the infection and prevent systemic dissemination of pathogens. The key elements of this process are the germline encoded pattern recognition receptors (PRRs) including Toll-like receptors (TLRs), NOD-like receptors (NLRs), ribonucleic-acid (RNA) helicases, C-type lectin receptors, and cytosolic deoxyribonucleic-acid (DNA) sensors, which sense evolutionarily conserved pathogen-associated molecular patterns (PAMPs) of microbiota. The detection of PAMPs by PRRs triggers sequential activation of intracellular signaling pathways resulting in induction of a wide range of cytokines and chemokines that unite the early host response to infection^[2]. If pathogens cannot be eliminated, they may elicit chronic inflammation, which may be partly mediated *via* TLRs. Additionally, chronic inflammation has long been suggested to trigger tissue tumorous transformation. Indeed, a higher incidence of intestinal cancers has been observed in IBD patients. However, the exact role of TLR-signaling in colitis-associated cancer (CAC) initiation and development is still unknown, therefore, we aimed to summarize the currently available information on the contribution of TLR-mediated immune responses to inflammation-related colonic carcinogenesis.

RELATION OF TOLL-LIKE RECEPTORS TO COLONIC MUCOSA

The highly conserved TLRs represent sentinels of the innate immune system. TLRs belong to the type 1 transmembrane glycoproteins, which contain extracellular leucine-rich repeated sequences and Toll/interleukin-1 receptor (TIR) signaling domains. TLRs have five TIR-containing adaptor proteins, Myeloid differentiation factor 88 (MyD88), MyD88 adaptor-like (TIRAP), TIR domain containing adaptor inducing interferon- β (TRIF), TRIF-related adaptor molecule (TRAM)^[3], and sterile α and heat-armor motifs^[4]. TLR4 was the first receptor to be identified, and currently 10 TLRs have been identified in humans, and 13 in mice^[5]. TLRs are mainly expressed in the cells of the innate and adaptive immune system [*i.e.*, monocytes, macrophages, lymphocytes, mast cells, dendritic cells (DCs)], however, all TLR1-9 have also been identified as being expressed in human intesti-

nal epithelial cells (IECs)^[6-8].

TLRs usually recognize microbial wall components, as well as DNA and RNA fragments. TLRs bind specific motifs appearing in bacteria, fungi, protozoa, and viruses^[9,10]. These motifs are mainly lipids and lipopeptides (TLR-1, -2, -4, -6), bacterial flagellin (TLR5), and nucleic acid fragments (TLR-3,-7, -8, -9). TLR3 binds double-stranded RNA from viruses, while TLR7 and -8 can recognize single-stranded RNAs. Moreover, TLR7 recognizes immunoglobulin/self-RNA complexes within autoimmune disease conditions. Imiquimod is a specific ligand for TLR7. TLR9 is activated by bacterial and viral DNA, immunoglobulin-DNA complexes, and synthetic oligodeoxynucleotides (ODNs), which contain unmethylated CpG sequences^[9,10].

In vitro data have demonstrated hyporesponsiveness of IECs to TLR ligands^[7,8]. Antigen-presenting cells (APCs) in the lamina propria (LP) also seem to be unresponsive to TLR ligands^[11]. Under physiologic conditions, TLR3, -7, -8, and -9 are expressed in endosomes, or basolateral membrane (TLR5), where these TLRs are not exposed to pathogens unless microbiota get into the cells or invade mucosa^[2]. Apical epithelial TLR9 activation by bacterial DNA fragments has been reported to take part in colonic homeostasis^[12]. These findings underline a unique feature of TLRs (and other PRRs) in IECs that establishes immune tolerance to the commensal flora of the colonic mucosal interface.

In addition, epithelial TLRs contribute to balancing the composition of luminal microorganisms by regulating the secretion of different antimicrobial peptides and mucosal IgA. TLR9^{-/-} mice have impaired expression of cryptidin (α -defensin) compared to wild-type mice^[12]. Signaling through TLR-2, -3, and -4 have all been implicated with the expression of β -defensins in IECs^[13,14]. Several TLR signals in IECs induce B cell-activating factors leading to immunoglobulin class switch recombination in B cells of the LP without T cell activation, resulting in IgA secretion^[15]. Moreover, activation of TLR-3 and -4 has been found to induce epithelial expression of an epithelial immunoglobulin transporter (polymeric immunoglobulin receptor) that enhances luminal IgA secretion^[16,17].

To date, TLR signaling can be classified into classical/canonical and alternative/noncanonical pathways^[18]. All TLRs, except TLR3, utilize the MyD88-dependent signaling pathway to induce the expression of proinflammatory cytokine genes^[19]. TLR3 exclusively uses the TRIF pathway^[19]. The classical inflammatory signaling pathway is mainly activated through MyD88, which, in turn, recruits IRAKs and TRAF6^[20]. TRAF6 activates transforming growth factor- β activated kinase 1 which phosphorylates and activates the inhibitor of kappa light polypeptide gene enhancer in B-cells kinase complex, finally resulting in the release and translocation of NF- κ B into the nucleus, thereby inducing the production of tumor necrosis factor (TNF)- α , interleukin (IL)-1, and IL-6, the key mediators of (intestinal) proinflammatory responses^[21-23]. However, TLR3 and some of the TLR4 signals utilize

the TRIF adaptor molecule signaling independently of MyD88. This alternative pathway culminates in the activation of TRAF3 and IRF3, resulting in the secretion of type I interferons (IFNs), even in the gut^[24]. TLR4 is unique among the TLRs as it can activate two distinct signaling pathways: the classical pathway (through TIRAP and MyD88) and the alternative pathway (*via* TRIF and TRAM)^[18].

ASPECTS OF COLITIS-ASSOCIATED CANCER

As early as ancient times, Hippocrates and Galenus realized the similarity between inflammation and cancer, and hypothesized that cancer evolved from inflammatory lesions^[25]. In 1863, Rudolf Virchow observed a close etiologic relation between chronic inflammation and carcinogenesis, realizing that tumors possess a typical “lymphoreticular infiltrate”^[26,27]. The first evidence of the antitumoral effects of microbial products dates to the beginning of the 18th century, when Deider reported that infection in patients with cancer could be accompanied by the remission of malignancies^[28]. In the 1890s, William B. Coley, a surgeon from New York, observed that repeated injections of a mixture of bacterial toxins served as an efficient antitumoral therapeutic agent^[29]. Later, in 1943, lipopolysaccharide (LPS) was discovered as the “hemorrhage-producing fraction” of Coley’s lysate, which accounted for its antitumoral effects^[28]. After the discovery of TLRs, their ligands and signaling pathways, it was found that microbe-derived factors act by stimulating TLR signaling and activating both the innate and adaptive immune responses to enhance anti-tumor immunity^[30].

In 2000, Hanahan and Weinberg^[31] proposed a model to define the six hallmarks of carcinogenesis. Generally, inflammation is required to fight microbial infections, heal wounds, and maintain tissue homeostasis, however, it can lead to cancer. Inflammation, the seventh hallmark of cancer may affect all phases of tumor development, including tumor initiation, promotion, invasion and metastatic dissemination, and can evade the immune system. Inflammation acts as a cellular stressor and may trigger DNA damage or genetic instability. Furthermore, chronic inflammation can provoke genetic mutations and epigenetic mechanisms which promote malignant cell transformation. Based on these results, nowadays increasing evidence suggests that inflammation should also be included in this list^[18,32]. In inflammation, a peculiar tissue microenvironment is induced with the capacity to tolerate tumor cell growth and metastasis by altering the immunoregulatory mechanism, and thus making the immune system incapable of destroying tumor cells^[18]. Moreover, the expression of TLRs in tumor cells may directly or indirectly contribute to tumorigenesis in several tissues and organs. Activation of TLR signaling pathways may promote tumor invasion, apoptosis resistance, chemoresistance, tumor progression and metastasis development^[18].

In chronic inflammatory conditions, when organs with large epithelial surfaces are affected, as in IBD, the epithelial barrier function is critical for disease onset. As the epithelium is densely inhabited by resident microbial flora, the role of native immunity is particularly important in recognising and distinguishing commensal enteric bacteria from invading bacteria, and thus, in maintaining tolerance and homeostasis. Subsequently, the chronic unrestrained inflammatory response which occurs in IBD is mainly driven by a disintegrated host immune regulatory network, and is further responsible for the increased susceptibility to colorectal cancer (CRC).

TLRs are involved in the maintenance and functioning of the epithelial barrier integrity in the gut and regulating the MyD88 adaptor protein. Therefore, TLRs may display a protective function in the control of intestinal inflammation and inflammation-associated cancer^[33]. Colorectal cancers in IBD patients are considered typical examples of inflammation-related cancers. However, tumors usually appear after several years of active disease, with a cumulative lifetime risk of 18%-20% in UC, and up to 8% in CD^[34-36]. Indeed, recent epidemiological data indicate that over 25% of all cancers are related to chronic infection and other unresolved inflammation^[37]. Current results indicate that TLRs have a potential role in microbiota-associated gastrointestinal cancer metastasis through the recognition of microbiota ligands, initiating inflammation, and promoting tumorigenesis^[38].

Most colorectal cancers are sporadic without any obvious connection to intestinal inflammation. Interestingly, IBD patients also have an increased susceptibility to other malignancies, such as lymphomas/leukemias and hepatocellular carcinoma suggesting that local inflammation could not only have intestinal, but also systemic tumor-promoting effects, or the genetic alterations that affect inflammatory and immune homeostasis in IBD also predispose patients to cancer in other tissues^[39,40]. In IBD, the increased susceptibility to extraintestinal tumors could also be related to immunosuppressive treatment. However, the types of tumors increasingly found in IBD patients are different from those observed in transplant patients under immunosuppression^[41,42].

Both intrinsic and extrinsic inflammatory pathways are linked to carcinogenesis. Intrinsic inflammation is mainly initiated by mutations leading to oncogene activation as well as to inactivation of tumor suppressors. The extrinsic pathway in terms of infection or inflammation increases cancer risk. Although in IBD patients inflamed intestinal cells already have CRC-related genetic abnormalities before developing dysplasia, in CAC, genetic alterations seem only to be a secondary cause rather than a primary cause of carcinogenesis^[43]. It is likely that abnormalities in PRR signaling lead to dysregulated expression of genes and enzymes involved in cell proliferation, apoptosis, and DNA repair prior to gene alterations. Frequent alternative cycles of mucosal injury and repair in the presence of tumorigenic cytokines, chemokines, and prostaglandins may also predispose to genetic mutations,

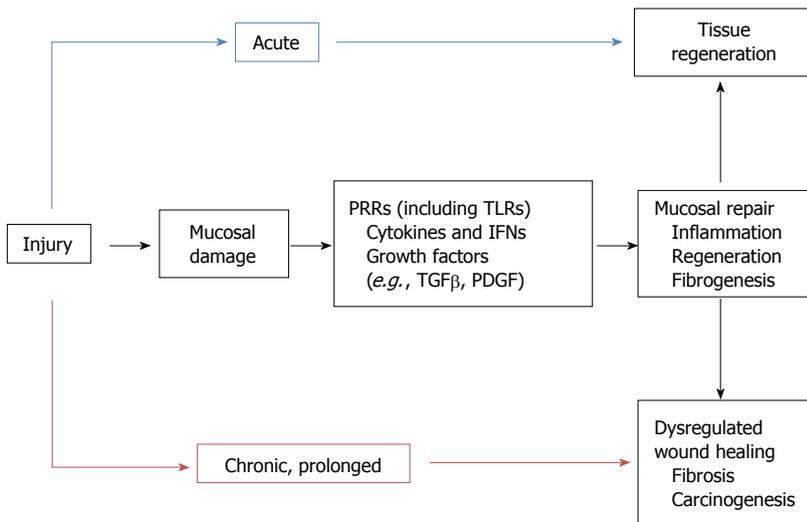

Figure 1 Relationship between pattern recognition receptors and tissue regeneration. In case of acute tissue injury, TLRs acts as mucosal healing factors. In the case of chronic, sustained inflammation, TLRs may promote dysregulated wound healing leading to cancer development. PRRs: Pattern recognition receptors; TLRs: Toll-like receptors; IFNs: Interferons; TGF: Transforming growth factor; PDGF: Platelet-derived growth factor.

which increase cancer risk^[44,45].

The definite similarities between tumor stroma and chronic wounds have led to the suggestion that cancers are wounds that do not heal, leading finally to uncontrolled tissue repair processes^[46] (Figure 1). CRC arises from the intestinal epithelium, a highly proliferative tissue which renews itself every several days under steady-state conditions. Repeated or prolonged wound repair responses to tissue injury may provoke malignant cell transformation^[47]. Epithelial regeneration and myofibroblast activation, two major events in wound-healing, are strongly influenced by TLR signaling. The contribution of TLR signals to regeneration can be found in the intestine, where a TLR2/TLR4/MyD88 cascade mediates mucosal healing in the regenerative phase of DSS-colitis^[48,49]. It has also been reported that TLR-mediated MyD88 signaling in macrophages of the LP regulate crypt stem cell differentiation and epithelial proliferation through cyclooxygenase-2 and prostaglandin (PG)E2 expression^[49,50]. TLR4 activation has also been shown to induce IEC proliferation *via* induction of EGFR ligands^[51,52]. Moreover, in inflammatory circumstances the surface expression of TLR-2 and -4 may be enhanced leading to IECs responsiveness to their ligands^[53,54]. Based on these results, it seems that abnormal TLR signaling may induce enhanced epithelial proliferation, and thus may contribute to colitis-associated carcinogenesis.

TOLL-LIKE RECEPTORS IN COLITIS-ASSOCIATED CANCER

Previous studies have shown that certain TLRs are expressed in colon cancers and colon cancer cell lines^[18]. In colorectal cancers, TLR3, -4, -5, -7, and -8 have been found to be expressed^[18], while several TLRs (including TLR7-9) are also expressed in the human colon carcino-

ma cell lines, HCT15, SW620 or HT29^[55-57]. TLR expression in tumor cells appears to promote tumorigenesis by facilitating survival and migration in a tumorous microenvironment that is characterized by chronic inflammation and PAMPs^[58]. On the other hand, the complicated interactions among tumor cells, immune cells, and PAMPs/DAMPs in the tumorous microenvironment may support an inappropriate immune response or antitumor immune tolerance through TLR signaling. With regard to tumorigenesis, a typical dual role of TLR signaling pathways has been proposed, as they may be critical for cancer cell survival and progression, however they may also elicit tumor death signaling. TLR-mediated signaling is directed toward cytoprotection or tumor cell suppression, thus the pro-survival or pro-death function is context-dependent, and influenced by many intra- and extracellular factors, such as the involved tissues, surrounding microenvironment, genetic background, and stage of tumor development, nevertheless its precise relation to cancer networks has not yet been fully elucidated^[18].

Toll-like receptor-mediated anti-tumorigenic effects

During the past two decades, studies have established that boosting TLRs and downstream mediators such as type I IFNs, can be used therapeutically to shift the balance from immunotolerance to antitumoral effects^[59].

The antigen-presenting capacity of tumor cells is poor, therefore, antitumoral immune responses usually depend on professional APCs like DCs^[60]. DCs have been a focus of cancer research due to their ability to initiate potent antitumoral immune responses. A lack of DC activation, often resulting from inhibitory signals from cancer cells, may also induce immune tolerance *via* T cell deletion or regulatory T cells (Tregs)^[60], which favors tumor progression. TLR-activated DCs can mediate antitumoral responses through antigen presentation, T cell activation, and direct cytotoxic effects on tumor cells^[61,62].

TLR5 activation on DCs as well as TLR9-stimulated plasmacytoid DCs promote antitumoral immunity^[63,64]. It is hypothesized that DC-mediated tumor cell killing triggers a more efficient antigen presentation to cytotoxic T cells, thus amplifying antitumoral responses.

Activation of TLRs on DCs regulates T cell activation not only *via* the class II major histocompatibility complex and co-stimulatory molecules, but also through TLR-induced signals in DCs that block the suppressive effect of regulatory T cells in an IL-6-dependent manner^[65]. Moreover, TLR8 activation can directly inhibit Treg function, hence support antitumoral immunity^[66]. TLR9 agonists as well as TLR-induced IFN α also have an important role since both are known to reduce tumor growth by blocking angiogenesis^[67,68].

In a recent study, the colonic tumor development modulatory effect of TLR5-dependent signaling was assayed in a mouse xenograft model of human colon cancer^[69]. The lack of MyD88 or TLR5 expression was found to enhance tumor growth and inhibit tumor necrosis. In contrast, TLR5 activation by peritumoral flagellin treatment substantially increased tumor necrosis, leading to significant tumor regression.

Within the TLR family, TLR9 is specifically stimulated upon sequence- and methylation-dependent DNA signaling. Self-DNA and oligonucleotides containing unmethylated CpG motifs are also sensed by and activate TLR9. Modifications in the structure of nucleic acids influence their immunomodulatory, *i.e.*, agonistic or suppressive, as well as pro- or anti-tumorigenic capacity^[57,70]. TLR9 activation by synthetic oligodeoxynucleotide agonists (CpG-ODN) has also demonstrated antitumor activity in xenograft models of murine colon cancer^[71]. Moreover, TLR9 agonists induce type I IFN secretion in DCs finally resulting in cytotoxic DCs, activated NK cells and cytotoxic T cells, all of which possess a remarkable antitumor immune response^[72,73].

Toll-like receptor-mediated pro-tumorigenic effects

TLRs may act as tumor promoting factors by transmitting proinflammatory, anti-apoptotic, proliferative or pro-fibrogenic signals in either the tumor cells or the tumorous microenvironment.

TLRs are key elements of inflammatory signaling which can be mediated by MyD88-dependent and MyD88-independent pathways. Enhancement of the signaling pathway of transcription factor nuclear factor (NF)- κ B is one of the major tumor-promoting effects of TLRs. TLR activation upregulates several tumorigenic inflammatory cytokines (*e.g.*, IL-1 β , TNF α , IL-6) in a NF- κ B-dependent manner^[59,74,75], which transcriptionally controls a large set of target genes that play important roles in cell survival, inflammation, and immune responses^[76].

TLR signaling is also involved in the inhibition of apoptosis. NF- κ B is considered an important anti-apoptotic pathway controlling the expression of anti-apoptotic genes and restricting the activation of pro-apoptotic pathways^[77,78]. TLR signaling can activate NF-

κ B through MyD88-dependent and MyD88-independent pathways, moreover, the TLR-mediated release of IL-1 β and TNF α promotes NF- κ B activation. In colorectal cancer, TLR-induced NF- κ B activation has been found to facilitate tumor cell survival^[48]. Furthermore, in the MC26 mouse colon cancer cell line TLR4 activation was found to mediate resistance of tumor cells to cytotoxic T cell-mediated cell death and favor tumor growth^[55].

The TLR-mediated promotion of wound healing may also lead to cancer development. After DSS-mediated injury, TLR2 and TLR4 activation facilitates epithelial repair *via* the MyD88-dependent pathway^[48], and TLR-MyD88 signaling also regulates the expression of epiregulin, which may contribute to colon cancer development^[78].

In mice, Faubion *et al.*^[79] demonstrated that chronic inflammation arising from the bowel may induce thymic involution and Treg cell suppression. These events are suggested to lead to the enhancement of inflammation-mediated processes, and worsen IBD. Restoration of homeostasis through suppression of TNF α production and fortification of Treg cells were proposed for the treatment of human IBD^[80]. In the existing connection between TLR-signaling and Treg cells^[65,81], these data on IBD may support the concept that uncontrolled inflammation weakens the Treg-mediated inhibition and increases the risk for inflammation-associated carcinogenesis.

Controversial data exist regarding the role of TLR2 in CAC. In one study, increased tumor development and higher IL-6, IL-17A and phospho-STAT3 levels were reported in a TLR2-deficient azoxymethane (AOM)-dextran sodium sulfate (DSS) murine model^[82], while there were no differences in CAC between wild-type and TLR2-deficient AOM-DSS colitic animals^[83].

The pro-tumorigenic role of TLR4 in CAC is well established. The intestinal microbiota, which normally colonize mucosal surfaces in symbiotic mutualism with the host is unique and quite stable over time^[84]. The basic challenge for intestinal immune recognition is the requirement of a simultaneous delicate balance between tolerance and responsiveness towards microbes^[85]. Several data suggest the existence of immune tolerance to antigens in an individual's bacterial flora, whereas its breakdown definitely contributes to IBD pathogenesis^[86]. In the colon, where there is a constant interaction between microbiota and IECs, TLR4 deletion significantly reduces inflammation and tumor size in the AOM-DSS induced CAC-model in mice^[87]. Additionally, overexpression of the constitutively activated TLR4 exhibits a higher sensitivity to CAC in a transgenic mouse model^[88]. Other studies^[89,90] also support the results that both the deletion of the TLR4 adaptor MyD88 molecule and the depletion of TLR4 activating gut microbiome reduce colon cancer development.

CONCLUSION

Inflammation affects many aspects of tumorigenesis. One of the important discoveries in the field of TLR sig-

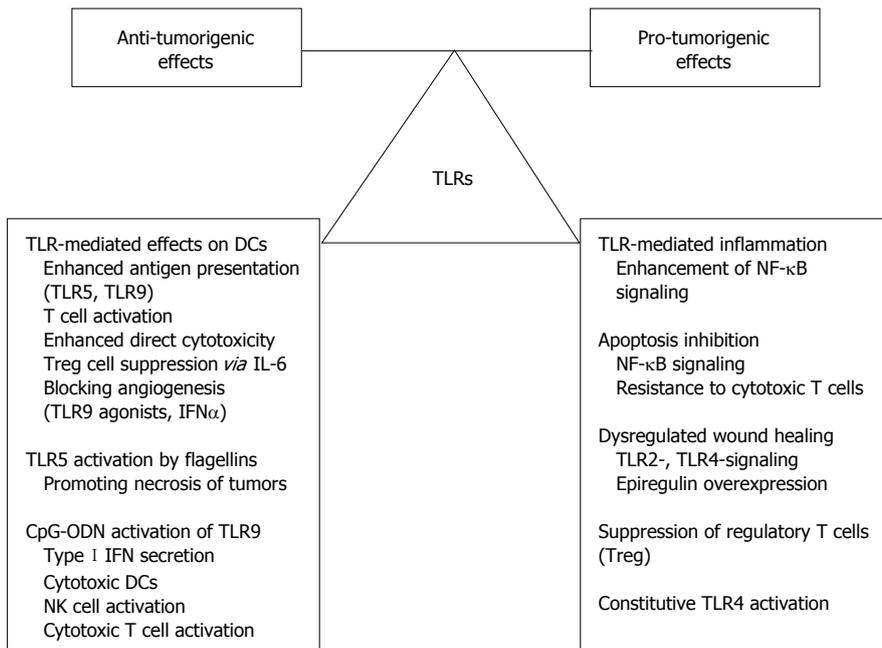

Figure 2 Dual role of Toll-like receptor signaling in colitis-associated carcinogenesis. While some direct and indirect effects of TLR-signaling act largely as an anti-tumorigenic factors, other effects may promote cancer development. TLR: Toll-like receptor; DC: Dendritic cell; IL: Interleukin; IFN: Interferon; ODN: Oligodeoxynucleotide; NF- κ B: Nuclear factor- κ B.

naling and inflammation-associated cancer biology is the realization that TLRs may promote or suppress tumor formation in certain organs, including the intestine.

Although recent data regarding the role of TLRs in the pathomechanism of CAC are rather conflicting, functionally they can be classified as “largely antitumoral” and “largely tumorigenic” molecules with the caveat that the underlying signaling pathways are mainly context, (*i.e.*, organ-, tissue-, cell-) and ligand-dependent (Figure 2). Advanced exploration and better understanding of the relationship amongst TLR-signaling, inflammatory microenvironment and colitis-associated carcinogenesis should provide further insight into cancer development in IBD patients.

Further detailed functional analyses of TLRs in inflammation-related tumor biology are needed to explore and define more precisely the subcellular and molecular mechanisms, hopefully allowing the introduction of selective new therapeutic approaches into daily practice.

Abstract

Crohn's disease (CD) is a complex, immune-mediated disorder that often requires a multi-modality approach for optimal diagnosis and management. While traditional methods include ileocolonoscopy and radiologic modalities, increasingly, capsule endoscopy (CE) has been incorporated into the algorithm for both the diagnosis and monitoring of CD. Multiple studies have examined the utility of this emerging technology in the management of CD, and have compared it to other available modalities. CE offers a noninvasive approach to evaluate areas of the small bowel that are difficult to reach with traditional endoscopy. Furthermore, CE maybe favored in specific sub segments of patients with inflammatory bowel disease (IBD), such as those with IBD unclassified (IBD-U), pediatric patients and patients with CD who have previously undergone surgery.

INTRODUCTION

Crohn's disease (CD) is a complex, immune-mediated condition. Diagnosis and management requires information from multiple modalities. These include clinical symptomatology, serologic and fecal testing, endoscopic assessment with histopathologic analysis and radiologic imaging. While the majority of CD patients have involvement of the small bowel, up to 30% have disease that is confined to the small-bowel alone^[1]. Historically, the small bowel was assessed using small bowel radiography, ileocolonoscopy, or push enteroscopy. With advances in technology and imaging, there are now other options

for evaluating the small bowel including computed tomographic enterography (CTE), magnetic resonance enterography (MRE), contrast ultrasonography, double balloon enteroscopy and capsule endoscopy (CE). CE offers a sensitive and noninvasive strategy for establishing the correct diagnosis, and the monitoring of disease activity. Findings on CE in CD include aphthae, deep ulcerations, and stricturing disease (Figure 1). Furthermore, CE is particularly useful in areas of the gastrointestinal tract that are not optimally seen on conventional endoscopy or radiologic imaging.

CE (Given, Yoqneam, Israel; Pill-Cam SB) was Food and Drug Administration (FDA) approved in 2001 for evaluation of the small bowel. CE is currently approved for the evaluation of obscure gastrointestinal bleeding and iron deficiency anemia in patients with a normal upper and lower endoscopy, as well as for the evaluation and monitoring of CD. Given imaging has recently launched its third generation of small bowel capsules, PillCam SB3, which has improved image detail, and adaptive frame rate technology leading to increased visualization of the small bowel, and improved efficiency. A competing capsule system was developed by Olympus (Lake Success, NY; EndoCapsule) that was FDA approved in 2007. Although the technology continues to improve, the main barrier to CE use in IBD has been its lack of specificity and concern for retention in the small bowel due to strictures^[2-4].

ESTABLISHING A DIAGNOSIS OF CD

Clinicians have relied upon endoscopic and histologic evaluation coupled with small bowel imaging, to define the location and extent of involvement in CD. Improvements in imaging technology have now led to the widespread use of cross sectional imaging in the diagnosis of CD (Table 1).

A number of studies have compared radiologic imaging studies to CE in CD. Albert *et al*^[5] prospectively compared CE to magnetic resonance imaging (MRI) and small bowel enteroclysis (SBEC) in 52 known or suspected CD patients. Of the 52 patients included in the study, 41 were confirmed to have CD. Following radiologic testing, 14 patients were noted to have strictures, with only the 27 remaining patients undergoing CE. CE detected small bowel lesions in 93% of patients, as compared to 78% and 33% for MRI and SBEC, respectively. Although the absolute difference in sensitivity favored CE, the study was underpowered to achieve statistical significance.

Hara *et al*^[6] prospectively imaged the small bowel of 17 patients with known or suspected CD with CE, CTE, colonoscopy with ileoscopy, and small bowel follow through (SBFT). The mean time between the first and last exam was 20 wk. The diagnostic yield, defined as the number of patients with evidence of CD over the number of patients studied, was 71% with CE, 65% with ileoscopy, 53% with CTE, and 24% with SBFT. Due to the small sample size, the study did not reach statistical

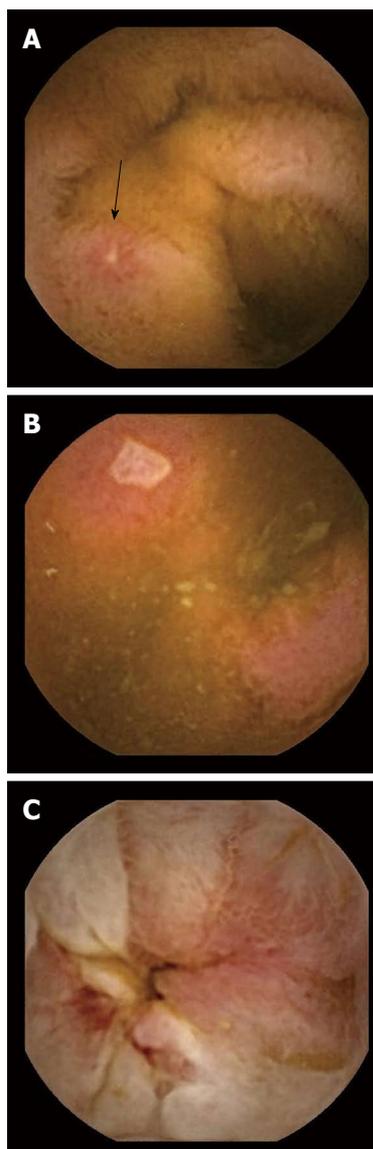

Figure 1 Findings on capsule endoscopy in Crohn's disease. A: Aphthous ulceration; B: Shallow ulcer; C: Small bowel stricture.

significance. This study was further limited by a lack of specificity as any erosion or ulcer seen on capsule endoscopy or ileoscopy was classified as CD. A major limitation of small bowel imaging is the lack of a reference standard for the diagnosis of CD. Without a gold standard, a sensitivity or specificity of CE in diagnosing small bowel CD cannot be calculated.

Solem *et al*^[7] conducted the only prospective study to overcome this limitation directly comparing CE to CTE, ileocolonoscopy, and SBFT using a consensus diagnosis based on clinical presentation, laboratory data, and the four imaging studies. Each interpreter classified patients with either active, suspicious, inactive or absent CD. These studies were performed sequentially over 4 d with CTE as the first exam. If no strictures were seen on radiologic imaging then the patient underwent CE followed by SBFT. Forty-two patients enrolled in the study, but only 28 underwent CE secondary to stricture, abscess, or

drop out. The authors found that the sensitivity of CE for active CD did not differ significantly from the other three modalities. The sensitivities were 83% for CE, 82% for CTE, 74% for ileocolonoscopy, and 65% for SBFT. The specificity of CE, however, was 53%, which was significantly lower than all other modalities.

Using histopathology for diagnosis of CD, Dubcenco *et al*^[8] evaluated the accuracy of CE in known or suspected CD. Thirty-nine patients without strictures underwent ileocolonoscopy, small bowel series (36 with SBFT and 3 with small bowel enema), and CE within an average of 22 d. Histology was able to confirm disease in 25/39 patients, exclude disease in 10/39 patients, and in 4 patients the tissue was not accessible. The sensitivity and specificity for CE was 89.6% and 100% respectively, with the sensitivity and specificity for small bowel series was 27.6% and 100% respectively.

A meta-analysis was performed by Dionisio *et al*^[9] including 19 trials, comparing CE to small bowel radiography (SBR), ileocolonoscopy, CTE, push enteroscopy (PE), and MRE in nonstricturing CD. The primary outcome measure was weighted incremental yield (IY_w), defined as the diagnostic yield of capsule endoscopy minus the diagnostic yield of the comparative modality. For suspected CD, CE was superior to CTE with an IY_w of 47% (68% vs 21%), SBR with an IY_w of 32% (52% vs 16%), and ileocolonoscopy with an IY_w of 22% (47% vs 25%). For known CD, CE was superior to PE with an IY_w of 57% (66% vs 9%), SBR with an IY_w of 38% (71% vs 36%), and CTE with an IY_w of 32% (71% vs 39%). There was no benefit found of CE over MRE likely secondary to the small sample size in this meta-analysis.

Jensen *et al*^[10] evaluated the diagnostic accuracy of CE compared to CTE and MRE. This study was not included in the previously mentioned meta-analysis. Ninety-three patients with suspected or newly diagnosed CD were enrolled in the study. Twenty-one patients were diagnosed with terminal ileal CD based on the gold standard of histopathology from ileocolonoscopy and/or surgery. Based

on the 21 patients with ileal CD, the sensitivity of CE compared to CTE was 100% vs 76%, respectively ($P = 0.03$). The sensitivity of CE was higher than MRE, 100% vs 81%, respectively; however this was not statistically significant. Specificities and positive predictive values were comparable across the three modalities.

The pediatric population with CD poses another area where the use of CE may prove beneficial. The FDA initially approved CE for pediatric use between the ages of 10 and 18 years of age in 2003, then expanded this age range in 2009 for children as young as 2 years of age^[11]. Physiologic differences exist between children and adults that change the risks associated with sedation in the pediatric population, and may result in a higher threshold to perform an invasive endoscopy in children. CE was therefore studied as an alternative to traditional endoscopy in pediatric patients with suspected CD. In one study, MRE was compared to capsule endoscopy in a pediatric population with suspected CD^[12]. Ileocolonoscopy was the gold standard, and 19/60 patients included in this study were diagnosed with CD. The sensitivity and specificity of CE and MRE were comparable, 91%, 92% and 100%, 97.6%, respectively.

A study by Levesque *et al*^[13] investigated whether CE was a cost effective tool in evaluating small bowel CD in patients with two previous negative tests using a decision analytic model. In this model, CE was not a cost-effective strategy after a negative ileocolonoscopy and a negative radiologic study (either CTE or SBFT) with a QALY of \$500000. The high cost of capsule endoscopy is directly related to the poor specificity of the test, and from a lack of standardization in grading and diagnosing CD. A limitation of this study was the model did not take into account the extent or severity of the disease, or the costs associated with changes in management, or lack thereof.

Based on the most recent evidence based recommendations^[14], patients with a high suspicion for CD with a negative ileocolonoscopy should next undergo small bowel imaging. If the patient has signs or symptoms of a

stricture and/or obstruction the modality of choice is either CTE, MRE, or patency capsule. If there are no signs or symptoms of obstruction, CE is a good option due to its high sensitivity.

USE OF CE IN IBD UNCLASSIFIED

In approximately 15% of patients with isolated colitis it is difficult to definitively distinguish between CD and ulcerative colitis (UC)^[15,16]. These patient phenotypes were originally called indeterminate colitis (IC)^[17], and are now classified as IBDU. The clinical course and prognosis of IBDU may be worse than UC, especially in patients that have undergone an ileal pouch anal anastomosis (IPAA) (Table 2)^[18].

Maunoury *et al*^[19] evaluated the role of CE in 30 patients with IBDU and negative ASCA and pANCA. As in the paper cited above, the definition of suspected CD that was used was the presence of three or more small bowel ulcerations, however this definition has not been prospectively validated. Five patients had findings suspicious of CD. In long term follow up, another five patients with normal CE were diagnosed with CD on repeat ileocolonoscopy.

Mehdizadeh *et al*^[20] evaluated the utility of CE in ulcerative colitis (UC) and IBDU. The indications for CE in UC patients were atypical symptoms, disease refractory to medical therapy, and new onset symptoms after total proctocolectomy with IPAA. Nineteen of the 120 patients (16%) had findings consistent with CD, defined as three or more small bowel ulcerations. In addition, 6 of the 21 patients (29%) who had undergone surgical treatment for UC (IPAA) were found to have CD.

Murrell *et al*^[21] investigated the role of preoperative CE in predicting outcomes after IPAA. This retrospective study identified 68 patients, 48 with UC and 20 with IBDU, who had a CE prior to surgery. CE was positive in 15 patients defined as ulcerations, erosions, or erythema. There was no correlation found between positive CE findings and acute pouchitis, chronic pouchitis, or *de novo* CD over a median follow up time of 12 mo.

We believe that all patients with IBDU should have some form of small bowel imaging to evaluate for CD, with capsule endoscopy as one of the options. Even if the decision to proceed with surgery is unchanged by the findings of a few nonspecific ulcerations in the small bowel, it may be useful to help set expectations for disease course subsequent to IPAA construction.

USE OF CE FOR POSTOPERATIVE RECURRENCE OF CD

CD typically recurs after ileocolonic resection just proximal to the surgical anastomosis. Endoscopic recurrence rates range from 70%-90% at one year with clinical recurrence rates of about 30% at three years^[22,23]. The current recommendation for diagnosing recurrent CD is an ileocolonoscopy between 6 mo to 1 year after resection^[24,25]. Noninvasive techniques including CE have been studied to assess for postoperative recurrence of CD. Aside from the benefit of a noninvasive test, CE should theoretically improve visualization of the neoterminal ileum, as the altered postoperative anatomy often can complicate intubation and visualization of the neoterminal ileum with standard ileocolonoscopy (Table 3).

Bourreille *et al*^[26] prospectively compared ileocolonoscopy (gold standard) to CE in the postoperative setting in 32 patients at a median time of 6 mo after surgery. Two independent observers interpreted the CE results. One patient was excluded because his neoterminal ileum was not visualized with ileocolonoscopy. Ileocolonoscopy detected recurrence in 19 of the 21 patients with a sensitivity of 90% and a specificity of 100%. In comparison, the sensitivity and specificity of CE were 62%-76% and 90%-100%, respectively. Interestingly, CE found proximal small bowel lesions, out of reach of the ileocolonoscopy, in two thirds of the patients, however these findings are of uncertain clinical significance.

A similar study by Pons Beltran *et al*^[27] reached a different conclusion. Out of 19 evaluable patients, ileocolonoscopy detected recurrence in only 25% of the patients, while capsule endoscopy detected recurrence in 68% of the patients. As in the previous study 59% had proximal small bowel lesions found on CE. The low detection rates of ileocolonoscopy are partially explained by the postsurgical anatomy, where the neoterminal ileum could not be reached in 3 patients. All of the patients included had a side to side anastomosis which may limit visualization of the neoterminal ileum. When assessing for patient comfort, all patients preferred CE over ileocolonoscopy.

All of the mentioned studies have small samples sizes. We do not recommend replacing ileocolonoscopy with CE for evaluation for recurrent CD at a surgical anastomosis that is reachable *via* ileocolonoscopy. However, in patients where the neoterminal ileum cannot be intubated or in patients with symptoms or abnormal labs (elevated

C-reactive protein or anemia) with a negative ileocolonoscopy. CE may identify inflammation elsewhere in the small bowel, though we expect this to be a small group of patients.

INFLUENCE OF CE FINDINGS ON MANAGEMENT OF CD

There is limited data on how CE may change management in patients with established CD (Table 4).

In a retrospective cohort of 71 established CD patients, Dussault *et al*^[28] evaluated how CE impacts treatment decisions. These patients underwent CE for either unexplained anemia, discrepancy between clinical and endoscopic findings, disease assessment, or for evaluation of mucosal healing. Moderate endoscopic lesions, defined as erythema and a few aphthous ulcers, were found in 32/71 patients (45%). Severe endoscopic lesions, defined as multiple and/or deep ulcers and/or stenosis without retention, were found in 12/71 patients (17%). There was a change in medication in 38/71 (54%) patients three months after CE, of which 27 initiated a new medication most commonly an immunomodulator or an anti-tumor necrosis factor (TNF) agent. Two patients required surgery. Seventy-five percent of patients with severe endoscopic lesions had a change in their management, compared to 53% with moderate lesions, and 4% with normal CE.

Long *et al*^[29] performed a retrospective cohort study of 128 CE studies in established IBD patients between 2003 and 2009 at a tertiary referral center. Four capsule studies were excluded since they were retained in the stomach. Indications for CE included CD in 86, IBDU in 15, and pouchitis in 23 patients. The median duration of CD or IBDU was 6 years. The IPAA group had longer disease duration of 13.5 years. The majority of CD patients had either a few or multiple ulcerations with 22% having a normal CE. Sixty-two percent of the CD patients had a change in their medical management, defined as initiation or discontinuation of an IBD specific medication. Budesonide was the most common initiated medication with 40% of the CD patients starting a new medication. Eighty percent of the IBDU patients had a normal CE or mild erythema. Two thirds of these patients had a change in medical management with 40% initiating a new IBD specific medication, most commonly

prednisone or budesonide. In addition, 44% of the IPAA patients had a normal CE or mild erythema with 57% of them starting a new medication. We suspect that given the disconnect between CE and treatment changes, the clinical symptoms or biomarkers played a more important role in management decisions. Capsule retention occurred in 15 of the CD patients, leading to either a small bowel resection or strictureplasty in 13% of the CD patients.

Overall, in patients with minimal findings on CE, 51% had a change in medical management compared to 73% of patients with severe findings. Due to the retrospective nature of this study, it is unclear if management changes were due to the CE findings or other factors. It is also unknown whether these medications changes impacted the disease course. In addition, only a small number of patients initiated immunosuppressants or biologics.

The effect of CE on the management of CD has been studied in the pediatric population as well. Min *et al*^[30] evaluated whether CE will change management in the pediatric population. Indications for CE included active CD with poor growth in 50, IBDU in 16, and suspected IBD in 17 patients, respectively. Treatments and clinical outcomes were recorded before and one year after CE was performed. The overwhelming majority of patients with CD had abnormal CE findings (86%). Treatment escalation was required in 75% of patients, with the majority adding an anti-TNF agent, and 18% adding an immunomodulator. Follow up of these patients one year after capsule endoscopy showed statistically significant improvement in growth parameters, clinical indices, and laboratory markers. Given that the majority of patients requiring dose escalation had poor growth or active symptoms, it would appear that CE played a supportive role rather than a definitive role.

Flamant *et al*^[31] studied the prevalence and significance of jejunal lesions on CE in established CD patients. CE studies from 108 CD patients were analyzed retrospectively, and 56% of these patients were found to have jejunal lesions (17% isolated to the jejunum). On multivariate analysis, jejunal lesions were the only factor associated with an increased risk of disease relapse over a median of two years with an adjusted hazard ratio of 1.99 (95%CI: 1.10-3.61, $P = 0.02$). These data suggest that patients with proximal lesions may benefit from management top down strategy. This was demonstrated by Lazarev *et al*^[32] who identified jejunal disease being associated with multiple abdominal surgeries.

While it does appear important to identify patients with jejunal disease given their higher risk for a complicated disease course, it's not clear whether any particular imaging modality has the advantage.

USE OF CE FOR MUCOSAL HEALING

Data for the use of CE to monitor disease or evaluate treatment efficacy in CD is limited. A small case series from Athens prospectively investigated the correlation of

mucosal healing by CE with clinical response, defined as a CDAI drop of > 100 or a CDAI < 150 ^[33]. Diagnosis of CD was confirmed histologically in 34 of the 40 patients. Patients included had active symptoms and the initial CE was done prior to any treatment. After treatment initiation, patients were followed up regularly until there was clinical improvement. Within one of day symptom improvement a second CE was performed to evaluate for mucosal healing. Three endoscopic variables were used for mucosal healing; number of aphthous ulcers, number of large ulcers, and the period of time that any endoscopic lesion was visible. The number of large ulcers significantly decreased, while the number of aphthous ulcers remained unchanged. Because only one of the three markers improved, the authors concluded that clinical response did not correlate with mucosal healing. A major limitation of this study was the significant heterogeneity among treatments, which were chosen by the managing physicians. Only 6 patients received immunomodulators and steroids or anti-TNF agents, and they had the most significant endoscopic improvement.

In an abstract presented at the 2013 Crohn's and Colitis Foundation of America meeting, Shafran *et al*^[34] retrospectively evaluated whether mucosal healing defined by CE was critical in management decisions. Twenty-three patients were analyzed of which 17 achieved mucosal healing, determined by a single expert physician reader along with a Lewis score if available. Of the 17 patients with mucosal healing, 15 remained in clinical remission on their current treatment plan. In the 6 patients who did not achieve mucosal healing, four patients achieved clinical remission with changes in medications, 1 patient required surgery, and 1 patient entered a clinical trial.

Larger prospective trials are needed to confirm the utility of serial CEs to assess mucosal healing in patients with nonstricturing isolated small bowel CD. It will be important to identify these patients early as they may benefit from more intensive treatments, but it is unclear if CE would be superior to radiology.

CAPSULE RETENTION

Capsule retention is the greatest concern in patients with IBD. Adding to this concern is that the majority of patients do not visualize the capsule passing in the stool. In a systematic review involving 227 articles with 22840 capsule studies, the overall pooled retention rate was 1.4%. The pooled retention rate for established CD was 2.6%^[3].

Capsule retention does not necessarily require surgical intervention. Some patients with retained capsules are asymptomatic, while others can be managed medically with steroids or anti-TNF agents, to allow for passage through an inflammatory stricture. Other cases can be managed endoscopically with retrieval accomplished by deep enteroscopy or colonoscopy. Surgery with resection of the strictured segment or strictureplasty is sometimes required.

Although capsule retention should be avoided, some believe that retention leads to the appropriate diagnosis

and management by allowing for localization of the culprit lesion. In a study by Cheifetz *et al*^[35] CE was used in 19 patients with suspected small bowel obstruction based on symptoms or imaging. The capsule was retained in four patients proximal to the stricture and they all underwent elective surgery. Since the capsule was not lodged in the stricture, emergent surgery was not indicated in any of these patients. The operative findings of these four patients were deep ulceration and stricture in midjejunum, a jejunal anastomotic stricture, focal ulcerated stricture in the jejunum, and an ileal stricture.

Given imaging has developed the Agile patency capsule, which is the same size as Pillcam SB. The capsule is composed of lactose and barium with an impermeable membrane that disintegrates in less than 30 h. It contains a radiofrequency identification chip, which can be detected by a scanner if retained in the small bowel.

Herrerias *et al*^[36] evaluated the Agile patency capsule in 106 patients with known intestinal strictures. In this series, 13 patients had obstructive symptoms that were possibly or probably secondary to the Agile patency capsule. The Agile patency system is recommended when there is a suspicion for an intestinal stricture or obstruction to anticipate the subsequent safe passage of CE.

SCORING SYSTEMS FOR CAPSULE ENDOSCOPY

A limitation of CE and of many of the studies reviewed in this article is interobserver variability. Two main scoring systems have been developed to address this problem. The Lewis Score quantifies mucosal change and disease extent by assessing villous appearance, presence of ulcers and stenosis over each segment of small bowel^[37]. In 2008, Gal *et al*^[38] developed the capsule endoscopy crohn's disease activity index which evaluates inflammation, extent of disease, and presence of stricture, all graded on a numeric scale with the small bowel divided into proximal and distal halves. The Lewis score has been made more accessible as it was incorporated into the PillCam software (Given, Rapid Reader). Nevertheless, neither scoring system is utilized routinely in clinical practice. Furthermore, there is no definitive correlation between the score and the patient's clinical status or CDAI^[11]. Although scoring systems may be useful for longitudinal monitoring of CD, they have not been validated for this purpose.

OUR PRACTICE

Multiple variables need to be taken into account when deciding which imaging test is best to the study the small bowel in patients with established or suspected CD. The availability of CTE is institution dependant, and there are concerns about cumulative ionizing radiation exposure in CD patients^[39]. MRE avoids radiation and allows for extraluminal imaging. It is often our first test of choice in newly diagnosed CD patients. However, CE is performed

by gastroenterologists and seems to have higher sensitivity for mucosal lesions compared to cross sectional imaging.

We use CE in post-operative evaluation when the neoterminal ileum cannot be intubated or in patients with symptoms, anemia, or biomarker elevation in the setting of a normal colonoscopy. Clinically, we can confirm the data of Efthymiou *et al.*^[35], when colonic mucosal healing did not result in correction of iron deficiency anemia and CE confirmed ongoing active inflammation (aphthous ulcers) in the small bowel. CE may be the preferred option in pediatric patients with nonstricturing disease as it seems to result in management changes that are more significant than in the adult population. Increasingly mucosal healing has become the preferred endpoint of medical management and CE, along with biomarkers and cross sectional imaging, will play an important role in noninvasive disease monitoring of the small bowel.

Abstract

The origin of inflammatory bowel disease is unknown. Attempts have been made to isolate a microorganism that could explain the onset of inflammation, but no pathological agent has ever been identified. Johne's disease is a granulomatous chronic enteritis of cattle and sheep caused by *Mycobacterium avium* subspecies *paratuberculosis* (MAP) and shows some analogies with Crohn's disease (CD). Several studies have tried to clarify if MAP has a role in the etiology of CD. The present article provides an overview of the evidence in favor and against the "MAP-hypothesis", analyzing the methods commonly adopted to detect MAP and the role of antimycobacterial therapy in patients with inflammatory bowel disease. Studies were identified through the electronic database, MEDLINE, and were selected based on their relevance to the objective of the review. The presence of MAP was investigated using multiple diagnostic methods for MAP detection and in different tissue samples from patients affected by

CD or ulcerative colitis and in healthy controls. On the basis of their studies, several authors support a close relationship between MAP and CD. Although increasing evidence of MAP detection in CD patients is unquestionable, a clear etiological link still needs to be proven.

Key words: *Mycobacterium avium paratuberculosis*; Crohn's disease; Inflammatory bowel disease; Johne's disease; Mycobacterial protein tyrosine phosphatase

Core tip: The etiology of inflammatory bowel disease (IBD) is unknown. Some analogies between Crohn's disease (CD) and Johne's disease, a granulomatous chronic enteritis of cattle and sheep caused by *Mycobacterium avium* subspecies *paratuberculosis* (MAP) have been identified. Several studies have tried to clarify if MAP has a role in the etiology of CD. However, the involvement of MAP in CD is still debatable. The present article provides a literature review of the evidence in favor and against the "MAP-hypothesis", the methods commonly adopted to detect MAP and the role of antimycobacterial therapy in treating IBD patients. In particular, new mechanistic findings seem to encourage the CD-MAP relationship.

INTRODUCTION

Inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC) represent a group of

chronic inflammatory alterations, whose etiology is still unknown and is notoriously multifactorial. According to the most accepted hypothesis, CD and UC are the result of an inappropriate and deregulated intestinal immune response against the normal bacterial flora. This is due to a complex interaction between environmental, genetic and immune factors. The above-mentioned factors are all necessary, but none of them, if singularly considered, is enough to explain the etiopathogenesis of IBD. We will focus our attention on analyzing the available data on this latter theory, mainly on the possible involvement of *Mycobacterium avium* subspecies *paratuberculosis* (MAP) in IBD.

On the basis of analogies between CD and some forms of infective enterocolitis, the hypothesis of a specific mycobacterial etiology has been proposed. In particular, some authors have studied the potential role of MAP in CD. MAP is the responsible agent in Johne's disease (JD), a chronic granulomatous enteritis affecting cattle and sheep, and could be implicated in the etiopathogenesis of disease in humans, according to clinical and histological similarities between the two diseases^[1,2]. The MAP hypothesis has aroused great scientific interest since the 1980s, following data reported by Chiodini *et al.*^[3,4]. There is now a renewed interest regarding the association between CD and MAP, due to the improvements in microbiological and genetic methods^[3,4]. However, published data on this issue are still contradictory. Two main hypotheses exist: MAP could represent the "primum movens" in causing CD or, alternatively, it could constitute an epiphenomenon of the disease, later colonizing the already inflamed mucosa in these patients^[5].

INFECTIVE THEORY

Many attempts have been made to isolate a microorganism that could act as the "primum movens" in the etiology of IBD (Table 1), however, to date no pathogen has been convincingly identified. Numerous bacterial pathogens such as *Listeria monocytogenes*^[6], *Pseudomonas maltophilia*^[7], *Mycobacterium kansasii*^[8], *Bacterioides fragilis*^[9], and *Chlamydia pneumoniae*^[10], and viral agents including the measles virus^[11,12] and *Cytomegalovirus*^[13] have been proposed as the cause of CD, but none have been accepted due to a lack of firm evidence.

Wakefield *et al.*^[12] proposed that CD is due to chronic infection of submucosal endothelium in the gut by the measles virus, inducing a granulomatous reaction and a microinfarction pathological process. This theory was supported by epidemiological studies which associated perinatal exposure to the measles virus^[14] and the attenuated measles vaccine^[15] with an increased risk of the development of CD. Because of the absence of an increased risk for CD in vaccinated patients^[16], the difficulty of detecting the virus in intestinal specimens^[17] and low antibody titers to measles in CD patients^[18], this hypothesis was rejected and measles has now been proposed as a possible cofactor rather than the primary causative agent of CD.

Table 1 The infective theory of inflammatory bowel disease etiology

| Infectious agent | Ref. | Current position |
|---|---------------|------------------|
| Bacterial | | |
| <i>Listeria monocytogenes</i> | [6] | Dismissed |
| <i>Pseudomonas maltophilia</i> | [7] | Dismissed |
| <i>Mycobacterium kansasii</i> | [8] | Dismissed |
| <i>Bacterioides fragilis</i> | [9] | Dismissed |
| <i>Chlamydia pneumoniae</i> | [10] | Dismissed |
| Adherent-invasive <i>Escherichia coli</i> | [19-22] | Active |
| Proteobacteria | [23] | Active |
| <i>Mycobacterium avium</i> subspecies <i>paratuberculosis</i> | [24-26] | Active |
| Viral | | |
| Measles virus | [11,12,14-18] | Dismissed |
| <i>Cytomegalovirus</i> | [13] | Dismissed |

Supporters of the infective theory have considered the possible role of adherent-invasive *Escherichia coli* (AIEC) in IBD etiology. The link between IBD and AIEC was first suggested in 1978 by Tabaqchali *et al.*^[19], who noted high titers of antibodies against AIEC O-antigens in IBD patients. Later, this organism was often isolated from the mucosa of CD patients compared to healthy controls, due to its ability to adhere to gastrointestinal epithelial cells and to demolish the intestinal barrier by producing an α -hemolysin^[20]. Further investigations revealed that AIEC stimulates the release of the pro-inflammatory cytokine, interleukin (IL)-8, which extensively replicates and induces tumor necrosis factor (TNF) α expression in macrophages, leading to the formation of granulomas. In an immunohistochemical study, 57% of tissue samples from CD patients contained *E. coli*, particularly near ulcers, along fissures, around abscesses, within the lamina propria and in the germinal centers of mesenteric lymph nodes^[21]. In another study using polymerase chain reaction (PCR), *E. coli* DNA was found in 80% of intestinal granulomas in CD patients^[22].

A recent review by Mukhopadhyaya *et al.*^[23] extensively described and eventually supported the role of Proteobacteria in the pathogenesis of IBD. They examined the importance of pattern recognition in the extracellular innate immune response of the host and postulated that Proteobacteria with adherent and invasive properties could exploit host defenses, driving proinflammatory changes, altering the intestinal microbiota, favoring dysbiosis and finally leading to the development of IBD.

Several clinical and histopathological similarities between IBD, particularly CD and JD, caused by MAP, indicated a potential role for this pathogen in CD etiology. Similar to *Mycobacterium tuberculosis* or *Mycobacterium leprae*, MAP is able to deregulate immune signaling as one of its survival strategies, resulting in a spectrum of disease manifestations, ranging from simple colonization with a healthy phenotype to severe inflammatory bowel disease^[24]. This association has aroused great scientific interest since the 1980s, when Chiodini *et al.*^[25] isolated MAP and its DNA from biological tissues in CD patients.

Based on these observations, the link between MAP and CD has been widely investigated through direct and indirect methods for MAP detection: PCR for MAP-DNA in blood, stool and biopsies, MAP-specific serological and cell-mediated response, cultures of MAP from intestinal tissues, milk and blood samples^[26].

MAP CHARACTERISTICS AND CLINICAL IMPLICATIONS IN ANIMALS

MAP is a Gram-positive, facultative obligate intracellular bacterial pathogen, acid-fast and dependent on mycobactin for its replication (a liposoluble substance that permits iron utilization). It grows very slowly *in vitro*, taking 8-16 wk or more for duplication, and it appears in human tissue in a cell-wall-deficient state (CWD), also known as “spheroplast”. This is the reason why, different from *Mycobacterium tuberculosis*, it cannot be highlighted by Ziehl-Neelsen staining^[27]. The discrimination between MAP and other organisms belonging to the *Mycobacterium avium* complex (MAC) is known to be problematic. The identification of a species-specific insertion sequence, a fragment of DNA of 1451 base pairs known as IS900, allowed easier distinction using the PCR technique^[28,29]. Through the use of IS900 restriction fragment length polymorphism, two variants of MAP have been identified: type C associated with cattle and S-type, less virulent, associated with sheep. Although these subtypes show a tendency to preferentially infect some animal species, cross-infection is possible and documented^[30].

It is thought that the contagion among animals primarily occurs *via* the fecal-oral route, through the ingestion of milk, colostrum or animal feed contaminated by MAP^[31]. The possibility of intrauterine transmission of this microorganism is also documented, especially in symptomatic animals (20%-40% infected born from a mother with clinically-manifested disease and 10%-20% infected born from a mother with subclinical infection). Once in an organism, MAP is able to invade macrophages in ileal lymphoid tissue and increase in number inside phagosomes, inhibiting their maturation and promoting the recruitment of inflammatory cells. This process, associated with T-lymphocyte activation and interferon (IFN)- γ production, results in granulomatous lesions that characterize JD, or paratuberculosis, a chronic widespread enteritis of cattle, sheep and other ruminants. The progression of disease is classically categorized into four stages: silent infection, subclinical stage, clinical stage and clinically evolved disease. Animals are generally infected at an early age. Clinical signs, dominated by diarrhea and weight loss, generally occur 3-5 years after infection. This long-lasting incubation period depends on the level of environmental contamination (MAP exposure dose), virulence of the MAP strain, the capacity of a single animal of hinder the infection (immune response is more efficient with age), and genetic susceptibility *vs* MAP (inter- and intra-species differences)^[32]. MAP has been isolated from the feces and milk of ruminants with clinical

and subclinical infection: this fact explains the wide diffusion of MAP infection and the vast environmental contamination^[33]. MAP can survive for a long period in different ecosystems, due to its high environmental resistance, but replication outside infected animals is not possible due to its dependency on mycobactin. Several studies have been carried out to identify environmental sources of human exposure to MAP, including its presence in water supplies (domestic water and rivers)^[34-36], milk, dairy products, and even in meat^[37]. MAP's ability to spread *via* the milk of infected animals has been proven and it has been shown that this microorganism is able to survive routine pasteurization methods, with persistence of vital mycobacteria and antigenic components in commercial milk^[38]. MAP is widely present in the human food chain, and even in dairy products representing a potential exposure source. Environmental diffusion of MAP could represent a favorable condition for IBD onset when associated with intestinal immunodeficiency in susceptible subjects^[39].

“MAP HYPOTHESIS”: SUPPORTING AND CONTRASTING EVIDENCE

The MAP hypothesis in CD is considered to have originated in the 1980s, when Chiodini *et al.*^[25] demonstrated that MAP isolated from human tissues can cause a granulomatous disease of the distal small intestine in experimental animals. The authors isolated from the intestinal tissues of two CD patients a mycobacterium which shared the acid-fast and mycobactin-dependent characteristics of MAP. When injected intravenously or intraperitoneally in experimental animals, this organism induced a disease characterized by hepatic and splenic granulomas in mice, but not in rats, guinea pigs, rabbits or chickens. It also resulted in granulomatous disease in the distal small intestine in young goats, when administered orally. Acid-fast bacilli were not found in autopsy sections of the intestine, however, a single organism with characteristics similar to the one administered was seen in microgranulomas of the mesenteric lymph nodes. The identification of MAP in human tissues is seldom reported, because of its CWD form, as Chiodini *et al.*^[25] stated. Two recent meta-analyses showed that the association between MAP and CD seems to be specific compared with individuals free of IBD. The pooled Odds Ratio from studies using PCR for tissue samples was 7.01 (95%CI: 3.95-12.4) and was 1.72 (95%CI: 1.02-2.90) in studies using enzyme-linked immunosorbent assay (ELISA) for serum^[40,41].

Indirect support for the “MAP hypothesis” comes from Shanahan *et al.*^[42] who found a similarity with *Helicobacter pylori*, an infectious agent widely dispersed, but able to cause peptic disease and gastric cancer only in a minority of exposed subjects. Similarly, *Mycobacterium tuberculosis* affects about one third of the world's population, but only 5%-10% develop clinically manifested disease. Analogies exist for MAP, in that it is widely dispersed and affects animals and humans, possibly playing a role in CD

Table 2 Direct methods for detection of *Mycobacterium avium* subspecies *paratuberculosis*

| Method | Tissue analyzed | Ref. | +/- | Advantage | Defect |
|--------------------------------|-------------------|------------|-----|--|--|
| MAP culture | Intestinal biopsy | [55] | + | Effective isolation of microorganism | Organism's fastidious nature; slow-growth |
| | Peripheral blood | [57,59,60] | - | | |
| PCR for MAP-specific IS900 DNA | Intestinal biopsy | [53-55] | + | Fast and easy isolation of MAP fragment | Not able to distinguish vital MAP <i>vs</i> fragment of killed MAP; confounded by frequent MAP opportunistic infection (oro-fecal route) |
| | Peripheral blood | [58] | + | | |
| | Peripheral blood | [59,60] | - | | |
| | Stools | [63] | - | | |
| PCR for MAP-specific IS900 DNA | Intestinal biopsy | [62] | + | Demonstrate the presence of active/vital metabolic processes | Difficult to reproduce (RNA half-life measured in min) |

onset only in few subjects.

A recent study by Xia *et al.*^[43] showed significantly higher levels of antibodies against a specific mycobacterial protein, tyrosine phosphatase (PtpA), in CD patients when compared to healthy controls. PtpA is secreted during MAP infection in a time-dependent manner from the human-derived monocyte cell line THP-1. The same evidence was not observed in UC patients, suggesting the exclusive involvement of MAP in CD^[43].

Although analogies exist between CD and JD, some discrepancies should be mentioned. JD does not present some of the basic patterns of CD: the segmental localization and features that can complicate the evolution of CD, such as fistula, fissures, bleeding, stenosis, adhesions, perforation and the formation of abscesses are not described in JD.

Against the "MAP hypothesis", immunosuppressive drugs, widely employed in IBD, should not be used in latent or clinically manifested mycobacterial infections, as they increase the risk of onset and/or worsening of the disease. Screening analyses are necessary to exclude any type of mycobacterial infections before administering anti-TNF α drugs. *Mycobacterium tuberculosis* massively proliferates with anti-TNF α drugs or steroid treatment, and the same for *Mycobacterium avium intracellulare* in the intestine of HIV-infected patients^[5]. It is possible that intracellular cell wall deficient MAP may not be able to replicate despite ongoing immunosuppressive therapy. Corticosteroid therapy was associated with lower MAP detection rates in the study by Autschbach *et al.*^[44].

In patients treated with infliximab, a decreased level of antibodies against PtpA was found and no statistical differences were observed in comparison to the controls. This observation suggests that inhibition of TNF α may reduce MAP growth probably with a negative effect on the secretion of PtpA^[43,45,46]. Alternatively, infliximab interferes with the antigen presentation system in macrophages dampening the immune B response and the antibody titer. In this respect, a statistical difference in antibody titer was observed between CD patients treated with azathioprine (AZA) and untreated patients; no significant difference was observed when patients were treated with either 5-ASA or steroids^[43]. "In vitro" studies

showed the ability of AZA^[47] and other immunosuppressants, such as cyclosporine^[48] and methotrexate^[49], to inhibit MAP growth in the culture system.

In addition, epidemiological evidence supporting the association between MAP and CD is still lacking. The prevalence of IBD is more common in urban areas, while no increased incidence of disease was detected among people in rural areas, especially in farmers and their families, despite major exposure to MAP^[50]. Furthermore, environmental conditions which should promote MAP transmission, such as poor hygienic conditions and overcrowding, seem to protect against CD^[51,52]. The lack of evidence for horizontal or vertical transmission of CD leads to MAP being a zoonotic agent or an opportunistic pathogen in humans.

It is hard to explain the paradox that an infection, although able to stimulate such an intense inflammatory reaction within the gut in CD patients, is not associated with a strong cellular or serologic reactivity against MAP. Detection of MAP-DNA in the granulomas of intestinal CD is neither disease-specific nor bacterial-specific, because other forms of bacterial DNA are also present^[22]. IS900 was scientifically proven to be species-specific in animals affected by JD, however, its specificity in human tissues or in environmental ecosystems is unknown. Past studies supporting the MAP hypothesis probably included a percentage of false positive findings, ascribable to other mycobacterial species. IS900 PCR should be used as a confirmation test, in addition to other methods able to detect MAP presence in tissues.

DIRECT METHODS FOR MAP DETECTION

Because of its presence in human tissues in an intracellular cell-wall-deficient shape, MAP cannot usually be identified by Ziehl-Neelsen staining. The direct detection of MAP in humans requires culture, PCR for MAP-DNA/RNA (Table 2).

Isolation of the microorganism by culture methods is considered the gold standard for MAP detection. This method remains problematic and time-consuming even in the best circumstances, due to the organism's fastidious nature and slow growth. Although the use of MGIT

(Mycobacterial Growth Indicator Tube - Becton Dickinson) reduces growth time to 10-12 wk, there are still difficulties in culture isolation. DNA amplification with PCR and *in-situ* hybridization are the two main methods for MAP detection, using the IS900 sequence as a target.

Several studies, based on cultural methods and/or molecular techniques, demonstrated a higher prevalence of both the microorganism and its DNA in CD patients compared to controls. The presence of MAP has been investigated in different tissues, such as intestinal biopsies and surgical specimens, blood and recently fecal samples.

Biopsy specimens have always been considered by researchers as irreplaceable biological samples and have been widely utilized for MAP detection. Sanderson *et al.*^[53] identified MAP IS900 DNA in 26 of 40 (65%) CD patients, 1 of 23 (4.3%) UC patients and 5 of 40 (12.5%) control subjects. Later, Bull *et al.*^[54] described a MAP-DNA prevalence of 92% in CD patients (34 of 37) *vs* 26% non-IBD controls (9 of 34) ($P = 0.0002$). In 2005, Sechi *et al.*^[55] found a highly significant difference between CD patients (83.3%) and the control group (10.3%) ($P = 0.000001$) for IS900 PCR presence in DNA extracts of fresh intestinal mucosal biopsies, as well as in culture using supplemented MGIT media (63.3% and 10.3%, respectively, $P = 0.00001$). In the same year, Autschbach *et al.*^[44] and Romero *et al.*^[56] published data on the prevalence of MAP in surgical tissues.

Several authors have investigated the presence of viable MAP through culture or the detection of MAP-DNA in peripheral blood using PCR. Naser *et al.*^[57] found a statistically significant positivity in the CD group compared to the control. This result was confirmed in the study by Bentley *et al.*^[58], who found a significant overrepresentation of MAP-DNA in patients with CD *vs* controls (33.8% *vs* 21.5%, $P = 0.002$) in a larger cohort. Two recent meta-analyses have been published showing a generally higher MAP prevalence in CD *vs* controls in different samples^[40,41].

However, a number of investigations have failed to demonstrate any evidence of an association between CD and detection of MAP-DNA. Parrish *et al.*^[59] reported that all CD patients were negative for MAP using PCR and only one healthy control patient was positive; however, no viable MAP was cultured from this individual and all blood cultures were negative for MAP, despite the large study size (130 CD, 130 healthy controls). Other authors found a high prevalence of MAP even in non-IBD controls^[60].

Molecular techniques for assaying MAP-DNA are not able to discern the presence of vital microorganisms from fragments of killed MAP. RT-PCR for IS900-RNA detection overcomes this problem by directly demonstrating the presence of active metabolic processes at the time of isolation^[61]. The most significant study in this field, although limited to a small number of patients (CD $n = 8$, UC $n = 2$, and controls affected by colon-rectal cancer $n = 2$), identified the presence of MAP-RNA in all ileal mucosal samples from CD and UC patients^[62]. RNA has a

half-life of minutes, therefore, detection of this molecule cannot only be related to the wide environmental spread of MAP, as would be legitimate to suppose in the case of DNA detection.

Recent studies have investigated the presence of IS900 DNA fragment in stools from CD patients, UC patients and from healthy controls. The use of human feces represents a new approach to investigate the "MAP hypothesis"; as it has the advantage that stools can be collected more easily than blood samples and biopsy specimens. In a previous study, the results revealed that detection of MAP DNA in human feces is very common: 21 of 31 CD (68%), 13 of 20 UC (65%) and 11 of 23 healthy controls were MAP-positive [CD *vs* controls: $P =$ no significance (NS), UC *vs* controls: $P =$ NS]^[63]. The IS900-positive percentage in IBD samples was higher than in healthy controls, but did not reach statistical significance, partially due to the small sample size. No significant correlation was observed when analyzing IS900 positivity in relation to disease activity in the IBD group^[63].

INDIRECT METHODS FOR MAP DETECTION

Besides direct methods for MAP identification, indirect techniques are also available, with the aim of testing humoral and cellular-mediated immune response using the blood of IBD patients and healthy controls (Table 3).

ELISA represents the main diagnostic method for identifying cattle affected with JD, and is the most frequently used method to identify subjects immune to MAP. However, an ELISA validated for humans is not presently available.

Many studies have assayed the presence of MAP antibodies in CD patients and controls, obtaining contrasting results that should be related to the use of different methodologies and heterogeneous antigens (nuclear extracts, soluble antigens from cultured filtrates, recombinant antigens). For example, 57% of CD patients were positive for the detection of antibodies against a 38-kDa antigen, while 53% manifested specific antibodies for 24-kDa and 18-kDa bacterioferritin, but only 18% showed simultaneous seropositivity for all the three antigens^[64]. Other studies demonstrated that the detection of anti-p36 antibodies is usually positive in CD patients (about 89%), while it seems to be less common in UC patients (about 15%). A specific reactivity against p35 and p36 is frequent in CD patients, but both these antigens are common to *Mycobacterium avium* subspecies *avium*, suggesting that cross-reactivity may influence results^[65]. Other mycobacterial components used for testing humoral response against MAP are 14-kDa AhpC antigen and the heat shock proteins^[66]. Of 13 studies included in a recent meta-analysis, 10 found that the prevalence of antibodies against MAP was higher in patients with CD than in controls, with a pooled odd ratio of 1.72 (1.02-2.90); similar pooled odd ratios were obtained when CD and UC pa-

tients were compared (1.88; 1.26-2.81)^[41].

Nevertheless, other studies on humoral response against MAP antigens did not find an association between CD and MAP: Brunello *et al*^[67] reported no significant differences in the titers of IgG antibodies against MAP protoplasmic antigen between CD (3.7%) and UC patients (5%). Walmsley *et al*^[68] determined anti-18 kDa mycobacterial bacterioferritin IgG or IgA titers in CD patients and controls without finding any differences, while the results from Bernstein *et al*^[69] showed a seropositivity rate for anti-PPA (anti-purified protoplasmic antigen) in 37.8% of CD patients, 34.7% of UC patients and 33.6% of healthy controls, with non-significant statistical differences among the groups.

Patients with IBD have an impaired barrier function of intestinal mucosa with increased bacterial translocation^[70]. In relation to these data, increased antibody titer against *E. coli*, aerobes, anaerobes and enteric bacterial pathogens has been reported both at the mucosal and systemic level^[21]. Thus, a pronounced humoral and cell-mediated immune response against bacteria is unavoidable. The same could be true for MAP, however, this is not enough to support its etiopathological role in CD onset.

Moreover, the cell-mediated response against MAP, dosing INF- γ and other inflammatory cytokines, have also been analyzed^[71,72].

In-vitro INF- γ lymphocyte production, derived from peripheral blood after stimulation with MAP PPD-antigen, was simultaneously evaluated with other MAP detection methods (PCR for MAP-DNA in tissues, direct culture isolation, ELISA for MAP-specific antibodies and cell-mediated response). The authors observed higher levels of MAP-specific INF- γ in the control group compared to IBD patients, supporting the hypothesis of a wide environmental diffusion of MAP and that healthy subjects could have a stronger cell-mediated immune response, better than the IBD patients.

However, Olsen *et al*^[73] found that isolated T CD4⁺ clones from gut biopsies of patients with active CD

significantly proliferate in response to MAP-specific antigens *vs* controls and were able to produce INF- γ and IL-17.

Protein tyrosine phosphatase (PtpA) and Protein Kinase (PknG) are a very recent indirect method of detecting the presence of MAP. Both proteins are involved in the signal transduction system of MAP and seem to have a critical role for survival of the pathogen within human macrophages, modulating the host's immune response^[45]. PtpA, is a specific mycobacterial protein tyrosine phosphatase secreted in a time-dependent manner during MAP infection from the human-derived monocyte cell line, THP-1, and can inhibit phagosome acidification and phagosome-lysosome fusion by dephosphorylating the host sorting protein VPS33B. When sera from CD and UC patients and controls were screened for these antibodies, there was a significantly higher titer in CD patients *vs* controls. In contrast, no significant difference was measured in UC patients^[43].

Nakase *et al*^[74] demonstrated that THP-1 cells infected with MAP produced a higher amount of TNF α when compared with either *Mycobacterium avium* or *Mycobacterium smegmatis*, suggesting that MAP is directly involved in the up-regulation of this cytokine.

ROLE OF COMBINED

ANTIMYCOBACTERIAL THERAPY IN CD

In animals, JD is a chronic progressive fatal condition. Not even pre-emptive administration of antibiotics prevents the infection. *In vitro* analysis showed that MAP is not responsive to traditional anti-tuberculous drugs. In addition, *in vivo* the association of isoniazid, ethambutol and rifampicin lacks efficacy in patients with CD, as demonstrated by a two-year clinical trial, followed by a three-year follow-up period^[75]. Because of its typical CWD form, antibiotics that interfere with bacterial wall synthesis do not show efficacy against MAP, which is similar to drugs that impede bacterial duplication at different levels, as MAP

has a low replication rate. Combined antibiotic therapies, including rifampicin and macrolide-derived drugs, for instance clarithromycin and azithromycin, demonstrated *in-vivo* and *in-vitro* efficacy both against MAP and other members of the *Mycobacterium avium* complex^[76]. Similar to *Mycobacterium tuberculosis*, the importance of a therapeutic scheme consisting of at least three drugs in order to prevent drug-resistance was also confirmed for other mycobacterial species.

It has been suggested that the most irrefutable evidence of the involvement of a microbial agent in CD etiology would be the long-term remission of clinical manifestations following the clearance of infection^[5]. With regard to this issue, Borody *et al*^[77] treated a series of 12 patients suffering from severe, obstructive or penetrating CD with a triple antibiotic therapy consisting of rifabutin, clofazimine and clarithromycin, and obtained a clinical, endoscopic and histological remission rate of almost 50%. In an English clinical trial based on the use of rifabutin, clarithromycin and azithromycin from 6 to 35 mo, with a follow-up of 7 to 41 mo, therapy was tolerated by 46 of 52 (89%) enrolled patients; in particular, 17 of 19 patients (91%) who were steroid-dependent before treatment were steroid-independent. Furthermore, the authors observed an important improvement in CDAI, maintained over the following 24 mo^[76]. In an American clinical trial, 36 patients positive for p35 and p36 MAP-specific antigens were followed for a period of 4-17 mo; 21 of 29 CD patients (58.3%) who seemed to tolerate antibiotic therapy with rifabutin and clarithromycin showed a clinical sustained improvement^[78].

These results seem promising, suggesting that at least a sub-group of CD patients benefit from antibiotic treatment. Nevertheless, these trials are not controlled, are based on a small number of patients and with variability concerning the antibiotics used. Selby *et al*^[79] published the result of a large controlled trial in which 213 patients with active CD were randomized to receive triple intracellularly active antibiotic treatment (clarithromycin, rifabutin, clofazimine) or placebo for two years, followed by one year of follow-up, in addition to a 16-wk tapering course of steroids. They observed a relapse rate of 59% in the antibiotics arm *vs* 50% in the placebo arm ($P = 0.54$) among the 32 patients who completed the study at the end of the two-year period. No statistically significant differences between the two arms of the study were noted either during the two-year treatment, or during the follow-up period.

Incongruity of these results may be due to the heterogeneity of the patient selection criteria, the drug type and dosage, the use of mono-therapy or combined therapy and the duration of treatment. Primary end-points were different (drug-capacity of inducing and/or maintaining clinic and/or endoscopic disease remission, relapse percentages after treatment suspension) with consequently different interpretation of the results. Furthermore, none of the previous studies included evaluation of MAP presence in the enrolled population. The eradication of

MAP after antibiotic therapy would strongly support the role of MAP in CD etiology.

FINAL CONSIDERATIONS AND PERSPECTIVES

The present data do not demonstrate that MAP is the causal agent in CD, however, a certain degree of involvement of this bacterium in the physiopathological steps of the disease is reasonable. The literature contains contrasting and contradictory evidence on this association with a lack of uniformity in the materials and methods adopted by different researchers for MAP detection and inappropriate patient and control selection parameters. The variability in quality and quantity of analyzed samples, the possible contamination during collection, transport and/or manufacturing of samples, produced further bias among studies^[80]. In order to consider an infectious agent as the cause of disease, it is necessary to demonstrate that infection precedes the disease onset. Even studies on the causative role of MAP in CD did not sufficiently support this association because they did not provide enough evidence between the timing of infection and the onset of intestinal disease. The detection of MAP-DNA in the blood of CD patients might suggest that a viable form of the organism is present in CD; however, this could be a secondary phenomenon due to increased intestinal permeability and/or the inability of macrophages to kill MAP in CD patients, rather than an etiological explanation for the disease.

To further elucidate the role of MAP in CD and IBD it would be useful to simultaneously evaluate different biological samples (blood, biopsies and stools) and to clarify whether the detection of MAP-DNA in stools or in biopsies may be related to its viable presence in blood, representing a possible marker of active infection. To our knowledge only two small studies on this issue have been published to date^[71,72].

There is no effective and readily accessible method available to diagnose MAP-infection in humans. CD histology suggests that the host's immune response is primarily cell-mediated. Therefore, studies which investigate cell-mediated reactivity against MAP, through the use of T-cell-based IFN- γ assays, could gain more relevance. The reliability of the quantiferon-TB Gold test in evaluating the contact with non-tubercular mycobacteria is still in doubt. The positive cut-off level for the Quantiferon test in patients with non-tubercular mycobacterial disease has not been determined^[81]. The development of "home-made" INF- γ release assays that specifically dose the quantity of this cytokine after stimulation with MAP-specific antigen, including proper negative and positive controls, is required.

As demonstrated, steroid therapies and combinations with immunosuppressive agents increase the risk of an indeterminate result in the Quantiferon test for the detection of latent tuberculosis infection^[82]. We know that

MAP infected human macrophages disrupt the host's immune response for its own benefit and a high amount of the cytokine, TNF- α , was found in MAP associated CD patients^[74].

The controversy regarding MAP and IBD has persisted far too long. Firstly, it is necessary to ratify criteria for sample collection, test performance and interpretation of results. Secondly, in order to establish a causal role of MAP in the etiology of CD, it is necessary to determine if clearance of MAP using drugs that specifically act against this organism, selectively change the natural history of the disease, guarantee a sustained clinical remission and an improvement in histological activity.

The interest in a possible link between MAP and CD would be of clinical relevance (development of diagnostic methods) and for the prevention of the disease (implementation of public health measures, modifications in food processing practices, develop screening MAP infection).

Heterogeneous clinical and histological features, disease course and response to therapies make CD a highly polymorphic entity^[83] and is better identified as a "syndrome". In this respect, CD may not have a singular etiology, but rather result from the concomitant action of multiple causal agents and triggering factors, including MAP.

Key words: Ulcerative colitis; Ileorectal anastomosis; Ileal pouch-anal anastomosis; Retained rectum; Neoplastic degeneration

Core tip: Ileal pouch-anal anastomosis (IPAA) is the most commonly performed procedure for treatment of UC patients refractory to medical therapy. However, IPAA carries on its own risks. Recently, some authors have proposed ileorectal anastomosis (IRA) as a valid surgical alternative to IPAA. IRA is an easier operation than IPAA associated with low complication rates and comparable long-term functional results. This manuscript reviews the pros and cons of both procedures and compares results.

Abstract

Total proctocolectomy with ileal pouch-anal anastomosis (IPAA) is the current gold standard in the surgical treatment of ulcerative colitis (UC) refractory to medical management. A procedure of significant magnitude carries its own risks including anastomotic failure, pelvic sepsis and a low rate of neoplastic degeneration over-time. Recent studies have shown that total colectomy with ileorectal anastomosis (IRA) has been associated with good long-term functional results in a selected group of UC patients amenable to undergo a strict surveillance for the relatively high risk of cancer in the rectum. This manuscript will review and compare the most recent literature on IRA and IPAA as it pertains to postoperative morbidity and mortality, failure rates, functional outcomes and cancer risk.

INTRODUCTION

The main goals of surgical treatment for ulcerative colitis (UC) are not only to alleviate symptoms and minimize cancer risk but also to obtain good functional outcomes and improve quality of life. Until the 1950s total proctocolectomy with end-ileostomy (TPC) was the only available procedure for UC patients failing medical management.

In the 1940s reports of subtotal colectomy with ileorectal anastomosis (IRA) as an alternative to TPC in selected patients were first published^[1]. During the 1950s and 1960s, Aylett^[2] became the leading proponent of this procedure describing it as a way to avoid a permanent stoma. At that time IRA represented a valid alternative to TPC in high selected patients with minimal rectal inflammation. It was a less invasive operation, performed in one

stage and not requiring pelvic dissection with the associated risk of sexual dysfunction^[3-5].

In 1978, Parks *et al*^[6] described an ileal pouch-anal anastomosis (IPAA). Since then, IPAA has become the procedure of choice for patients affected by UC with excellent long-term functional results, low risk of persistent cuff inflammation or neoplastic degeneration in the retained rectum^[7,8]. Consequently, many surgeons have abandoned IRA in favor of IPAA and TPC has remained an option for patients not candidates for IPAA. The counterargument is that IPAA, as a major procedure, carries its own risks including anastomotic failure and pelvic sepsis that could result in poor pouch function, pouchitis and infertility in young women, as well as pelvic nerve damage and portal vein thrombosis^[3-5,9,10]. In addition few cases of cancer have been reported arising not only in the anal transitional zone but also in the pouch itself^[7,8].

Interestingly, recent series^[11-14] of selected UC patients undergoing IRA showed long-term functional results similar to IPAA.

The aim of the current study was to review and compare the most recent literature on IRA and IPAA as it pertains to postoperative morbidity and mortality, failure rates, functional outcomes and cancer risk. It will help surgeons to provide a tailored treatment for UC patients.

ILEORECTAL ANASTOMOSIS

Chronic UC begins in the rectum and extends proximally in a continuous fashion. The severity of the disease also seems to be higher distally with the exception of fulminant pancolitis presentation. However, distal disease is sometimes alleviated by topical treatment and patients with minimal rectal involvement and no dysplastic changes in the rectum could be considered for IRA. Furthermore, an adequate rectal compliance and a normal anal sphincters function are critical for good long-term results. These functions can easily be assessed by digital rectal examination but more accurately by rigid/flexible proctoscopy and manometry. Patients with poor sphincter function, severe rectal disease, and non-distensible rectum should not be offered an IRA. On the contrary, patients with colitis associated colorectal cancer and advanced metastatic disease may benefit from an IRA because of their short life expectancy and the palliative

nature of their treatment.

Several studies^[11,13,15-17] have shown IRA for UC to be safe, with low postoperative morbidity and mortality. During the years, overall morbidity has been reported between 8% and 28% and mortality between 0% and 4% (Table 1). These studies including the work of Elton *et al*^[18] and Andersson *et al*^[19], focused their attention on postoperative complications including small bowel obstruction, anastomotic leak and abdominal abscess. The fatal events were due to anastomotic leak and subsequent sepsis and to a pulmonary embolism.

The majority of published data has included mainly primary anastomosis with leak rates ranging from 2% to 9%^[11,13,15-20]. Diverting ileostomies have been utilized in selective cases at the surgeon discretion. Turnbull^[21] suggested that preservation of grossly involved recto-sigmoid colon was the main cause of IRA failure. In his opinion an anastomosis at 6 cm or less above peritoneal reflexion improved rectal inflammation during the first months and reduced the likelihood of IRA failure.

IRA does not involve extensive pelvic dissection, unlike IPAA or TPC, minimizing the risk of sexual and urinary dysfunction. Hence, higher fertility rates may be expected in IRA patients compared to IPAA although definitive studies providing evidence for better fertility rates in UC patients are lacking. Thus, colectomy with IRA could be considered when treating women in their reproductive age^[20].

Some authors^[2,11,13,15,18,22] have shown acceptable long-term success rate after IRA. Aylett^[2] in 1966 reported on a total of 300 cases operated on over a ten-year period with only 7% failure rates. Lepistö *et al*^[22] and Pastore *et al*^[15] reported a cumulative probability of having a functioning IRA at five years of 84%. Elton *et al*^[18] had 88% success in their 18 patients, but the follow-up in that study was shorter. Ten year cumulative success (69%) in Lepistö's series^[22] was higher than reported by Leijonmarck *et al*^[13] (51%) in 1990. At 20-years the current probability of having a functioning IRA has ranged between 46% and 69%^[20]. One recent study proposed by da Luz Moreira *et al*^[11], from Cleveland Clinic, compared 22 IRA with 66 IPAA patients matched for age, gender, and follow-up time, including IRAs performed in the past 25 years showed a cumulative probability of having a functioning IRA at 5, 10, 15 and 20 years of 81, 74, 56

and 46 percent respectively in accordance with previously published work.

In terms of functional results, the da Luz Moreira's series^[11] reported six bowel movements per day (range 2-11), 1/22 (5%) night-time seepage and 15/22 (68%) reporting frequent urgency. Leijonmarck *et al*^[13] showed four bowel movements per day and none during the night, with 100% of continence (25% of patients are on antidiarrheal medication), after a mean follow-up of 13 years. Elton *et al*^[18] had no significant difference between preoperative and 1-year postoperative stool frequency, 11/12 patients had no problems with continence, and three were using antidiarrheal medication. Pastore *et al*^[15] described a median number of six bowel movements per day (range 2-20). The median number of nocturnal bowel movements was one (range 0-10) and three patients had more than eight daily stools with frequent soiling and urgency. At the time of follow-up, antidiarrheal medications were taken by 53.3% of patients, whereas 31.3% required low doses of systemic or topical steroids. More than 90% of patients considered that their health status had improved after the operation. Quality of life was improved in 84%.

All the studies above showed that IRA is a safe procedure with an acceptable function and quality of life but unfortunately it is not necessarily a definitive operation, especially for young patients. Specifically, Andersson and colleagues^[19] reported an estimated cumulative failure rate of 10.1% and 24.1% respectively at 5 and 10 years. In his series Leijonmarck *et al*^[13] had 57% of failure after 13-year follow-up. Pastore *et al*^[15] suggested that time between IRA and additional surgery in his series was 3.9 ± 4.7 years. In da Luz Moreira's series^[11], 38 patients (44%) continued to have a functioned IRA after a median follow-up of 11 years (range 1-30 years). The rectum was resected in 46 (53%) of 86 patients and the median follow-up between IRA and completion proctectomy was 10 years (range 1-33 years).

The main indication for proctectomy is recurrent proctitis refractory to medical management^[11,13,15-19,22,23], followed by dysplasia or cancer, and the development of Crohn's disease. The options for these patients include IPAA, Brooke ileostomy, or a continent ileostomy (Kock pouch). Very Often IPAA can be safely performed in the majority of these patients thus preserving bowel continuity and avoiding permanent fecal diversion^[11].

Cancer risk

Mucosal dysplasia is a premalignant pathological state associated with long standing UC^[24]. Dysplasia in general is considered an indication for surgery in UC, even though this paradigm is rapidly changing. Epithelial dysplasia of the colon and rectum was graded as mild, moderate, or severe depending on whether the upper one-third, upper two-thirds, or entire glands displayed nuclear anisocytosis and hyperchromatism, as well as loss of nuclear polarity and the normal goblet cell configuration of colonic mucosa. Since dysplastic changes were often patchy, only

the highest degree of dysplasia was considered. Johnson *et al*^[25] had shown in 1983 that the probability of developing rectal adenocarcinoma after a diagnosis of mild or severe dysplasia in IRA patients reached 42% at nine years from diagnosis. The rate of dysplasia and cancer, in patients with UC, increases with time and leaving the rectum in place contributes to the increased risk. The overall cumulative probability of rectal dysplasia in the retained rectum increases from 9% at 10 years to 25% at 20 years^[11]. The overall incidence of rectal cancer after an IRA varies in the literature based on length of follow-up, ranging from 0% to 18%. Grundfest *et al*^[17] reported on four patients who developed carcinoma of the rectum during their study period (4.8% at 8-year follow-up), although he estimated the risk of rectal cancer to be 13% at more than 25 years of follow-up. Oakley *et al*^[23] found nine patients with rectal cancer in the stump (3.1%) at an 8-year follow-up while Andersson *et al*^[19] showed an overall risk of cancer of 1.9% at a 5.4-year follow-up. However, some series reported higher rates of degeneration as Baker *et al*^[26] who described, in 1978, a cumulative cancer risk of 6% after 20 years rising to 18% after 35 years in a series of 374 unselected patients. In da Luz Moreira's series^[11], the cumulative probability of developing dysplasia and cancer was 7%, 9%, 20% and 25% and 0%, 2%, 5% and 14% at 5, 10, 15 and 20 years respectively. On the other hand, Leijonmarck *et al*^[13] and Lepistö *et al*^[22] had reported no case of cancer in more recent series at 13 and 18-year follow-up, respectively. Pastore *et al*^[15] showed a cumulative probability of remaining free of cancer around 85.5% at 12 years (95%CI: 57.7%-100%).

Most patients who develop rectal cancer in the retained rectum presented at an advanced stage (stage III-IV) suggesting the possibility of a more aggressive biology and making close surveillance imperative^[11,27]. For instance, in Baker's study 62% of patients who had developed rectal cancer died within three years of diagnosis. Johnson *et al*^[27] reported a total of 10 rectal cancers, 8 of which had either nodal or distant metastases. The patients in the series reported by Oakley *et al*^[23] fared better, with just 2 of 9 patients with rectal cancer dying over a 22-year time period. Rectal biopsies taken from multiple sites every 6 to 12 mo are advised following IRA in UC patients. If dysplasia is found, completion proctectomy is indicated. Patients with long standing UC who are not able or willing to undergo surveillance should not be offered an IRA. It is also important to emphasize that colectomy with IRA should not be offered to patients with preexisting dysplasia or cancer due to the increased risk of further neoplastic degeneration^[28]. In addition, the presence of dysplasia or cancer in the resected colon should cause particular concern about the fate of the remaining rectum suggesting that a completion proctectomy would be indicated in these cases. In fact, Oakley *et al*^[12] reported on five surviving patients who had cancer in their colonic specimens; three of the five were found on follow-up to have cancer or severe dysplasia in the rectal remnant. Grundfest *et al*^[17] described nine patients

Table 2 Morbidity and mortality after ileal pouch-anal anastomosis

| Period | No. of studies | No. of patients | Pelvic sepsis (% <i>, 95%CI</i>) | Pouch failure (% <i>, 95%CI</i>) | Pouchitis (% <i>, 95%CI</i>) | Mortality (% <i>, range</i>) |
|--|----------------|-----------------|-----------------------------------|-----------------------------------|-------------------------------|-------------------------------|
| Meta-analysis studies < 2000 ^[32] | 43 | 9317 | 9.5 (8.2-10.9) | 6.8 (5.8-8.4) | 18.8 (15.7-22.4) | - |
| Meta-analysis studies ≥ 2000 ^[33] | 53 | 14966 | 7.5 (6.1-9.1) | 4.3 (3.5-5.3) | 26.8 (21.0-33.5) | 0 (0-2.9) |

with a colitis-associated colon cancer or severe dysplasia who underwent subtotal colectomy, eight of whom survived; of the eight, five developed severe dysplasia or cancer in the retained rectum.

ILEAL POUCH-ANAL ANASTOMOSIS

Restorative proctocolectomy with IPAA is currently the procedure of choice for the surgical treatment of UC. The main reason for its popularity is its avoidance of a permanent stoma with stable functional results and good quality of life. In over 30 years of its existence, the IPAA has undergone several refinements in the quest of achieving optimal results. Examples include different shapes of the pouch, different anastomotic techniques, use of defunctioning ileostomy and various dissection methods^[29-31]. Surgeons have also obtained greater experience and familiarity with the technique, which has also benefited outcomes.

A large body of literature exists on the outcomes of IPAA. Most studies, however, are retrospective cohorts reporting outcomes from a single institution. Due to large variations between studies, an overview is needed for reliable assessment of the IPAA outcomes. A meta-analysis of 43 observational studies, all published before 2000, has provided pooled estimates of complications and functional outcomes after IPAA^[32]. This meta-analysis showed a pouch failure risk of 6.8% (95%CI: 5.4%-8.4%), increasing to 8.5% (95%CI: 5.4%-13.2%) when only patients with a minimal follow-up of 5 years were considered^[32]. Other pouch related complications were also studied. Pelvic sepsis and pouch fistulas, both major post-operative complications, were observed in 9.5% (95%CI: 8.2%-10.9%) and 5.5% (95%CI: 4.3%-7.0%), respectively. Sexual dysfunction was present in 3.4% (95%CI: 2.7%-4.7%), while pouchitis was reported in 18.8% (95%CI: 15.7%-22.4%).

A recent meta-analysis, including 53 studies published after 2000, showed significant improvements in these results^[33]. The overall rate of pouch failure was significantly reduced to 4.3% (95%CI: 3.5%-5.3%), and pouch failure after at least 5 years of follow-up was 4.7% (95%CI: 3.4%-6.4%). An improvement was also seen in most other complications. Pelvic sepsis, pouch fistula and sexual dysfunction were reported in 7.5% (95%CI: 6.1%-9.1%), 4.5% (95%CI: 3.5%-5.7%) and 3.0% (95%CI: 1.7%-5.2%) of patients. The only complication showing a substantial increase was pouchitis, with a rate of 26.8% (95%CI: 21.0%-33.5%).

Thus it seems that the rate of complications after

IPAA has declined over time (Table 2). The authors of the meta-analyses have noticed that the decline was largest in the earlier period of the IPAA, but seems to have continued over time. Nonetheless, IPAA remains a complex surgery with substantial risk of morbidity. The high rate of pouchitis is also worrisome, since this complication can affect functional outcomes, quality of life and might also increase risk of dysplasia in the pouch. It should be noted that the meta-analyses discussed above did not distinguish between acute and chronic pouchitis, which is an important distinction in terms of course and health implications^[34-36].

Functional outcomes after IPAA were similar in studies published before and after 2000^[33]. Average frequency of bowel movements per 24 h was 5.9 (95%CI: 5.0-6.9), of which 1.5 (95%CI: 1.0-2.1) overnight. Mild and severe faecal incontinence were reported in 14.3% (7.3%-25.9%) and 6.1% (2.9%-12.3%) of patients, respectively. The authors conclude that functional outcomes of IPAA may be determined by an intrinsic limitation of the IPAA procedure, rather than growing expertise or technical refinement. This is in line with other studies showing no improvement in functional outcomes based on technical developments, such as type of anastomosis or laparoscopic approach^[36,37]. However, most patients consider the functional outcome after IPAA to be highly satisfactory, with good quality of life and social functionality that are comparable to those in a healthy reference population^[38,39]. As expected, achieving these adequate quality of life scores was highly correlated with achieving of good functional outcomes^[40].

Cancer risk

The IPAA has as an important advantage the removal of the whole colon and virtually the entire rectum as part of the procedure. This minimizes chances of colon and rectal cancer in this high-risk population. A proctocolectomy should be considered almost mandatory when dysplasia is present. Even when only low-grade dysplasia has been identified by colonoscopy, the risk remains substantial. In such patients, studies show a risk of concomitant cancer or high-grade dysplasia of 15% and a 5-year progression rate of up to 54% if not operated on^[28,41].

When a double-stapled approach for IPAA is used, a mucosal remnant at the anal transition zone (ATZ) is left in place. The risk of cancer in this area is a matter of controversy. In three series with long-term follow-up focused on this outcome, dysplasia and cancer in the anal transitional zone after stapled pouch surgery was found to be infrequent^[7,42,43]. Dysplasia was observed in 8/178

Table 3 Main advantages and disadvantages of ileorectal anastomosis and ileal pouch-anal anastomosis

| | IRA | IPAA |
|---------------|--|---|
| Advantages | Easier operation Lower infertility rate Lower risk of urinary and sexual dysfunction Fewer bowel movements per day Better continence | Lower risk of cancer No need for medical therapy Less urgency |
| Disadvantages | Need for maintenance therapy Risk of recurrent/persistent disease Higher risk of neoplastic degeneration Need for strict surveillance More dietary and work restrictions | Major operation Risk of postoperative complications (pelvic nerves damage, pelvic sepsis, portal vein thrombosis) Pouchitis |

IRA: Ileorectal anastomosis; IPAA: Ileal pouch-anal anastomosis.

(4.4%), 7/210 (3.3%) and 0/135 (0%) after at least 10 years of follow-up. In most of these cases, dysplasia developed in the first 2 to 3 years and often disappeared on repeated biopsies. None of the series found cancer in the ATZ after such prolonged follow-up. These data strongly emphasize the extent to which IPAA minimizes the risk of cancer.

The best evidence regarding the development of dysplasia and adenocarcinoma after IPAA can be obtained from a recent study from the Cleveland Clinic^[44], in which 3203 patients undergoing an IPAA from 1984 to 2009 were analyzed. Cumulative incidences for pouch neoplasia at 5, 10, 15, 20, and 25 years were 0.9%, 1.3%, 1.9%, 4.2%, and 5.1%, respectively. Overall, 23 patients (0.72%) developed dysplasia, while 11 (0.36%) developed adenocarcinoma of the pouch and/or the ATZ. Risk factors for pouch neoplasia were also evaluated. Preoperative established cancer [hazard ratios (HR) = 13.43, 95%CI: 3.96-45.53, $P < 0.001$] or dysplasia (HR = 3.62, 95%CI: 1.59-8.23, $P = 0.002$) were the only independent factors associated with increased risk of pouch neoplasia. Mucosectomy did not protect against this risk, and the rate of pouch cancer was actually higher after mucosectomy with a rate of 1.3% (6/451) compared to 0.3% (9/2734) after the double-stapled approach. The authors^[44] concluded that the risk for neoplasia in patients with UC and IPAA is small, and that it is mainly determined by the presence of preoperative dysplasia or cancer.

Additionally, in a review of literature, 26 published case reports were identified between 1984 and 2008^[45]. Certain observations from this review are noteworthy. First, of the 26 carcinomas, 14 (52%) arose from rectal mucosa or from the anal transition zone, while 6 (23%) were from ileal pouch mucosa. Second, adenocarcinomas developed after mucosectomy in 17 patients, and after a double-stapled approach in 8 patients (1 case not reported). Also worth noting, the indication for the IPAA was due to neoplasia in 19 patients (9 cancers and 10 dysplasia) and non-neoplasia in 6 patients. The median time for development of pouch lesions was the shortest in patients operated on for cancer (median 3 years), compared to a median of 6.5 in the other patients. This review is in line with results from the above mentioned study, and

further establishes the following conclusions: (1) the low number of reported cases; (2) cancer can develop both after mucosectomy or double-stapled approach; and (3) the close relationship between surgery for neoplasia and development of cancer. The review was not able to estimate the incidence of cancer after IPAA, since the total number of IPAA cases was not stated in most case reports. Branco *et al.*^[45] did publish their own case as part of this review, which was the first case they observed in a cohort of 520 patients (0.2%) from 1978 to 2008. This percentage is also in line with the Cleveland study^[44].

Despite this seemingly small risk, surveillance of selected patients has been recommended by some authors^[46,47]. This approach might especially be important in UC patients with dysplasia or cancer present at time of surgery, or patients with retained rectal mucosa and active inflammation (*i.e.*, cuffitis). Also the presence of chronic pouchitis might be a valid indication for surveillance, since this has been associated with increased risk of low-grade dysplasia (odds ratio 13.48, $P < 0.02$), as well as high-grade dysplasia (3/66 vs 0/210, $P = 0.01$)^[35].

CONCLUSION

In the current era IPAA is the preferred approach for patients with UC requiring surgical treatment. The removal of all diseased mucosa and the lower risk of cancer after IPAA compared to IRA are the main advantages of this technique (Table 3). Therefore, IPAA should certainly be performed when the rectum is actively involved in the disease or when dysplasia or cancer are present in any part of the colon or rectum. Nonetheless, there is still a role for IRA and TPC for selected patients and for patients not candidates for IPAA.

Total abdominal colectomy with IRA is justified in UC patients with normal anal sphincters tone without severe perineal disease, and spared and distensible rectum with no evidence of dysplasia or cancer at the time of intervention. It can be also proposed to young women as a possible interim procedure based on concerns for infertility after IPAA.

The risk of cancer is of particular concern in the comparison between these two techniques. Current evi-

Table 4 Risk of cancer after ileorectal vs ileal pouch-anal anastomosis in ulcerative colitis

| | Period | n | Follow-up average (yr) | Overall cancer rate (%) | Estimated cumulative risk after 20 years (%) |
|---|-----------|------|------------------------|-------------------------|--|

| Kariv <i>et al</i> ^[44] | 1984-2009 | 3203 | ± 12 | 0.4 | 4 |
| Branco <i>et al</i> ^[45] | 1978-2008 | 520 | ± 15 | 0.2 | - |

¹Cumulative risk at 12 years (rather than 20).

dence shows a large variation in the reported rates of cancer after IRA from 0% to 8%. For IPAA, this risk is much smaller, and two large series have shown a rate of cancer of about 0.3%. Few studies have calculated the cumulative risk of cancer as well. Similarly, estimated cumulative risk of cancer after 20 years was higher after IRA (6% to 14%) compared to IPAA (4.2%) (Table 4).

Therefore, every patient undergoing IRA should be informed about the risk of recurrent proctitis and cancer in long standing disease. They have to fully understand the need for meticulous surveillance and agree to comply with at least yearly endoscopy with rectal biopsies. Unless these conditions are met, patients should not be offered an IRA. Also, patients with widely metastatic colorectal cancer may benefit from an IRA as a palliative procedure.

Functional results seem to be better after IRA with lower frequency of bowel movements and less night-time seepage but with more urgency compared to patients with an IPAA. The overall quality of life is similar, although the IRA group has significantly more dietary and work restrictions^[11].

Finally, TPC still remains the procedure of choice in patients with impaired anal sphincter function and high-risk of pouch failure.

Abstract

Nutritional concerns, linear growth deficiency, and delayed puberty are currently detected in up to 85% of patients with Crohn's disease (CD) diagnosed at childhood. To provide advice on how to assess and manage nutritional concerns in these patients, a Medline search was conducted using "pediatric inflammatory bowel disease", "pediatric Crohn's disease", "linear growth", "pubertal growth", "bone health", and "vitamin D" as key words. Clinical trials, systematic reviews, and meta-analyses published between 2008 and 2013 were selected to produce this narrative review. Studies referring to earlier periods were also considered if the data was relevant to our review. Although current treatment strategies for CD that include anti-tumor necrosis factor- α therapy have been shown to improve patients' growth rate, linear growth deficiencies are still common. In pediatric CD patients, prolonged diagnostic delay, high initial activity index, and stricturing/penetrating type

of behavior may cause growth deficiencies (in weight and height) and delayed puberty, with several studies reporting that these patients may not reach an optimal bone mass. Glucocorticoids and inflammation inhibit bone formation, though their impact on skeletal modeling remains unclear. Long-term control of active inflammation and an adequate intake of nutrients are both fundamental in promoting normal puberty. Recent evidence suggests that recombinant growth factor therapy is effective in improving short-term linear growth in selected patients, but is of limited benefit for ameliorating mucosal disease and reducing clinical disease activity. The authors conclude that an intense initial treatment (taking a "top-down" approach, with the early introduction of immunomodulatory treatment) may be justified to induce and maintain remission so that the growth of children with CD can catch up, ideally before puberty. Exclusive enteral nutrition has a key role in inducing remission and improving patients' nutritional status.

Key words: Bone health; Enteral nutrition; Growth; Height; Pediatric inflammatory bowel disease; Pediatric Crohn's disease; Linear growth; Pubertal growth; Vitamin D; Weight loss

Core tip: This review focuses on current evidence for managing growth issues in children diagnosed with Crohn's disease. Long-term control of active inflammation and an adequate intake of nutrients are both essential in promoting puberty. Exclusive enteral nutrition has a key role, as it induces disease remission and improves nutritional status. The early introduction of immunosuppressants or biologics may be justified in children to achieve disease remission and enable their growth to catch up, ideally before puberty. Recent evidence suggests that recombinant growth factor therapy is effective in improving short-term linear growth.

INTRODUCTION

Crohn's disease (CD) is a global health concern and a condition that significantly affects patients' quality of life, as well as placing a heavy financial burden on the community^[1]. CD is currently without a cure, and its incidence is rising not only in Western countries, but also in most developing countries. It manifests in childhood or adolescence in up to 25% of cases^[2].

The microbial ecosystem colonizing the human bowel is influenced by diet, which prompts metabolic processes essential to bowel metabolism^[3-7]. Genetic susceptibility, intestinal microbiota, lifestyle and environmental factors are amongst the potential mechanisms involved in the pathogenesis of inflammatory bowel diseases (IBD)^[3]. Prolonged diagnostic delays, high initial activity indexes, and stricturing/penetrating behavior patterns may predict subsequent complications and the need for surgery, thus justifying a resort to early intensive therapy. The early introduction of immunomodulatory therapy favorably affects the course of IBD^[8-12]. Growth failure and impaired nutritional status are seen in 65%-85% of children and adolescents diagnosed with CD, and 15%-40% of these patients continue to suffer from growth deficiency throughout the course of their disease^[1,13]. Exclusive enteral nutrition has become a key treatment strategy for inducing disease remission in pediatric CD, offering the advantage of improving patients' nutritional status as well as enabling the mucosa to heal at much the same rate as is achievable with corticosteroids^[1,14-17].

GROWTH ISSUES IN PEDIATRIC CROHN'S DISEASE

Growth deficiency can severely affect quality of life for children and adolescents with CD, and complicate their management^[18-20]. It occurs in a significant proportion of patients (up to 85%), and may even precede any clinical evidence of bowel disease. Abraham *et al*^[21] recently conducted a systematic review focusing on understanding the long-term risks of growth deficiency, disease reclassification and extension, hospitalization, cancer, and death among patients with childhood IBD^[21] (Table 1): in 41 studies considered, concerning 3505 patients with CD, 2071 with ulcerative colitis (UC) and 461 with non-IBD colitis, growth failure was identified more often in CD (10%-56%) than in UC (0%-10%) or non-IBD controls. Growth improved after surgical resection in patients with CD^[21].

Among IBD sufferers, male patients are more vulner-

able to growth deficiencies than females of the same age because the male growth spurt in puberty is greater, occurs later, and lasts longer than in females^[22]. Vasseur *et al*^[23] examined a total of 261 pediatric patients with CD registered in the EPIMAD registry in northern France. At diagnosis, 25 children (9.5%) had a height more than 2 standard deviations below the norm, and the same applied to the weight of 70 children (27%), and the BMI of 84 children (32%). At maximal follow-up, 18 children (6.9%) had a growth deficiency and 40 (15%) suffered from malnutrition. Nutritional status was more severely impaired in children with stricturing disease. Growth and nutritional deficiency at diagnosis, young age, male gender, and extraintestinal manifestations at diagnosis were indicators of a poor prognosis. The authors concluded that young boys with substantial inflammatory manifestations of CD are at higher risk of subsequent growth failure, especially when their growth is already deficient at diagnosis^[23].

Assessing growth in IBD patients of a developmental age is so important that it was included among the key points in the Paris classification of pediatric CD, which replaced the previous Montreal classification^[24]. The following factors are implicit in the physiopathology of growth deficiency in pediatric IBD^[22]: (1) chronic calorie insufficiency: these patients' malnutrition is due to a lower intake, protein malabsorption, abnormal intestinal losses, and anorexia correlating with the pathological picture [tumor necrosis factor- α (TNF- α) also has a direct influence at the hypothalamic level]. Inflammatory mediators trigger an increase in basal metabolism too, coinciding with a further deterioration in nutritional status; (2) direct cytokine effects: insulin-like growth factor (IGF)-1 is produced in the liver and is the principal mediator of the effects of growth hormone (GH). Patients suffering from CD have significantly reduced IGF-1 blood levels, irrespective of their GH levels. TNF- α and interleukin (IL)-6 also have a direct inhibitory effect on GH. Other pathways independent of IGF-1 inhibition by means of which the inflammatory cytokines inhibit the linear growth rate have recently been identified as well; (3) effects of chronic treatment with corticosteroids: these drugs induce a central suppression of GH production and reduce IGF-1 synthesis in the liver, as well as interfering with its peripheral receptor activity; (4) effects of IBD on endocrine growth mediators: delayed puberty gives rise to a sex hormone deficiency that may be involved in growth deficiencies; and (5) genetic factors: polymorphisms of NOD2/CARD15 and other already-identified genes appear to generate a cytokine pattern capable of contributing to pediatric IBD patients' growth deficiency; promoter regions of the gene coding for TNF- α and IL-6 also seem to be involved.

NUTRITIONAL CONCERNS IN PEDIATRIC CROHN'S DISEASE

Nutritional issues are often associated with CD, especially in pediatric cases, with underweight and stunting

Table 1 Summary of the main studies that were reviewed on nutritional concerns in pediatric Crohn's disease

| Ref. | Type of study | Patients | Results | Conclusion |
|--|---|--|---|--|
| Vaisman <i>et al</i> ^[25] , <i>Nutrition</i> 2006 | Prospective cohort study | 16 pts with CD; Age 19-57 yr Remission of disease (CDAI Activity Disease Index < 150); 2 groups (BMI 18.5 kg/m ² as a cutoff point) | Subjects with lower BMIs tended to have less lean body mass ($P = 0.006$), less bone mineral density ($P = 0.006$), and lower resting energy expenditure ($P = 0.003$); No correlation between BMI and energy intake, although percentage of malabsorption negatively correlated with BMI ($P = 0.07$) | In the presence of similar energy intake, resting energy expenditure does not seem to contribute to lower BMI, although nutrient malabsorption is higher in malnourished patients with CD in remission; Malabsorption should be evaluated in patients with CD who fail to gain Wt during disease remission, to establish their extra caloric requirements |
| Gupta <i>et al</i> ^[26] , <i>Inflamm Bowel Dis</i> 2013 | Retrospective review | 43 IBD pts (mean age 12.8 yr; range 5.1-17.4 yr) 67% M 33% F | Reductions in erythrocyte sedimentation rate ($P < 0.0001$) and C-reactive protein ($P < 0.02$), and increases in albumin ($P < 0.03$); Mean PCDAI score 26.9 at baseline and 10, 2 at follow-up ($P < 0.0001$); Induction of remission achieved in 65% and response in 87% at a mean follow-up of 2 mo (1-4 mo) | Novel protocol for enteral nutrition (80%-90% of patient's caloric needs) seems to be effective for the induction of remission in CD children; The protocol may result in improved EN acceptance and compliance and will be evaluated prospectively |
| Wiskin <i>et al</i> ^[29] , <i>J Hum Nutr Diet</i> 2012 | Prospective cohort study | 46 IBD children | No children scored low risk with STAMP, STRONGkids or PNRS; 23 children scored low risk with PYMS; Good agreement between STAMP, STRONGkids, and PNRS ($K > 0.6$); Modest agreement between PYMS and the other scores ($K = 0.3$); No agreement between the risk tools and the degree of malnutrition based on anthropometric data ($K < 0.1$) | Relevance of nutrition screening tools for children with chronic disease is unclear; There is the potential to under recognize nutritional impairment (and therefore nutritional risk) in children with IBD |
| Valentini <i>et al</i> ^[30] , <i>Nutrition</i> 2008 | Prospective, controlled, multicentric study | 94 pts with CD (CDAI 71 +/- 47) 61 F 33 M 50 UC (UCAI 3.1 +/- 1.5) 33 F 17 M 61 healthy control subjects 41 F 20 M from centers in Berlin (Germany), Vienna (Austria), and Bari (Italy) 47 well-nourished patients with IBD pair-matched to healthy controls by BMI, sex, and age | 74% IBD patients were well-nourished according to the SGA, BMI, and serum albumin; Body composition analysis demonstrated a decrease in BCM in patients with CD ($P = 0.021$) and UC ($P = 0.041$) compared with controls; Handgrip strength correlated with BCM ($r = 0.703$, $P = 0.001$) and was decreased in patients with CD ($P = 0.005$) and UC ($P = 0.001$) compared with controls; Lower BMC in patients with moderately increased serum CRP levels compared with patients with normal levels | In CD and UC, selected micronutrient deficits and loss of BCM and muscle strength are frequent in remission and cannot be detected by standard malnutrition screening |
| Chan <i>et al</i> ^[31] , <i>Am J Gastroenterol</i> 2013 | Prospective cohort study | 300724 participants (recruited into the European Prospective Investigation into Cancer and Nutrition study) 177 UC and 75 CD | No associations with the four higher categories of BMI compared with a normal BMI for UC (P trend = 0.36) or CD (P trend = 0.83); Lack of associations when BMI analyzed as a continuous or binary variable (BMI 18.5 kg/m ² vs ≥ 25 kg/m ²); Physical activity and total energy intake not associated with UC (P trends 0.79-0.18) or CD (P trends 0.42-0.11) | Obesity as measured by BMI not associated with the development of incident UC or CD; Alternative measures of obesity required to further investigate the role of obesity in the development of incident IBD |
| Werkstetter <i>et al</i> ^[32] , <i>J Crohns Colitis</i> 2012 | Prospective cohort study | 39 IBD children in remission; 27 CD, 12 UC 24 M; 39 healthy age-sex-matched controls | IBD pts vs controls: Lower Z-scores for phase angle α [-0.72; 95% CI: (-1.10-0.34)] Lower grip strength [-1.02 (-1.58-0.47)] Lesser number of steps per day [-1339 (-2760-83)] Shorter duration of physical activity [-0.44 h (-0.94-0.06)], particularly in F and patients with mild disease. Quality of life and energy intake did not differ between patients and controls | In spite of quiescent IBD, lean body mass and physical activity were reduced; Interventions to encourage physical activity may be beneficial in this lifelong disease |

| | | | | |
|--|--------------------------|---|---|---|
| Gerasimidis <i>et al</i> ^[33] <i>Inflamm Bowel Dis</i> 2013 | Prospective cohort study | 184 new pediatric IBD Dg 139 one year follow-up IBD children 84 children treated with EEN | 72% anemic at Dg; Anemic children with CD had shorter diagnosis delay, lower BMI, lower Dg delay ($P < 0.001$) and BMI Z-score, $P = 0.003$) than non-anemic patients; Extensive colitis associated with severe anemia in UC; After EEN, severe anemia decreased (32%-9%, $P < 0.001$) and hemoglobin concentration increased by 0.75 g/dL | Anemia is frequent at Dg and follow-up and should receive more attention from the clinical team; The focus should remain suppression of inflammatory process in active disease |
|--|--------------------------|---|---|---|

Dg: Diagnosis; pt/pts: Patient/patients; CD: Crohn's disease; UC: Ulcerative colitis; IBD-U: Unclassified IBD; rhGH: Recombinant growth factor; ESR: Erythrocyte sedimentation rate; BMC: Body cell mass; BMI: Body mass index; Ht: Height; Wt: Weight; BMD: Bone mineral density; DXA: Dual-energy X-ray absorptiometry; EEN: Exclusive enteral nutrition; GH: Growth hormone; (P)CDAI: (Pediatric) Crohn's disease activity index; PUCAI: Pediatric ulcerative colitis activity index; M: Male; F: Female.

commonly seen at presentation, as well as linear growth retardation and delayed puberty developing later on^[1]. Undernutrition has been reported in 65%-75% of patients with CD^[25] (Table 1), and recent weight loss is one of the triad of clinical manifestations of the disease. Although medical treatment can soon restore body weight, this is not reflected in concomitant changes in body composition. Children with CD have the features of nutritional cachexia, with normal fat stores but depleted lean mass. Poor bone health, delayed puberty, and growth failure are other possible features complicating their clinical management^[26].

As growth impairment is mainly secondary to disease activity, all available pharmacological steps to induce remission in a given patient (depending on their disease phenotype) should have a positive effect on growth as well. Exclusive enteral nutrition has been used as a therapeutic approach to CD because it can improve patients' nutritional status and induce remission (mucosal healing) as quickly as corticosteroids^[1,27]. Exclusive enteral nutrition has thus become a fundamental option at many centers treating pediatric CD^[1]. A recent retrospective review by Gupta *et al*^[28] (Table 1) assessed the efficacy of enteral nutrition (EN) in delivering 80%-90% of patients' calorie needs with a view to inducing remission in pediatric patients with CD. This approach allowed for patients to ingest the remainder of the calories they needed from a normal diet, and so it differs from the standard practice of providing EN to cover 100% of patients' calorie needs. The sample's mean Pediatric Crohn's Disease Activity Index score (PCDAI) at the baseline was 26.9 and it dropped to 10.2 at follow-up ($P = 0.0001$). Remission was induced in 65% of cases and response in 87% after a mean 2 mo of follow-up (1-4 mo). The authors concluded that this novel EN protocol seems to be effective in inducing remission in pediatric patients with CD, helping to increase their weight and improve their laboratory markers. This protocol may also make EN more readily acceptable to patients and improve their compliance^[28].

There has recently been increasing interest in the use of nutrition risk assessment tools in children to identify those needing nutritional support^[29] (Table 1). Four screening tools that are not disease-specific [the Screening tool for the assessment of malnutrition in pediatrics

(STAMP), the screening tool for risk on nutritional status and growth (STRONGkids), the pediatric Yorkhill malnutrition score (PYMS), and the simple pediatric nutrition risk score (PNRS)] were applied by Wiskin *et al*^[29] to 46 children with IBD. The degree of malnutrition was measured by anthropometry alone using the World Health Organization's International Classification of Diseases (ICD-10) criteria. There was a good agreement between STAMP, STRONGkids, and PNRS ($K > 0.6$), but only a modest agreement between PYMS and the other scores ($K = 0.3$), and no agreement between the risk tools and the degree of malnutrition based on anthropometric data ($K < 0.1$). The authors concluded that the relevance of nutrition screening tools for children with chronic intestinal disease is unclear, and there is a risk of their failing to recognize nutritional impairment (and consequent nutritional risk) in children with IBD^[29].

A study by Vaisman *et al*^[25] (Table 1) focused on identifying the relative contribution of factors causing malnutrition in a sample of 16 patients with CD in remission (age 19-57 years). Resting energy expenditure (REE) was studied by indirect calorimetry and body composition by dual-energy X-ray absorptiometry. Subjects with lower BMIs tended to have less lean body mass ($P = 0.006$), a lower bone mineral density ($P = 0.006$), and lower REE ($P = 0.003$). No correlation emerged between BMI and energy intake, although the percentage of malabsorption correlated negatively with BMI ($P = 0.07$). The authors concluded that nutrient malabsorption is more severe in malnourished patients with CD in remission, and consequently suggested that malabsorption should be assessed in CD patients who fail to gain weight while in remission in order to establish their extra calorie needs^[25].

A prospective, controlled, multicentric study by Valentini *et al*^[30] (Table 1) considered nutritional status (subjective global assessment [SGA], BMI, albumin, trace elements), body composition (bioelectrical impedance analysis, anthropometry), muscle strength, and quality of life in 94 patients with CD and 50 with UC, all in clinical remission, and 61 healthy controls. Most patients with IBD (74%) were well-nourished according to their SGA, BMI, and serum albumin levels, but body composition analysis demonstrated a lower body cell mass (BCM) in patients with CD ($P = 0.021$) and UC ($P = 0.041$) than in

controls. Handgrip strength correlated with BCM ($P = 0.001$) and was again lower in patients with CD ($P = 0.005$) and UC ($P = 0.001$) than in controls. These differences were seen even in patients classified as well-nourished. BCM was lower in patients with moderately increased serum C-reactive protein levels than in patients with normal levels. The authors concluded that selected micronutrient deficits and loss of BCM and muscle strength are frequent in CD and UC in remission, and go undetected in standard malnutrition screening^[30].

Obesity is associated with a pro-inflammatory state that may be involved in the etiology of IBD. Chan *et al*^[31] (Table 1) conducted the first prospective cohort study to identify any association between obesity and the onset of incident IBD in a sample of 300724 participants recruited for the European Prospective Investigation into Cancer and Nutrition study. At recruitment, anthropometric measurements were taken of patients' height and weight, and their physical activity and total energy intake were recorded using validated questionnaires. The cohort was monitored and 177 participants developed incident UC, while 75 developed incident CD. No associations emerged vis-à-vis UC or CD between the four higher BMI categories and a normal BMI level. Physical activity and total energy intake (factors influencing BMI) also revealed no association with UC or CD. The authors concluded that obesity, as measured by the BMI, is unassociated with the onset of incident UC or CD. Alternative obesity measures are needed to further clarify the role of obesity in the onset of incident IBD^[31].

Physical activity is important for muscle and bone strength in growing children and may be limited in pediatric IBD patients, even when their disease is quiescent^[32]. A recent study by Werkstetter *et al*^[32] (Table 1) compared 39 IBD patients (27 CD, 12 UC) in remission (or with only mild disease activity) with 39 healthy age- and sex-matched controls. The patients had lower Z-scores for phase angle α and lower handgrip strength than controls. They tended to take fewer steps per day and engage in shorter periods of physical activity, particularly among females and patients with mild disease. The authors concluded that, even with quiescent disease, IBD patients have reduced levels of lean body mass and physical activity. Action to encourage them to engage in physical exercise may therefore be beneficial in this lifelong disease^[32].

Low concentrations of plasma micronutrients are commonly reported in IBD patients, but may be difficult to interpret in the presence of an acute phase response, and other body store adequacy indices are needed. Anemia is a common extraintestinal manifestation in IBD children: these are primarily cases of iron-deficiency anemia, with anemia of chronic disease coming second^[33]. A study by Gerasimidis *et al*^[33] (Table 1) explored the epidemiology of anemia and associated factors in children with IBD at the time of their diagnosis, after 1 year, and during treatment with exclusive enteral nutrition (EEN). At diagnosis, 72% of the children were anemic. Children with CD who were anemic had a shorter diagnostic delay

and a lower BMI than those who were not ($P = 0.003$). Extensive colitis was associated with severe anemia in UC. After EEN, the cases of severe anemia decreased (32%-9%; $P = 0.001$), and hemoglobin concentrations increased by 0.75 g/dL. The authors concluded that children with IBD are highly likely to have anemia at diagnosis, and that this matter should receive more attention during their follow-up, even though clinicians should focus on suppressing the inflammatory process in cases of active disease^[33].

Deficiencies in the liposoluble vitamins A-D and E, and zinc are also possible features of IBD patients^[34-36].

Vitamin D

Vitamin D is a key factor not only for its role in the mineralization of bone and teeth, but also because of its other metabolic functions and its protective role in immune-mediated diseases and allergies^[37-39]. Vitamin D status is assessed by testing its metabolite 25-hydroxy-vitamin D (25-OH-D) in plasma or serum, which reflects the amount of vitamin D converted in the skin through sunlight exposure and ingested in the diet^[37]. Poor vitamin D status may have detrimental consequences for the future health of a child, so an optimal vitamin D status is a crucial public health goal. Vitamin D levels are classed as severely deficient for levels < 37 nmol/L, insufficient for levels < 50 nmol/L, and suboptimal for levels of 50-75 nmol/L^[37]. Exposure to sunlight is generally the most important source of vitamin D3, while the contribution of vitamin D from foods and supplements is fundamental in populations living at latitudes with limited hours of sunlight^[37]. Obesity is a risk factor for vitamin D deficiency because a greater proportion of the body's vitamin D remains stored in adipose tissue^[37].

Current national recommendations suggest a daily intake of 7.5 mcg of vitamin D^[37]. Foods containing large amounts of vitamin D include oily fish and eggs. Vitamin D is produced endogenously in the skin by the photo-reduction of 7-dehydrocholesterol by ultraviolet light. Human exposure to sunlight is limited throughout their lives and some foods are fortified with vitamin D (*e.g.*, milk, some juices, breads, and cereals). Children with chronic diseases are consequently at risk of vitamin D deficiency. The Institute of Medicine recommends a vitamin D intake of 600 IU/d in individuals 1-70 years of age, plus 700-1300 mg/d of calcium (depending on age) to promote healthy skeletal growth^[40]. Vitamin and mineral deficiencies have been described in patients with IBD and are attributed to gut mucosa inflammation and a reduced oral intake^[34]. Cranney *et al*^[41] conducted a systematic qualitative review of 167 eligible studies (112 randomized controlled trials (RCTs), 19 prospective cohort studies, 30 case-control, and 6 before-after studies). The largest body of evidence on vitamin D status and bone health concerned older adults, while few studies focused on infants, children, and adolescents. There was inconsistent evidence of an association between circulating 25(OH)D levels and bone mineral content in infants. In adoles-

cents, there was a fair amount of evidence for an association between 25(OH)D levels and changes in BMD. There was solid evidence of the use of foods fortified with vitamin D (11 RCTs) consistently increasing serum 25(OH)D in both young and older adults. In short, the studies generated fairly good evidence of an association between circulating 25(OH)D concentrations and some bone health outcomes (established rickets, PTH, falls, BMD). When compared with a placebo, vitamin D(3) (> 700 IU/d) with calcium supplementation reportedly had a small beneficial effect on BMD and reduced the risk of fractures and falls, although this benefit may be confined to specific subgroups^[42]. A recent retrospective study performed by Alkhouri *et al.*^[34] in the US investigated the prevalence of vitamin and zinc deficiencies in 61 children (age 1-18 years) with newly-diagnosed IBD from 2006 to 2010 (80% with ileal inflammation) by comparison with a control group of 61 age- and sex-matched individuals. While none of the IBD patients had folate or vitamin B12 deficiency, 62% of them had vitamin D deficiency (*vs* 75% in the control group), 16% had vitamin A deficiency, 5% had vitamin E deficiency (*vs* 8% in the control group), and 40% had zinc deficiency (*vs* 19% in the control group). The authors concluded that vitamin B12 and folate deficiencies are rare in children with newly-diagnosed IBD in the United States, so there is no reason to support their routine monitoring. On the other hand, vitamin A and zinc deficiencies were statistically more prevalent among the IBD cases than in controls, so their levels should be assessed at the time of their diagnosis to enable enteral supplementation to be started^[34]. Vitamin D deficiency was common in the population tested, so routine screening for this deficiency and supplementation are warranted. These results contrast with previous studies by Yakut *et al.*^[43] and Chowers *et al.*^[44].

To sum up on vitamin D, there is still no strong evidence in the literature of an association between circulating 25(OH)D concentrations and bone health outcomes, and an improvement in BMD in particular. Only partial benefits of administering vitamin D(3) (> 700 IU/d) and calcium supplementation have been seen in terms of BMD and a lower risk of fractures and falls, and only in specific subgroups^[41]. Supplementing vitamin D in pediatric patients is nonetheless generally recommended when its levels are found to be depleted, given its action not only on bone metabolism but also in terms of immunomodulation^[37,40].

BONE HEALTH AND PEDIATRIC CROHN'S DISEASE

Although current treatment strategies for CD that include therapy against TNF- α have been found to speed up growth, linear growth deficiencies persist even with optimized therapy^[22]. Children with CD continue to suffer from short stature and slow growth, and several studies have indicated that children with IBD may fail to achieve optimal bone mass^[45-47]. Children with CD have multiple

risk factors for impaired bone accrual^[48]. The skeleton is a highly dynamic tissue regulated by local, systemic, and environmental clues that modify osteoblastic (bone formation) and/or osteoclastic (bone reabsorption) activities. IBD affects bone regulation at all levels: environmentally through intestinal barrier breaks and/or a microbial composition in the gut; systemically with the circulation of gut immune cells and cytokines throughout the body; and locally by causing inflammation of extra-intestinal organs (such as the bone marrow)^[49].

Bone formation and reabsorption are significantly involved in bone health and growth. In children with CD, both of these processes are impaired, so bone growth is ultimately suboptimal^[49]. Factors contributing to this derangement are inflammation, delayed growth and puberty, lean mass deficiencies, and the use of glucocorticoids^[50,51]. A recent study by Irwin *et al.*^[52] examined the effect of experimental IBD on bone health. Interleukin-10-deficient animals infected with *Helicobacter hepaticus* (*H. hepaticus*) were used as a murine model of colitis, and the molecular and histological properties of their bone and intestine were examined to identify the immunopathological consequences of colitis in mice. Six weeks after they were infected, male (but not female) mice revealed significant trabecular bone loss in the distal femur and vertebrae. The authors concluded that the severity of *H. hepaticus*-induced colitis and the associated bone loss are gender-related, possibly as a result of gender-specific effects on *H. hepaticus* colonization in the mouse gastrointestinal tract and the consequent immunopathological responses^[52].

A prospective study by Kim *et al.*^[45] (Table 2) aimed to examine the risk factors and extent of bone mass reduction and to analyze the impact of IBD developing early, before bone mass has peaked (*i.e.*, before the maximal bone mineral density has been reached during development). Bone mineral density (BMD) was assessed in the lumbar spine and hip bone in 44 IBD patients (21 of them < 30 years old). Younger patients had a significantly more severe bone mass reduction in the lumbar spine than patients aged > 30 years (multivariate analysis showed a hazard ratio of 3.96, $P = 0.06$)^[45]. On the other hand, a recent prospective cohort study by Tsampalieros *et al.*^[53] (Table 2) suggested that younger age provides a window of opportunity for skeletal recovery. The aim of their study was to examine changes in BMD and cortical structure after CD had been diagnosed, and to identify associations with growth, glucocorticoids, and disease activity. The authors concluded that CD was associated with a persistently low trabecular BMD, although younger participants showed a greater potential for recovery. A greater linear growth was associated with a greater recovery of cortical dimensions, especially among participants with less glucocorticoid exposure and inflammation. So, although glucocorticoids and inflammation inhibit bone formation, their impact on skeletal modeling is still not clear^[53].

Another longitudinal study performed by Schmidt *et al.*^[51] (Table 2) on a total of 144 patients with IBD (including 83 with UC and 45 with CD) concluded that IBD

Table 2 Summary of the main studies that were reviewed on growth issues and bone health in pediatric Crohn's disease

| Ref. | Type of study | Patients | Results | Conclusion |
|--|----------------------------|--|---|--|
| Abraham <i>et al</i> ^[21] <i>J Clin Gastroenterol</i> 2012 | Systematic review | 3505 CD, 2071 UC, and 461 IBD-U (age at onset < 18 yr) | Growth failure was reported in CD (10% and 56%) more often than UC (0%-10%) or non-IBD controls; Improvements in growth occurred after surgical resection in CD pts; Increase in disease reclassification over time from UC and IBD-U Dg to CD; CD pts had higher number of hospitalizations and hospital days per year <i>vs</i> UC pts in most studies; The reported surgery rates in CD ranged between 10% and 72%; the colectomy rates in UC ranged between 0% and 50% | Childhood-onset IBD pts had growth failure reported in pts with CD more often than those with UC, and had a reclassification of disease type to CD over time; Higher rates of surgery and hospitalizations were found with CD than with UC |
| Kim <i>et al</i> ^[45] <i>Clin Endosc</i> 2013 | Prospective cohort study | 44 IBD (21 aged < 30 yr; 23 aged > 30 yr) | Significant bone mass reduction at the LS in IBD patients aged < 30 yr <i>vs</i> patients aged > 30 yr (BMD $P < 0.01$; T-score $P < 0.01$; Z-score $P < 0.01$); Multivariate analysis: risk factor of bone mass reduction for patients < 30 yr \rightarrow HR = 3.96, $P = 0.06$ | Bone mass reduction is more severe in patients diagnosed with IBD before the age of 30 yr |
| Schmidt <i>et al</i> ^[51] <i>J Pediatr Gastroenterol Nutr</i> 2012 | Longitudinal cohort study | 144 IBD pts (83 UC, 45 CD) | Children with UC and CD had significantly lower mean BMD Z-scores for the LS at baseline and after 2 yr; The reduction in BMD was equally pronounced in patients with UC and CD; Neither group improved their Z-score during the follow-up period; Significantly lower mean BMD Z-scores for the LS were found at baseline in M ($P < 0.001$), but not in F; Lowest BMD values in the group of patients ages 17 to 19 yr in M and in F | The entire group of pediatric patients with IBD showed permanent decreases in their BMD Z-scores for the LS; however, afflicted children have the potential to improve their BMD by the time they reach early adulthood |
| Tsampalieros <i>et al</i> ^[53] <i>J Clin Endocrinol Metab</i> 2013 | Prospective cohort study | CD (age 5-21) | Disease activity improved over the study interval ($P < 0.001$); Trabecular BMD-Z improved over the first 6 mo; Increases associated with improved disease activity ($P < 0.001$), younger age ($P = 0.005$), and increases in vitamin D levels ($P = 0.02$); Greater increases in tibia length associated with greater increases in cortical area-Z ($P < 0.001$); Greater glucocorticoid doses and disease activity significantly associated with failure to accrue cortical area, and more pronounced with greater linear growth (interaction $P < 0.05$); Mean \pm SD trabecular BMD and cortical area Z-scores significantly reduced at the final visit | CD was associated with persistent deficits in trabecular BMD; Younger participants demonstrated greater potential for recovery; Greater linear growth associated with greater recovery of cortical dimensions, especially among participants with lesser glucocorticoid exposure and inflammation; Younger age and concurrent growth provide a window of opportunity for skeletal recovery |
| Malik <i>et al</i> ^[54] <i>J Crohns Colitis</i> 2012 | Prospective cohort study | 36 children with CD (Male 22) | 28 (78%) CD children treated with adalimumab went into remission; Overall 42% of children showed catch-up growth, which was more likely in: Pts who achieved remission ($P = 0.007$); Pts who were on immunosuppression ($P = 0.03$); Pts whose indication for adalimumab was an allergic reaction to infliximab ($P = 0.02$); Pts who were on prednisolone when starting adalimumab, ($P = 0.04$) | Clinical response to adalimumab is associated with an improvement in linear growth in a proportion of children with CD; Improved growth is more likely in patients entering remission and on immunosuppression but is not solely due to a steroid sparing effect |
| Malik <i>et al</i> ^[55] <i>Arch Dis Child</i> 2012 | Retrospective cohort study | 116 CD children; 68 M; Mean age at diagnosis 10.8 yr (range 4.9-15.5); Mean age at maximum follow-up of 15.4 yr (9.4-19.3) | At T0, mean height SD score was -0.5 (-3.3-2.6) compared to a mid-parental mean height SD score of 0.2 (-2.0-1.4) ($P = 0.002$); At T1, T2, T3, and maximum follow-up, mean height SD score was -0.6 (-4.8-7.8), -0.6 (-2.9-2.2), -0.7 (-3.6- 2.5) and -0.5 (-3.5-2.9), respectively; Mean Ht velocity SDS at T1, T2, T3 and maximum follow-up was -1.4 (-7.4-7.4), -0.6 (-7.5-6.1), -0.1 (-6.6 -7.6) and 0.6 (-4.8-7.8), respectively ($P < 0.05$) | In final models: Mean Ht velocity SDS was associated negatively with the use of prednisolone ($P = 0.0001$), azathioprine ($P = 0.0001$), methotrexate ($P = 0.0001$), and weight SDS (WtSDS) $P = 0.0001$; Mean Ht velocity SDS was associated positively with age ($P = 0.0001$) and Wt SDS ($P = 0.01$); Δ Ht SDS was associated negatively with use of prednisolone ($P < 0.02$) |

|--|------------------------------|--|---|--|
| Laakso <i>et al</i> ^[56] <i>Calcif Tissue Int</i> 2012 | Cross-sectional Cohort Study | 80 IBD pts (median age 14.9 yr, range 5-20), median disease duration 3.4 yr; 51 UC, 26 CD, and 3 IBD-U | IBD pts had lower bone age-adjusted LS and whole-body areal BMD ($P < 0.001$ for both) and whole-body composition adjusted for Ht ($P = 0.02$) than controls; Lean mass and fat mass Z-scores did not differ between the groups, but IBD patients had lower whole-body composition relative to muscle mass ($P = 0.006$); Vitamin D deficiency in 48%, despite vitamin D supplementation; In IBD cumulative weight-adjusted prednisolone dose > 150 mg/kg for the preceding 3 yr increased the risk for low whole-body areal BMD (OR = 5.5, 95% CI: 1.3-23.3, $P = 0.02$). Vertebral fractures found in 11% of patients and in 3% of controls ($P = 0.02$) | IBD in childhood was associated with low areal BMD and reduced bone mass accrual relative to muscle mass; The risk for subclinical vertebral fractures may be increased; Careful follow-up and active preventive measures are needed |
| Ahmed <i>et al</i> ^[60] <i>J Pediatr Gastroenterol Nutr</i> 2004 | Prospective cohort study | 47 CD and 26 UC (median age of 13.5 yr - range, 5.5-18.2 yr) | Pts with CD were shorter than those with UC ($P < 0.05$); Median ppBone Area for LS and total body for the whole group was 85% and 81%, respectively; ppBone Area at both sites was directly related to height SDS and BMI SDS ($r > 0.5$; $P < 0.005$); Median BMD SDS for LS and total body was -1.6 and -0.9, respectively; Median ppBMC for LS and total bone was 98% and 101%, respectively; ppBMC showed no relationship to ppBone Area ($r = 0.1$, NS); Children with osteopenia 22% after adjustment for bone area | Children with IBD often have small bones for age because they have growth retardation; When DXA data are interpreted with adjustment for bone size, most children have adequate bone mass; Correct interpretation of DXA is important for identifying children who may be at a real risk of osteoporosis |
| Burnham <i>et al</i> ^[61] <i>J Bone Miner Res</i> 2004 | Prospective cohort study | 104 children and young adults with CD 233 healthy controls (age 4-26) | CD pts had significantly lower Ht Z-score, BMI Z-score, and lean mass relative to Ht compared with controls (all $P < 0.0001$); After adjustment for group differences in age, Ht, and race, the ratio of BMC in CD relative to controls was significantly reduced in M (0.86; 95% CI: 0.83-0.94) and F (0.91; 95% CI: 0.85-0.98) with CD; Adjustment for pubertal maturation did not alter the estimate; addition of lean mass to the model eliminated the bone deficit; Steroid exposure was associated with short stature but not bone deficits | Importance of considering differences in body size and composition when interpreting DXA data in children with chronic inflammatory conditions; Association between deficits in muscle mass and bone in pediatric CD |
| Boot <i>et al</i> ^[62] <i>Gut</i> 1998 | Prospective cohort study | 55 pts (34 M 21 F, age range 4-18 yr) 22 CD, 33 UC | Mean SDS of LS BMD and total body BMD were significantly lower than normal (-0.75 and -0.95, both $P < 0.001$); Height SDS and BMI SDS were decreased. The decrease in BMD SDS could not be explained by delay in bone maturation; The cumulative dose of prednisolone correlated negatively with LS BMD SDS ($r = -0.32$, $P < 0.02$); BMI SDS correlated positively with total body BMD SDS ($r = 0.36$, $P < 0.02$); CD pts had significantly lower LS and total BMD SDS than UC pts, even after adjustment for cumulative dose of prednisolone; In the longitudinal data cumulative dose of prednisolone between the measurements correlated negatively with the change in LS and total BMD SDS; Lean tissue mass measured by dual X-ray absorptiometry had a strong correlation with lean body mass measured by bioelectrical impedance analysis ($r = 0.98$) | IBD children have a decreased BMD; CD children have a higher risk of developing osteopenia than UC children; Corticosteroid therapy and nutritional status are important determinants of BMD in IBD pts |

Dg: Diagnosis; pt/pts: Patient/patients; CD: Crohn's disease; UC: Ulcerative colitis; IBD-U: Unclassified IBD; rhGH: Recombinant growth factor; ESR: Erythrocyte sedimentation rate; BMC: Body cell mass; BMI: Body mass index; Ht: Height; Wt: Weight; BMD: Bone mineral density; DXA: Dual-energy X-ray absorptiometry; EEN: Exclusive enteral nutrition; GH: Growth hormone; (P)CDAI: (Pediatric) Crohn's disease activity index; PUCAI: Pediatric ulcerative colitis activity index; M: Male; F: Female.

children have the potential to improve their BMD by the time they reach early adulthood. Children with UC and CD had significantly lower mean BMD Z-scores for the lumbar spine (LS), both at the baseline and after 2 years.

Sub-analyses of the different age groups at the baseline found the lowest BMD values for patients aged 17 to 19 years, be they boys or girls; at follow-up, these patients' BMD had significantly improved, however^[51].

A recent study by Malik *et al*^[54] (Table 2) assessed the frequency of short stature and poor growth, and how they correlated with the course of the disease and the therapy administered in children with CD. The anthropometric and treatment details regarding 116 children showed that mean height SDS was negatively associated with the use of prednisolone ($P = 0.0001$), azathioprine ($P = 0.0001$), or methotrexate ($P = 0.0001$) and with weight SDS (Wt SDS) ($P = 0.0001$)^[54]. Another study by Malik *et al*^[55] (Table 2) focused on growth and disease activity over 12 mo in 36 children with CD who started taking adalimumab. Disease remission was achieved in 78% of these cases, and an overall 42% of the children caught up in terms of their growth. This was more likely to happen for those in remission, taking immunosuppressants, and those starting adalimumab therapy due to an allergic reaction to infliximab. An increase in growth rate was also seen in 15 children who were on prednisolone therapy when they started taking adalimumab. The authors concluded that clinical response to adalimumab therapy is associated with an improvement in linear growth in some children with CD, and that this is more likely for patients entering remission and on immunosuppression, although the effect is not due to a steroid-sparing effect alone^[55].

Another recent cross-sectional cohort study by Laakso *et al*^[56] (Table 2) compared the skeletal characteristics of 80 children and adolescents suffering from IBD with 80 healthy controls matched for age and gender. The IBD patients had a lower bone age (BA)-adjusted lumbar spine, total body bone area BMD ($P < 0.001$ for both), and whole-body bone mineral content (BMC) than controls, after adjusting for height ($P = 0.02$). Lean mass and fat mass z-scores did not differ between the groups, but IBD patients had a lower whole-body BMC relative to muscle mass ($P = 0.006$). Despite 48% of the IBD patients receiving vitamin D supplementation, deficiencies of this vitamin were common. In the IBD group, a cumulative weight-adjusted prednisolone dose > 150 mg/kg for the preceding 3 years increased the risk of low whole-body aBMD ($P = 0.02$). Vertebral fractures (VFs) were found in 11% of patients and 3% of controls ($P = 0.02$). The authors concluded that IBD in childhood is associated with a low aBMD and reduced bone mass accrual relative to muscle mass; the risk of subclinical VFs may increase. These observations warrant careful follow-up and active preventive measures^[56].

There is a well-established relationship between the long-term use of glucocorticoids for any disease indication and a higher risk of osteoporosis and fractures^[57-59], but the relationship between CD or UC and bone loss remains controversial. Inability to achieve peak bone mass when the disease starts in childhood, malnutrition, immobilization, low BMI, smoking, and hypogonadism may all have a part to play in the pathogenesis of bone loss. Although evidence is sparse on the topic of bone health in children and adolescents with IBD, most authors recommend bone health screening, monitoring growth parameters and pubertal development, checking vitamin

D status and vitamin D and calcium intake, and prescribing exercise and nutritional support^[30]. Bone health status should be assessed systematically in patients treated for more than 6 mo, particularly during puberty^[50].

Assessing BMD with dual energy X-ray absorptiometry (DXA) generally involves a comparison with age- and gender-matched reference ranges, and such studies show a high prevalence of osteopenia in children with IBD^[60]. A recent study by Ahmed *et al*^[60] (Table 2) aimed to compare the prevalence of osteopenia using two interpretation methods, one adjusted for age and gender, the other adjusted for bone size and gender. Forty-seven patients with CD and 26 with UC were considered, and the former were found shorter than the latter (median height, SDS, -0.9 vs 0 , $P < 0.05$). The authors concluded that children with IBD often have small bones for their age because they have a growth deficiency. When DXA data were interpreted after adjusting for bone size, most of the children were found to have an adequate bone mass. It is therefore important to interpret DXA findings correctly to identify children who may be at real risk of osteoporosis^[60].

A study by Burnham *et al*^[61] (Table 2) was designed to assess BMC relative to growth, body composition, and maturation in CD cases compared with controls. Whole-body BMC and lean mass were assessed by DXA in 104 CD subjects and 233 healthy controls. CD was associated with significant deficits in BMC and lean mass, relative to height. Individuals with CD had significantly lower z-scores for height and BMI, and a lower lean mass relative to height than controls ($P < 0.0001$). After adjusting for group differences in age, height, and race, males and females with CD had a significantly lower BMC than controls. Steroid exposure was associated with short stature but not with bone deficits. This study pointed to the importance of considering differences in body size and composition when interpreting DXA data in children with chronic inflammatory conditions, as well as showing an association between deficits in muscle mass and bone in pediatric CD^[61].

A study by Boot *et al*^[62] (Table 2) assessed BMD, nutritional status, and determinants of BMD in 55 children with IBD (34 boys and 21 girls, age range 4-18 years; 22 years with CD, 33 years with UC). The mean SDS for lumbar spine BMD and total body BMD were significantly lower than normal (both $P < 0.001$). The SDS for height and BMI were low as well. The decrease in BMD SDS could not be explained by any delay in bone maturation. The cumulative dose of prednisolone correlated negatively with lumbar spine BMD SDS ($P < 0.02$). Patients with CD had significantly lower lumbar spine and total body BMD SDS than patients with UC, even after adjusting for the cumulative dose of prednisolone. The authors concluded that: children with IBD have a reduced BMD; children with CD are at higher risk of osteopenia than children with UC; and corticosteroid therapy and nutritional status are important determinants of BMD in these patients^[62].

A very interesting report from Whitten *et al*^[63] sup-

ported the role of enteral nutrition in improving bone metabolism. The authors enrolled 23 children with newly-diagnosed CD and 20 controls. Children with CD were treated for 8 weeks with EEN, and inflammatory markers, nutritional markers (height, weight), bone markers [C-terminal telopeptides of Type-1 collagen (CTX), and bone-specific alkaline phosphatase (BAP)] were measured before and after the treatment. At diagnosis, children with CD had higher serum CTX than controls ($P = 0.0003$). After the period of EEN, their CTX levels fell significantly ($P = 0.002$), and their serum BAP levels ($P = 0.07$) increased significantly ($P = 0.02$), both normalizing to control levels. This evidence indicates that, as well as reducing inflammation, decreasing disease activity, and improving nutrition in children with newly-diagnosed CD, EEN therapy also normalizes serum markers of bone turnover, suggesting an improvement in bone health^[63].

To sum up, although current therapy for CD is associated with a better growth rate for the first few years, a substantial proportion of children with CD remain short. Depending on the population considered, the prevalence of osteoporosis has been variably reported to range from 12% to 42% in patients with IBD^[13]. While prospective studies suggest sustained bone loss at both trabecular and cortical sites in long-term glucocorticoid users with IBD^[57], a decrease in bone mass is also seen in patients with active CD not using glucocorticoids^[49,50]. Be that as it may, it is strongly recommended that excessively long periods of corticosteroid therapy be scrupulously avoided, particularly for patients of developmental age, and enteral nutrition should be used (whenever possible) as an alternative front-line therapy because it helps to contain the need for corticosteroids and thus limits their unwanted effects on growth, as well as cosmetic issues (which are very important in adolescence)^[22]. Data on vertebral fractures are scarce and there is no agreement about the risk of non-vertebral fractures in patients with CD, though it has been suggested that patients with IBD may carry a 60% higher risk of non-vertebral fractures. The main question is whether all patients with CD should be treated with bone-protecting agents on the assumption that they could all potentially develop osteoporosis, or whether these agents should be used only in patients clearly at risk of osteoporosis and fractures (providing such patients can be identified)^[49].

PUBERTY-RELATED ISSUES IN PEDIATRIC CROHN'S DISEASE

Many nutritional, inflammatory, immunological, and endocrine factors affecting patients suffering from IBD and influencing their growth also have an important impact on the initiation and progression of puberty. The onset of IBD before puberty is frequently associated with an underdeveloped stature and weight, and with patients having a significantly slower growth rate and lower final height by comparison with the parental target. This is more evident in children with CD than in cases of

UC^[64,65]. Other correlations include delayed puberty and menarche, an extended duration of the pubertal phase, and secondary amenorrhea^[64]. Potential causes of late puberty in patients developing IBD in pre-pubertal and pubertal age include^[64]: (1) malnutrition: this correlates mainly with a delay in menarche and sexual maturity. A link has been suggested between late puberty and reduced fat mass, which is normally rich in the aromatases that induce the conversion of androgens into estrogens and the consequent active production of female hormones; and (2) interactions between proinflammatory cytokines and the endocrine system: endocrine functions seem to be disrupted in IBD patients, also due to a direct effect of proinflammatory cytokines, such as TNF- α , IL-6, and IL-1 β , on hormonal feedback mechanisms.

A recent retrospective study by Mason *et al*^[66] (Table 3) aimed to ascertain the impact of CD and UC on the pubertal growth spurt. Pubertal growth was assessed by calculating peak height velocity (HV) SDS (PHV SDS), height SDS at diagnosis, height SDS at PHV, and age at PHV in patients with CD (30 boys, 11 girls) and UC (14 boys and 12 girls). Systemic markers of disease activity were also recorded. Altered pubertal growth parameters were apparent in the CD cases by comparison with the normal population, particularly in boys. In the group as a whole, age (PHV) showed an association with erythrocyte sedimentation rate ($r = 0.4$; $P = 0.005$) and an inverse association with BMI ($r = 0.4$; $P = 0.001$)^[66].

MANAGEMENT OF GROWTH AND PUBERTAL ISSUES IN PEDIATRIC CROHN'S DISEASE

Healthy children grow at an annual rate of 4–6 cm up until puberty, when their rate of growth doubles for over a year^[22]. A declining trend in growth chart percentiles for height and weight arouses the suspicion of growth deficiency vis-à-vis a child's targets for gender and age^[22]. An early diagnosis of CD is fundamentally important, but the early signs of IBD vary and can easily go unnoticed, meaning that a statural growth deficiency and concomitant late puberty quite often precede the intestinal manifestations of the disease^[22]. It is essential to monitor patients' growth, taking their initial height (as measured before the onset of IBD) for reference and routinely reassessing patients as their disease evolves in order to fully appreciate its impact on their growth^[22]. Monitoring patients' growth rate is also important to see how they are responding to therapy over time^[22]. Precise serial check-ups should always include an assessment of patients' pubertal development, which should be correlated with their statural growth. If any discrepancies come to light, action can be taken without delay: radiology is used to establish patients' skeletal age and thus identify their residual potential for growth^[22]. On average, it takes about 12 mo to see any response to treatment in terms of linear growth or pubertal development, so the intervals

Table 3 Summary of the main studies that were reviewed on management of growth and pubertal issues in pediatric Crohn's disease

| Ref. | Type of study | Patients | Results | Conclusion |
|--|--|--|---|---|
| Mason <i>et al</i> ^[66] <i>Horm Res Paediatr</i> 2011 | Retrospective cohort study | IBD adolescents 41 with CD, 30 M 11 F 26 with UC, 14 M 12 F | Altered parameters of pubertal growth observed in the CD groups compared to the normal population: In the CD M group, median Ht at Dg was -0.56 ($P = 0.001$) and median age at peak Ht velocity was 14.45 yr ($P = 0.004$) In the CD F group, median Ht at Dg was -1.14 ($P = 0.007$) and Ht at peak Ht velocity was -0.79 ($P = 0.039$). Individually, 8/30 CD M cases had one or more parameter affected: In the whole group, age at peak Ht velocity showed an association with ESR ($r = 0.4$; $P = 0.005$) and an inverse association with BMI ($r = 0.4$; $P = 0.001$) | Disorders of pubertal growth are more likely to occur in CD (particularly M) |
| Tietjen <i>et al</i> ^[69] <i>Turk J Gastroenterol</i> 2009 | Prospective cohort study | 40 pts with CD 26 M, 14 F mean age 16,7 yr (median: 17 yr, range: 4-29 yr) | Urinary GH levels were found as normal in CD; Corticosteroid therapy did not appear to be the most responsible factor for growth failure in CD | Growth failure in patients with CD is not caused by GH deficiency; A high PCDAI score has an important impact on impaired growth in children and adolescents with CD |
| Wong <i>et al</i> ^[70] <i>J Pediatr Endocrinol Metab</i> 2007 | Retrospective data analysis | 7 pts with CD 5 M | Median chronological age and median difference between chronological age and bone age was 15.9 yr (range, 13.0-17.9 yr) and 1.7 yr (-0.7-3.3 yr), respectively; Median dose of rhGH at T+0 was 0.23 mg/wk (0.15-0.31); Pubertal status remained unchanged in 6/7 patients; Median albumin and C-reactive protein were similar at T+0 and T+6; Median height SDS at T+0, T+6 and T+12 was -2.2 (-4.0 to -1.5), -1.9 (-4.1 to -0.8), -1.9 (-4.1 to -0.7), respectively (NS). Median Ht velocity SDS at T+0 and T+6 was -2.5 (-4.8-1.4) and -0.9 (-5.3 to 3.4), respectively (NS); Positive correlation between percentage change in Ht velocity SDS at T+6 and dose of rhGH at T+0 ($r = 0.8$, $P = 0.03$) | Introduction of rhGH therapy was associated with a cessation in the deterioration in linear growth; An improvement in Ht SDS was not observed over the period of the study |
| Wong <i>et al</i> ^[71] <i>Clin Endocrinol (Oxf)</i> 2011 | Randomized controlled trial in 2 tertiary Children's Hospitals | 22 children with IBD 21 with CD | Median Ht velocity increased from 4.5 (range, 0.6-8.9) at baseline to 10.8 (6.1-15) cm/year at 6 mo ($P = 0.003$) in the rhGH group, whereas in the Ctrl group, it was 3.8 (1.4-6.7) and 3.5 cm/yr (2-9.6), respectively ($P = 0.58$); Median percentage increase in Ht velocity after 6 mo in the rhGH group was 140% (16.7%-916.7%) compared with 17.4% (-42.1%-97.7%) in the Ctrl group ($P < 0.001$). No significant differences in disease activity and proinflammatory cytokines at baseline and 6 mo in both groups | rhGH can improve short-term linear growth in children with CD; The clinical efficacy of this therapy needs to be further studied in longer-term studies of growth, glucose homeostasis, and disease status |

Dg: Diagnosis; pt/pts: Patient/patients; CD: Crohn's disease; UC: Ulcerative Colitis; IBD-U: Unclassified IBD; rhGH: Recombinant growth factor; ESR: Erythrocyte sedimentation rate; BMC: Body cell mass; BMI: Body mass index; Ht: Height; Wt: Weight; BMD: Bone mineral density; DXA: Dual-energy X-ray absorptiometry; EEN: Exclusive enteral nutrition; GH: Growth hormone; (P)CDAI: (Pediatric) Crohn's disease activity index; PUCAI: Pediatric ulcerative colitis activity index; M: Male; F: Female; NS: Not significant.

between follow-up assessments should never be less than six months^[22].

To prevent and manage growth deficiencies in pediatric IBD patients, we must first establish the most appropriate nutritional, pharmacological, and surgical treatment for their underlying disease: managing their chronic inflammatory status and providing adequate nutrition are two synergically interacting aspects of the same approach^[22]. Ensuring long-term control of active inflammation and administering an adequate intake of nutrients are both fundamental to promoting normal puberty^[64]. Controlled clinical trials have documented a significant correlation between enteral nutrition, a reduced mucosal production of cytokines, and endoscopic healing. Enteral nutrition is potentially capable of inducing remission and

achieving a nutritional recovery. Trials have also established that the effect of exclusively enteral nutrition on the inflammatory picture is influenced by factors such as the disease being localized in the small intestine or of recent onset, whereas the age factor appears to be less influential^[22]. Immunomodulators other than corticosteroids used for pediatric IBD include the thiopurines (azathioprine and 6-mercaptopurine), which are used to maintain remission and have no demonstrated side-effects on growth, and biologics (infliximab and adalimumab), which potentially improve growth velocity by inducing and maintaining disease remission. Artificially-inducing puberty with the aid of estrogens and testosterone carries the risk of causing early growth cartilage calcification, giving rise to statural deficiencies^[64].

Role of treatment with recombinant growth factor for pediatric Crohn's disease

Current treatment strategies for CD that include therapy against TNF- α have been found to improve growth velocity, but linear growth deficiencies persist even with optimized therapy^[67]. Through complex mechanisms that include reducing IGF-1 levels and inducing systemic and hepatic GH resistance, cytokines such as TNF- α and IL-6 - which are commonly elevated in active CD - are important mediators of linear growth delay^[68]. The potential for linear growth impairment as a complication of chronic intestinal inflammation is unique to pediatric CD patient populations^[67]. IGF-I, produced by the liver in response to GH stimulation, is the key mediator of GH effects on the growth plate of bones. There is a well-known association between impaired growth in children with CD and low IGF-I levels. Early studies emphasized the role of malnutrition in suppressing IGF-I production. The direct, growth-inhibiting effects of pro-inflammatory cytokines have been increasingly recognized and explored. The role of non-cytokine factors (such as lipopolysaccharides) and their potential for negatively influencing the growth axis have also been investigated^[67]. Recent evidence suggests that recombinant growth factor (rhGH) therapy is effective in improving short-term linear growth in selected patients^[2], but is of limited benefit as a therapy for improving mucosal disease or reducing clinical disease activity^[67]. A clinical analysis was performed by Tietjen *et al*^[69] (Table 3) on 40 children, adolescents, and young adults with CD to see whether their growth failure was caused by impaired GH secretion. To assess growth hormone excretion, the authors measured urinary growth hormone with an in vitro immunoradiometric assay in three morning urine samples. They found normal urinary growth hormone levels in CD, concluding that growth failure in patients with CD is not caused by GH deficiency. Corticosteroid therapy did not appear to be the main culprit responsible for growth failure in CD either^[69]. A retrospective data analysis was conducted by Wong *et al*^[70] (Table 3) on 7 patients with CD treated with rhGH, after which the deterioration in their linear growth came to a stop, but no improvement in their height SDS was observed during the study period^[70]. Another randomized controlled trial at two tertiary children's hospitals on 22 children with IBD (21 being cases of CD)^[71] (Table 3) investigated the effects of rhGH on HV and glucose homeostasis over a 6-mo period. The median HV increased from 4.5 (range 0.6-8.9) at the baseline to 10.8 (6.1-15) cm/year at 6 mo ($P = 0.003$) in the rhGH group, while in the control group it was 3.8 (1.4-6.7) and 3.5 cm/year (2.0-9.6), respectively ($P = 0.58$). The median percentage increase in HV over 6 mo was 140% (16.7-916.7) in the rhGH group and 17.4% (42.1-97.7) in the control group ($P < 0.001$). There were no significant differences in disease activity or pro-inflammatory cytokines at the baseline or after 6 mo in either group, and the change in bone age for chronological age was also similar in the two groups^[71]. This was

the first randomized controlled trial on rhGH in children with IBD and growth retardation, and it showed - albeit over a brief period of 6 mo - that a dose of 0.067 mg/kg per day of rhGH improves linear growth. The authors also emphasized the continuing need to optimize the child's disease status (*i.e.*, to induce and maintain remission of IBD activity), as they found a greater growth response to rhGH in patients in biochemical remission. In short, although these data provide evidence of the efficacy of rhGH treatment in terms of height velocity over a short- to medium-term follow-up, patients treated with GH experienced no significant improvements in disease activity and pro-inflammatory cytokines by comparison with controls; and long-term follow-up data are lacking. In conclusion, based on currently-available evidence, the efficacy of rhGH in treating growth failure associated with CD is still unclear, and future studies should explore the use of higher doses of rhGH in CD^[70].

CONCLUSION

Despite current treatment strategies for CD including anti-TNF- α medication, short stature and slow growth are still encountered in children with CD. Several studies have shown that children with IBD may not achieve optimal bone mass^[25], and those with CD have multiple risk factors for impaired bone accrual^[22]. A declining trend in growth chart percentiles for height and weight with respect to a patient's targets for gender and age should arouse the suspicion of a growth deficiency^[22]. An early diagnosis is fundamentally important, but signs of the onset of IBD vary and can easily go unnoticed, meaning that statural growth deficiencies and concomitant late puberty quite often precede the intestinal manifestations of the disease^[64].

Nutritional concerns are common in pediatric CD patients, who are often underweight at presentation^[1]. Undernutrition has been reported in up to 65%-75% of such patients^[25], and a low dietary intake due to poor appetite and aversion to food is a major cause of undernutrition in pediatric IBD, though the systemic release of proinflammatory cytokines also contributes significantly^[26]. Although medical treatment can quickly restore body weight, this does not reflect concomitant changes in patients' body composition, which is characterized by normal fat stores but depleted lean mass. Poor bone health, delayed puberty, and growth failure may also complicate these patients' clinical management^[26]. Vitamin and mineral deficiencies have been described in patients with IBD and are attributed to mucosal inflammation in the gut and a low oral intake. Although 25(OH) vitamin D levels have yet to be convincingly demonstrated to correlate with BMD^[56], poor vitamin D status may have detrimental consequences for any child's future health, so an optimal vitamin D status still represents a crucial public health goal^[37]. Corticosteroid therapy and nutritional status are important determinants of BMD in CD patients^[49].

It is indispensable to monitor CD patients' growth, taking their initial height as a reference and routinely reassessing them as their disease evolves in order to fully appreciate its impact on their growth^[22]. Monitoring patients' growth rate is also essential to enable their response to therapy to be assessed over time^[22]. Precise serial check-ups should always include an assessment of patients' pubertal development, which should be correlated with their statural growth, so that action can be taken without delay in the event of any discrepancies coming to light. A radiological examination of patients' skeletal age enables their residual potential for growth to be identified^[22]. Recent evidence suggests that rhGH therapy is effective in improving short-term linear growth for a selected group of CD patients, but is of limited benefit as a therapy for improving mucosal disease and reducing its clinical activity^[70]. Exclusive enteral nutrition is a potentially effective option for treating CD because it can improve patients' nutritional state as well as inducing disease remission (mucosal healing) just as quickly as corticosteroids^[1,27].

Abstract

Of the diverse biological agents used for patients with ulcerative colitis, the anti-tumor necrosis factor- α agents infliximab and adalimumab have been used in large-scale clinical trials and are currently widely used in the treatment of inflammatory bowel disease patients. Recent studies have indicated that golimumab, oral tofacitinib and vedolizumab reportedly achieved good clinical response and remission rates in ulcerative colitis patients. Thus, we believe that the detailed investigation of various studies on clinical trials may provide important information for the selection of appropriate biological agents, and therefore, we have extensively reviewed such trials in the present study.

Key words: Ulcerative colitis; Immune dysfunction; Biological therapy; Remission; Clinical trial; Inflammatory bowel disease

Core tip: In the last two years, the use of the Janus kinase 3 inhibitor (oral tofacitinib) and the $\alpha 4\beta 7$ integrin

blocker (vedolizumab) reportedly achieved good clinical response and remission rates in ulcerative colitis patients. Thus, we believe that the detailed investigation of various studies on clinical trials performed thus far may provide important information for the selection of appropriate biological agents, and therefore, we have extensively reviewed such trials in the present study.

INTRODUCTION

Inflammatory bowel disease (IBD), which is broadly classified as ulcerative colitis (UC) and Crohn's disease (CD), is characterized by chronic intestinal inflammation. Although its causes have not been clearly understood, it is believed to be influenced by genetic susceptibility, changes in the commensal enteric flora, and immune imbalance^[1-5]. Increase in the production of T cells, cytokines, and chemokines, as well as increased trafficking of immune cells is associated with immune imbalance, and is considered as therapeutic targets for the biological treatment of IBD^[6-9]. The current treatment goals of UC include induction of clinical remission, maintenance of clinical remission, and prevention of UC-related complications^[10,11].

Although the therapeutic agents of UC, such as aminosalicylates, corticosteroids, thiopurines, and cyclosporine, are effective in most cases, biological agents are needed in cases where the disease is refractory or intolerant to therapeutic agents. Anti-tumor necrosis factor (TNF)- α agents are biological agents that are relatively safe and have been utilized for a long duration in UC patients. Anti-TNF- α agents appear to exert their effects

Table 1 Summary of ACT1, ACT2, ULTRA1 and ULTRA2 trials for moderate-to-severe ulcerative colitis

| Trial | Clinical scenario | Drug | Dosage | Patients (n) | Follow-up (wk) | Outcome and P value |
|---|------------------------------|------------|--|--------------|----------------|---|
| ACT1 Rutgeerts <i>et al</i> ^[12] | Moderate-to-severe active UC | Infliximab | 5 mg/kg IV 10 mg/kg IV (intravenously at weeks 0, 2, and 6 and then every eight weeks) | 121 122 | 54 | Clinical response at week 8 (placebo/5 mg/10 mg) -37.2%/69.4%/61.5% ($P < 0.001$, $P < 0.001$) Clinical remission at week 8 -14.9%/38.8%/32.0% ($P < 0.001$, $P = 0.002$) Clinical remission at week 54 -8.9%/25.7%/16.4% ($P = 0.006$, $P = 0.149$) |
| ACT2 Rutgeerts <i>et al</i> ^[12] | Moderate-to-severe active UC | Infliximab | 5 mg/kg IV 10 mg/kg IV | 121 120 | 30 | Clinical response at week 8 (placebo/5 mg/10 mg) -29.3%/64.5%/69.2% ($P < 0.001$, $P < 0.001$) Clinical remission at week 8 -5.7%/33.9%/27.5% ($P < 0.001$, $P < 0.001$) Clinical remission at week 30 -3.3%/18.3%/27.3% ($P = 0.010$, $P < 0.001$) |
| ULTRA1 Reinisch <i>et al</i> ^[15] | Moderate-to-severe active UC | Adalimumab | 160/80 mg SC (160 mg at week 0, 80 mg at week 2, 40 mg at weeks 4 and 6) 80/40 mg SC (80 mg at week 0, 40 mg at weeks 2, 4 and 6) | 130 130 | 8 | Clinical remission at week 8 (placebo/ADA160/80mg/ADA80/40 mg) -9.2%/18.5%/10.0% ($P = 0.031$, $P = 0.833$) |
| ULTRA2 Sandborn <i>et al</i> ^[16] | Moderate-to-severe active UC | Adalimumab | 160/80 mg SC (160 mg at week 0, 80 mg at week 2, and then 40 mg every other week) | 248 | 52 | Clinical remission at week 8 (placebo/ADA) -9.3%/16.5% ($P = 0.019$) Clinical remission at week 52 -8.5%/17.3% ($P = 0.004$) |

UC: Ulcerative colitis; ADA: Adalimumab.

by inhibiting the large amount of TNF- α present in the deeper layers of colonic tissues in UC patients^[7]. In addition to anti-TNF- α agents, many studies have been performed on the use of molecules involved in varied inflammatory pathways as biological agents. However, in the present study, we aimed to focus on the mechanism of action, clinical outcomes, and future prospects of infliximab, adalimumab, and golimumab (anti-TNF- α agents); tofacitinib (a Janus kinase (JAK) 3 inhibitor); and vedolizumab (an $\alpha 4\beta 7$ integrin blocker).

ANTI-TNF- α AGENTS: CLASSIC OR NEW GENERATION

Infliximab and adalimumab, the most commonly used anti-TNF- α agents at present, are administered intravenously and subcutaneously, respectively, and have been found to be effective for the treatment of moderate-to-severe UC in clinical trials. Anti-TNF- α , which was first officially approved by the US Food and Drug Administration (FDA) for the treatment of CD in 1998, was also approved by the FDA for the treatment of UC in 2010.

Both infliximab - chimeric mouse-human recombinant monoclonal antibody (25% murine and 75% human) - and adalimumab - completely human anti-TNF- α IgG1 - exert their effects by binding to free and membrane-bound TNF- α in order to prevent TNF- α from attaching to TNF-receptor type1/receptor type2. In ACT1 and ACT2 studies that reported the

effects of infliximab in UC patients^[12], no difference in the effect was noted between the 5-mg/kg administration group and the 10-mg/kg administration group, although a marked improvement was observed in the clinical response and remission rates after 8 wk ($P < 0.001$, Table 1), along with a significant improvement in mucosal healing ($P < 0.001$). Similar effects in the clinical remission rate were observed after 30 and 54 wk of treatment (Table 1). No differences in adverse effects were noted between the infliximab and placebo groups. Moreover, infliximab is well known as a useful rescue therapy to avoid colectomy^[13,14].

In the first 8-wk multicenter randomized controlled study that utilized adalimumab, defined as ULTRA 1, the subjects were divided into 160/80 mg and 80/40 mg groups, based on the loading dose, and were then compared with the placebo group^[15]. The clinical remission rate at week 8 in the adalimumab 160/80 mg group was 2 times higher than that of the placebo group, whereas this value in the adalimumab 80/40 mg group did not differ from that of the placebo group. Thereafter, a 52-wk randomized controlled study, defined as ULTRA2, was performed, which indicated that the clinical remission rate at week 52 in the adalimumab 160/80 mg group was 2 times higher than that of the placebo group ($P = 0.004$, Table 1)^[16]. Following a subanalysis, it was observed that the anti-TNF- α naïve patient group exhibited approximately 2 times higher clinical remission rates at week 8 and week 52, respectively compared to the placebo group (21.3% *vs* 11.0%, 22.0% *vs* 12.4%) In the recently per-

Table 2 Studies for the use of Golimumab, Tofacitinib and Vedolizumab for the treatment of ulcerative colitis

UC: Ulcerative colitis; GLM: Golimumab.

formed study on the effects of adalimumab on hospitalization for UC, the first 8 wk of adalimumab therapy indicated a significant reduction in the risk of all-cause, UC-related, and UC- or drug- related hospitalization compared to the placebo group (40%, 50%, and 47%, $P < 0.05$ for all comparisons)^[17]; however, significant differences were not observed in the rates of colectomy between the groups. The adalimumab and placebo groups did not show any differences in the adverse events^[15,16,18]. The primary failure rate of anti-TNF induction therapy is reportedly 40% in IBD clinical trials; when switching to another anti-TNF agent, the treatment becomes effective at 50%^[19]. A secondary loss of response can also occur at 1 year after anti-TNF initiation in IBD patients^[19], and solutions for the issues in anti-TNF- α treatment of UC are expected to be elucidated in the future.

Golimumab - a novel, completely human IgG1 anti-TNF- α antagonist - is subcutaneously administered and is approved for use in rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis patients^[20-22]. As shown in the PURSUIT-SC study, at week 6, the clinical response and remission rates showed a noticeable change in both the golimumab 200/100 mg and 400/200 mg groups (all $P < 0.0001$, Table 2)^[23]. The PURSUIT-maintenance study, which is a phase 3, placebo-controlled, randomized withdrawal study, compared the clinical response and remission rates between the golimumab 50/100 mg group and placebo group up to week 54 at intervals of 4 wk; they observed that a notable change was observed in the golimumab 100 mg

administration group ($P < 0.001$, $P = 0.004$, Table 2)^[24]. After adjusting for the follow-up duration, no difference was noted in adverse events between the placebo and golimumab 100 mg groups.

PROMISING JAK1/JAK3 INHIBITOR AND INTEGRIN BLOCKING ANTIBODY

The JAK-STAT pathway is associated with inflammation, autoimmune diseases, hematopoietic disorders, and transplant rejection^[25-30]. Tofacitinib (formally known as CP-690550) is a selective oral inhibitor of JAK 1 and 3, which is known to inhibit the differentiation of pathogenic Th1 and Th17 cells and innate immune cell signaling^[31]. The effects of tofacitinib in active UC patients showed clinical response rates at week 8 of 32%, 48%, 61%, and 78% for the 0.5 mg, 3 mg, 10 mg, and 15 mg twice daily groups, respectively. The tofacitinib 3 mg, 10 mg, and 15 mg twice daily groups exhibited marked differences in clinical and endoscopic remission rates compared to the placebo group (all $P \leq 0.001$, Table 2)^[32]. The levels of low-density and high-density lipoprotein cholesterol increased in a dose-dependent manner, and an absolute neutrophil count of < 1500 was observed in 2% of patients in the tofacitinib group. Thus, tofacitinib is considered to be an effective and safe drug for moderate-to-severe UC patients.

$\alpha 4\beta 7$ integrin, a molecule that is expressed on circulating B and T lymphocytes, interacts with the ligand of the mucosal addressin-cell adhesion molecule

(MAdCAM-1)^[33,34]. The bound lymphocyte migrates to the lamina propria and tissues, and then induces the inflammatory cascade^[35]. Vedolizumab - a humanized monoclonal antibody that inhibits the binding of $\alpha 4\beta 7$ integrin complex and MAdCAM-1-selectively blocks gut lymphocyte trafficking^[36,37], and thus demonstrates therapeutic effects in IBD patients^[38,39]. Consequently, unlike natalizumab which is a $\alpha 4\beta 7$ and $\alpha 4\beta 1$ integrin antagonist, vedolizumab does not affect the cerebrospinal fluid T-lymphocyte immunophenotype and therefore, it does not cause progressive multifocal leukoencephalopathy^[40]. When vedolizumab (300 mg) was administered at week 0 and week 2 and then administered at intervals of 4 or 8 wk, a marked response in the clinical response and remission rates was noted after week 6 ($P < 0.001$, $P = 0.001$, respectively; Table 2)^[41]. A noticeable change in the clinical remission rate at week 52 was observed, regardless of whether the medication was administered at 4- or 8-wk intervals (all $P < 0.001$).

CONCLUSION

Biological agents have been used for UC treatment for 10 years, and various types of biological agents have been developed and used worldwide, with the most common being anti-TNF- α agents. This increase in the development of biological agents provides further immunologic information in addition to offering a wide range of drugs for use. Thus, biological agents may serve as another appropriate option for clinicians in the treatment of UC patients who may not be effectively treated with conventional drugs. Since an accurate understanding of biological agents can be achieved through clinical trials, performed as part of large-scale randomized controlled studies, we have reviewed them in detail. In the future, we believe that biological agents with superior therapeutic effects and fewer side effects, compared to those used currently, will be developed, thus bridging the therapeutic gap present in the treatment of UC patients.

among patients diagnosed with IBD, and the discovery of proteome biomarkers to diagnose or predict cancer risks. Host genetic factors influence the etiology of IBD, as do microbial ecosystems in the human bowel, which are not uniform, but instead represent many different microhabitats that can be influenced by diet and might affect processes essential to bowel metabolism. Further advances in basic research regarding intestinal inflammation may reveal new insights into the role of inflammatory mediators, referred to as the inflammasome, and the macromolecular complex of metabolites formed by intestinal bacteria. Collectively, knowledge of the inflammasome and metagenomics will lead to the development of biomarkers for IBD that target specific pathogenic mechanisms involved in the spontaneous progress of IBD. In this review article, our recent results regarding the discovery of potential proteomic biomarkers using a label-free quantification technique are introduced and on-going projects contributing to either the discrimination of IBD subtypes or to the prediction of cancer risks are accompanied by updated information from IBD biomarker research.

Key words: Inflammatory bowel disease; Biomarker; Proteomics; Tailored medicine; Colitic cancer

Core tip: Our recent achievements in discovering biomarkers to predict cancer risk are introduced. Ultimately, models based on combinations of genotype and gene expression data referenced with clinical, biochemical, and serological data may permit the development of tools for individualized risk stratification and efficient treatment selection, as well as complete rescue from complications, including colitis-associated cancer, in the near future.

Abstract

Recent advances in genomic medicine have opened up the possibility of tailored medicine that may eventually replace traditional "one-size-fits all" approaches to the treatment of inflammatory bowel disease (IBD). In addition to exploring the interactions between hosts and microbes, referred to as the microbiome, a variety of strategies that can be tailored to an individual in the coming era of personalized medicine in the treatment of IBD are being investigated. These include prompt genomic screening of patients at risk of developing IBD, the utility of molecular discrimination of IBD subtypes

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic inflammatory disease that causes injury to the gastrointestinal (GI) tract and is accompanied by clinical characteristics of remission and relapse. The two common types of IBD are ulcerative colitis (UC) and Crohn's disease (CD). Although many molecular methods for the investigation of protein and gene sequences have contributed to diagnostic methodologies, the diagnosis of IBD is primarily based on clinical, endoscopic, radiological, and histological criteria. Unfortunately, there has been little to no change in this traditional approach to diagnosis, despite modern advances in genomics and proteomics. However, progress in treatment strategies involving the incorporation of marketed biologicals and molecular targeted therapeutics has led to the development of the concept of "deep remission" or "mucosal healing" in the treatment of IBD^[1,2]. Furthermore, there has been major innovation in diagnostic methods, including the development of more complicated endoscopic and non-invasive imaging methods. These techniques are used to improve quality of life (QOL) of patients, predict complications, and contribute to the prevention or surveillance of cancer associated with IBD such as colitis-associated cancer (CAC)^[3].

Recent developments in the molecular pathogenesis of IBD have highlighted three aspects. First, IBD is caused by complex disorders influenced by susceptibility genes, and is characterized by disturbed epithelial barrier function, and abnormal innate and adaptive immunity. Second, the compositions of gut microflora are altered or the epithelial barrier function is disorganized, which leads to a response from the immune system. Third, a murine model has been very helpful in unraveling the pathogenesis/mucosal immunopathology of IBD^[4] by suggesting that the abnormal immune reaction to normal microbiota results from dysregulation of the mucosal immune system^[5]. For example, the composition of microbes in the gastrointestinal tract may impair the patient's lifestyle in developed countries and a pathogenic infection in the gastrointestinal tract has a significant function in modulating the immune system. These data may explain why developing and some Asian countries are confronting steep increases in the incidence of IBD. Developments in gene-sequencing technologies, such as next generation sequencing, as well as the emergence of several bioinformatic tools have led to novel insights into the microbe balance in the human gastrointestinal tract and the effect

of microbes on human physiology and pathology^[6].

Additional innovative technologies, such as mass spectrometry (MS)-based proteomics, also referred to as next generation proteomics, have discovered new classes of proteomic biomarkers that can be used to explore the accurate and comprehensive molecular characterization of IBD genes and proteomes. These advances are expected to lead to more reliable identification of IBD diagnostic- or progression-specific targets and enable molecular diagnosis, as well as provide guidance regarding the selection of treatment options and the risk of cancer development in cases with longstanding remission and relapse^[7]. A more robust molecular definition of IBD subtypes is likely to be based on specific molecular pathways that determine not only disease susceptibility, but also disease characteristics, such as location, natural history and therapeutic response. Furthermore, such advances could be applicable in defining "deep remission", which has not been feasible with currently-used scoring systems or endoscopic evaluation. Discovering biomarkers for IBD may allow objective measurements of disease activity and severity while also serving as prognostic indicators for therapeutic outcomes^[8]. Furthermore, the discovery of one or more biomarkers predictive of the risk of IBD-associated cancers, such as CAC, combined with advanced therapeutics, may lead to tremendous improvements in patient QOL in the near future.

In this review article, our recent achievements in discovering biomarkers to predict cancer risk are introduced. Ultimately, models based on combinations of genotype and gene expression data referenced with clinical, biochemical, and serological data may permit the development of tools for individualized risk stratification and efficient treatment selection, as well as complete rescue from complications, including CAC, in the near future^[9].

Molecular pathogenesis of colorectal cancer and CAC

Chronic inflammatory diseases are associated with cancer incidence, which is dependent on the duration and severity of the diseases. For example, Barrett's esophagus is relevant to esophageal cancer, chronic *Helicobacter pylori*-associated chronic atrophic gastritis is relevant to gastric cancer, and UC or CD are relevant to CAC. These are well-acknowledged examples that support a connection between gut inflammation and cancer. In fact, it has been reported that patients with IBD are at enhanced risk of colorectal cancer (CRC): approximately 15% of CRC patients have related IBD etiology^[10]. Although general carcinogenesis is a multi-factorial process that combines accumulation of genetic mutations, post-translational modification, and cell-matrix reciprocal action, inflammation-prone carcinogenesis is somewhat different^[11]. The utility of biomarkers for CAC can be extended to permit earlier detection of dysplasia; therefore, the targeted manipulation of biomarkers might lead to advances in cancer therapies and cancer preventions, and may prove to be effective in reducing the development of CAC, with clinical interventions such as blocking agents or

endoscopic treatments. Regarding molecular aspects, the mechanism of CAC in IBD differs from CRC, which is a well-known adenoma-to-carcinoma sequence. CAC appears to take place from either flat dysplastic tissue or dysplasia-associated lesions or masses^[12]. The major pathways of sporadic CRC and CAC comprise chromosomal instability, hypermethylation and microsatellite instability; however, CAC shows inflamed colonic mucosa before histological changes of dysplasia or cancer. Patients with IBD have a high risk of CAC following diagnosis, and patients have common symptom, such as colitis^[13]. The risk of CAC is increased in younger patients, those with more extensive colitis, those with concomitant primary sclerosing cholangitis, and a family history of CRC^[14]. Most cancers show no high risk related to proctitis; however, increased in pancolitis, *i.e.*, left-sided colitis, carries an intermediate cancer risk^[15]. Patients with CD and UD have the same risk of CRC and the prevalence in the US is greater than 200 cases per 100000, representing a total of between 1 and 1.5 million patients with IBD. Fortunately, the incidence of CAC is lower than CRC in the United States and other western countries^[16]. A biological background for the high risk of CRC in IBD gives a one-sided interpretation, patients with high levels of inflammatory mediators production may progress to CAC. The key signal of IBD-induced carcinogenesis is inflammatory cytokines induced by mucosal and immune cells in the gut. The key molecules of inflammation, including nuclear factor kappaB (NF- κ B) and cyclooxygenase-2 (COX-2), are important links between inflammation and cancer. Recently, other factors, such as tumor necrosis factor- α (TNF- α) and interleukin-6 (IL-6) -induced signaling, have been proven to induce cancer development in animal models of CAC^[17]. Based on these aspects of molecular carcinogenesis, we have tried to apply biologicals such as infliximab to neutralize TNF- α , a proton pump inhibitor based on mechanisms including the inhibition of NF- κ B as well as attenuation of oxidative stress, and aspirin/celecoxib to inhibit cancer-prone COX enzymes. As expected, all of these efforts to block inflammation-promoted carcinogenesis efficiently prevented CAC in our mouse model experiments^[18,19]. The recent descriptions of epigenetic alterations, in particular alterations in DNA methylation, that have been observed during inflammation and inflammation-associated carcinogenesis, led us to explore nutritional interventions as a means of targeting and correcting epigenetic oncogenic abnormalities, as a form of CAC prevention^[20].

Prediction of CAC

Patients with long-standing UC and CD are at increased risk of developing CRC, and patients with small intestinal CD have a high risk for developing small bowel adenocarcinoma. Unlike the sporadic CRC that can develop in those with IBD, CAC development is intimately associated with IBD. In those with IBD, CAC results from a process that is believed to begin with mutagenic benign inflammation that develops into indeterminate, low-grade

and high-grade dysplasia, and eventually to carcinoma. Regarding the risk factors predisposing to carcinoma in IBD, the risk is increased depending on duration, severity of colitis, presence of sclerosing cholangitis, degree of inflammation and family history of CRC. Evidence-based medicine advises that patients with colitis should be kept under surveillance colonoscopy after diagnosis for 8 to 10 years. As surveillance guidelines for early detection of CAC, the general approach of periodic endoscopic examinations and systematic random biopsies of involved mucosa is generally recommended^[21]. Recently, advanced colonoscopic techniques, including narrow band imaging, chromoendoscopy and confocal microendoscopy, have been used to identify abnormal areas in targeted, but not random, biopsies, and biomarkers could be adopted for high resolution endoscopy^[22]. Although medications such as aminosalicylates, folic acid and ursodeoxycholic acid seem to be chemopreventive, potent preventive therapeutics, as well as surveillance of high risk patients through the use of potential biomarkers, would seem to be ideal^[23].

Current Status Of Biological Markers For IBD

Serological markers for IBD are rapidly developing. However, the most studied antibodies, anti-*Saccharomyces cerevisiae* antibodies (ASCA) and atypical perinuclear antineutrophil cytoplasmic antibodies (P-ANCA), have limited sensitivity. Thus, the relationship between serological markers of disease pattern and phenotype may be of greater value than the use of serological markers as diagnostic tools. For example, patients with CD who have high titers of various serological makers have more serious small intestine disease than those with low titers of antibodies^[24]. On the genetic level, application of a genome wide association study design in CD has provided new insights into the immunopathogenesis of CD, identifying links to genes of the innate and adaptive immune system^[25]. One patient had CD associated with gene mutations of *NOD2* and the *ATG16L1* autophagy gene, both of which affect the intracellular processing of bacterial components. In addition, genetic variation of the IL-23 receptor, *STAT3* and *NKX2-3* genes, were associated with CD and UC in Asian patients. Although comparative analyses of gene associations between CD and UD can identify unique mechanisms of immunopathogenesis of IBD, such results have limited applicability in real-world clinical settings because of ethnic, racial, and environmental differences in the samples studied. Since the advent of the concept of proteomics, a plethora of proteomic technologies have been developed to study proteomes. In IBD, several studies have used proteomics to better understand the disease and discover molecules that could serve as therapeutic targets. The advance of proteomic technologies will have an important effect on the development of new biomarkers for IBD^[26]. Further advances in proteomic technologies have allowed us to use label-free quantification to detect biomarkers in various IBD patients for the first time. The results are

expected to provide additional insights in to the molecular biomarkers of IBD that may be used in predicting responses to treatment^[27].

Classic serological and fecal markers in IBD

Currently, diagnosis of IBD from the blood and stool of patients represent reliable and quantitative tools to clinicians^[28]. The C-reactive protein (CRP) and fecal-based leukocyte markers, calprotectin (Cal) or lactoferrin (Lf), can help clinicians to assess disease activity and to distinguish IBD from non-inflammatory diarrhea and simple colitis. Serological tests including both ASCA and P-ANCA can be used to determine the current status and risk of IBD^[29]. The progression of IBD and inflammatory processes are assessed by tests for CRP and the erythrocyte sedimentation rate (ESR). In addition, clinicians might measure the levels of drug metabolites and antibodies against therapeutic agents that aim to determine why patients do not respond to treatment and to select alternative therapy. The advantages of using the fecal markers including, Cal or Lf, are their ease of detection and use of an inexpensive ELISA technique, as well as their long-term stability in feces^[30]. However, several limitations have been associated with these classical serological and fecal markers in IBD. The ESR technique is simple to perform, widely available, and inexpensive; however, it has several disadvantages, such as a concentration that depends on age, several confounders, and the use of certain drugs^[31]. Several factors can affect the utility of CRP, including long half-life and prolonged latency period after changes in chronic IBD. Determination of fecal Cal or Lf markers is very helpful into diagnosis chronic IBD, while other GI diseases, ischemic colitis, and non-steroidal anti-inflammatory drug-associated intestinal damage show greater leukocyte elimination in feces^[32]. In spite of 80%-100% diagnostic accuracy levels, fecal markers are not specific for IBD and may be elevated in a range of organic conditions. To compensate for these limitations, Langhorst *et al.*^[33] evaluated fecal levels of PMN-elastase (PMN-e) in addition to the aforementioned markers and concluded the IBD and IBS can be discriminated by the fecal markers Cal, Lf, and PMN-e. However, these fecal markers have shown a similar capacity to indicate endoscopic pathology, and are more efficient for diagnosis than CRP. Therefore, the combined diagnosis using fecal markers and CRP with disease-specific activity index will be very useful when assessing endoscopic inflammation in UC. It should be noted that these fecal markers were proven to be very efficient in diagnosing IBD as well as in predicting impending clinical relapse in pediatric patients with IBD^[34]. Despite the benefits that can be derived from these serum and fecal biomarkers, there remains considerable room for improvement regarding disease prediction and prognosis assessment, as none of them can be applied to predict future risk of CAC development in IBD.

Proteomic biomarkers in IBD

Matrix-assisted laser desorption/ionization time-of-flight

(MALDI-TOF) mass spectrometry (MS) and surface-enhanced laser desorption/ionization (SELDI)-TOF MS, have become popular methods recently for the analysis of macromolecules of biological origin such as tissues, serum, or plasma^[35]. MALDI-TOF MS is used in clinical medicine to identify disease markers in combination with classic protein gel analysis (1-D) and two dimensional gel electrophoresis separation, accomplished through either peptide mass fingerprinting or peptide sequence tag (2-D) analysis followed by a data base search using proteome blot analysis software^[36]. Using these applications, evaluation of samples by MALDI-TOF MS can give novel data regarding peptides present at high molecular mass and may therefore be valuable to assess potential disease markers of IBD. For example, Nanni *et al.*^[37] determined serum proteins of 22 healthy subjects and 41 patients with IBD (15 CD, 26 UC) extracted with reversed-phase (C18) and subsequently performed MALDI-TOF MS. The results of serum protein profiles showed the highest overall prognosis capability (96.9%) of identifiable protein biomarkers involved in IBD discrimination. Similarly, in a study by Liu *et al.*^[38], serum proteins from 74 CRC samples compared with 48 healthy samples were applied to SELDI-TOF MS using a ProteinChip reader. The diagnostic pattern could distinguish samples according to status of CRC from normal samples with sensitivity and specificity of 95% by independent analysis of the samples. These two studies demonstrated the high potential for biomarker discovery in patients with IBD or CRC in clinical settings, and further clinical validation in large patient cohorts is expected to promote the use of novel biomarkers in clinical practice^[39]. In addition to protein identification, 2-D difference gel electrophoresis (2D DIGE) is good method protein quantification; however, isobaric tags for relative and absolute quantification (iTRAQ) and stable isotope labeling by amino acids (SILAC) are the best methods developed recently. Sample preparation is important to the success or failure of such analysis and subcellular fractionation can be used to give more specific protein localization analysis than total cellular proteins^[40-42]. In our recent study^[43], we applied advanced technologies such as iTRAQ and SILAC for label-free quantification in samples obtained from a mouse model of UC and CAC to identify potential biomarkers for cancer-prone inflammation in IBD and to evaluate empirical therapeutics.

PROTEOMIC BIOMARKER DISCOVERY FOR CAC: A CLASSICAL PROTEOMIC APPROACH

Multiple chemical and biological systems, including intestinal tissue, its associated immune system, the gut microbiota, xenobiotics, and their metabolites, meet and interact to form a tightly regulated state of tissue homeostasis. Disturbance to this state of homeostasis can cause IBD as well as CAC through intercalated multi-factorial

mechanisms. Many strong pathological and mechanistic correlates exist between mouse models of CAC and the clinically relevant situation in humans, allowing for the use of systems biology approaches^[44]. Furthermore, the close proximity of colonic tumors to the myriad of intestinal microbes, as well as the instrumental implication of microbiota in IBD, introduces microbes as new factors capable of triggering inflammation and possibly promoting CAC, necessitating high throughput metabolomic approaches^[45]. Additionally, a detailed understanding of these interactions may also provide a means of preventing CAC^[46]. In a small study, Watanabe *et al.*^[47] performed a low density array analysis of 149 genes implicated in CAC and identified 20 genes showing differential expression between UC- and non-UC-associated CAC, including cancer-related genes such as *CYP27B1*, runt-related transcription factor 3, sterile alpha motif domain-containing protein 1, EGF-like repeats and discoidin I-like domain 3, nucleolar protein 3, *CXCL9*, integrin beta2, and *LYN*. Colliver *et al.*^[48] demonstrated that 392 transcripts showed differential expression during progression from UC to CAC. Both dysplasia and CAC showed 224 transcripts in common and it was concluded that some genes showed same modification both in dysplasia and CAC, signifying that they might be related to tumor initiation and progression. Following these studies, a host of potential biomarkers have been reported in the literature, including cytokeratin 7/20^[49], a-methylacyl-CoA-racemase^[50], transgelin, a frame shift mutation in the TGF- β type II receptor^[51,52], HSP47^[53], methylation of the estrogen receptor^[54], association with certain HLA class II alleles^[55], DNA methyltransferase-1^[56], 8-nitroguanine or 8-oxo-deoxyguanine^[57-59], CCL20^[60] and activation-induced cytidine deaminase^[61]. We used our experimental animal model for colitic cancer, which was provoked with repeated bouts of UC, and an additional proteomic method based on 2-D electrophoresis and MALDI-TOF MS to analyze proteins related in CAC. In detail, 38 proteins were differentially expressed between CAC and healthy samples, using comparative 2-D electrophoresis analysis. Through validation studies, 27 proteins, including enolase, GRP94, HSC70 prohibitin and transgelin, were identified. Among these identified proteins, the downregulation of transgelin in mouse colitic cancer was supported by western blotting and immunohistochemistry. Moreover, transgelin was significantly decreased in colon tumors compared with non-tumorous regions in humans, implying that reduced levels of transgelin could be a good biomarker for CAC^[62].

BIOMARKER DISCOVERY FOR CAC: THE NEXT GENERATION OF PROTEOMICS

Currently, knowledge of proteomics is important and provides researches with complicated label and label-free techniques. This next generation of proteomics may provide effective perspectives in the diagnosis and treatment of gastrointestinal disease and allow for translation of proteomics from the bench to the bedside. Currently,

proteomic studies focus not only in the identification of proteins in a sample, but also the quantification of them. Various protein expression profiles are examined because they provide useful information, especially in clinical proteomics, involving molecular targets related to specific diseases. The technology for proteomics study is continuously developing, and both of labeled and label-free methods have their several advantages. Currently, label-free and isotope-label techniques are used to study proteins quantitatively. The label-free approach, combining spectral and signal quantitation, for identifying amino acids provides accurate relative protein expression data and is an easy way to determine quantitative information. However, this strategy is subject errors from variation in protein preparation that may be reduced when various stable isotopes are inserted in the specimens to make protein isotopomers, which have different spectra according to their different masses. Therefore, several metabolic labeling strategies that apply stable isotopes to minimize error have been developed recently and have been applied in animal models.

Biomarkers to predict CAC risk discovered via label-free quantification analyses

A comparative label-free quantification analysis was conducted in eight patients with UC, eight patients with CD and eight patients with irritable bowel syndrome (IBS). Colonic tissue biopsies were obtained during colonoscopy after written consent and stored in a deep freeze until the assay. Using an Agilent HPLC-Chip 6520 Q-TOF MS system and a label-free quantitative technique (IDEAL-Q v1.0.6.3), signal pathway analysis associated with carcinogenesis was conducted to discover potential biomarkers in CAC (Figure 1). The analysis was conducted according to the degree of intestinal inflammation, type of IBD, and extent of inflammation. To compare against the analysis from IBS samples, the proteins implying CAC risk were isolated (Figure 2A and B). As seen in Figure 2A, 22 significant proteins were found to be potential biomarkers predicting CAC risk in patients with UC. Figure 2B shows the 19 proteins found to be potential biomarkers for CAC risk in patients with CD. Further analysis yielded four important protein biomarkers: proteoglycan 2 (PRG2), S100A6 (calcylin), ribosomal protein L18 (RPL18), UDP-glucose dehydrogenase (UGDH) as potential target proteins and predictive biomarkers for CAC risk in IBD (Figure 3). PRG is a major component of the animal extracellular matrix and has been shown to be involved in the differentiation process across the epithelial-mesenchymal axis. It is a potential biomarker inferred principally through its ability to bind growth factors and modulate their downstream signaling; malignant tumors have their individual characteristic PRG profiles closely associated with their differentiation and biological behavior. PRG2 has further been implicated as a biomarker for neuropathic pain attributable to advanced pancreatic cancer^[63] in an animal model of CAC^[27], and as an inflammation related gene of several cancers, including prostate,

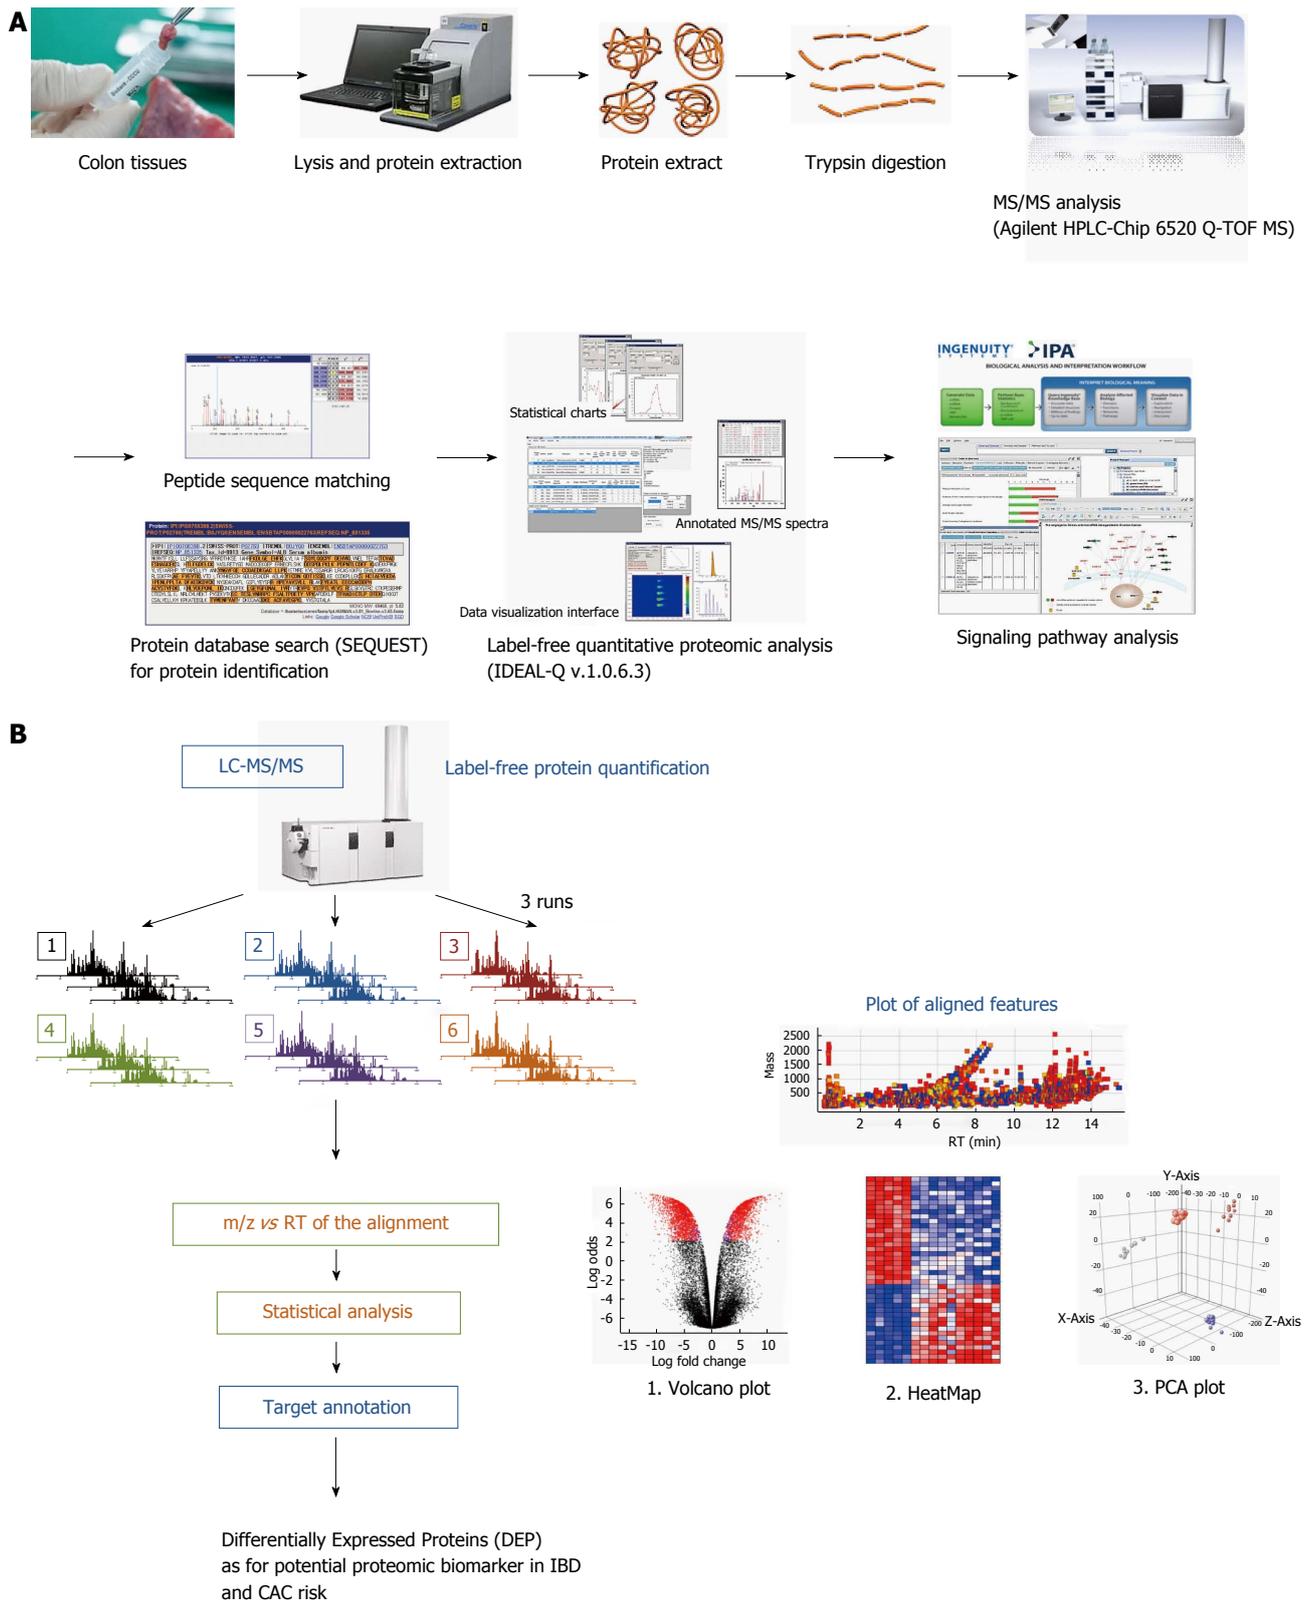

Figure 1 Schematic presentation showing proteome analysis to discover potential biomarkers and label-free quantification analysis in inflammatory bowel disease. A: Applying the label-free quantification method to discover proteomic biomarkers in patients with different types and different stage of inflammatory bowel disease (IBD). Comparative analysis was done in eight patients with ulcerative colitis (UC), eight patients with Crohn's disease (CD) and eight patients with irritable bowel syndrome (IBS). Biopsied colon tissues were obtained during colonoscopy after written consent, and stored in a deep freeze until assayed. Using Agilent HPLC-Chip 6520 Q-time-of-flight mass spectrometry (TOF-MS) and label-free quantitative proteome analysis (IDEAL-Q v1.0.6.3), significant signal pathway analysis was done. In the current review, the analysis done according to the degree of intestinal inflammation, type of IBD, and extent of inflammation from 24 patients, eight from non-IBD normal patients; *i.e.*, IBS patients, eight from patients with UC, and from patients with CD; B: Label-free protein quantification scheme for potential biomarker for colitis-associated cancer (CAC) risk in 16 patients with IBD.

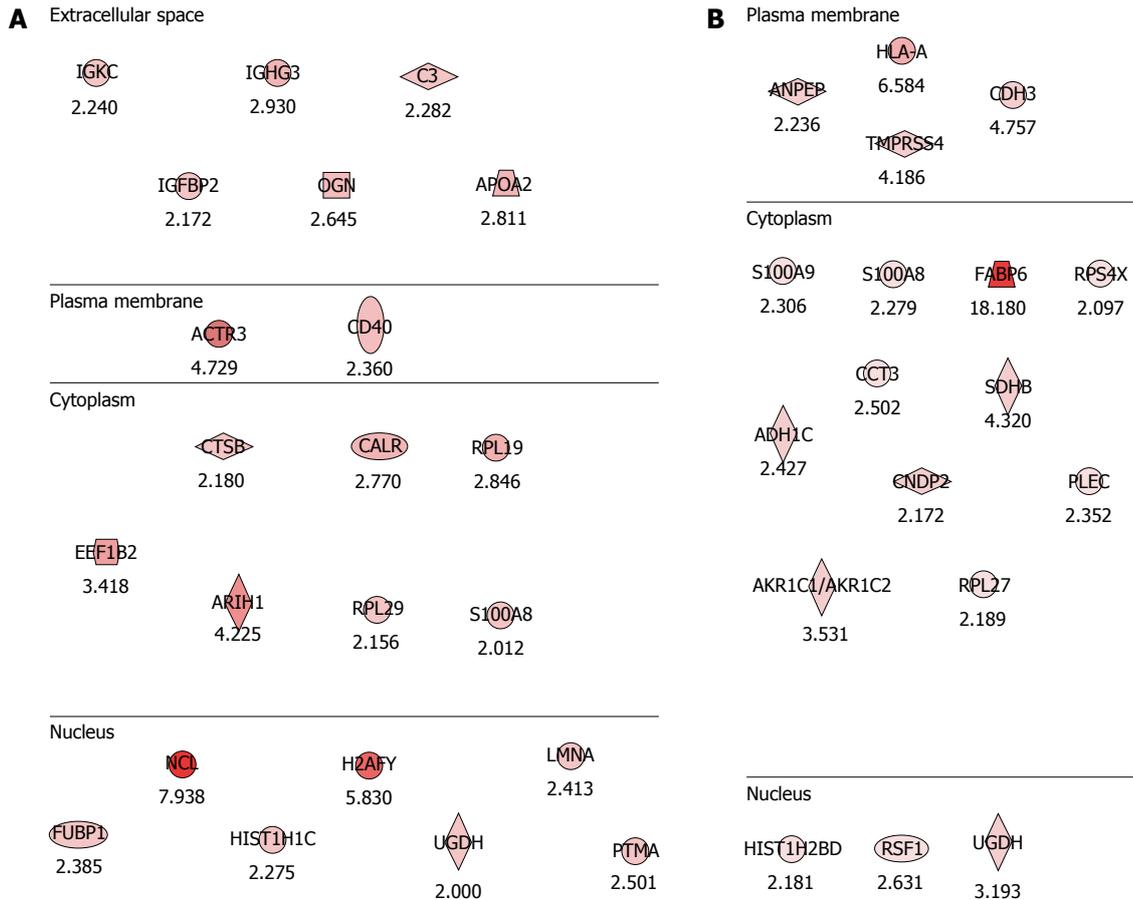

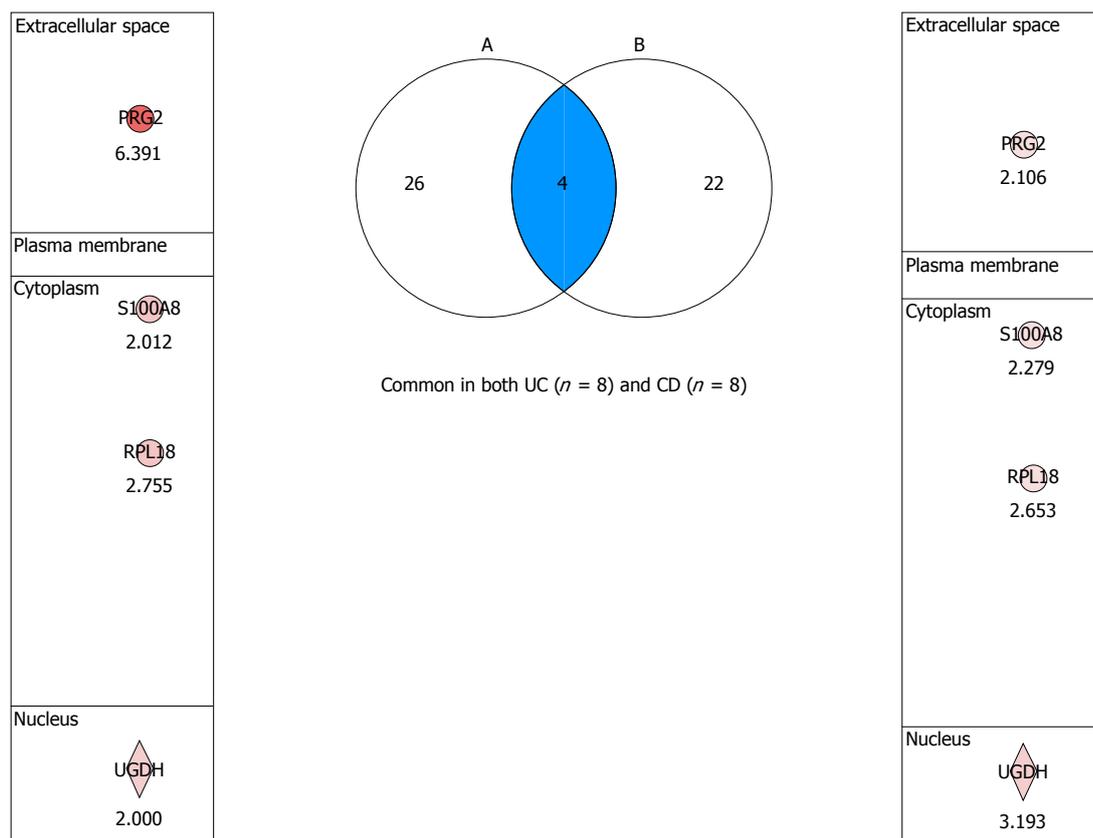

Figure 2 Potential proteomic markers signifying colitis-associated cancer risks in inflammatory bowel disease. A: Proteomic markers for colitis-associated cancer (CAC) risk in patients with ulcerative colitis (UC). The analysis was performed according to the degree of intestinal inflammation, type of inflammatory bowel disease and extent of inflammation. Compared with the analysis of CAC, 22 significant potential biomarkers of CAC risk were obtained from patients as p with UC, six biomarkers existing in the extracellular space, two biomarkers at the plasma membrane, seven are from the cytoplasm, and seven are nuclear proteins; B: Proteomic markers for CAC risk in patients with Crohn's disease (CD). Eighteen potential biomarkers for the risk of CAC were identified in patients with CD. Four were from the plasma membrane, 11 from the cytoplasm, and three from the nucleus.

lung, CRC^[64] and pancreatic cancer^[65]. The expression of S100 calcium binding protein A6 (S100A6) is upregulated in proliferating and differentiating cells^[66], and has been reported to be a possible biomarker for hepatocellular carcinoma^[67,68], pancreatic cancer^[69], acute lymphoblastic leukemia^[70], CRC^[71] and breast cancer^[72]. RPL18 is a 60S ribosomal protein expressed in stem cells^[73] and during adipogenesis^[74] UGDH has been suggested as biomarker for cancer metabolism. The oxidation of UDP-glucose is catalyzed by UGDH to generate UDP-glucuronic acid (UDP-GlcA), a precursor of glycosaminoglycans (GAGs). Wang *et al*^[75] showed decreases in the expressions of UGDH, UDP-GlcA and GAG expression after treatment with a UGDH-siRNA in HCT-8 colon cancer cells and concluded that UGDH could be a new target for CRC clinical treatment^[76]. Additionally, UGDH has been identified as a potential biomarker for prostate cancer^[77,78], hepatocellular carcinoma^[79] and breast cancer^[80].

Biomarkers to predict CAC risk discovered via label-based protein quantification analyses

Proteomic techniques with blood and biopsy provide reliable and accurate tools that provide support to clinicians

in the diagnosis and treatment of IBD. For example, clinically meaningful biomarkers may be used in the differential diagnosis of CD and UC, or as predictors of treatment responses. Tandem mass spectrometry (MS/MS) is commonly used proteomic analysis. However, various workflows are possible for peptide analysis before MS/MS, as well as bioinformatics, to identify peptides, for which 2-D electrophoresis and subsequent MS, liquid chromatography-MS, 2D DIGE, and iTRAQ are under development. In our previous publication^[43], the present status and perspectives regarding these developed proteomic methods were discussed, with descriptions of examples of new biomarkers for the diagnosis, treatment and prognosis of IBD and CAC in mouse models and in humans. In detail, we showed new concepts and technologies of proteomics, such as protein identification and proteome coverage, as determined by iTRAQ with different shotgun proteomic methods in samples from an animal model of CAC that used repeated oral administration of dextran sulfate sodium (DSS) to induce CAC. As previously reported, iTRAQ protein quantification analysis identified fibrinogen beta, prohibitin, transgelin, Hsc-70-interacting protein, suppression of tumorigenicity 13

| Symbol | Entrez gene name | Fold change (CD) | Fold change (UC) | Location | Type (s) |
|--------|---|------------------|------------------|---------------------|----------|
| PRG2 | proteoglycan 2, bone marrow (natural killer cell activator, eosinophil granule major basic protein) | 2.106 | 6.391 | Extracellular space | Other |
| RPL18 | ribosomal protein L18 | 2.653 | 2.755 | Cytoplasm | Other |
| S100A8 | S100 calcium binding protein A8 | 2.279 | 2.012 | Cytoplasm | Other |
| UGDH | UDP-glucose 6-dehydrogenase | 3.193 | 2.000 | Nucleus | enzyme |

Figure 3 Proteomic markers for colitis-associated cancer risk in patients with both ulcerative colitis and Crohn's disease. After analyzing signaling pathways from label-free quantitative analysis, four important proteome biomarkers were identified: proteoglycan 2 (PRG2), S100 calcium binding protein A8 (S100A8), ribosomal protein L18 (RPL18), and UDP-glucose dehydrogenase (UGDH), all of which showed fold changes. Validation is ongoing to investigate these biomarkers for predicting colitis-associated cancer risk in patients with inflammatory bowel disease. UC: Ulcerative colitis; CD: Crohn's disease.

(ST13), a TKL kinase of the MLK family, dual leucine zipper kinase (MKL1), actin, beta, protein-coding gene (*ACTB*), ubiquitin carboxyl-term, esterase L3 (UCHL3), coronin, actin binding protein, 1A (CORO1A), hypoxanthin-guanine phosphoribosyltransferase (HPRT), glutathione peroxidase 1 (GPX1), estrogen receptor 1 (ESR1), transcriptional repressor protein 1 (YY1), transcription activator1, ATP-dependent helicase SMARCA4 (BRG1), brahma gene (BRM) and ornithine aminotransferase (OAT) as potential biomarkers for CAC in the DSS-induced colitic cancer model^[43].

CONCLUSION

MALDI imaging mass spectrometry (IMS) is a new technology to analyze small peptides in various samples and is a novel tool for studying molecular mechanisms in biological tissues. Recent studies have demonstrated considerable diagnostic and prognostic value, which should be

applicable to clinical settings in the near future^[81,82]. However, one challenge associated with the use of MALDI-IMS in the identification of potential biomarkers involves the systematic identification of peptides introduced in the MALDI matrix with association of top-down and bottom-up analysis^[83]. IMS will be investigated without target-specific reagents to identify new markers for the diagnosis, treatment, and prognosis of CAC, as well as the determination of effective therapies. In the near future, an era of tailored medicine will provide for diagnostic algorithms that include molecular parameters for the detection of early disease and treatment algorithms guided by predicting the individual course of the disease. However, more trials focused on discovering proteomic biomarkers will be necessary to guide the treatment of IBD with more advanced levels of biologicals or molecular targeted therapeutics for inflammation. Using label-free quantification methods on biopsied tissue from patients with IBD, four potential biomarkers, PRG2, S100A6 (calcy-

clin), RPL18, and UGDH, have been discovered. Further validation of these potential biomarkers will be necessary to ascertain their clinical value.

Abstract

Extraintestinal manifestations of inflammatory bowel disease (IBD) are a systemic illness that may affect up to half of all patients. Among the extraintestinal manifestations of IBD, those involving the lungs are relatively rare and often overlooked. However, there is a wide array of such manifestations, spanning from airway disease to lung parenchymal disease, thromboembolic disease, pleural disease, enteric-pulmonary fistulas, pulmonary function test abnormalities, and adverse drug reactions. The spectrum of IBD manifestations in the chest is broad, and the manifestations may mimic other diseases. Although infrequent, physicians dealing with IBD must be aware of these conditions, which are sometimes life-threatening, to avoid further health impairment of the patients and to alleviate their symptoms by prompt recognition and treatment. Knowledge of these manifestations in conjunction with pertinent clinical data is essential for establishing the correct diagnosis and treatment. The treatment of IBD-related respiratory disorders depends on the specific pattern of involvement, and in most patients, steroids are required in the initial management. Corticosteroids, both systemic and aerosolized, are the mainstay therapeutic approach, while antibiotics must also be administered in

the case of infectious and suppurative processes, whose sequelae sometimes require surgical intervention.

Key words: Inflammatory bowel diseases; Crohn's disease; Ulcerative colitis; Lung diseases

Core tip: The clinicopathological patterns of pulmonary involvement in inflammatory bowel disease (IBD) consist of airway disease, lung parenchymal disease, thromboembolic disease, pleural diseases, enteric-pulmonary fistulas, and pulmonary function test abnormalities. The treatment of IBD-related respiratory disorders depends on the specific pattern of involvement, and in most patients, steroids are required in the initial management. This review focuses on the pulmonary manifestations of IBD in an attempt to avoid further health impairment and to alleviate symptoms by prompt recognition and treatment.

INTRODUCTION

Inflammatory bowel diseases (IBDs) are chronic inflammatory diseases of unknown etiology that commonly involve the gastrointestinal tract^[1]. Crohn's disease (CD) and ulcerative colitis (UC) are the two main forms of chronic IBD. Extraintestinal and systemic manifestations occur commonly in patients with IBD (21%-41%)^[2-4], increase with duration of intestinal disease, and affect most organ systems^[5]. The extraintestinal manifestations are a significant cause of morbidity and may be particularly distressing for the patient^[6]. Extraintestinal manifestations are more common in CD and may include cutaneous

ous (pyoderma gangrenosum and erythema nodosum), ocular (anterior uveitis and episcleritis), hepatic (pericholangitis and fatty liver), and articular (peripheral and axial arthropathies) diseases^[7]. Mouth ulcers and venous thrombosis also occur^[8]. In contrast, pulmonary involvement is rare^[9,10].

A possible link between UC and respiratory disease was described first by Turner-Warwick^[11] in 1968, but it was not until the work of Kraft *et al*^[12] in 1976 that respiratory involvement came to be included in the list of established complications of IBD. The authors described six adult patients with IBD who developed chronic bronchial suppuration with or without bronchiectasis. Following this report, many investigators described a similar pattern, and other manifestations of pulmonary involvement were described, including: interstitial pneumonitis, panbronchiolitis, bronchiolitis obliterans organizing pneumonia (BOOP), inflammatory tracheal stenosis, serositis, pulmonary vasculitis, apical fibrosis, Langerhan's cell histiocytosis, sarcoidosis, and conditions resembling Wegener's granulomatosis^[13-23]. Respiratory diseases occurring in IBD may consist merely of a subclinical abnormal lung function or, in contrast, they may manifest as clear interstitial lung disease^[15].

Pulmonary alterations are often overlooked, especially when respiratory symptoms are already present before the diagnosis of IBD. The true prevalence of lung involvement in IBD remains unknown and it seems rather variable, because in some series only a few cases of respiratory complications have been found^[24]. However, it can be difficult to establish a relationship between respiratory diseases and IBD in patients who are already affected with pulmonary disease at diagnosis of IBD, or who are current smokers.

An ongoing bowel inflammation is not a prerequisite for the onset of respiratory alterations, because broncho-pulmonary diseases that develop after colectomy have been reported^[25]. Pulmonary abnormalities in IBD can present years after the onset of the bowel disease and can affect any part of the lungs. These may be overt or subclinical and do not correlate with the duration of IBD. The pulmonary manifestations are variously reported as occurring frequently during active disease, independent of disease activity, and even in post-colectomy patients^[26,27].

The pathogenesis of IBD causing lung abnormalities involves some of the following mechanisms: both the colonic and respiratory epithelia share an embryonic origin from the primitive foregut and have columnar epithelia with goblet cells and submucosal mucus glands; the lungs and gastrointestinal tract contain submucosal lymphoid tissue and play crucial roles in host mucosal defense^[28,29]. The similarity in the mucosal immune system causes the same pathogenic changes that may result from epithelial exposure to common antigens by inhalation and ingestion, leading to sensitization of the lymphoid tissue and inflammation^[13]. The activated inflammatory cells in the bowel tissues are capable of producing several circulating cytokines such as interleukin (IL)-1, IL-2 and IL-6 and tumor necrosis factor (TNF)- α . These and other media-

tors can regulate the endothelial cell adhesion molecules, alter leukocyte migration, increase production of damaging reactive oxygen metabolites, and induce damage of lung parenchyma^[6,30,31].

Although pulmonary involvement is well described in the literature, the evaluation and treatment of pulmonary disease associated with IBD remain a problem. The pulmonary associations of IBD are poorly characterized and early recognition is important^[32]. Here, we review the pulmonary manifestations that are associated with IBD.

PULMONARY DISEASES ASSOCIATED WITH IBD

Airway diseases

Airway disease from the trachea to the bronchioles has been reported in association with IBD^[29,33-50]. IBD was four times more prevalent among patients with airways disease compared with published local IBD prevalence in a retrospective analysis of outpatients over a 10-year period^[51]. The pathogenesis of IBD-related airway disease is unknown, but it is clearly inflammatory in nature. Severe tracheal inflammation and obstruction are rare manifestations of IBD and correspond to the presence of irregularly friable and hemorrhagic tissue at endoscopy^[52]. The tracheal epithelium is often ulcerated and is replaced by a thin layer of fibrin. The main symptoms are coughing, dyspnea, stridor and hoarseness^[42]. Upper airway involvement comprises glottic/subglottic stenosis, tracheal inflammation and stenosis^[13,40,42,43]. Most of this rare entity involves the trachea, presenting with shortness of breath, dysphonia, and cough^[45,46,53]. It can often be identified by history, complemented by a clear X-ray film and obstructive pattern on pulmonary function testing. Laryngoscopic evaluation is necessary because airway compromise can occur. The mucosa may exhibit a cobblestone appearance similar to that seen in affected intestines^[54]. Chest radiographs and computed tomography (CT) may show narrowing of any portion of the trachea, with circumferential tracheal wall thickening on CT^[27]. No predilection seems to exist for specific gender or type of bowel disease.

Large airway disease, strongly associated with UC^[18], is the most common presentation of pulmonary manifestations. Bronchial inflammation and suppuration are the most common manifestations of pulmonary involvement in IBD and include chronic bronchitis and bronchiectasis in which bronchial dilatation is visualized on chest X-ray or CT scan. Bronchiectasis is the most commonly reported entity and is noted in 66% of cases of IBD involving the large airways^[13,34,35,39,50]. Infrequently, in IBD patients developing new, persistent and unexplained symptoms of respiratory disease, particularly chronic productive cough, the presence of bronchiectasis may be demonstrated^[18]. The majority of patients with bronchiectasis have UC. IBD is inactive in many cases and curiously, in 60% of patients, the symptoms develop a few days to a few weeks following colectomy^[39,42,55]. The second most common

large airway disease in IBD is chronic bronchitis, which is distinguished from bronchiectasis only by the degree and extent of pulmonary abnormality^[56], and further abnormalities include suppurative large airway disease and acute bronchitis. The main symptom is chronic cough with purulent sputum poorly responsive to antibiotics^[57]. Bronchial biopsy shows similar features: squamous cell metaplasia in the mucosa that is sometimes infiltrated by neutrophils and a dense cuff of lymphocytes and plasma cells infiltrating the submucosa^[8].

Clinically, small airway disease is less frequently reported and is described as occurring in isolation from large airway disease. However, the recent advent of high-resolution CT has increased the detection of small airway involvement in these patients. These abnormalities seem to occur earlier in the course of the disease and at a younger age than large airway disease^[41,47-49,58-60]. Moreover, small airway disease is more frequently apparent before the onset of IBD than other airway diseases^[48]. CT shows bronchiolar wall thickening, mucoid impaction, centrilobular ground-glass nodules, and mosaic attenuation because of air trapping, and some patients have normal pulmonary function test (PFT) findings^[32].

Bronchiolitis is an inflammatory and potentially fibrosing condition affecting mainly the intralobular conducting and transitional small airways^[61]. Among small airway diseases are associated with IBD, bronchiolitis is the most frequently detected^[62,63]. Chronic bronchiolitis contributes to morbidity and/or mortality if it persists and/or progresses to diffuse airway narrowing and distortion or complete obliteration. Bronchiolitis in specific settings leads to bronchiolectasis, resulting in bronchiectasis. The main symptoms of bronchiolitis associated with IBD include mild productive cough and chronic bronchorrhea; wheezes are heard at auscultation. Small airway involvement can precipitate abnormalities on PFTs. Histological samples show varied patterns ranging from nonspecific fibrosing and stenosing bronchiolitis to an inflammatory lesion indistinguishable from the original description of panbronchiolitis^[8]. The CT appearances coupled with the evaluation of pulmonary function parameters usually lead to the diagnosis.

In IBD-related large airways disease, steroid drugs are effective, but recommendations for their use including dosage, duration and route of administration remain empirical. Steroids are the major therapy although some patients do not require systemic therapy. Clinical improvement with inhaled steroids alone or in combination with systemic steroids has been reported^[18,29,43,64]. Ineffectiveness of inhaled corticosteroids may be due to airways filled with inspissated secretions, in which case either topical corticosteroids via bronchoalveolar lavage (BAL) or systemic corticosteroids are recommended^[57]. Broadly speaking, inhaled steroids seem more effective and are better tolerated than oral steroids. Rarely, other forms of immunomodulation have been used to treat IBD-related airway disease^[65]. Small airway disease is usually refractory to inhaled steroids, and the improvement brought about by oral steroids ranges from slight to modest^[8]. Lung

transplantation has been required in some cases. Surgery of the colon, which may aggravate prior airway disease^[37], is not recommended for treatment of airway disease.

Lung parenchymal diseases

Lung parenchymal disease associated with IBD is relatively uncommon. Analysis of diffuse lung disease in IBD patients is further confounded by documented pulmonary sequelae to various medical therapies used to treat IBD. In contrast to other extraintestinal manifestations, lung parenchymal disease associated with IBD is seen more commonly with UC than CD^[8]. Age of onset varies, and there is a slight female predominance.

BOOP is the most commonly reported parenchymal manifestation of IBD^[63,66-69]. BOOP is often caused by inhalation injury, or results from a post-infection origin or drugs and may present acutely or subacutely with fever, cough, dyspnea and pleuritic chest pain^[15,70,71]. Chest radiography shows focal to diffuse peripheral predominant airspace opacities. CT shows scattered, nonsegmental, unilateral, or bilateral foci of consolidation, ill-defined centrilobular nodules, and large irregular nodules. It can be associated with other autoimmune diseases such as rheumatoid arthritis, lupus and Wegener's granulomatosis. Dyspnea and cough are the most common presenting symptoms. Systemic steroids are recommended for treatment but BOOP may also remit without treatment in a minority of cases^[13].

Other forms of parenchymal disease that may be related to IBD or drug toxicity are eosinophilic pneumonia and nonspecific interstitial pneumonitis. Although interstitial disease most commonly involves drug-induced reactions with mesalamine and sulfasalazine, a small number of unrelated cases of fibrosing alveolitis and eosinophilic pneumonia have been reported^[72-77]. On CT, peripheral consolidation predominates in cases of eosinophilic pneumonia, whereas nonspecific interstitial pneumonitis shows ground-glass opacities, interlobular septal thickening, and irregular linear opacities^[78]. The interstitial lung infiltrates have been proven histologically to be either pulmonary vasculitis^[79-81] or more often granulomatous disease^[82-85].

Pulmonary nodules have been infrequently reported in patients with IBD. Histologically, these lesions have been reported to be necrobiotic, granulomatous, or otherwise^[86]. Necrobiotic nodules, composed of sterile aggregates of neutrophils with necrosis, may also be seen in rheumatoid arthritis, Wegener's granulomatosis, or septic pulmonary emboli, and should be differentiated from malignancy and infection. An infectious origin should be excluded because necrobiotic nodules will respond to steroids but not to antibiotics. Sarcoidosis and CD are both granulomatous diseases, of the lung and bowel, respectively. It is not surprising that these two diseases may simultaneously appear in the same patient, with pulmonary involvement^[87], even though this happens rarely and the two diseases usually follow an independent clinical course^[88]. An infectious cause, specifically atypical *Mycobacterium* has been postulated to contribute to granuloma

formation in both sarcoidosis and CD, and has even been detected in tissues from patients with both diseases^[89].

The manifestations of lung parenchymal disease in IBD usually respond dramatically to inhaled and/or systemic steroids. Steroids administered orally lead to marked improvement in patients with interstitial lung disease, BOOP, pulmonary infiltrates with eosinophilia, and necrotic nodules. Intravenous steroids are required in the initial management of life-threatening complications such as extensive interstitial lung disease. The addition of cyclophosphamide or infliximab may show rapid clinical and radiological response and are well tolerated in some cases^[90,91].

Thromboembolic diseases

IBD is a chronic inflammatory condition, characterized by microvascular and macrovascular involvement. Inflammation and immune response could lead to endothelial dysfunction, which is the earliest stage of the atherosclerotic process^[92]. Chronically inflamed intestinal microvessels of IBD patients have demonstrated significant alterations in their physiology and function compared with vessels from healthy and uninvolved IBD intestine^[93]. Thromboembolism is an extraintestinal manifestation and an important cause of mortality in IBD^[94]. The incidence of thromboembolic events in IBD patients is three to four times higher than in age-matched control subjects^[95,96]. It happens at an earlier age than in non-IBD patients. The majority of thromboembolic events among IBD patients are venous thromboembolism, manifested as either deep venous thrombosis or pulmonary embolism, but arterial thromboembolism and venous thrombosis at unusual sites have also been reported^[97]. Prothrombotic risk factors in IBD patients could be distinguished as acquired, such as active inflammation, immobility, surgery, steroid therapy, and use of central venous catheters, and inherited^[93].

The risk of thromboembolism appears to be multifactorial and related to mucosal inflammatory activity in most patients. Pulmonary embolism should be always considered in IBD patients with breathing difficulties. However, the diagnosis of venous and arterial thromboembolism is extremely challenging and requires a high degree of vigilance. Deep vein thrombosis and pulmonary embolism may be clinically silent or manifest with only a few specific symptoms. Up to one-third of thromboembolic events in this population occur while IBD is quiescent, suggesting an unknown risk factor that is unrelated to treatment or disease activity^[13]. The pathogenesis of increased thrombotic risk among patients with IBD is unclear. About 80% of IBD patients have active disease when pulmonary embolism occurs^[98]. Early diagnosis plays a central role in optimizing the therapeutic intervention and reducing the risk of short-term and long-term thrombosis-associated complications. The decision regarding the duration of systemic anticoagulation must take into account the individual risk of intestinal bleeding^[99].

Pleural diseases

Rarely, IBD involves the pleural space and pericardium,

causing inflammatory exudative pleural and/or pericardial effusions^[100,101]. This is a relatively rare presentation of the uncommon and probably under-reported and under-recognized pulmonary extraintestinal manifestations of IBD^[102]. Pleuropericardial inflammatory disease and effusion can be directly related to IBD, its complications, associated infections, or the medications used to treat it^[103]. Most patients are young, male, and have UC during the quiescent phase of the disease. The manifestations of pleural disease can be classified as: pneumothorax^[104], pleural thickening^[105], pleuritis, and pleural effusion^[106]. Pleural fluid directly related to IBD is usually unilateral, an exudate with neutrophils, and may be hemorrhagic. Mesalazine may also induce lupus-like symptoms, such as arthralgia, pericarditis, tamponade, and/or pleural effusion, with positive antinuclear antibody^[107]. It is important to evaluate pleural effusion and rule out other etiologies before making this diagnosis. Pleural or pericardial biopsies are rarely necessary, and probably show nonspecific acute and chronic inflammatory changes^[103]. Although the specific pathophysiology of pleuropericardial disease in patients with IBD remains unclear, the response to systemic steroids is usually adequate. However, pleural drainage may be required occasionally.

Enteric-pulmonary fistulas

Fistula formation is frequent in CD and occurs in 33% of patients^[107]. Most of the fistulas appear in the perineal area^[108]; to date, only a few reports (mostly as single cases) are available on the occurrence of enteric-pulmonary fistulas in IBD, such as colobronchial^[109-112], ileobronchial^[113], and esophagobronchial^[114,115] fistulas. In most cases, colobronchial fistulas extend from the splenic flexure in the colon to the lower lobe of the left lung. This is likely due to the anatomical proximity between the two structures. However, Mercadal *et al.*^[116] reported a rare case of right-sided colobronchial fistula in a 47-year-old, severely malnourished man with a history of regional enteritis and recurrent right lower and middle lobe pneumonia, medically managed with the addition of the immunomodulator infliximab prior to surgery.

Diagnosis of fecopneumothorax is based on meticulous clinical examination and additional diagnostic procedures. Recurrent pneumonia with feculent sputum in patients with CD should raise suspicion of colobronchial fistula. Once the abnormal connections between the bowel and respiratory tract are suspected, an enema using water-soluble contrast medium certainly helps to confirm the presence of fistulas^[110]. Abdominal and thoracic CT scan or magnetic resonance imaging could provide additional information about the stage of the disease and exclude the presence of abscess or fluid collection in the abdominal cavity. Colopleural fistula and fecopneumothorax are rare but life-threatening complications of CD^[117]. Surgical treatment is mandatory as soon as the diagnosis is established^[118].

Pulmonary function test abnormalities

PFT abnormalities are found frequently in patients with

IBD without presence of any respiratory symptoms and lung radiograph findings^[20]. IBD patients show significantly decreased lung function tests in comparison to healthy controls. In a review including over 600 patients with UC, more than 50% of patients showed abnormal PFT results when compared to healthy controls, and the decrease in diffusion capacity of the lung for carbon monoxide (DLCO) was the most common defect^[15]. Various studies testing pulmonary function in patients with IBD have revealed a spectrum of abnormalities including restrictive disease, obstructive disease, bronchial hyperresponsiveness and hyperinflation as well as a decreased diffusion capacity of the lung^[119-133]. The severity and frequency of these PFT abnormalities that are detected even in the remission periods increase with disease activity. There is no difference between UC and CD in PFTs^[51], and smoking status is not predictive of these abnormalities.

The most commonly described abnormality is a decrease in lung diffusion capacity^[66]. In most studies, this alteration could not be predicted by current or past smoking status, occupational history, or current medication use. Lung transfer factor for carbon monoxide abnormalities is related to the degree of disease activity^[122]. Pulmonary involvement in IBD is often asymptomatic and detectable only at the time of lung function investigation. This is further supported by the finding of Wallaert *et al.*^[134] of a high proportion of latent lymphocytic pulmonary alveolitis in the BAL of 18 consecutive patients with CD; all free from respiratory symptoms and showing normal chest X-ray. Therefore, PFT may be used as a noninvasive diagnostic procedure in determining the activation of IBD and might aid early diagnosis of latent respiratory involvement^[135]. Early recognition is important, because PFT abnormalities can be steroid responsive^[136].

PFT studies in IBD suggest that subclinical pulmonary disease may be present in a large subpopulation of patients. A high degree of suspicion is necessary to detect the pulmonary abnormalities in IBD, because a large proportion of symptom-free patients have abnormal findings on pulmonary function testing. Although the mechanism of these abnormalities remains unclear, it may be a result of the increased capacity of alveolar macrophages to produce superoxide anions, which has been shown in some patients with CD^[137].

DRUG-RELATED LUNG DISEASES

Although drug-related diseases are not “proper” IBD-associated diseases, because IBD patients use several drugs for prolonged periods of time, it is not surprising that some of these may also cause problems to the lungs. Therefore, this type of pathology must be kept in mind for patients taking azathioprine (AZA), 6-mercaptopurine (6-MP), sulfasalazine, mesalamine, methotrexate, and anti-TNF- α .

AZA and 6-MP

AZA and 6-MP are therapeutic options for patients with moderate to severe IBD^[138]. However, between 10% and

29% of patients treated with these drugs are forced to stop therapy due to side effects. Pulmonary toxicity due to these drugs has been reported infrequently in the literature, although interstitial pneumonitis^[139], BOOP^[140], chronic pneumonitis/fibrosis and pulmonary edema^[141] have been described after use of AZA and 6-MP. Although rare, AZA and 6-MP can cause direct, dose-dependent and serious pulmonary toxicity^[140,142]. The largest number of cases of lung toxicity related to AZA was described in seven patients undergoing renal allograft transplant immunosuppression with AZA^[142]. Lung biopsies revealed interstitial pneumonitis in 5 patients and diffuse alveolar damage in 2; 3 patients died and the other 4 improved after stopping AZA, and in 2 of these patients, cyclophosphamide therapy was needed to resolve this side effect completely. Thus, it is important for clinicians to have a high index of suspicion for this adverse reaction, which occurs within 1 mo after purine analog use in IBD.

Sulfasalazine and mesalamine

Sulfasalazine and mesalamine are commonly used medications for the long-term treatment of IBD, and their side effects may be dose-related or idiosyncratic and should be differentiated from the respiratory involvement occurring in IBD and due to the underlying disease, although this is challenging because they share similar pathological features^[47]. Commonly reported lung pathology related to the use of these compounds is mostly due to interstitial disease^[54,128,143-145], although eosinophilic pleuritis^[146], eosinophilic pneumonia^[71,147-150], and bronchiolitis obliterans^[67] have also been described. Patients present with progressive respiratory symptoms such as dyspnea, chest pain and cough, and radiographic abnormalities. Alternatively, sulfasalazine and mesalamine may induce asymptomatic lung injury more commonly than is presently suspected^[151]. Although sulfasalazine or mesalamine-induced lung injury is a rare entity, its possibility should be fully considered in patients developing unexplained respiratory symptoms while on sulfasalazine or mesalamine therapy^[150]. In most cases, symptoms appear after 2-6 mo of drug use, whereas in a few cases they appear after a few days or after many years. These pulmonary toxicities appear reversible after withdrawal of the drug, and in some cases, with the use of systemic corticosteroids^[152,153].

Methotrexate

Methotrexate (MTX) may be useful in the treatment of IBD^[154], but can cause adverse effects in the lungs, which in some cases are lethal^[155]. The mechanism of MTX-induced lung pathology remains unclear. A hypersensitivity reaction was suggested by lung biopsy findings: interstitial pneumonitis, granuloma formation and bronchiolitis^[156], and by BAL findings: lymphocytic alveolitis, increased eosinophils and reversed CD4/CD8 ratio^[157], together with the clinical findings of fever, peripheral eosinophilia and response to corticosteroids. MTX may also cause pneumonitis^[158], and abnormal ventilation is an early sign and should lead to further investigation^[159]. The diagnosis of

MTX-induced lung disease is difficult because there are no pathognomonic findings and this condition may mimic other pulmonary diseases. The most frequent complaints include dyspnea, fever and nonproductive cough. PFTs show a restrictive picture with low CO diffusion capacity. MTX-related lung toxicity is potentially fatal, thus, regular monitoring of the status of the respiratory system in MTX-treated patients is necessary and patients should be instructed to report any new pulmonary symptoms without delay^[160]. Besides supportive therapy, withdrawal of MTX seems to be a logical approach.

Biological therapy

Biological therapy with anti-TNF drugs such as infliximab, adalimumab and certolizumab has represented a significant advance in the treatment of IBD over the past few years^[161-163]. However, serious side effects do occur, necessitating careful monitoring of therapy^[164]. Several associated opportunistic infections have been observed as a result of suppression of T-cell-mediated immunity; the most frequent being tuberculosis^[165-167]. Physicians should be aware of the increased risk of reactivation of tuberculosis in patients treated with anti-TNF agents and regularly look for usual and unusual symptoms of tuberculosis. Moreover, the use of biological therapy has been associated with *Pneumocystis carinii* pneumonia^[168], as well as with other pulmonary infections (coccidiomycosis, histoplasmosis, aspergillosis, nocardia asteroides, actinomycosis and listeriosis)^[169-173], especially in older patients^[174].

Although infective complications are the most feared after the use of biological agents, these may induce other uncommon effects in the lung, such as acute respiratory distress syndrome^[175], diffuse alveolar hemorrhage^[176], non-bronchiolitis inflammatory nodular pattern of the lung^[177], and interstitial lung disease^[178-180]. Close observation of patients undergoing treatment with TNF inhibitors for evolving signs and symptoms of autoimmunity is required. Organ involvement is unpredictable, which makes correct diagnosis and management extremely challenging.

CONCLUSION

Pulmonary manifestations of IBD are being increasingly recognized. The involvement of the respiratory system in IBD, which can range from a simple defect of pulmonary function without symptoms, to fibrosing alveolitis with a greater risk of mortality, is relatively rare but sometimes potentially harmful. Early identification of latent pulmonary involvement is important to prevent future and more severe respiratory impairment and can be life-saving. The manifestations in the lung vary and often represent a confounding diagnostic problem. It is imperative for clinicians to maintain a high index of suspicion for the development of pulmonary disease in the setting of IBD in order to institute appropriate treatment early and avoid further complications and morbidity in IBD patients, and to recognize prompt treatment for these events. Steroids are effective in the majority of cases.

Abstract

Patients with inflammatory bowel disease (IBD) have an increased risk of vascular complications. Thromboembolic complications, both venous and arterial, are serious extraintestinal manifestations complicating the course of IBD and can lead to significant morbidity and mortality. Patients with IBD are more prone to thromboembolic complications and IBD *per se* is a risk factor for thromboembolic disease. Data suggest that thrombosis is a specific feature of IBD that can be involved in both the occurrence of thromboembolic events and the pathogenesis of the disease. The exact etiology for this special association between IBD and thromboembolism is as yet unknown, but it is thought that multiple acquired and inherited factors are interacting and producing the increased tendency for thrombosis in the local intestinal microvasculature, as well as in the systemic circulation. Clinicians' awareness of the risks, and their ability to promptly diagnose and manage thromboembolic complications are of vital importance. In this review we discuss how thromboembolic disease is related to

IBD, specifically focusing on: (1) the epidemiology and clinical features of thromboembolic complications in IBD; (2) the pathophysiology of thrombosis in IBD; and (3) strategies for the prevention and management of thromboembolic complications in IBD patients.

INTRODUCTION

Thromboembolic events, both venous and arterial, are serious extra-intestinal manifestations complicating the course of inflammatory bowel disease (IBD) and can lead to significant morbidity and mortality. The increasing evidence that patients suffering from both Crohn's dis-

ease (CD) and ulcerative colitis (UC) are more prone to thromboembolic complications compared to the general population implicates the IBD *per se* as a risk factor^[1,2]. Moreover, recent data support the theory that thrombosis and thromboembolism are disease-specific manifestations in IBD, and that they also may be contributing factors in the pathogenesis of the luminal disease. In this review we discuss how thromboembolic disease is related to IBD, specifically, the following: (1) the epidemiology and clinical features of thromboembolic complications in IBD; (2) the pathophysiology of thrombosis in IBD; and (3) strategies for the management, prevention and treatment, of thromboembolic complications in IBD patients.

IBD AND THROMBOEMBOLIC COMPLICATIONS

Historically, in 1936, Barger and Barker^[3] first reported arterial and venous thrombotic complications in UC patients. In a large Mayo Clinic survey, Talbot *et al*^[4] found that 1.3% of their IBD patients manifested thromboembolic complications, while other early studies reported an even higher incidence, up to 7%^[5-8]. Moreover, an important and interesting observation came from autopsy studies which found a much higher incidence of venous thromboembolic complications, up to 39%, in UC patients, implying that most of the thromboembolic episodes were either not clinically overt or were overlooked. The thromboembolic complications were the third leading cause of death (10%) in those patients^[9].

Thrombosis occurs more often in the deep veins of the legs and the pulmonary circulation^[4]; however, arterial thromboembolic complications (ATEs) and numerous other less frequent sites of venous thrombosis have also been described, including cerebrovascular (CVA) disease^[10,11], internal carotid artery occlusion^[12], mesenteric and portal vein thrombosis^[13], Budd-Chiari syndrome^[14], cutaneous gangrene secondary to microvascular thrombosis^[15], retinal vein occlusion^[16-18], and ischemic heart disease (IHD)^[19].

Venous thromboembolism

Over the past decade in particular, many large case-controlled and cohort studies, in centers throughout the world, have focused on defining the association of IBD with the risk of venous thromboembolism (VTE) and have contributed to significant progress in clarifying the epidemiological and the clinical features of VTEs in IBD^[1,2,20].

Some assessed the incidence and the risk of VTE in IBD patients compared to the general population^[21-25], while others evaluated the risk of VTE in hospitalized IBD patients compared to hospitalized non-IBD patients^[26-30]. A few studies were more focused, and analyzed the risk of VTE in pregnant females with IBD^[31,32], the risk of VTE in postoperative IBD patients^[33,34] and, finally, one study evaluated the risk of recurrent DVT in adult IBD patients^[35].

The overall risk of VTEs, deep vein thrombosis (DVT) and pulmonary embolism (PE), in IBD patients has been estimated in two recent meta-analyses^[1,36]. Despite the heterogeneity and the limitations of the studies included, both meta-analyses revealed an approximately 2-fold increased risk for VTEs in IBD patients. Yuhara *et al*^[36], reported that the overall relative risk (RR) for DVT and PE in patients with IBD compared to subjects without IBD was 2.20 (95%CI: 1.83-2.65), and Fumery *et al*^[1] reported that the overall risk of VTE in IBD patients was increased by 96% compared to the general population (RR = 1.96; 95%CI: 1.67-2.30) with no differences between CD and UC patients.

In a recent nationwide multicenter study conducted in Austria, Papay *et al*^[37] investigated the prevalence and the incidence of VTEs in 2811 IBD patients and described many related clinical features. The overall prevalence of all VTEs was 5.6% (157/2811) and the incidence of all VTEs was 6.3/1000 person years. The majority of VTEs were DVT and/or PE (about 90%; 142/157), while other locations of venous thrombosis were rare (about 10%; 15/157) including the portal, the superior mesenteric, the splenic, the internal jugular, and the cerebral veins. No difference was found between CD and UC for the frequency of all VTEs, although the prevalence and incidence for DVT and/or PE was a little higher in CD patients.

VTEs occur earlier in life in IBD patients than in non-IBD thrombotic patients^[21,26,38,39]. Bernstein *et al*^[21] analyzed data from IBD and non-IBD hospitalized patients and found that the risk of VTE, DVT and/or PE, was overall higher in hospitalized IBD patients. The most striking difference in the risk was observed in patients who were less than 40 years of age, with an incidence rate ratio (IRR) for VTE of 4.5 for UC and 9.6 for CD compared with the non-IBD patients.

Thromboembolic complications are a significant cause of morbidity and mortality in IBD patients^[39-42]. In the study by Talbot *et al*^[4], 25% of IBD patients with thromboembolic complications had a fatal outcome during the thrombotic episode. Recently, Nguyen and Sam^[27], also reported higher rates of VTEs in hospitalized IBD patients than in non-IBD hospitalized patients. As was the case in Bernstein's report, those who were less than 40 years of age were at the greatest risk. Hospitalized IBD patients with thrombosis had a greater in-hospital mortality risk when compared to hospitalized IBD patients without thrombosis (OR = 2.5; 95%CI: 1.83-3.43) and to non-IBD hospitalized patients with thrombosis (OR = 2.1; 95%CI: 1.6-2.9). In addition, the occurrence of VTEs in hospitalized IBD patients significantly increased the length of hospital stay and health resource utilization cost.

Patients with IBD are at increased risk for postoperative VTE^[43]. Merrill and Millham^[33] reported that IBD patients were at increased risk for developing postoperative DVT or PE compared to non-IBD patients, especially after non-intestinal surgery. Furthermore, Wallaert *et al*^[34] studied VTE during the first 30 postoperative days in a

IBD: Inflammatory bowel disease; VTE: Venous thromboembolism; UC: Ulcerative colitis; CD: Crohn's disease.

large cohort of IBD patients having colorectal surgery (10431 patients, 5001 with UC and 5430 with CD) and found an overall incidence of 2.3% for VTEs (242 VTEs; 178 DVTs and 46 PEs). The rates of VTEs were higher for UC patients compared to CD patients (3.3% *vs* 1.4% respectively). The thromboembolic episodes occurred at an average of 10 d postoperatively and were associated with significant morbidity and mortality.

Recurrence of thromboembolic events has been previously reported as being 10%-13% in IBD patients^[4,39]. Novacek *et al*^[35] reported an approximately 30% probability of VTE recurrence in IBD patients 5 years after discontinuation of the anticoagulant treatment for the first VTE. The risk for recurrent VTE was higher in IBD patients compared to non-IBD patients. IBD, irrespective of the activity status, was found to be an independent risk factor for recurrent VTE with a relative risk of 2.5 (95%CI: 1.4-4.2). In accordance with that, Papay *et al*^[37] reported a similar incidence of recurrent VTEs (25%) in IBD patients; in the majority, the VTEs occurred in the same location (70%) and were of the same type (DVT or PE) as with the first episode.

Thromboembolic events are more frequent during active phases of IBD and correlate with the extent and location of the disease; most of them occur without evidence of provoking factors^[4,22,40,44]. Complicated IBD (fistula, stenosis, abscess)^[22,27], use of corticosteroids^[24], and recent hospitalization for IBD^[24] were all associated with increased risk for VTEs. Solem *et al*^[40] reported that 80% of IBD patients (both CD and UC) had active disease at the time of VTE. Regarding the extent of disease in patients with VTE, 76% of the UC patients had pancolitis and 79% of the CD patients had colonic involvement. In contrast to the above, Talbot *et al*^[4] found that almost 30% of VTEs occurred when the disease was in remission and that 77% of the peripheral VTEs occurred

spontaneously. In a recent study, Grainge *et al*^[25] assessed the risk of VTE at various activity phases of IBD (flare, chronic activity, remission) in a retrospective cohort study of 13756 IBD patients and 71672 matched controls from the prospectively generated General Practice Research Database (United Kingdom). They found that there is a significantly increased overall risk of VTE in IBD patients compared to controls during all phases of IBD (HR = 3.4; 95%CI: 2.7-4.3). The risk was most prominently increased during a flare (HR = 8.4; 95%CI: 5.5-12.8) compared with periods of chronic activity (HR = 6.5; 95%CI: 4.6-9) and periods of clinical remission (HR = 2.1; 95%CI: 1.6-2). In this unique study, the overall relative risk of VTEs in ambulatory IBD patients compared to controls appeared to be higher than in hospitalized IBD patients compared to controls (HR = 4.3; 95%CI: 3.3-5.7 *vs* HR = 2.1; 95%CI: 1.4-3.2). This apparent difference in the risk between ambulatory and hospitalized IBD patients compared to controls was even higher during periods of disease flares (HR = 15.8 *vs* 3.2, respectively). However, when the data were expressed as absolute risk of VTEs per 1000-person years it was obvious that the hospitalized IBD patients were more prone to thrombosis (25.2) than the non-hospitalized IBD patients (1.8), especially during a flare of the disease (37.5 *vs* 6.4, respectively). Finally, the risk of VTEs was higher during flares and chronic activity periods compared to periods of remission of the disease, both in ambulatory and hospitalized IBD patients. These data are further supported by the recent study of Papay *et al*^[37] who reported that 77% of VTEs in the IBD cohort occurred spontaneously, 77% occurred in outpatients and 66% occurred during an active period of the disease.

Collectively, all the recent studies discussed above confirm that patients with both CD and UC are at an approximately two-fold increased risk for VTEs compared to the general population or to non-IBD patients. The VTEs, mainly DVT and/or PE, tend to occur spontaneously, at a younger age, and more frequently during periods of active disease, in both ambulatory and hospitalized patients. There is also increased risk during periods of remission, during pregnancy, and postoperatively. They also recur frequently after the first episode. The VTEs in IBD patients are associated with significant morbidity and mortality (Table 1).

Arterial thromboembolism

Numerous cases and case series have reported ATEs in IBD patients. In general, ATEs occur less frequently than VTEs in IBD patients, and may involve the thrombosis and/or occlusion of the cerebral^[11,16], retinal^[16,17], carotid^[12,45,46], coronary^[19], splanchnic^[47], iliac^[48,49], renal^[48,49], and limb (upper and lower)^[50,51] arteries or the aorta^[48,49,52]. They are more common after interventional or surgical procedures, but they can also occur spontaneously^[4,51].

Recent studies^[53-59] and a meta-analysis^[60] provide evidence for an association between IBD and ATE, similar to that which exists with VTEs, despite the fact there

Table 2 Incidence, risk and clinical features of arterial thromboembolism in inflammatory bowel disease patients

IBD: Inflammatory bowel disease.

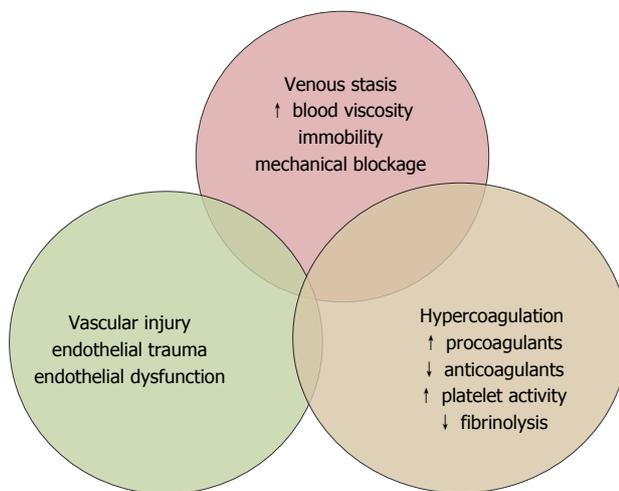

Figure 1 Basic mechanisms of thrombosis (Virchow's triad).

are some controversial findings in other studies^[30,61,62]. In their meta-analysis Singh *et al*^[60] analyzed data from 9 studies and found that IBD was associated with a modest increase for the risk of cardiovascular morbidity. In particular, 5 studies reported 2424 CVA events in 98240 patients with IBD and six studies reported 6478 occurrences of IHD in 123907 patients with IBD, which translates to a modest 18% increase in the overall risk for both CVA (adjusted OR = 1.18; 95%CI: 1.09-1.27) and IHD (adjusted OR = 1.18; 95%CI: 1.08-1.31). In addition, the risk was higher in females and young patients (age < 40-50 years). There were no differences between UC and CD patients. Finally, 2 studies reported 148 patients with peripheral arterial disease in 25559 patients with IBD, but the analyses showed that IBD was not associated with a significant increase for the risk of peripheral arterial disease (adjusted OR = 1.15; 95%CI: 0.96-1.38).

A nationwide United States study^[30], which investigated the association of cardiovascular diseases in 148229 hospitalized subjects with IBD compared to 17261952 controls, showed a significantly increased risk for mesenteric ischemia (adjusted OR = 3.4; 95%CI: 2.9-4.0) and thromboembolic disease in hospitalized IBD patients. Fumery *et al*^[11], in their meta-analysis, con-

cluded that overall IBD was associated with an increased risk of thrombovascular events. The major risks were for VTE and mesenteric ischemia and, to a lesser degree, for arterial thromboembolism and ischemic heart disease. Although they did not find an increase in the risk of cardiovascular mortality in IBD patients, Kristensen *et al*^[54], who investigated the risk of myocardial infarction (MI), stroke, and cardiovascular death in patients with IBD with correlation to disease activity in a nationwide Danish cohort, reported that the IBD is associated with increased risk of MI, stroke, and cardiovascular death during periods with active disease, including acute flares or persistent activity.

To summarize, recent data show that patients with IBD, both CD and UC, are at an increased risk for ATEs, mainly CVA, IHD and mesenteric ischemia, albeit to a lesser degree than for VTEs. The ATEs tend to occur spontaneously or post-surgically, at a younger age, in females, more frequently during periods of active disease and are associated with significant morbidity and mortality (Table 2).

MECHANISMS OF THROMBOSIS IN IBD

In contrast to hemostasis, which is a normal response to vascular injury, thrombosis is pathological coagulation occurring spontaneously or following a minimal vascular injury. The underlying cause of thrombosis is an imbalance between prothrombotic and antithrombotic mechanisms. The tendency towards thrombosis is related to three basic mechanisms, as defined by the Virchow's triad: vascular stasis, endothelial injury/vascular damage and hypercoagulability (Figure 1).

Evidence from the literature suggests that thrombosis is a specific feature of IBD that is involved in both the occurrence of thromboembolic events and the pathogenesis of the disease itself^[44]. Multifocal vascular infarcts in the intestinal microcirculation, characterized by chronic vasculitis, with focal arteritis and fibrin deposition, have been reported in patients with CD^[63]. Histological studies have also found mucosal capillary thrombi in patients with UC^[64]. In addition, Thompson *et al*^[65], in a large study involving 129 hemophilia centers in United Kingdom, reported a lower than expected incidence of IBD in 9562 patients with hemophilia or von Willebrand's disease and concluded that a congenital bleeding diathesis may have a protective role against the development of IBD. Furthermore, Miehsler *et al*^[22] demonstrated that IBD *per se* is a risk factor for thromboembolic and concluded that thromboembolism is a specific feature of IBD since neither rheumatoid arthritis, another chronic inflammatory disease, nor coeliac disease, another chronic bowel disease, had an increased risk of thromboembolism.

The exact etiology for the higher occurrence of thromboembolism in IBD and the specific association between them is yet unknown, though it seems that multiple acquired and inherited factors may be involved (Table 3).

General acquired prothrombotic factors such as

Table 3 Acquired and hereditary thrombotic risk factors in inflammatory bowel disease patients

| Factors | Mechanism |
|--|---|
| Acquired | |
| Inflammation | Hypercoagulation, vascular endothelial injury |
| Immobilization | Stasis |
| Indwelling IV catheters | Vascular injury |
| Dehydration | Stasis |
| Steroid use | Hypercoagulation |
| Oral contraceptives | Hypercoagulation |
| Surgery | Stasis, hypercoagulation, vascular injury |
| Pregnancy | Stasis, hypercoagulation |
| Cancer | Hypercoagulation |
| Infections | Hypercoagulation |
| Age | Hypercoagulation |
| Smoking | Hypercoagulation |
| Hereditary | |
| Proteins C and S deficiencies | Hypercoagulation |
| Antithrombin deficiency | Hypercoagulation |
| Factor V Leiden | Hypercoagulation |
| Hyperhomocysteinemia-MTHFR gene mutation | Hypercoagulation |
| Prothrombin gene mutation G20210A | Hypercoagulation |
| Dysfibrinogenemia | Hypercoagulation |

inflammation, older age, surgery, prolonged immobilization, central venous catheters, fluid depletion, steroid therapy, smoking, and oral contraceptives are frequently observed in IBD patients, but their presence cannot adequately explain the increased risk for thromboembolisms in IBD^[44]. On the other hand, many studies and reviews have failed to establish a significant association of the inherited thrombophilias, such as factor V Leiden, prothrombin G20210A mutation, MTHFR mutation-related hyperhomocysteinemia, protein C, S and antithrombin deficiencies, with the increased risk of thrombosis in IBD patients, although their co-existence with IBD has a synergistic role in thromboembolic complications^[44,66,67]. Multiple risk factors are often present in IBD patients^[40], although none of them is more significant than the others, it seems obvious that as more risk factors accumulate in a patient, thrombosis is more likely to occur in that patient.

Inflammation and hypercoagulation in IBD

Inflammation, both intestinal and systemic, is the prominent feature in IBD. Inflammation and thrombosis are probably interrelated in IBD, through complex and as yet not fully understood pathways. Consequently, local and systemic intravascular hypercoagulable and prothrombotic states or even frank thrombosis, may represent contributing underlying factors in IBD pathogenesis^[68].

The hypercoagulable state has been associated particularly with active disease^[69]. Several studies have reported abnormalities in various components of hemostasis and the coagulation cascade during exacerbations of IBD (Table 4), as follows: (1) elevated levels of coagulation factors (V, VIII, von Willebrand, and fibrinogen) and

Table 4 Prothrombotic abnormalities of hemostasis and coagulation in inflammatory bowel disease patients

| Category | Abnormality |
|---|--------------------------------------|
| Coagulation factors | ↑ V, VIII, vWf, and fibrinogen |
| Products of thrombin generation | ↑ F1 + 2, TAT |
| Products of fibrin formation | ↑ fibrinopeptide A, D-Dimers |
| Vascular endothelium activation | ↑ vWf, thrombomodulin |

products of thrombin and fibrin formation (fibrinopeptide A, prothrombin fragment 1+2 [F1+2], thrombin-antithrombin complex [TAT], and D-Dimers)^[70-74]; (2) increased markers of vascular endothelial activation (von Willebrand factor and thrombomodulin)^[74-78]; (3) acquired deficiencies and dysfunction of natural anticoagulants (protein C, protein S, and antithrombin)^[79-82]; (4) defects in the fibrinolytic system [low levels of tissue plasminogen activator (t-PA), high levels of plasminogen-activator inhibitor type-1 (PAI-1)]^[83,84]; and (5) elevated number of circulating platelets, platelet activation and increased platelet aggregation tendency^[85-87]. However, in other studies, activation of coagulation was observed both in active and inactive IBD^[88-90], an observation that is in accordance with the occurrence of thromboembolic complications even in IBD patients with quiescent disease.

The hypercoagulable state in IBD has recently been reviewed thoroughly elsewhere^[67]. It can be postulated that, in IBD patients, a persistent latent activation of hemostasis exists in both active and inactive disease states, and is implicated in the thrombotic diathesis and perhaps in disease pathogenesis. Hence, two questions emerge: what is the underlying mechanism for the abnormal hemostasis activation and why do clinically overt thromboembolic complications occur only in a relatively small fraction of IBD patients? A possible explanation for the latter question is the fact that for a thromboembolic event to occur, hypercoagulability alone is not sufficient, and that many other predisposing risk factors have to be present at the same time. On the other hand, for the former question to be answered, one must search deeper into the pathophysiology of intestinal inflammation.

Inflammation and vasculopathy in IBD

As a result of the chronic inflammation in IBD patients, abnormalities exist in both the local intestinal microvasculature and the systemic circulation. Bargen and Barker, almost 80 years ago, stated that, in a subgroup of UC patients, the disease should be described using the term “thrombo-UC”^[3]. Histological studies have revealed vas-

culitis in a subgroup of UC patients^[91], while other studies have shown mucosal capillary thrombi in rectal biopsies from UC and CD patients^[64], although this finding is not specific for IBD^[92]. Wakefield *et al*^[63], proposed that multifocal infarcts in the intestinal microcirculation caused by arteritis with fibrin deposition due to focal vasculitis, might be implicated in CD pathogenesis. Moreover, the proximal demarcation line between involved and uninvolved colon in UC suggests that a microvascular abnormality may be associated with the pathogenesis and the extent of inflammation in UC^[93].

The hemostatic and the inflammatory pathways are closely related in a bi-directional fashion, and the vascular endothelium has been proven to be the interface of their interactions^[68,94-97]. The “vascular hypothesis” suggests that endothelial dysfunction in the intestinal microcirculation plays central role in both UC and CD pathogenesis^[98-100]. Furthermore, the vascular endothelial dysfunction associated with chronic inflammation is critically involved with the hypercoagulable state and the development of thrombosis and atherosclerosis in IBD patients, and clinically manifested as systemic vascular (venous and arterial) thromboembolic complications or IHD^[99-101]. Normally, the “quiescent” intact endothelium exhibits a strong thrombo-resistant surface, expressing antiplatelet, anticoagulant and fibrinolytic properties. An “activated” endothelium is rapidly transformed into a prothrombotic surface, which promotes blood coagulation, inhibits fibrinolysis and activates platelets. The transformation of the vascular endothelial surface from anti-coagulant to pro-coagulant is triggered by mechanical damage, or by perturbation and activation of the vascular endothelial cells. Agents including cytokines, endotoxins, blood mediators, hypoxia, and hemodynamic forces are involved in endothelial cell activation^[102].

Inflammation turns the “quiescent” endothelium into a potent pro-coagulant surface. Interleukin-1 (IL-1), tumor-necrosis factor- α (TNF- α) and other cytokines, which are increased in IBD, are responsible for this pro-coagulant, thrombophilic effect, and increase both white cell and platelet adhesion molecules on the endothelial surface. Many studies suggest that IL-1, TNF- α and other pro-inflammatory cytokines, increase various thrombophilic factors and have a significant contribution in intravascular thrombosis^[103,104].

On the other hand, both thrombosis and “activated” endothelium can promote inflammation. The central role of the endothelial cell in initiation and propagation of inflammation takes place through the recruitment of leukocytes by cell adhesion molecules. The expression of cell adhesion molecules on the endothelial surface is induced by IL-1, TNF- α , and other proinflammatory cytokines. In IBD, the activated endothelial cells express increased surface levels of various intercellular adhesion molecules, such as ICAM-1 (intercellular adhesion molecule-1) and VCAM-1 (vascular cell adhesion molecule-1)^[105]. PECAM-1 (platelet endothelial adhesion molecule-1) is expressed in high levels even in areas of

the colon not affected by UC^[106]. The selectin family (E-, P-, L- selectins), which is involved in leukocyte rolling on the endothelial surface, is increased in IBD^[107]. Furthermore, the CD40/CD40L co-stimulatory pathway, which is involved in inflammation and coagulation, is activated in IBD tissue. In active IBD, CD40 is overexpressed in the microvascular endothelial cells, CD40L is overexpressed in platelets and leukocytes, and the soluble form of CD40L (sCD40L) is increased in the circulation in patients with active disease. The contact of the CD40L+ leukocytes and platelets with the CD40+ endothelial cells in the intestinal microvasculature results in activation of these cells, which in turn promote leukocyte recruitment, platelet aggregation, thrombosis, vascular damage and tissue injury, through a vicious cycle of enhanced production of cytokines and chemokines, and overexpression of adhesion molecules and the tissue factor on endothelial cells^[108-110]. All or some of these molecules are possible therapeutic targets in IBD management^[107-109,111].

Moreover, the production of potent vasoconstrictors from the activated endothelium, such as endothelin-1 and thromboxanes, may contribute to ischemia-reperfusion vascular and tissue injury^[107]. The increased reactive oxygen metabolites (ROMs) found in IBD come from leukocytes and endothelial cells, and may be the products of a recurrent ischemia-reperfusion injury of the vascular epithelium after microthrombi formation^[112,113]. ROMs, in turn, may be implicated in the inflammatory reaction and tissue injury in IBD through activation of NF- κ B factor, which promotes the production of various pro-inflammatory cytokines^[114].

Thrombin, besides its actions in regulating hemostasis, possesses “non-coagulant” functions (Figure 2)^[96,115,116]. Thrombin promotes the production of monocyte chemoattractant protein-1 (MCP-1) from monocytes and interleukins-6 and -8 (IL-6 and IL-8) from fibroblasts, epithelial cells, monocytes and endothelial cells. Thrombin enhances leukocyte adhesion on endothelial cells through induction of endothelial PAF (platelet activating factor) formation^[117-122].

Collectively, a possible pathway in IBD pathogenesis could involve the combination of a “sepsis” model with a persistent, low-grade, controlled and compensated disseminated intravascular coagulation due to infection-induced hemostasis activation^[96,97,123-125] and an “endothelial perturbation-inflammation” model due to ischemia-reperfusion injury^[98,107,126]. It is well known that the increased intestinal permeability in IBD results in an inflammatory reaction in the bowel wall, due to the dysregulated mucosal uptake of luminal bacterial, toxic and antigenic substances. Both the inflammatory reaction and the endotoxemia might promote hemostasis activation and hypercoagulation^[123]. Endotoxin and endotoxin-induced microclots in the systemic circulation have been found in a high proportion of IBD patients^[124,125]. Furthermore, ischemia/reperfusion-induced endothelial dysfunction^[126] promotes inflammation, thrombosis, vas-

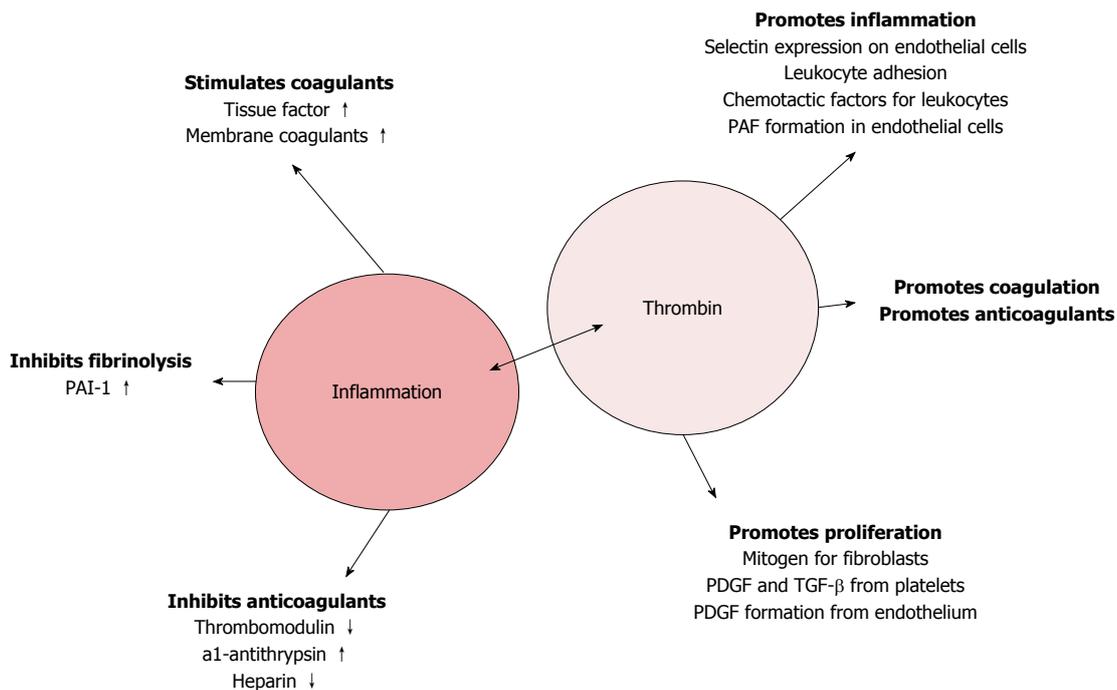

Figure 2 Inflammation and coagulation pathways are interrelated. PAF: Platelet activating factor; PAI-1: Plasminogen-activator inhibitor type-1; TGF: Transforming growth factor.

Table 5 Management of thromboembolic complications in inflammatory bowel disease patients

| Primary prevention of thromboembolic complications | |
|---|---|
| Ambulatory patients | Hospitalized patients |
| General measures | General measures |
| Physician awareness | Disease activity amelioration |
| Patient education | Early mobilization |
| Active disease treatment and remission maintenance | Judicious use of catheters |
| Recognition, elimination or modification of risk factors | Dehydration or nutritional deficiencies restoration |
| Steroid use | Medication modification |
| Smoking | Peri-operatively or in severely ill non-surgical patients |
| Oral contraceptives | Prophylactic anticoagulation (UH or LMWH) |
| Cardiovascular risk factors and other co-morbidities | Plus mechanical measures when increased thrombosis risk or mechanical measures only, when anticoagulation contraindicated with high bleeding risk |
| Long-distance flights | |
| Post-hospitalization period | |
| Compressive stockings? | |
| Treatment of a thromboembolic event | |
| Amelioration of disease activity | |
| Hematology consultation and thrombophilia screening | |
| Therapeutic anticoagulation - UH or LMWH | |
| Thrombolysis - interventional radiology/surgical consultation | |
| Secondary prevention of thromboembolic complications | |
| After a first TE episode | |
| Active disease - spontaneous event | |
| Short term anticoagulation? - 3 to 6 mo | |
| Plus anticoagulation during subsequent flares? | |
| Inactive disease - spontaneous event | |
| Long term anticoagulation? | |
| Recurrent TE or inherited thrombophilia | |
| Hematology consultation | |
| Long term anticoagulation | |

UH: Unfractionated heparin; LMWH: Low molecular weight heparin.

cular anatomic and functional changes, and tissue injury through a self-propagating loop (Figure 3).

MANAGEMENT OF THROMBOEMBOLISM IN IBD PATIENTS

The management of thromboembolism in IBD patients includes primary prophylaxis of first Thromboembolic complication, treatment of a Thromboembolic complication and secondary prophylaxis of the recurrence of a thromboembolic complication (Table 5). Currently, there are no universal and specific guidelines for the management of Thromboembolic in IBD patients in various clinical settings, except for the primary prophylaxis of VTE in hospitalized IBD patients with severe active disease^[127-132].

Primary prevention of venous thromboembolic complications

Hospitalization is an important risk factor for VTEs for many patient groups, including IBD patients^[25,27]. According to the American College of Chest Physicians (ACCP) guidelines for the prevention of VTE^[127],

hospitalized patients with IBD are at a moderate risk (10%-40%) of developing DVT and prophylaxis is the recommended beneficial strategy. The first choice is prophylaxis with a low-molecular-weight heparin (LMWH), low-dose unfractionated heparin (LDUH), or fondaparinux. Mechanical thromboprophylaxis is recommended for patients at high bleeding risk, or if anticoagulants are contraindicated^[127]. International and national IBD organizations and societies in North America and Europe have adopted these recommendations in their recent guidelines for the management of IBD patients requiring hospitalization^[128-132]. The recommendations are more clearly stated for patients with severe UC^[128-131].

However, there are some issues regarding anticoagulation of hospitalized IBD patients which need special consideration. Rectal bleeding is a common symptom in IBD patients (mainly UC) and therefore there is a theoretical concern about worsening the rectal bleeding. Data derived from randomized trials which used UH^[133,134] or LMWH^[135-138] as a treatment for active IBD (UC) and a meta-analysis^[139] showed that although a clear benefit from the heparin use in ameliorating the disease activity was not demonstrated, its use was safe, without major adverse events. Heparin could be an ideal drug for IBD treatment, especially for UC, because of its anticoagulant, anti-inflammatory, immunomodulatory and mucosal healing properties. The failure of the existing trials to prove its efficacy for the UC treatment could be related to the small patient number and the heterogeneity of these studies regarding the compound of LMWH and the dosage administered, the duration of treatment and the definition of response to treatment. Larger studies may be needed to clarify this issue and to reveal the optimal dosing of heparin and the features of a subgroup of patients with active UC who may benefit from LMWH administration.

Recently, Ra *et al*^[140] retrospectively assessed the safety of prophylactic anticoagulation in hospitalized IBD patients. They reported that 80% of the IBD patients received anticoagulation, mainly in the form of LMWH (93%). Anticoagulation administration was more frequent to IBD patients on the surgical service, those with more extensive disease and predominantly those without rectal bleeding. They also found that the rates of major or minor bleeding were not significantly higher in patients who received prophylactic treatment compared to those who did not. The authors concluded that the use of anticoagulation in IBD hospitalized patients is safe, even in the presence rectal bleeding provided that there are no signs of hemodynamic instability^[140].

Another issue which needs discussion is whether anticoagulation prophylaxis should be administered only to severely ill hospitalized IBD patients or to all hospitalized IBD patients. Since hospitalization is an independent risk factor for VTEs in IBD patients and these patients may have additional risk factors for thrombosis (inflammation, catheters, immobilization, complicated disease), it would be reasonable to take measures in order to reduce the

other risk factors by aiming to: ameliorate disease activity, institute early mobilization, use IV catheters judiciously, avoid/treat dehydration and nutritional deficiencies, and minimize medications predisposing to thrombosis. Finally, it would be prudent to expand the indication for prophylaxis to inpatients with IBD who are not necessarily too ill to be confined to bed^[25,27] or even are in remission and hospitalized for other indications, since there is significantly increased risk for VTEs in these groups as well^[25]. Prophylaxis, together with the increased awareness for signs VTEs during the routine clinical assessment of the IBD patients admitted to the hospital, may be more feasible and cost-effective in clinical practice than the use of expensive screening tests^[141].

Another important question that needs an answer is the duration of prophylactic anticoagulation in non-surgical IBD patients after discharge from the hospital. Studies have demonstrated that many VTEs occur during the immediate post-hospital period both in the general population^[142] and in IBD patients^[24,25]. Patients with IBD are discharged from the hospital with improved, but not necessarily fully remitted, disease and to date there are no data for extended VTE prophylaxis during this post-hospitalization period, although its use could be justified in patients with increased risk for thrombosis^[143-145].

Patients with IBD are at increased risk for postoperative VTE^[33,34,43]. According to the data from these studies and to the ACCP guidelines, patients with CD have a moderate risk of VTEs after intestinal surgery, while the patients with UC have a high risk of post-surgical VTEs^[146]. Furthermore, Scarpa *et al*^[147] reported that a standard prophylactic dose of LMWH was inadequate to prevent VTEs in IBD patients with major colorectal surgery and in particular in patients with UC. These data suggest that the perioperative prophylactic anticoagulation in IBD patients should include higher doses of LMWH, for longer periods post-operatively, or even be combined with adjunct mechanical methods^[146-148].

Recent data have confirmed that ambulatory IBD patients with active disease are at increased risk for VTEs^[25,37]. Although, Grainge *et al*^[25] reported that the risk of VTEs was significantly higher during flares and chronic activity periods compared to periods of remission of the disease, both in ambulatory and hospitalized IBD patients, currently there are no guidelines for the primary prevention of VTEs nor is sufficient data for the beneficial use of anticoagulants in the ambulatory setting^[145]. However, general prophylactic measures could also be applied in the ambulatory setting and include: patient education about the risks and the presenting symptoms of thromboembolic complications; enhancement of clinician awareness of this ominous extraintestinal manifestation, with attention to the history and clinical signs of TE in the routine clinical assessment of IBD patients; aggressive treatment of active disease and maintenance of remission; early recognition and elimination or minimization of modifiable risk factors (steroid use, smoking, oral contraceptives, hormone-replacement therapy, long-

distance flights)^[149-151]. Furthermore, in a recent decision analysis study, Nguyen and Sharma^[152] explored the cost-effectiveness of pharmacological VTE prophylaxis in ambulatory IBD patients and concluded that pharmacological VTE prophylaxis in ambulatory IBD patients with acute disease could not be recommended, even though it was beneficial, because it was not cost-effective.

There are no direct data that anticoagulation for VTE prophylaxis in IBD patients actually works since there are no randomized controlled trials that have evaluated this issue yet. However, indirect evidence demonstrated that in acutely ill medical patients pharmacological prophylaxis significantly reduces the incidence of VTE and mortality^[127,143,144].

Primary prevention of ATEs

Apart from the general measures mentioned previously and anticoagulation prophylaxis during hospitalization or post-operatively, clinicians should routinely assess IBD patients for cardiovascular risk (hypertension, diabetes, hyperlipidemia, obesity, hyperhomocysteinemia, positive family history) and preventive measures and/or treatment of these risk factors should be applied^[2].

Therapy of VTE and secondary prevention

The treatment of an acute thromboembolic episode in IBD patients is similar to non-IBD patients. Pharmacological anticoagulation (AC) with UH or LMWH is usually administered in mild to moderate Thromboembolic events, while thrombolysis or catheter-directed thrombolysis (CDT) are reserved for more severe TEs including massive thrombosis and organ- or life- threatening vascular occlusion^[2,150]. Therapeutic doses of anticoagulants or thrombolytics for the treatment of TEs in IBD patients presents a major safety concern regarding the risk of gastrointestinal (GI) and systemic hemorrhagic complications, since many of the patients have active disease with rectal bleeding. The management decisions should be individualized according to the clinical setting in each patient and episode, and often requires a multidisciplinary approach^[2,150]. The safety of UH and LMWH has been proven in previous studies which evaluated heparin for the treatment of active IBD^[139]. Tabibian *et al*^[153] in a systematic review evaluated the clinical outcomes with anticoagulation and CDT in IBD patients with TE, and reported that both CDT and AC were well tolerated by IBD patients with TE. They suggested that CDT may be used preferentially in patients with severe life-threatening TE, while AC may be more suitable in patients with less clinically significant Thromboembolic or patients at higher risk for bleeding. Furthermore, they demonstrated the safety of these treatments, even when they were used in patients with rectal bleeding, provided that there was no concurrent major GI hemorrhage^[153,154].

The duration of anticoagulation is another important issue because of the increased risk of recurrence of TEs in IBD patients. The duration of anticoagulation after initial treatment for Thromboembolic ranges from 3 mo

to lifelong, depending on the individual case. In cases where a Thromboembolic event occurred during active disease, the anticoagulation must be continued at least until clinical remission occurs^[2,154]. In a recent decision analysis study, Nguyen and Bernstein^[155] suggested that lifetime anticoagulation was marginally more beneficial than the time-limited (6-mo) anticoagulation after a first unprovoked VTE in the absence of active disease. They also recommended that in the case of VTE during a flare of the disease, time-limited anticoagulation with or without prophylaxis during subsequent flares would be a more suitable option^[155]. In general, LMWHs, vitamin K antagonists (VKAs; warfarin) or even the new direct oral anticoagulants (NOACs; rivaroxaban, dabigatran, apixaban, and edoxaban) can be used for the long term treatment of TEs. For NOACs new evidence from studies suggests that they have comparable efficacy to that of VKAs with a more favorable safety profile, but there is no direct evidence for their use in IBD patients yet^[156,157].

Physicians' perceptions of the risks and practices in VTE prophylaxis in IBD patients

The risk of thrombosis in IBD patients is high, with significant morbidity and mortality. It is important for the treating physicians to be aware of this serious extraintestinal manifestation and to be able to efficiently recognize and treat the Thromboembolic events. As previously mentioned, international and national IBD organizations and societies in North America and Europe have recently published guidelines for the prevention of TEs in IBD patients^[128-132]. However, surveys which have evaluated the practices of gastroenterologists regarding the issue of VTE prophylaxis in IBD patients have shown that although a significant proportion is aware of the increased risk of TEs in hospitalized IBD patients, their practices for VTE prophylaxis is variable^[158-161].

Razik *et al.*^[158] reported that among 56 Canadian academic gastroenterologists, 55% reported the existence of standard hospital protocols for DVT prophylaxis in hospitalized IBD patients, and more than 80% reported the administration of some form of VTE prophylaxis, but only 50% of them were aware of the existing guidelines. Sam *et al.*^[159] in a similar survey among 135 gastroenterologists in United States, practising mainly in an academic setting (77%), reported that although most of them (84%) had IBD patients with VTE and realized the risks of VTEs, only 67% had protocols for VTE prophylaxis, 45% were aware of the guidelines and finally, 14% would never administer prophylaxis in their IBD inpatients. Gastroenterologists with high volumes of IBD patients were more likely to administer VTE prophylaxis. In addition, Tinsley *et al.*^[160] reported that the awareness of the heparin use for VTE prophylaxis was more frequent among gastroenterologists who were in academic settings, and those who had high volumes of IBD patients, and those who had less than 5 years of practice experience. Finally, Tinsley *et al.*^[161], in another study,

investigated retrospectively the rates of pharmacologic VTE prophylaxis in UC inpatients at a tertiary referral center and concluded that pharmacologic prophylaxis was not ordered or was administered inadequately in a substantial proportion of UC patients admitted in the hospital despite the existing guidelines.

To summarize, all these data clearly show that there are significant variations in practice regarding VTE prophylaxis in hospitalized IBD patients due to a high level of unawareness of current guidelines. It is important for Gastroenterology societies and organizations to more aggressively pursue the education of gastroenterologists, especially those with low volumes of IBD patients, so that they better understand the risks and the adverse outcomes of thromboembolism in IBD patients. The goals are to have them routinely incorporate clinical assessment for signs and symptoms of TEs and to have them efficiently prevent or treat TEs^[162]. Very recently, during finalization of the present review, the Canadian Association of Gastroenterology (CAG) published (in press-on line first) specific recommendations for the prevention and the treatment of VTE in IBD patients in various clinical settings^[163]. The CAG has addressed many of the gaps which exist in the management of VTE in this patient group and has provided a useful and applicable evidence-based guide for the physicians who are involved with the care of IBD patients. The recent CAG guidelines give solid recommendations for some of the important issues we have outlined in Table 5.

CONCLUSION

Evidence from the literature suggests that thrombosis is a specific feature of IBD that can be involved in both the occurrence of thromboembolic events and the pathogenesis of the disease itself. The precise etiology for the higher rates of thromboembolism in IBD and the specific association is as yet unknown, but multiple acquired and inherited factors are implicated. Hypercoagulability is thought to be involved in IBD pathogenesis and future research may reveal potential therapeutic targets for the IBD management. More importantly, both arterial and venous thromboembolic complications are serious and challenging extra-intestinal manifestations to manage, with significant morbidity and mortality in IBD patients. However, thromboembolism is preventable and, therefore, clinician awareness of the risks, and the knowledge of how to efficiently prevent or treat TEs in patients with IBD are of vital importance. Future clinical trials should clarify the ill-defined issues of the thromboprophylaxis in ambulatory patients with active disease, the thromboprophylaxis in patients during the immediate post-hospitalization period, and the duration of thromboprophylaxis. In addition, clinical trials should provide clinicians with reliable methods or markers for assessing the prothrombotic risk in IBD patients in order to promptly apply preventive measures.

Abstract

The authors revise the latest evidence in the literature regarding managing of osteoporosis in ulcerative colitis (UC), paying particular attention to the latest tendency of the research concerning the management of bone damage in the patient affected by UC. It is wise to assess vitamin D status in ulcerative colitis patients to recognize who is predisposed to low levels of vitamin D, whose deficiency has to be treated with oral or parenteral vitamin D supplementation. An adequate dietary calcium intake or supplementation and physical activity, if possible, should be guaranteed. Osteoporotic risk factors, such as smoking and excessive alcohol intake, must be avoided. Steroid has to be prescribed at the lowest possible dosage and for the shortest possible time. Moreover, conditions favoring falling have to be minimized, like carpets, low illumination, sedatives assumption, vitamin D deficiency. It is advisable to assess the fracture risk in all UC patient

by the fracture assessment risk tool (FRAX[®] tool), that calculates the ten years risk of fracture for the population aged from 40 to 90 years in many countries of the world. A high risk value could indicate the necessity of treatment, whereas a low risk value suggests a follow-up only. An intermediate risk supports the decision to prescribe bone mineral density (BMD) assessment and a subsequent patient reevaluation for treatment. Dual energy X-ray absorptiometry bone densitometry can be used not only for BMD measurement, but also to collect data about bone quality by the means of trabecular bone score and hip structural analysis assessment. These two indices could represent a method of interesting perspectives in evaluating bone status in patients affected by diseases like UC, which may present an impairment of bone quality as well as of bone quantity. In literature there is no strong evidence for instituting pharmacological therapy of bone impairment in UC patients for clinical indications other than those that are also applied to the patients with osteoporosis. Therefore, a reasonable advice is to consider pharmacological treatment for osteoporosis in those UC patients who already present fragility fractures, which bring a high risk of subsequent fractures. Therapy has also to be considered in patients with a high risk of fracture even if it did not yet happen, and particularly when they had long periods of corticosteroid therapy or cumulative high dosages. In patients without fragility fractures or steroid treatment, a medical decision about treatment could be guided by the FRAX tool to determine the intervention threshold. Among drugs for osteoporosis treatment, the bisphosphonates are the most studied ones, with the best and longest evidence of efficacy and safety. Despite this, several questions are still open, such as the duration of treatment, the necessity to discontinue it, the indication of therapy in young patients, particularly in those without previous fractures. Further, it has to be mentioned that a long-term bisphosphonates use in primary osteoporosis has been associated with an increased incidence of dramatic side-effects, even if uncommon, like osteonecrosis of the jaw and atypical sub-trochanteric and

diaphyseal femoral fractures. UC is a long-lasting disease and the majority of patients is relatively young. In this scenario primary prevention of fragility fracture is the best cost-effective strategy. Vitamin D supplementation, adequate calcium intake, suitable physical activity (when possible), removing of risk factors for osteoporosis like smoking, and avoiding falling are the best medical acts.

Key words: Ulcerative colitis; Osteoporosis; Fragility fracture; Bone mineral density; Trabecular bone score; Hip structural analysis; Fracture assessment risk tool; Dual energy X-ray absorptiometry

Core tip: Diagnosis and treatment of osteoporosis in ulcerative colitis are discussed according to the latest evidence. Innovative applications of new programs derived from bone densitometry to evaluate bone quality and to predict fracture risk in patients affected by ulcerative colitis are described. Charts for ten years fracture risk may be utilized to refer patients to bone densitometry and/or to prescribe drugs against osteoporosis. Trabecular bone score and hip structural analysis may be considered to assess bone quality, that could be impaired by malabsorption and chronic inflammatory status. Advices for prevention and treatment of bone damage are given, also considering cost-effectiveness.

INTRODUCTION

Osteoporosis is a well known extraintestinal manifestation of the inflammatory bowel diseases (IBD), more common in Crohn's disease (CD) than in ulcerative colitis (UC). Nowadays its management has been recognized as a relevant aspect in patients' follow up. As IBD is a chronic condition lasting the whole life of the patient, the effects of the disease and of its treatment, together with the ageing of the population, determine an increase in the prevalence and in the incidence of osteoporosis. The present article revises the latest evidences (2009-2014) in the literature regarding this theme, paying particular attention to the latest tendency of the research concerning the management of bone damage in the patient affected by UC. The authors have consulted PubMed, Embase, Cochrane Library, National Institute for Health and clinical excellence. In addition, the official positions of the gastroenterological societies and the leading guidelines for the management of osteoporosis have been examined.

ULCERATIVE COLITIS

UC is a chronic inflammatory disease of colon and rectum. The disease reaches from the anal verge to a variable proximal extension of the colon. The main peak incidence is between the second and the fourth decade, but the disease may also start later. Both men and women are affected with a similar frequency.

Aetiology is unknown. Regarding pathogenesis, the inflammation is probably caused by a pathologic immune response to an unknown environmental stimulus in the lumen of the colon in genetic susceptible people. A defective colonic epithelium may allow commensal bacteria to be sampled by dendritic cells of the mucosa and act as antigenic stimulus to induce an immune response, sustained by T-cells, leading to inflammation^[1].

Symptoms are rectal blood and mucus, tenesmus, urgency and diarrhoea, depending on the extent and the severity of the disease. Usually UC is classified in mild, moderate and severe, depending on the clinical manifestations according to the Montreal criteria^[2] (Table 1).

About one third of patients presents immune mediated inflammatory extra intestinal manifestations, which may affect liver and biliary system, joints and bone, skin, eyes.

The usual course of UC presents periods of acute inflammation and phases of remission of symptoms. In rare cases there is only one flare of disease, which can be very severe ("fulminant" colitis). The recurrences are variable in extent and severity and unpredictable in timing. Aim of the therapy is to induce the remission and to maintain it as long as possible.

Systemic and/or topical therapy is focused against pathologic immune response. Mainsteps of the pharmacological treatment are 5-aminosalicylic acid, glucocorticoids, azathioprine and its derivative 6-mercaptopurine, cyclosporine and biological agents such as infliximab and adalimumab.

Bone implication of UC is represented by osteoporosis, even if it is less frequent than in CD.

OSTEOPOROSIS

Osteoporosis is defined as a systemic disease characterized by low bone mass and micro-architectural deterioration of the bone tissue, with a consequent increase in bone fragility^[3]. The compromised bone strength leads to an increased risk of fracture, as bone strength reflects the integration of bone mineral density (BMD) and bone quality^[4]. The disease typically occurs in postmenopausal women and in the elderly people (primary osteoporosis) or in patients with diseases affecting bone mineral metabolism, like IBD (secondary osteoporosis). Also glucocorticoid treatment is a well-known factor leading to osteoporosis.

Common sites of osteoporotic fractures are the spine, the hip, the distal forearm and the proximal humerus. Osteoporotic fractures also occur at many other sites in-

Table 1 Montreal classification of extent and severity of ulcerative colitis

| Extent | Anatomy | Severity | Definition |
|---|---|----------------------------|---|
| E1: Ulcerative proctitis | Limited to the rectum | S0: Clinical remission | Asymptomatic |
| E2: Left sided (distal) ulcerative colitis | Limited to a proportion of the colorectum distal to the splenic flexure | S1: Mild | ≤ 4 stools/d (with or without blood), absence of systemic illness, and normal inflammatory markers |
| E3: Extensive (pancolitis) ulcerative colitis | Extends proximally to the splenic flexure | S2: Moderate S3: Severe | > 4 stools/d but minimal signs of systemic toxicity ≥ 6 bloody stools/day, pulse ≥ 90 beats/min, temperature ≥ 37.5 °C, haemoglobin < 1.05 g/L, and erythrocyte sedimentation rate ≥ 30 mm in the first hour |

cluding pelvis, ribs and distal femur and tibia.

Osteoporotic fractures are associated with high rates of disability and mortality. Approximately 50% of fracture-related deaths in women are due to hip fractures, 28% to clinical vertebral fractures and 22% to other fractures^[3]. In individuals who experience hip fractures, 20% die within the next year and 20% will require permanent nursing home care^[4-6]. Vertebral fragility fractures are the most frequent fractures in osteoporotic patients, and even if this kind of injuries has less severe complications than hip fractures, they are associated with substantial disability due to impairment in spine dynamics and static biomechanics. Furthermore, the number and the severity of vertebral fractures are related to an exponential increase of subsequent fractures^[7,8].

The gold standard method for the diagnosis of osteoporosis is the dual energy X-ray absorptiometry (DXA) which is a radiological tool based on the principle of photon absorptiometry developed in the sixties^[9] that allows to quantify the BMD^[10].

Bone densitometry scans for diagnostic classification and prediction of fracture risk are performed according to the international guidelines^[11] on lumbar spine and proximal femur, which are the most important sites of fragility fractures. Absolute values of BMD are expressed as T-score and Z-score. T-score is calculated as standard deviation from the normal reference population, and Z-score is calculated as standard deviation from the sex and age matched population. Osteopenia is defined as a T-score between -1 and -2.5. Osteoporosis is defined as a

T-score < -2.5^[10]. Low BMD is directly correlated with an increase in fracture risk^[3].

The goal of the pharmacological therapy of osteopenia and osteoporosis is to increase bone strength, in order to decrease the risk of fracture^[3] mainly by increasing BMD. This can be achieved by decreasing bone resorption and/or increasing bone formation.

A lot of effective medications are approved for the prevention and the treatment of osteoporosis. Drugs can be divided into two categories: anti-resorptive (or anti-catabolic) and anabolic agents. Anti-resorptive agents, which include oestrogens, selective oestrogen receptor modulators (raloxifene), calcitonin, bisphosphonates (alendronate, risedronate, ibandronate, zoledronate) and denosumab, reduce osteoclast activity, preserving bone mineral density. The currently used anabolic agent is teriparatide (PTH 1-34) which stimulates osteoblast activity. Strontium ranelate is another agent that reduces fracture risk. It improves bone strength mainly through effects on bone formation and bone properties^[3], even if it also has an anti-resorptive action.

The anti-fracture efficacy of the most frequent used drugs for osteoporosis is illustrated in Tables 2 and 3.

The effectiveness of drugs in primary and secondary prevention of fragility fracture is quite different. Regarding vertebral fractures, all the considered drugs are effective in preventing secondary osteoporotic fractures, whereas not all these drugs are also effective in primary prevention. No effectiveness is found in reduction of vertebral fracture rate in osteopenic patients. There are very few evidences regarding the prevention of hip and non-vertebral fractures: only few drugs seem to be useful, and among them only some of the bisphosphonates and denosumab^[3,12].

In addition, to enhance the effectiveness of the pharmacological treatment, calcium and vitamin D supplements may be prescribed. In fact, vitamin D deficient patients do not show the same increase in bone mass and reduction in fracture rate as observed in vitamin D repleted patients^[13].

Moreover, in order to improve bone mass, some changes in lifestyle are suggested, such as increasing physical activity, stop smoking, avoiding excessive alcoholic intake, maintaining an adequate body weight. Furthermore, in order to reduce fracture risk also the prevention of falling is important; so it is advisable to avoid inappropriate housing conditions (*e.g.*, carpets, low illumination), and the use

Table 3 Effect on nonvertebral/hip fracture rates (from randomized controlled trials)

of hypnotic and sedative drugs^[12].

Patients should also be aware of the importance of the adherence to the treatment. In fact, it has been observed that only a low percentage (about 30%) of patients still follows therapy after one year^[14].

ULCERATIVE COLITIS AND OSTEOPOROSIS

In literature it has been estimated that osteopenia in UC is found in about 35% of the patients, and osteoporosis in about 15%, based on DXA scans^[15]. However, studies about the prevalence of osteopenic/osteoporotic fractures in patients with UC are scarce, with a small sample size and with a follow up that is not sufficiently prolonged to allow fracture detection^[16]. Another bias is that investigated IBD patients' groups are not homogeneous regarding age, gender, severity and activity of disease, and type of treatment (steroids, supplementation of calcium and vitamin D). A recent retrospective ten years database analysis on UC male patients found a prevalence of fragility fractures of 7.9% in osteoporotic patients, 4.4% in osteopenic patients and 1.1% in patients with normal BMD^[17]. Low bone mass in UC is also related to the severity of the disease, in so far mild and moderate UC seem not to represent a risk factor for osteoporosis^[18]. Obviously, severe UC presents a higher level of inflammation and therefore the need of steroid administration, which are per se risk factors for bone loss and fracture.

Many factors have been suggested to be implicated in the pathogenesis of osteoporosis in UC. They are mainly classified in two groups: nutritional factors and inflammatory mechanisms.

In UC patients poor nutrition and malabsorption, particularly of calcium, vitamin D and K, can be caused by anorexia, insufficient diet, diarrhoea. On the other hand, IBD associated inflammatory cytokines [interleukin 1 (IL1) and 6 (IL6), tumour necrosis factor alfa (TNF- α)] have been shown to affect bone metabolism directly^[19]. These cytokines are known to increase synthesis of receptor-activated nuclear factor K B ligand (RANKL), which is produced by osteoblasts and which activates proliferation

and differentiation of osteoclasts, thereby inducing bone resorption^[19]. In fact, the biological drugs inhibiting TNF alfa have been shown to increase BMD^[19]. Moreover, recent studies in animals have indicated that these cytokines also negatively act on intestinal and renal absorption of minerals and vitamins^[20]. Of course, the usual risk factors for osteoporosis may also be present in UC patients, such as low body mass index, older age, immobilization, smoking, prolonged use of corticosteroids, low peak of bone mass particularly in the case of paediatric onset of the disease.

Anyway, the two most important factors for developing OP in UC seem to be systemic inflammatory activity and the prolonged use of glucocorticoid. Corticosteroid treatment in UC patients is related to the inflammatory status, being cumulative doses of steroid directly related both to the severity of UC and the risk of low BMD^[17].

Glucocorticoids act negatively on bone mineral metabolism inducing an impairment of bone cells coupling and activity, stimulating osteoclasts formation and activity, promoting osteoblasts apoptosis, inhibiting osteoblasts proliferation and synthesis of type I collagen and osteocalcin. In addition, they reduce intestinal absorption of calcium and increase urinary calcium excretion, leading to an increase in PTH secretion. Moreover, they reduce sex hormones production by inhibiting hypothalamic-pituitary-gonadal axis^[21].

It has to be kept in mind that all these actions of glucocorticoid finally lead to a significant increase in bone loss and in vertebral and non-vertebral fracture risk. This effect is already observed in the first three-six months of steroid treatment, and it is already present with daily doses of 5 or more milligrams of prednisone equivalent^[22].

SOMETHING NEW IN THE MANAGEMENT OF OSTEOPOROSIS IN ULCERATIVE COLITIS

The most cited scientific gastroenterological societies such as American Gastroenterological Association^[23], American College of Gastroenterology^[24], British Society of Gastroenterology^[25], have dealt in their guidelines with

the management of osteoporosis in IBD patients. They give general recommendations regarding prevention and removing of fracture risk, indication of DXA test and prescription of specific pharmacological treatment of osteoporosis. These suggestions do not substantially differ from guidelines for prevention, diagnosis and treatment of primary and secondary osteoporosis in the general population^[26-31].

In recent years, besides DXA test, another tool for assessing fracture risk has been proposed by the Health Organization Collaborating Centre for Metabolic Bone Diseases, University of Sheffield (United Kingdom), and introduced in clinical practice.

Prediction of fracture risk

Fracture risk assessment tool (FRAX[®] tool - <http://www.shef.ac.uk/FRAX/>^[32]) is based on the collection of the main anagraphic, anthropometric and anamnestic data regarding fracture risk factors, with or without BMD. This collection allows to compile a chart, available both for men and women aged 40 years or more, that predicts the 10-year probability of a hip fracture or of a major osteoporotic fracture, such as clinical spine, hip, forearm and humerus fractures. At the moment these charts are prepared for 59 countries worldwide.

Frax score is calculated by online compiling twelve fields of an algorithm: age; gender; height and weight; history of minimal trauma fractures; history of parental hip fractures; corticosteroid exposure (defined as oral glucocorticoids for more than 3 mo at a dose of prednisolone equivalent of 5 mg daily or more); concomitant rheumatoid arthritis; secondary strongly associated causes of osteoporosis, such as type I (insulin dependent) diabetes, osteogenesis imperfecta in adults, untreated long-standing hyperthyroidism, hypogonadism or premature menopause (< 45 years), chronic malnutrition, malabsorption and chronic liver disease; more than three units of daily alcohol intake; smoking. Lastly, if available, BMD may be inserted, expressed as absolute value (g/cm²) or T-score.

Entering these variables one can obtain a number, that quantifies the probability of having a major or a hip fracture in the subsequent ten years. This parameter helps the clinician in the decision whether to prescribe or not a pharmacological treatment for osteoporosis, according to a threshold of intervention. This threshold is not uniquely established and has not the same cut-off for all countries, depending on the clinical contest and health economic factors. The fracture risk varies markedly between the different countries, whereas the T-score varies only by a small amount. In addition, the clinical interpretation of a given T-score for fracture risk in women of every country depends on the age and on the presence of clinical risk factors. Intervention thresholds are also partly determined by the willingness to pay for health care in osteoporosis and by the access to DXA, which vary from country to country^[29].

The use of FRAX tool in assessing fracture risk in

UC patients was examined only in two retrospective studies^[15,33]. Results are controversial, but encourage to explore the utility of this clinical tool in the management of IBD. The first^[15] shows that the clinical FRAX score alone can accurately predict the risk of a osteoporotic fracture, reducing the need for DXA scans and for unnecessary pharmacological treatment for osteoporosis. As indicated in a position paper of the National Osteoporosis Guideline Group (NOGG)^[34], if the patient results at low risk, no DXA scan is required. If the FRAX score, based only on clinical risk factors, is intermediate, patients should undergo DXA scanning and once the BMD is known, the FRAX score has to be recalculated to determine the need for specific anti-osteoporosis treatment.

The Authors of the first cited study^[15] confirmed an increased prevalence of osteoporosis in their UC population and found that by using the FRAX score over 5 years they could have avoided 36% of DXA scans. They also found that patients who carry a high clinical risk of fracture are frequently not considered for treatment when this decision is based on T-score alone. Furthermore, considering NOGG guidelines^[35], 8% of the patients examined in the study were over-treated with bisphosphonates. As illustrated by the Authors there are, however, some limitations in using FRAX tool in IBD patients. First, the FRAX algorithms are based on general population cohort studies undertaken in over 40 years old people, and have not been validated in IBD populations, where younger, under 40 years old people are frequently represented. In this condition FRAX tool calculates the risk for patients under the age of 40 using the data of individuals aged 40 years or more. It is likely, therefore, that the fracture risk in IBD subjects could be overestimated. It will be useful to collect specific data for patients under 40, particularly in IBD populations, but probably it will take several decades to complete a prospective cohort observation in young patients for the collection of an adequate number of fractures. Second, body mass index, a component of the FRAX score, in the general population does not fluctuate at the same rate as in IBD, where periods of active disease may cause substantial weight loss. Third, although the FRAX score includes corticosteroids use as a dichotomous risk factor (yes/no), it does not take into account the cumulative dose of steroids.

The other cited retrospective study^[33] in IBD patients, raising from a population database of the province of Manitoba (Canada), examined the risk of major osteoporotic fractures (MOF) and of hip fractures after controlling for FRAX, independently from FRAX probability. The Authors did not find an increase in the risk of MOF in IBD patients after having controlled the FRAX probability, estimated both with and without BMD. The results for patients with CD and UC considered separately were similar. They found, conversely, an increase in the risk of developing a hip fracture, even after having controlled the FRAX probability, estimated both with and without

BMD. Due to the small number of events (hip fracture) it was not possible to compare UC and CD. The addition of the femoral neck BMD to calculate the risk did not significantly increase the estimated risk for hip fractures associated with IBD, suggesting, therefore, that IBD exerts a BMD independent effect on hip fracture risk. It may be useful that further studies confirm these results, differentiating UC from CD. It would be also desirable that IBD would be added as anamnestic dichotomous factor in FRAX risk calculation.

Assessment of bone structure

DXA represents the gold standard method for the diagnosis of osteoporosis^[10]. However, while BMD is clearly one of the major determinants of bone strength^[36], the assessment of fracture risk by BMD could lack sensitivity. In fact, many fragility fractures occur in osteopenic individuals (T-score between -2.5 and -1.0), not only in subjects with osteoporosis (T-score < -2.5)^[37]. Other factors in addition to BMD account for bone strength and fracture risk, like bone geometry and bone microarchitecture, that concur to determine bone quality^[38].

The best method for the direct assessment of bone micro-architecture is histomorphometry of the transiliac crest bone biopsy, but it is an invasive procedure and, moreover, it does not necessarily reflect microstructure at sites where the fragility fractures occur, like spine and femur. A number of techniques have been developed to assess bone geometry, as quantitative computed tomography (QCT)^[39,40], high resolution peripheral quantitative computed tomography (HRpQCT)^[41] and magnetic resonance imaging^[42]. However, these techniques present more invasivity, higher costs, long time for their execution (long lasting scans). Alternatively, adaptation of X-ray based images, like plain radiographs, using gray-level textural features, have been tested, utilizing fractal dimension^[43-45] and Fourier analysis^[46-48]. An ideal solution, in terms of practicability, costs and risks, could be the adaptation of DXA-based images. DXA can be used to identify existing vertebral fractures^[49-52], to evaluate hip geometry and to estimate femoral strength^[53-55]. Moreover, a new DXA-based technique that considers bone mineral distribution in the proximal femur, instead of only bone mineral density, may be well-suited to enhance standard densitometric evaluation as a predictor of hip fracture risk^[56]. The latest development is the trabecular bone score (TBS), a new gray-level textural measure that can be extracted from the 2-dimensional lumbar spine DXA image to estimate trabecular microstructure. TBS may provide skeletal informations that are not captured by the standard BMD measurement. Based on experimental variograms of the projected DXA image, TBS has the potential to discern differences in 3-dimensional (3D) micro-architecture between 2-D DXA measurements that are similar to each other^[57,58]. An elevated TBS value correlates with better skeletal texture (a reflection of better microarchitecture); a low TBS value correlates with weaker skeletal texture (a reflection of degraded

microarchitecture). The relationship between TBS texture parameters and 3D micro-architecture parameters has been documented by several *ex vivo* studies that have reported significant correlations between TBS and various micro-structural parameters of bone assessed by micro-computed tomography^[57,59,60].

TBS is an imaging technique adapted directly from the DXA image of the lumbar spine. Thus, it is potentially readily and widely available. In recent years, a large number of studies have demonstrated that TBS is significantly associated with direct measurements of bone microarchitecture, and may be a useful adjunct to BMD for detection and prediction of fragility fractures in primary osteoporosis^[58]. Thus, it promises potential utility also in secondary causes of osteoporosis^[61]. In some conditions, like glucocorticoid-induced osteoporosis and in diabetes mellitus, the TBS appears to out-perform DXA. It also appears useful in numerous other diseases associated with diminished bone health, such as primary hyperparathyroidism, androgen-deficiency, hormone-receptor positive breast cancer treatment, chronic kidney disease, and autoimmune diseases like rheumatoid arthritis^[61]. Further research is required to establish clearly the role of TBS in these and other disorders that adversely affect bone health, like CD and UC.

In adjunction to BMD measurement, TBS can be a useful tool also for monitoring treatment efficacy over time.

Assessment of hip geometry

Hip geometry, like BMD, has been shown to relate independently to hip fracture risk^[62]. Loading forces on bone are distributed over the bone material in cross sections. The concentrations of loading forces, defined stresses, are a function of bending moments and cross sectional geometry. Based on the principle described by Martin and Burr^[53,63] a specific program for bone densitometry has been developed, named hip structural analysis (HSA), that derives the cross sectional geometry from images acquired from a bone mineral scanner by the means of DXA. The main structural parameters are the surface area of the bone in the cross section (CSA) and the section modulus (Z), which are inversely related to maximum stresses due to axial and bending loads, respectively^[64,65]. CSA is an index of bone resistance to axially directed loads. Z is computed from the cross sectional moment of inertia (CSMI) that weights the area in the cross section by the square of its distance from the centroid. CSMI reflects the flexural strength and is an index of structural rigidity. The maximum distance between the center of mass and outer cortex over the average cortical thickness provides a stability index of the cortex under compressive loads, bending included, the so called buckling ratio.

A few works have been published about HSA in primary and secondary osteoporosis^[62,64,66-68] and to estimate bone quality variations after pharmacological treatment for osteoporosis^[69]. A combination of BMD assessment

and geometric structural measurements may represent an additional and helpful mean in estimating bone strength and fracture risk. After therapy, particularly with new bone formation agents, changes in axial and bending strength and, for some drugs, in cortical thickness, are expected.

No data about these topics are available in UC patients and their investigation could be of considerable interest.

Treatment of osteoporosis in ulcerative colitis

Calcium and vitamin D represent a well-known non-pharmacological treatment for osteoporosis, which is usually employed in conjunction with drugs for primary and secondary fragility fracture prevention. Measurement of serum 25-OH-cholecalciferol is the standard method to assess vitamin D status. A recent point of view of the Institute of Medicine of the United States National Academies^[70], considers at least 50 nmol/L (20 ng/mL) the sufficient level for the general healthy population and suggests a daily global intake of vitamin D of about 700-800 IU for the general population. However, this position is not overall accepted and other recommendations suggest higher doses of vitamin D intake for healthy adults^[71].

Vitamin D insufficiency is a condition associated with rickets and osteomalacia, reduced muscle strength, reduced appendicular muscle mass, increase in muscle pain, increase in body sway and consequent risk of falls, and reduced response to osteoporosis treatment. For insufficiency [30-50 nmol/L (12-20 ng/mL)] or deficiency [$<$ 30 nmol/L (12 ng/mL)] a greater amount of vitamin D supplementation is required, identified by IOM up to a maximum daily dose of 4.000 IU. In this case, a periodic check of the vitamin D status is necessary (every 1-3 mo), considering the extreme individual variability in the response, due to various clinical conditions such as malabsorption.

In UC vitamin D insufficiency and deficiency are common, ranging from 45% to 60% of patients^[72,73]. Therefore, it appears advisable to routinely check 25OH-vitamin D in UC patients in order to identify and treat adequately the vitamin D pathological status. Vitamin D in association with calcium has been used in the treatment of osteoporosis in UC, without significant BMD improvement.

In the last decade vitamin D has gained a new surge of scientific interest for its extra-skeletal effects beyond its action on bone metabolism. The vitamin D receptor (VDR) has been isolated in tissues other than intestinal epithelium, distal renal tubules and osteocytes: adrenals, parathyroids, pituitary gland, mammary gland, ovary, testis, skin, heart, thymus, lymphocytes and promyelocytes, hepatocytes, biliary epithelial cells and colon. Also 1 α -hydroxylase, the vitamin D activating enzyme, is expressed in colonic cells^[74,75]. A local production of 1,25(OH)₂-vitamin D has been found in skin, lymph nodes, pancreas, brain, adrenal medulla, monocytes

and macrophages, and colon^[76]. A recent meta-analysis showed that higher blood 25OH vitamin D levels were associated with a reduced risk of colorectal cancer: pooled adjusted OR was 0.94 per 10 nmol/L increase in 25OH-vitamin D concentration^[77]. All these experimental data indicate that vitamin D plays a role in the function of the cited tissues and organs. It is notable that in colonic biopsies' specimens of patients with UC both VDR expression and VDR protein are reduced respect to normal. Therefore it is hypothesised that vitamin D supplementation may be useful in UC patients not only for osteoporosis treatment purpose, but also for its extra-skeletal actions.

Moreover, in UC patients various other actions of vitamin D might be useful, considering its involvement in inflammation and immune modulation: reduction of inflammatory cytokines^[78,79], protective immune modulating properties^[80,81], maintenance of integrity of the epithelial barrier of the colon^[82].

Few original clinical trials regarding medical treatments for low bone mass in UC have been published in literature since the eighties. A recent systematic review and meta-analysis^[83] has listed only nine works concerning anti-osteoporotic drugs in UC patients. However, populations considered in these studies are mainly not homogenous, including both CD and UC, male and female, pre- and post-menopausal women, active and non-active disease, different steroid exposure. Within the analyzed anti-osteoporotic treatments, there are variable concomitant medications, with different dosages of calcium and vitamin D supplementation. Seven of the cited nine studies have used anti-osteoporotic drugs and two non-pharmacological treatments (calcium and vitamin D supplementation). Among the seven using drugs, six utilized anti-resorptive agents (bisphosphonates and calcitonin) and one an agent stimulating bone formation (fluoride). Also the duration of the studies is quite different, ranging from few weeks to few years; this is important because the effect of osteoporosis treatment on bone mass and fracture risk is assessable in a reliable way only on a long period, lasting several years. Moreover, not all these studies are of outstanding quality.

For all these reasons it is difficult to draw firm conclusions, and consequently, definitive recommendations.

To our knowledge in the last five years only three clinical trials dealt with anti-osteoporotic drugs in UC^[84-86]. These Authors have utilized bisphosphonates (alendronate, risedronate) and calcitonin. Kitazaki and Kriel used bisphosphonates to prevent glucocorticoid associated osteoporosis in active UC disease. Alendronate improved spine BMD after one year of treatment in a steroid treated UC population very heterogeneous for age (17-70 years, mean age 41 years)^[84]. Kriel administered risedronate for a very short period (two months)^[85]. Pappa prescribed calcitonin to study its short term efficacy on spine BMD in UC children and adolescents, without seeing significant clinical advance^[86].

Amino-bisphosphonates, like alendronate and risedro-

nate, inhibit the enzyme farnesylpyrophosphate-synthase implicated in the biosynthesis of cholesterol. This action significantly reduces the prenylation of GTPase proteins, thus disrupting function of osteoclasts, leading to their apoptosis^[87]. Experimental data in cell culture have shown that the described bisphosphonate action occurs also in various cancer cell lines^[88]. GTPase proteins have been found to be involved in cancer of colon and rectum^[89,90]. Being very poorly absorbed (less than 1%), oral bisphosphonates reach the colon and come in contact with the intestinal epithelium. Thus, they could lead colon cancer cells to apoptosis with the same mechanism^[88]. Moreover, there are experimental evidences that bisphosphonates could hinder the growth of colon and rectum cancer inhibiting macrophages^[91,92] and stimulating a subset of T-cells^[93,94] involved in cancer developing. This potential therapeutic effect could be relevant in UC, where the risk of developing a colorectal cancer is notoriously increased.

FINAL CONSIDERATIONS ABOUT MANAGING OSTEOPOROSIS IN ULCERATIVE COLITIS

Osteoporosis in UC patients is a high prevalent and a high incident pathology, and fracture prevention is a mandatory question. On the other hand, there are scarce evidences about this issue, and therefore it appears not reasonable to give specific, population-based-approach recommendations about primary and secondary prevention of fragility fractures in UC patients. So it may be more advisable to suggest an individual-high-risk-approach, inspired by the consolidated guidelines for the diagnosis and treatment of post-menopausal osteoporosis.

First step

It is wise to assess vitamin D status in UC patients to recognize who is predisposed to low levels of vitamin D. Serum levels of 25OH-vitamin D could be measured in all patients and particularly in those who present well-known risk factors for deficiency: severe disease, elderly patients, reduced sun light exposure. Deficiency has to be treated, preferably with an oral daily cholecalciferol or calcifediol supplementation. Intermittent large doses, orally or parenterally, should be reserved in the case of reduced adherence to therapy. An adequate dietary calcium intake or supplementation and physical activity, if possible, should be guaranteed.

Osteoporotic risk factors such as smoking and excessive alcohol intake must be avoided. Steroid has to be prescribed at the lowest possible dosage and for the shortest possible time. Moreover, conditions favouring falling have to be minimized, like carpets, low illumination, sedatives assumption, vitamin D deficiency.

Secondly

It is advisable to predict the ten years fracture risk in all

UC patient by the FRAX[®] tool, that calculates the risk for many countries of the world for the population aged from 40 to 90 years.

The use of FRAX in clinical practice demands a consideration about the fracture probability at which it is useful to intervene, both for treatment (intervention threshold) and for BMD testing (assessment threshold).

Assessing fracture probability could be useful to help physicians in deciding whether to treat or not for osteoporosis in order to prevent fragility fractures. A high risk value could indicate the necessity of treatment, whereas a low risk value suggests a follow-up only. An intermediate risk supports the decision to prescribe BMD assessment and a subsequent patient reevaluation for treatment. The thresholds are variable, since they depend critically on local factors varying from country to country, like fracture incidence, willingness and capability to pay for access to BMD measurement and for health care in osteoporosis. Different scenarios are represented for example by The National Osteoporosis Foundation recommendation for the United States (www.nof.org) and by The National Osteoporosis Guideline Group (NOGG) for the UK (www.shef.ac.uk/NOGG/)^[35].

Thirdly

Bone densitometry could be used not only for BMD measurement, but also to collect data about bone quality by the means of TBS and HSA assessment. These two indices could represent a method of interesting perspectives in evaluating bone status in patients affected by diseases like UC, in which there may be an impairment of bone quality as well as of bone quantity. Bone quantity accounts for most, but not for all, of the fragility fractures. No data are published about TBS and HSA in UC population, and this could be an interesting field for research.

Fourthly

In literature there is no strong evidence for instituting a pharmacological therapy in UC patients for clinical indications other than those that are applied to the patients with established osteoporosis.

Therefore, a reasonable advice is to prescribe pharmacological treatment for OP in those UC patients who present fragility fractures, that bring a high risk for subsequent fractures. Therapy has also to be considered in presence of a high risk of fracture, particularly when corticosteroid therapy is prolonged and with high cumulative doses. In patients without fragility fractures or steroid treatment, fracture risk assessment could support the medical decision about treatment, and in this case FRAX could be of relevant help.

Among drugs for osteoporosis the bisphosphonates are the most studied, with the best and longest evidence of efficacy and safety. Despite this, several questions are still open, such as the lasting of treatment, the necessity to discontinue it, the indication of therapy in young patients, particularly in those without previous fracture.

Further, a long-term bisphosphonates use in primary osteoporosis has been associated with an increased incidence of dramatic, even if uncommon, side effects, like osteonecrosis of the jaw and atypical sub-trochanteric and diaphyseal femoral fractures.

UC is a long-lasting disease and the majority of patients are relatively young. In this condition primary prevention of fragility fracture is the best cost-effective strategy. Vitamin D supplementation, adequate calcium intake, suitable physical activity (when possible), removing usual risk factors for osteoporosis (like smoking), and avoiding falling, are the best and the cheapest medical acts.

Key words: Inflammatory bowel disease; Herbs; Herb medicine; Ulcerative colitis; Therapy; Safety

Core tip: Herbal medicine has already been used for some diseases including infections and headache in China since the third century BC. Recently, herbs have emerged as a useful treatment for ulcerative colitis as shown by clinical trials. A better understanding of the herbal bioactivities may provide new alternatives to our current treatment for ulcerative colitis.

Abstract

Ulcerative colitis (UC), an idiopathic inflammatory disorder in the colon, has become a clinical challenge, owing to the increasing incidence and poor prognosis. The conventional treatments for UC including aminosalicylates, corticosteroids, and immunosuppressants, induce remission in only half of patients. Meanwhile, the treatments often come with serious side effects which can be life-threatening. Herbal medicine, one of the most common traditional Chinese medicine modalities, has been introduced for centuries into clinical treatment of many human diseases such as infections and functional disorders. Recently, the potential effectiveness of herbs has been suggested as the treatment of UC, as shown by a variety of clinical trials and experimental studies. The herbs reported in the literature include *aloe vera* gel, butyrate, tormentil extracts, wheat grass juice, and curcumin. In the review, bioactivity of the herbs and

INTRODUCTION

Ulcerative colitis (UC), one type of inflammatory bowel disease (IBD), is characterized by uncontrolled inflammation in the colon and rectum. The incidence and prevalence of UC have been reported to be increasing over the past two decades^[1]. Due to its unknown etiology, high risk of recurrence, and poor prognosis, UC has become a clinical challenge in terms of treatment. Meanwhile, conventional therapies for UC fail to successfully induce remission and prevent relapse, and also possibly cause various side effects. Therefore, studies exploring the alternative therapies for UC have become a topic of great interest.

In recent years, herbal medicine, the most common modality of alternative and complementary treatment,

has been established for the treatment of UC, and the bioactivities of herbs have been explored by taking a bench-to bedside approach. Intriguingly, combination treatments with traditional Chinese medicine, especially herbs, have shown to exhibit the preferential effect than single conventional treatment for UC^[2], indicating that herb medicine may be a promising alternative treatment for UC in future. In this review, we summarize the potentials of these herbs and their involvement in clinical management of UC.

PATHOGENESIS OF UC

UC is characterized by aberrant innate and adaptive immune responses. Neutrophils, the first line of innate immune cells, are responsible for intestinal tissue damage, through releasing a large amount of toxic components and free radicals upon stimulation, during the progression of UC^[3,4]. Meanwhile, atypical T helper cell (Th) type 2 responses is reported in the pathogenesis of UC, including excessive activation of non-classic natural killer T cells and Th2 cells, as well as substantial production of cytokines, *e.g.*, interleukin (IL)-5 and IL-13. Elevated cytokine levels are noted in UC patients, including IL-5, IL-13, and other proinflammatory cytokines such as tumor necrosis factor (TNF). Once released by immune cells, the cytokines act to further trigger immune responses, induce apoptosis of epithelial cells and upregulate claudin-2 expression, which result in impairment of tight junction of intestinal epithelial cells, and herein damage of the epithelial barrier^[5-7].

Nuclear factor kappaB (NF- κ B) is a transcription factor regulating the expression of a variety of genes, *e.g.*, TNF, in response to extracellular inflammatory stimuli^[8]. Since elevated TNF expression is reported in blood^[9], stool samples^[10], and the mucosa^[11] of patients with active UC, it is widely accepted that NF- κ B plays a pivotal role in the development of UC. The relevance of NF- κ B inhibition in IBD is further demonstrated by treatment of experimental colitis with a NF- κ B antisense oligonucleotide, which resulted in amelioration of inflammation in the colon^[12].

Intestinal microbiota is also suggested to participate in the progression of UC. A recent study has showed that fecal microbiota composition of UC patients varies significantly from healthy subjects, indicating the potentials of microbial alterations in patients with UC^[13]. Intestinal immune cells are tolerant to lumina commensal antigens, but such tolerance is broken as seen in patients with UC and Crohn's disease^[14,15]. The current findings suggest that the defective dynamic balance between commensal microbiota and host defense may contribute to the pathogenesis of UC^[16].

HERBAL MEDICINE: THERAPY FOR UC

Herbal medicine is the traditional Chinese clinical practice using plants or/and plant extracts for medical treatment. Due to lack of desirable efficacy and poor toler-

ance of conventional drugs, more and more populations prefer to accept herb medicine under disease conditions, *e.g.*, headache and infections. Approximately 9.6% to 12.1% of the US adults use one or more forms of herbal products to alleviate disease symptoms, amongst them proximately 10% for digestive symptoms^[17]. Recently, herb medicine is employed in clinical trials for UC treatment in many countries including China and India^[18].

To study the clinical effect of herbal medicine treatment on UC patients, we searched the controlled clinical trials in PubMed, Google Scholar, and Cochrane Trial Register databases. As a result, a total of 9 controlled studies were included regarding the treatment for UC patients by herb medicine. Among them, 5 were randomized, double-blind, placebo-controlled studies, and one was individually controlled cohort study. These herbs/herb extracts used in the clinical trials included *aloe vera* gel, butyrate, tormentil extracts, wheat grass juice, and curcumin, which are mainly summarized in Table 1.

ALOE VERA GEL

The *aloe vera* plant has been used for skin care as well as medicine for centuries. The leaf of the *aloe vera* plant consists of two main parts: an inner central leaf pulp that stores *aloe vera* gel, the bioactive component, and an outer leaf pulp responsible for transportation of *aloe vera* latex. Aloe vera gel becomes well known due to its anti-inflammatory properties, and is under therapeutic evaluation for UC treatment^[19]. For example, *aloe vera* gel inhibits prostaglandin E2 and IL-8 secretion, while having no effect on thromboxane B2 production in the human colorectal mucosa^[20]. *Aleo vera* gel has been further reported to inhibit the release of reactive oxygen species (ROS) by PMA-stimulated human neutrophils, and abrogate the ROS-dependent cytotoxicity of neutrophils such as lysis of red blood cells^[21]. The anti-inflammatory activities of *aloe vera* gel provide the evidence that it may have a therapeutic effect on IBD.

The clinical value of *aloe vera* gel has been assessed. In a randomized, double-blind, placebo-controlled trial, 44 hospitalized patients with mild or moderate UC received oral *aloe vera* gel treatment or placebo, 200 mL daily for 4 wk^[22]. Clinical remission, improvement and response of the disease had been observed in 9 (30%), 11 (37%) and 14 (47%), respectively, of 30 UC patients taking *aloe vera*, compared to one (7%), one (7%), and two (14%), respectively, of 14 UC patients receiving placebo. The clinical colitis activity index and histological scores of the patients decreased significantly during treatment with *aloe vera* ($P = 0.01$ and $P = 0.03$, respectively), but not with placebo. Endoscopic score and laboratory variables displayed no significant differences in both groups of patients with *aloe vera* or placebo treatment. Side events were minimal and similar between *aloe vera* and placebo.

BUTYRATE

Butyrate, a four-carbon short-chain fatty acid, is the main

Table 1 Summary of trials using herbal therapy for patients with ulcerative colitis

| Ref. | Herbal medicine | Patient number | Trial design | Treatment method | Duration of treatment | Remission on herb | Remission on placebo |
|---------------------------------------|--------------------|----------------|--|------------------|-----------------------|--|----------------------|
| Langmead <i>et al</i> ^[22] | Aloe vera gel | 44 | Randomized, double-blind, placebo-controlled study | Oral | 4 wk | 30% | 7% |
| Vernia <i>et al</i> ^[34] | Butyrate | 25 | Randomized, double-blind, placebo-controlled study | Oral | 6 wk | 58.3% | 38.4% |
| Huber <i>et al</i> ^[39] | Tormentil extracts | 16 | Individually controlled cohort study | Oral | 3 wk | - | - |
| Ben-Arye <i>et al</i> ^[42] | Wheat grass juice | 23 | Randomized, double-blind, placebo-controlled study | Oral | 4 wk | Not stated, but wheat grass improved symptoms and bleeding more than placebo | Not stated |
| Singla <i>et al</i> ^[45] | Curcumin | 45 | Randomized, double-blind, placebo-controlled study | Enema | 8 wk | 43.4% | 22.7% |
| Hanai <i>et al</i> ^[46] | | 89 | Randomized, double-blind, placebo-controlled study | Oral | 6 mo | 95.3% | 79.5% |

metabolite in the colon derived from bacterial fermentation, and also an important energy source of intestinal epithelial cells. Depletion in butyrate-producing microbial communities has been reported in colon mucosal samples from UC patients, attributing to deficiency of butyrate production and exhaustion of energy supplies to intestinal epithelial cells^[23,24]. Nevertheless, oral supplement of butyrate exhibits anti-inflammation functions, and ameliorates murine colitis, *via* reduction of neutrophil infiltration and attenuation of intestinal inflammation^[25]. Currently, functions of butyrate have been linked with regulation of innate immune responses. For example, butyrate down-regulates lipopolysaccharide-induced expression of proinflammatory mediators by macrophages and neutrophils, including nitric oxide, IL-6, and IL-12, through inhibition of NF- κ B activation and histone deacetylase activities^[26-29]. Butyrate has also emerged as a modulator of adaptive responses, owing to its multiple bio-functions, *i.e.*, restoring transforming growth factor beta and IL-10 production in the colon mucosa, inducing T cell apoptosis and dampening interferon- γ (IFN- γ) secretion^[30].

Clinical trials have shown the effectiveness of butyrate monotherapy or/and in combination with conventional treatment in patients with UC, diversion colitis, as well as acute radiation proctitis^[31-33].

A randomized, double-blind, placebo-controlled pilot study on UC patients was conducted to evaluate the safety and efficacy of oral sodium butyrate tablets, coated with a pH-dependent soluble polymer^[34]. Administration of butyrate (4 gram daily) in combination with mesalazine significantly improved the disease activity score in 25 patients with active UC, in comparison with mesalazine treatment alone. The combined treatments other than mesalazine alone decreased disease activity index score, and significantly improved disease outcomes *vs* baseline values ($P < 0.05$). Meanwhile, the histological and endoscopic scores improved after treatment in both groups ($P < 0.05$). The similar observations were reported in other non-controlled clinical trials using oral administration or enemas of butyrate^[32,35,36].

TORMENTIL EXTRACTS

Tormentil is a member of the rose family that grows wild over Europe. Tormentil extracts contain a high content of tannins which displays potent superoxide-scavenging effects, suggesting tannins as an anti-inflammatory agent. Tormentil has also been shown to be effective in treatment of diarrhea or intestinal inflammation^[37,38]. *In vitro* studies have further confirmed the anti-inflammatory, anti-oxidative, and bacterial growth regulatory effects of tormentil extracts^[37].

Positive results of tormentil extract treatment have been observed in individual patients with UC^[39]. Sixteen patients with active disease took oral tormentil extracts in escalating doses of 1200, 1800, 2400, and 3000 mg every day for three weeks each. Every treatment phase was followed by a 4-wk washout phase. During treatment with 2400 mg of tormentil extracts per day, the clinical activity index, and C-reactive protein levels decreased from 8 mg/L (range: 6-10.75 mg/L) and 8 mg/L (range: 3-17.75 mg/L) at baseline to 4.5 mg/L (range: 1.75-6 mg/L) and 3 mg/L (range: 3-6 mg/L), respectively. During treatment, the clinical activity index improved in all patients, but it turned to increase during the washout phase. There were no apparent side effects with tormentil extract treatment observed during the study.

WHEAT GRASS JUICE

Wheat grass juice is the extract from the pulp of wheat grass and has been used for the treatment of various intestinal diseases and thalassemia for several years. By radical scavenging in correlation with phenolic and flavonoid contents inside, wheatgrass extracts exhibited an antioxidant activity^[40]. In particular, pigenin, the main constituent in wheat grass, was shown to inhibit the production of proinflammatory cytokines, *e.g.*, IL-1 β , IL-8, and TNF in LPS-stimulated human and mouse macrophages, by inactivating NF- κ B through suppression of p65 phosphorylation^[41].

The clinical usage of wheat grass juice in UC treat-

ment has been reported^[42]. In a randomized double-blind placebo-controlled trial, 23 patients with active UC were randomly grouped to receive either 100 mL of wheat grass juice, or the same volume of placebo, daily for 1 mo. Efficacy of treatment was evaluated by disease activity index, bleeding feces, number of bowel movements, sigmoidoscopic evaluation, and global assessment. The patients treated with wheat grass juice showed significant reductions in disease activity index ($P = 0.031$) and severity of rectal bleeding ($P = 0.025$), in contrast to those receiving placebo. No adverse effects of wheat grass juice were observed.

CURCUMIN

Curcumin is an active phytochemical substance in turmeric, and exhibits pharmacologic activities that might benefit patients with UC. A large number of publications have reported the promising pharmacologic effects of curcumin, *i.e.*, inhibition of expression of a variety of inflammatory genes, including cyclooxygenase (COX)-1, COX-2, lipoxygenase, TNF, IFN- γ , inducible nitric oxide synthase, as well as abrogation of NF- κ B activation^[43]. Recently, curcumin has been shown to attenuate colonic inflammation through direct inhibition of neutrophil chemotaxis and chemokinesis, and partly through inhibition of the chemokine expression^[44].

Clinical trials have evaluated the therapeutic effect of curcumin in patients with mild-to-moderate UC. In a randomized, double-blind, single-centre pilot study, 45 patients received oral 5-aminosalicylic acid in combination with either curcumin preparation (140 mg in 20 mL water) or placebo enema. The patients receiving additional curcumin preparation treatment showed improvements in disease activity, compared with those patients with placebo enema^[45]. Another group also showed the similar efficacy of combination treatment of curcumin (2 g daily) and sulfasalazine or mesalamine in maintenance therapy for 89 patients with quiescent UC, indicating that curcumin may confer additional therapeutic advantages when used in combination with conventional anti-inflammatory medications in UC^[46].

SAFETY OF HERB MEDICINE

So far, it remains unclear about the safety of herb medicine. Butyrate, the most common treatment used for UC patients, has been shown to be relatively safe for UC patients. Hallert *et al.*^[47] reported that supplement of dietary fiber elevated the fecal butyrate level, and kept UC patients in remission, without increment in gastrointestinal complaints during the trial. Recently, a meta-analysis evaluated the efficacy and tolerance of herbal medicines in patients with IBD. With the results from seven placebo-controlled clinical trials, the analysis has showed that herbal medicines can induce clinical response and remission in IBD patients, without serious side events^[48].

Due to limitation of human studies, animal models

become alternatives to explore the safety of herbs. Acute toxicity of Tormentil rhizomes was assessed in rats and mice, with a single dose administration by gavage of 2.5 and 6.8 g/kg (body weight), respectively^[49]. No apparent toxic effects have been recorded at two weeks after the administration of Tormentil rhizomes. Nevertheless, some researchers questioned the safety of herbs with the evidence that fatal hepatic and irreversible renal failure occurred with some herb preparations, and that interactions of herbs with conventional drugs were potentially detrimental^[50]. Meanwhile, a recent study has reported the increased incidences of mucosa hyperplasia and goblet cell hyperplasia in the colon of rats and mice at 13 wk after exposure to drinking water containing *aloe vera*^[51]. Thus, the safety and long-term benefits of herb medicine need to be intensively investigated before it can be applied for patients.

CONCLUSION

Because of the relatively natural and multiple biological properties, herbs have emerged as the alternative for current treatment of inflammatory disorders, including UC. Clinical trials have indicated the promising possibility of herb medicine for UC treatment. However, there have some concerns to be clarified before herb medicine can be securely introduced into UC patients. So far, the clinical trials with herb medicine treatment were conducted in a small number of UC patients, and large case-controlled studies and reliable data about the detailed mechanism of the herbs are still lacking. Meanwhile, herbal preparations are the mixture containing a huge range of biological compounds, other than purified single component. It might not be known which component in the herbs provides the exact pharmacological effects, even in some cases the herb mixtures exhibit clinical benefits. Thus, determination of herb components, dosage and course of herb treatment becomes a challenge for clinical employment. In addition, the safety of herb medicine remains to be further investigated, especially under long term treatment.

Overall, herb medicine treatment becomes widespread and prevalent, with encouraging results from clinical trials. Further evidence about the components of herbs and their bio-functions will shed light on clinical administrations of herb medicine in future. With discerned safety of herbs, herb medicine itself or in combination with conventional therapies would largely benefit patients with UC and other immune disorders.

Abstract

Recurrence after ileocelectomy for Crohn's disease (CD) is common and occurs in up to 80% of patients. Such recurrence can result in repeated surgical interventions, an increased need for medical treatment and, frequently, an impaired quality of life. The aim of this overview is to provide a summary of the factors associated with disease recurrence after ileocelectomy for CD. Recurrence can be measured clinically or endoscopically using established scoring systems. Radiology and serologic tests can also be used, oftentimes in conjunction with endoscopy and/or clinical findings. Many patient and operative factors as well as pharmacologic treatments have been studied as potential predictors of recurrence. Of these, only smoking and immunomodulatory or biologic medical treatment have repeatedly been shown to effect recurrence. Genetic predictors have been studied and suggested but further evaluation in larger cohorts is necessary. This paper highlights validated, reproducible scoring systems for recurrence and the key findings of studies including patient demographics, operative techniques, various pharmacological treatments and histological findings

as predictors of recurrence post ileocelectomy in CD.

Key words: Crohn's disease; Ileocelectomy; Recurrence; Surgical genetics; Inflammatory bowel disease

Core tip: Disease recurrence after ileocelectomy for Crohn's disease is common. Studies have been very heterogenous in defining recurrence as it can be clinical, endoscopic, radiologic or serologic. Of the potential predictive factors studied, smoking has been consistently demonstrated to increase the risk of recurrence. While immunomodulator and biologic medical treatment have been shown to increase the time between surgery and recurrence and may decrease overall risk. Genetic predictors have been suggested but further evaluation in large groups is needed. Several other demographic and operative factors have been studied. However, none have been consistently shown to affect recurrence risk.

INTRODUCTION

Crohn's disease (CD) is a chronic immune mediated disease of the gut that was first described as "regional ileitis" by Crohn, Ginzburg and Oppenheimer in a case series presented at American Medical Association annual meeting in 1932^[1]. CD is characterized by inflammation, abscesses, fistulization and stricturing that can affect any part of the gastrointestinal tract. However, the most common distribution is the ileocolic region, the location where the small

Table 1 Types of postoperative recurrence and evaluation type

| Type of recurrence | Evaluation method |
|--------------------|--|
| Clinical | Questionnaire, CDAI, Harvey-Bradshaw Index, IBDQ |
| Endoscopic | Rutgeerts score, Crohn's disease endoscopic index of severity |
| Radiographic | CT or MR enterography, barium enema small bowel follow through |
| Serological | Measurement of CRP and ESR |
| Surgical | Requirement for repeat surgery |

CDAI: Crohn's disease activity score; IBDQ: Inflammatory Bowel Disease Questionnaire; CT: Computed tomography; MR: Magnetic resonance; CRP: C reactive protein; ESR: Erythrocyte sedimentation rate.

Table 2 Factors in the Crohn's disease activity score

| |
|---|
| General well-being |
| Number of stools/d |
| Abdominal pain |
| Weight loss |
| Presence of arthralgia, fistuli, fever and/or ocular, dermatological or anal manifestations |
| The need for anti-diarrheal medication |
| Abdominal mass |
| Hematocrit |

Based on patient symptoms during the 7 d prior to taking the survey.

Table 3 Factors in the Rutgeerts endoscopic recurrence score for postoperative recurrence of Crohn's disease in the distal ileum

| Endoscopic appearance | Score |
|---|-------|
| No aphthous ulcers | 0 |
| < 5 aphthous ulcers | 1 |
| > 5 aphthous ulcers with normal mucosa between the ulcers | 2 |
| Diffuse aphthous ulcers throughout the ileum with intervening inflamed mucosa | 3 |
| Large ulcers with diffuse inflammation, nodules or narrowing of the ileum | 4 |

bowel and colon meet. Approximately 55% of all CD patients have an ileocolic disease distribution, followed by colonic and small bowel distributions in approximately 20%-30% and 15%-20% and of patients respectively^[2].

Although not curative, surgery is commonly required for the sequelae CD (*e.g.*, abscess, fistula, perforation, bleeding and failure of medical treatment). Up to 80% of CD patients require at least one surgical intervention in their lifetime. The most common resection is the ileocelectomy. Recurrence at the site of the anastomosis is common and challenging^[3,4]. Multiple resections due to recurrent disease can lead to short gut syndrome, malabsorption and malnutrition with significant morbidity, decreased quality of life and increased hospital and outpatient costs^[5]. This review highlights the patient and disease related factors that are associated with an increased risk of disease recurrence after ileocelectomy in its many forms including clinical, endoscopic and radio-

logic recurrence.

Defining recurrence

Recurrence can be defined in several different ways using a multitude of modalities. Such inconsistency in regard to what constitutes recurrence in conjunction with heterogeneity among patient populations and prophylactic measures against recurrence given leads to a large variance in recurrence rates between studies (Table 1)^[6]. Clinical and endoscopic recurrence are most commonly reported.

Clinical recurrence is loosely defined as an increase in patients' symptoms including diarrhea, weight loss and abdominal pain. For the most appropriate investigation and reporting of clinical recurrence, established validated quality of life questionnaires such as the Inflammatory Bowel Disease Questionnaire^[7] or scoring systems such as the Crohn's disease activity score (CDAI) or Harvey-Bradshaw Index should be used^[8]. The CDAI can be clinician or self-administered and contains subjective questions (on general well-being and symptoms such as abdominal pain) as well as objective measures (such as hematocrit, numbers of stools per day, weight loss, the presence of arthralgia, fistuli, fever, an abdominal mass and/or ocular, dermatological or anal manifestations) (Table 2)^[9,10]. Endoscopic recurrence uses colonoscopy or ileoscopy as appropriate to determine the presence of recurrence, which is most commonly found at the site of the anastomosis. The Rutgeerts visual grading system evaluates the presence and number of aphthous ulcers and the intervening mucosa in the perianastomotic region and is the most commonly used internationally recognized endoscopic grading system for post ileocelectomy recurrence (Table 3)^[11,12]. Radiographic recurrence is less commonly studied and is often utilized as an adjunct to clinical or endoscopic recurrence. CT or MR enterography, small bowel follow through and/or barium enema are the modalities currently employed^[13]. Serological recurrence is defined by the elevation of serum inflammatory markers such as C reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Although more novel interleukin markers have been studied, none are in clinical use to date. Surgical recurrence is determined by the requirement for repeat ileocelectomy and is often indicative of more severe disease. Oftentimes, these different classifications of recurrence are studied in conjunction with each other.

Endoscopic, radiographic and serologic recurrence rates are in actuality higher than reported as frequently, only clinically symptomatic patients are investigated. Additionally, there is limited concordance between the different types of recurrence in the individual patient. For example, Bordieianou *et al*^[14] compared endoscopic, symptomatic and surgical recurrence rates in approximately 200 ileocelectomy patients and found that while 31.2% of their cohort had documented endoscopic recurrence, only 23.1% had symptomatic and 11% had surgical recurrence. This disparity was also demonstrated

Table 4 Overall recurrence rates by post ileocelectomy follow up and type of recurrence

| Time post ileocelectomy | Type of recurrence | % of ileocelectomy Patients | Ref. |
|-------------------------|----------------------|-----------------------------|---|
| 1 yr | Clinical | 0%-44% | McLeod <i>et al</i> ^[61] , Walters <i>et al</i> ^[10] , Aratari <i>et al</i> ^[27] , Bordeianou <i>et al</i> ^[14] , Sorrentino <i>et al</i> ^[28] , Pascua <i>et al</i> ^[53] |
| | Endoscopic | 0%-84% | Bordeianou <i>et al</i> ^[14] , Walters <i>et al</i> ^[10] , McLeod <i>et al</i> ^[15,61] , Regueiro <i>et al</i> ^[16,82] , Rutgeerts <i>et al</i> ^[11] , Pascua <i>et al</i> ^[53] , Domènech <i>et al</i> ^[80] , Sorrentino <i>et al</i> ^[28] , Meresse <i>et al</i> ^[40] , Lasso <i>et al</i> ^[89] |
| | Surgical | 4%-25% | Aratari <i>et al</i> ^[27] , Iesalnieks <i>et al</i> ^[57] |

| | Endoscopic | 55%-77% | Bordeianou <i>et al</i> ^[14] , McLeod <i>et al</i> ^[15] , Yamaoto <i>et al</i> ^[42] |
| | Symptomatic Surgical | 50% 4%-25% | Bordeianou <i>et al</i> ^[14] Bordeianou <i>et al</i> ^[14] , Aratari <i>et al</i> ^[27] , Riss <i>et al</i> ^[56] , Yamamoto <i>et al</i> ^[42] |
| 10 yr | Clinical | 52% | Aratari <i>et al</i> ^[27] |
| | Endoscopic | 74% | Malireddy <i>et al</i> ^[17] , Bordeianou <i>et al</i> ^[14] |
| | Surgical | 12%-57% | Stocchi <i>et al</i> ^[18] , Aratari <i>et al</i> ^[27] , Riss <i>et al</i> ^[56] , Iesalnieks <i>et al</i> ^[57] |

in McLeod *et al*^[15] 1997 study which included a variety of CD resections, of which 60% were ileocelectomies. Interestingly, 21% of patients with severe symptoms had minimal endoscopic or radiologic evidence of recurrence. Conversely, 28% of the asymptomatic patients studied had endoscopic or radiologic evidence of severe recurrence. Similarly, Regueiro's study of 24 CD patients 1 year post ileocelectomy demonstrated a poor correlation between CDAI scores, serum CRP or ESR and endoscopy findings^[16]. Only 87% of patients with endoscopic or radiologic recurrence had symptoms in Malireddy's study^[17].

Endoscopic recurrence generally occurs earlier than other types of recurrence with an overall mean time from surgery to endoscopic recurrence ranging from 6 mo to 4 years^[14,17]. Mean time to symptomatic recurrence is approximately 5 years^[14]. Mean time to repeat surgery has the longest duration, approximately 7 (range of 5-11) years^[9]. Overall, rates of approximately 30% for endoscopic, 23% for symptomatic or clinical and 11%-50% for surgical recurrence are documented in the literature^[3,14,18]. However, it is more clinically relevant to evaluate recurrence by time period, according to time since ileocelectomy. Overall recurrence rates by time period are shown in Table 4. The multiple factors affecting recurrence are discussed below.

Table 5 Effect of smoking on postoperative recurrence

| Association | Number and type of patients | Ref. |
|---|--|--|
| Recurrent clinical symptoms (OR = 2.96) | 59 patients post colonic resection | Kane <i>et al</i> ^[22] |
| Shorter duration to clinical relapse (104 wk shorter) | for CD (not only ileocelectomies) | |
| Recurrent clinical symptoms (worse CDAI scores) | 182 post colonic resection for CD | Cottone <i>et al</i> ^[23] |
| Increased rates of endoscopic recurrence | (not only ileocelectomies) | |
| Increased likelihood of requiring surgery | | |
| Smoking at the time of the 1 st ileocelectomy conferred a 2.1 fold increased likelihood of requiring another operation | 176 post ileocelectomy patients with at least 1 recurrence | Unkart <i>et al</i> ^[21] |
| OR of 2.2 for clinical recurrence | Meta-analysis of | Reese <i>et al</i> ^[24] |
| Increased risk of surgical recurrence particularly at 10 years (OR = 2.6) | 16 studies, 2962 patients | |
| Smokers had a lower 5 and 10-yr recurrence free likelihood (65 and 45% vs 81 and 64% in nonsmokers) | 141 ileocelectomy patients | Yamamoto and Keighley ^[26] |
| Recurrence free rates were lower in those that smoked > 15 cigarettes per day | | |
| Patients that quit smoking are less likely to require redo ileocelectomy | 266 | Ryan <i>et al</i> ^[25] |
| No association with recurrence | 89 lap ileocelectomy patients | Malireddy <i>et al</i> ^[17] |
| No association with clinical or surgical recurrence | 83 | Aratari ^[27] |
| No association with clinical or endoscopic recurrence | 43 resections (30 = ileocelectomies) | Sorrentino ^[28] |

CD: Crohn's disease; CDAI: Crohn's disease activity score.

PATIENT FACTORS

Demographics

Although gender, age at diagnosis, age at surgery and disease duration have been studied as potential predictors of post-operative recurrence, no correlation has been consistently demonstrated^[14,17,19,20].

A positive family history of IBD was demonstrated to confer a 2.2 fold increased likelihood of requiring a second ileocelectomy in Unkart's study of 176 post ileocelectomy patients with at least one surgical recurrence. However, this result has not been replicated in the literature^[21].

The most studied and most recognized risk factor for post-operative recurrence is smoking (Table 5). Several studies evaluating smoking as a predictor of recurrence do not exclusively study ileocelectomies. One such study by Kane *et al*^[22] followed 59 CD patients post colonic resection. Sixty-nine percent of smokers vs 23% of nonsmokers had recurrence documented using a clinical symptom activity score. Odds ratio for recurrence was 2.96 in the smoking cohort and a strikingly shorter dura-

tion to clinical relapse was seen in smokers (130 *vs* 234 wk in nonsmokers). Cottone *et al.*^[23] similarly followed 182 surgical CD resection patients for 6 years and demonstrated that both smoking and greater disease extent were associated with worse clinical (CDAI) scores and increased risk of endoscopic recurrence. Although several variables were studied, the only significant predictor of surgical recurrence was smoking. Meta-analysis of 16 studies published between 1966-2007 inclusive of 2962 patients undergoing resection for CD demonstrated an OR of 2.2 for clinical postoperative recurrence in smokers and an increased risk of surgical recurrence particularly at 10 years (OR = 2.6, 55.5% *vs* 32.1% in nonsmokers)^[24]. However, again, this analysis was not limited to patients who had undergone ileocelectomies only.

Studies that focus solely on ileocelectomy recurrence include Unkart *et al.*^[21] study which demonstrated that smoking at the time of the 1st ileocelectomy confers a 2.1 fold increased likelihood of requiring another operation. http://www.ncbi.nlm.nih.gov/pubmed?term=Unkart%20J%5BAuthor%5D&cauthor=true&cauthor_uid=18536967 Repeat ileocelectomy rates of 59%-69% in smokers have been noted by Cullen *et al.*^[31] and Ryan *et al.*^[25]. Another study evaluated the relationship between the number of cigarettes smoked daily and recurrence in 141 ileocelectomy patients. Smokers had lower 5 and 10 year recurrence free likelihoods (65% and 45 % *vs* 81% and 64% in non-smokers). Recurrence free rates were lower in those that smoked > 15 cigarettes per day^[26]. Although the majority of studies have shown an increased risk for reoperation, Maliredu, Aratari and Sorrentino did not see such an association in their studies which included approximately 195 patients combined^[17,27,28].

Genetics

Since the advent of genome wide associations studies, several studies inclusive of large cohorts of both IBD patients and healthy individuals have been performed thus creating a pool of IBD-associated genes and single nucleotide polymorphisms (SNPs). To date, over 300 SNPs and 150 genetic loci have been associated with IBD^[29]. With these IBD-associated genes established, a shift towards using these markers to further characterize disease behavior, including postoperative recurrence in CD, has begun^[30]. Several "surgical genetics" studies have identified markers of the need for resection in their CD cohorts including mutations within the NOD2, TNFSF15 and C13ORF31 genes^[31]. However, fewer studies have focused on determining a marker of recurrence.

NOD2 (nucleotide-binding oligomerization domain-containing protein 2), also known as CARD15 (caspase recruitment domain-containing protein 15), was the first gene to be associated with IBD in 2001^[32]. Located on chromosome 16, the gene is expressed in several different cell types key to the pathogenesis of CD such as dendritic cells, monocytes, intestinal epithelial cells and Paneth cells. Its protein product is involved in the rec-

ognition a dipeptide found in the bacterial cell wall^[33]. NOD2 has been previously associated with ileal^[34] and stricturing CD^[35].

An early German study evaluated the NOD2 genotypes of 51 post ileocelectomy patients. Fourteen patients required a repeat ileocelectomy. Of the 14, 12 harbored at least 1 NOD2 mutation^[36]. This association may be specific to patients of German and other not yet determined ethnicities, as this increased incidence of NOD2 mutations in patients with recurrent disease was not replicated in an Italian multi-center study of 253 CD patients, 42% of whom had ileocolic disease. In this study, no relation between NOD2 genotype, age at diagnosis or smoking status and recurrence was found^[37]. Similarly, in a recent meta-analysis of 6 studies inclusive of 1003 patients with CD NOD2 genotype was not associated with surgical recurrence. Overall, 39% of patients with a NOD2 mutation required further resection *vs* 30.5% of patients without a mutation ($P = 0.06$). However, the included studies were very heterogeneous, which may have affected results^[38].

Another study of only ileocelectomy patients demonstrated the presence of a mutation in the autophagy associated IRGM (Immunity-related GTPase family, M) gene to be significantly associated with more frequent ileocelectomies and earlier time to reoperation in 66 CD patients. Ileocelectomy was performed every 6.8 +/- 1.3 years on average in patients with the at risk genotype for SNP rs4958847 *vs* once every 11.4 years in patients with the wild type genotype^[39].

Meresse *et al.*^[40] studied G microsatellite genotype with the anti-inflammatory gene, IL10 in 36 post ileocelectomy patients. Although genotype affected IL-10 production, no association was seen with endoscopic recurrence.

Nutritional status

Poor nutritional status has been consistently associated with poor outcomes in CD surgery^[41]. Thus postoperative enteral feeding has been studied as a potential way to reduce the risk of complications and recurrence. Often, such studies are technically difficult to perform, particularly after patients are discharged from the hospital, and mid-study patient exclusion due to noncompliance is common. In one such Japanese study of 40 post ileocelectomy patients followed for 5 years, 20 received nighttime continuous nasogastric feeding with an elemental diet and a low fat diet during the day. The other 20 did not receive the nighttime feed and had an unrestricted diet. No postoperative steroid, immunosuppressants or biologics treatment was given to either cohort. Thirty percent of the nighttime feeding group *vs* 70% of the controls had endoscopic recurrence at 1 year. Twelve months after surgery, 10% of the night feed and 45% of the control group required biologics during the follow up. Rates for surgical recurrence were 5% and 25% in the 2 groups but this was not statistically significant^[42].

Much attention has been given to the gut microbi-

ome and how it interacts with the disease process in CD^[43]. However, few studies have centered on altering the gut microbiome to maintain remission in patients who have undergone resection. A meta-analysis of 10 controlled clinical trials evaluating disease recurrence, demonstrated that probiotics were not associated with either endoscopic or surgical remission. In this meta-analysis patients who had undergone surgery or medical treatment prior to the administration of probiotics were not considered separately^[44]. Another systematic review of 24 manuscripts evaluating endoscopic recurrence demonstrated that enteric diets were associated with 61% reduction in endoscopic scores. However, again postoperative patients and patients in medical remission were not considered separately^[45]. One multicenter randomized study by Van Gossum *et al.*^[46] focused only on post ileocelectomy patients and the effect of administration of the probiotic LAl *vs* placebo on early (12 wk) post ileocelectomy recurrence in 49 patients. Patients were stratified according to smoking status. There was no difference in endoscopic or clinical recurrence scores seen between the 2 groups. Twenty one percent of the placebo *vs* 15% of the probiotic group had recurrence scores indicative of severe recurrence but this difference was not statistically significantly different.

DISEASE BEHAVIOR

Penetrating vs non-penetrating

Disease behavior is difficult to use as a predictor of endoscopic recurrence due to the varying course of CD typically seen within the individual patient. The Montreal classification of inflammatory *vs* stricturing *vs* penetrating (fistulizing/abscessing) disease is commonly used to classify CD according to its behavior^[47]; however, behavior often changes from inflammatory to stricturing or penetrating over time^[48-50]. Also, at any time point a patient may have more than 1 type of disease behavior, (*i.e.*, a stricture and a fistula) presenting challenges with classification. Additionally, penetrating disease that is initially responsive to a particular medical treatment may lose responsiveness with repeated doses and thus transform from a penetrating to inflammatory to penetrating phenotype when responsiveness ceases^[51].

Nonetheless, several studies have attempted to correlate disease behavior with risk of post-operative recurrence. In multiple studies, including 2 large Italian multicenter studies, disease behavior was not shown to affect the risk of disease recurrence clinically, surgically or endoscopically^[14,20,27,52]. Although not a primary end point of the study, a meta-analysis of 12 randomized controlled trials that evaluated medical therapies after CD resections (not exclusively ileocelectomies) from 1966 to 2005, demonstrated that fistulizing disease was significantly associated with endoscopic but not clinical recurrence in patients who had been given placebo treatment^[53].

Granulomatous disease

Granulomas, or histologic areas of macrophage fusion,

are a hallmark of CD but need not be present for a definitive diagnosis^[54]. An association between granulomas and disease severity has been suggested but not proven^[55]; however, an association between the presence of granulomas in the ileocolic resection specimen and recurrence has been consistently demonstrated. In an observational study by Malireddy *et al.*^[17] recurrence rates in 89 patients who had undergone laparoscopic ileocelectomy from April 1994-August 2006 (with a median follow up of 3.5 years) were evaluated. A 61% endoscopic, radiologic or pathologic recurrence rate was noted. The median time for recurrence was 13.1 mo (range, 1.3 mo to 8.7 years). Several potential prognosticators for recurrence including postoperative biologic and other medical treatment were also studied. The only significant predictor of recurrence found on multivariate analysis was the presence of granulomas in the initial resection specimen. An earlier Irish study of 139 patients who underwent ileocelectomy between 1980 and 2000 evaluated the presence of symptoms, endoscopic recurrence and radiological recurrence. Again, the presence of granulomas in the specimen was significantly associated with **clinical and surgical** recurrence^[3]. In a similar early study of 114 ileocelectomy patients, 66% with granulomas *vs* 48% without experienced an endoscopic recurrence within the first year after an ileocelectomy^[11]. In 1997, Anselme *et al.*^[20] evaluated 130 CD patients undergoing a variety of resections. After multivariate analysis, the presence of granulomas was significantly associated with recurrence.

INDEX ILEOCELECTOMY DETAILS

Urgent vs elective resection

Several groups have hypothesized that if a patient's first ileocelectomy is performed under emergency circumstances, this likely reflects more severe disease and thus may predict an increased likelihood of recurrence. One retrospective multicenter Italian review evaluated clinical recurrence (defined as the need for steroids in conjunction with endoscopic or radiologic findings) and surgical recurrence in 83 CD patients who underwent ileocelectomy for severe disease at the time of diagnosis *vs* 124 who underwent surgery later in their disease for medical refractory disease and/or complications secondary to their disease. Recurrence was evaluated at 1, 5 and 10 years. Clinical recurrence was less frequent in the early surgery group at all-time points. No difference was seen in the need for or timing of repeat surgery between the 2 groups^[27]. Another retrospective study of 116 consecutive patients undergoing their first ileocelectomy at a large Austrian referral center between 1997 and 2006 demonstrated that urgent index ileocelectomy increased the risk of repeat surgery approximately 6 fold^[56].

Sepsis

Another potential marker of severe disease is perioperative sepsis at the time of index ileocelectomy. However, results are conflicting and further study is warranted. Elevated white cell count was associated with endoscopic

recurrence on univariate analysis in Caprilli *et al.*^[52] study of 110 ileocelectomy patients. However, an increased risk of recurrence in urgent *vs* elective ileocelectomy patients was not demonstrated. Iesalnieks *et al.*^[57] studied 282 patients who underwent 331 varied CD resections between 1992-2005. On multivariate analysis, postop intraabdominal septic complications and history of a previous resection were associated with increased surgical recurrence risk at all-time points studied from 1-10 years. At 1 year patients with a history of sepsis had a recurrence rate of 25% *vs* 4% of those without sepsis. At 10 years rates were 57% and 38% respectively.

Laparoscopic vs open approach

As laparoscopic surgery and stapled anastomosis initially gained popularity for use in the CD population in the 1980s, an interest in determining if either technique decreases the risk of recurrence post ileocelectomy led to several studies. One such retrospective review of 113 patients undergoing their index ileocelectomy between 1987-2003 (with a mean follow up of approximately 70 mo) demonstrated a slightly lower, but not significantly different, rate of postoperative medical treatment requirement in laparoscopic *vs* open patients (39% *vs* 54%). Surgical recurrence was seen in 9.5% (6/63) of laparoscopic *vs* 24% (12/50) of open ileocelectomy patients during a mean follow up of 81 mo. Time to recurrence was not affected. Both groups had a median time to recurrence of approximately 60 mo^[58]. Similarly, Stocchi *et al.*^[18] performed a prospective randomized trial in which 77 patients underwent laparoscopic ileocelectomy and 29 underwent an open procedure. Both cohorts had a similar postoperative prophylactic medication regimen and a mean follow up of 10.5 years. Reoperation rates were the same in the 2 groups (approximately 26% in each). Endoscopic and radiologic recurrence rates were similar. Forty-eight percent of laparoscopic patients experienced endoscopic or radiologic recurrence *vs* open patients who demonstrated a 66% endoscopic recurrence and 52% radiologic recurrence rate. The most recent meta-analysis on laparoscopic *vs* open approach included 33 studies and included 2519 patients. No statistical difference was seen in surgical recurrence rates which were 25 per 1000 person years in the laparoscopic group *vs* 34 per 1000 person years in the open group^[59].

Resection margins and type of anastomosis

Stapled anastomosis has now virtually replaced the hand sewn technique in the majority of centers performing ileocelectomies for CD. Two studies, inclusive of 199 and 89 ileocelectomy patients, evaluated resection margins and anastomotic type. In both studies, no difference in clinical recurrence was found between patients whose resection margins were affected by disease *vs* those who had unaffected margins. There was also no difference seen between stapled or hand sewn anastomoses^[14,17]. In the only randomized study to date, Fazio *et al.*^[60] evaluated recurrence in 131 ileocelectomy patients random-

ized to undergo resections with proximal margins either 2 or 12 cm from the macroscopically diseased tissue followed up for median of 56 mo. The resection specimen was also studied for microscopic signs of disease. Surgical recurrence was found in 25% of patients who had undergone a limited resection *vs* 18% of those who had undergone the more extensive resection ($P > 0.05$). Clinical recurrence was demonstrated in 33% *vs* 29% of those with limited and extended resections respectively. No relation was seen between microscopic CD found at the resection margin and recurrence.

In Bordeianou's study of approximately 200 ileocelectomies, stapled anastomosis although significant on univariate analysis, lost significance on multivariate analysis^[14]. End-to-end *vs* side-to-side anastomotic techniques has also been evaluated in 2 randomised trials comparing anastomosis types in 98 and 139 CD patients respectively. Both studies failed to demonstrate a difference in symptomatic or endoscopic recurrence rates between the groups. The first study demonstrated an endoscopic recurrence rate of 42.5% in the end-end *vs* 37.9% in the side-side anastomosis groups and a symptomatic recurrence rate of approximately 22% in both groups^[61]. The second study demonstrated that overall, on multivariate analysis, anastomosis type did not affect endoscopic recurrence. However, a 3 fold risk of recurrence was seen in a subgroup of patients with end-end anastomoses who were treated with 5 aminosalicylates (ASAs). This increased risk was not seen in those not treated with ASAs^[52]. Meta-analysis of 8 studies published between 1992-2005 inclusive of 661 ileocelectomy patients compared end-to-end anastomosis *vs* other anastomotic configurations (stapled side-to-side, end-to-side or side-to-end, stapled circular end-to-end). No significant difference was found in clinical or surgical recurrence between the different groups^[62].

Techniques to potentially minimize risk of recurrence are currently under development. The Kono-S is one such novel technique. This technique utilizes a linear stapler-cutter to transversely divide the tissue for resection. The corners of the 2 stapled lines are sutured together and antimesenteric longitudinal enterotomies are created on both sides. The enterotomies are then closed transversely in two layers resulting in an anti-mesenteric functional end-to-end anastomosis. This technique has shown promise in a small cohort of 18 patients, 43% of whom have undergone follow-up endoscopic surveillance with an average Rutgeert's score of 0.7 (0-3) at a mean of 6.8 mo^[63].

MEDICAL TREATMENT TO PREVENT DISEASE RECURRENCE

Key studies on the effect of medical treatment for the prevention of recurrence are highlighted in Table 6. Traditionally, treatment paradigms for CD followed a "bottom up" approach with initial treatment comprised of corticosteroids, antibiotics and/or 5 ASAs. Escalating

Table 6 Key studies on medical treatment for the prevention of postoperative recurrence in post ileocelectomy patients

| Interventions Compared | Study Design | Study Numbers (end of follow-up) | Follow-up | Clinical Improvement | Endoscopic Improvement | Other | Ref. |
|------------------------------------|---|--|---------------|---|--|---|---|
| Mesalamine vs Placebo | Double Blind, Multicenter | 87 | 12 mo | 59% of placebo vs 41% of mesalamine had a clinical relapse | Significantly less severe and less frequent lesions in mesalamine group ($P < 0.008$) | Severe endoscopic or radiologic was 24% in mesalamine vs 56% of placebo ($P = 0.004$) | Brignola <i>et al</i> ^[68] |
| Budesonide vs placebo | Double-blind, randomized trial | 129 | 12 mo | No difference in CDAI at any time point in the study | Only patients who underwent surgery for increased disease symptoms (not fibrostenotic or fistulizing disease) had a significantly lower endoscopic recurrence rate (32% vs 65% of the placebo group) | AT 12 mo the ESR value was 13.3 mm/h in the budesonide group vs 20.2 mm/h in the placebo group ($P = 0.017$). Mean CRP values after disease increased from 19.0 to 6.2 mg/L in the budesonide group and from 12.7 to 12.2 mg/L in the placebo group ($P = 0.018$) | Hellers <i>et al</i> ^[64] |
| Mesalamine vs placebo | Double-blind, placebo controlled ^{1,2} | 246 | 48 wk | 25% of the mesalamine vs 36% of the placebo had a relapse [(per CDAI) $P = 0.06$] On subgroup analysis ileocolonic patients had fewer relapses on mesalamine (21% vs 41%) $P = 0.003$ | | 10% vs 23% surgical recurrence ($P = 0.13$) | Sutherland <i>et al</i> ^[67] |
| Mesalamine vs placebo | Randomized | 163 post-surgical patients ¹ 109 were post ileocelectomy | Maximum 72 mo | | Endoscopic and radiological recurrence was significantly decreased in the mesalamine group with relative risks of 0.6 ($P = 0.016$) | 31% symptomatic recurrence rate (symptoms plus endoscopic and/or radiological confirmation of disease) vs 41% in the control group, $P = 0.03$ | McLeod <i>et al</i> ^[69] |
| 6 MP, mesalamine or placebo | Multi (5) center, double blind, randomized | 131 | 24 mo | Clinical recurrence was improved by mesalamine or 6 MP. Clinical recurrence rates at 24 mo were 50% for 6 MP, 58% for mesalamine and 77% for placebo ($P = 0.04$) | Only 6 MP, not mesalamine was superior to placebo to prevent endoscopic and radiographic recurrence at 24 mo. Relapse was 43% with 6 MP, 63% with mesalamine, 64% with placebo ($P = 0.03$) | Radiographic recurrence rates were 33% for 6 MP, 46% for mesalamine and 49% for placebo ($P > 0.05$) | Hanauer <i>et al</i> ^[76] |
| Infliximab vs mesalamine (control) | Prospective, multicenter pilot study to determine if giving infliximab after diagnosis of postoperative endoscopic ileocolic CD recurrence at 6 mo can induce endoscopic remission at 54 wk | 24 (19 had ileocaecal disease) | 54 wk | No clinical recurrence in the infliximab group at 6 mo 18% of mesalamine who had clinical relapse by 9 mo | No endoscopic remission at 54 wk in the mesalamine group vs the infliximab group 54% had endoscopic remission at 54 wk ($P = 0.01$) | | Sorrentino <i>et al</i> ^[28] |
| Adalimumab vs AZA vs mesalamine | Randomized | 51 | 2 yr | | The ADA treated patients had the lowest incidence of endoscopic recurrence (6.3% vs 64.7% of the AZA group and 83.3% of the mesalamine group) | | Savarino <i>et al</i> ^[83] |

| | | | | | | | |
|--|----------------------------|--|---------------------------|--|--|--|--|
| Infliximab vs placebo | Randomized | 24 | 1 yr | Clinical remission was higher in the IFX group (80% vs 54%) but $P = 0.38$ | Endoscopic and histologic recurrence was significantly lower at 1 yr in the patients treated with infliximab (1 of 11; 9.1% and) vs placebo (11 of 13 patients; 84.6%). $P = 0.0006$ | Lower histologic recurrence in the IFX group (3 of 11/27% vs 11 of 13/85% of placebo) $P = 0.01$ | Regueiro <i>et al</i> ^[82] |
| Metronidazole +AZA or placebo | 62 | Randomized | 12 mo | Endoscopic recurrence was observed in 14 of 32 (43.7%) patients in the AZA group and in 20 of 29 (69.0%) patients in the placebo group at 12 mo post-surgery ($P = 0.048$. At 1 yr 21% of the AZA group were lesion free vs 3% of the placebo ($P = 0.04$) | | | D'Haens <i>et al</i> ^[77] |
| Metronidazole vs placebo | Double-blind controlled | 51 | 3 yr | Clinical recurrence rates at 1 yr were 4% in the metronidazole vs 25% of placebo) NSD $P = 0.04$. Reductions at 2 yr (26% vs 43%) and 3 yr (30% vs 50%) both NSD | At 12 wk, 21 of 28 patients (75%) in the placebo group had recurrent lesions in the neoterminal ileum vs 12 of 23 patients (52%) in the metronidazole group ($P = 0.09$) | | Rutgeerts <i>et al</i> ^[65] |
| Immunosuppressants (AZA/6 MP or MTX) vs control (5 ASAs or no treatment) | | 26 patients undergoing their 2 nd ileocelectomy | 3 yr (range 17-178 mo) | Clinical recurrence was lower in the immunosuppressant group vs the control group (3/12, 25% vs 6/10, 60%; $P < 0.05$) No difference in time to recurrence was seen (approximately 27 mo in both groups) | | The control group required a 3 rd resection more commonly. (7/12, 58% vs 2/14, 17% $P < 0.02$) | Alves <i>et al</i> ^[79] |
| AZA therapy commenced immediately post resection | Prospective, observational | 56 consecutive patients 15 or 27% had ileocelectomies | Mean 12-84 mo | No clinical recurrence at 12 mo | 70% had endoscopic recurrence at 12 mo. The cumulative probability of endoscopic recurrence was 82% at 5 yr | | Domènech ^[90] |

¹Study included non ileocelectomy patients in addition to ileocelectomy patients; ²Study included medically treated patients in addition to ileocelectomy patients. AZA: Azathioprine; 6 MP: 6 mercaptopurine; ASAs: Aminosalicylates.

treatment in the form of immunomodulators or biologics either replaced this treatment or was added to it as the disease flared or progressed. Steroids and antibiotics are rarely given as monotherapy to prevent relapse in CD currently. Thus, studies that focus on their efficacy are commonly from the 1980s and 1990s. One such double-blind, randomized trial performed in 13 European centers followed 63 patients given budesonide and 66 patients given placebo post ileocelectomy. At 1 year, no difference in endoscopic recurrence was seen between

the 2 groups. However, a significantly lower endoscopic recurrence rate was seen in a subgroup of patients treated with budesonide, namely those who had undergone surgery for increased disease symptoms rather than obstruction or fistulization (32% vs 65% of the placebo group)^[64].

Studies on antibiotic monotherapy have been limited to metronidazole. In a double-blind controlled trial evaluating the use of metronidazole as monotherapy post ileal resection in 51 patients, recurrent lesions were

seen in 75% of the placebo group *vs* 52% of the metronidazole group at 12 wk ($P = 0.09$). At 1 year, clinical recurrence rates were much lower in the metronidazole group (4% *vs* 25%); however significance was lost at 2 years (26% *vs* 43%)^[65].

The commonly used aminosalicylate based drugs, including mesalamine, generally have low side effect profiles and have been shown by meta-analysis to prevent relapse in inactive CD^[66]. However, results from studies evaluating their long term efficacy in the prevention of post ileocelectomy recurrence are not impressive, particularly in regard to clinical recurrence. One large double blind, placebo controlled study by Sutherland *et al*^[67] compared clinical recurrence as defined by CDAI scores in medical and surgical CD patients (who had undergone a variety of resections) treated with either mesalamine or placebo. At 48 wk, 25% of the mesalamine *vs* 36% of the placebo had a clinical recurrence. However, disease recurrence was only 10 d later in the mesalamine treated patients. Interestingly, ileocolonic patients had fewer relapses on mesalamine (21% *vs* 41% given placebo) on subgroup analysis. In another double-blind, multicenter clinical trial published in 1995, 87 patients were treated with mesalamine or placebo within 1 mo after undergoing ileocelectomy. At 12 mo, 41% of the 17 patients who relapsed clinically had been given mesalamine. Using endoscopic and radiological evaluation with scoring systems, the mesalamine group had significantly less frequent and less severe lesions and milder disease. Disease was classified as "severe" in 24% of the mesalamine treated patients *vs* 56% of those given placebo^[68]. In another study published the same year, 163 post resection patients (of whom 109 had undergone ileocelectomy) were randomized to receive either mesalamine twice a day or placebo. During a maximum follow up of 72 mo, 31% of those given mesalamine experienced a symptomatic recurrence defined as symptoms plus endoscopic and/or radiological confirmation of disease *vs* 41% in the control group^[69].

A new paradigm of a "top down" approach to the treatment of CD in which surgery and early institution of immunomodulatory and/or biologic drug therapy has been suggested by large trials such as the SONIC trial. This approach has demonstrated improved mucosal healing, a reduction in steroid use, longer remission times and faster clinical response than the traditional bottom up approach^[70,71]. Additionally, multidrug therapy has been proven to increase drug serum levels, address multiple disease mechanisms and potentially reduce the production of anti-drug antibodies^[70,72,73]. The immunomodulatory drugs azathioprine (AZA) and 6 mercaptopurine (6 MP) are two drugs commonly used in the top down approach. Used on their own or in conjunction with other IBD medications, these drugs have a high success rate in treating flares, reducing the steroid requirement and increasing remission rates in medically treated disease and^[74,75] have been suggested to be effective at reducing recurrence and increasing duration from

surgery to recurrence. In a 5 center, double blind study inclusive of 131 post ileocelectomy patients randomized to receive 6 MP, mesalamine or placebo, only 6 MP was superior to placebo for the prevention of endoscopic and radiographic recurrence at the study endpoint of 24 mo. Clinical recurrence rates were improved by mesalamine or 6 MP administration with recurrence rates of 50% for 6 MP, 58% for mesalamine and 77% for placebo at 24 mo demonstrated. Endoscopic and radiologic recurrence rates were 43% and 33% for 6 MP, 63% and 46% for mesalamine and 64% and 49% for placebo^[76].

The utility of immunomodulatory drugs has been studied in subgroups of patients who are at increased risk for recurrence. D'Haens *et al*^[77] studied 62 patients who were aged < 30, had a history of multiple ileocelectomies and/or had penetrating disease. Post ileocelectomy, all patients were given metronidazole for 3 mo with either azathioprine or placebo for 12 mo. At 12 mo, a significant difference in endoscopic recurrence was observed with 43.7% of patients in the AZA group experiencing recurrence *vs* 69.0% of those in the placebo group. Endoscopically, 21% of the AZA group were lesion free *vs* 3% of the placebo ($P = 0.04$). Mañosa *et al*^[78] virtually reversed this study and administered AZA to 50 ileocelectomy patients postoperatively. At 3 mo, patients were randomized to receive either metronidazole or placebo. At 12 mo, endoscopic recurrence was seen in 36% of the metronidazole and 56% of the placebo group. However, this difference was not significant, suggesting that AZA on its own may be sufficient. In another high risk group, those undergoing their 2nd ileocelectomy for anastomotic recurrence, immunosuppressant drugs were shown to decrease clinical and surgical recurrence. Twenty-six patients were randomized to receive an immunosuppressant drug (6 MP, AZA, Methotrexate, $n = 14$) or a control treatment (5 ASAs, $n = 5$ or no treatment, $n = 7$). Clinical recurrence rates were lower in the immunosuppressant treated group *vs* the control group (3/12, 25% *vs* 6/10, 60%; $P < 0.05$). No difference in time to recurrence was demonstrated between the groups (approximately 27 mo in both groups). The control group required a 3rd resection more commonly (7/12, 58% *vs* 2/14, 17%, $P < 0.02$)^[79]. Other evidence suggests that AZA/6 MP treatment may delay but not prevent recurrence. Fifty-six consecutive patients commenced on AZA treatment immediately after resection were studied in Domènech *et al*^[80] observational study. Fifteen (27%) had ileocelectomies. Seventy percent of the cohort had endoscopic recurrence at 12 mo. However, no clinical recurrence was observed. At approximately 3 years' follow up, 30% of patients maintained endoscopic remission. At 5 years, the cumulative probability of endoscopic remission dropped to 18%. Due such evidence, the American Gastrological Association has recommended that as 6 MPs likely reduce the risk of clinical and endoscopic recurrence, they should be used in those at "high risk" for recurrence or in whom postoperative recurrence would have deleterious effects^[81].

The anti-tumor necrosis factor (TNF) drugs, including infliximab and adalimumab are among the newest IBD drugs and have rapidly gained popularity over the past 10 years. A role for these drugs in the prolongation of postoperative remission has been suggested by preliminary studies. In one such study, significantly lower 1 year postoperative endoscopic and histologic recurrence rates were demonstrated in patients who had undergone ileal resection who were treated with infliximab. 9.1% (1 of 11) of these patients had endoscopic recurrence *vs* 27% (3 of 11) that were given placebo. Clinical remission rates were also higher in the infliximab group (80% *vs* 54% of the placebo group) but this difference wasn't significant^[82]. One prospective, multicenter but also small Italian study, aimed to determine if the administration of infliximab after diagnosis of postoperative endoscopic recurrence of ileocolic CD can induce endoscopic remission at 54 wk. Mesalamine was used as the control. In the mesalamine group ($n = 11$), no endoscopic remission was seen at 54 wk. Two patients had clinical recurrences at 8 and 9 mo. In the infliximab group ($n = 23$), 54% had endoscopic remission at 54 wk. None had clinical recurrence^[28].

Infliximab is the most commonly used and studied anti-TNF drug. However, a recent randomized control trial evaluated the efficacy of adalimumab for the prevention of post ileocelectomy recurrence^[83]. Fifty-one patients were randomized to receive adalimumab, AZA or mesalamine postoperatively. At 2 years, the adalimumab treated patients had the lowest incidence of endoscopic recurrence (6.3% *vs* 64.7% of the AZA group and 83.3% of the mesalamine group). Similarly clinical recurrence was lower in the adalimumab treated patients (12.5% *vs* 65% in both the AZA and mesalamine groups).

The timing of postoperative treatment has sparked a great interest due to the side effects of many IBD medications. The use of a "tailored treatment approach" to determine the effect of the timing of drug commencement on symptomatic recurrence after ileocelectomy was studied by Bordeianou *et al*^[41]. In their cohort of 199 ileocelectomy patients, 35% were given immediate post ileocelectomy prophylaxis in the form of antibiotics, 5 ASAs, immunomodulators (6 MP/AZA) and/or anti-TNFs. Sixteen percent were commenced on a drug regimen at the time of endoscopic recurrence and 49% percent did not receive any treatment. Symptomatic recurrence occurred in 29% of those treated immediately postoperatively *vs* 44% of those who were treated after recurrence. After multivariate analysis, the significant difference between the 2 groups was lost and the only remaining significant prognostic factor recurrence was Charlson Comorbidity Index^[84]. Malireddy *et al*^[17] studied pre *vs* postoperative administration of anti-TNFs and immunomodulators in 89 laparoscopic ileocelectomies. Timing of treatment did not affect recurrence rates. Postoperative medical treatment lengthened the time to recurrence with a median time to recurrence of 25 mo demonstrated in the group given pharmacoprophylaxis

vs 16 mo in the control group. However, this difference was not statistically significant.

SERUM MARKERS

Serum markers such as CRP and ESR are relatively non-invasive to obtain and have been demonstrated to reflect disease activity. Thus such markers may be potential prognosticators for post ileocelectomy recurrence. ESR and CRP were studied in a randomized controlled multicenter Italian trial of 98 patients undergoing their first ileocelectomy. When evaluating endoscopic recurrence at 6, 12, 24, and 36 mo post operatively, ESR and CRP were not correlated with endoscopic recurrence^[52].

Pro and anti-inflammatory cytokines are not measured in clinical practice. However, they offer the potential to be used as markers of disease activity and, possibly, disease recurrence. Yamamoto *et al*^[85] evaluated levels of the proinflammatory cytokines IL-6 (interleukin 6), IL1B and TNF α in blood, ileal biopsies and rectal biopsies at enrollment and 1 year after ileocelectomy in 36 patients. On univariate analysis, the 16 patients who experienced a clinical relapse (determined by CDAI scores) demonstrated significantly higher IL1B, IL-6 and TNF α levels in their ileal mucosa compared to the 20 patients who did not experience clinical relapse. There was no association with these markers in either the blood or rectal mucosa and relapse demonstrated. On multivariate analysis, IL-6 remained as an independent predictor of clinical relapse. IL-6 has also been demonstrated to be increased in the serum of CD patients with previously quiescent CD experiencing a disease flare^[86]. IL10 is a well-known anti-inflammatory cytokine. Meresse *et al*^[40] studied IL-10 levels and endoscopic recurrence in 36 patients 3 mo post ileocelectomy. Recurrence rate was 53%. Patients with recurrence had significantly lower IL-10 production. When ileal mRNA expression levels were compared with the patients' individual genotypes, varying IL10 production based on IL-10. G microsatellite genotype was seen. However, there was no correlation between genotype and endoscopic recurrence.

Faecal calprotectin (FC) and lactoferrin have been widely studied as noninvasive markers of gut inflammation. Recently, several groups have attempted to correlate levels of these markers with risk of postoperative recurrence in CD. Lamb *et al*^[87] were among the first to study a potential correlation. In their cohort of 13 post-surgical CD patients followed for 1 year (3 of whom had ileocolic disease) and a separate cohort of 104 patients who gave a single stool sample at a median of 24 mo postoperatively (28 of whom had ileocolic disease) both FC and lactoferrin correlated with clinical symptoms as evaluated by Harvey Bradshaw Index. Both markers were found to be more accurate at predicting clinical recurrence than CRP, platelet count and endoscopic appearance. Patients with Harvey Bradshaw scores indicative of severe disease activity ($n = 28$) had FC and lactoferrin levels of 661 $\mu\text{g/g}$ and 116.6 $\mu\text{g/g}$ *vs* 70.2 $\mu\text{g/g}$

and 5.9 µg/g in those with clinically inactive disease ($n = 43$) ($P < 0.001$). Although levels of both markers were slightly higher in those with endoscopic recurrence, this difference was not statistically significantly different between the groups. Subsequently, FC levels of 29 ileocelectomy patients were studied by Lobatón *et al*^[88] Levels correlated more closely with clinical recurrence than CRP, white cell count and platelet count. Endoscopic recurrence scores also correlated with levels. Lasson *et al*^[89] in a study published in Jan 2014, evaluated FC levels in 30 ileocelectomy patients in specimens collected monthly postoperatively for 1 year. Fifty-eight percent had endoscopic remission at one year. FC levels fluctuated over time and were mainly affected by diarrhea. Although median calprotectin levels were not significantly different between patients in remission and patients with recurrence, the majority of patients with high values had recurrence. This may have been influenced by diarrhea at the time of sampling.

CONCLUSION

Crohn's disease cannot be cured. Surgical resection offers an opportunity for "resetting" the disease into a state of temporary remission. It is known that after surgical resection recurrence rates range from 20 to over 60 percent. Identifying modifiable risk factors for postoperative disease recurrence can assist the clinician in implementing more aggressive prophylactic treatment to prevent recurrence and to sustain remission. The application of an optimal strategy for preventing postoperative recurrence is a multidisciplinary task that includes the gastroenterologist and the colorectal surgeon, as well as all the supporting staff that can ensure preoperative optimization, detailed and timely surgical intervention and early implementation of appropriate treatment to keep the patient in remission.

Abstract

The intestinal microbiota plays an important role in inflammatory bowel disease (IBD). The pathogenesis of IBD involves inappropriate ongoing activation of the mucosal immune system driven by abnormal intestinal microbiota in genetically predisposed individuals. However, there are still no definitive microbial pathogens linked to the onset of IBD. The composition and function of the intestinal microbiota and their metabolites are indeed disturbed in IBD patients. The special alterations of gut microbiota associated with IBD remain to be evaluated. The microbial interactions and host-microbe immune interactions are still not clarified. Limitations of present probiotic products in IBD are mainly due to modest clinical efficacy, few available strains and no standardized administration. Fecal microbiota transplantation (FMT) may restore intestinal microbial ho-

meostasis, and preliminary data have shown the clinical efficacy of FMT on refractory IBD or IBD combined with *Clostridium difficile* infection. Additionally, synthetic microbiota transplantation with the defined composition of fecal microbiota is also a promising therapeutic approach for IBD. However, FMT-related barriers, including the mechanism of restoring gut microbiota, standardized donor screening, fecal material preparation and administration, and long-term safety should be resolved. The role of intestinal microbiota and FMT in IBD should be further investigated by metagenomic and metatranscriptomic analyses combined with germ-free/human flora-associated animals and chemostat gut models.

Key words: Inflammatory bowel disease; Intestinal microbiota; Probiotics; Fecal microbiota transplantation; Synthetic microbiota transplantation

Core tip: Several lines of evidence strongly support the link between intestinal microbiota and inflammatory bowel disease (IBD). This review discusses the potential microbial pathogens, disturbance of intestinal microbiota, and immune interactions between host and microbes in IBD. Furthermore, alternative IBD treatment approaches aimed at restoring the disturbed intestinal microbiota have become a major interest in recent years. This article also reviews the present literature concerning the clinical use of probiotics, especially fecal microbiota transplantation and its barriers, and future directions in the management of IBD.

Intestinal microbiota pathogenesis and fecal microbiota transplantation for inflammatory bowel disease. *World J Gastroenterol* 2014; 20(40): 14805-14820 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i40/14805.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i40.14805>

INTRODUCTION

Inflammatory bowel disease (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), is a chronic relapsing nonspecific inflammatory disorder of the gastrointestinal (GI) tract. The etiology of IBD is unknown. Contributing factors to the pathogenesis of IBD include disturbance of the intestinal microbiota and its metabolites, the host's genetic susceptibility, and the host's innate and acquired immunity^[1,2]. Many studies based on metagenomics have profiled the normal patterns of the human intestinal commensal microbiota. For example, 3.3 million microbial genes, up to 10 bacterial phyla, and > 1000 bacterial species (> 90% species belong to the phyla *Bacteroidetes* and *Firmicutes*) have been identified in the human intestine^[2,3]. Commensal fungi and viruses have also been detected in the human gut^[2,4]. Several lines of evidence strongly support the link between intestinal microbiota and IBD such as: (1) animal studies confirm that intestinal microbiota has an essential role in the pathogenesis of IBD, because colitis cannot be induced in germ-free animal models^[5,6]; (2) fecal stream diversion prevents recurrence of CD in the neoterminal ileum, but reinfusion of luminal contents into bypassed colonic segments rapidly results in recurrent disease^[7,8]; (3) fecal and intestinal mucosa-associated microbiota of IBD patients is characterized by decreased biodiversity and abnormal compositions (*e.g.*, an imbalance between protective and harmful microbes)^[2,9]; (4) the disturbed metabolites of intestinal microbiota (*e.g.*, abnormal butyrate metabolism) are implicated in the pathogenesis of IBD^[10,11]; (5) several probiotic products may be effective in relieving intestinal symptoms and preventing relapse in UC^[12]; (6) some non-absorbable antibiotics may induce and maintain remission in IBD^[12,13]; (7) many environmental factors such as the westernized diet, modern lifestyle, or abuse of antibiotics, have an important effect on the composition of intestinal microbiota and contribute to the significant increased incidence of IBD^[9,14]; and (8) IBD-related genetic susceptibility loci are mainly associated with the host-microbe immune interactions^[15-17].

Previously, researchers have tried to determine the specific microbial pathogens associated with the onset of intestinal inflammation of IBD^[18-22]. Recently, metagenomic studies have increased with the development of high-throughput DNA sequencing and bioinformatics analysis technology^[2,23,24]. Therefore, many studies have focused on the composition and function of gut microbiota in IBD patients, but the defined alteration of intestinal microbiota, the microbial interactions and host-microbe interactions are still not conclusive^[2,9,25]. Furthermore, IBD-related conventional medical treatments use aminosalicylates, steroids, immunosuppressive agents and biological therapies with many adverse effects, and no cure is available. Alternative IBD treatment approaches aimed at restoring the disturbed intestinal microbiota have become a major interest in recent years. Many clinical trials have been performed to investigate the efficacy of probiotics in IBD. The beneficial effect of

probiotics is modest, although several probiotic products can induce and maintain remission in UC^[26,27]. Recently, fecal microbiota transplantation (FMT) has re-emerged as a hot research topic^[28-30], largely due to its efficacy on the management of recurrent *Clostridium difficile* infection (CDI). FMT is now recommended as an alternative to standard therapy with antibiotics for recurrent CDI^[31,32]. Importantly, FMT may restore the balance of intestinal microbiota, so it is also proposed as an alternative treatment for IBD^[33]. Thus so far, several case series have shown the efficacy of FMT in refractory IBD, and IBD combined with CDI^[34-37], but it is not clear whether FMT has potential therapeutic value for IBD patients with mild IBD. FMT clinical application in IBD still leaves many unanswered questions. FMT-related screening of donor, fecal material preparation and administration is not standardized, and the defined microbial restoration mechanisms and long-term safety of FMT are still not clarified^[38,39]. Moreover, FMT researchers have to prepare and submit the complex investigational new drug applications in the future^[40]. This study reviews the present literature concerning the potential microbial pathogenesis in IBD, particularly FMT and its role in the management of IBD.

POTENTIAL MICROBIAL PATHOGENS IN IBD

Many studies have investigated the specific microbial pathogens contributing to the onset of IBD; however, no definitive pathogens have been confirmed^[10]. The potential bacterial, fungal or viral pathogens related to IBD are listed in Table 1. *Mycobacterium avium* subspecies *paratuberculosis* can colonize the ileal mucosa of CD patients^[19], which has been often linked to the etiology of CD, but with no conclusive evidence to its involvement^[41-43]. Moreover, *Escherichia coli* (*E. coli*) strain LF82 was isolated from the ileum of CD patients^[18]. Several studies have shown that CD patients have a higher prevalence of adherent-invasive *E. coli* (AIEC) in ileal lesions, which indicates a specific association of AIEC with CD^[20,44]; higher expression of the outer membrane porin C of

AIEC can be observed in patients with CD^[45]. AIEC proliferation has also been found in the colonic mucosa of UC patients^[46]. Although the enhanced adherence and invasion of AIEC is present among IBD patients, the potential mechanisms between AIEC and IBD still need to be clarified. Furthermore, CDI is common among IBD patients, and similar symptoms between CDI and IBD makes it difficult to distinguish between them^[47]. CDI can activate the intestinal proinflammatory response and is responsible for the development or exacerbation of IBD. IBD itself may contribute to the increased risk of CDI^[47]. However, there is no clear evidence that CDI precedes IBD. Much evidence has shown that fungal pathogens may be involved in the pathogenesis of IBD, especially CD^[1]. Anti-*Saccharomyces cerevisiae* antibodies (ASCAs) as one of the serological markers for CD can also be induced by *Candida albicans* (*C. albicans*)^[7,48]. *C. albicans* can be isolated from the intestine more frequently in CD patients and their healthy relatives, but the positive association between ASCAs level and the amount of *C. albicans* in CD is still controversial^[49,50]. Inhibition of interleukin (IL)-17A by secukinumab is ineffective in active CD patients^[51], which may be linked to *C. albicans* thriving in the gut induced by loss of control by IL-17^[52]. In addition, large amounts of *Candida* sp. can also be detected in the feces or intestinal mucosa among UC patients^[50], and the clinical symptoms and intestinal inflammation may be improved after antifungal treatment. Although many studies have shown a higher prevalence of pathogenic microbes in IBD, no specific pathogenic microbe has been identified to date, and the cause and consequence relationship of the single pathogenic microbe and IBD development is still controversial. Increasing evidence has confirmed that the disturbance of the intestinal microbial community may be responsible for the pathogenesis of IBD.

DISTURBANCE OF INTESTINAL MICROBIOTA IN IBD

With the development of culture-independent techniques such as metagenomic analysis, the disturbance of intestinal microbiota associated with IBD has been better described. This includes the involvement of the feces/colonic mucosa-associated microbiota, inflamed lesions-/normal mucosa-related microbiota^[53], and even the intestinal microbiota in IBD remission and relapse^[54]. Although the conclusions about the altered intestinal microbiota are still uncertain, more consistently observed alterations of intestinal bacterial microbiota linked to IBD have been reported. The decrease in biodiversity and depletion of the phyla *Bacteroidetes* and *Firmicutes* can be observed in feces/mucosa-associated microbiota among IBD patients^[2,55,56]. The bacterial communities in the intestine are significantly different between UC and CD patients and healthy individuals^[57,58]. Furthermore, at the genus level, many potentially protective bacteria and normal anaerobic bacteria such as *Bacteroides* sp., *Eubacterium*

sp. and *Lactobacillus* sp., are significantly decreased both in active UC and CD patients, and even in patients with inactive IBD^[59-68]. In addition, the abnormal metabolites of intestinal bacterial microbiota can also contribute to the pathogenesis of IBD^[69,70]. For example, butyric acid, which is the main energy source of the intestinal epithelial cells, can inhibit the signal pathway of proinflammatory cytokines. Butyrate-producing bacteria and their culture supernatants can improve the intestinal inflammation and necrosis in the animal model of colitis^[71]. In parallel, some studies have confirmed that the levels of some butyrate-producing bacteria (*e.g.*, *Clostridium* clusters IV and XIVa) and the availability of butyrate reduced significantly in UC patients^[11,72]. Moreover, the metabolic activity of intestinal microbiota in UC is disturbed, with increased levels of taurine and cadaverine^[73]. Until now, the highly reproducible profiles of intestinal microbiota established for IBD patients have been limited. Recently, one study based on a phylogenetic network analysis showed that the human intestinal mucosal bacterial community could be organized into five preserved microbial modules and two IBD-associated microbial modules displayed enhancement of the oxidative response and glycan metabolism pathways relevant to host-pathogen interactions^[25].

The fungal communities are also important components of microbiota in the human GI tract; most of which have co-evolved with the host in a symbiotic relationship^[21]. Early studies based on culture-dependent methods reported that fungi were detected in the digestive tract of 70% of healthy adults^[74], and the number of fungi in the human colon is 10²-10⁶ cfu/mL; most of which are aerobic or facultatively anaerobic. Recently, metagenomic analysis of 124 individuals reported that only 0.1% of microbial genes in feces were of eukaryotic or viral origin^[2], which was consistent with previous reports of intestinal microbiome accounting for 0.03% of the fecal microbiota^[75]. There is limited information available about the prevalence and classification of the intestinal fungal microbiota. The study of the fungal microbiota is in its infancy, and much remains to be determined^[75]. There were significant differences in fungal communities related to IBD compared to non-IBD controls. The fungal sequences could be detected in the colonic mucosa of all IBD patients, and the diversity of the intestinal microbiome increased clearly among IBD patients, but the proportion of microbiome in the whole intestinal microbiota was low^[75]. Moreover, whether the intestinal microbiome interacts with the mucosal immune system or influences intestinal disorders is unknown. Recently, a study connected intestinal fungal microbiota with the host immune system through Dectin-1 in a mice model of dextran-sulfate-sodium-induced colitis^[1], which confirmed the fungal etiology in IBD.

Overall, the diversity and abundance of intestinal bacterial microbiota are reduced in IBD, and the bacterial microbiota metabolites are also disturbed. However, a specific IBD microbiota has not yet been revealed, which might in part be because of inter-individual vari-

ability, different IBD characteristics or subtypes, and different data analysis methods. In addition, whether the microbiota pathogenesis is the initiating factor in IBD or is secondary to IBD still cannot be answered. Moreover, further studies based on fungal high-throughput DNA sequencing should be conducted on whether the change of the fungal community structure is secondary to the imbalance of the intestinal bacterial community, or independent pathogenic factors of IBD.

HOST-MICROBE IMMUNE INTERACTIONS IN IBD

The human immune system is usually tolerant of the commensal microbiota colonized in the GI tract. Abnormal activation of the host immune response against the imbalanced intestinal microbiota may be the potential pathogenesis mechanism of IBD^[76]. Additionally, an abnormal intestinal microbiota offers persistent stimulation of the immune system in individuals who are genetically susceptible to IBD, which results in dysfunction in immune tolerance and regulation. The resulting chronic intestinal inflammation in the GI tract can initiate intestinal lesions and lead to IBD-associated symptoms. Intestinal mucosal epithelial cells are continuously exposed to the intestinal microbiota, and they can recognize various cell wall components of pathogenic and commensal microbes, which are the main sources of pathogen-associated molecular patterns. The pattern recognition receptors (PRRs) on intestinal cells include Toll-like receptors (TLRs)^[77], NOD-like receptors (NLRs) and C-type lectin receptors (CLRs), which are essential for a human host to recognize endogenous/exogenous microbes, and trigger and maintain intestinal mucosal innate and acquired immunity. The immune responses mediated by PRRs on intestinal cells include microbial binding and phagocytosis; induction of antimicrobial effect or mechanisms; and the production of endogenous antimicrobial peptides, cytokines and chemokines. Moreover, the majority of IBD-related genetic susceptibility loci are associated with PRRs. For example, the polymorphisms in NOD2 have been identified to increase the risk of CD in western populations, and the polymorphisms in TLRs are associated with UC and CD. In addition, CLRs such as Dec-1 can contribute to the recognition of intestinal fungi and influence the immune function of intestinal mucosa in UC^[1].

CLINICAL USE OF PROBIOTICS IN IBD

The intestinal dysbiosis in IBD has been confirmed by molecular techniques, and there is a compelling rationale for modulating the altered intestinal microbiota among IBD patients. Animal studies have confirmed that probiotics enhance the intestinal mucosal barrier function, regulate intestinal mucosal immunity, recover intestinal microbial community structure, and improve chronic intestinal inflammation. Clinical trials in humans have in-

vestigated whether the present probiotic products could be a treatment option in IBD. Some bacterial strains of *Lactobacillus* sp.^[78,79], *Bifidobacterium* sp.^[80,81], *Escherichia* sp. (e.g., *E. coli* Nissle 1917)^[82,83], and the fungal strain *Saccharomyces boulardii* (*S. boulardii*)^[84,85], are the most common investigated probiotics in the treatment of IBD. In addition, except for the single probiotic strain, some probiotic combinations such as VSL#3, an eight probiotic consisting of four strains of *Lactobacillus*, three strains of *Bifidobacterium*, and one strain of *Streptococcus*, have shown efficacy by maintenance of remission both in adults and children with active IBD^[86-88].

According to the efficacy of probiotics in UC, patients may experience fewer relapses when probiotics of *Lactobacillus* sp. are added to their usual therapies or when they cannot tolerate standard medications^[89]. In addition, *E. coli* Nissle is an effective alternative to aminosalicylates for maintenance of UC remission^[82,83]. Administration of *S. boulardii* during maintenance treatment with mesalazine induced clinical remission in 71% of patients with active mild to moderate UC^[85]. Moreover, VSL#3 resulted in a combined induction of remission/response rate of 77% among patients with active mild to moderate UC and who did not respond to conventional therapy^[87]. Furthermore, the effects of probiotics on pouchitis are by far the most convincing data. VSL#3 is more effective than placebo for prevention and treatment of pouchitis for postoperative UC patients^[90]. Overall, a Cochrane review showed that conventional therapy combined with probiotics has few beneficial effects on the induction of remission in active mild to moderate UC, but probiotics may be useful in the maintenance of remission in non-active UC and in the prevention of postoperative recurrence; the outcomes from the present clinical trials on probiotics in UC need to be confirmed. On the other hand, current data show that *S. boulardii* has no beneficial effects on maintaining remission in CD patients^[84], but might lead to fewer relapses when combined with mesalamine^[91]. Moreover, probiotics of *Lactobacillus* sp. cannot prevent postoperative relapse of CD^[78,92]. There is insufficient evidence to draw any conclusions about the efficacy of probiotics for induction or maintenance of CD remission^[27]. Importantly, *Faecalibacterium prausnitzii* (*F. prausnitzii*) identified as a butyrate-producing species, may contribute to the gut homeostasis and play a protective role in IBD, especially in CD^[71]. The levels of *F. prausnitzii* in feces and intestinal mucosal biopsies decrease both in CD and UC^[93-96], and the lower level of *F. prausnitzii* on the ileal mucosa of CD patients is associated with recurrence. However, one study showed an increased level of *F. prausnitzii* in mucosal biopsies associated with reduced bacterial diversity in pediatric CD^[97]. Generally, *F. prausnitzii* is a potential and promising probiotic, and its protective role in IBD is worthy of investigation.

In summary, the clinical efficacy of the present probiotic products in the treatment of IBD is modest; they are currently used only as supplements in IBD treatment, and not as alternatives or substitutes for conventional

therapy. The application of probiotics should be based on the principles of evidence-based medicine, but well-designed randomized controlled trials (RCTs) are lacking. Further appropriate study designs and larger numbers of patients will be needed to determine the optimal probiotics for IBD.

INDICATIONS FOR FMT

FMT, also called stool/fecal transplantation or fecal bacteriotherapy, refers to infusion or engraftment of a homogenized fecal suspension from a healthy individual into the GI tract to cure a specific disease^[29,32,98]. Due to the elucidation of the composition and function of intestinal microbiota by the development of metagenomics studies, many researchers have begun to explore therapeutic interventions in human diseases associated with intestinal dysbiosis from the viewpoint of microecology. Although various probiotics, prebiotics and synbiotics have been administered in clinical practice, most are recommended as supplementary treatments due to poor therapeutic effects and the limited number of available strains. So far, only the preliminary application of FMT exhibits marked clinical effectiveness, especially in the treatment of recurrent CDI and IBD^[30,33,99,100]. Traditionally, CDI is mainly treated with antibiotics such as vancomycin and metronidazole. However, the therapeutic effect is poor due to the drug resistance of *C. difficile*. The recurrence rate of CDI is much higher, and can be up to 15%-26%^[101]. FMT can be considered to replace antibiotics for recurrent and refractory CDI that has relapsed more than three times^[31]. A recent RCT about FMT suggested that 81% of recurrent CDI patients achieved remission of symptoms after FMT, while only 31% of patients receiving only vancomycin treatment exhibited symptom remission^[102]. A multicenter long-term follow-up study on FMT treatment of recurrent CDI through a colonoscopy route demonstrated a 91% primary cure rate and 98% secondary cure rate^[101]. A recent systematic review showed that FMT could achieve clinical remission in 63% of IBD patients, while 76% of the patients could stop taking IBD-related drugs and their GI symptoms were reduced^[33]. Several preliminary studies using FMT for GI disorders including irritable bowel syndrome, antibiotic-associated diarrhea and chronic constipation have also met with some success. In addition, non-GI disorders such as diabetes mellitus and insulin resistance^[103], metabolic syndrome, childhood autism, chronic fatigue syndrome, multiple sclerosis, fibromyalgia, myoclonus dystonia and Parkinson's disease are reported to be improved and cured with FMT^[39,104].

FMT IN THE MANAGEMENT OF IBD

The treatment of IBD is rapidly evolving, and many conventional and novel drug treatments have proven effective, including aminosalicylates, steroids, immunosuppressive agents and biological therapies. However, some

patients become refractory to standard management, and some have significant adverse effects, with many patients requiring surgery. Despite medical treatment, a significant number of patients live with mild active symptoms and have a poor quality of life. Given the role of the intestinal microbiota in driving inflammation in IBD, treatments that manipulate the microbiota have been investigated including the use of probiotics and prebiotics, with variable evidence for their efficacy. FMT is becoming an alternative microbiota treatment for IBD with astounding efficacy.

The main case series and case reports of FMT for IBD treatment are shown in Table 2. The first case report of FMT for IBD was published in 1989, in which the author himself confirmed UC for 7 years that was refractory to sulfasalazine and steroids. Six months after transplantation of a healthy donor stool by retention enemas, he remained symptom free^[34]. Moreover, a case series of six patients with refractory UC apparently achieved complete, medication-free remission after FMT with no disease recurrence after 1-13 years follow-up^[35]. Recently, a system evaluation reported that FMT could achieve clinical remission in 63% of IBD patients, while 76% of patients could stop taking IBD-related drugs and their GI symptoms were reduced^[33]. However, a study including five patients with moderate to severe active UC showed that none of them achieved remission after FMT by week 12, and a positive clinical response was observed only in one patient^[105]. The poor response in that study may have been associated with the severity of UC itself, rather than the optimal administration of FMT. FMT may be an optimal treatment for refractory IBD with no response to current conventional therapy, such as anti-inflammatory agents, steroids, immunosuppressive and biological drugs. For refractory IBD, continuously repeated FMT is needed to cure or achieve effective remission^[38]. However, no unified standard exists in the procedures of FMT treatment in IBD. In addition, CDI is common among IBD patients with an incidence of 3.7%^[106]. Once combined with CDI, the severity of IBD can be aggravated, while the recurrence rate of CDI can be increased^[107]. There is no standard therapy for UC combined with CDI. For example, vancomycin and metronidazole would be preferred but with poor efficacy, and it remains controversial whether IBD-related therapeutics should be continuously used. FMT may be a viable therapeutic approach for IBD combined with CDI. Recently, one study evaluated the feasibility and safety of FMT in 10 children with UC. After FMT by retention enemas (freshly prepared fecal enemas) daily for 5 d, 78% and 67% of patients achieved a clinical response within 1 wk and 1 mo, respectively^[108]. Overall, studies of FMT in IBD are rare and restricted to case series or reports, so the available evidence is limited and weak. However, FMT still has the potential to be an effective and safe treatment when standard IBD management has failed. Compared with CD, the efficacy of FMT in UC is more promising, but further investigation is required^[33,39,109]. Moreover, except for refractory IBD, it is

FMT: Fecal microbiota transplantation; UC: Ulcerative colitis; CDI: *Clostridium difficile* infection; CD: Crohn' disease; NR: Not reported.

not yet clear whether FMT has any potential therapeutic value for IBD patients induced into remission *via* conventional medical therapy or those with mild IBD.

With regard to adverse events of FMT in IBD treatment, some patients may exhibit belching, abdominal distension, abdominal colic, diarrhea, constipation and other short-term symptoms. Fever and a temporary increase of C-reactive protein can develop transiently after FMT^[105]. However, most of these discomforts and symptoms disappear within 2 d after transplantation^[37]. Furthermore, other rare complications such as GI bleeding and peritonitis are mainly related to the endoscopic procedures in the process of FMT. Few serious adverse events occur during treatment of IBD by FMT, but it is noteworthy that IBD-related symptoms can be aggravated by FMT in

some cases with moderate to severe UC^[105]. Furthermore, one case report showed that FMT caused UC-related intestinal inflammation in one elderly male patient with CDI, who had been in long-term remission of UC for > 20 years without any UC-related treatment^[110]. Moreover, the long-term follow-up data of FMT such as infection, intestinal inflammation and tumors are still lacking, and need to be further investigated. Nevertheless, there are many impediments limiting the therapeutic potential of FMT in IBD^[111], such as rare FMT trials in IBD, ethical and social issues, poor screening of donors, no standard administration of FMT, no standardized preoperative preparation and pretreatment, no standardized preparation of fecal samples, and a lack of FMT-related basic investigations. All the above-mentioned limitations will

BARRIERS AND FUTURE DIRECTIONS OF FMT CLINICAL PRACTICE IN IBD

Screening and selecting criteria for donors

Microbiota donation has a higher requirement for the screening of donors in the management of patients undergoing FMT, compared with blood donation. The donor must provide informed consent and detailed medical certificates including medical history, relevant examinations, stool and serological testing. Currently, the donor's inclusion and exclusion criteria are mainly from the self-determined standards of different studies and are more consistent overall, and are listed in Table 3. The feces and serological screening for common and known microbial pathogens are shown in Table 4. The donors are mainly selected from individuals who are closely related to the recipient including intimate partners, family members, and friends, whose microecological environment may be similar to that of the recipient; therefore, a more positive outcome to FMT may be produced, at least theoretically. Most opinions are that the stools from relatives or friends of the recipients show better efficacy compared with those from unrelated donors, and the difference in sex between donor and recipient had little impact on disease remission, but this conclusion is still lacking evidence^[99]. Unrelated healthy individuals are also potential donors.

Donor feces can be frozen and thawed without loss of effectiveness, enabling FMT-related microbiota banking^[112]. In addition, the human intestinal microbiota can be divided into three types: *Bacteroides*, *Prevotella* and *Ruminococcus* by the high-throughput sequencing methods^[24]. This means that matching enterotype between donor and recipient based on metagenomic analysis may improve the therapeutic efficacy of FMT. At present, FMT from a healthy donor is mainly used to perform allogeneic FMT. The fecal samples are mainly obtained from a related or unrelated healthy donor, who must face the series of ethical issues in receiving another person's feces, and the effects of the donor's intestinal microbiota on the intestinal immune and pathophysiological functions are unclear without effective theoretical supports. For those patients with mild IBD, it may be good that the fecal samples can be collected and stored in the remission stage and offered to the same patients when they come into the active stage of IBD. However, whether autologous or allogeneic FMT can relieve IBD-related clinical symptoms and induce/maintain the remission of IBD effectively is worthy of further investigation.

Preoperative preparation of donor and recipient

At present, a standardized method of IBD-related preoperative preparation for FMT has not been established^[52]. The donor should be administered a gentle osmotic laxative the night before FMT, and should avoid any infections between screening and time of donation. For the FMT recipient, large-volume bowel preparation (*e.g.*, polyethylene glycol) is required regardless of the route of

FMT. In addition, GI motility inhibitors such as loperamide may be optional for the retention of transplanted microbiota, and proton pump inhibitors should be given to recipients before FMT *via* upper GI routes. Importantly, current studies claim that IBD patients who intend to receive FMT need to receive antibiotic pretreatment^[35,105], although it still needs to be verified whether antibiotic pretreatment is necessary. In animal models, antibiotic pretreatment before FMT can cause serious damage to the intestinal microbiota structure and may affect the intestinal colonization of the donor's microbiota^[113].

Preparation of fecal samples

Generally, the preparation of fecal samples for IBD treatment can refer to the FMT guidelines for treating CDI^[32]. FMT practitioners face many challenges in implementing protocols for donor fecal preparation in a clinic setting. Donor fecal samples should be kept in an airtight container and chilled. The samples should be delivered to the institution preferably within 6 h of passage to undergo dilution with proper diluents such as normal saline, homogenization with a blender to achieve a liquid slurry, and filtration to remove particulate matter^[39]. Several issues should be noted during the fecal preparation. Initially, the majority of studies utilized fresh fecal material, which means that the fecal collection, preparation and transplantation should be performed on the day of planned FMT^[102]. However, fresh fecal material for FMT is not always practical due to issues including delay caused by screening tests, sanitation and aesthetics. Several studies have confirmed that frozen donor fecal material has equal efficacy in the treatment of recurrent CDI compared with fresh fecal material^[112]. The frozen material preparation should be processed within 2 h of collection; the specific steps of which are in accord with those of fresh fecal material; the finished fecal suspensions should be stored at -80 °C after adding sterile glycerol. On the day of FMT, the frozen material is thawed and diluted with sterile normal saline^[112]. Importantly, the frozen preparation is beneficial to establish the FMT-related gut microbiota banks.

In addition, the ideal volume of fecal material for instillation has not been standardized. A systematic review showed that > 500 mL of fecal suspensions allowed 97% of patients with recurrent CDI to achieve remission, while only 80% of patients obtained remission with 200 mL of fecal suspensions^[99]. However, it is difficult to standardize the procedure due to the different diluted concentrations of fecal material. Use of < 50 g fecal material may increase the relapse rate of CDI by four times compared with > 50 g fecal material^[99]. Overall, practitioners who regularly perform FMT favor 50-60 g of 250-300 mL diluent, respectively^[104]. Larger volumes (*e.g.*, 250-500 mL) should be used for delivery from the lower GI tract (*e.g.*, *via* colonoscopy or enema), and smaller volumes (*e.g.*, 25-50 mL) should be used for delivery from the upper GI tract (*e.g.*, *via* a nasoenteric or nasogastric tube). FMT practitioners prefer normal saline, sterile water or 4% milk

to dilute the stool sample at present, but which is the optimal diluent still needs to be investigated^[99].

Route of FMT administration

FMT is mainly performed *via* the lower GI route, including colonoscopy and retention enema, and/or *via* the upper GI route such as nasoenteric tube, nasogastric tube and gastroduodenoscopy. To date, approximately 75% of cases with recurrent CDI worldwide are administered with FMT *via* the lower GI tract and 25% *via* the upper GI route^[104]. FMT *via* the lower GI tract may be more effective than *via* the upper GI tract, although this has yet to be validated^[99,100]. Until 1989, retention enema was the most common technique for FMT; however, various alternative methods including nasoenteric tube, gastroscopy and colonoscopy have been used subsequently. A recent long-term follow-up study that involved 77 patients with recurrent CDI showed that colonoscopic FMT was well received by participants and was highly successful, with an overall primary cure rate of 91% and a secondary cure rate of 98%^[101]. Moreover, a systematic review showed that colonoscopic FMT had a higher cure rate (91%) for recurrent CDI, compared with the other upper GI routes^[99]. Colonoscopic FMT has even been proposed as first-line therapy for the treatment of CDI^[114]. For example, the fecal suspensions are sprayed through the biopsy channel of colonoscopy from the terminal ileum, while the colonoscopy is slowly removed until approximately 500 mL of fecal suspensions thoroughly perfuse the colon. Patients should avoid defecation within 1 h after FMT. In patients with severe colitis and significant colonic distention, colonoscopy may be technically challenging and potentially dangerous. Until now, few studies have directly compared routes of FMT administration.

A recent RCT demonstrated that 81% of patients had resolution of recurrent CDI after the first FMT by duodenal infusion^[102]; the remarkable cure rate by the nasoenteric tube matched that of colonoscopic FMT. FMT through the upper digestive tract is easy to perform and has a low risk, but it remains unclear whether donor fecal material can be distributed throughout the full colon and increase the risk of small intestinal bacterial overgrowth. According to the optimal FMT route for IBD, a study that involved IBD cases worldwide showed that up to 80% of IBD patients were administered FMT by colonoscopy and/or retention enema^[33]. Overall, there are many unanswered questions regarding the best route of administering FMT; the standardized and optimal route for FMT is determined by the needs and status of the patients, and the intestinal microbiota characteristics^[103].

Potential therapeutic mechanisms of FMT

Theoretically, the fecal suspension from a healthy donor can reconstruct the damaged intestinal microbiota, restore the intestinal colonization resistance and defend against colonization and infection with *C. difficile* and other pathogenic microorganisms. Thus, the imbalanced structure and function of the intestinal flora is restored

to improve the relevant clinical symptoms. However, the beneficial changes in the intestinal flora generated by FMT and its potential mechanisms are still not clear. Recently, high-throughput sequencing and bioinformatics techniques have been widely applied to describe the intestinal microbial community structure and functions. So far, only a few studies have been conducted that aim to analyze the restoring mechanisms of FMT on the recipient's damaged intestinal microbiota. Several studies based on the bacterial 16S rDNA-based sequencing analysis in recurrent CDI patients found that the diversity and richness of fecal microbiota was clearly reduced^[115-117]. The significant changes in *Clostridiales* and *Lactobacillales* from the phylum *Firmicutes*, and *Enterobacteriales* from the phylum *Proteobacteria* could be observed between recurrent CDI and post-FMT patients and healthy donors^[116]. The fecal microbiota of recurrent CDI patients becomes more similar to that of healthy donors after FMT, which means that FMT has a permanent action in improving the damaged intestinal microbiota and the clinical symptoms of the recipient^[116,117]. Moreover, the reconstructive efficacy of FMT can be maintained for a long time and last for 24 wk^[118]. Recently, one study based on the 16S rDNA pyrosequencing showed that abundant donor-related bacterial microbiota could be established in UC recipients, but the efficiency and stability of donor microbiota colonization varied greatly^[105]. Several anti-inflammatory and/or short-chain-fatty-acid-producing species such as *F. prausnitzii*, *Roseburia faecis* and *Bacteroides ovatus* were only able to colonize successfully in one UC patient with a positive clinical response after FMT for up to 12 wk^[105]. Overall, the influence of FMT on the structure/stability of the intestinal microbiota in IBD patients remains unclear. More longitudinal human and animal studies are needed to verify the permanent reshaping mechanism of FMT. At present, metagenomic analysis combined with germ-free animals, human flora-associated animals, and the chemostat gut models *in vitro* can be used to investigate the mechanism of FMT-related restoring of intestinal microbiota.

An investigational new drug application for FMT

Recently, the US Food and Drug Administration (FDA) has tightened the regulations of FMT, because the complex nature of the fecal microbiota products present specific scientific and regulatory challenges. FDA has announced that fecal microbiota collected from healthy individuals is a biologic product, meaning physicians must submit an investigational new drug (IND) application. However, published data have confirmed the astounding efficacy of FMT, which may be the best therapeutic modality for the treatment of recurrent CDI.

Physicians and scientists are concerned that it is no easy task to file the IND application for FMT practitioners, which could make FMT unavailable and suggest an alternative regulatory approach to ensure the widespread availability of FMT for those patients with recurrent CDI. FDA has acknowledged these concerns and has

published the alternative enforcement discretion regarding the IND requirements for the use of FMT to treat CDI not responding to standard therapies. FDA intends to exercise this discretion provided that the FMT practitioners obtain adequate informed consent for the use of FMT products, stating that FMT products to treat CDI are investigational drugs, and explaining any potential risks for FMT treatment. Unfortunately, the use and study of FMT for diseases or conditions other than CDI is not included in this enforcement discretion policy. Therefore, physicians wishing to ensure access to FMT for IBD or other conditions need to file an IND application. Recently, several articles provided step-by-step guidance to physicians on how to navigate the regulatory requirements of FDA and prepare the IND application for FMT^[40,119]. The use of an IND will also allow collection of more data on the efficacy and safety of FMT and likely further support its use. Except for the application of IND, the clinical application of FMT in IBD still faces many issues. Once these issues are addressed, standardized clinical trials can move forward with the hope of not only increasing access to FMT but also developing a well-tolerated and reliable drug that decreases any potential long-term consequences from FMT.

Patients' attitudes toward FMT

Patients are a powerful evolutionary force, whose perceptions and attitudes are important for the clinical application of FMT. A survey showed that up to 95% of adult UC patients and parents of children with UC would consider FMT and are eager for it to become available^[120,121]. Moreover, a long-term follow-up study among patients who had FMT for recurrent CDI showed that 97% of patients were willing to receive another FMT once CDI occurred in the future, and 53% of patients claimed to choose FMT as the first treatment option for substitution of antibiotics^[101]. Another survey reported that when aware of the fecal nature of FMT, 81% of patients still consider it as an alternative treatment for recurrent CDI, especially when recommended by physicians^[122]. Patients recognize the inherently unappealing nature of FMT, but they are nonetheless open to considering it as an alternative treatment for recurrent CDI. Overall, the strong willingness of patients has important implications for the clinical application of FMT and the other microbiota-based treatments in the future.

Synthetic microbiota transplantation

Emerging data showed that two recurrent CDI patients were cured by synthetic microbiota transplantation (SMT) instead of FMT; the synthetic stool was composed of 33 bacterial strains isolated from the feces of an unrelated donor, grown in culture and subsequently administered as a suspension in sterile normal saline^[123]. SMT composed of large numbers of well-defined bacterial strains derived from stools, combined with FMT, can be defined as microbial ecosystem therapeutics^[124]. Recently, the concept of "Robogut" has been proposed^[28], which is actually

a type of chemostat. The chemostat *in vitro* mimics the human gut, even the whole GI tract, and is mainly composed of complex media, a pH and temperature monitor, anaerobic gas, and a stirrer^[28].

For several decades, microbial ecologists have been trying to develop a chemostat resembling the human gut, in which a probiotic gut microenvironment consisting of beneficial anaerobic microbial species by the continuous culture can be manufactured^[125]. SMT based on the chemostat resembling the human gut can be viewed as the next logical step in the development of microbiota therapeutics. For example, if the beneficial bacterial species could be cultured artificially and combined into flora with optimal proportion and magnitude to achieve standardized SMT, the safety and controllability of bacterial origin can be ensured, thus enabling effective quality control and reducing the process of screening donor. Moreover, the synthetic bacteria can be made of freeze-dried powder or capsules in the future to restore the disturbed intestinal microbiota, thereby curing those conditions associated with gut dysbiosis.

CONCLUSION

Evidence from animal and human studies strongly supports the role of intestinal microbiota in the etiology of IBD. The single microbial pathogen in IBD is still undefined, which may not contribute to the onset of IBD. However, many studies based on culture-independent techniques have confirmed aberrant intestinal microbiota and its metabolites in patients with IBD, although whether the intestinal microbiota is the initiating factor in IBD or is secondary to IBD is still not resolved. The present single or combined probiotic products have modest efficacy in IBD treatment; most of which are supplementary therapeutics. FMT is the most radical way to restore the disturbed homeostasis of intestinal microbiota in IBD, but there has been no consensus regarding the selection and screening of donors, the optimal volume and route of administration, pretreatment and preparation before transplantation, efficacy durability and long-term safety profiles. In addition, studies on the mechanisms of FMT for the recovery of intestinal microbial homeostasis and host immunity are still lacking, thus not providing adequate theoretical support for clinical application of FMT.

Currently, FMT application is mainly driven by its remarkable efficacy and the strong demand of clinicians and patients, while institutions have not paid much attention to FMT, especially in technological innovation for the preparation of fecal microbiota products. Moreover, many case series have shown the clinical efficacy of FMT in the management of refractory IBD; several controlled clinical trials have been registered (www.clinicaltrials.gov) and are underway to evaluate the efficacy of FMT in IBD. The hypothesis that whether autologous or allogeneic FMT can induce and maintain persistent remission of mild IBD needs to be confirmed by animal models and pilot clinical trials. At present, data related to the use

and study of FMT to treat IBD other than CDI are still limited. Compared with FMT in CDI treatment, FMT in the management of IBD has to face more rigorous IND application. In addition, SMT as a promising microbiota therapeutic option should also be evaluated rigorously by germ-free and human flora-associated animal models, and the chemostat gut model *in vitro* may also be an excellent technique for the evaluation and production of SMT. Microbiota pathogenesis and therapeutics in IBD is a promising field, and identification and resolution of key issues are imperative to move this field forward.

Abstract

Many studies have demonstrated the linkage between the *IBD3* region (6p21.1-23), an area which encompasses the famous human leukocyte antigen (HLA) complex, and Crohn's disease (CD) or ulcerative colitis (UC). *IBD3* is the only region that meets genome-wide significance, and provides stronger evidence of the linkage than 16p13.1-16q12.2 (*IBD1*), the locus that contains the susceptibility gene *CARD15*. However, despite these findings, *IBD3* susceptibility genes remain elusive and unclear due to the strong linkage disequilibrium, extensive polymorphism, and high gene density that characterize this area and also due to varying allele frequencies in populations around the world. This area presents an extremely high abundance of genes, including the classical

and non-classical major histocompatibility complex (*MHC*) class I and II genes, and other genes, namely *MHC* class III genes tumor necrosis factor (*TNF*)- α and - β , and *Hsp*, whose proteins play key functions in immunological processes. To date, it is not clear which genes within the *MHC* family contribute to the *IBD* pathogenesis, although certain *HLA* alleles have been associated with *IBD*. Recent insights into the biological function of other genes encoded within the *IBD3* region, such as the *MHC* class I chain-related (*MIC*) genes, have led investigators to a more comprehensive exploration of this region. *MHC* class I chain-related molecule A (*MICA*) is highly polymorphic and interacts with *NKG2D*, its receptor on the surface of NK, $T\gamma\delta$ and $T CD8^+$ cells. Increased expression of *MICA* in intestinal epithelial cells and increased expression of *NKG2D* in $CD4^+$ T cells (lamina propria) in patients with *CD* have also been reported. *MICA* alleles have also been associated with *IBD*, and a variation at amino acid position 129 of the $\alpha 2$ -heavy chain domain seems to categorize *MICA* alleles into strong and weak binders of *NKG2D* receptor, thereby influencing the effector cells' function. In this regard, a relevant role of *MICA*-129-Val/Met single nucleotide polymorphism has recently been implicated in the pathogenesis of *IBD*. *TNF*- α and - β also play an important role in inflammatory response. In fact, *IBD* is commonly treated with *TNF*- α inhibitors. Additionally, polymorphisms of *TNF*- α gene are known to affect the gene expression level and particular *TNF*- α genotypes may influence the response of *IBD* patients treated with *TNF*- α inhibitors.

Key words: *IBD3*; Tumor necrosis factor; *MICA*; *HLA*; Inflammatory bowel disease

Core tip: This review gathers information about the importance of *IBD3* genomic region in susceptibility to inflammatory bowel disease (*IBD*). The new and old immunogenetic biomarkers of the *IBD3* region (human leukocyte antigen, *MHC* class I chain-related molecule A,

MHC class I chain-related molecule B, and tumor necrosis factor- α and - β) and their role on IBD susceptibility are discussed in the light of recent publications. *IBD3* gene polymorphisms and their clinical relevance for the treatment of the IBD patients are also discussed. Insights into the natural history of these complex diseases may allow in the future appropriate patient selection for early aggressive therapy aimed at modifying the course of the disease.

INTRODUCTION

Inflammatory bowel diseases (IBD) are an idiopathic disease that seems to involve an immune reaction of the body to its own intestinal tract. The two major types of IBD are ulcerative colitis (UC) and Crohn's disease (CD). Although both UC and CD present different pathologic findings, a significant percentage of patients are classified as indeterminate IBD. Twin studies and segregation analysis strongly support IBD, especially CD, as complex genetic traits^[1], whose etiology also involves immunological and environmental factors. These pathologies are polygenic-related diseases that share some susceptibility loci, but differ at others. A number of studies have been performed to identify IBD susceptibility chromosomal regions, and in some of them causative genes have been found^[2-5]. However, although these studies have indicated multiple regions of interest, the replication of these results has been rather limited. IBD susceptibility genes have classically been identified with different and consecutive names, depending on the chromosomes involved [*e.g.*, 5q31 (*IBD2*), 6p21 (*IBD3*) and 19p (*IBD4*)], while several loci of interest (*e.g.*, at 3p, 3q, 14q and others) require further follow-up.

From a functional point of view, active IBD is immunologically defined as an infiltration of the lamina propria by innate immune cells (neutrophils, macrophages, dendritic and NK cells) and adaptive immune cells (B and T cells). Increased numbers and activation of these cells in the intestinal mucosa enhance local levels of tumor necrosis factor (TNF), located in the *IBD3* region, and other pro-inflammatory interleukins^[3,6]. Cytokines are also essential mediators of the interaction between activated immune cells and non-immune cells, including epithelial and mesenchymal cells. Moreover, germ-line variation in *IL23R*, *IL12B*, *JAK2* and *STAT3* has recently been associated with IBD susceptibility, consistent with the newly described role for IL-23 signaling and Th17 cells in inflammatory disease pathogenesis. Additionally, several

genes involved in different aspects of bacterial handling, such as *NOD2* (from now on called CARD15) on human chromosome 16 (*IBD1*) and the autophagy genes *ATG16L1* and *IRGM*, are defective only in CD. *IL10* and *ECM1* are associated with UC, and an inherited variation at the human leukocyte antigen (HLA) region (*IBD3*) is related to an inflammatory colonic phenotype^[7-16]. In fact, other non-classical *HLA* genes, such as HLA-G and MIC (major histocompatibility complex (MHC) class I related chain), are also implicated in IBD pathology^[4,17,18].

In the last years, the application of genome-wide association studies (GWAS) has been successful in defining the genetic architecture of CD and UC and in delivering genuinely novel and important insights into disease pathogenesis. The recent "ImmunoChip" study^[19], carried out by the International IBD Genetics Consortium, has led to the validation of 163 genetic loci containing susceptibility genes for IBD^[5,20,21], including 71 newly established, a number that is expected to double in the next years. In the "ImmunoChip" study, the maximal genetic association for UC at single nucleotide polymorphism (SNP) rs6927022 mapped adjacent to HLA-DQA1 class II gene (between DQB1 and DRB1). However, there was no evidence of this SNP conferring the risk of developing CD. CD maximal association mapped to HLA class I region and showed no association with UC. These results showed that the HLA region, central to autoimmunity, is especially important and broad-based (influencing a large segment of the at-risk population) to UC. On the other hand, the HLA association with CD seems to be less important and distally located, at least in Caucasians.

Finally, although important obstacles need to be overcome, the successes of the last years suggest that a detailed description of the genetic basis of IBD is a realistic goal. This has unearthed a plethora of attractive targets for the development of future therapeutics. Insights into the natural history of these complex diseases may allow in the future appropriate patient selection for early aggressive therapy aimed at modifying the course of the disease.

In this review, we will analyze the new and old immunogenetic biomarkers of the *IBD3* region and their role on IBD susceptibility, in the light of recent publications. In this context, HLA, MICA, MICB, and TNF- α and - β are the most important genes involved.

HLA SYSTEM AND IBD

Since the first report of an HLA association with IBD in 1972, more than 150 studies investigating the role of *HLA* genes in determining susceptibility and phenotype of IBD have been published^[22]. The HLA complex encodes more than 225 genes, and GWAS have shown consistent evidence of its linkage to *IBD3* (6p21.1-23)^[23-25]. This has been demonstrated in several independent studies of both CD and UC^[26-28]. The structure of this region is shown in Figure 1. The importance of this area was further highlighted by a meta-analysis of ten published genome-wide scans^[3]. *IBD3* was the only locus that met

study showed that *DRB1*15* allele was also increased in patients with extra intestinal manifestations. In CD, female patients showed an increased frequency of the *DRB1*13*, **15*, and *DQB1*06* alleles and *DRB1*13-DQB1*06* haplotype, whereas male patients showed a significant increase of the *DRB1*07*, *DQB1*02* alleles, and *DRB1*07-DQB1*02* haplotype. These recent results suggest a significant association of the homozygous HLA-*DRB1*07* genotype with UC and CD and of several HLA-*DR/DQ* alleles and haplotypes with the clinical phenotypes of these diseases. At the same time, it had also been reported that IBD patients had lower odds of DQ2/8 positivity compared with healthy controls in an Italian population^[41]. Similarly, a pathogenetic link of HLA-B27 between CD and primary sclerosing cholangitis in South Africans has been reported^[42].

HLA-C gene has also been reported to associate with IBD in a study that suggests that HLA-*C*07* and *-C*12* alleles may be strongly associated with the susceptibility to UC and CD, respectively^[43]. Interestingly, GWAS of Japanese population^[44] showed that although HLA-*C*12:02-B*52:01-DRB1*15:02* haplotype increases susceptibility to UC when compared with the frequency of healthy controls, this haplotype reduces the risk of non-colonic CD, whereas it has no effect on colonic CD.

HLA-G is another gene associated with IBD (Figure 1). HLA-G is a non-classical MHC class Ib molecule, predominantly expressed in cytotrophoblasts and, under pathological conditions, in chronically inflamed tissue.

An interesting study investigating a 14-bp deletion polymorphism (Del+/Del-) (rs16375) within exon 8 of the HLA-G gene revealed significant differences between UC and CD^[18]. Heterozygous genotype and the homozygous Del- phenotype were significantly increased, whereas the homozygous Del+ phenotype was significantly decreased when UC was compared with CD. The fact that the deletion in exon 8 of the *HLA-G* gene seems to influence its transcription activity suggests that the HLA-G gene might play a role in the pathogenesis of IBD.

Other polymorphisms in this region have also been associated with IBD. In this regard, significant association with the rs2395185 variant of the *HLA* gene and steroid-response, and positive family history in UC patients has recently been reported^[45]. For the HLA-rs2395185 SNP this association persisted both in the adult- and in the pediatric-onset subset of patients with a positive family history.

The unclear role of different HLA molecules in IBDs might be explained by either different affinity to the same peptide or by the HLA molecules binding with different strength to different molecules. In this respect, the IBDs might be explained by molecular mimicry hypothesis^[1,15]. Cross-reactivity of peptides derived from bacterial luminal flora (similar in their structure to HLA antigens) with host “self” antigens present in the gut may lead to the generation of auto-reactive T lymphocytes that either stimulate or inhibit the immune system.

Recent insights into the biological function of other genes encoded within the *IBD3* region have also led investigators to a more comprehensive exploration of this region. An example of this is the analysis of MIC genes presented in the next section.

MIC GENES AND IBD

Polymorphism of MIC Molecules

On the 2 Mb class I segment in the short arm of human chromosome 6, multiple MHC class I chain-related (MIC) loci have been identified^[46,47]. The genes at these loci represent a second lineage of mammalian MHC class I genes. The MIC genes include seven members (MICA to MICG), five of which are pseudogenes and gene fragments, and two, namely MICA and MICB, are functional genes closely related to each other (Figure 1).

They code for stress-induced cell surface molecules, which do not associate with $\beta 2$ -microglobulin and do not appear to present peptides^[48], since the putative peptide-binding groove is too narrow to accommodate a ligand. This suggests that MICA/MICB are not antigen-presenting molecules^[49]. MICA gene has an overall homology of 83% with MICB gene, but their homology with the classical MHC class I genes is quite low, ranging from 15% to 35%^[50].

MICA/MICB polymorphic residues are positioned on the outer edge of an antigen-binding cleft, apparently bordering an invariant ligand-binding site, unlike MHC class I molecules^[51,52]. The functional significance of these polymorphisms is unknown, although certain changes in the amino acid sequence of the protein influence the abnormal expression^[4,53,54] or the affinity in the interaction with NKG2D/DAP10, its ligand on the surface of NK, T $\gamma\delta$ and T CD8+ lymphocytes. MIC triggers the cytotoxicity mediated by these NKG2D-bearing cells (Figure 2). It has been demonstrated that the allelic diversity at the MICA locus affects ligand binding between MICA and NKG2D, potentially affecting NK-cell activation and the modulation of T-cell responses^[4,46,55]. Therefore, the presence of methionine or valine at codon 129 of $\alpha 2$ domain could confer strong and weak affinity, respectively. Alleles at the MICA locus can be defined as strong or weak binders depending on their capacity to bind NKG2D. The strong NKG2D binding alleles share methionine at position 129, whereas weak binding alleles have valine at this position. In this respect, high-affinity alleles include *MICA*001*, **002*, **007* and **017*, while low-affinity alleles include *MICA*004*, **006*, **008*, **009* and **010*^[51]. Although the significance of high/low affinity for NKG2D in terms of immune activation is unclear, knowledge of specific haplotypes may provide valuable information with regard to modern population's ancestry, admixture and the selective pressures maintaining such as linkage.

The crystal structure of the MICA-NKG2D complex has also revealed that NKG2D binds as a homodimer to one molecule of MICA^[4,55]. One of the NKG2D

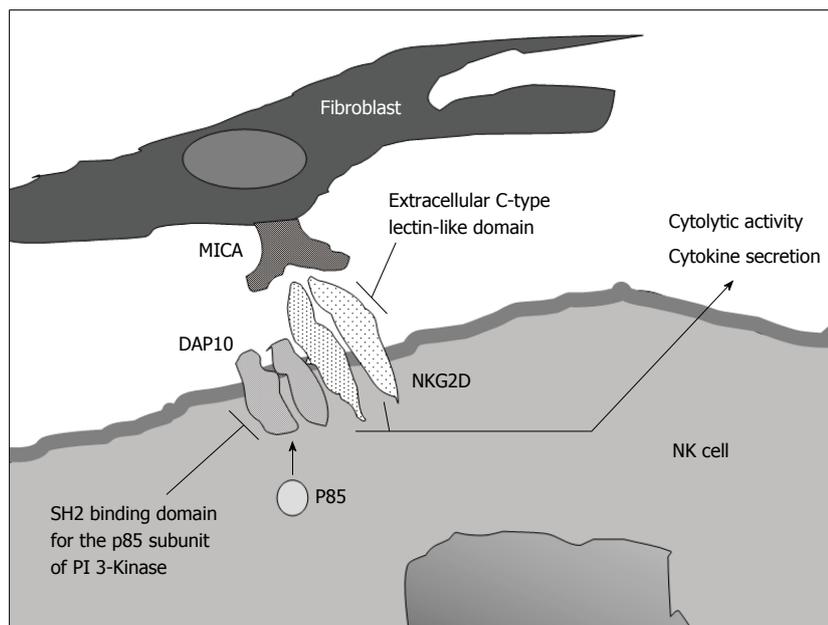

Figure 2 NKG2D signalling requires association with the DAP10 adapter protein. Engagement of NKG2D on NK cells [e.g., via binding of the ligand MHC class I chain-related molecule A (MICA)] can trigger cytotoxic activity. It can also elicit cytokine production (e.g., MIP-1 β , TNF- α and IFN- γ)^[7].

molecules binds mostly to the $\alpha 1$ domain of MICA, while the other NKG2D molecule binds mostly to the $\alpha 2$ domain. The NKG2D homodimer overlays MICA diagonally, and $\alpha\beta$ TCR overlays MHC class I molecules in a similar way. The hypothetical binding pockets of MICA remain free of any ligand confirming that MICA is not an antigen-presenting molecule. The half-life for the MICA-NKG2D complex indicates that it is more stable than the complexes formed by TCR and MHC class I molecules^[50].

Furthermore, some authors have also suggested that MICA should be considered a cell homeostasis sensor rather than a cell stress sensor whose up-regulated expression is induced not only by cell distress but also by strong proliferation and pro-inflammatory stimuli that disrupt the cellular homeostasis and elicits a cytotoxicity that eliminates altered cells, thus contributing to the restoration of the normal homeostasis^[56].

MICA has also been shown to play a role in very different aspects of the immune response, such as solid transplant rejection, immune response against viruses and intracellular bacteria, inflammation, homeostasis of epithelia, mother-fetus tolerance and immune response against tumors^[55-59].

MICA/MICB Molecules in Intestinal Pathology

Different studies have demonstrated that MIC genes are implicated in intestinal homeostasis. In fact, MICA is a stress-inducible cell surface antigen that is recognized by intestinal epithelial V $\delta 1$ $\gamma\delta$ T cells, NK cells and CD8⁺ T cells with their NKG2D receptor participating in the immunological reaction in intestinal mucosa. With regard to intestinal pathology, patients suffering active celiac disease with villous atrophy showed a strong MICA expression on the cells of crypts^[60]. MICA is also expressed in villous epithelial cells of the gut in normal or disease-free individuals, but its localization is mostly intracellular.

IL-15, which is over-expressed in the intestine of patients with celiac disease, appears to be involved in this up-regulation of MICA expression and contributes to the cytotoxicity of NKG2D+ intraepithelial lymphocytes (IELs)^[61-63]. These cells lyse target epithelial cell lines in a NKG2D-dependent way, developing villous atrophy.

On the other hand, MICA-A5.1 polymorphism has been associated with the risk of atypical celiac disease, while a double dose of MICA 5.1 allele could predispose to celiac disease with gastrointestinal symptoms^[64,65]. Another study has shown that MICB gene is also associated with celiac disease and that both MICB*008 and MICB*002 alleles are part of the celiac disease susceptibility extended haplotypes B8/DR3/DQ2, B18/DR3/DQ2, and DR4/DQ8^[66].

With respect to IBD pathology, increased expression of MICA in intestinal epithelial cells and increased expression of NKG2D in CD4+ T cells (lamina propria) in patients with CD have been reported^[67].

Lü *et al.*^[68] investigated the association of the microsatellite polymorphisms in the intron 1 of MICB and the MICA-MICB haplotype with the susceptibility to UC in the Chinese population. All the subjects were of Chinese Han ethnicity. The frequency of MICB-CA18 was significantly higher in UC patients compared with healthy controls and was increased in the female patients compared with the female healthy controls. Thus, MICB-CA18 seems to be positively associated with UC in the Chinese population.

The same group generated MICA*A5.1-expressing Raji cells by gene transfection in a later study^[69] which also showed that the frequency of MICA*A5.1 was significantly higher in UC patients compared with the healthy controls and that the frequency of a MICA*A5.1/A5.1 homozygous genotype was increased in UC patients. Raji cells with MICA*A5.1 expression produced indeed more soluble MICA than Raji cells with full-length

MICA expression in culture supernatant. Raji cells with MICA**A5.1* expression were more resistant to killing by NK cells than Raji cells with full-length MICA expression. Thus, the MICA**A5.1* allele and MICA**A5.1/A5.1* genotype seem to be significantly associated with Chinese UC patients in central China. The authors suggested that MICA**A5.1* may play a role in the development of UC by producing more soluble MICA and resistance to NK cells. The association of MICB exon 2-4 polymorphisms and sMICA expression with the susceptibility to UC in central China was also investigated by the group^[70]. Their results showed that allele frequency of MICB0106 was significantly higher in UC patients than in healthy controls, especially in patients with extensive colitis, moderate and severe disease, extraintestinal manifestations, male patients, and patients over the age of 40 years. The sMICA level was also significantly higher in UC than in healthy controls but not associated with the MICB0106 genotypes. In 2011, they obtained intestinal mucosal biopsies from patients with UC^[71] and observed that the relative amount of MICA mRNA in the colonic mucosa of UC patients was significantly higher compared with controls, as were the MICB and NKG2D mRNA expressions. Confocal microscopy resonance scanning also showed that MICA was localized predominantly on the basolateral membranes of the epithelium. Further flow cytometry confirmed that the percentage of IFN- γ producer NK cells that expressed NKG2D in peripheral blood lymphocytes was higher in UC patients than in the healthy controls. Thus, MICA, MICB and NKG2D were up-regulated in the colonic mucosa of UC and were associated with activating NK cells with enhanced NKG2D and IFN- γ production.

On the other hand, our group found no statistical differences in the distribution of MICA alleles between the IBD, CD and UC patients in the Spanish population, in a recent study^[4]. Our data corroborated the first reported studies showing no association of CD pathology and MICA allele polymorphism and contradict other studies showing that UC is mostly associated with MICA**007*, and Type 2 IBD peripheral arthropathy with MICA**008*^[17,67,72].

The association between the polymorphism of the transmembrane region of MICA and the genetic susceptibility in Tunisian patients with IBD has been recently studied^[73]. No MICA alleles were significantly increased in IBD compared with controls. The MICA-A5.1 allele was significantly decreased in CD patients. In UC, MICA-A6 was associated with the presence of extraintestinal manifestations, whereas MICA-A5 was associated with late age of onset. In CD, MICA-A6 was significantly increased in active disease patients when compared with moderately active or inactive disease. In conclusion, MICA seems to play a disease-modifying role, rather than being an important gene in the susceptibility to IBD in the South Tunisian population.

Finally, a recent meta-analysis shows that MICA alleles are associated with ulcerative colitis in Asians^[74].

On the other hand, a variation at amino acid position 129 of the α 2-heavy chain domain (MICA-129 Val and Met) seems to categorize MICA alleles into strong and weak binders of the NKG2D receptor and thereby to influence effector cells' function^[4,53]. Evidence supporting this hypothesis was provided by Zhao *et al.*^[54]. The authors showed that the frequency of MICA-129 Val/Val genotype, as well as serum sMICA levels were significantly higher in UC patients than in the controls. Moreover, higher levels of sMICA were associated with severe colitis in the patients.

On the contrary, we have recently found a higher frequency of MICA-129 Met/Met and a lower frequency of MICA-129 Val/Met genotypes in IBD patients (mainly in UC) compared with control subjects^[4,75]. All these preliminary data suggest a relevant role of MICA-129-Val/Met SNP (weak/strong binders of NKG2D receptor) in the pathogenesis of IBD^[55]. However, MICA may be in linkage disequilibrium with another gene or genes that are in fact responsible for the protection against IBD, in which case it would involve a secondary disease association. In any case, these facts need to be confirmed by further studies. In conclusion, a relevant role of MICA-129-Val/Met SNP (weak/strong binders of NKG2D receptor) in the pathogenesis of IBD may imply an association with the protection against the disease, although whether it confers primary or secondary protection remains to be determined.

TNF- α AND TNF- β

TNF- α and - β are key cytokines known to play a role in inflammatory responses, and the loci for these genes are found in the *IBD3* region on chromosome 6p21, which is known to be associated with an increased risk for IBD.

TNF- α /TNF receptor interactions do not only play a pivotal role in the pathogenesis of the inflammatory response, but also cause apoptosis, cell proliferation, and differentiation^[76]. Alterations in the regulation of TNF- α , especially TNF- α over-production, have been implicated in a variety of symptoms associated with autoimmune disorders, including IBD, and especially CD^[77]. Inflammation, anorexia, and weight loss are also all associated with increased levels of circulating TNF- α that are seen in CD^[15].

In fact, three anti-TNF agents, namely infliximab (IFX), adalimumab and certolizumab pegol have been approved by the US Food and Drug Administration for the treatment of luminal CD^[6]. IFX has also been approved for fistulising CD and UC. The advent of these anti-TNF- α agents has also changed the way of treating IBD refractory to standard medications^[76,78]. Clinical trials showed that IFX response varies among patients. It would be beneficial if the efficacy could be predicted by genetic factors since these treatments are very expensive. In this sense, a recent report shows a relationship between the TNF receptor polymorphism and the IFX response in Japanese patients^[78].

Several SNPs in the TNF- α promoter region are known to affect its gene expression (*e.g.*, -238G/A and -308G/A)^[79]. Such variations in the TNF- α promoter region have previously been associated with the susceptibility to a range of autoimmune disorders, asthma, psoriasis and rheumatoid arthritis^[79-82]. The -238G/A SNP is associated with a lower production of TNF- α in patients with ulcerative colitis^[83]. Conversely, the -308A allele is associated with enhanced TNF- α production in cells *in vitro* and in CD patients *in vivo*^[84,85].

The TNF- α -308G/A and the TNF- β NcO1 polymorphisms have also been associated with survival in sepsis or septic shock of various origins. Polymorphisms of the TNF- α -308 and TNF- β +252 do not correlate with age, gender, disease activity or lesion site^[86,87] in the Chinese population.

In a recent study, we did not find differences in individual TNF- α -238G/A and -308G/A SNPs allele and genotype frequencies between CD, UC and IBD patients. These data contrast with other reports showing that the -308 G/A SNP could be associated with IBD susceptibility^[79], while they agree with Cao *et al.*^[86]. A recent meta-analysis showed that TNF- α -308 polymorphisms are also associated with ulcerative colitis in Asians^[74], whereas another study from Northern India [evaluating TNF- α (-1031T > C, -863C > A and -857C > T)] showed that the high-producing genotype of TNF- α (-863AA) was associated with increased risk of IBD, and more so with UC^[88]. Similarly, the combined effect of TNF- α polymorphisms in haplotype analysis demonstrated additionally increased risk of IBD.

However, in the TNF- α promoter gene polymorphism (-308G/A SNP) study, we found an increased frequency of the -308A allele and -308GA genotype in the non-responders to anti-TNF treatment compared with responder patients^[89]. This -308GA genotype has been classified as a high producer of TNF- α cytokine^[80,82], which could explain the different response of IBD patients to TNF- α inhibitor treatment. It can be argued that in situations with a higher production of TNF- α , its inhibitor could not be completely inhibitory, thus promoting a worse clinical response to TNF- α inhibitors. In addition, no differences were found between the two drugs used^[89]. In any case, more polymorphisms affecting the biological response and the responder/non-responder status of anti-TNF should be investigated, since the contribution of these genotypes to the immune response may be weak. It should also be mentioned that no analysis of the biological response of anti-TNF has been performed in this study.

Given the inter-individual variability in the response to the anti-TNF monoclonal antibody IFX, the predictive value of TNF and/or IL1 β as surrogate markers of IFX response was recently studied^[90]. Baseline serum concentrations of TNF and IL1 β were higher in UC patients than in CD patients. CD patients showing < 0.64 pg/mL IL1 β at baseline were more frequently responders than non-responders, and the C allele of the IL1B polymor-

phism was associated with higher IL1 β serum concentrations and with poorer clinical remission after 14 wk of IFX treatment. No significant association was found between serum TNF concentration or TNF polymorphisms and patient response to IFX.

New data on adaptive immunity are emerging, indicating that: (1) the mucosal Th1 and Th2 responses of IBD may be actually secondary to defects of the innate immune response; (2) the dysfunction of regulatory T cells may be contributing to mucosal immune abnormalities; and (3) the newly described Th17 cells are also prominently involved in the gut inflammatory response in both forms of IBD^[15]. In fact, TNF is synthesized by different cells, mostly of monocyte line and T lymphocytes^[6], and also intestinal epithelial cells (IEC). All known responses to TNF are triggered by binding to one of two distinct receptors, designated TNFR1 (also known as TNFRSF1A, CD120a, p55) and TNFR2 (also known as TNFRSF1B, CD120b, p75), which are differentially regulated on various cell types in normal and diseased tissue^[79].

TNF- α induces the expression of various genes, such as urokinase plasminogen activator, cyclooxygenase II (COX II) and vascular endothelial growth factor by activating the nuclear factor- κ B^[91]. In this way TNF- α performs multiple biological functions, such as increasing leukocyte recruitment (induction of leukocyte adhesion molecules)^[92,93], modulation of nitric oxide (NO) production (by increasing vascular permeability)^[94,95], induction of secretion of proinflammatory cytokines^[96], and the proliferation and differentiation of immune cells.

Chronic ulcerative colitis (CUC) is characterized by increased IEC apoptosis associated with elevated TNF, inducible nitric oxide synthase (iNOS), and p53. In addition, p53 has been reported to be increased in crypt IECs in human colitis and is needed for IEC apoptosis in chronic dextran sulfate sodium-colitis^[97]. Goresky *et al.*^[97] examined the roles of TNF and iNOS in the regulation of p53-induced IEC apoptosis in CUC. The IEC TUNEL staining, caspases 3, 8, and 9, and p53 protein levels, induced by anti-CD3 mAb activation of T cells, were markedly reduced in TNF receptor 1 and 2 gene knockout mice. Induction of IEC apoptosis correlated with increased p53, which was attenuated in iNOS(-/-) mice. IEC p53 levels and apoptosis were also reduced in IL-10 (-/-) colitic mice treated with neutralizing TNF mAb and the iNOS inhibitor, aminoguanidine, further suggesting that TNF and iNOS are upstream of p53 during colitis-induced IEC apoptosis. IEC apoptosis and p53 levels were assessed in control *vs* untreated or anti-TNF-treated CUC patients with equivalent levels of inflammation. In this study, IEC apoptosis and p53 levels were clearly higher in untreated CUC but markedly reduced in patients treated with anti-TNF mAb. Therefore, TNF-induced iNOS activates a p53-dependent pathway of IEC apoptosis in CUC. The inhibition of IEC apoptosis may be an important mechanism for mucosal healing in anti-TNF-treated CUC patients.

However, the mechanisms of action of anti-TNF- α

agents are still unclear^[6,98,99]. The neutralization of TNF- α in the inflamed mucosa is unlikely to be a sufficient explanation. Antibody-dependent cytotoxicity also induces apoptosis or lysis of TNF- α -producing cells^[59,100]. This mechanism involves the Fc portion of antibodies that increases the pro-apoptotic factor caspase-3^[76].

Finally, RNA interference (RNAi) holds great promise for the specific and selective silencing of aberrantly expressed genes, such as TNF- α in IBD. A very recent study investigates the efficacy of an amphiphilic cationic cyclodextrin (CD) vector for effective TNF- α siRNA delivery to macrophage cells and to mice with induced acute-colitis^[101]. RAW264.7 cells were transfected with CD.TNF- α siRNA, stimulated with lipopolysaccharide (LPS). Female C57BL/6 mice were exposed to dextran sodium sulphate (DSS) and treated by intra-rectal administration with either CD. TNF- α siRNA or a control solution. *In vitro*, siRNA in CD nanocomplexes remained intact and stable in both fed and fasted simulated colonic fluids. RAW264.7 cells transfected with CD.TNF- α siRNA and stimulated with LPS displayed a significant reduction in both gene and protein levels of TNF- α and IL-6. CD. TNF- α siRNA-treated mice revealed a mild amelioration in clinical signs of colitis, but significant reductions in total colon weight and colonic mRNA expression of TNF- α and IL-6 compared to DSS-control mice were detected. This data seems to indicate the clinical potential of a local CD-based TNF- α siRNA delivery system for the treatment of IBD.

In sum, a number of IBD immunogenetic markers have been identified^[102-104], and further investigation may establish new approaches to these enigmatic pathologies.

To conclude, further large-scale and functional studies of *IBD3* genes and polymorphisms are required in order to determine specific associated variations within the loci responsible for the gene dysfunction that confers the risk of IBD, and to identify gene variants that may alter the response to the treatment.

Abstract

Ulcerative colitis (UC) is a leading form of inflammatory bowel disease that involves chronic relapsing or progressive inflammation. As a significant proportion of UC patients treated with conventional therapies do not achieve remission, there is a pressing need for the development of more effective therapies. The human gut contains a large, diverse, and dynamic population of microorganisms, collectively referred to as the enteric microbiota. There is a symbiotic relationship between the human host and the enteric microbiota, which provides nutrition, protection against pathogenic organisms, and promotes immune homeostasis. An imbalance of the normal enteric microbiota composition (termed dysbiosis) underlies the pathogenesis of UC. A reduction of enteric microbiota diversity has been observed in UC patients, mainly affecting the butyrate-producing bacteria, such as *Faecalibacterium prausnitzii*, which can repress pro-inflammatory cytokines. Many studies have shown that enteric microbiota plays an important role in anti-inflammatory and immunoregulatory activities, which can benefit UC patients. Therefore, manipulation of the dysbiosis is an attractive

approach for UC therapy. Various therapies targeting a restoration of the enteric microbiota have shown efficacy in treating patients with active and chronic forms of UC. Such therapies include fecal microbiota transplantation, probiotics, prebiotics, antibiotics, helminth therapy, and dietary polyphenols, all of which can alter the abundance and composition of the enteric microbiota. Although there have been many large, randomized controlled clinical trials assessing these treatments, the effectiveness and safety of these bacteria-driven therapies need further evaluation. This review focuses on the important role that the enteric microbiota plays in maintaining intestinal homeostasis and discusses new therapeutic strategies targeting the enteric microbiota for UC.

INTRODUCTION

Inflammatory bowel disease (IBD) refers to chronic relapsing or progressive inflammatory conditions that may affect the entire gastrointestinal tract. Ulcerative colitis (UC) and Crohn's disease (CD) are two main clinically defined forms of IBD^[1]. In UC, inflammation is limited to the lining of the colon, whereas transmural inflammation occurs along any part of the gastrointestinal tract in CD^[2]. The incidence and prevalence of IBD have continued to increase over the past few decades throughout various regions around the world^[3]. Although the precise pathogenesis is unknown, it is thought that the etiology of IBD involves dysfunction of the mucosal immune system, which develops from complex interactions between the host immune system and genetic and environmental factors^[4].

The gastrointestinal tract is possibly the most complicated immune organ of the entire human body. The intestinal mucosa is continuously exposed to a variety of commensal microbiota and food antigens. The gut must suppress excessive immune responses to antigen stimulation, and thus uses both acquired and innate immune systems to maintain intestinal homeostasis. Evidence suggests that the development and function of the intestinal immune system depend on its specific enteric microbiota, which appears to have co-evolved^[5]. However, a disruption in this system can lead to aberrant immune responses to the enteric microbiota and cause chronic inflammation within the gut^[5,6]. This review focuses on the important role the enteric microbiota plays in maintaining intestinal homeostasis and discusses new therapeutic strategies for UC that are based on the enteric microbiota.

HUMAN ENTERIC MICROBIOTA

The human gut is a complex anaerobic environment with a large, diverse, and dynamic enteric microbiota composed of more than 100 trillion microorganisms - which is ten times greater than the total estimated number of human cells^[7]. Until the 1990s, the characterization of the enteric microbiota was limited to the use of bacteriological culture. However, less than 30% of fecal microorganisms observed under the microscope can be cultured. More recent advances in culture-independent techniques, such as 16S rRNA gene probing-based strategies and metagenomics, have broadened our knowledge of the complexity of this ecosystem^[8,9]. The enteric microbiota is comprised of more than 1000 different bacterial species^[10]. The majority of these organisms are from seven phyla: *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, *Fusobacteria*, *Verrucomicrobia*, *Cyanobacteria* and *Actinobacteria*. Over 90% of the human enteric microbiota are from the *Firmicutes* and *Bacteroidetes* phyla, though *Proteobacteria* are also common^[11,12].

There is a beneficial, symbiotic relationship between the host and the enteric microbiota. The host provides a nutrient-rich habitat to support the microbiota, which in

return confers a huge diversity of genes and metabolic functions. First, the enteric microbiota provides nutrition to the host by fermenting non-digestible substrates and producing short chain fatty acids, and aiding in the absorption of ions, amino acids and vitamins. Second, the microbiota provides a barrier against pathogenic bacteria. Furthermore, the microbiota plays an important role in regulating immune and gut homeostasis^[13]. Importantly, an imbalance of this symbiotic state, termed dysbiosis, underlies the pathogenesis of several inflammatory diseases, including allergic skin and respiratory disorders, rheumatoid arthritis, type I diabetes and IBD^[14].

Enteric microbiota in IBD

Quantitative and qualitative changes in the composition of the enteric microbiota have been observed in IBD, through a decrease in the diversity and an increase in the concentration of bacterial species^[13,15]. Dysbiosis in patients with CD has been well characterized, with a loss of bacteria from the *Firmicutes* phylum, including *Faecalibacterium prausnitzii* (*F. prausnitzii*), the major butyrate-producing bacterium in cluster IV of the *Clostridium leptum* phylogenetic group in the gut^[16]. Butyrate, the key energy source for colonic epithelial cells, represses the production of pro-inflammatory cytokines in the intestinal mucosa. The reduction of *F. prausnitzii* in mucosal and fecal samples represents the most replicated species-specific finding so far in CD^[17-19].

The decrease in enteric microbiota diversity has also been described in UC^[20-22]. Researchers found significantly fewer *Bacteroides* and *Clostridium* (*C. coccoides* and *C. leptum*) in fecal samples of UC patients^[23], and a higher amount of *Enterococcus* and *Gammaproteobacteria*^[21,22,24]. Additionally, Machiels *et al.*^[25] found that two well-known butyrate-producing *Firmicutes* bacteria, *Roseburia hominis* and *F. prausnitzii*, were reduced in UC patients. Moreover, the presence of butyrate-producing members of the clostridial cluster was found to vary with disease activity^[26]. Varela *et al.*^[27] found that counts of *F. prausnitzii* were associated with relapse and maintenance of clinical remission, with low counts corresponding to short-term remission, and counts increasing during remission. In another study that analyzed both fecal and biopsy UC specimens, *F. prausnitzii* was sharply decreased in both, whereas *Bifidobacterium* was significantly increased in the biopsy specimens of active UC^[28]. However, the composition of fecal and mucosal-associated microbiota changes throughout the progression of UC^[26,29].

It is still not clear whether the observed dysbiosis contributes to the development or is a consequence of UC. Although studies documenting the association between microbial changes and UC do not necessarily predict cause-effect relationships, they at least demonstrate that the enteric microbiota plays an important role in anti-inflammatory and immunoregulatory activities, which can benefit UC patients^[30].

THERAPIES ASSOCIATED WITH ENTERIC MICROBIOTA

Current therapeutic strategies for treating UC typically follow a step-up strategy, including mesalazine, steroids, immunosuppressants and biologics^[31]. Although a considerable proportion of patients maintain remission when using this approach, a significant number of them experience persistent disease activity and ultimately require colectomy^[32]. Therefore, the development of new and effective therapies is needed. Manipulation of the dysbiosis is an attractive therapeutic approach, particularly because the interaction between enteric microbiota and the host immune system perpetuates the inflammation in UC.

Fecal microbiota transplantation

Fecal microbiota transplantation (FMT) involves the administration of fecal material from a healthy donor into the intestinal tract of a recipient. This approach attempts to recover the composition and function of the enteric microbiota in patients with chronic gastrointestinal infections and IBD^[33]. FMT was first used in 1985 when standard treatments for *Clostridium difficile* infection (CDI) failed. The efficacy achieved by this application^[34] has since brought greater attention to FMT, which is increasingly being used for treatment of IBD, and UC in particular.

A case report published in 2003 documented six patients with UC who were treated with FMT^[35]. Some symptoms of UC improved within one week, and a complete reversal of symptoms was achieved in all patients by four months after FMT. In addition, there was no clinical, colonoscopic, or histologic evidence of UC in any patient after 1 to 13 years, even without any UC medication. Another study observed ten children with mild to moderate UC for four weeks after receiving FMT^[36]. Seven of these subjects showed a clinical response within one week, and six maintained a clinical response after one month. Among these, three subjects achieved clinical remission after one week, which was maintained throughout the four-week observation period. Furthermore, no serious adverse events were noted.

In contrast, some studies report only temporary clinical improvement from FMT rather than remission. Kump *et al.*^[37] reported short-term clinical improvement with colonoscopic FMT in six patients that were non-responsive to standard medical therapy. Although there were significant changes in the composition of the intestinal microbiota that resulted in a partial improvement of UC-associated dysbiosis, none of the patients achieved clinical remission. Similar results were obtained in a study of five patients with moderate to severe active UC by Angelberger *et al.*^[38]. Only one patient was observed to have some clinical improvement, and none of the five patients achieved remission during the 12-wk study. A transient increase in the similarity to donor microbiota and an increase in phylotype richness were detected in two patients less than four weeks after FMT. Notably, the microbiota

of the sole clinical responder was similar to the donor's, even 12 wk after FMT, which was characterized by successive colonization by the anti-inflammatory and short-chain fatty acid-producing *F. prausnitzii*, *Roseburia faecis* and *Bacteroides ovatus*.

There are several possible explanations for the failure of FMT in some UC patients^[39]. First, enteric microbiota in non-responsive patients may be affected by other factors, including dietary intake or exposure to cigarette smoke. Second, the dysbiosis may be a result of UC, rather than the cause. Finally, the type of patients used in these studies may have affected the results, as those with more severe disease and for whom current medical therapies had failed were chosen.

Because of the uncertain effectiveness and safety issues, the study of FMT in UC is complicated. Further studies should identify the best candidates for FMT, such as patients with mild to moderate UC, those who already have a medically induced remission, or those who are newly diagnosed. In addition, more attention should be paid regarding the side effects accompanying FMT. A recent case report of a patient with UC that had been in remission for more than 20 years experienced a UC flare-up after FMT for treatment of CDI^[40]. Thus, additional careful studies are needed to determine the effectiveness and safety of FMT, and to facilitate the development of FMT as potential therapy for UC patients.

Probiotics and prebiotics

Probiotics are living non-pathogenic microbes, including *Lactobacilli*, *Bifidobacteria*, *Enterococci* and some yeast species^[41], which can benefit the host and affect the structure and function of the enteric microbiota through diverse mechanisms^[42]. Prebiotics, which also confer benefits to the host, are defined as non-digestible, selectively fermented, short-chain carbohydrates that allow specific changes in the composition and/or activity of the enteric microbiota^[43]. Probiotics and prebiotics have been widely used in the prevention and treatment of important gastroenterological conditions, such as irritable bowel syndrome (IBS) and IBD, and infectious diarrhea.

A probiotic mixture named VSL3, consisting of four strains of *Lactobacilli*, three strains of *Bifidobacteria* and one strain of *Streptococcus thermophiles*, was effectively used as maintenance therapy in patients with recurrent or chronic pouchitis^[44-46]. Further evidence supporting the use of probiotics was provided by a one-year, placebo-controlled, double-blind study involving a total of 29 children with active UC who received either VSL3 or a placebo in addition to steroid induction and mesalamine maintenance treatment^[47]. A greater number of patients receiving the placebo relapsed within one year, suggesting that VSL3 is effective in maintaining remission. In two randomized, double dummy trials, Nissle 1917, a non-pathogenic strain of *Escherichia coli* (*E. coli*), was as effective as standard mesalamine in maintaining remission in UC^[48,49]. In both studies, there were no differences in the percentage of patients who relapsed or the safety profile

of one-year treatments with *E. coli* Nissle 1917 or mesalazine. However, an open-label, randomized trial by Zocco *et al.*^[50] demonstrated that treatment with *Lactobacillus* GG was more effective than mesalazine in prolonging the relapse-free time in UC patients.

Probiotics also have the capability to induce remission. In a multicenter, randomized, double-blind, placebo-controlled trial including 147 adult patients with mild to moderate UC, a greater percentage of patients receiving VSL3 for 12 wk achieved remission or had greater activity reduction [reduced UC disease activity index (UCDAI) score] than those receiving a placebo^[51]. In a similarly designed clinical trial, 144 patients who received VSL3 for 8 wk in addition to their standard pharmaceutical therapy had greater improvement in UCDAI scores, and a significant reduction in rectal bleeding^[52]. A study by Oliva *et al.*^[53] demonstrated that local administration of *Lactobacillus reuteri* ATCC 55730 with standard oral mesalazine reduced the inflammation of rectal mucosa in pediatric UC patients.

The prebiotic germinated barley foodstuff has also been shown to reduce the clinical activity of UC together with the baseline treatment, and to maintain remission^[54,56]. The combined use of probiotics and prebiotics, such as *Bifidobacterium* and galacto-oligosaccharide, has also been shown to improve the clinical status of UC patients^[57]. However, other studies using combinations of probiotics and prebiotics have been less successful^[58,59]. Future probiotic and prebiotic treatments for UC patients should be more personalized, taking into consideration the age of patient, the phase of disease, and the molecular pattern of dysbiosis^[60]. Moreover, therapeutic outcomes may be improved by careful selection of agents, and protective commensal enteric species may be more suitable.

Antibiotics

There have been conflicting results over the past few decades concerning the efficacy of antibacterial therapies for the treatment of UC^[31]. However, a combination of broad-spectrum antibiotics completely inhibited spontaneous colitis in animal models, suggesting a possible rationale for antibiotic combination therapy for the treatment of UC^[61,62]. A two-week antibiotic combination therapy consisting of amoxicillin, tetracycline and metronidazole (ATM) was shown to be effective against *Fusobacterium varium* in UC patients^[63,64]. *F. varium* has been detected in the colonic mucosa of a large number of UC patients^[65] and can induce UC lesions in experimental animals^[66]. ATM treatment was also shown to provide more efficient improvement, remission and steroid withdrawal than a placebo in a double-blind, multicenter trial including 105 patients that was conducted in patients with chronic mild to severe relapsing UC^[67]. This treatment has also shown efficacy in the treatment of refractory or steroid-dependent UC^[68].

Helminth therapy

Modern hygienic practices prevent exposure to helminth

parasites, though epidemiological data suggest that people who carry helminths have fewer immune-mediated diseases^[69,70]. Helminth infections may alter the abundance and composition of enteric microbiota, resulting in a greater proportion of anti-inflammatory strains^[71]. The biocomplexity of the gut, including the interactions between parasites and the enteric microbiota, can influence inflammatory processes^[72]. Studies in rodent models revealed that intestinal parasites and parasite products regulate host immunity and alleviate IBD-like inflammation^[73]. In a randomized, double-blind, placebo-controlled trial involving 54 patients with active UC, a greater number of patients who received 12 wk of treatment with *Trichuris suis* ova showed improvement with no side effects^[74]. Similarly, three patients with active UC in an open trial attained remission with 12-wk *T. suis* ova treatment with no side effects^[75].

Dietary polyphenols

Diet can modulate enteric microbiota composition, with a strong effect on human health^[76]. Polyphenols are members of a large family of plant-derived compounds that have drawn attention due to their antioxidant and anti-inflammatory properties^[77]. Some *in vitro* and *in vivo* studies indicate that dietary polyphenols and their metabolites can interact with the enteric microbiota, and enhance the growth of probiotic bacteria^[78-84]. Due to the prebiotic potential and anti-inflammatory effects, polyphenol supplementation could potentially serve as a complementary medicinal approach to UC. However, there have been no clinical trials evaluating the use of dietary polyphenols for the treatment of UC.

CONCLUSION

As a form of IBD, UC has its own genetic, pathogenic and therapeutic identity. Despite recent advances in UC therapeutic resources, a considerable proportion of UC patients are still refractory to conventional treatment. Dysbiosis is an important immunologic and pathologic process in UC. Accumulating knowledge of dysbiosis has promoted the use of enteric microbiota regulation as a novel promising adjuvant in UC therapy. Therapeutic approaches, such as FMT, probiotics, antibiotics, dietary polyphenols, and helminth therapy, can alter the abundance and composition of enteric microbiota, and improve patient outcomes. However, the safety and effectiveness of bacteria-driven therapies need further evaluation.

Abstract

Tumor necrosis factor- α (TNF- α) inhibitors are biological agents introduced in the late 1990s for the treatment of different immune-mediated diseases as inflammatory bowel disease, rheumatoid arthritis and psoriasis. The most commonly used TNF- α antagonists are infliximab, adalimumab, and certolizumab pegol, and though highly effective in lowering inflammation, the efficacy must be weighed against the potential for adverse events. The treatment-induced immunosuppression is suspected to increase the risk of infections, including the risk of reactivation of latent tuberculosis, as the TNF- α cytokine plays an important role in the immune function. In this topic highlight a short overview of the infection risk associated with TNF- α inhibitor therapy is outlined with a focus on the overall risk of serious infections, mycobacterial infection and latent viral infections.

Key words: Inflammatory bowel disease; Biological treatment; Tumor necrosis factor- α inhibitors; Risk; Infections; Ulcerative colitis; Crohn's disease

Core tip: The use of tumor necrosis factor- α (TNF- α)

inhibitors are increasing worldwide for the treatment of several chronic immune-mediated diseases as rheumatoid arthritis and inflammatory bowel disease (IBD). As the drugs are relatively new on the market, their long-term safety profile remains uncertain. In particular, a concern regarding an increased infections risk has been debated. In the current topic highlight, a brief overview of the current literature regarding the risk of infections in patients with IBD exposed to TNF- α inhibitors is outlined.

Risk of infections associated with biological treatment in inflammatory bowel disease. *World J Gastroenterol* 2014; 20(43): 16014-16019 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i43/16014.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i43.16014>

INTRODUCTION

Inflammatory bowel disease (IBD), comprising ulcerative colitis (UC) and Crohn's disease (CD) are relapsing inflammatory conditions affecting the gastrointestinal tract. Since their introduction in the late 1990s, tumor necrosis factor- α (TNF- α) inhibitors have altered the treatment paradigm in IBD and other chronic inflammatory conditions as rheumatoid arthritis and psoriasis. TNF- α inhibitors are chimeric, partly or fully humanized monoclonal antibodies or antibody fragments impairing the pro-inflammatory cytokine, TNF- α . Initially, TNF- α inhibitors were approved for treating fistulizing CD but rapidly their indication expanded and currently, infliximab, adalimumab, certolizumab pegol and golimumab are approved for the treatment of moderate to severe active IBD in adults (certolizumab pegol solely approved for CD and golimumab solely approved for UC)^[1-5], and recently infliximab has been approved for refractory CD and UC in pediatric patients^[6,7]. Assembled, the benefits

of TNF- α inhibitors in the management of IBD are indisputable, but concerns about potential adverse events remain an important issue. TNF- α has a central role in the immune system stimulating the differentiation of monocytes into macrophages, recruitment of neutrophils and creation of granulomas^[8]. Inhibiting this cytokine in the case of inappropriate immune responses as seen in IBD, could potentially impair the effectiveness of the host immune function in the defense against infectious organisms, thereby leading to an increased risk of infections, including the risk of opportunist infections. Shortly after the introduction of infliximab a concern regarding the risk of reactivation of latent tuberculosis (TB) was raised and has led to obligate screening for latent TB prior to TNF- α inhibitor exposure^[9]. Early randomized clinical trials examining the risk of infectious complications have primarily suggested that there is no overall increased risk of infections after treatment with TNF- α inhibitors, but, the true risk profile often relies on ongoing surveillance during the post marketing period with the accumulation of a large number of unselected exposed patients. For this purpose, population- and register-based observational studies are useful, though residual confounding often challenges the interpretation of these studies. Further, drug specific analyses are complicated by the fact that the majority of IBD patients receiving TNF- α inhibitors have concurrent exposure to other immunomodulators as azathioprine and prednisolone, drugs also known to possess an infection risk *per se*^[10-12]. Hence, multiple factors must be taken into account when analyzing and interpretation the infectious risk estimates related to biological treatment.

The aim of the current topic highlight is to give a brief up-date on the existing evidence on the potential increased risk of infections, including the risk of reactivation of latent TB and viral pathogens in IBD patients treated with TNF- α inhibitors.

OVERALL INFECTION RISK

Prior to the approval of infliximab for IBD in the late 1990's, several large, randomized pivotal phase 3 clinical trials were conducted in order to assess the effectiveness of the drug and outline a safety profile. Lichtenstein *et al*^[13] performed a pooled analysis of infections risk based on these sponsor-initiated trials, including the ACCENT I^[3,14], ACCENT II^[15] and SONIC^[1] trials in CD and the ACT I and ACT 2^[2] trials in UC. Authors found that a larger proportion of infliximab- than placebo-treated UC patients had at least one infection (50.1% *vs* 36.3%; $P < 0.001$) whereas the proportion of CD patients treated with infliximab *vs* placebo who had one infection was similar (49.1% *vs* 45.3%; $P = 0.402$). The proportion of IBD patients having one serious infection was similar in infliximab *vs* placebo treated patients (4.7% *vs* 3.7%; $P = 0.427$). Infections expressed as incidences per 100 person-years revealed that infliximab-treated IBD patients had an incidence of 113.80 (95%CI: 109.12-118.62)

vs 115.79 (95%CI: 104.26-128.25) in placebo-treated IBD patients. Similarly, no significant difference between infliximab-treated and placebo-treated IBD patients in incidence of serious infections was observed and authors concluded that infliximab treatment in patients with IBD did not appear to affect incidences of infections. However, the design of randomized clinical trials is often with stringent inclusion and exclusion criteria, and limited follow-up and sample size, hence presenting selected patients populations, that are not optimal for evaluation of the overall, long-term risk of adverse events. In 2009, Fidler *et al*^[16] conducted a single-centre cohort study, evaluating the long-term safety of infliximab in 734 exposed IBD patients followed for a median of 58 mo. The study suggested that the infection rate was similar in IBD patients treated with infliximab compared to IBD patients treated with conventional therapies. In contrast, a prospective, observational study with equivalent follow-up time, based on data from the North American TREAT (Crohn's Therapy, Resource, Evaluation, and Assessment Tool) registry found that infliximab treatment was associated with a significant 43% increased risk of serious infections (HR = 1.43; 95%CI: 1.11-1.84) but authors pointed out that CD severity and use of prednisone and narcotic analgesic carried higher risks, thus the increased risk of serious infection might be attributed to disease severity rather than the infliximab treatment *per se*^[17]. Another North American study including combined data from four large databases in the SABER (Safety Assessment of Biologic Therapy) project investigated the rate of serious infections in patients with different autoimmune disease (IBD, RA, psoriasis, psoriatic arthritis, and ankylosing spondylitis) exposed to TNF- α inhibitor treatment compared with the rate in propensity score matched non-users^[18]. Among 2323 patients with IBD exposed to TNF- α inhibitors no increased risk of serious infections was observed (365 d risk window) following exposure, with an adjusted HR of 1.13 (95%CI: 0.85-1.50) whereas an insignificant trend towards an increased risk was observed for those with concomitant glucocorticoid treatment (> 10 mg/d) with a HR of 1.38 (95%CI: 0.98-1.95). Only for RA patients did the study have sufficient power to analyze the risk of serious infections for the different TNF- α inhibitors separately and stratified analyses revealed that exposure to infliximab was associated with a 25% significant increased risk of serious infections when compared to non-biological treatment (HR = 1.25; 95%CI: 1.07-1.48). There were no increased risk of serious infections related to adalimumab. A small cohort study from Korea compared the risk of serious infections between infliximab and adalimumab in 175 patients with different autoimmune disorders (including 54 with IBD) and found similar infections rates in patients exposed to adalimumab and infliximab but no analyses with a comparison group were performed^[19].

From the Food and Drug Administration Adverse Event Reporting System, Deepak *et al*^[20] studied the association between infections risk and different drugs, in-

cluding TNF- α inhibitors in patients with IBD. Authors found that the risk of serious infections was increased in IBD patients treated with TNF- α inhibitors as monotherapy (OR = 1.95; 95%CI: 1.06-3.59) and further revealed that there was no incremental increase in risk, when combining the treatment with other immunomodulators. A register-based study from the United Kingdom compared the risk of serious infections in patients with rheumatoid arthritis (RA) exposed to TNF- α inhibitors with those exposed to conventional treatments and found a small, significant increased risk related to TNF- α inhibitor exposure (HR = 1.2; 95%CI: 1.1-1.5) with no significant difference between the different TNF- α inhibitors^[21]. Further, when limiting the follow-up to the first 90 days after exposure to TNF- α inhibitors revealed an augmented increased risk of serious infections (HR = 1.8; 95%CI: 1.3-2.6) suggesting that the risk of serious infections is dependent on time since exposure with an increased risk in the early post-treatment period. The study also studied the effect of age on risk of infections and although increasing age was an independent risk factor for serious infections in both treatment groups, there was no difference in relative risk of infection in patients on TNF- α inhibitor therapy in the older population.

To summarize, the overall risk of infections related to TNF- α inhibitor exposure in patients with IBD tend to be limited during long follow-up and mostly driven by patient factors including comorbidities and steroid use. However, the potential for TNF- α inhibitor therapy to improve disease control and allow for steroid dose reduction or elimination, could even out the risk estimates and mask a more substantial increased infections risk related to TNF- α inhibitors *per se*. There is a need of further longitudinal observational studies examining the risk in the different TNF- α inhibitors separately and during different risk windows to assess the potential of a time varying effect.

MYCOBACTERIAL INFECTIONS

According to the World Health Organization, an estimated 8.6 million people developed Tuberculosis (TB) and 1.3 million died from the disease in 2012 making the disease a major global health problem^[22]. Shortly after introduction of infliximab, the concern of reactivation of latent TB in patients receiving TNF- α inhibitors was raised as reports from the Food and Drug Administration Adverse Events Reporting System revealed higher rates of TB in patients exposed to infliximab compared to the background rates^[9]. There were 70 reported cases of TB in patients exposed to infliximab for a median of 12 wk and in 48 patients, TB developed after three or fewer infusions. Of the 70 cases, 91% were from countries with low incidence of TB. The association is further strengthened by the biological plausible link, as TNF- α plays an important role in granuloma formation, which is responsible for the sequestration of mycobacteria. The risk of TB reactivation following TNF- α inhibitor

treatment is mostly studied in patients with rheumatoid arthritis^[23-25] and there is a wide variation in TB rates observed amongst the different studies and a consensus report stated that the relative risk of TB increases 1.6-25 times with exposure to TNF- α inhibitors depending on the clinical context, the drug used and the patient's country of origin^[26]. Interestingly, two studies investigating the risk of reactivation of latent TB in patients with CD did not find any cases of TB and this raises the possibility of a substantial lower risk of TB in patients with IBD compared to those with rheumatoid arthritis, possibly partly because of the younger age of IBD patients^[27,28]. In light of the significant morbidity and mortality associated with TB reactivation, current guidelines demand that patients with IBD who are to be treated with TNF- α inhibitors should first be screened for latent TB with a chest x-ray and tuberculin skin test^[29,30] (in case of a negative test in patients at high TB risk a Quantiferon test should be considered^[29,31-33]). If there is evidence of latent TB infections, patients should begin treatment with isoniazid therapy prior to introducing TNF- α inhibitor treatment.

LATENT VIRAL INFECTIONS

An increased risk of viral infections has also been associated with TNF- α inhibitor exposure as TNF- α has an important role in viral clearance. Particularly the risk of reactivation of varicella zoster virus (VZV), cytomegalovirus (CMV) and viral chronic hepatitis B has received attention.

TNF- α plays a role in the immune response against VZV as it blocks antigen expression and viral virus replication^[34]. Infection with VZV in children causes chickenpox (primary infection) and the infection then becomes latent and may be reactivated in adults causing herpes zoster (shingles). The potential association between TNF- α inhibitors and herpes zoster is mainly studied in patients with RA. A German study including 5040 patients with RA revealed that exposure to the TNF- α inhibitors infliximab and adalimumab was associated with an 82% significant increased risk after adjustment for age, disease severity and glucocorticoid use (HR = 1.82; 95%CI: 1.05-3.15)^[35]. However a more recent study, including 33324 new users of TNF- α inhibitors in patients with RA, IBD, psoriasis, psoriatic arthritis, or ankylosing spondylitis did not find a higher risk of herpes zoster in patients with IBD or other inflammatory diseases who initiated TNF- α inhibitor therapies compared with patients who initiated non-biologic treatment regimens^[36]. As the evidence is not clear, clinicians should be aware of the potential increase risk of herpes zoster, particularly in the light of the high prevalence of VZV seropositive patients. Prior to initiation of TNF- α inhibitor treatment, VZV vaccine may be administered to all adults without evidence of immunity to VZV, but administration of live attenuated VZV vaccine is contraindicated during TNF- α inhibitor therapy and should be given at least 3 wk prior to initiation of any immunosup-

Table 1 Testing to undertake prior to initiation of tumor necrosis factor- α inhibitor treatment

| Infection | Tests | Consequences |
|-----------|--|--|
| TB | Latent TB infection should be tested by a combination of patient history, chest X-ray, tuberculin skin test and interferon-gamma release assays (Quantiferon test) according to local prevalence and national recommendations. The Quantiferon test is preferred in patients receiving immunosuppressive therapy and in BCG immunized patients | Patients diagnosed with latent TB infection prior to TNF- α inhibitor exposure should be treated with a complete therapeutic regimen for latent TB. TNF- α inhibitor treatment should not be initiated prior to one month after the introduction of anti-TB treatment When active TB is diagnosed, anti TB-therapy must be started, and TNF- α inhibitor therapy must be stopped but can be resumed after two months if needed |
| HBV | Blood test for HBsAg, anti- HBsAb and HBeAb to determine HBV status. In patients with positive HBsAg, viremia (HBV-DNA) should also be quantified | Patients with acute HBV infection (HBsAg positive) should be treated with antiviral drugs and treatment with TNF- α inhibitors should not be initiated before a test of HBV DNA is negative In case of evidence of quiescent HBV infection patients should be regularly monitored for evidence of HBV replication during treatment with TNF- α inhibitors |
| HIV | Blood test for HIV serology | In patients with uncontrolled HIV infection, treatment with TNF- α inhibitors is contra-indicated |
| VZV | In case of a negative history of chicken pox/herpes zoster infection VZV serology should be tested | Patients with negative serology for VZV should be vaccinated and treatment with TNF- α inhibitor should be awaited three weeks |

TB: Tuberculosis mycobacterium; TNF- α : Tumor necrosis factor- α ; HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; HBsAb: Hepatitis surface antibody; HBeAb: Hepatitis B core antibody; HIV: Human immunodeficiency virus; VZV: Varicella zoster virus.

pressant including TNF- α inhibitors.

Cytomegalovirus is another member of the Herpes virus family and has a high seroprevalence in adults^[37]. The primary infection in immune-competent patients is nearly always asymptomatic or comparable to mild mononucleosis-like symptoms but afterwards the infection often becomes latent. Treatment with TNF- α inhibitors has been related to reactivation of latent CMV infections in patients with IBD^[37,38]. The handling of CMV infection in IBD patients remains a challenge as the distinction between active CMV infection and active CMV disease (the presence of both CMV infection and the presence of clinical signs and symptoms, such as fever, leukopenia, or end organ involvement) may be difficult. As there are no current consensus on how to manage active CMV infections/CMV disease in IBD patients treated with TNF- α inhibitors or other immunosuppressant drugs large, controlled trials on antiviral treatment are needed to clearly elucidate the benefits of antivirals in this setting, and to possibly identify risk factors that help identify patients who need antiviral therapy^[39].

The awareness of hepatitis B virus (HBV) infections has increased because of several case reports of severe hepatitis B virus reactivation in patients exposed to TNF- α inhibitors^[40-42]. Although the role of TNF- α in chronic viral hepatitis is limited, there is evidence that TNF- α synergizes with interferons in suppressing viral replication^[43] and is essential in clearing HBV^[44]. Hence, inhibiting the TNF- α cytokine could potentially increase HBV replication leading to active disease. Currently, it is recommended that all patients with IBD are screened for HBV before introducing TNF- α inhibitor therapy and if active HBV replication is detected, antiviral treatment should be administered prior to introducing TNF- α inhibitor therapy.

Table 1 summarizes which tests to undertake prior to initiation of treatment with TNF- α inhibitors.

Based on the current ECCO (European Crohn Colitis Organisation) consensus on preventing opportunistic infections in patients with IBD the following vaccinations are recommended to be given prior to the initiation of TNF- α inhibitors: Influenza (annual), Pneumococcal, Hepatitis B, Varicella, HPV (only women)^[45].

CONCLUSION

There is limited evidence of a substantial increased overall risk of serious infections in patients with IBD exposed to TNF- α inhibitors, however, a small increased risk may not be ruled out, particularly in patients receiving concomitant treatment with corticosteroids and comorbidity. Additionally, it seems that there is an association between exposure to TNF- α inhibitors and different site- and pathogen-specific infections. The risk of reactivation of latent TB infections should be recognized and minimized by TB testing prior to the initiation of TNF- α inhibitor treatment, particularly in countries with high TB incidence. Likewise, it is recommended to screen for latent hepatitis B virus infection and VZV prior to TNF- α inhibitor treatment. The magnitude of the risk of reactivation of CMV in IBD patients exposed to TNF- α inhibitors and other immunosuppressant drugs is not clear and there is no current consensus on how to manage these patients.

In the future, with a growing number of patients exposed to TNF- α inhibitors and hence increasing power, there is need for studies examining the risk of infections following TNF- α inhibitor exposure in patient sub-groups, as for example the elderly. Further there is a need of studies investigating the risk of infections according to specific TNF- α inhibitors separately.

Abstract

The association between ulcerative colitis (UC) and colorectal cancer (CRC) has been acknowledged. One of the most serious and life threatening consequences of UC is the development of CRC (UC-CRC). UC-CRC patients are younger, more frequently have multiple cancerous lesions, and histologically show mucinous or signet ring cell carcinomas. The risk of CRC begins to increase 8 or 10 years after the diagnosis of UC. Risk factors for CRC with UC patients include young age at diagnosis, longer duration, greater anatomical extent of colonic involvement, the degree of inflammation, family history of CRC, and presence of primary sclerosing cholangitis. CRC on the ground of UC develop from non-dysplastic mucosa to indefinite dysplasia, low-grade dysplasia, high-grade dysplasia and finally to invasive adenocarcinoma. Colonoscopy surveillance programs are recommended to reduce the risk of CRC and mortality in UC. Genetic alterations might play a role in the development of UC-CRC. 5-aminosalicylates might represent a favorable therapeutic option for chemoprevention of CRC.

Key words: Ulcerative colitis-associated colorectal can-

cer; Risk factor; Dysplasia; Surveillance colonoscopy; Chemoprevention

Core tip: Colorectal cancer (CRC) is more frequent in patients with long-term ulcerative colitis (UC), and is one of the most serious and life threatening consequences of UC. Knowledge of risk factors for CRC is important to identify UC patients who need surveillance. Colonoscopy surveillance programs are recommended to reduce the risk of CRC and mortality in UC. Genetic alterations might play a role in the development of CRC in UC patients. 5-aminosalicylates might represent a favorable therapeutic option for chemoprevention of CRC.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disease showing mucosal inflammation from the rectum to the oral side. Crohn and Rosenberg reported the first case of adenocarcinoma complicating UC in 1925^[1]. The risk of developing colorectal cancer (CRC) is found to be high in patients with long-term UC^[2,3]. UC-CRC is considered to develop from a non-neoplastic inflammatory epithelium to dysplasia to cancer. Therefore, colonoscopic surveillance in patients with long-standing UC has been recommended. UC-CRC shows characteristic clinicopathological features of CRC. In this paper, the characteristic properties of UC-CRC are reviewed.

CLINICAL FEATURES OF COLITIS-ASSOCIATED CRC

Clinicopathological features

UC-CRC patients are younger, more frequently have mul-

multiple cancerous lesions, and a macroscopically permeating pattern of spread, including mucinous or signet ring cell carcinomas, compared with sporadic CRC^[1-3]. The advanced stage at presentation causes less favorable outcome of UC-CRC in IBD patients.

Incidence of UC-CRC

An inflammatory environment is believed to play an important role in the pathogenesis of UC-CRC in patients with chronic colitis^[4]. UC-CRC accounts for about 1% of all CRC^[5]. The risk of CRC begins to increase 8 or 10 years after the initial diagnosis^[6-8]. Table 1 summarizes representative reports on the risk of developing colorectal cancer in patients with UC. Eaden *et al*^[9] conducted a meta-analysis of 116 studies, and found that the probability of CRC in patients with UC increased with the duration of disease; 1.6% at 10 years after an onset of UC, 8.3% at 20 years after, and 18.4% at 30 years after. This increased incidence of UC-CRC is four to ten times greater than that for sporadic CRC, and the average age of onset is 20 years earlier. Several other studies reported that the risk of UC-CRC in UC patients was 5%-7% at 20 years after onset of disease^[10-14], 7%-14% at 25 years^[15,16] and 7.5%-18%^[9,17] at 30 years. Eaden *et al*^[9] confirmed that there is an increased risk for UC-CRC in pancolitis (5.4%), while the incidence in all patients with UC was 3.7%. In some countries, patients with UC have not been found to be at increased risk of CRC development. Winther *et al*^[18] reported that the probability of CRC in Denmark was 0.4% by 10 years, 1.1% by 20 years, and 2.1% by 30 years of disease, suggesting that neither the overall cancer risk nor the UC-CRC risks increased after a median of 19 years of follow-up evaluation. This low rate of CRC development may reflect the high rates of surgical approach and chemoprevention for UC in Denmark. Taken together, the 5-aminosalicylic acid (5-ASA) treatment and frequent surveillance colonoscopy with proctocolectomy for dysplasia could explain the reduction in the incidence of CRC in UC patients. Moreover, current studies indicate that the risk of CRC seems to be lower. Rutter and co-workers reported cumulative incidences of UC-CRC of 2.5% at 20 years of colitis duration, 7.6% at 30 years, and 10.8% at 40 years^[19] indicating only a 1.5 to 2-fold increased risk for CRC (5%) in comparison with the non-UC population. Söderlund *et al*^[20] indicated that the overall cumulative incidence of CRC at 10, 20, and 30 years after the inflammatory bowel disease (IBD) diagnosis was 1%, 1.5%, and 2.7%, respectively. Manninen *et al*^[21] reported only slightly increased risk for UC-CRC in UC patients in a Finnish cohort. Hata *et al*^[22] reported that the cumulative risks for the development of invasive cancer at 10, 20, and 30 years were 0.5%, 4.1%, and 6.1%, respectively, while those for the development of definite dysplasia at 10, 20, and 30 years were 3.1%, 10.0%, and 15.6%, respectively. A further current systematic review with meta-analysis in 2014, based on 81 studies and 181923 patients, reported that the risk of UC patients

developing colorectal cancer has decreased steadily, and the incidence rate decreased from 4.29/1000 patient-years in the 1950s to 1.21/1000 patient-years in the last decade^[23]. The risk of developing CRC with longstanding Crohn's colitis is considered to be similar to that of UC, while the incidence of CRC in Crohn's disease showed various ranges in cancer risk^[24-27].

Patients with UC who have undergone proctocolectomy have a very small risk of dysplasia in the ileal pouch^[28]. Anal transitional zone dysplasia after ileal pouch-anal anastomosis is infrequent. Anal transitional zone preservation did not lead to the development of cancer in the anal transitional zone after five to ten years of follow-up^[29].

Patients with UC who develop CRC have a worse prognosis than for CRC patients without UC^[30-33], and the long-term prognosis of UC-CRC is even worse when patients with the same tumor stage are compared^[32]. UC-CRC is frequently diagnosed at an advanced stage^[33]. These findings emphasize the importance of knowledge of risk factor for UC-CRC and surveillance for patients with UC.

RISK FACTORS OF UC-CRC

Knowledge of risk factor for CRC is important to categorize subgroups of UC patients who need frequent surveillance or intense treatment. Risk factors for CRC in UC patients include, anatomical extent, young age at diagnosis, duration of disease, concurrent primary sclerosing cholangitis (PSC) and family history of CRC. In addition, smoking, pseudopolyps, persistent inflammation of the colon and backwash ileitis are also risk factor for CRC^[34,35]. These UC patients with risk factors should be enrolled in an intensive surveillance program.

Pancolitis

The anatomical extent of colitis is an independent risk factor for the development of CRC. A meta-analysis showed that the incidence of CRC in patients with extensive UC was 5.4%^[36]. Patients with pancolitis are at high risk of CRC, left-sided colitis is moderate risk, and proctitis and proctosigmoiditis are low risk, being similar to the non-UC population^[20,37,38]. Ekbom *et al*^[38] reported that UC patients with pancolitis had a 15-fold higher risk of CRC compared with the non-UC group, in contrast to an increased risk of 2.8 for patients with left-sided colitis and no significant increased risk for those with proctitis, and reported an overall risk of 4.8 for UC patients with extensive disease.

Young age

Young age at onset of colitis has been reported as an independent risk factor for CRC^[6]. CRC risk varied by age at initial diagnosis of UC; patients diagnosed at childhood (0-19 years old) had a relative risk of 43.8 followed by those diagnosed in young (20-39 years old) with a relative risk of 2.65^[39].

UC: Ulcerative colitis.

Long disease duration

Duration of UC is an important risk factor for CRC development. Among patients with IBD, the median time from diagnosis of IBD to CRC was 17 years; 21% of IBD patients developed tumors within 10 years after onset^[40].

PSC

IBD patients with PSC, a chronic cholestatic liver disease, have an increased risk of CRC^[41]. Broomé *et al*^[42] revealed a cumulative risk of CRC in UC patients with PSC of 9% after 10 years duration of symptoms, 31% after 20 years and as high as 50% after 25 years; compared with 2%, 5% and 10% in patients with UC alone matched for each duration. A meta-analysis found that 21% of UC patients with PSC developed CRC compared with 4% of UC patients without PSC. The risk of CRC in UC patients with PSC was 4.8-fold higher than that in patients with UC without PSC^[43].

Family history of colorectal cancer

A family history of CRC in UC patients increases the risk of CRC, irrespectively of the type and extent of IBD, as compared with patients with UC without positive family history for CRC^[44-46].

MOLECULAR FEATURES OF UC-CRC

Genetic characteristics detected in sporadic CRC, such as genetic mutations, microsatellite instability (MSI), and DNA hypermethylation, were also recognized in UC-CRC^[4,33,47-50]. Mutations in *p53* occur early in the adenoma-carcinoma sequence and are often detected in non-dysplastic or indefinite dysplasia in UC, while *p53* mutations occur in the late phase in sporadic adenoma^[51]. MSI is also relatively frequent in non-dysplastic inflamed epithelia, and transforming growth factor β receptor type II (*TGF β RII*) is one of genes targeted by the MSI process in UC-CRC^[50]. Hyper-methylation of *bMLH1*^[50,52], *p16INK4a*^[53], and *p14ARF*^[54] seems to precede dysplasia and contribute to the genetic alterations in UC-CRC^[55]. MicroRNAs (miRNAs) play a critical role in regulating key pathogenic mechanism in IBD^[56]. The miRNA-124a

gene has a tumor-suppressive function and is methylated during carcinogenesis in UC patients, and the methylation level of miR-124a-3 is a promising marker for estimating individual risk for CAC^[57]. By contrast, miRNA-155 overexpression is particularly associated with MSI in CA-CRC^[58]. These molecules might be useful biomarkers for early detection and treatment response of CRC in IBD patients.

Inflammatory stresses, such as reactive oxygen species and some free radicals, may cause these genetic changes^[59-61] and are considered to be factors in the pathogenesis of UC-CRC^[62,63].

SURVEILLANCE COLONOSCOPY

Cancer surveillance is based on the high-risk factors that identify patients who are likely to develop cancer. The management of UC has changed with biological therapies, surgical treatment, and surveillance tools, which have reduced the risk of CRC in patients with UC^[9,20,23]. Surveillance is recommended during the remission state to reduce the difficulty of differentiating reactive change from dysplasia^[64]. Data from an 18-year surveillance program demonstrated that cancer was detected at an early stage in 80% of surveyed patients, compared with only 41% of non-surveyed UC patients^[65]. There is evidence that surveillance colonoscopy reduces the risk of CRC and mortality in UC: The overall 5-year survival rate was 77% for the surveillance group, compared with only 36% for the control group^[33,35,65]. It has been reported that a prior history of surveillance colonoscopy reduces the odds of developing CRC by 60%-80%^[35,66].

These guidelines, commissioned by the Clinical Services' Committee of the British Society of Gastroenterology for clinicians and allied professionals caring for patients with IBD in the United Kingdom, provide an good clinical practice for surveillance and treatment^[67]. The guidelines state that UC patients should be advised to have a review colonoscopy 8-10 years after disease onset to check the extent of colitis. Current recommendations are for regular surveillance every 1-2 years in the second decade of the disease to yearly by the fourth decade. The recommended guidelines for the surveillance of CRC in

Table 2 Timing of surveillance colonoscopy for colorectal cancer in ulcerative colitis

| Ref. | Year | Guidelines | Beginning of surveillance (years after onset of symptoms) | Surveillance schedule |
|---|------|--|---|--|
| Van Assche <i>et al</i> ^[73] | 2013 | European Crohn's and Colitis Organization (ECCO) | 8 yr | High risk ¹ ; 1-2 yr Low risk ¹ ; 3-4 yr |
| Farraye <i>et al</i> ^[72] | 2010 | American Gastroenterological Association (AGA) | 8 yr | Extensive colitis or left-sided colitis; 1-2 yr Patients with PSC; 1 yr High-grade or low-grade dysplasia; colectomy or repeat colonoscopy within 6 mo Indefinite dysplasia; 3 to 12 mo No dysplasia; 1-2 yr |
| Kornbluth <i>et al</i> ^[70] | 2010 | American College of Gastroenterology (ACG) | 8-10 yr | 1-2 yr |
| Cairns <i>et al</i> ^[68] | 2010 | British Society of Gastroenterology (BSG) | 10 yr | lower risk ² ; 5 yr intermediate risk ³ ; 3 yr higher risk ⁴ ; 1 yr |
| Leighton <i>et al</i> ^[69] | 2006 | American Society for Gastrointestinal Endoscopy (ASGE) | 8-10 yr | 1-2 yr (indefinite dysplasia: 3 to 6 mo) |
| Eaden <i>et al</i> ^[71] | 2002 | United Kingdom | 8-10 years (pancolitis) 15-20 yr (left-sided colitis) | 3 yr (second decade) 2 yr (third decade) 1 yr (fourth decade) |

¹Low-risk is 0-2 points and high-risk is 3-4 points; Risk factor: Pancolitis, endoscopic and/or histological inflammation, pseudopolyps, and family history of CRC: each risk factor is counted with one point; ²lower risk: extensive colitis with no active inflammation or left-sided colitis; ³intermediate risk: extensive colitis with mild active inflammation or post-inflammatory polyps or family history CRC in FDR aged ≥ 50 ; ⁴higher risk: active inflammation or stricture in past 5 years or dysplasia in past 5 years declining surgery or PSC/transplant for PSC or family history CRC in FDR aged < 50 . PSC: Primary sclerosing cholangitis; CRC: Colorectal cancer; FDR: First-degree relatives.

UC by some societies^[67-75] are summarized in the Table 2. These recommend surveillance programs are summarized as follows: (1) surveillance colonoscopy should be performed during remission state; (2) initial surveillance colonoscopy for CRC should be performed 8-10 years after onset; (3) regular surveillance should be performed annually or biannually; (4) surveillance colonoscopy for patients with PSC should be performed annually from the beginning of PSC diagnosis; (5) random biopsy of four lesions might be taken every 10 cm through the colon; and (6) if dysplasia is detected, the biopsies should be reviewed by a second gastrointestinal pathologist.

The main aim of surveillance programs is to detect dysplastic alterations. The cumulative probability of developing dysplasia or CRC in UC patients was 7.7% at 20 years and 15.8% at 30 years^[13]. CRC incidence was 14 of 1000 UC patients-years' duration and the incidence of any advanced lesion was 30 of 1000 person-years' duration. When low-grade dysplasia (LGD) is detected on surveillance, there is a 9-fold risk of developing cancer and 12-fold risk of developing any advanced lesion^[76]. Among patients with LGD who undergo colectomy, 19% will already harbor CRC or high-grade dysplasia (HGD) and 30%-50% will develop advanced neoplasia over the following 5 years^[77-79]. HGD carries a 43% risk of synchronous cancer^[80].

The guidelines described random biopsy^[67]. A study

of multiple biopsies taken at colonoscopy suggested that 33 biopsies are required to give a 95% chance of detecting dysplasia^[81]. In contrast, targeted biopsies are recommended to increase the frequency of dysplasia detection, compared with random biopsies. Chromoendoscopy might improve the imagining of subtle mucosal changes that are suggestive of neoplasia, compared with standard endoscopy^[82]. Indigo carmine contrast dye highlights irregularities in the mucosal architecture, improving the precision of endoscopic diagnosis. Methylene blue stains the normal epithelium of the colon; the absence of staining might indicate the presence of neoplastic changes in the intestine. Magnifying endoscopy could assist us to further visualize the delicate surface patterns^[83].

On the other hand, some studies have highlighted the failures of surveillance colonoscopy by the guidelines^[39,84,85]. In 50%-80% of cases with colitis-associated neoplasms, the lesions are not visible upon endoscopy^[38]. It would be necessary to clarify that the surveillance systems could contribute to the decline of the mortality of UC patients.

TREATMENT FOR DYSPLASIA

Histopathological diagnosis of polypoid mucosa of UC is important with respect to clinical treatment for dysplasia. UC with HGD usually leads to a total colectomy because

of the high incidence of adenocarcinoma (42%-67% of the colectomy specimens)^[75,79,86]. When HGD in flat mucosa is the initial discovery, surgery or polypectomy is done. Polypectomy should be performed along with biopsies taken from the surrounding mucosa. If the polypectomy is confirmed as complete and biopsies of the adjacent mucosa are negative for dysplasia, a follow-up examination within 6 mo should be performed^[75,78]. If the dysplastic lesion persists or “dysplasia associated lesions or masses” (DALM) exists, a proctocolectomy should be performed^[75].

In contrast, the management of LGD is controversial^[87]. About 30%-50% of patients with LGD progressed to HGD or CRC; an unrecognized synchronous CRC may already be present in up to 20% of UC patients with LGD^[77,79], which indicates that LGD is a risk factor for CRC. In contrast, some studies have shown that patients with LGD have a lower rate of CRC than previously reported^[88].

Dysplasia found in DALM or in areas without any macroscopically visible mucosal alteration is believed to be the origin CRC^[89,90]. The guidelines also state that particular attention should be paid to DALM that harbor a high risk of progression to CRC^[71]. In addition, patients with DALM are recommended to undergo prophylactic proctocolectomy with an ileoanal pouch. By contrast, some polyps, such as adenoma-like mass (ALM), are unrelated to colitis and can be managed by endoscopic polypectomy because of less carcinogenic potential^[91].

The serrated neoplasia pathway was recently proposed in CRC^[92]. Serrated epithelial changes and sessile serrated polyps are uncommonly detected (0.2%-1%) by colonoscopy in chronic ulcerative colitis and Crohn's disease patients^[93], while Bossard *et al*^[94] found that serrated lesions, such as hyperplastic polyps and sessile serrated polyps/adenomas, accounted for approximately 7% of premalignant lesions in the inflamed mucosa of patients with IBD.

CHEMOPREVENTION

Chemoprevention refers to the use of an anti-inflammatory therapy or other substance to reduce or prevent the development of cancer. The current decreased incidence of CRC might be due to a better control of inflammation by improved medical therapy and higher rates of mucosal healing^[95]. Intervening before the development of neoplasia might be promising method to decrease cancer and prevent colectomy.

5-ASA

5-ASA, the nuclear kappa-B pathway inhibitor, is a first line agent for anti-inflammatory therapy^[96]. Continuing inflammation is a plausible mechanism causing malignant transformation; therefore, anti-inflammatory therapy might be useful for chemoprevention in UC patients. 5-ASA reduces oxidative stress, inhibits cell proliferation and promotes apoptosis^[96]. Most reports indicated that

5-ASA reduces the risk of CRC in chronic ulcerative colitis^[34,35,97,98], however, a few did not. A meta-analysis performed by Herrinton *et al*^[85] showed a protective association between the use of 5-ASA and CRC or a combined end point of CRC/dysplasia: in a pooled analysis of 334 CRC cases among patients with UC, regular use of 5-ASA reduced the risk of CRC by approximately 50%, similar to the regular use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients without UC^[99]. In contrast, several studies did not find any chemopreventive effect of 5-ASA^[100-102].

Ursodeoxycholic acid

Ursodeoxycholic acid (UDCA) may be a practical chemoprevention against colonic exposure to bile acid in patients with PSC^[103]. UDCA use was closely associated with decreased prevalence of neoplasia because UDCA reduces the colonic concentration of the secondary bile acid as a carcinogen^[104,105]. It has been reported that UDCA reduced the risk of CRC in PSC patients with IBD by 80%^[103].

Steroids, aspirin, NSAIDs

There are several studies that suggest steroids, aspirin, and NSAIDs may reduce the incidence and mortality of CRC in UC^[34,35,106].

Total colectomy

The cumulative CRC risk in patients with UC is 30%-40% at 20-30 years after onset of disease, which might suggest that total colectomy is recommend after 15 years of disease in patients with UC. However, the role for prophylactic colectomy in patients with IBD remains controversial.

FUTURE DIRECTION

Accumulating studies about UC-CRC suggest that control of long-term background inflammation and mucosal damage is vital. The use of maintenance chronic ulcerative colitis therapies could be an important strategy for reducing CRC risk in UC patients. Inflammatory stresses, such as reactive oxygen species and some free radicals, have been considered to cause genetic damages of UC epithelium. UC-CRC shows characteristic clinicopathological features. Analysis of the correlation between these genetic features and clinicopathological features might be useful to develop new therapies and to reduce the risk of UC-CRC in the future.

Abstract

The intestinal microbiota is the collection of the living microorganisms (bacteria, fungi, protozoa, and viruses) inhabiting the gastrointestinal tract. Novel bacterial identification approaches have revealed that the gastrointestinal microbiota of dogs and cats is, similarly to humans, a highly complex ecosystem. Studies in dogs and cats have demonstrated that acute and chronic gastrointestinal diseases, including inflammatory bowel disease (IBD), are associated with alterations in the small intestinal and fecal microbial communities. Of interest is that these alterations are generally similar to the dysbiosis observed in humans with IBD or animal models of intestinal inflammation, suggesting that microbial responses to inflammatory conditions of the gut are conserved across mammalian host types. Studies have also revealed possible underlying susceptibilities in the innate immune system of dogs and cats with IBD, which further demonstrate the intricate relationship between gut microbiota and host health. Commonly identified microbiome changes in IBD are decreases in bacterial groups within the phyla *Firmicutes* and *Bacte-*

roidetes, and increases within *Proteobacteria*. Furthermore, a reduction in the diversity of *Clostridium* clusters XIVa and IV (i.e., *Lachnospiraceae* and *Clostridium coccooides* subgroups) are associated with IBD, suggesting that these bacterial groups may play an important role in maintenance of gastrointestinal health. Future studies are warranted to evaluate the functional changes associated with intestinal dysbiosis in dogs and cats.

Microbiota alterations in acute and chronic gastrointestinal inflammation of cats and dogs. *World J Gastroenterol* 2014; 20(44): 16489-16497 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i44/16489.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i44.16489>

INTRODUCTION

The intestinal microbiota is the collection of the living

microorganisms (bacteria, fungi, protozoa, and viruses) inhabiting the gastrointestinal (GI) tract. Novel bacterial identification approaches have revealed that the gastrointestinal microbiota of dogs and cats is, similarly to humans, a highly complex ecosystem, comprising at least several hundred different bacterial phylotypes^[1-3]. It has been suggested that the intestine of mammals is home to a total of 10^{10} - 10^{14} microbial cells, which is approximately 10 times more than the number of host cells. This complex microbial ecosystem and its interplay with eukaryotic host cells have a significant impact on health and disease of dogs and cats. The stimulation of the host immune system and the microbial metabolites produced by the resident microbiome are thought to be one of the most important driving forces behind the coevolution of gastrointestinal microbiota with their host. Gut microbes aid the host by acting as a defending barrier against enteropathogens. They also aid in digestion of complex fiber sources and produce various short-chain fatty acids and other metabolites that provide nutritional support for enterocytes, and which play an important role in the development and regulation of the host immune system^[4,5].

Several studies in dogs and cats have demonstrated that acute and chronic gastrointestinal diseases, including inflammatory bowel disease (IBD), are associated with alterations in small intestinal and fecal microbial communities^[6-14]. Of interest is that these alterations are generally similar to the dysbiosis observed in humans with IBD or animal models of intestinal inflammation^[15-20], suggesting that microbial responses in inflammatory conditions of the gut are conserved across mammalian host types, and dogs and cats may serve as models to study therapeutic approaches to spontaneous inflammatory conditions of the gastrointestinal tract. Recent data support this model, as it has been shown that for example probiotic products (*i.e.*, VSL#3 strains) show similar clinical benefits in dogs with IBD as have been previously demonstrated in humans^[21].

Studies have also revealed possible underlying susceptibilities in the innate immune system of dogs and cats with IBD, which further demonstrates the intricate relationship between gut microbiota and host health^[10,22-25]. Currently, a major hurdle for a more detailed understanding of host-microbe interactions in dogs and cats is the fact that to date most studies evaluating microbiota in GI diseases have examined only a single time point or have evaluated only a small number of diseased animals.

Yet the possibility to alter the microbiome holds promise as a therapeutic mean in veterinary medicine, and recent studies would confirm that direct or indirect manipulations of the intestinal microbiome *via* antibiotics, diet and/or probiotics may have beneficial effects in gastrointestinal diseases of dogs and cats^[21,26-29].

INTESTINAL MICROBIOTA IN HEALTHY DOGS AND CATS

Various studies have evaluated the bacterial communities

in healthy dogs and cats using either traditional bacterial culture or novel next-generation sequencing approaches. Based on traditional bacterial culture, the small intestine of dogs and cats harbors generally low bacterial counts, ranging between 10^2 to 10^5 cfu/g of small intestinal content; however, some studies have identified much higher counts in healthy dogs and cats with up to 10^9 cfu/g^[30,31]. Cats appear to have higher counts of anaerobic bacteria compared to dogs in the proximal small intestine^[31]. The total bacterial count in the colon ranges between approximately 10^9 and 10^{11} cfu/g and the most abundant cultivable groups are *Bacteroides*, *Clostridium*, *Lactobacillus*, *Bifidobacterium*, and *Enterobacteriaceae*^[32,33]. Next-generation sequencing studies of the 16S rRNA gene have described the canine and feline microbiome, which on higher phylogenetic levels resembles the microbiome of humans and other mammals. On average, 10 different bacterial phyla have been identified in the feline and canine gut, with *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, *Fusobacteria*, and *Actinobacteria* making up the vast majority of all gut microbes^[1,3,11,34-36]. Minor abundant members are the phyla *Tenericutes*, *Verrucomicrobia*, *Cyanobacteria*, and *Chloroflexi*. The *Firmicutes* contain various sequences affiliated with *Clostridium* cluster IV and *Clostridium* cluster XIVa and these are together with *Bacteroides* or *Prevotella* the predominant bacterial groups in fecal samples^[3,35,37]. *Helicobacter* are the predominant group in the stomach (> 90% of sequencing reads)^[38], while the duodenum is home to *Enterobacteriaceae*, *Clostridiales*, *Bacteroidales*, and *Lactobacillales*^[36].

The canine^[39] and feline^[40,41] fecal metagenomes (*i.e.*, shotgun sequencing of genomic DNA) have also been studied. This approach yields information regarding microbial genes present in a sample, and allows assessment of the functional capabilities of the microbiota, summarized in Figure 1. Despite variation in the microbial populations of cats and dogs, the functional capabilities are noted to be highly conserved.

More detailed overviews about the canine and feline microbiota in healthy animals have been reported previously^[42-45].

MICROBIOME IN GASTROINTESTINAL DISEASES OF DOGS AND CATS

In recent years, the GI microbiota has garnered strong interest due to the potential etiopathologic role in host health and disease. Many studies in humans and animal models have suggested that various GI disorders are associated with alterations of the GI microbiota. While specific enteropathogens have been recognized in cats and dogs (*i.e.*, *Campylobacter jejuni*, *Clostridium difficile*, *Clostridium perfringens*, and *Salmonella*), most of them are found in similar frequency across healthy animals. Therefore, their cause-effect relations remain unclear^[46,47]. It is now well recognized that more broad changes in the intestinal microbiome are associated with acute and chronic GI disease. Examples of recent studies in companion ani-

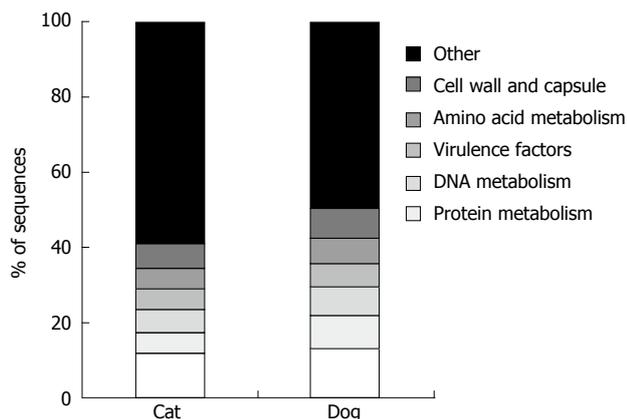

Figure 1 Relative proportion of major microbial gene functions in cats and dogs. Metagenomic data adapted from Swanson *et al.*^[39], Barry *et al.*^[40], and Tun *et al.*^[41].

mals and their findings are summarized in Table 1. The cause-effect relationships of the alterations are still being elucidated, but especially in chronic enteropathies such as IBD there is now strong evidence that the gut microbiota plays an important part in the pathogenesis of the disease. Studies in humans have shown an association between IBD and microbial dysbiosis in the intestine. In these studies, a decrease in the bacterial phyla *Firmicutes* and *Bacteroidetes*, and an increase in *Proteobacteria* and *Actinobacteria* were associated with IBD^[16]. Furthermore, a reduction in the diversity of *Clostridium* clusters XIVa and IV (*i.e.*, *Lachnospiraceae* and *C. coccooides* subgroups) are associated with IBD, suggesting that this bacterial group may play an important role in maintenance of gastrointestinal health, possibly due to production of short chain fatty acids (SCFA). Similar studies have now been reported in dogs and cats with IBD, and a comparison of the observed microbial shifts for humans, dogs, and cats with IBD is provided in Table 2.

Microbiota alterations in canine and feline IBD

In veterinary medicine, chronic enteropathies with intestinal inflammation are commonly seen in dogs and cats. The response to treatment is used to allow for distinction of different types of enteropathies, such as food-responsive diarrhea, antibiotic-responsive diarrhea, and steroid-responsive diarrhea. Idiopathic IBD is a subgroup of enteropathies and it is defined as an inflammation of the GI tract with persistent or recurrent GI signs due to unknown cause^[48]. To diagnose IBD, known causes for GI inflammation need to be excluded. Therefore, empirical treatments are applied sequentially, starting with a dietary trial, followed by antibiotic therapy if there is a lack of response to diet, and finally, treatment with anti-inflammatory drugs, if response to previous treatments was inadequate. Similarly to human IBD, the exact pathogenesis of canine/feline IBD is unknown, but is suspected to be the result of an abnormal interplay between an altered intestinal microbiota, an underlying genetic susceptibility of the host, and dietary and/or en-

vironmental factors^[48]. Consequently, several studies have revealed possible underlying susceptibilities in the innate immune system of dogs and cats with chronic GI inflammation. These include altered differential expression of Toll-like receptors (TLR)-2 and 4^[25,49], single nucleotide polymorphisms that lead to hyper-responsiveness of TLR-5 to flagellin in German Shepherd dogs (GSDs)^[22], and decreased expression of CD11c(+) cells in dogs with IBD^[50]. There is also well known anecdotal evidence that certain breeds are more prone to chronic GI inflammation. In addition to GSDs, which have been shown to possess polymorphisms in the TLR-4 and TLR-5 genes that are significantly associated with IBD^[51], other dog breeds such as Rottweiler, Border Collie, Boxer dog, and Weimaraner have been shown to possess increased risks for developing IBD^[23]. Of those breeds, breed specific studies evaluating the association between mucosa-adherent microbiota and intestinal inflammation were performed only in GSDs and Boxer dogs. In GSDs with chronic intestinal inflammation, the mucosa-adherent microbiota were analyzed in small intestinal brush samples and showed a significant over-representation of *Bacilli* and *Erysipelotrichi* when compared to healthy Greyhound dogs^[6]. Interestingly, this is somewhat different to the results observed in other studies where more diverse populations of dogs with chronic intestinal inflammation were evaluated. In these studies, the most frequently observed changes in the mucosa-adherent microbiota in the small intestine were increases in members of the *Proteobacteria*, especially *Escherichia coli*-like organisms^[9] or *Pseudomonas*^[8], with concurrent decreases of members of *Firmicutes* and *Bacteroidetes*. In a more recent study evaluating mucosa-adherent microbiota in the duodenum of dogs with IBD by next-generation sequencing, the proportions of *Fusobacteria*, *Bacteroidaceae*, *Prevotellaceae*, and *Clostridiales* were significantly increased in healthy dogs. In contrast, specific bacterial genera within *Proteobacteria*, including *Diaphrobacter* and *Acinetobacter*, were either more abundant or more frequently identified in dogs with IBD^[7]. One study evaluated specifically the presence of *Mycobacterium avium* subspecies *paratuberculosis* in duodenal biopsies of dogs with IBD or intestinal neoplasia by qPCR and reported that 19% of diseased dogs were PCR positive for this organism^[52]. Less published information is available about the mucosa-adherent microbiota of cats with IBD. While sequencing methods have not yet been reported for the characterization of feline IBD, a study using fluorescent *in situ* hybridization (FISH) has revealed an increase in *Enterobacteriaceae* in duodenal biopsies of cats with IBD^[10]. Furthermore, a relationship between increased bacterial numbers and the severity of histological inflammation was observed^[10].

Several studies have evaluated the fecal microbiota in dogs and cats with chronic GI disease. In one study, cats with IBD had lower FISH counts for total bacteria, *Bacteroides* spp., and *Bifidobacterium* spp., but higher counts of *Desulfovibrio* spp. compared to healthy cats^[53]. *Desulfovibrio* spp. are a sulfate-reducing bacterial group and able to

Table 1 Reported microbial shifts in dogs and cats with gastrointestinal disease

produce hydrogen sulfides, which may be associated with the pathogenesis of feline IBD. However, another study did not identify significant differences in FISH counts

between cats with IBD and controls, although the same bacterial groups were targeted^[54]. A recent study utilized 454-pyrosequencing of 16S rRNA genes to describe

Table 2 Comparison of reported microbial shifts in inflammatory bowel disease relative to healthy subjects across species

¹Based on mucosal samples; ²Based on fecal samples; ³Granulomatous colitis in Boxer dogs and French bulldogs; ⁴Quantitative polymerase chain reaction; ⁵Fluorescent *in situ* hybridization; ⁶454-Pyrosequencing; ⁷Gene clone libraries. *E. coli*: *Escherichia coli*.

changes in fecal microbiota in cats with chronic diarrhea and their response to dietary modifications¹²⁹. Several bacterial groups correlated with improved fecal scores after therapeutic response to diet. Those included *Slackia* spp., *Campylobacter upsaliensis*, *Enterobacteriaceae* *Raoultella* spp., *Collinsella* spp., and unidentified genera within *Clostridiales* and *Lachnospiraceae*¹²⁹.

More data about the fecal microbiota are available in dogs. In one study, fecal samples from healthy dogs, dogs with acute non-hemorrhagic diarrhea, dogs with acute hemorrhagic diarrhea, and dogs with active or therapeutically controlled idiopathic IBD were analyzed by sequencing of the 16S rRNA gene¹⁴¹. Dogs with acute diarrhea, especially those with acute hemorrhagic diarrhea, had the most profound changes in bacterial groups in their microbiome. Dogs with acute hemorrhagic diarrhea had significant decreases in *Blautia*, *Ruminococcaceae* including *Faecalibacterium*, and *Turicibacter* spp., and significant increases in genus *Sutterella* and *C. perfringens* compared to healthy dogs. In another recent study, the fecal microbiome of healthy dogs, dogs with chronic enteropathies, and dogs with acute hemorrhagic diarrhea was evaluated by qPCR assays for selected bacterial groups¹⁵⁵. The most pronounced changes were decreases in *Faecalibacterium* spp., *Turicibacter* spp., and *Ruminococcaceae* in CE and AHD. *E. coli* and *C. perfringens* were significantly increased in CE and AHD¹⁵⁵. Especially *Faecalibacterium* spp. is an important group that frequently appears depleted in canine GI disease. This has been confirmed in another study evaluating the fecal microbiota of dogs with idiopathic IBD, in which *Faecalibacterium* spp. was the major bacterial group decreased in diseased dogs¹²¹. Noteworthy, *Faecalibacterium* spp. correlated with improvement in clinical activity index, suggesting that *Faecalibacterium* spp. may be important for canine GI health, and also may be useful as a monitoring marker for improvement of fecal dysbiosis^{14,21}.

While the above discussed studies have reported

changes in microbial groups in GI disease of dogs and cats, only limited information is available about the metabolic consequences that are associated with this dysbiosis, as currently no comprehensive functional studies have been reported in dogs or cats. Alterations in the composition of intestinal microbiota are thought to be an important factor in the pathogenesis of chronic GI diseases. It can be hypothesized that the observed microbiome changes may lead to altered intestinal barrier function, damage to the intestinal brush border and enterocytes, an increased competition for nutrients and vitamins, and to an increased deconjugation of bile acids. Of interest is that commonly depleted groups in GI disease are *Lachnospiraceae*, *Ruminococcaceae*, and *Faecalibacterium*. These bacterial groups, important producers of SCFA, may play an important role in maintenance of gastrointestinal health, as their depletion leads to decreased production of SCFA (e.g., butyrate, acetate), which may impair the capability of the host to down-regulate aberrant intestinal immune response. The importance of some of these bacterial groups that are depleted in IBD have recently been demonstrated in humans. For example, *Faecalibacterium prausnitzii* is consistently reduced in human IBD and this bacterium has been shown to secrete metabolites with anti-inflammatory properties, thereby down-regulating interleukin (IL)-12 and interferon gamma and increasing IL-10 secretions¹⁵⁶. Disturbances may result in a dysregulation of adaptive immune responses, and lead to inflammation and/or reduced activity against infection. Also, some bacteria produce various toxic agents such as ammonia, D-lactate, endotoxin (LPS), or exotoxin (enterotoxin), and compete for vitamins or other nutrients. Consequently, depletions in serum vitamin B12 concentrations and also increases in serum concentrations of D-lactate are potential consequences of intestinal dysbiosis in cats¹⁵⁷. However, more comprehensive metabolomics studies are needed in companion animals to elucidate the consequences of

the dysbiosis observed in GI disease.

Invasive and adherent bacteria

A specific form of colitis occurs in Boxer dogs^[58] and occasionally also in French Bulldogs^[59]. This disease is termed granulomatous colitis. Microbiota analysis based on sequencing of 16S rRNA genes in combination with FISH has revealed invasive bacteria in the colonic mucosa of Boxer dogs with granulomatous colitis. Based on comparative 16S rRNA gene analysis, these bacteria have high phylogenetic similarity to *Escherichia coli* (*E. coli*) and *Shigella*. *In situ* analysis with 16S rRNA gene based FISH probes against *E. coli* showed multifocal clusters of invasive bacteria within macrophages in the colonic mucosa^[58]. The eradication of these invasive *E. coli* in Boxer dogs and French Bulldogs with granulomatous colitis correlates with clinical remission, inferring a causal relationship between these bacteria and the disease^[59]. Of interest is that these observed phylotypes of *E. coli* isolated from Boxer dogs have high phylogenetic resemblance to *E. coli* associated with Crohn's disease in humans^[16,59]. The breed specific predisposition of Boxer dogs and French bulldogs to *E. coli* associated granulomatous colitis highly suggests the presence of a genetic susceptibility that impairs their ability to fend off adherent and invasive *E. coli*.

Bacteria invading the intestinal mucosa may also be part of neutrophilic IBD in other dog breeds. Due to the recognized association of granulomatous and neutrophilic IBD with invasive bacteria, specialized testing based on FISH has been developed that allows localizing the bacteria in intestinal biopsies for better guidance of treatment decisions^[59].

ALTERATIONS IN FUNGAL MICROBIOTA

While bacteria are by far the most abundant constituents of the mammalian GI tract, it is now recognized that the gut harbors a highly diverse population of fungal organisms. FISH and shotgun sequencing studies of human and canine fecal DNA have estimated the abundance of fungal organisms and archaea as < 2% of total microbiota^[39,60]. A recent metagenomic approach estimated that the feline GI microbiota constitutes 0.02% fungi, 0.09% archaea, and 0.09% viruses^[41]. Fungi were described using pyrosequencing of the fungal 18S rRNA gene in pooled fecal samples of cats^[3], with *Aspergillus* and *Saccharomyces* being the most abundant fungal genera. A study reported the prevalence and identification of fungal organisms in the small intestine of healthy dogs and dogs with chronic enteropathies^[61]. The results indicated a high prevalence (up to 76.1% of dogs) and high diversity of fungal organisms in the canine duodenum. Furthermore, dogs with gastrointestinal disease harbored opportunistic fungal pathogens. A total of 51 different phylotypes were identified, with the most frequently observed phylotypes being *Pichia* spp., *Cryptococcus* spp., *Candida* spp., and *Trichosporon* spp.^[61].

A recent study has characterized the fungal micro-

biome (mycobiome) of 19 dogs (12 healthy dogs and 7 dogs with acute diarrhea) using fungal tag-encoded FLX-Titanium amplicon pyrosequencing^[62]. Five distinct fungal phyla were identified, with *Ascomycota* (median: 97.9% of obtained sequences) and *Basidiomycota* (median 1.0%) being the most abundant. A total of 219 fungal genera were identified across all 19 dogs with a median (range) of 28 (4-69) genera per sample. *Candida* was the most abundant genus found in dogs. However, no significant differences were observed in the relative proportions of fungal communities between healthy and diseased dogs. Therefore, additional studies are needed to elucidate the importance of fungi on intestinal health and disease of animals.

CONCLUSION

Studies using molecular approaches have provided clear evidence for alterations in microbial communities in the small and large intestine of dogs and cats with GI disorders. However, currently there is a lack of comprehensive studies evaluating the functional consequences of these alterations. A better understanding of these mechanisms will allow for the development of treatment modalities (*e.g.*, prebiotics, probiotics, metabolites) aiming at modulating microbial communities and their produced metabolites. Anecdotal case reports have reported some success using fecal transplantation in dogs with chronic diarrhea. Results of initial studies suggest that the administration of probiotic strains can be useful in dogs with GI disease. For example, probiotic strains have shown benefits in dogs with IBD^[21], puppies with acute parvoviral enteritis^[63], and adult dogs with non-specific diarrhea^[26,27]. In cats, probiotics strains have been shown to be beneficial in cats with chronic diarrhea^[28] and stress-related diarrhea in a shelter environment^[64]. However, future studies will need to evaluate how these microbial changes impact the immune and metabolic status of dogs and cats.

(CRC) that is a common disease of high economic costs in developed countries. The CRC has been increasing in recent years and its mortality rates are very high. Multiple biological and biochemical factors are responsible for the onset and progression of this pathology. Moreover, it appears absolutely necessary to investigate the environmental factors favoring the onset of CRC and the promotion of colonic health. The gut microflora, or microbiota, has an extensive diversity both quantitatively and qualitatively. *In utero*, the intestine of the mammalian fetus is sterile. At birth, the intestinal microbiota is acquired by ingesting maternal anal or vaginal organisms, ultimately developing into a stable community, with marked variations in microbial composition between individuals. The development of IBD is often associated with qualitative and quantitative disorders of the intestinal microbial flora (dysbiosis). The healthy human gut harbours about 10 different bacterial species distributed in colony forming units which colonize the gastrointestinal tract. The intestinal microbiota plays a fundamental role in health and in the progression of diseases such as IBD and CRC. In healthy subjects, the main control of intestinal bacterial colonization occurs through gastric acidity but other factors such as endoluminal temperature, competition between different bacterial strains, peristalsis and drugs can influence the intestinal microenvironment. The microbiota exerts diverse physiological functions to include: growth inhibition of pathogenic microorganisms, synthesis of compounds useful for the trophism of colonic mucosa, regulation of intestinal lymphoid tissue and synthesis of amino acids. Furthermore, mucus seems to play an important role in protecting the intestinal mucosa and maintaining its integrity. Changes in the microbiota composition are mainly influenced by diet and age, as well as genetic factors. Increasing evidence indicates that dysbiosis favors the production of genotoxins and metabolites associated with carcinogenesis and induces dysregulation of the immune response which

Abstract

Patients with inflammatory bowel disease (IBD) have an increased risk of 10%-15% developing colorectal cancer

promotes and sustains inflammation in IBD leading to carcinogenesis. A disequilibrium in gut microflora composition leads to the specific activation of gut associated lymphoid tissue. The associated chronic inflammatory process associated increases the risk of developing CRC. Ulcerative colitis and Crohn's disease are the two major IBDs characterized by an early onset and extraintestinal manifestations, such as rheumatoid arthritis. The pathogenesis of both diseases is complex and not yet fully known. However, it is widely accepted that an inappropriate immune response to microbial flora can play a pivotal role in IBD pathogenesis.

Key words: Dismicrobism; Inflammatory bowel disease; Colorectal Cancer; Dysbiosis; Eubiosis; Heat shock proteins

Core tip: Dysbiosis could be the common denominator of inflammatory bowel disease (IBD) and colorectal cancer. A well balanced gut microbiota promotes the health of colocytes through the production of important compounds and the correct modulation of immune system. Qualitative and quantitative modifications in the bacterial composition are responsible of changes in the biochemistry and in the cell cycle of colocytes. The aim of this work is to focus on the molecular mechanisms that connect dysbiosis, IBD and colorectal cancer. Experimental studies are oriented towards the discovery of new probiotic-based therapies for the treatment and prevention of inflammatory and carcinogenetic processes.

INTRODUCTION

Inflammatory bowel diseases (IBD), such as Crohn's disease (CD) and Ulcerative colitis (UC), are pathologies characterized by a chronic inflammation of the gastrointestinal tract. In UC, rectal and descending colon involvement is a typical feature whereas CD can affect any part of the gastrointestinal tract from the mouth to the anus. Their aetiopathogenesis is not yet fully understood^[1,2]. It is now well established that close interactions exist between the luminal bacterial flora and the intestinal immune cells and tissues. Such interactions are involved in the onset and progression of several diseases including IBDs and colorectal cancer (CRCs)^[3-7]. Dysbiosis of gut microflora may represent the "primum movens" of the chronic

inflammation characterizing IBD and triggering the stimulation of the immune system^[8-13]. Dismicrobism can cause alterations in the immune response and can, in particular, lead to gut associated lymphoid tissue (GALT) activation^[14]. The terms dysbiosis and dismicrobism are being used interchangeably, however, dismicrobism is sometimes more used in reference to the condition evolving consequent to the administration of antibiotics. Specifically, the microbiological imbalance (dysbiosis) causes to a modification of intercellular tight junctions^[15] leading to an effective penetration of antigens responsible of the activation of GALT with consequent tissue damage^[16]. Olsen and Co-workers tested the reactivity of intestinal T cells derived from patients with CD, UC and undetermined colitis against some bacteria. The results showed that T lymphocytes isolated from CD patients had a high reactivity against *Mycobacterium avium* compared to patients affected by UC and undetermined colitis. Moreover, the isolated T cells produced inflammatory cytokines like interferon (IFN)- γ and IL-17^[17]. These data suggest a possible involvement of *Mycobacteria* in CD immunopathology. Other bacteria belonging to *Clostridia* group, *Fusobacterium*, *Mycobacterium*, adherent invasive *Escherichia coli* (*E. coli*), *Proteus mirabilis*, *Klebsiella pneumonia* and *Proteobacteria* such as *Helicobacter spp* were found over-represented in the IBD condition^[18,19]. Nowadays several studies focus on the possibility to control IBD through the modulation of the immune system by re-establishment of eubiosis through specific probiotic mixtures. The homeostasis of the immune system is very important and involves the equilibrium between pro-inflammatory and anti-inflammatory cytokines such as IL-10 and others. Mgl1^{-/-} mice with a DSS induced colitis were studied before and after probiotic treatment. The induction of colitis in wild type mice showed a less severe phenotype compared to Mgl1^{-/-} mice and a lowered expression of IL-10 in the mutant mice, leading to the evidence that Mgl1 is involved in the regulation of IL-10 production. The results showed that *Lactobacillus* and *Streptococcus* were able to bind to Mgl1 receptor, leading to the hypothesis that these bacterial strains may be able to induce an anti-inflammatory response^[20]. These findings highlight the importance of gut microbiota both in the triggering and in the modulation of immune system in the chronic inflammatory diseases of the gastrointestinal tract.

Diagnosis of dysbiosis

There is a relatively wide spectrum of diagnostic tests used for the diagnosis of dysbiosis. They cover all four patterns of dysbiosis by analysis of both stool and urine for respective markers. Reference laboratories specializing in the evaluation of dysbiosis offer a comprehensive testing of various aspects of digestion, absorption, microbiology, metabolic markers and immunology including fetal secretory IgA and sometimes calprotectin. In addition, in some cases of medical necessity, fecal analysis may also include other standard components such as stool culture, stool parasitology and fecal occult blood^[21,22].

ETIOLOGICAL LINK DYSIOSIS TO IBD AND CRC

The etiology of IBD is linked to three basic parameters: (1) genetic predisposition; (2) a dysregulated immune response; and (3) an altered reaction to gut microorganisms. It is also well established that the mechanism of intestinal inflammation, acute or chronic, involves a complex myriad of pathogens (bacteria, viruses or fungi), chemicals, radiation, dietary components and hormones among others^[1,11,23]. It also involves another complex series interactions between immune cells (T cells B cells, NK cells, mast cells, macrophages), interleukins, bradykinins, complement system factors, prostaglandins, tumour necrosis factors, histamines, hormones and activated neutrophils products like myeloperoxidase, radicals and oxydants^[1,23]. In some cases, the body's reaction is not enough to rid itself from etiological agents and infecting organisms. The reaction persists as a chronic inflammation which proliferates into multiple complications, escalating the damage, especially in genetically susceptible individuals. The big question is how could this chronic inflammation progress and express itself, and how could its complications lead to the formation of cancerous cells? It is well documented that patients with this condition are more prone to the development of malignancy and that the microbiota could sustain the chronicity of the inflammatory state in the presence of a dysregulated immune response^[3,6]. Such a persistent inflammation is believed to play a significant role in CRC development^[24-26]. Studies in this field reported underlying genetic, proteomic, and epigenetic changes in IBD's and CRC's. Individuals with IBD have mostly permissive rather than causative genes^[23].

In CD, an early discovery on chromosome 16 (*IBD 1* gene) led to the identification of 3 single nucleotide polymorphisms (2 missense, 1 frameshift) in the *NOD2* gene (now called CARD 15 is a polymorphic gene involved in the innate immune system and has more than 60 variations, of which 3 play a role in 27% of patients with CD, primarily in patients with ileal disease. Another early genome-wide association study looked at Jewish and non-Jewish case-control cohorts and identified 2 single nucleotide polymorphisms in the *IL23R* gene, which encode 1 subunit of the interleukin-23 receptor protein. Actually, 21 new loci were identified with an increased risk of developing CD such as the genes *CCR6*, *IL12B*, *STAT3*, *JAK2*, *LRRK2*, *CDKAL1*, and *PTPN22*. Most of these genes are involved in signal transduction in immune function. There is also a strong support for IBD-susceptibility genes on chromosome 5p131.1 which is a gene desert but does modulate expression of the *PTGER4* gene. A murine *PTGER4* knockout model has also a significant susceptibility to severe colitis^[26,27].

In UC, however, the genetic predisposition is less than that of CD. Actually, there is a set of genetic susceptibilities that show significant overlap with CD. A recent genome-wide association study found a

previously unknown susceptibility locus at *ECM1* and showed several common risk loci between UC and CD. Genes that are a risk of both diseases appear to have an influence on the immune environment of the intestine^[28].

Further susceptibility loci for UC have been found on 1p36 and 12q15. The 1p36 single nucleotide polymorphism is located near the *PLA2G2E* gene; involved in releasing arachidonic acid from membrane phospholipids, which leads to other pro-inflammatory lipids. The first 12q15 signal is located near the interferon (*IFN*)- γ , interleukin (*IL*)-26, and *IL-22* genes, whereas the second 12q15 signal is located in *IL-26*. These genes have roles in the immune response to pathogens as well as the tissue inflammation processes. It was also shown that genetic predisposition increases the risk for one form of IBD while decreasing that of the other^[27].

Chlorinated adducts of DNA and RNA, which are generated from reaction with MPO products, are associated with repetitive infiltration of neutrophils and macrophages to the site of inflammation. Furthermore, these chlorination products increased in amount as the inflammatory state lengthened. Importantly, infiltration by these innate immune cells was accompanied by cancer initiation and progression. Actually, the contributing factors to the onset of colon carcinoma were infiltration of phagocytes and macromolecular damage to DNA and RNA (chlorination) mediated by neutrophil activity. In cases of UC, *IL-8*, *Cl-Tyr*, *SAA*, *CRP*, procalcitonin, *G-CSF*, and tissue plasminogen activator have been identified, whereas for CD cases, procalcitonin, *SAA*, *Nitro-Tyr*, and *IP-10* were identified as the most influential factors^[23].

Albumin is the most abundant chlorinated species found in serum; it is synthesized and released in the liver, indicating the liver as a possible site for innate cell activation in IBD patients, and therefore a possible source of the chlorination and nitration products observed in serum. This finding suggests that 5-Cl-dC may be a contributing factor in the initiation of colon carcinogenesis through either mutational or gene silencing mechanisms. In addition, two interesting proteins were identified from a proteomics study: Orosomucoid 2 ("1-acid glycoprotein 2) and Peptidylglycan recognition protein 2 (*PGRP2*, also named *N-acetylmuramoyl-L-alanine amidase*). Association of orosomucoid 2 with UC disease activity was not established, but it was associated with development of colorectal cancer^[23].

Concerning colorectal cancer, it has been reported for several decades that carcinomas mostly develop from adenomas and chronic inflammations. In 1988, Vogelstein described four specific mutations that accumulate during the progression of adenomas to carcinomas. These mutations seem to involve gatekeeper genes, which enable genetic or epigenetic instability and support tumor growth^[29].

Various factors have been shown to be responsible for the accumulation of mutations in CRC including inheritance and environmental factors (*e.g.*, composition

of diet, obesity, diabetes mellitus, smoking, alcohol consumption) as well, besides the fact that chronic inflammation sustained by microbial flora is regarded as an important risk factor for the development of cancer^[30].

On the other hand, IL-6 is regarded as an important tumor promoting factor in many types of human cancer including glioma, lymphoma, melanoma as well as breast, ovarian, pancreatic, prostate, renal and, colorectal cancer^[29,31].

Various studies have found an increased expression of IL-6 in patients with CRC, where IL-6 levels are elevated in the serum of patients and in tumor tissue itself. According to a review article by Knupfer and Preiss, IL-6 expression can be associated with tumor stage, size, metastasis and survival of patients with CRC^[32].

Many studies have revealed that IL-6 is an important regulator of IBD pathogenesis, mainly through its effect on immune cell function in the gut. IL-6 trans-signalling has been shown to activate T cells in the lamina propria of patients with IBD and induces resistance of these cells against apoptosis through upregulation of anti-apoptotic factors such as Bcl-2 and Bcl-xl. IL-6 is deemed to act as a link between chronic inflammation and tumor development due to its increased expression in IBD patients^[29].

Dysbiosis and diet

There is a myriad of factors, in addition to intestinal microbiota, that play a crucial role in the development of IBD and CRC. An altered microbiota, termed dysbiosis, could lead to altered immune functions and increased risk of disease^[33]. The influence of diet on the composition of the microbiota has been well documented during the initial colonization phase, postnatally and beyond, even in adult life^[34]. Several studies demonstrated that dietary factors have a dominating role in altering the microbial community resulting in biological changes to the host. Actually dietary changes could explain 57% of the total structural variation whereas genetic factors accounted for less than 12%^[35]. For example, the “Western” diet, which is high in sugar and fat, causes dysbiosis affecting both gastrointestinal (GI) metabolism and immune homeostasis^[30]. Vegetarianism, which is high in fibers, results in increased short chain fatty acid production by microbes leading to a decrease in intestinal pH and consequently preventing the growth of potentially pathogenic bacteria such as *E.coli* and members of the Enterobacteriaceae^[36]. In brief, it is becoming well documented that the microbiota could be modified through dietary factors to enrich beneficial microbes and prevent diseases associated with dysbiosis or promote such diseases like; IBDs metabolic diseases like diabetes, obesity as well as irritable bowel syndrome, celiac disease and also CRC. Diet-induced dysbiosis affects disease susceptibility^[37].

Understanding how extrinsic factors such as diet alter disease susceptibility through modification in the microbiota could shed light onto the function of

microbes in healthy and diseased individuals. A strong and well documented correlation exists between the composition of the gut microbiota and diet. In general, dietary change could explain most of the total structural variation in gut microbiota in metabolic syndrome repeats^[35].

Such microbial changes in the GI tract have profound effects on host inflammatory and metabolic responses. So far, it is not known for sure whether diet-induced dysbiosis is a transient or long-term event^[38]. This is a very dynamic area of research since dietary choices are proven to modify the ecology of intestinal microbiota which could increase susceptibility to disease like, IBD and CRC.

Dysbiosis in CRC

The next-generation sequencing and taxonomic studies, based on ribosomal 16S bacterial genes, give a clearer picture of the microorganisms inhabiting our intestine in physiological and pathological conditions, although a healthy core microbiota has not been clearly identified. The microbiota analysis on tissues and fecal materials has identified various microbial groups associated with CRC. Stool samples derived from CRC patients harbour a higher population of bacteria belonging to the group *Bacteroides-Prevotella* compared with normal controls^[24]. Another study showed an enrichment in the luminal compartment of CRC patients compared to controls of bacteria belonging to *Enterococcus*, *Escherichia*, *Shigella*, *Klebsiella*, *Streptococcus*, and *Peptostreptococcus*, and a depletion of bacteria belonging to *Lachnospiraceae* family (butyrate-producing bacteria)^[25,39]. CRC is a multi-step process that includes adenoma formation. Studies of microbiota on intermediate stages revealed an increased abundance of *Firmicutes*, *Bacteroidetes*, and *Proteobacteria* at the intestinal mucosal surface in patients with adenoma compared with non-adenoma subjects^[34]. Moreover, resected tissues from adenocarcinoma patients and adjacent non-malignant sites showed expansion of the phyla *Bacteroidetes* and reduction of *Firmicutes* in tumors compared with healthy subjects^[4]. Interestingly, through whole-genome and RNA-sequencing approaches two independent groups found a high prevalence of *Fusobacterium* (over-represented also in IBD) in colonic tissues of CRC patients compared with normal controls^[40,41].

Modulation of immune response in IBD

The intestinal microbiota is involved in aetiopathogenesis of autoimmune and allergic diseases and can also play a role in the development of CRC^[6]. Many cancers arise from sites of infection and chronic inflammation. The strongest association of chronic inflammation with malignant diseases is found in inflammatory bowel diseases of the colon with a lifetime incidence of 10% or more. Thus, patients with IBD have a higher risk of CRC occurrence^[1,42]. Both innate and adaptive immune responses have been involved in the pathogenesis of IBD. The first one involves particular receptors

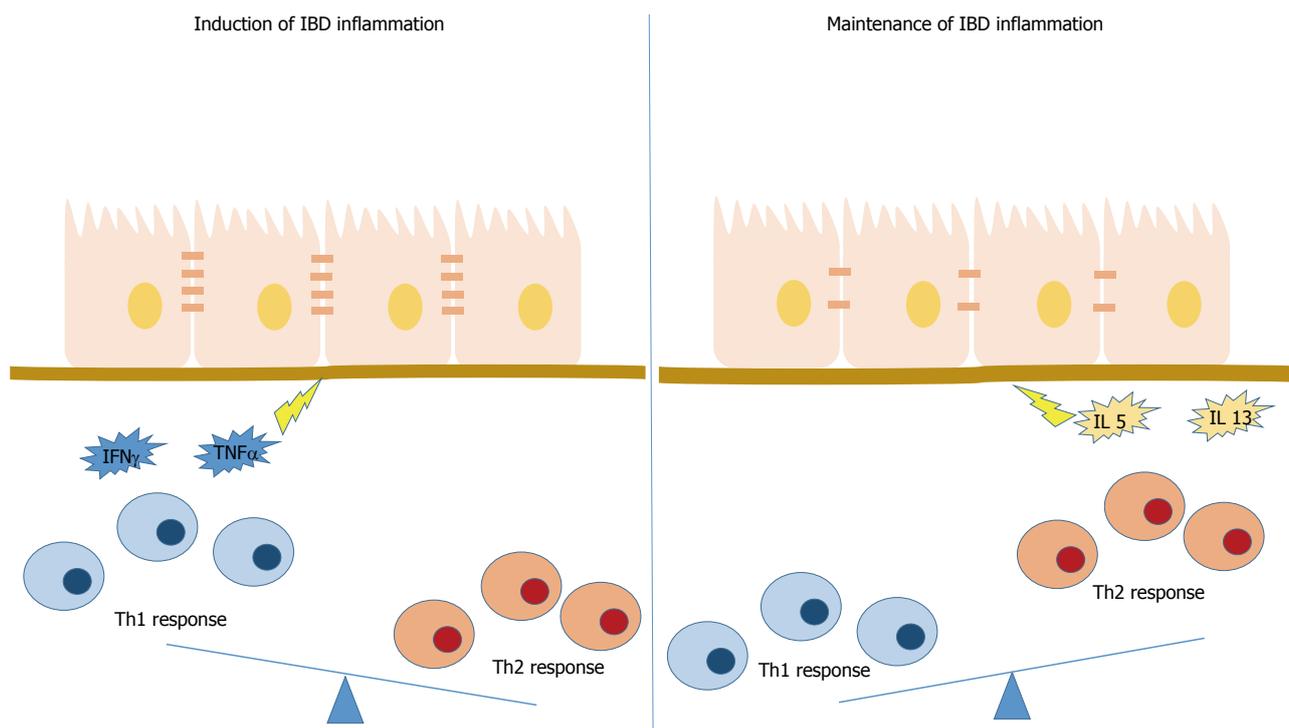

Figure 1 One hypothesis on the initiation of the inflammatory process in inflammatory bowel disease bases on an abnormal Th1 response mediated by the secretion of interferon gamma and tumor necrosis factor- α while the chronic inflammation is supported by interleukin-5 and interleukin-13 secreted by Th2 cells. IFN: Interferon; TNF: Tumor necrosis factor; IL: Interleukin; IBD: Inflammatory bowel disease.

called Toll like receptors or PRR (Pattern recognition receptors). It has been considered as an impairment of the innate immune response rather than an excessive activation, which may be involved in the development of CD. In fact some genes such as *NOD2* (an intracellular PRR involved in the recognition of the bacterial muramyl dipeptide) showed mutations consisting in a loss rather than a gain of function^[43]. Regarding the adaptive immune response, IBD is characterized by dysregulated T lymphocyte effector cells, and shows a Th1 and Th17 activation to the endogenous microbiota, and a lack of immune suppression typically afforded by Tregs^[44]. CD is considered a disease with an increased Th1 response while UC is a Th2-mediated disease. This paradigm relies on evidence showing that intestinal tissues derived from patients with active CD contain elevated levels of IL-12 and IL-18 (Th1-polarizing cytokines), compared with UC patients^[45,46]. Moreover, in CD patients, an increased amount of Th1 lymphocytes has been reported compared to control subjects^[45]. Evidence from studies conducted on humans and animal models suggest that the different subsets of lymphocytes play their role in different stages of IBDs^[43]. Studies of CD pathogenesis in SAMP1/YitFc mice indicate an involvement of Th1 cells in the initiation process of the disease. The establishment of chronic inflammation is supported by IL-5 and IL-13 cytokines, indicating a role of Th2 subset in this stage of CD^[47]. These data indicate that adaptive immune responses involved in IBD pathogenesis are more complex than the traditionally dichotomous Th1/Th2 paradigm (Figure 1).

Modulation of immune response in CRC

About 1%-2% of CRC patients have a pathological background consisting of intestinal mucosa inflammation^[48]. This “inflammatory background” of colonic mucosa can evolve to a less (low-grade) or more severe (high-grade) dysplasia, which through neoplastic transformation gives rise to carcinoma “*in situ*” and finally “*invasive*” carcinoma. Interestingly, many lines of evidence highlighted the importance of intestinal microbiota in the development of CRC^[42] and that the type of immune response generated by the gut commensal bacteria could potentially influence tumor immunity^[49]. Mice colonized with enterotoxigenic *B. Fragilis* exhibit colonic Th17 inflammatory infiltrates that are involved in induction of colon tumors, as indicated by inhibition of colon tumor formation following treatment with anti-IL-17 antibody^[50]. It is, therefore, possible that a microbiota favouring commensal bacteria, that induces a Th17 response, could have differential effects on tumors depending on the type of tumor or the stage of tumor development^[49]. The amount of lymphocytes infiltrated in the tumoral tissue is correlated to the prognosis of the patients affected by CRC^[51]. Among the different subsets of T lymphocytes studied in the immune system is the $\gamma\delta$ population. This lymphocytic subset is characterized by the presence of $\gamma\delta$ chains in their TCR and their representation in peripheral blood is < 10%. Since $\gamma\delta$ T cells express both natural killer receptors (NKG2D) and $\gamma\delta$ T cell receptors, they are considered as a link between innate and adaptive immunity^[52]. CRC comprises a small population of cancer stem cells (CSC) responsible for

tumor resistance to therapies. It has been observed that the treatment with the bisphosphonate zoledronate sensitizes colon CSCs to $\gamma\delta 2$ T cell cytotoxicity through the production of pro-inflammatory cytokines [IFN γ and tumor necrosis factor (TNF)- α] and granule exocytosis pathway. The $\gamma\delta$ T cells response is highly dependent on isoprenoid production by tumor cells^[53]. Isoprenoids are a class of natural compounds derived from five-carbon isoprene units assembled and modified in different ways. Most of them have multicyclic structures found in all classes of living organisms such as bacteria. These compounds are under investigation for their involvement in bacterial metabolism and immunomodulation of $\gamma\delta 2$ T lymphocytes. Isoprenoids are synthesized through the mevalonate pathway or the alternative 2C-methyl-D-erythritol 4-phosphate (MEP) pathway. It has been observed that the MEP intermediate pathway 1-hydroxy-2-methyl-2-(E)-butenyl 4-diphosphate (HMB-PP) can activate human $\gamma\delta 2$ T cells. Some pathogen bacteria such as *Campylobacter jejuni* and *Salmonella enterica* have genes involved in the MEP pathway. Since HMB-PP and other isoprenoids are able to induce activation of $\gamma\delta 2$ T cells, this metabolic feature shared by bacteria and host cells should be used to fight together dysbiosis and the tumorigenesis process of CRC.

Modulation of Heat shock proteins by gut microflora

The “chaperoning system” is a concept that was proposed in 2008^[54]. Heat shock proteins (Hsps) are cellular complexes involved in processes like folding, refolding, translocation and degradation of intracellular proteins under normal and stress conditions^[6,55]. Hsp chaperones are also involved in many cellular processes and interact with the immune system. They start to be considered as potential biomarkers of carcinogenesis, correlating their expression to the degree of differentiation and aggressiveness of certain tumors. Pathological conditions in which chaperones become etiological factors are called “chaperonopathies” and are classified into three categories: by defect, by excess, and by mistake^[56]. Commensal microbiota may affect the immune system influencing the expression of specific Hsps. In particular, Hsp60 and Hsp70, both constitute a group of auto-antigens able to trigger immune-regulatory pathways, involved also in other human inflammatory processes such as rheumatoid arthritis^[57], Type 1 diabetes mellitus^[58], atherosclerosis^[59] and allergy^[60], through the stimulation of both innate and adaptive immune responses^[61]. These proteins were found increased in both tissue and serum of patients with UC^[7]. The microbiota is able to regulate Hsp expression. Studies conducted on patients affected by IBD showed a decrease of Hsp60, Hsp10 and Hsp70 in epithelium and lamina propria after a combined therapy of 5- amino salicylic acid plus probiotics (*Lactobacillus Salivarius*, *Lactobacillus Acidophilus*, and *Bifidobacterium Bifidum*)^[62]. Treatment of gut epithelial cells with *Lactobacillus GG* showed an increase in Hsp25 and Hsp72 (considered as cytoprotective Hsps) in a time

and concentration dependent manner. These data suggest that the microbiota is able to influence Hsps expression in colocytes.

Double role of microbiota: Prevention or promotion of carcinogenesis

Gut microflora has a great importance; it influences the colonocyte's life under multiple aspects. In certain groups of individuals, the onset of CRC is strongly related to diet and composition of the microbiota^[42]. The aforementioned correlation could be explained through the anticancer effects of bioproducts of microflora metabolism^[63]. Small-chain fatty acids (SCFAs), particularly butyrate, formed from the bacterial fermentation of indigestible carbohydrates, are nutrients and growth signals for the intestinal epithelium and may play a role in CRC prevention^[64]. In normal colonocytes, butyrate prevents apoptosis and subsequent mucosal atrophy^[10,65]. In contrast, in colon carcinoma cells, butyrate exerts a protective role against the onset of colonic cancer stimulating differentiation, inhibiting cell proliferation, inducing apoptosis and inhibiting angiogenesis^[66]. The role of butyrate resides in its effects on enzymatic functions such as the inhibition of the histone deacetylase. This enzyme is responsible of the maintenance of the acetylated state of the histones. Acetylation is important for the access to the chromatin by the enzymes responsible of the transcription of important genes such as those involved in the inhibition of tumorigenesis (*p21/Waf1*)^[67]. Inhibition of histone deacetyltransferases enzymes (HDAC) is one of the therapeutic approaches used in anticancer therapy. Microbial metabolism of cruciferous vegetables or garlic leads to the production of compounds such as sulforaphane N-acetyl-cysteine, allyl mercaptan and butyrate. Thus, microbe-derived metabolites can counteract the carcinogenetic process by triggering cell cycle arrest and apoptosis of tumoral cells through interference with HDAC activity^[10,68]. Endoluminal accumulation of toxic compounds can exert a mutagenic action on intestinal mucosa. The microbial fermentation of charred meat leads to the production of polyheterocyclic amines (PAH). These compounds are able to damage the DNA of colonocytes. Bacteria belonging to the *Clostridium* species are able to convert the bile acids into secondary products like deoxycholic acid (DCA). This compound is capable to induce the carcinogenesis process^[69]. Tumorigenesis is a multi-step process in which the damage in the DNA is the essential pre-condition for tumoral induction. *E. coli* has a genic cluster called Pks that encodes for a toxin called calibactin. This was illustrated in studies conducted in mice which are not able to produce IL-10. They were treated either with one strain of *E. coli* in which Pks was deleted and the others with the wild type strain. The results of this experiment showed that the genic cluster Pks was only able to induce damage on the DNA (assessed through the presence of H2AX marker) but not sufficient to induce

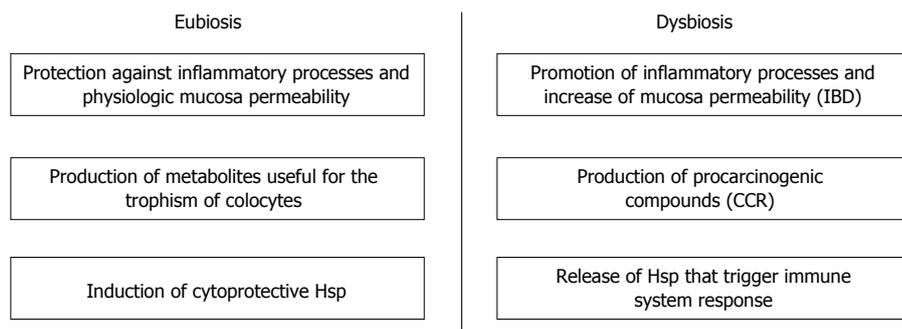

Figure 2 Eubiosis and dysbiosis exert different biochemical effects in the context of colocytes pathophysiology. IBD: Inflammatory bowel disease.

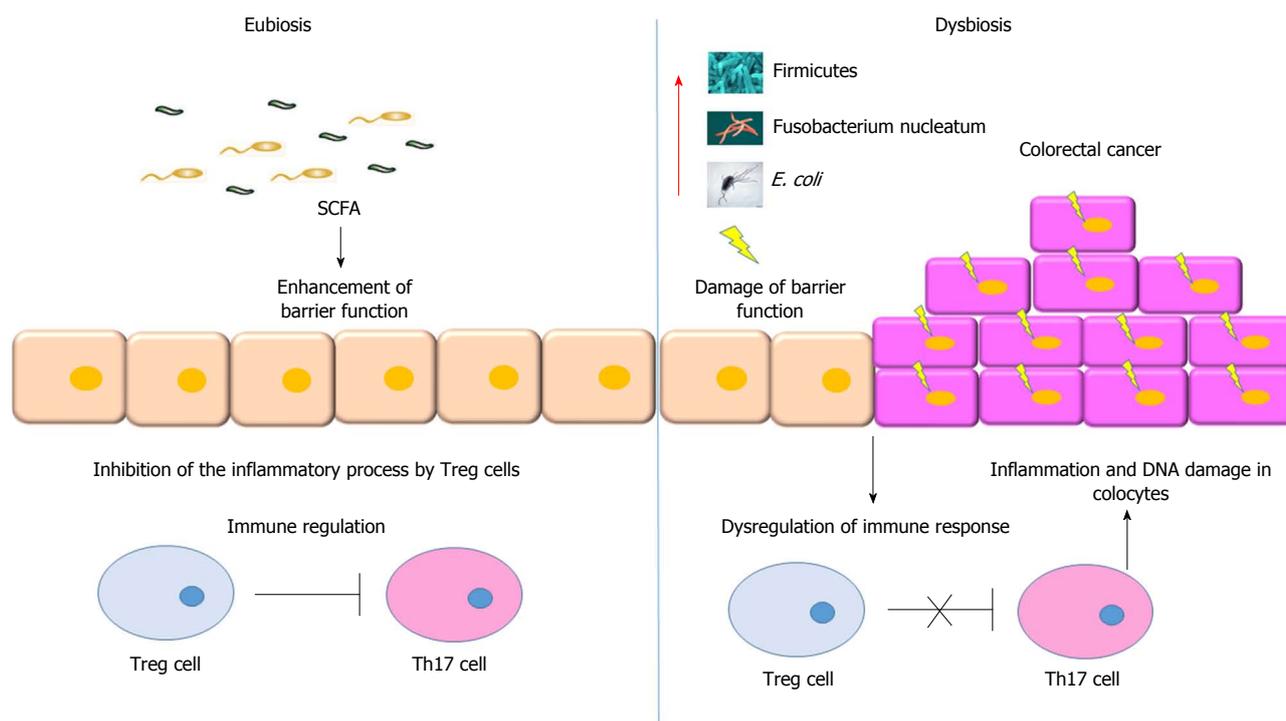

Figure 3 At eubiosis stage, the intestinal epithelium hosts a rich and equilibrated microbiota that promotes the barrier function. Microbial dysbiosis favors the production of genotoxins and metabolites associated with carcinogenesis. Moreover dysbiosis induces dysregulation of immune responses that cause inflammation promotion of carcinogenesis. SCFA: Small-chain fatty acids; *E. coli*: *Escherichia coli*.

rectal carcinogenesis^[65,70]. Experimental data show that consumption of omega-3 polyunsaturated fatty acids is able to decrease the incidence of sporadic colorectal cancer. Eicosapentaenoic free fatty acid reduces polyp formation and growth in models of familial adenomatous polyposis^[71]. The intake of docosahexaenoic acid can modify the gut microflora. Breast milk is rich in omega-3 fatty acids. Some studies showed that *Bifidobacteria* are more represented in breastfed infants rather than in formula-fed infants. In another study, it was shown that the supplementation with fish oil is able to determine changes in *Bacterioidetes* among children 9-18 mo old^[72]. An understanding of the comprehension of the correct equilibrium in the prevalence of the different bacterial strains composing human microbiota may represent one of the keys for the better understanding of CRC etiopathogenesis. In fact, bacterial metabolism has a high impact on the biochemistry of colocytes (Figure 2). This field of study may open the road to therapies oriented

not only towards specific probiotic-based therapies but also to targeted “prebiotic-based” approaches for the prevention or treatment of CRC.

CONCLUSION

The role of environmental factors involved in CRC aetiopathogenesis remains to be fully elucidated. The qualitative and quantitative modifications of the microbiota can make people more susceptible to develop IBD. In fact, these changes can trigger the production of inflammatory mediators in the mucosa that, in a large temporal window, can also exert a pro-carcinogenic role. The immunological and biochemical evidences related to dysbiosis allow the global comprehension of the background on which relies the development of CRC (Figure 3). These findings suggest a close connection between dysbiosis, IBD and CRC. Up till now, the direct or indirect role of bacteria in the induction of genomic

damages in colocytes is not fully confirmed. Several clinical trials have focused the preventive and therapeutic action of probiotics in the treatment of digestive diseases. Probiotics could inhibit the inflammatory and the carcinogenic processes through several pathways including the re-equilibration of the host immune responses and through the anti-proliferative activity on tumor cells. However, further clinical studies seem necessary to clarify the complex interplay between dysbiosis, inflammation and CRC.

Abstract

Inflammatory bowel disease (IBD) is a chronic inflammatory disease thought to be mediated by the microbiota of the intestinal lumen and inappropriate immune responses. Aberrant immune responses can cause secretion of harmful cytokines that destroy the epithelium of the gastrointestinal tract, leading to further inflammation. Interleukin (IL)-22 is a member of the IL-10 family of cytokines that was recently discovered to be mainly produced by both adaptive and innate immune cells. Several cytokines and many of the transcriptional factors and T regulatory cells are known to regulate IL-22 expression through activation of signal transducer and activator of transcription 3 signaling cascades. This cytokine induces antimicrobial molecules and proliferative and antiapoptotic pathways, which help prevent tissue damage and aid in its repair. All of these processes play a beneficial role in IBD by enhancing intestinal barrier integrity and epithelial innate immunity. In this review, we discuss recent progress in the involvement of IL-22

in the pathogenesis of IBD, as well as its therapeutic potential.

Key words: Inflammatory bowel disease; Interleukin-22; Signal transducer and activator of transcription 3

Core tip: Interleukin (IL)-22 is expressed by adaptive immune system cells and innate lymphocytes. Several cytokines and many transcriptional factors and T regulatory cells can regulate IL-22 expression. Through activation of signal transducer and activator of transcription 3 signaling cascades, IL-22 induces antimicrobial, proliferative and antiapoptotic pathways, which can help fix damaged tissue and promote tissue repair mechanisms. IL-22 is also associated with inflammatory bowel disease (IBD) susceptibility genes that regulate inflammatory responses in tissues. All of these processes play crucial roles in IBD pathogenesis and collectively provide an important rationale for the development of novel therapeutic measures for this disease.

INTRODUCTION

Inflammatory bowel disease (IBD) is a group of inflammatory conditions of the small intestine and colon, and includes Crohn's disease (CD) and ulcerative colitis (UC). Despite extensive research efforts, however, the etiology of IBD remains unclear. The current opinion about IBD pathogenesis is that the disease results from interactions between environmental factors, mainly microbes of the intestinal lumen and their products,

and dysregulation of immune responses in genetically susceptible individuals^[1]. Certain harsh environments that may affect barrier integrity (to increase barrier permeability to luminal macromolecular substances, such as protein antigens and microbial products) and over-absorption of luminal microbial products (which has been ascribed to a number of mucosal pathologies) can lead to an over-activation of immune system, thus resulting in mucosal inflammation^[2].

Interleukin (IL)-22, a member of the IL-10 cytokine family which is composed of IL-10, IL-19, IL-20, IL-24 and IL-26^[3], is expressed by both the cells of the innate immune system [such as dendritic cells (DCs), lymphoid tissue inducer (LTi)-like cells and natural killer (NK) cells] as well as on the surface of adaptive lymphocytes (including CD4⁺ T cell subsets, CD8⁺ T cells and so on)^[4]. Several cytokines [such as IL-23, IL-6, tumor necrosis factor (TNF) α , IL-1 β , transforming growth factor (TGF) β and IL-17], many of the transcriptional factors (signal transducer and activator of transcription (STAT) 3, RAR-related orphan receptor (ROR) γ t and aryl hydrocarbon receptor (AhR)]^[5] and T regulatory cells (Tregs) are known for their regulation of IL-22 expression^[6]. Through activation of the Jak-STAT signal transduction pathway, IL-22 induces proliferative and anti-apoptotic pathways, as well as the production of antimicrobial peptides, which help prevent tissue destruction and assist in its repair and restoration^[7]. IL-22 is also associated with IBD susceptibility genes that are crucial for regulating tissue responses during inflammation^[8]. All of these processes play critical roles in the pathogenesis of IBD. In recent years, it was demonstrated that treatment with recombinant cytokine or gene therapy involving IL-22 can suppress the inflammatory response and alleviate tissue injury^[8,9]. Thus, these findings suggest that further research focused on IL-22 may elucidate the underlying mechanisms of IBD and facilitate the development of novel effective, targeted therapeutic approaches for IBD. This review focuses on IL-22 and its functional role in IBD.

IL-22

IL-22 signaling

The IL-22 receptor is a heterodimer composed of IL-22 receptor 1 (IL-22R1) and IL-10 receptor 2 (IL-10R2)^[10]. IL-10R2 is ubiquitously expressed by most cell types, while the expression of IL-22R1 is limited to nonhematopoietic cells (such as hepatic cells, pancreatic cells, kidney cells, epithelial cells, and skin keratinocytes)^[10,11]. Therefore, the expression profile of IL-22R1 determines how IL-22 specifically targets innate cell populations, and not adaptive immune cells^[12].

STAT3, STAT1 (in a relatively small number of cells) and STAT5 (in certain cells) were shown to be activated after IL-22 stimulation^[13]. Further analysis has also demonstrated that IL-22 signaling propagates downstream phosphorylation signals, including several

of the mitogen-activated protein kinase (MAPK) pathways (extracellular signal-regulated kinase (ERK)1/2, MEK1/2, C-Jun N-terminal kinase (JNK), and p38 kinase), and STAT1, STAT3 and STAT5 by utilizing Janus kinase (JAK)1 and tyrosine protein kinase (TYK)2^[14] (Figure 1). The capacity of IL-22 to activate JNK, ERK1/2 and p38 MAPK pathways has been implicated in liver diseases^[14]. Moreover, the strong activation of IL-22 to stimulate STAT3 has been confirmed in human colon cancer cell lines, human colonic biopsy, as well as the primary mouse colonic epithelial cells^[15,16]. In fact, a recent study has shown that, compared with IL-6, IL-22 has a stronger ability to activate STAT3^[17]. Pickert *et al*^[18] have demonstrated that in dextran sulfate sodium (DSS)-induced colitis, the activation of epithelial STAT3 is more dependent on IL-22 than on IL-6, a well known activator of STAT3. This is due to IL-22R1 utilizing its constituent C-terminal tail to interact with the coiled-coil domain of STAT3, which has been to conformed in a recent discovery as a novel mechanism to activate STAT3^[19]. Similar to other IL-10 family cytokines, IL-22 primarily relies on STAT3 to mediate its functions. Binding of cytokines to this receptor results in the activation of STAT3 signaling pathways, which in turn leads to the induction and production of various tissue-specific genes, including serum amyloid A (SAA), antimicrobial proteins (β -defensin, Reg3c and lipocalin-2) and mucins. Meanwhile, IL-22 also induces proliferative and antiapoptotic pathways in some responsive cells of certain tissues^[10,20].

Cellular sources of IL-22

Basu *et al*^[21] have suggested that both innate lymphoid cells (ILCs) and T cells produce IL-22. They showed that IL-22 produced by ILCs was strictly IL-23-dependent, and that the development of IL-22 induced by CD4⁺ T cells was *via* an IL-6-dependent mechanism that was augmented by IL-23 and was dependent on both transcription factors T-bet and AhR. At the same time, Wolk *et al*^[22] confirmed that activation of murine T cells, especially T helper (Th) 1 cells, mainly express IL-22. A novel Th subset - the Th17 cells - was identified in 2005^[23,24]. IL-17 (or IL-17A), a hallmark cytokine preferentially expressed by Th17 cells, distinguishes these cells from other Th subsets, such as Tregs, Th1 and Th2 cells^[25]. Th17 cells play an essential role in host defense, especially against extracellular bacteria and other infectious bacteria, and are involved in the pathogenesis of various autoimmune diseases^[26,27].

The level of IL-22 produced by Th17 cells is much higher than that of the production from undifferentiated Th0 cells or Th1 cells. However, the expression and regulation of IL-22 and IL-17 produced in T cells are unparalleled. Researchers have discovered that IL-6 and TGF β are both required for inducing IL-17 expression in naïve T cells, yet IL-6 alone can sufficiently promote the expression of IL-22^[28-30]. In fact, TGF β has been shown to suppresses IL-22 production in a dose-

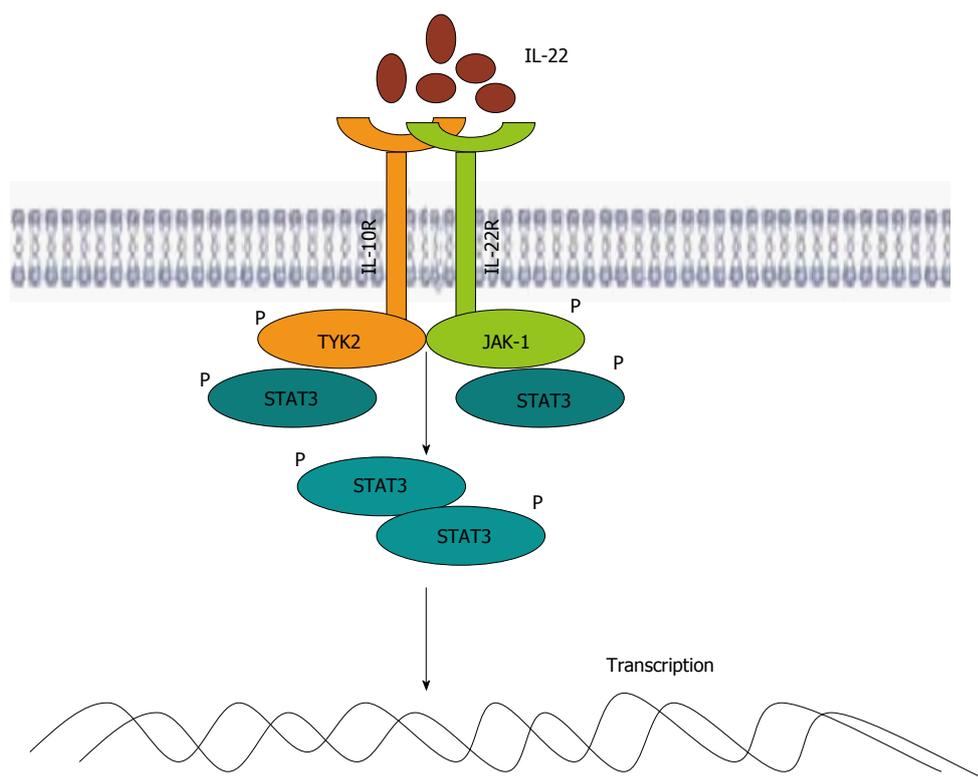

Figure 1 Interleukin-22 signaling pathway. IL-22 binds to a heterodimeric receptor composed of IL-10R2 and IL-22R1, activating JAK1 and TYK2, which self-phosphorylate, resulting in binding and phosphorylation of STAT3. Then, STAT3 translocates to the nucleus and induces target genes. IL: Interleukin; JAK: Janus kinase; TYK: Tyrosine protein kinase; STAT: Signal transducer and activator of transcription.

dependent manner^[28]. Through activation by anti-CD3 or concanavalin A (ConA), human T cells can produce IL-22^[31]. Based on studies using the lineage marker chemokine CCR6 and CCR4, human Th17 cells produced *in vitro* or purified *ex vivo* from blood were shown to preferentially express IL-22^[32,33]. Moreover, IL-17- and IL-22-expressing cells in human peripheral blood mononuclear cells (PBMCs) are defined by another surface maker, CD161^[34]. The above-mentioned Th17 cells can produce IL-22 and IL-17; in addition, CD161⁺ human CD8⁺ T cells can also generate these two cytokines^[35].

Recent studies have also demonstrated a unique cell subset, designated as the IL-22-producing CD4⁺ Th subset, in human peripheral blood, which expresses neither IL-17 nor interferon (IFN)- γ ^[36-38]. In skin, these cells mainly express CCR10. Moreover, the human IL-22-producing T cells can also be generated from naïve CD4⁺ T cells in the presence of IL-6, rather than TGF β , which is consistent with what has been reported in the mouse system^[36]. Human Langerhans cells are able to differentiate T cells into the only IL-22-producing Th cells *in vitro*^[39].

The human innate immune cell types, such as NK and LTi cells, can also produce IL-22^[40,41]. In addition to CD4⁺ T cells, the Th17 cells, CD8⁺ T cells and NK T cells also express high levels of IL-22 upon activation, especially when activation occurs along with IL-23 intervention^[28,42]. Recently, LTi cells and developmentally-

related NK-like cells (NK22), which express the NK marker NKp46, were demonstrated to be the main innate sources of IL-22 expression, especially in the intestinal tract^[43,44]. Treatment of NK cells with IL-2 and IL-12 was shown to lead to expression of IL-22^[45]. Human immature NK cells, defined as CD161⁺CD117⁺CD34⁻CD94⁻ cells, express both IL-22 and AhR^[46]. The equivalent NKp46⁺ NK-like cells in mice have been found to be developmentally linked to LTi cells^[47,48].

Finally, subsets of myeloid cells express the IL-23 receptor (IL-23R) and combine with IL-23 to release lower levels of IL-22^[49,50]; those cells that produce high levels of IL-22 may be the major cells of IL-22 origin in mucosal immunity. In contrast to the IL-22 produced by leukocytes, such IL-22 targets mainly tissue epithelial cells rather than immune cells^[51]. Although expression of IL-10R2 is widespread, IL-22R1 expression has only been detected on epithelial cells. Upon binding to its receptors on the surface of these epithelial cells, IL-22 produces an accelerating effect on the proliferation and differentiation of these cells, and induces these cells to express genes involved in host defense and wound-healing responses^[52].

These cellular functions of IL-22 underlie its crucial role in epithelial barrier defense, especially against invading extracellular bacteria. In fact, in a preclinical model of mucosal immune responses to Gram-negative bacteria, such as *Klebsiella pneumoniae* and *Citrobacter rodentium*, IL-22 played an indispensable role^[53]. Moreover, IL-22 is associated with the development of various

human autoimmune diseases^[25]. The expression of IL-22 is unregulated in autoimmune diseases, such as IBD, rheumatoid arthritis and psoriasis. IL-23 appears to be a principal inducer of IL-22 in Th17, NK or NK-like cells, suggesting that IL-22 acts a pivotal mediator in IL-23-dependent immune reactions in skin and mucosal epithelia by stimulating innate antimicrobial responses as well as promoting tissue repair^[54].

Regulation of IL-22 expression

IL-23 is a member of the IL-12 cytokine family, and its stimulation of activated T cells induces IL-22 expression^[54]. Research has found that *il23a*^{-/-} and *il22*^{-/-} mice are both highly susceptible to infection with extracellular Gram-negative bacteria, suggesting that a critical function of IL-23 in infection is to induce IL-22 expression^[55,56]. Additionally, IL-23 has been found to be important in the terminal differentiation of Th17 cells, assisting in their proliferation and effector functions^[56]. Therefore, the ability of IL-23 to enhance Th17 cell proliferation appears to be linked to IL-22 expression.

In addition to IL-23, other cytokines have been found to regulate the expression of IL-22. In cultures of purified naïve murine CD4⁺ T cells, IL-6 and T cell receptor (TCR) stimulation, or IL-6, TNF α , IL-1 β and TCR stimulation, was sufficient to induce IL-22 expression^[57]. Increasing concentrations of TGF β dose-dependently inhibited IL-22 expression while maintaining stable IL-17A expression. It has recently been demonstrated that IL-17A can partially inhibit the expression of IL-22 from Th17 cells *in vitro* and *in vivo*, indicating that Th17 cell-associated IL-17A can also negatively regulate IL-22 expression. IL-22 expression in $\gamma\delta$ T cells can also be induced independently of IL-23 and TCR stimulation by IL-1 β , as well as Toll-like receptor (TLR) 1, TLR2, and dectin-1 ligands^[54,58].

Similar to cytokine-mediated regulation of IL-22, many of the transcriptional factors are known for regulation of IL-22 expression. STAT3 is critically involved in the induction of IL-22 expression in T cells^[59]. Similarly, ROR γ t, a lineage-specifying transcription factor for the differentiation of Th17 cells, is also required for optimal expression of IL-22. STAT3 and ROR γ t both control expression of IL-23R, and this regulation may account for their ability to promote IL-22 production in Th17 cells. Therefore, many of the same transcription factors involved in Th17 cell differentiation are also required for IL-22 expression in CD4⁺ T cells^[60]. In addition, AhR is a ligand-dependent transcription factor that is best known for its role in mediating toxicity to the organic compound dioxin. AhR also partially contributes to the differentiation of Th17 cells and is required for expression of IL-22, thus linking IL-22 and Th17 cells to toxicity following exposure to different environmental compounds^[61]. A number of IL-22-producing innate cell populations have also been found to express STAT3, ROR γ t and AhR, yet the involvement of these transcription factors in regulating IL-22 expression

in innate cell populations has yet to be examined^[62] (Figure 2).

Recent studies have demonstrated a close relationship between CD4⁺Foxp3⁺ Tregs and proinflammatory IL-17-producing Th17 cells expressing the lineage-specific transcription factor ROR γ t. It has been shown that IL-17-secreting Foxp3⁺ T cells that express ROR γ t share features of conventional ROR γ t⁺ Th17 cells. However, ROR γ t⁺Foxp3⁺ Tregs mostly fail to secrete IL-22 after phorbol 12-myristate 13-acetate/ionomycin stimulation^[63]. Foxp3 transcription factor binding sites (TFBSs) in the IL-22 promoter restrain ROR γ t⁺Foxp3⁺ T cells to produce IL-22 at the transcriptional level^[64]. Despite the decreased expression of IL-22 in Foxp3⁺ Tregs, it has been found that Tregs can promote naïve T cell differentiation. In a mouse model of infection with oral *Candida albicans*, Foxp3⁺ Tregs were shown to powerfully promote the transition of naïve CD4⁺ T cells to responding CD4⁺ cells (Tresps)^[65]. Tresps markedly produce IL-22. Therefore, there is the possibility that Tregs can regulate the expression of IL-22.

IL-22 IN PATHOGENESIS OF IBD

IL-22 regulates intestinal barrier immunity

The IL-22 signaling pathway is activated through a heterogeneous receptor complex composed of two subunits, IL-22R1 and IL-10R2^[66]. Although IL-10R2 is widely expressed on almost all of the cell types, the expression of IL-22R1 is restricted to the surfaces of nonhematopoietic cells such as epithelial cells, hepatocytes and keratinocytes^[67]. This limited expression of IL-22R1 on nonhematopoietic cells allows IL-22 to specifically target innate cell populations within such tissues as the skin, kidney, digestive tract and respiratory systems^[68]. A wide variety of innate and adaptive immune cells, including CD4⁺ T cells, and most notably Th17 and Th22 cells, CD8⁺ T cells, LTI cells, NK cells and DCs, can produce IL-22^[69]. Upon binding to the IL-22R1 and IL-10R2 receptor complex, these cells produce IL-22 to activate receptor-associated JAK1 and TYK2, resulting in tyrosine phosphorylation of STAT3^[70]. This in turn allows IL-22 to induce different kinds of tissue-specific genes, including those encoding proteins involved in antimicrobial defense, cellular differentiation, and expression of mucins; a large, heavily glycosylated family of proteins in the gastrointestinal tract forms a protective layer, which serves to separate commensal bacteria from pathogenic bacteria in the epithelium layer, thereby minimizing the immune response^[71]. Through the production of antimicrobial peptides, enhancement of epithelial regeneration, and regulation of wound healing, IL-22 plays a particularly vital role in regulating intestinal inflammatory responses^[72]. Furthermore, a direct effect of IL-22 on colonic epithelium is proliferation of epithelial cells, which maintains the integrity of the intestinal epithelium.

Recent studies have focused on possible protective

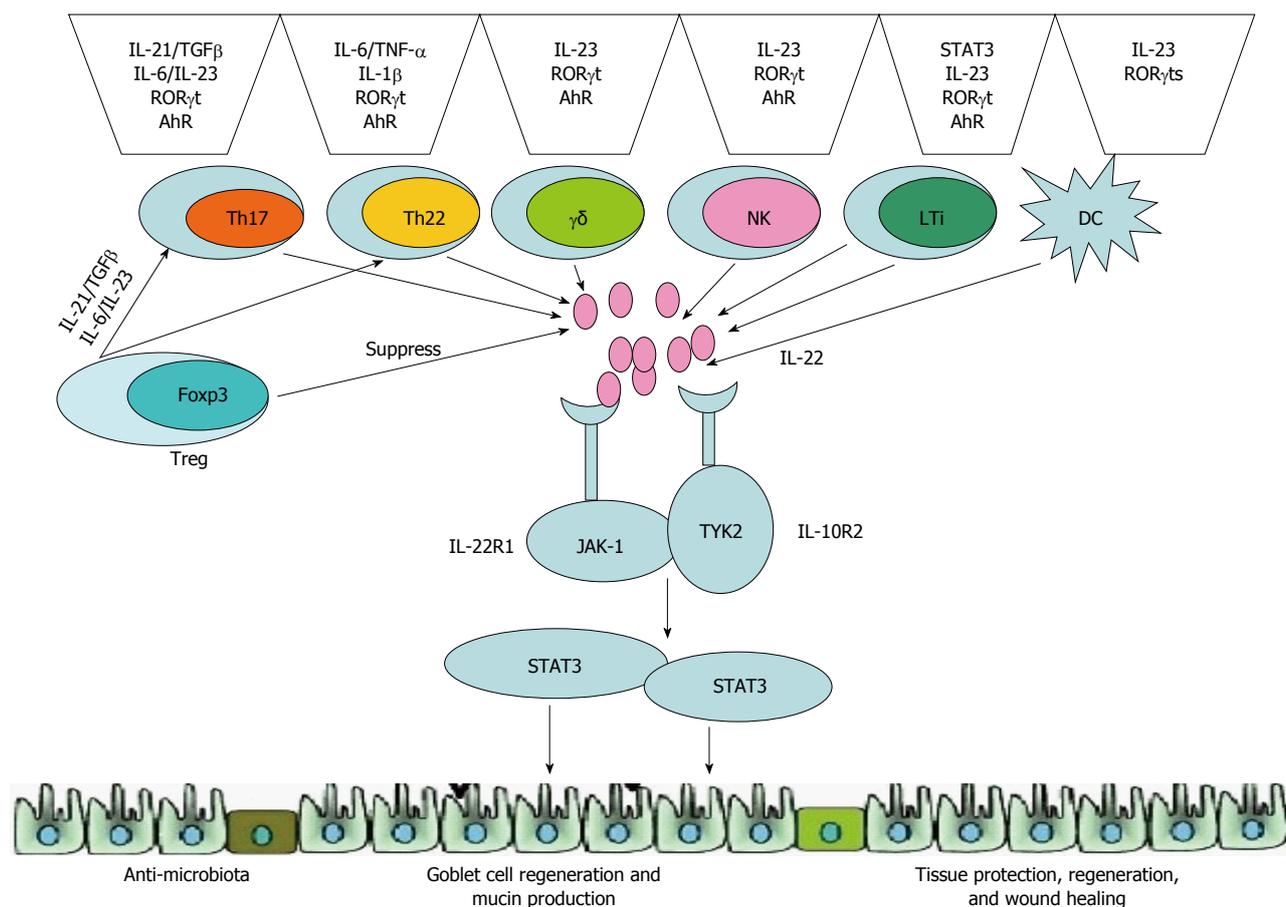

Figure 2 Protective function of interleukin-22 in inflammatory bowel disease. In the intestine, innate and adaptive immune cells, cytokines and many of the transcriptional factors can induce and regulate expression of IL-22. Through activation of STAT3 signaling cascades, IL-22 induces antimicrobial molecules and proliferative and antiapoptotic pathways, and helps regenerate goblet cells and produce mucin proteins, which could prevent tissue damage and aid in its repair. IL: Interleukin; STAT: Signal transducer and activator of transcription.

effects of IL-22 in IBD, and have used several DSS-induced as well as Th1- and Th2-mediated colitis mouse models^[73,74]. In the DSS-induced colitis model, feeding mice DSS causes disruption of the intestinal epithelial barrier, leading to colitis within 1 wk. In IL-22 knockout mice or wild-type (WT) mice, administration of neutralizing anti-IL-22 antibodies leads to more extensive epithelial destruction and inflammation in the colon, more severe weight loss, and more impaired recovery compared to the DSS-induced acute colitis model. In addition, T cells from IL-22^{-/-} mice or IL-22-deficient mice cause a more severe colitis in the T cell transfer model of IBD^[75]. In a Th1-cytokine-mediated model of colitis, expression of IL-22 by CD4⁺ T cells is crucial for relief of disease severity. Sugimoto *et al*^[76] showed that receipt of supplemental IL-22 leads to rapid amelioration of local intestinal inflammation in the colons of Th2-mediated chronic colitis. IL-22 knockout mice showed delayed recovery from DSS-induced acute colonic injury. Treatment with neutralizing anti-IL-22 antibodies also impaired the recovery of WT mice. Finally, in IL-22-deficient and RAG1-deficient double knockout mice, lacking both T and B cells, no recovery was observed^[77].

IL-22 gene delivery mediates STAT3 activation

specifically within colonic epithelial cells and enhances reconstitution of goblet cells and production of mucus, thereby reinforcing the mucus barrier function within the gastroenterology tract^[78]. In DSS-induced acute colonic injury, recovery is significantly impaired and delayed in IL-23R-deficient and RAG2-deficient double knockout mice lacking of IL-22 expression, and treatment with recombinant IL-22 rescues the recovery in these mice^[79]. Pancreatic cells produce TGFβ and IL-10 upon IL-22 stimulation, which can inhibit IFN-γ production, facilitating relief of intestinal injury. These mouse models of colitis suggest that IL-22 plays a protective role in IBD through its ability to improve the integrity of the mucosal barrier and enhance the inherent epithelial defense function.

IL-22 responses to intestinal pathogens

In addition to maintaining the mucosal barrier function in the gastrointestinal tract, IL-22 induces genes to encode anti-microbial proteins involved in bacterial defense and protection of intestinal mucosa, suggesting a role for IL-22 against extracellular bacteria in the innate immune system. CD and UC are thought to be driven by an abnormal immune response to the intestinal

flora^[80]. However, since intestinal dysbacteriosis is also a characteristic of IBD pathogenesis, it is difficult to determine whether there is an inflammatory response to abnormal flora or if an abnormal inflammatory response is altering the microbial communities^[81]. Intestinal flora, as an environmental factor, may be associated with genetic susceptibility that alters the interactions between ourselves and our microbiome. The first major susceptibility gene discovered for CD is NOD2 (or CARD15), which is known as a receptor for bacterial peptidoglycan (PGN)^[82]; another susceptibility gene, ATG16L1, has been shown to be critical for autophagy^[83]. The intestinal flora may also lead to disorders of intestinal lymphoid cell subsets, such as Th17 cells and innate lymphocytes, which are important for regulating mucosal immunity^[83]. Although there have been numerous studies investigating stool samples of and mucosa-associated bacteria in IBD patients, there has been a lack of consensus between the associations observed in these studies^[83].

Although extensive changes have been reported, such as expansion of the *Proteobacteria* phylum in IBD patients^[84], only few specific associations have been reproducibly identified. Although the causes of changes in microbiota species that can trigger IBD remain unclear, and studies on this subject are continuing, the general theme observed so far is that the diversity of microbial communities is significantly decreased in IBD^[85]. There have also been repeated observations of the microbiota composition being disrupted during inflammation, resulting in dysbiosis that may induce or perpetuate the inflammatory condition. However, both host genotype and the environment have major impacts on the shape of such dysbiosis, as well as upon which members of the microbiota can stimulate pathogenic immune responses^[86].

By promoting the maintenance of intestinal epithelial barrier function, IL-22 can prevent the spread of pathogenic microorganisms in the gut, such as enteropathogens, including *Citrobacter rodentium* and *Salmonella typhimurium* (enteric ecotype) in the gastrointestinal tract, thereby limiting bacterial growth. Tregs promote IL-22-dependent clearance of fungi during acute *Candida albicans* infection^[87,88]. In addition, IL-22 can help to eliminate pathogenic microorganisms by inducing various anti-microbial proteins (Figure 2). IL-22 has already been confirmed as a regulator of the expression of antimicrobial proteins such as the S100 family proteins (S100A7, S100A8 and S100A9), β -defensin family proteins (β -defensins BD2 and BD3), Reg family proteins (Reg IIIa, Reg IIIb and Reg IIIc) and lipocalin-2^[83,89-91]. These proteins may be important in the control of gut pathogens. IL-22 plays a protective role in the host inflammatory response to microbial infections or in promoting the release of inflammatory mediators, depending on the type of pathogenic microorganisms causing the infection.

Song *et al.*^[92] showed that IL-22 plays an crucial role in host defense immunity against infection with the

Gram-negative enteric bacteria *Citrobacter rodentium*, as an inducer of the expression of antibacterial peptides in colonic epithelial cells. The protective effect of IL-22 in systemic infections caused by *Salmonella enterica* has been demonstrated. IL-23-dependent IL-22 was required for both liver cells' survival and pathogen defense against systemic *Salmonella* infection in mice, especially when accompanied by decreased production of IL-12^[93].

IL-22 is not only able to protect our intestine against bacterial pathogens, but also plays a protective role in intestinal fungal infections with *Candida albicans*. Compared with infected WT mice, IL-22 knockout mice infected with *Candida albicans* hyphae intragastrically had a higher fungal burden and showed signs of more severe mucosal inflammatory hyperplasia in the stomach and colon^[94,35]. These results indicate that IL-22 serves as a protective guardian in regulating inflammatory responses and maintaining mucosal barrier integrity in a variety of intestinal infections. However, IL-22 has also been shown to promote intestinal inflammation in parasite infection^[95]. *Toxoplasma gondii*-infected IL-22 knockout mice and mice whose IL-22 was neutralized with an anti-IL-22 monoclonal antibody developed significantly less intestinal pathology and had less weight loss and mortality, despite having similar parasite burdens to infected WT mice. Perhaps the strongly skewed Th1 immune response caused by the *Toxoplasma gondii* infection may explain this difference.

As mentioned above, IL-22 produced by Th17 cells can be regulated by the gut microbiota. Different from the neutrophil induction response of IL-17, IL-22 serves an important role in tissue repair during mucosal immune system response^[96]. Regardless, the relationship between the intestinal microbiota and IL-22-producing cells is extremely close. Most notably, it was recently shown that IL-22-producing innate lymphocytes play a crucial role in preventing systemic inflammation by inhibiting systemic dissemination of commensal bacteria^[83]. Sonnenberg *et al.*^[97] administrated Rag1^{-/-} mice a neutralizing anti-IL-22 monoclonal antibody, and found that the signs of systemic inflammation increased as did levels of lipopolysaccharide (LPS); in addition, bacteria could be cultured from the spleens and livers of these mice. The disseminated commensal bacteria were subsequently identified as *Alcaligenes* sp.

Therefore, together with the protective role against IBD, IL-22 also serves as a mucosal protector and plays a critical role in separating our intestinal tract from our gut flora. Under gut homeostatic conditions, viable bacterial pathogens are sampled by DCs that carry them to the mesenteric lymph nodes and these microbes do not disseminate systemically to secondary lymphoid tissues, indicating that a mesenteric guardian may act in concert with a mucosal firewall to distinguish intestinal bacteria^[98].

IL-22 in tissue protection, regeneration and wound healing

In addition to its antibacterial activity, IL-22 can enhance the survival and proliferation of epithelial cells for

tissue differentiation and healing^[99]. IL-22 induces the expression of antiapoptotic proteins, including Bcl-xL, Bcl-2 and Mcl-1, as well as proteins directly involved in cell cycle and proliferation, such as c-Myc, cyclin D1, Rb2 and CDK4, and anti-inflammatory or protective proteins, such as IL-11 and follistatin^[100-102]. Moreover, IL-22 has been shown to be capable of stimulating a colonic cancer cell line to express a molecule termed deleted in malignant brain tumor 1 (DMBT1), which may play a vital role in the differentiation of epithelial cells^[103]. IL-22 has also been shown to induce RegI α , which serves as a trophic and antiapoptotic factor in the inflamed colon of UC patients. Recent research has determined that, through the activation of STAT3, IL-22 can induce the proliferation and reconstruction of mucosal epithelial cells in the intestinal tract^[104]. This increased healing response can further prevent the penetration of microorganisms into the intestinal epithelial layers.

IL-22 is associated with IBD susceptible genes

An attractive biological feature of IL-22 is its functional association with some major IBD susceptibility genes. Interaction of IL-23 with IL-23R has been implicated in the development of IL-22-producing innate cells, including ILCs, LTI cells and NK cells^[4,33,34], and in the maintenance of IL-22-producing Th17 cells^[105,106]. Functional polymorphisms of the IL-23R gene have been negatively correlated with development of both CD and UC^[105,106]. IL-22 is located within a UC-risk locus on chromosome 12q15^[107]. IL-22 can be combined with its receptors that are composed of IL-10R2 and IL-22R1. Polymorphisms of *il10r2* are positively associated with both CD and UC^[108].

Binding of IL-22 with its cognate receptor induces rapid activation of STAT3 through JAK1 and TYK2. *Stat3*, *jak1* and *tyk2* are all well-defined susceptibility genes of CD and, to a lesser extent, of UC^[95,96]. STAT3 activation stimulates epithelial cells to produce Muc1. A recent genome-wide association study proposed *muc1* as a potential candidate gene associated with CD^[109]. In addition, genome-wide association analysis of IBD patients has identified gene mutations involved in encoding IL-22 and the IL-10R2 subunit of the IL-22R complex^[110,111].

IL-22 AS A POTENTIAL THERAPUTIC FOR IBD

Due to its crucial roles in regulating barrier immunity and antimicrobiota, IL-22 may have therapeutic potential for IBD. Understanding the various mechanisms of IL-22 in regulating immunity, together with development of immunosuppressive drugs, may open up a new path for the future treatment of IBD.

Treatment with recombinant cytokine or gene therapy delivery of IL-22 may alleviate tissue damage during inflammatory responses. Suppressing the immune system *via* anti-inflammatory treatments, such as TNF α

inhibition, can lead to unwanted dampening of the immune response, impairing the ability of its response to infection. However, IL-22 is an ideal therapeutic candidate because it specifically affects tissue responses and does not have direct effects on the immune response. IL-22 has produced the expected results in an experimental animal model of IBD. Administration of a more specific targeting agent of IL-22 *via* microinjection of an IL-22 DNA vaccine into already inflamed colonic tissues of mice with IBD has been shown to lead to reduce infiltration of inflammatory cells as well as to increase number of goblet cells^[112]. This enhances the production of mucin, thereby buffering the colonic epithelium from commensal bacteria that may otherwise initiate an immune response. Andoh *et al.*^[113] did not find IL-22 expression in the gut mucosa of patients with infectious colitis. It seems that IL-22 plays a protective systemic role in CD^[114] and a protective local role in UC^[115,116]. It should be mentioned at this point that recently, Leppkes *et al.*^[117] demonstrated that the adoptive transfer of IL-22-deficient T cells into RAG1-deficient mice caused severe colitis that was indistinguishable from that caused by transferred WT cells.

Genome-wide linkage analysis of IBD patients has identified gene mutations involved in encoding IL-22 and the subunit complex of IL-10R2 and IL-22R1^[111]. The IL-22R complex is highly expressed within the gastrointestinal tract and in the inflamed colon; IL-22 is expressed by CD4⁺ T cells, likely Th17 cells, and innate lymphocytes, such as NK cells and LTI-like cells. Using different experimental models of IBD - DSS-induced colitis, which is thought to be mainly driven by innate immune response cells, and CD4⁺CD45RB^{high} T cell-mediated colitis, in which naive T cells devoid of Tregs are transferred into T cell-deficient mice where they proliferate unimpeded leading to colitis - IL-22 has been shown to be protective^[118,119]. Furthermore, Strengell *et al.*^[118] showed that IL-22 can be therapeutic in IBD; gene therapy transfer of the IL-22 gene into the colons of already inflamed mice resulted in amelioration of inflammation. In addition, the authors reported that *in vivo* gene delivery of IL-22 attenuates Th2-mediated colitis and regulates the expression of genes related to mucus layer formation^[120].

Some existing biologic therapies are also able to mediate effects on IL-22 expression in patients. Anti-TNF α antibodies (such as infliximab) and the anti-IL-6 antibody tocilizumab have been used to treat IBD. Th22 cells depend on TNF α for differentiation; therefore, both Th17 and Th22 cells depend on IL-6 for differentiation, and they can indirectly decrease IL-22 expression in patients to treat IBD^[121,122]. Lastly, ustekinumab is able to target both IL-12 and IL-23 and therefore prevent the differentiation of Th1, Th17 and Th22 cells, eliminating several sources of IL-22; this drug is currently being studied in Phase III clinical trials of CD^[123]. The treatments mentioned above suppress inflammation by indirect inhibition of IL-22.

CONCLUSION

IL-22 plays a critical role in the regeneration of damaged epithelial monolayers and stimulates antimicrobial peptide generation. Importantly, the ability of IL-22 to promote intestinal wound healing and proliferation of intestinal epithelial cells in mice and humans has been reproducibly demonstrated by independent groups using different experimental methods, and recent advances in genome-wide association studies have led to results suggesting that the IL-22 pathway is closely related to some major IBD susceptibility genes. These collective findings clearly highlight IL-22 as a promising target for IBD therapy. Therefore, further extensive research on IL-22 is necessary to bring about novel and practical interventions for improving the quality of life of patients with IBD in a safe and effective way. Further understanding of the regulation and function of IL-22 would certainly play a favorable role in the future treatment of IBD.

Key words: Collagenous colitis; Lymphocytic colitis; Microscopic colitis; Intraepithelial lymphocytes; Thickened collagen band; Diarrhea-predominant irritable bowel syndrome

Core tip: The gastroenterologist and gastrointestinal pathologist should keep this common condition in mind as a cause of unexplained nonbloody diarrhea with normal mucosal appearance on colonoscopy to avoid misdiagnosis that may affect treatment of patients. Referral of patients with pathogen negative chronic diarrhea to medical centers that have facilities for colonoscopy and biopsy is vital in the developing world.

Abstract

Microscopic colitis (MC) is characterized by chronic, watery, secretory diarrhea, with a normal or near normal gross appearance of the colonic mucosa. Biopsy is diagnostic and usually reveals either lymphocytic colitis or collagenous colitis. The symptoms of collagenous colitis appear most commonly in the sixth decade. Patients report watery, nonbloody diarrhea of a chronic, intermittent or chronic recurrent course. With collagenous colitis, the major microscopic characteristic is a thickened collagen layer beneath the colonic mucosa, and with lymphocytic colitis, an increased number of intraepithelial lymphocytes. Histological workup can confirm a diagnosis of MC and distinguish the two distinct histological forms, namely, collagenous and lymphocytic colitis. Presently, both forms are diagnosed and treated in the same way; thus, the description of the two forms is not of clinical value although this may change in the future. Since microscopic colitis was first described in 1976 and only recently recognized as a common cause of diarrhea, many practicing physicians may not be aware of this entity. In this review, we outline the epidemiology, risk factors associated with MC, its etiopathogenesis, the approach to diagnosis and the management of these individuals.

INTRODUCTION

Microscopic colitis is regarded as one of the common causes of chronic watery diarrhea. The incidence rate for collagenous colitis is 0.8/100000-6.2/100000. Many cases have been reported in western countries and in Asian countries like India. Lindstrom and Freeman described the term collagenous colitis concurrently in 1976. Microscopic colitis (MC) refers to two medical conditions which cause diarrhea: collagenous colitis and lymphocytic colitis. The following triad of clinicopathological features characterizes both conditions: (1) chronic watery nonbloody diarrhea; (2) normal mucosal appearance on colonoscopy; and (3) characteristic histopathology.

Patients are characteristically, although not exclusive-

ly, middle-aged females. They present with a long history of watery nonbloody diarrhea which may be profuse. There is a strong association between autoimmune diseases, for example arthritis, Sjogren's syndrome and celiac disease, and microscopic colitis. There are reports of associations with multiple drugs, especially non-steroidal anti-inflammatory drugs. Colonoscopy is normal or near normal. The changes are often patchy, so multiple colonic biopsies must be taken in order to make a correct histological diagnosis^[1-3]. A full colonoscopy is required as an examination limited to the rectum will miss cases of MC.

EPIDEMIOLOGY

The true incidence of MC is not known. The disease has been increasingly diagnosed over the past 20 years but is still uncommon. A recently published population-based study found the incidence of microscopic colitis to increase significantly from 1.1 per 100000 persons in the late 1980s to 19.6 per 100000 persons by the end of 2001. More recent epidemiological studies done in this century confirmed these high incidence numbers, showing that actual incidence and prevalence numbers are higher than initially thought and are still able to show rising incidences, although the rise is far less pronounced than before. Most recent north American studies show incidence rates of 7.1 per 100000 person-years for collagenous colitis and 12.6 per 100000 person-years for lymphocytic colitis^[4].

Morbidity is limited to the consequences of diarrhea, including metabolic abnormalities such as hypokalemia and dehydration, weight loss and fatigue. This is not considered a life-threatening condition; however, profuse watery diarrhea may lead to severe dehydration and electrolyte abnormalities requiring intensive resuscitation.

Lymphocytic colitis affects similar numbers of men and women, while collagenous colitis is up to 20 times more frequent in women than in men^[5].

Both conditions are observed most commonly in people over the age of 40 years, with peak incidence in the sixth and seventh decades of life, and the incidence of both conditions increases with age. Isolated cases have been reported in younger populations, including children^[5-8].

ETIOPATHOGENESIS

The etiology of MC is most likely multifactorial with a mucosal inflammatory response to yet not specified noxious luminal agent occurring in a predisposed host. The noxious luminal agent may be a single one or multiple ones summing up to an individual threshold. Technically, MC is an inflammatory bowel disease (IBD) and the disease shares a number of etiological aspects with the so-called classical inflammatory bowel diseases like Crohn's disease and ulcerative colitis. Among the possible predisposing and/or contributing factors for microscopic colitis, genetic factors and intraluminal noxious factors

are best studied. Although a limited number of familial clusters of microscopic colitis have been reported, there is only minimal evidence of a genetic component within the etiology of MC. All reported so-called family clusters are very small and comprise of a maximum of two reported family members. In contrast, there is evidence of a predisposition of sensitivity to gastrointestinal inflammatory insults in patients with microscopic colitis since up to 12% of patients with MC have a family history of celiac disease or even inflammatory bowel disease^[8]. The meaning of the association between Human Leukocyte antigen (HLA-DQ2, DQ1, DQ3) and microscopic colitis and the high prevalence of a tumor necrosis factor (*TNF α*) gene polymorphisms in patients with microscopic colitis deserves further attention as it may lead to a discovery of a hereditary component of microscopic colitis of presently unknown penetration^[9]. Furthermore, metalloproteinase-9 gene variations have been reported to be associated with collagenous colitis^[10]. However, the meaning of all the presently reported genetic associations is poorly understood and the respective research is presently not driven by hypotheses, rather than by incidental observations or genetic screening. Very strong evidence exists for an autoimmune basis to the development of both collagenous and lymphocytic colitis. The association of MC with autoimmune-based disorders such as celiac, thyroid disease and rheumatoid arthritis, as well as the female preponderance, supports the notion that both forms of MC have a strong association with autoimmune diseases and may well be an autoimmune disorder themselves. However, to date, no specific autoantibody has been identified as being diagnostic for or being associated with collagenous or lymphocytic colitis^[11]. It is known that MC can be found together with various autoantibodies and phenotypes, like human leukocyte antigen (HLA)-DR3 phenotype, although these associations are not strong enough to be regarded as being diagnostically relevant or useful, nor do we know what these associations mean. A case series of 4 patients is described in which subjects developed classic symptoms of lymphocytic-collagenous colitis with typical mucosal histopathology during treatment with omeprazole/esomeprazole (proton pump inhibitors)^[12]. Symptoms promptly stopped and mucosal biopsies returned to normal with drug withdrawal. Disease quickly recurred in 2 patients who were re-exposed to the drugs, one with biopsy documented recurrent collagenous colitis. Luminal factors of whatever kind seem to play an important role in the pathogenesis of microscopic colitis. Numerous drugs were reported to have a high or at least intermediate probability of causality in microscopic colitis^[13]. Other luminal factors like infectious or even toxic agents are supported by studies that found either onset of MC following a gastrointestinal infection or improvement of symptoms with the initiation of antibiotics in the context of a proven or suspected gastrointestinal infection. *Yesinia* species^[14], *Clostridium difficile*^[15] and *Campylobacter* species^[16] were suggested in published case reports to cause MC; although, interpreting these observations in the context of

current knowledge, it is most likely that these cases are of sporadic nature. In some small retrospective case series, bile acid malabsorption was found in up to 60% of patients with lymphocytic and up to 44% of patients with collagenous colitis, supporting the notion that MC may at least in some patients be caused by bile acid malabsorption. Whether bile acid malabsorption is causative or not remains questionable, as later studies were unable to confirm these observations^[17]. Still, this may direct therapeutic decisions and especially in patients with a cholecystectomy, a bile acid directed treatment should be considered. Basic science is still in its infancy when it comes to studying microscopic colitis and possible causes, drivers, mechanisms or even pathophysiological models. A recent bench side study employing sigmoid tissues from patients with collagenous colitis and lymphocytic colitis was able to identify that sodium transport and epithelial barrier function are disturbed in patients with microscopic colitis^[18]. Unfortunately, it remains unclear whether these reported changes are of causal nature, of transient nature, or a consequence of the underlying microscopic colitis. Even although these descriptive studies at least initiate a scientific discussion on what may be mechanisms underlying or involved in the development and the resolution of microscopic colitis, these small mechanistic studies have to be carefully taken since such studies are highly artificial in the techniques they use and therefore the results are most likely influenced not only by numerous circumstances like laboratory procedures and protocols but also by patient drug use, age and even nutritional status. Thus, such information has to be considered as hypotheses generating information that hopefully guides future prospective studies that help us to understand the mechanisms involved in the pathogenesis, maintenance and resolution of microscopic colitis and symptoms associated with the histological changes.

Using molecular techniques, it was reported that in patients with MC, increased interferon- γ , TNF- α and IL-1 β levels suggest a Th1 cytokine profile being involved in the inflammatory process^[18]. The differences in mucosal lymphocyte subsets seen in patients with collagenous and lymphocytic colitis^[19] is not fully understood presently. This information may help us to understand the inflammatory mechanisms involved and may be useful for future therapeutic approaches. Environmental factors may play a crucial role in the etiology of MC, although other than cigarette smoking, presently no other factors are confirmed. For both collagenous and lymphocytic colitis, cigarette smoking is more prevalent compared to subjects without MC and first reports suggest that lung cancer is associated with MC^[20-22]. The odds ratio (OR) for lymphocytic colitis and smoking (OR = 3.8) is higher than for collagenous colitis and smoking (OR = 2.4), although this difference was calculated on a small cohort of 120 patients with collagenous colitis, 70 patients with lymphocytic colitis, and 128 controls, and thus has to be verified in larger groups of patients^[23]. Interestingly, it was additionally shown that MC occurs roughly 10 years earlier when the respective person is an active

smoker, stressing the relevance of cigarette smoking to the pathophysiology of microscopic colitis. Beyond the strong results from association studies, it would be of great impact to learn whether cessation of smoking would cure MC or at least be beneficial to the patient's symptoms, and a prospective clinical trial answering this seems worthwhile. In addition to the inflammatory component in the pathophysiology of MC, there may be an additional neuronal component to pathophysiology. A recent study identified increased chromogranin A, chromogranin B and secretoneurin levels in feces of patients with collagenous colitis compared to relevant control groups. These observations may point to a neurogenic involvement in MC and, additionally, these stool markers are suggested to be helpful in discriminating MC from irritable bowel syndrome or classical inflammatory bowel disease^[24].

The precise mechanism of diarrhea in these patients is not well understood. Factors that may play a role include bile salt induced injury, active chloride excretion, decrease in net sodium absorption, creation of a diffusion barrier by collagen band and increased local inflammatory mediators such as nitric oxide and prostaglandins. It remains unclear which of these results in the symptoms reported by patients. Two studies have looked at inflammatory cytokines in MC. Patients with MC seem to have a predominantly TH1 type cytokine profile with significant increases in interferon gamma, TNF- α and interleukin 15, as well as an increased inducible nitric oxide synthetase. Others have found increased levels of Transforming growth factor- β in patients with collagenous colitis^[25].

CLINICAL PRESENTATION

Collagenous and lymphocytic colitis present with very similar symptoms and from a clinical perspective, there is no specific symptom or clinical feature that allows discriminating one from the other. Thus, the differentiation between the two entities is made by histology only. The typical clinical presentation involves chronic (either recurrent or intermittent) relapsing watery, nonbloody diarrhea. Symptoms may have been present for several months to 2-3 years before medical attention is sought and a diagnosis is made. Less frequent complaints include abdominal cramping, fecal incontinence and weight loss, although weight loss may be seen in 40% or more of patients with collagenous colitis. Incontinence is probably more a reflection of the advanced age of those individuals who are affected and patients with this problem may do well if treated with antidiarrheal agents^[26,27]. The natural history of MC is variable. Many cases are self-limiting, with symptoms lasting a few weeks or months. Others may be symptomatic for years in a relapsing or continuous pattern. Although a small number of case reports have suggested that MC may lead to development of ulcerative colitis, a small case series of patients with MC showed that none developed ulcerative colitis or Cohn's disease after a follow-up of at least 6 years^[28]. There are case reports on spontaneous and colonoscopy induced

Figure 1 Micrograph of collagenous colitis, a type of microscopic colitis showing sub epithelial band of collagen H and E stain.

colonic perforations in patients with MC^[29-30].

DIAGNOSIS/HISTOPATHOLOGY

The diagnosis of MC is dependent on (1) a convincing clinical history with other etiologies ruled out; (2) normal or near normal endoscopic and/or radiographic findings; and (3) endoscopic biopsies with histopathological findings consistent with MC.

The first step in the diagnostic process is a thorough history with particular attention paid to risk factors and the disease associated with MC. A complete history helps one to rule out other etiologies that may cause a similar clinical picture, such as IBD, celiac disease, diarrhea-predominant irritable bowel syndrome or infectious colitis.

Laboratory and radiographic investigations can be employed to rule out other entities on the differential diagnosis list but they are typically unremarkable.

Endoscopy with biopsy is necessary to arrive at the diagnosis. Colonoscopy generally reveals normal mucosal appearance. However, non-specific changes such as erythema, edema, abnormal vascular markings or even tears associated with perforation have been described. The hallmark of microscopic colitis is an increase in inflammatory cells (*i.e.*, lymphocytes) in colonic biopsies with an otherwise normal appearance and architecture of the colon. Inflammatory cells are increased both in the surface epithelium (“intraepithelial lymphocytes”) and in the lamina propria. In lymphocytic colitis, these are the only abnormal features.

In collagenous colitis, the features of lymphocytic colitis are present, with the additional presence of a characteristic thickened sub epithelial collagen band which may be up to 30 μm thick (Figure 1)^[31].

As the mucosa is not ulcerated or otherwise disrupted, the diarrhea generally does not contain blood or pus^[32]. The diarrhea in collagenous colitis is likely due to inflammatory process and sub epithelial collagen serves as a cofactor in the role of a diffusion barrier and increased levels of immunoreactive prostaglandins E2 in stool water may lead to secretory diarrhea. Some cases may have fibrosis due to increased mucosal secretion of vascular endothelial growth factor^[32,33]. One important question is how many biopsies need to be taken and how

many biopsies are needed to confirm or rule out microscopic colitis. Numerous studies showed that the microscopic lesions can be skipped and therefore random multiple colonic biopsies should be taken^[34].

Treatment

Treatment recommendations for MC are largely based on case reports and uncontrolled studies. Specific agents evaluated include 5-aminosalicylic acid (5-ASA), prednisone, immunomodulators, bismuth, probiotics and *Boswellia* extract. Small randomized controlled trials have shown that agents such as budesonide offer promise as an effective form of symptomatic therapy for both collagenous and lymphocytic colitis. As a first step in managing MC, an in depth medication history should be taken with potentially precipitating medications stopped where possible. Associated conditions such as celiac disease should be appropriately managed. In patients with mild symptoms, dietary restrictions like avoiding caffeine and lactose might be helpful.

Anti-diarrheal therapies

Non-specific anti-diarrheal therapies such as loperamide are commonly used in the management of MC. Retrospective studies have suggested benefit with doses ranging from 2 to 16 mg/d^[34]. Due to the safety of this agent and the possibility of spontaneous remission, loperamide is the first-line therapy for MC.

Aminosalicylates

Uncontrolled retrospective series have suggested symptomatic improvement in up to 50% of patients with MC treated with mesalamine (5-ASA). A recent randomized trial of 64 MC patients compared mesalamine (800 mg *tid*) to mesalamine (800 mg *tid*) and cholestyramine (4 g/d). Treatment resulted in resolution of diarrhea in 84% overall after 2 wk. If treatment was continued over 6 mo, clinical and histological remission was achieved in 85% of those with lymphocytic and 91% of those with collagenous colitis. The number of relapsing patients after 6 mo of treatment was low and symptomatic relapses could be successfully retreated. Overall, the combination of mesalamine with cholestyramine was slightly superior^[35,36].

Budesonide

Budesonide is currently the most promising treatment for collagenous colitis. Three trials involving 94 patients have shown that budesonide therapy (9 mg/d for 6-8 wk) compared to placebo resulted in statistically significant improvements in clinical symptoms and quality of life. A recent Cochrane database meta-analysis reported pooled OR of 12.3 for clinical response with budesonide with a number needed to treat of two. Although effective in the short-term, all trials showed a high rate (61%-80%) of relapse within 2 wk of budesonide cessation. Age < 60 years was a significant risk factor for relapse. Although there are no studies to support a tapering course of budesonide, many clinicians employ this in an effort to

minimize the likelihood of relapse.

One randomized controlled trial of budesonide for the treatment of lymphocytic colitis has been conducted. When compared to the placebo arm, the patients randomized to budesonide (9 mg/d × 6 wk) had a statistically significantly higher rate of remission (< 3 bowel movements per day) at 3 and 6 wk^[37-41].

Prednisolone

A double-blind, placebo-controlled randomized trial of oral prednisolone 50 mg/d for 2 wk for collagenous colitis was inconclusive because of the low number of patients enrolled^[42]. Studies examining the effect of prednisone in the treatment of lymphocytic colitis have not been performed.

Immunosuppressive therapy

Immunosuppressive therapy with azathioprine or methotrexate has been utilized in patients either refractory to corticosteroid therapy or corticosteroid dependent, but there are no randomized controlled trials to guide therapy with these medications.

Other therapies

Small clinical trials studying bismuth subsalicylate, *Boswellia serrata* extract, probiotics and empirical antibiotic treatment for collagenous and lymphocytic colitis look promising but cannot be suggested outside of such trials. Finally, case reports suggest that pentoxifylline, verapamil and subcutaneous octreotide might be treatment options, but their use cannot be recommended at this time. When medical therapy was unsuccessful and symptoms were very severe, surgical interventions, such as a temporary or permanent loop ileostomy or even a proctocolectomy, have been employed in smaller case series.

CONCLUSION

To conclude, the term microscopic colitis is now used to describe both lymphocytic and collagenous colitis and the condition should be kept in mind in any patient with unexplained watery nonbloody diarrhea with normal endoscopic findings. Biopsy is a must to rule out either form of microscopic colitis. Based on symptom severity and disease duration, a stepwise approach to treatment is suggested.

Key words: Ulcerative colitis; Mucosal healing; Prognosis; Evidence

Core tip: In recent years, the concept that the management of ulcerative colitis patients should aim to heal the mucosa rather than resolve symptoms has been decisively proposed. Herein, we review the current evidence supporting this statement and analyze the possible practical implications in the current management of ulcerative colitis patients.

Abstract

In recent decades, the prominent role of endoscopy in the management of ulcerative colitis (UC) has been translated into the concept of mucosal healing (MH) as a fundamental therapeutic end-point. This is partially the consequence of growing evidence of a positive prognostic role of MH on the disease course and partially due to market cues indicating a higher rate of MH in patients treated by novel potent biologic agents. The aim of the present review is to clarify the current knowledge of MH in UC, analyzing the definition, the putative prognostic role and the association of MH with the current drugs used to treat UC patients. Because solid data about the management of UC patients based solely on the healing of the mucosa are not yet available, a tailored approach for individual patients that considers the natural history of UC and the presence of prognostic indicators of aggressive disease is desirable. Consequently, unnecessary examinations and treatment would be avoided and restricted to UC patients who require the maximum amount of effort to affect the disease course in the short and long term.

INTRODUCTION

A crucial topic that physicians have long faced in the management of ulcerative colitis (UC) patients is the identification of a reference parameter for the assessment of disease activity. Indeed, UC is a chronic inflammatory disease of the colon, characterized by limitation of the inflammation to the mucosa and the proximal extension of the disease starting from the rectum^[1]. Indeed, the term “UC” comprises a heterogeneous condition with differing involvement of the colon in terms of its extension and the grade of inflammation, which in turn can lead to possible alterations of laboratory parameters and symptom occurrence and severity. The clinical, biochemical and mucosal alterations do not always directly correlate, and questions have been raised about which parameter should be used as the “gold standard” for disease activity assessment.

For the capacity to directly evaluate the colon, which is the target organ of the disease, endoscopy has been indicated as the more accurate tool to assess the activity of the disease, further supported by the possible misleading role of symptoms in the evaluation of UC patients^[2,3]. Unfortunately, colonoscopy is an invasive, costly and time-consuming procedure, and the routine repetition of the examination is not feasible. Different objective surrogate parameters have been described to aid physicians in the correct evaluation of the activity state of patients with inflammatory bowel disease (IBD), including serological (*i.e.*, C-reactive protein) and fecal (*i.e.*, calprotectin, lactoferrin) markers^[4], as well as clinical scores^[5].

During the last decade, the addition to the IBD therapeutic arsenal of anti-TNF- α biologic drugs, which were formerly used in other chronic inflammatory conditions, has launched a “Copernican revolution” in the clinical approach to both Crohn’s disease (CD) patients and UC patients. In fact, together with a rapid and consistent improvement of symptoms and laboratory parameters, such potent anti-inflammatory compounds have resulted in rapid and dramatic improvements of the intestinal mucosal lesions characteristic of IBD, as documented by endoscopic evaluation before and after the induction therapy^[6]. Since this time, the relevance of the endoscopic activity of disease has been definitively stated, and “mucosal healing” (MH) has been proposed with increasing strength as a fundamental therapeutic goal of IBD treatment, claiming its prognostic relevance in the natural history of the disease^[3]. Since the first studies that described the efficacy of Infliximab in CD patients^[7,8], some 15 years have passed, and the therapeutic options for IBD patients have consistently expanded. At present, two biologic anti-TNF agents are currently approved in Europe for utilization in both CD and UC (Infliximab and Adalimumab), and some biologic agents have already shown efficacy in randomized clinical trials and are indicated for market release^[9]. The emphasis on the efficacy of such novel drugs for the amelioration of mucosal inflammation has contributed to making the concept of MH a paramount therapeutic goal, and we are passing from a symptom-targeted to a mucosa-targeted approach in the management of IBD patients^[10]. Several observations have contributed to encourage this shift in IBD management, outlining the relation between mucosal healing and the favorable long-term outcome of the disease in terms of reductions in flares, hospitalizations, the need for surgery and cancer incidence^[11].

Although the MH concept has recently been particularly emphasized in CD, the importance of endoscopic remission in UC has been known for a long time^[12]. In fact, the achievement of MH in UC appears of particular relevance for the localization of the disease (mucosal and limited to the colon), which renders the endoscopic examination relatively easier compared with CD, in which the inflammation is transmural and can potentially involve areas of the intestine not accessible to endoscopic inspection. Considering that more than half of

UC patients present inflammation limited to the left side of the colon^[13], the possibility that the involved areas can be easily scoped to evaluate MH in such patients is particularly tempting.

Nonetheless, specific treat-to-target studies addressing the effective role on the natural progression of the disease of a treatment strategy focused electively on the achievement of MH are still lacking. The relevance of MH to the management of UC, although intriguing and rational, remains to be firmly established. The possibility that the importance of MH would tend to be overrated due to the influence of sponsored trials underlining the association between MH and biologic drugs must be considered. Moreover, data coming from randomized clinical trials (RCTs) are usually not completely applicable to the “real-life” IBD population. In fact, a recent retrospective analysis of consecutive mild-moderate IBD patients at a United States tertiary referral center found that only 31.1% of patients would fulfill the inclusion criteria of the major RCTs of biologic agents and that the outcomes of patients fulfilling the criteria are significantly more favorable compared with those not meeting the criteria^[14].

Besides scientific and commercial suggestions, a careful revision of the actual evidence in support of MH is essential. The risk of a blind and excessively enthusiastic adherence to the MH suggestion is concrete, and physicians need to be aware of the over-prescription of unnecessary endoscopic examinations and/or the over-treatment of patients. In an era of resource optimization, this would risk minimizing the same advantages that the MH strategy is claiming, *i.e.*, the reduction of disease costs by reducing complications and hospitalizations. Extensive systematic reviews of MH are already available in the literature (*i.e.*, Neurath *et al.*^[11]), and such a review is beyond the aim of the present work. Here, we intend to perform a synthetic and careful revision of the state-of-the art research on MH. To this end, we critically reviewed the definition of MH, the quality of the actual evidence of its prognostic relevance, and the capacity of the therapies currently used for UC to achieve MH, with the final goal of clarifying the potential correct application of the concepts of MH to the current practical management of patients affected by UC.

MH: DEFINITION

Although a standardized definition of MH has not been established, a practical currently accepted definition is “the complete resolution of the visible alterations or lesions, irrespective of their severity and/or type at baseline colonoscopy”^[11]. Nonetheless, at present, an easy to use, validated and clinically relevant endoscopic score for UC activity evaluation is lacking, reflecting the complexity in measuring disease activity in UC^[15]. In fact, although a great number of scoring systems have been developed (Baron score, Mayo score, Sutherland, Powell-Tuck and Rachmilewitz indices, among others)^[16-24], none of them have been prospectively validated. The main problems

regarding the majority of the indices include the overlap of mucosal features (such as vascularity, granularity, erythema, friability, bleeding, and ulceration), leading to inter-observer variation in endoscopic evaluation, and the lack of clear and standardized thresholds for endoscopic remission or improvement. The Mayo Clinic endoscopy subscore has been the most commonly used in recent clinical trials, defining MH as a score of ≤ 1 (normal mucosa or loss of vascular pattern, but no mucosal friability), when the endoscopy subscore was 2 or 3 at baseline. The problem of a standardized definition of MH is not theoretical but implies concrete and practical consequences. In fact, in recent clinical trials, heterogeneous definitions may have contributed to the higher rate of patients with MH when compared with that of patients achieving clinical remission^[25], although alternative explanations are possible (*e.g.*, the simultaneous presence of irritable bowel syndrome, dysmotility). Moreover, a recent RCT testing the use of mesalamine in UC patients showed consistently different results after a revision of the endoscopic examination findings by a blinded central reader^[26].

In further support of the aforementioned difficult evaluation of UC endoscopic activity, two novel scores have been very recently developed and prospectively validated, the Ulcerative Colitis Endoscopic Index of Severity and the Ulcerative Colitis Colonoscopic Index of Severity^[27,28]. Data about the applicability of such new scores in clinical trials and in clinical practice are awaited and will hopefully aid the move toward a standardized definition of MH.

Recently, data indicating a prognostically relevant role for histologic activity in the mucosa of UC patients, in addition to the macroscopic activity, have opened the door to the concept of “histological MH”, with the complete absence of clinical, laboratory, endoscopic and histological features of active inflammation^[29]. Indeed, the term “mucosal healing” was initially proposed only for the disappearance of the inflammatory infiltrate in the histological examination^[30]. At present, although some scoring systems for histologic activity have been described, none have been properly validated or commonly used, and therefore, the definition of histological MH remains without consensus.

MH: EVIDENCE FOR PROGNOSTIC RELEVANCE

The increasing relevance of the MH achievement in UC has been demonstrated by a growing body of data showing the different courses of the disease in patients with and without MH, with a reduction of complications such as flares as well as reductions in hospitalization, colectomy and cancer incidence in patients with MH.

As early as 1966, Wright *et al.*^[31] reported a higher relapse rate in patients who did not achieve MH after oral and rectal steroids when compared with patients who did achieve MH (40% *vs* 18%). In the ACT1 and ACT2

trials, patients treated with infliximab who exhibited MH at week 8 showed a higher rate of clinical remission at week 30 than patients without MH (48.3% *vs* 9.5%)^[32]. Yamamoto *et al.*^[33] reported that UC patients who achieved clinical remission and MH after leukocytapheresis had a higher rate of sustained clinical response when compared with patients with only a clinical response (88% *vs* 41%). Ardizzone *et al.*^[34] showed that the lack of mucosal healing at 3 mo after the first corticosteroid treatment was the only factor associated with negative outcomes at 5 years (use of immunosuppressants, hospitalization and colectomy).

An observational study of the IBSEN cohort showed that in 513 UC patients, the colectomy rate was lower in patients with MH [defined by a simple endoscopic score of 0-1 (0, normal; 1, light erythema or granularity)] at a 5-year follow-up (2% *vs* 8%, $P < 0.05$)^[35]. Similar results were shown by Soldberg *et al.*^[36], who reported a decrease in the colectomy rate in UC patients with MH at 1 year after diagnosis, regardless of the therapy used to achieve it, and in a post-hoc analysis of the ACT1/ACT2 trials conducted by Colombel *et al.*^[37], in which a Mayo Clinic endoscopy subscore of 0-1 in Infliximab-treated patients was related to a lower probability of colectomy than a score of 2-3 through a follow-up period of 54 wk. Interestingly, in the latter article by Colombel *et al.*^[37], MH in the placebo group did not show the same positive prognostic value as it did in the Infliximab-treated group, questioning the prognostic value of MH “*per se*” and suggesting that the drugs used to achieve the MH may play a specific role in the long-term outcome.

The increased risk of colorectal cancer incidence in UC patients is still a matter of debate^[38]. Nonetheless, the inflammatory burden appears to be an important determinant, and consequently, MH is likely to reduce the risk. An Italian cohort study indicated a lower CRC risk at 17 years of follow-up in azathioprine (AZA)-treated UC patients with MH^[39].

Recently, appealing data have indicated a possible prognostic role for histologic remission in terms of reductions in flares, surgery/hospitalization and CRC incidence, suggesting histologic remission as the ultimate therapeutic goal in UC management^[29]. In fact, Bitton *et al.*^[40] have reported basal plasmacytosis at rectal biopsy as an independent predictor of early relapse in UC patients, and Bessisow *et al.*^[41] have described a higher rate of flares in patients with macroscopically healed mucosa but histologic activity when compared with patients with both the macro- and microscopic absence of disease. Nonetheless, correlations with macroscopic and microscopic activity are not always straightforward^[42], and routine biopsies are not suggested by the current guidelines. At present, more evidence is needed before considering histological MH as a possible goal of treatment in UC patients.

MH: CURRENT THERAPIES

Biologic agents

As mentioned, the MH concept has been clearly defined

Table 1 Randomized clinical trial of biologic agent in ulcerative colitis and the relative mucosal healing rates

| Ref. | Patients (n) | Treatment protocol duration | Evaluation time from baseline | MH rate |
|--|--------------|---|-------------------------------|-------------------------|
| Rutgeerts <i>et al</i> ^[32] | 728 | IFX 5 or 10 mg/kg every 8 wk | Week 8 | 60.7% IFX |
| | | Placebo | | 32.3% placebo |
| | | 30 wk (ACT2) | Week 30 | 50.6% IFX |
| Panaccione <i>et al</i> ^[50] | 231 | AZA 2.5 mg/kg | Week 16 | 27.4% placebo |
| | | IFX 5 mg/kg | | 46.0% IFX |
| | | IFX 5 mg/kg + AZA 2.5 mg/kg | | 18.2% placebo |
| Sandborn <i>et al</i> ^[25] | 494 | ADA 160/80 and then 40 mg eow | Week 8 | 37% AZA |
| | | Placebo | | 55% IFX |
| | | 52 wk | Week 52 | 63% AZA + IFX |
| Reinisch <i>et al</i> ^[43] | 390 | ADA 160/80 mg or 80/40 mg at weeks 0 and 2 followed by 40 mg at weeks 4 and 6 | Week 8 | 41.1% ADA |
| | | Placebo | | 31.7% placebo |
| | | 52 wk | Week 52 | 25.0% ADA |
| Feagan <i>et al</i> ^[44] | 225 | VED 300 mg at week 0 and 2 and then every 4 or 8 wk | Week 6 | 15.4% placebo |

MH: Mucosal healing; IFX: Infliximab; ADA: Adalimumab; AZA: Azathioprine; VED: Vedolizumab; GOL: Golimumab.

only in the biologic era, and the trials of biologic drugs present a better evaluation of this aspect than previous studies. In particular, the MH definition has been standardized by the utilization of the Mayo endoscopic subscore, which identifies as MH as a score of 0 or 1. However, MH has always been considered as a secondary end-point in clinical trials, and studies still present heterogeneity in terms of inclusion criteria (and, therefore, baseline endoscopic severity), design and follow-up. Nonetheless, the MH rates in the short (induction) and long term (maintenance) are consistent and significantly superior to those of placebo in all studies (Table 1), which is even more remarkable considering the baseline severity of the UC patients included, although, in most of the studies, MH was only observed in a minority of the patients^[25,32,43-46]. Moreover, as mentioned, patients in RCTs are superselected, and the results may be not directly applicable to the “real-life” IBD population.

Azathioprine

From the first early report by Jewell *et al*^[47] of increased MH after 4 wk in UC patients treated with corticosteroids plus AZA *vs* corticosteroids plus placebo (92% *vs* 71%, $P = ns$), few studies with a limited number of patients have addressed MH rates in AZA-treated UC patients. In all of the reported studies, MH was a secondary end-

point, and the MH definition, base-line endoscopic activity, timing of the endoscopic evaluation and concomitant therapies differed; therefore, conclusive results are hard to extrapolate.

With the aforementioned limitations, Paoluzi *et al*^[48] reported 57% and 45% rates of MH in UC patients treated with AZA at 6 mo ($n = 42$ patients) and 4 years ($n = 22$ patients), respectively, and a similar 6-mo rate was reported by Ardizzone *et al*^[49] [19/36 patients treated with AZA (53%) *vs* 7/36 of patients treated by 5ASA (19%)]. Recently, a study by Panaccione *et al*^[50] (available only in abstract form) reported a 36% MH rate in patients treated with AZA in monotherapy and a 63% MH rate in patients treated with AZA plus Infliximab at 4 mo, with nearly 80 patients per group, indicating that combination therapy may increase the rate of MH.

Corticosteroids

Unlike CD, in which corticosteroids are traditionally considered ineffective for the achievement of MH^[51], corticosteroids may induce MH and a clinical response in UC. The first evidence supporting a favorable role of corticosteroids in inducing MH dates back to 1954, when True-love reported a double-blind placebo-controlled randomized multicenter trial of 120 UC patients and demonstrated higher rates of MH in the oral cortisone (100 mg/d) group

than in the placebo group (30% *vs* 10%) within 6 wk^[16].

In the last six decades, a great number of studies have reported positive effects of corticosteroid therapy on the improvement/resolution of mucosal alterations in UC, irrespective of the route of administration (oral or rectal) and the type of corticosteroids (traditional systemic steroids or agents with low systemic availability)^[52-59]. Generally, a certain discrepancy between the clinical and endoscopic responses was present in the majority of the studies evaluating MH in UC after corticosteroid treatment. A meta-analysis by Marshall *et al*^[55] examining the role of rectal corticosteroid preparations showed similar clinical (approximately 45% of cases) and endoscopic (approximately 33% of cases) remission rates for conventional corticosteroids (hydrocortisone, prednisolone, methylprednisolone and betamethasone) and topically active corticosteroids (beclomethasone, budesonide and prednisolone metasulphobenzoate). Recently, Ardizzone *et al*^[34], in a study of 157 consecutive newly diagnosed UC patients, explored the potential prognostic significance of a 3-mo clinical and endoscopic response after the first course of corticosteroid treatment. After 3 months, 60 patients (38.2%) had a complete clinical and endoscopic response, 39 (24.8%) had a clinical but not an endoscopic response, and 58 (36.9%) had no response. Interestingly, failure to achieve endoscopic remission at the end of the first course of steroids was related to a more aggressive disease behavior.

Data obtained from the use of topical steroids present a reduced variability between clinical and endoscopic responses. Indeed, in a recent meta-analysis exploring the efficacy of rectal beclomethasone dipropionate, the clinical and endoscopic rates of improvement or remission were similar (65.3%) and concordant, although in the four trials considered for the meta-analysis, a clear definition and evaluation of mucosal healing were lacking^[60].

Several problems arise in the attempt to analyze and compare the results of the above-mentioned studies. Diversity in the timing of endoscopy and in the use of endoscopic indices (*e.g.*, Sigmoidoscopic score, Rachmilewitz index, Baron score) along with the lack of a univocal MH definition, possible inter-observer variations or heterogeneity of the included patient cohorts may have generally contributed to consistent variability in the MH rates in steroid trials.

Aminosalicylates

Mesalamine was approved by the Food and Drug Administration in late 1987, and since this time, it has become the cornerstone therapy for mild-moderate UC^[61]. Mesalamine can be administered orally and/or topically, and it is present on the market in different formulations specific to both methods of administration. Many studies show the ability of mesalamine to induce MH. A recent meta-analysis of 49 studies has concluded that MH is achieved in approximately 37% and 50% of patients treated with oral and topical mesalamine, respectively^[62]. Nonetheless, the results from single studies are dramatically different,

ranging from approximately 0% to 77% for oral mesalamine^[23,63] and from approximately 10% to 93% for topical formulations^[54,64]. This variability may be attributed to the different definitions of MH, but this is unlikely to be the only reason. While MH rates do not appear to be related to the release mechanisms of oral mesalamine^[62], in accordance with previous studies reporting similar effectiveness between different formulations^[61,65,66], studies continue to present great heterogeneity in terms of total dose in grams, disease extension, months of follow up and endoscopic score at baseline. Notably, the MH rates in placebo groups are reported to be high, up to 46% in a study of oral placebo *vs* oral mesalamine at 8 wk^[63] and 26%-37% in a study of topical placebo *vs* topical mesalamine after 6 wk^[67]. Moreover, in studies with therapeutic regimens of adequate dose and duration, the MH rate appears to be higher^[68-70], and the lack of achievement of MH in patients with clinical remission has been indicated as a possible negative prognostic factor for relapse occurrence^[71].

CONCLUSION

After the emergence of novel biologic therapies for UC, the old concept of the relevance of the endoscopic activity of disease has been translated into the new concept of MH as the therapeutic goal to achieve. Although this idea has been supported by a growing body of scientific evidence indicating the favorable prognostic value of a healed mucosa in the natural history of UC, it is also suggested commercially, as a high rate of MH is claimed when utilizing the new biologic agents. Indeed, endoscopic evaluation appears to be the “gold standard” for the evaluation of disease activity in UC patients, and healing of the mucosa is likely to be an important factor for the control of the disease in the short and long term. However, specific studies showing the superiority of a management based solely on MH over the “traditional” approach are lacking. To date, most of the evidence supporting the prognostic relevance of MH comes from studies in which MH is not considered as the primary endpoint as well as from retrospective investigations. In the present study, we provocatively addressed the issue of the relevance of MH for UC patients management. A careful review of the current evidence regarding MH in UC shows that, due to the high heterogeneity of the available studies (particularly for those from the pre-biologic era), crucial points are still far from being conclusively determined, including the MH definition, the expected rate of MH with the current medication, and whether a systematic assessment of MH and an optimization of therapy based on MH alone would improve long-term disease outcome. Moreover, the prognostic value of MH “*per se*” needs to be investigated to clarify whether the current drugs may be safely reduced or interrupted after MH achievement. The latter issue may also present consistent economic implications regarding the elevated cost of long-term maintenance therapy with biologic drugs. However, in most cases, MH appears to be achiev-

able only in a minority of UC patients and most likely with the utilization of potent and potentially dangerous therapeutic regimens. In the near future, the development of novel drugs and an increase in our knowledge of the complexity of IBD are desirable, as they may increase the efficacy of our therapeutic approach to the disease.

Notably, going back to the natural history of the disease, more than one-half of UC patients have a benign disease course, while up to one-third are likely to experience frequent flares and potentially dangerous complications. In fact, the large population study by Solberg *et al.*^[36] (IBSEN cohort), which evaluated the first 10 years of the disease course in a population of 519 patients with UC, highlighted an overall good prognosis. Their study showed that at 10 years, more than half of patients were in remission or had mild disease, while 37% and 6%, respectively, reported chronic intermittent and chronic continuous symptoms. In a large Danish cohort study, approximately one-third of patients had no flares within 10 years after the first attack of UC. Moreover, the cumulative probability of having a course without relapses after 10 years in patients in remission is 40%-60%^[72]. However, the colectomy rate is estimated to vary from 8.7% to 30% in different populations^[72-74], and after the first relapse, the cumulative rates of a second course of systemic steroids are 13%, 41% and 48% at 1, 5 and 10 years, respectively^[36].

In times of resource optimization, the ideal disease management would imply an aggressive treatment and endoscopic follow-up for the achievement of MH in patients with an unfavorable disease course. Accordingly, together with a better definition of the MH concept and its specific role in the management of UC patients, further research for the characterization of clinical and/or genetic features predictive of an aggressive behavior of the disease is urgently needed. Similarly, the identification and the implementation of clinical and laboratory parameters strongly correlated with the endoscopic activity, such as clinical scores, to better follow-up these patients, appear to be of relevance^[75]. Consequently, it is advisable that the aforementioned shift from a symptoms-based to a mucosa-based approach in the management of UC patients would not result in a trend to over-scope and/or over-treat patients for the achievement of MH. Indeed, because more solid evidence will be available regarding the role of MH, a rational approach to UC patients should reserve close monitoring and more potent therapies for “high-risk” patients, overcoming the dualism between symptom- and mucosa-targeted approaches and focusing increasingly on a “patient-based” approach.

Abstract

Inflammatory bowel disease (IBD) is believed to develop *via* a complex interaction between genetic, environmental factors and the mucosal immune system. Crohn's disease and ulcerative colitis are two major clinical forms of IBD. MicroRNAs (miRNAs) are a class of small, endogenous, noncoding RNA molecules, and evolutionary conserved in animals and plants. It controls protein production at the post-transcriptional level by targeting mRNAs for translational repression or degradation. MiRNAs are important in many biological processes, such as signal transduction, cellular proliferation, differentiation and apoptosis. Considerable attention has been paid on the key role of miRNAs in autoimmune and inflammatory disease, especially IBD. Recent studies have identified altered miRNA profiles in ulcerative colitis, Crohn's disease and inflammatory bowel disease-associated colorectal cancer. In addition, emerging data have implicated that special miRNAs which suppress functional targets play a critical role in regulating key pathogenic mechanism in IBD. MiRNAs were found involving in regulation of nuclear transcription factor kappa B pathway (*e.g.*, miR-146a, miR-146b, miR-122, miR-132, miR-126), intestinal epithelial barrier function

(*e.g.*, miR-21, miR-150, miR-200b) and the autophagic activity (*e.g.*, miR-30c, miR-130a, miR-106b, miR-93, miR-196). This review aims at discussing recent advances in our understanding of miRNAs in IBD pathogenesis, their role as disease biomarkers, and perspective for future investigation and clinical application.

Key words: Crohn's disease; Inflammatory bowel disease; MicroRNA; Treatment; Ulcerative colitis; Biomarker

Core tip: MicroRNAs (miRNAs) are a class of small, noncoding RNA molecules that post-transcriptionally regulate gene and protein expression. Recent studies have identified altered miRNA profiles in inflammatory bowel disease (IBD). Special miRNAs which suppress functional targets have been found to play a critical role in regulating key pathogenic mechanism in IBD. In this review, we discuss the possibility to use miRNAs as biomarkers and therapeutic target in IBD.

INTRODUCTION

Inflammatory bowel disease (IBD) refers to chronic remittent or progressive inflammatory conditions that may affect the entire gastrointestinal tract. Crohn's disease (CD) and ulcerative colitis (UC) are two major clinical forms of IBD^[1]. The incidence and prevalence of IBD is continuously increasing over the past decades in different regions around the world^[2]. Although the precise pathogenesis of IBD remains obscure, several reports have

indicated that dysfunction of the mucosal immune system which develops *via* a complex interaction between genetic factors, the host immune system and environmental factors plays an important role in its etiology^[3]. The chronic inflammation of IBD is associated with marked molecular changes in gene and protein expression^[4]. So small molecules targeted at the pathways involving in these processes may be potential for IBD diagnosis and treatment.

MicroRNAs (miRNAs) are considered as promising candidate. They are a class of single-stranded non-coding RNA molecules on an average 22 nucleotides long^[5], and are highly conserved throughout evolution^[6] and discovered in all eukaryotic cells except fungi^[7]. MiRNAs regulate gene expression both at a transcriptional and translational level^[8], and mediate post-transcriptional gene silencing by directly binding to the 3' untranslated region (UTR) of target mRNA. Depending on the level of sequence complementarity between miRNA and target site, mRNA transcripts targeted by miRNAs are either silenced if the base-pair match is imperfect or degraded if there is an identical base-pair match^[9]. The mRNAs inhibited by miRNAs move to cytoplasm and accumulate in cytosolic processing bodies until they are eventually degraded^[10]. Each miRNA can target hundreds of genes, and a particular gene is usually the target of multiple miRNAs, adding complexity to the regulation of gene transcriptional network^[11]. It has been reported that miRNAs play an important role in many biological processes, such as signal transduction, cellular proliferation, differentiation, apoptosis and immune response^[12,13]. Recently, miRNAs have been recognized as critical elements in the regulation of the innate and adaptive immune responses, and changes in miRNAs expression are related to many autoimmune diseases, including systemic lupus erythematosus, rheumatoid arthritis, psoriasis and IBD^[14-17].

In this review, we summarize the current understanding of the connection between miRNAs and IBD. We mainly focus on special dysregulated miRNAs in CD and UC, which lead to inappropriate expression of targeted mRNA and may contribute to IBD pathogenesis, diagnosis and treatment. Table 1 summarizes the altered miRNAs involved in IBD and their mRNA targets.

MIRNAS REGULATE NUCLEAR TRANSCRIPTION FACTOR KAPPA B PATHWAY

The nuclear transcription factor kappaB (NF- κ B) was identified as one of the important regulators in the immune system and inflammatory diseases^[18]. NF- κ B is markedly induced in IBD patients and strongly influences the course of mucosal inflammation through its ability to promote the expression of various pro-inflammatory genes^[19]. Nucleotide-binding oligomerization domain 2 (NOD2) was found to be the first IBD susceptibility gene^[20], which is mainly expressed in Paneth cells, monocytes, macrophages, dendritic cells and some types of

intestinal epithelia cell^[21]. NOD2 can be activated by muramyl dipeptide (MDP), a component of bacterial cell wall, which induces the activation of NF- κ B^[22].

MiR-146a was reported to regulate gut inflammation *via* NOD2-sonic hedgehog (SHH) signaling^[23]. SHH signaling is an important pathway that maintains gut homeostasis and directs gut development. The expressions of NOD2-induced iNOS and NO were increased in MDP-treated macrophages, which further induced the level of miR-146. Promoter luciferase analysis with miR-146a promoters revealed that NF- κ B was a critical transcription factor that regulate NOD2 mediated expression of miR-146a. NOD-2 induced miR-146a target NUMB, a negative regulator of SHH signaling, alleviating the suppression of SHH signaling and subsequently increasing the pro-inflammatory cytokines expression.

Feng *et al*^[24] proved that up-regulation of miR-126 may contribute to pathogenesis of UC by targeting I κ B α . They found miR-126 was significantly increased in active UC tissues compared to healthy controls. I κ B α , an inhibitor of NF- κ B pathway and the target of miR-126, was markedly decreased in active UC tissues. The expression of miR-126 and I κ B α were inversely correlated in patients with active UC. MiR-126 could inhibit the level of I κ B α in HT29 cells. They further demonstrated that miR-126 may activate NF- κ B signaling pathway by targeting I κ B α and contribute to the development of UC. Another study showed that the anti-inflammatory activities of the red wine polyphenolics were, at least in part, mediated by the induction of miR-126^[25]. CAMs, such as intracellular cell adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), are expressed on the surface of fibroblasts^[26]. It has been demonstrated that the expression of ICAM-1 was increased in CD patients^[27] and inhibition of CAMs could suppress various forms of experimental inflammatory and immune responses in colon fibroblast cells^[28]. VCAM-1 has been confirmed as one of the targets of miR-126 before^[29]. Angel-Morales *et al*^[25] found the polyphenolic red wine extract (WE) exerted an anti-inflammatory effect in LPS-stimulated human colon-derived CCD-18Co myofibroblast cells through inactivating NF- κ B and down-regulating a wide range of downstream pro-inflammatory genes including tumor necrosis factor (TNF)- α , interleukin-6 (IL-6) and CAMs. Furthermore, they found the up-regulation of miR-126 was induced by WE in CCD-18Co cells and protected human colon cells from inflammation through targeting VCAM-1.

MiR-122 was found dysregulated in association with CD progression^[30]. Chen *et al*^[31] identified NOD2 as a target of miR-122. Overexpression of miR-122 in LPS-stimulated HT-29 cells inhibited LPS-induced apoptosis and down-regulated LPS-induced NOD2 expression. Pretreatment with miR-122 in LPS-stimulated HT-29 cells decreased the pro-inflammatory cytokines and increased the anti-inflammatory cytokines by targeting NOD2-induced NF- κ B signaling pathway. Taken together, miR-122 might decrease intestinal epithelial cell injury in Crohn's disease by targeting NOD2. Besides regulating the activation of NF- κ B pathway, Ye *et al*^[32] demonstrated
