Japanese Society of Gastroenterology^[10] and the Japan Society of Hepatology^[11]. In a second nationwide analysis, only 125 of 388 patients (32%) had an established diagnosis of IBD, 79% of whom had UC, whereas only 6.4% were diagnosed with CD^[11]. Ang *et al.*^[12] also reported a low association rate of 20% (2/10) between PSC and IBD in Singapore. The association of PSC with IBD varies depending on geographical location, with higher rates in European and American populations, and a significantly lower association in Asian patients^[13]. However, the incidence of IBD in PSC patients in our series was higher (68.9%) than that already reported in Japan^[14]. We speculate that this high incidence was noted because only PSC patients who had undergone total colonoscopy at clinical onset were enrolled in our study. Yamagishi *et al.*^[15] also reported a higher incidence of IBD in PSC patients (93%) examined by colonoscopy. It is possible that we overlooked the endoscopic findings, as we did not perform a careful total colonoscopy because the symptoms of IBD are mild and the endoscopic findings of the colon show only slightly abnormal changes. The second national survey in Japan also reported that the incidence of IBD in PSC patients increased to 61% when only PSC patients examined by total colonoscopy were enrolled^[11]. Therefore, the frequency of PSC-IBD should be evaluated among patients undergoing careful total colonoscopy. This selection criterion might decrease the observed differences in frequency between eastern and western countries.

The age at clinical onset of IBD is controversial and has not been clarified. Loftus *et al.*^[9] reported that the mean age of IBD diagnosis was higher among PSC-IBD patients (32 years) compared with controls (28 years). In contrast, Brackmann *et al.*^[16] reported that IBD patients with PSC were significantly younger at the onset of IBD symptoms (PSC: 19 years *vs* no PSC: 29 years; $P = 0.04$), whereas the colitis-colorectal cancer interval was similar to that of IBD patients without PSC (17 years *vs* 20 years; $P = 0.236$). Joo *et al.*^[4] showed that PSC patients with UC presented with UC at a significantly earlier age (mean age: 24.5 years) compared with UC controls (mean age: 33.8 years).

Takikawa *et al.*^[10,11] discovered two peaks in the PSC age distribution, which has never been observed in other countries, and revealed that most Japanese PSC patients associated with IBD were adolescents or young adults. A recent study from Canada also reported two peaks in the PSC age distribution^[17]. Our previous study also showed a two-peaked age distribution, and that patients with PSC-IBD were significantly younger than PSC patients without IBD (33.6 years *vs* 58.9 years, $P < 0.001$)^[14].

Although the diagnosis of IBD precedes that of PSC in most patients, a recent study found that a shift in the timing of diagnosis of the two diseases has occurred in recent years, with PSC more often being diagnosed first. PSC was diagnosed before IBD in a recent

cohort (2003–2007) when compared with a early cohort (1993–1997) (50% vs 35%, $P = 0.0009$)^[18].

MECHANISM OF PSC-IBD PATHOGENESIS

Several important observations, coupled with the strong association between certain human leukocyte antigen (HLA) haplotypes and the frequency of concurrent extrahepatic autoimmune disorders, support the concept that PSC is an immune-mediated phenomenon^[19,20]. Three UC susceptibility loci to be associated with PSC, harboring the putative candidate genes REL, IL2 and CARD9 were identified^[19]. A recent study reported 12 significant genome-wide associations outside the HLA region, 9 of which were new, increasing the number of known PSC risk loci to 16. Despite comorbidity with IBD in 72% of the included cases, 6 of the 12 loci showed significantly stronger associations with PSC than with IBD, suggesting overlapping yet distinct genetic mechanisms for these two diseases^[20].

The pathogenesis of PSC has been elucidated from the standpoint of PSC-IBD. Translocation of microbial flora across an inflamed, permeable gut with subsequent activation of the immune system and inflammation of the biliary tree is a hypothesized mechanism for the development of PSC. Activated intestinal lymphocytes enter the enterohepatic circulation and persist as memory cells that cause hepatic inflammation. Chemokines and adhesion molecules shared by the intestine and liver could contribute to immune cell binding at both sites^[21]. The observations that PSC can develop after colectomy^[22] and that IBD can develop after liver transplantation^[23] have led some investigators to suggest that aberrant homing of lymphocytes between the intestine and liver could be involved in the pathogenesis of PSC^[21]. Three recent studies indirectly supporting this theory have been published. Patients who received a liver trans-

plant had lower clinical and histological IBD activity than the non-transplant group^[24]. Marelli *et al*^[25] reported that progressive PSC requiring liver transplantation is associated with a milder course of UC, including reduced disease activity and less use of steroids, azathioprine, and surgery. Navaneethan *et al*^[26] reported that severe, progressive PSC requiring liver transplantation appeared to reduce the disease activity of UC and the need for colectomy.

However, these theories cannot explain why only 2%–7.5% of IBD patients develop PSC^[8], whereas PSC is strongly associated with IBD, or why CD is less associated with PSC. It is also unclear why immunosuppression does not improve PSC.

CLINICOPATHOLOGIC CHARACTERISTICS OF PSC-IBD

Previous studies have suggested that PSC-IBD differs from IBD without PSC in several aspects. Table 1 summarizes the reports concerning PSC-IBD^[3,4,9,14,24,27]. PSC-IBD has been reported to show an increased incidence of pancolitis, rectal sparing, backwash ileitis, mild symptoms, and colorectal malignancy^[8]. However, these results are controversial. All of the investigators agree that inflammation involved in PSC-IBD is milder than that in typical UC without PSC. Moreover, the majority of PSC-IBD patients show no or few IBD symptoms. Moayeri *et al*^[28] reported that the number of hospitalizations and courses of steroid therapy decreased significantly in UC-PSC patients compared with UC controls. Our study also indicated that none of the enrolled patients had a severe clinical course, and that half of them were asymptomatic^[14].

However, varied findings concerning the extent of PSC-IBD have been reported. Although some authors have reported that pancolitis is characteristic of PSC-IBD^[3,4,9], others have insisted that right-sided IBD is

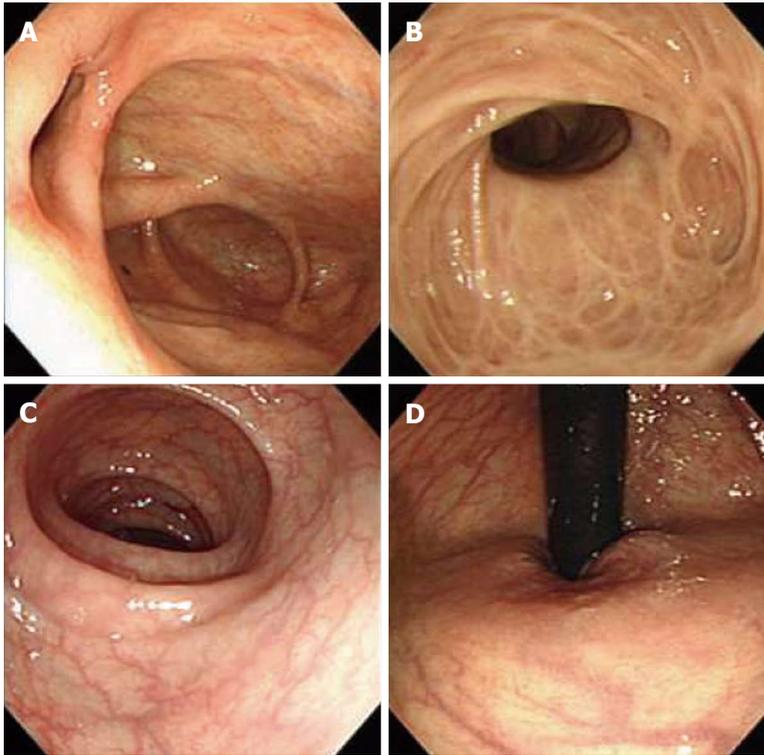

Figure 1 Colonoscopic findings at clinical onset. A: Cecum; B: Ascending colon; C: Sigmoid colon; D: Rectum. A 43-year-old female patient diagnosed with asymptomatic, concurrent primary sclerosing cholangitis-inflammatory bowel disease. The first colonoscopy showed multiple white scars in the ascending colon and right-sided transverse colon and no abnormal findings in the left-sided transverse colon, descending colon, sigmoid colon, or rectum.

characteristic^[14,24]. A recent report concluded that when IBD precedes PSC, pancolitis is common, whereas when PSC precedes IBD, right-sided IBD is common^[27].

Two reports revealed that the degree of inflammation was stronger in the right colon than the left colon using the histological studies. The first report demonstrated severe inflammatory cell infiltration in the cecum and ascending colon of PSC-IBD patients, whereas the degree was mild in the rectum/descending colon ($P = 0.0012$); goblet cell disappearance was also observed more frequently in the cecum/ascending colon than in the rectum/descending colon ($P < 0.05$)^[14]. The second report revealed that the histopathological signs of inflammation involved the right colon in 86% of patients and were purely right-sided in 23%. The frequency of inflammatory findings was higher in the right colon than the left colon ($P < 0.01$), but the general level of inflammatory activity was low^[24]. They also reported that inflammatory findings were more frequent on histology than on endoscopy.

These discrepancies may be due to differences in the geographical location between studies or the method used to assess total colitis based on the maximal extent of colitis at any time during the study period. Fluctuations in the extent of inflammation may therefore explain the high frequency of total colitis^[24,29].

The frequency of rectal sparing and backwash ileitis differs between reports, with the frequency of backwash

ileitis ranging from $< 10\%$ to 51%. Jørgensen *et al.*^[24] speculated that repeated examination or different patient selection criteria account for these differing results, and also reported that the frequency of rectal sparing on histological examination (20%) was higher than that on endoscopic examination (12%). Nakazawa *et al.*^[5] speculated that the different results were due to the definition and criteria of backwash ileitis.

The frequency of rectal sparing ranges from $< 10\%$ to 66%. Loftus *et al.*^[9] reported that rectal sparing was observed in 52% of UC-PSC patients compared with only 6% of UC patients without PSC on endoscopy. Jørgensen *et al.*^[24] reported that rectal sparing was observed in 66% of patients on endoscopy and was consistent with the results of pathological examination. In their study, the patients were considered to have rectal sparing if the inflammation involved the rectum but was less severe than that of the more proximal area of the colon. Joo *et al.*^[4] reported that rectal sparing was observed in only 27.5% of patients on histologic studies. Rectal sparing was defined as predilection if all biopsies from the rectum or the entire rectal mucosa from a resection specimen showed histologically normal mucosa. Rectal sparing was considered relative if at least one biopsy from the rectum at any time period or one portion of the rectal mucosa from the colonic resection specimen showed histologic features of chronicity, but at least mild activity was present in the areas of the mucosa proximal

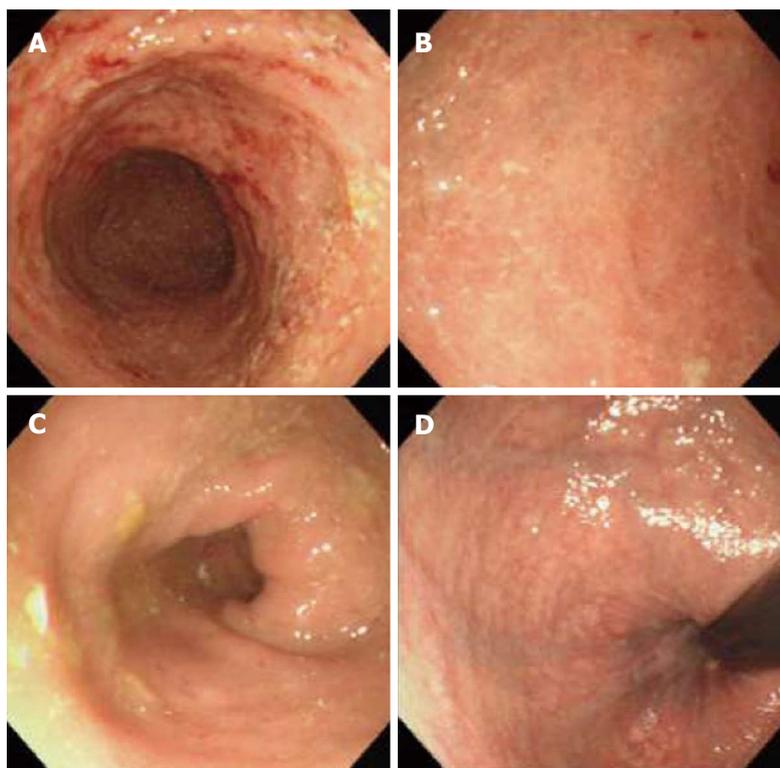

Figure 2 Colonoscopic findings seven months later. A: Cecum; B: Ascending colon; C: Sigmoid colon; D: Rectum. A repeat colonoscopy seven months later showing inflamed mucosa with multiple erosions and redness from the ascending colon to the right-sided transverse colon. Mucosal vessels are clearly visible in the descending colon, sigmoid colon, and rectum.

to the rectum.

The extent of colon involvement, rectal sparing, and backwash ileitis should be defined internationally to clarify the characteristics of PSC-IBD.

In our experiences with endoscopy, inflammation was more severe on the right, and rectal sparing appeared to be present on endoscopy (Figures 1 and 2), by contrast, less inflammatory cell infiltrations was observed in the rectum on histology. These findings are very useful in the diagnosis of PSC. In the presence of multiple biliary stenoses on magnetic resonance cholangiography, inflammatory findings dominant in the right colon and rectal sparing by total colonoscopy, invasive endoscopic retrograde cholangiography can be avoided in clinical practice.

COLORECTAL NEOPLASIA IN PSC-IBD PATIENTS

PSC-IBD patients are at particularly high risk for the development of colorectal cancer. Boonstra *et al*^[3] estimated that the colorectal cancer risk was increased 10-fold in PSC-IBD patients compared with UC controls. Claessen *et al*^[29] have reported that patients with PSC-IBD have a high long-term risk of developing colorectal cancer, and that this risk is approximately three-fold higher than that of cholangiocarcinoma. In patients with PSC-IBD, the 10-year and 20-year risks of colorectal cancer have

been reported to be 14% and 31%, respectively. Among 75 PSC-IBD patients, PSC was the only independent risk factor for the development of colorectal cancer, and the overall survival rate without liver transplantation was also reduced^[30].

PSC-IBD patients tend to be younger at colorectal cancer diagnosis^[31]. Colorectal cancer develops at a much younger age in these patients (39 years, range: 26-64 years) compared with IBD controls (59 years, range: 34-73) ($P = 0.019$)^[3].

Colorectal cancer in PSC-IBD patients predominantly develops in the right colon. The tumors were located proximally to the splenic flexure in 18 (67%) patients with PSC and in 52 (36%) patients without PSC ($P = 0.006$)^[29]. Thackeray *et al*^[32] also reported that colorectal cancer is most prevalent in the proximal colon (65%). When such patients are diagnosed with cancer, they tend to have more advanced tumors than IBD patients without concurrent PSC. In their study, patients with PSC had significantly more tumors with an American Joint Committee on Cancer tumor stage of 3A or higher when compared with patients with IBD alone (61.5% and 38.5%, $P = 0.003$). The reason for the preferential right-sided location of colorectal cancer in PSC patients remains unknown, although it has been speculated that the overall increased frequency of colorectal cancer in these patients could be due to a cytotoxic effect on the colonic mucosa caused by an altered bile acid composi-

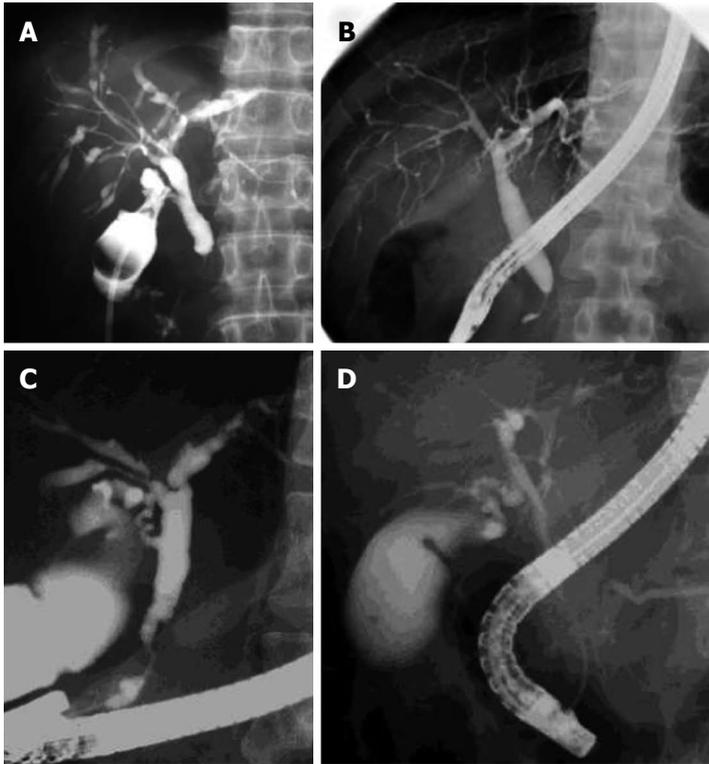

Figure 3 Cholangiographic examples of immunoglobulin G4-related sclerosing cholangitis and primary sclerosing cholangitis. tion. The predominance of right-sided inflammation is also a predisposing factor^[24]. The two reports showing that the histologic findings of inflammation were higher in the right compared to the left colon in PSC-IBD patients are consistent with the preferential right-sided location of colorectal cancer^[14,24].

Previous studies have shown conflicting results regarding the course of IBD after liver transplantation in patients with PSC. Recent studies have shown that the increased risk of neoplasia is maintained after liver transplant and proctocolectomy. Hanounch *et al*^[33] reported that patients with PSC-IBD after liver transplantation had a similar rate of colon neoplasia compared to those without liver transplantation (34% vs 30%, *P* = 0.24) during a mean follow-up period of 54.7 ± 47.7 mo. Jørgensen *et al*^[24] showed that macroscopic colonic

inflammation was more frequent after liver transplantation than before transplantation. The rate of relapse after transplantation was higher than that before transplantation, and the overall clinical IBD activity was also increased. Immunosuppression affects IBD activity after liver transplantation in patients with PSC.

Early cancer detection through enrollment in surveillance programs is the only strategy available to decrease cancer risk^[31]. More extensive colitis with a concurrent mild or even asymptomatic course, resulting in diagnostic delay and a lower colectomy rate, may contribute to an increased risk of colorectal cancer development^[9]. With the initial diagnosis of PSC in subjects with IBD, immediate and annual surveillance colonoscopy and biopsy analysis, of the entire colon, are recommended^[32,34].

The role of ursodeoxycholic acid (UDCA) as a chemopreventive agent is controversial. A meta-analysis showed no significant protective association between UDCA use and colorectal neoplasia. However, there was a significant chemopreventive effect on the risk of advanced colorectal neoplasia (OR = 0.35, 95%CI: 0.17-0.73), and low-dose UDCA use (8-15 mg/kg per day) was associated with a significantly reduced risk of colorectal neoplasia^[35]. There were no significant differences in cholangiocarcinoma incidence between the high-dose UDCA (17-23 mg/kg per day) and placebo groups^[36]. A recent study showed that patients treated with high-dose UDCA had a significantly higher risk of developing colorectal neoplasia during the study compared with those who received placebo (HR = 4.4, *P* = 0.02)^[37].

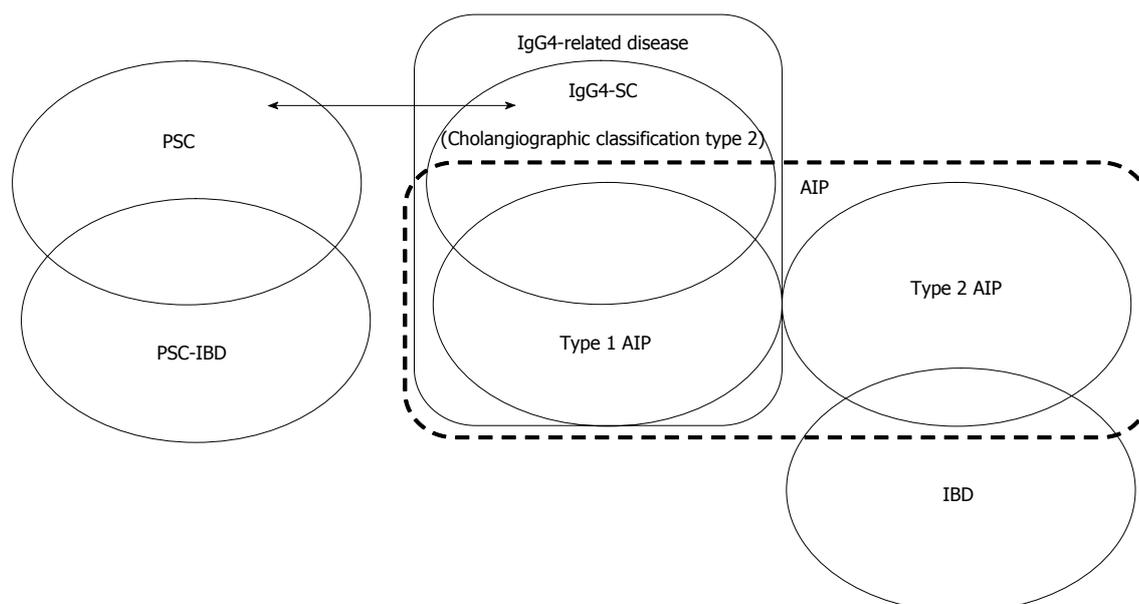

Figure 4 Correlation between inflammatory bowel disease and sclerosing cholangitis. PSC is frequently associated with characteristic PSC-IBD, whereas IgG4-SC is not associated with IBD. IgG4-SC is frequently associated with type 1 AIP, whereas type 2 AIP is frequently associated with IBD. PSC: Primary sclerosing cholangitis; PSC-IBD: IBD-associated with PSC; IBD: Inflammatory bowel disease; IgG4-SC: Immunoglobulin G4-related sclerosing cholangitis; AIP: Autoimmune pancreatitis.

THE USEFULNESS OF PSC-IBD CHARACTERISTICS IN THE DIAGNOSIS OF SCLEROSING CHOLANGITIS

Recently, IgG4-SC has attracted much attention following the emergence of clinical characteristics that distinguish it as a new clinical entity^[5]. IgG4-SC shows various cholangiographic features similar to those of pancreatic cancer, PSC, and cholangiocarcinoma^[7]. The characteristic cholangiographic features of IgG4-SC can be classified into four types based on the stricture location revealed by cholangiography and differential diagnosis^[6]. Type 2 IgG4-SC, in which stenosis is diffusely distributed throughout the intrahepatic and extrahepatic bile ducts, should be differentiated from PSC^[38] (Figure 3).

The differential diagnosis of PSC and IgG4-SC is important because patients with IgG4-SC show a good response to steroid therapy. We previously reported the differences between IgG4-SC and PSC^[7]. The age at clinical onset was significantly higher for IgG4-SC patients. Among the chief complaints in IgG4-SC, obstructive jaundice, reflecting marked concentric stenosis of the large bile duct, was most frequently observed. An elevated serum IgG4 level is a characteristic feature of IgG4-SC^[39]. An elevated serum IgG4 level and the association with type 1 autoimmune pancreatitis (AIP) are the most useful findings for discriminating between IgG4-SC and PSC^[6]. However, elevation of the serum IgG4 level alone is not useful because some PSC cases also show increased IgG4 levels. In addition, some IgG4-SC cases are not associated with AIP^[40]. Mendes *et al*^[41] measured the serum IgG4 levels in 127 patients with PSC and

found that it was elevated in 12 patients (9%). Björns-son *et al*^[42] reported elevated serum IgG4 levels in 12% of 285 patients with classic PSC. We performed a multicenter study in Japan to establish a cutoff value to differentiate IgG4-SC from controls^[43]. Serum IgG4 levels were compared between 56 patients with type 2 IgG4-SC and 110 patients with PSC. The serum IgG4 levels of the IgG4-SC patients were significantly higher than those of the PSC patients (799 ± 800 mg/dL *vs* 68.7 ± 86.0 mg/dL, respectively, $P < 0.001$). When we set the IgG4 cutoff value at 135 mg/dL, the sensitivity, specificity, and accuracy were 94.5%, 85.0%, and 90.5%, respectively. We also identified 13 of the 110 PSC patients (11.8%) with IgG4 values higher than the cutoff value of 135 mg/dL^[43]. Further studies are expected to clarify the differences between IgG4-SC and PSC patients with high serum IgG4 levels.

In contrast, the diagnosis of PSC is difficult because there are no useful markers of PSC. As such, an association with IBD is a very useful finding in the diagnosis of PSC. The frequencies of IBD associated with IgG4-SC are summarized in Table 2^[5,41,44-46]. No association between IBD and IgG4-SC has been reported, which is in contrast to the strong association between IBD and PSC (60%-80%)^[5,44-46]. One study reported that 6% of IgG4-SC cases were associated with IBD^[46], as IBD is common in western countries. We are unable to describe the details of IBD-associated IgG4-SC, although we speculate that the unique characteristics of PSC-IBD can be used to distinguish PSC from IgG4-SC.

IgG4-SC is frequently associated with type 1 AIP^[5]. Type 1 AIP is a different clinical entity from type 2 AIP, which is closely associated with IBD. Type 2 AIP is not

associated with IgG4-related diseases, including IgG4-SC, and elevated serum IgG4 levels are not observed^[47]. Clinically diagnosed IBD is incorporated in the diagnostic criteria for type 2 AIP in international consensus diagnostic criteria for autoimmune pancreatitis^[47]. These complicated associations are illustrated in Figure 4. There are no reports concerning the characteristics of IBD associated with type 2 AIP. If IBD associated with type 2 AIP shows characteristic findings, they might be useful not only in discriminating type 2 AIP from type 1 AIP, but also in elucidating the mechanism of sclerosing cholangitis.

In summary, PSC-IBD is associated with an increased incidence of pancolitis, mild symptoms and colorectal malignancy. Although an increased incidence of pancolitis is also a characteristic finding, some cases are endoscopically diagnosed as right-sided UC. Pathological studies have revealed that the findings of inflammation were more prevalent in the right colon than the left colon. The frequency of rectal sparing and backwash ileitis should be investigated in a future study based on the same definition. The rare association between IBD and IgG4-SC and the unique characteristics of PSC-IBD are useful for discriminating between PSC and IgG4-SC. In particular, when IBD is characterized by right-sided UC, rectal sparing, and backwash ileitis, the possible diagnosis of PSC-IBD should be considered. In the presence of multiple biliary stenoses on magnetic resonance cholangiography, inflammatory findings dominant in the right colon and rectal sparing by total colonoscopy, invasive endoscopic retrograde cholangiography can be avoided in clinical practice.

Abstract

Inflammatory bowel disease (IBD) includes Crohn's disease and ulcerative colitis. The exact etiology and pathology of IBD remain unknown. Available evidence suggests that an abnormal immune response against the microorganisms in the intestine is responsible for the disease in genetically susceptible individuals. Dysregulation of immune response in the intestine plays a critical role in the pathogenesis of IBD, involving a wide range of molecules including cytokines. On the other hand, besides T helper (Th) 1 and Th2 cell immune responses, other subsets of T cells, namely Th17 and regulatory T cells, are likely associated with disease progression. Studying the interactions between various constituents of the innate and adaptive immune systems will certainly open new horizons of the knowledge about the immunologic mechanisms in IBD.

Key words: Crohn's disease; Inflammatory bowel disease; Proinflammatory cytokines; T helper cells; T

helper 17 cells; Ulcerative colitis

Core tip: The etiology and pathology of inflammatory bowel disease (IBD) remain elusive, and dysregulation of the mucosal immune response toward commensal bacterial flora together with genetic and environmental factors may play important roles in the pathogenesis of IBD. A better understanding of the mechanisms of immune responses in the intestinal mucosa will provide new insights into the pathogenesis of IBD, and shed some light on targeted immune therapy for this disease.

Dysregulation of mucosal immune response in pathogenesis of inflammatory bowel disease. *World J Gastroenterol* 2014; 20(12): 3255-3264 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i12/3255.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i12.3255>

INTRODUCTION

The etiology and pathogenesis of inflammatory bowel disease (IBD) remain elusive, and accumulating evidence has indicated that sustained intestinal infections, mucosal barrier defects, mucosal immune dysregulation, genetic and environmental factors are involved in the disease process^[1-4]. Among these, the dysfunction of the mucosal immune system plays an important role in the pathogenesis of IBD (Figure 1). Among a variety of inflammatory cells in the gut, mucosal CD4⁺ T cells are thought to play a central role in both the induction and persistence of chronic inflammation by producing proinflammatory cytokines. Previous studies have indicated that T helper (Th) 1-related cytokines [*e.g.*, tumor necrosis factor (TNF), interferon (IFN)- γ , interleukin (IL)-12] as well as Th17-associated cytokines (*e.g.*, IL-17A, IL-21, IL-23) are markedly increased in inflamed mucosa of Crohn's disease

(CD) patients, whereas the cytokine profiles in inflamed areas of ulcerative colitis (UC) patients seem to exhibit increased production of the Th2-associated cytokines such as IL-4 and IL-13^[1-3]. These proinflammatory cytokines are potent *in vitro* stimulators of intestinal mucosal effect or functions, including T cell and macrophage proliferation, adhesion molecule expression, chemokine expression, and secretion of other proinflammatory cytokines.

ABNORMAL IMMUNE RESPONSE IN THE INFLAMED MUCOSA OF IBD PATIENTS

Antigen-specific activation of various lymphocytes within the intestinal mucosa by enteric pathogens is an important feature of IBD immunopathology^[1-4]. Under physiological conditions, a large number of innate and immune cells are located in the intestinal lamina propria, such as T, B, natural killer (NK), NKT cells, macrophages (M ϕ), dendritic cells (DCs), mast cells, neutrophils, eosinophils, as well as stromal cells (such as fibroblasts). It is actually surprising that the large lymphoid system in the intestine coexists so peacefully with the external environment, a single epithelial layer away from the luminal microbial flora. However, under inflammatory conditions, a large number of activated immune cells infiltrate into the intestinal mucosa. These immune cells and some stromal cells not only express high levels of adhesion molecules and auxiliary signal molecules (such as CD54, CD62L), but also express high levels of inflammatory mediators and chemokine receptors (such as CCR5, CCR6, and CCR9) and integrin (such as integrin $\alpha 4\beta 7$). Moreover, fibroblasts and capillary endothelial cells in the intestinal mucosa also express high levels of chemokines, selectins (*e.g.*, selectin E) and intracellular adhesion molecule-1 (ICAM-1, or CD54), which further induce intermolecular interactions of leukocytes in the blood circulation to migrate into the intestinal mucosa, and promote local inflammatory response^[1-4].

Evidence has demonstrated that CD4⁺ T cells isolated from inflamed mucosa of CD patients, when stimulated *in vitro*, are able to produce large amounts of Th1/Th17-associated proinflammatory cytokines (*e.g.*, IFN- γ , TNF, and IL-17A), while in UC inflamed tissue CD4⁺ T cells and NK T cells secrete high levels of Th2-related cytokines (*e.g.*, IL-4 and IL-13) and Th17-associated proinflammatory cytokines (*e.g.*, IL-17A)^[1-4]. The unbalance of pro/antiinflammatory cytokines contributes to intestinal mucosal inflammation. Recent studies have found that some proinflammatory cytokines (*e.g.*, IL-12, IL-18, IL-21, and IL-23) are significantly increased in inflamed mucosa of CD patients^[5-7], and that some inhibitory cytokines (*e.g.*, TGF- β , IL-10, IL-25, IL-33, and IL-37) are significantly reduced. Moreover, loss of forkhead proteins (Foxp)3⁺ regulatory T cells (Treg) and FoxP3 IL-10⁺ CD4⁺ cells are also found in the inflamed mucosa of IBD patients, and these events result in not maintaining intestinal mucosal immune tolerance and further promoting local intestinal mucosal immune response, leading to

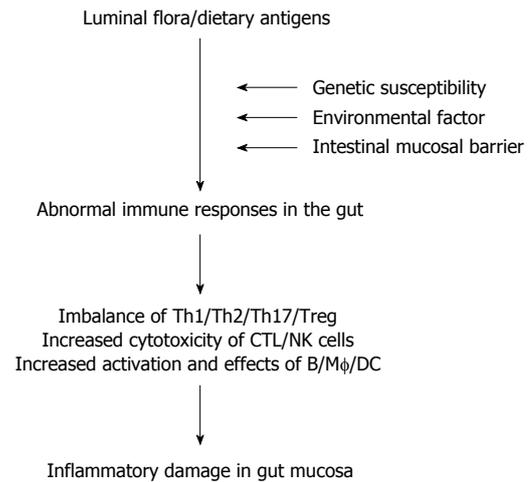

Figure 1 Pathogenesis of inflammatory bowel disease. DC: Dendritic cell; NK: Natural killer; Th: T helper; Treg: T regulator cell; CTL: Cytotoxic T lymphocyte; M ϕ : Macrophages.

the intestinal mucosal injury^[8].

PLEIOTROPIC ROLE OF IL-21 IN IMMUNE RESPONSE

IL-21 is a member of the IL-2 family of cytokines, expressed mainly by CD4⁺ T cells, including Th1, Th2, and Th17 cells (Figure 2)^[9,10]. IL-21 receptor (IL-21R) is structurally related to IL-2R and IL-15R, and is expressed in T, NK, B cells, and DCs^[9]. IL-21 exhibits a pleiotropic capacity to regulate T cell differentiation and function, enhances clonal expansion of antigen-activated naive CD4⁺ and CD8⁺ T cells, and induces the expression of genes encoding IL-12R, IL-18R, IFN- γ , IL-2R α , and the Th1-associated transcription factor T-bet in activated memory T cells^[11,12]. IL-21 is also associated with the Th2-mediated immune response and plays a role in inhibiting the differentiation of naive Th cells into IFN- γ -producing Th1 cells. In synergy with IL-15, Fc γ 3 ligand, and stem cell factor, IL-21 promotes human NK cell maturation and activation. It exerts further biological functions in B cells, regulates differentiation and antibody production, including production of all IgG isotypes, and synergizes with anti-CD40 mAb to stimulate B-cell activation, clonal expansion, and maturation (Figure 2)^[13-15].

In recent years, IL-21 has been found to be produced in excess in the intestine of IBD patients and may be involved in the pathogenesis of human IBD^[16-18]. When mucosal T cells from CD patients are activated *in vitro* with anti-CD3 in the presence of either a neutralizing anti-IL-21 antibody or an IL-21R-IgG fusion protein, the production of both IL-17A and IFN- γ is reduced. These results together with the demonstration that IL-21-deficient mice are resistant against Th1/Th17 cell-driven colitis support the key role of IL-21 in positively regulating Th1 and Th17 cell-associated inflammatory pathways. IL-21 exerts further biological functions that could contribute to its proinflammatory effect in the gut. For

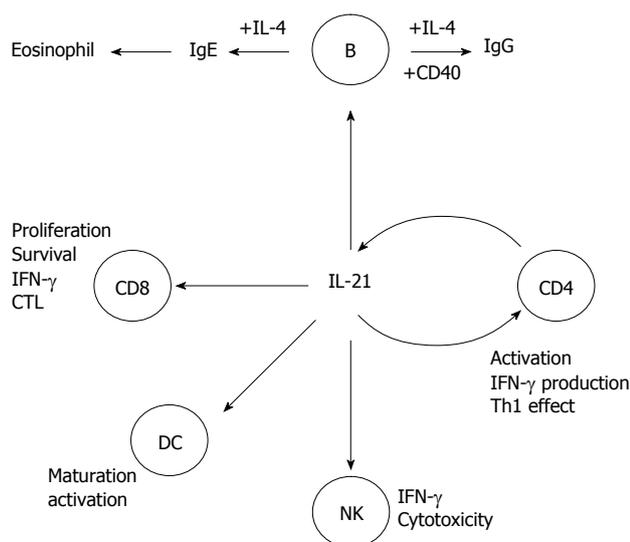

Figure 2 Pleiotropic role of interleukin-21 in immune responses. IFN: Interferon; IL: Interleukin; CD: Crohn's disease; DC: Dendritic cell; NK: Natural killer; CTL: Cytotoxic T lymphocyte.

example, IL-21 stimulates stromal cells to produce tissue-degrading proteases and enhances secretion of the T-cell chemoattractant macrophage inflammatory protein-3a by intestinal epithelial cells. IL-21 potentiates the expression of Th1-related transcription factors and IFN- γ in T and NK cells and the cytotoxic activity of NK cells. IL-21 also inhibits the peripheral differentiation of Tregs and makes CD4⁺ T cells resistant to Treg-mediated immune suppression. Therefore, through the multiple pathways IL-21 can damage the gut, and neutralizing IL-21 may have a therapeutic potential in the management of IBD^[13,18].

We have also investigated expression of IL-21R in inflamed mucosa of IBD patients and evaluated its role in the induction of NK cell cytotoxicity and activation as well as Th17 differentiation^[5]. The results have shown that IL-21R-positive cells are significantly increased in inflamed mucosa of IBD patients compared with healthy controls, and IL-21R is mainly expressed in freshly isolated peripheral blood (PB)- and lamina propria (LP)-CD4⁺, CD8⁺ T, B, and NK cells. When stimulated with immobilized human IgG and IL-21, PB-NK cells from IBD patients produce higher levels of IFN- γ and TNF than those from controls. IL-21-primed IBD NK cells show a more potent antitumor cytotoxicity to NK-sensitive K562 cells than controls. Moreover, PB-T and LP-T cells from IBD patients produce larger amounts of proinflammatory cytokines (*e.g.*, TNF and IFN- γ) than those from controls when stimulated with IL-21 and anti-CD3. Importantly, IL-21 facilitates IBD CD4⁺ T cells to differentiate into Th17 cells^[5]. In our further study, we have also evaluated the role of anti-TNF mAb (infliximab, IFX) in regulating IL-21 expression and Th17 cell infiltration in the intestinal mucosa of CD patients. Twenty-six CD patients were treated with IFX at weeks 0, 2 and 6. IL-21 and Th17 cells were found to be expressed highly

in inflamed mucosa of active CD patients compared with healthy controls. Ten weeks after IFX infusion, CD activity index, erythrocyte sedimentation rate, serum C-reactive protein (CRP) and intestinal mucosal healing were improved markedly in CD patients. Moreover, IL-21 expression and Th17 cell infiltration were also found to be significantly decreased compared with those before IFX therapy^[19]. These data indicate that IL-21 plays an important role in the pathogenesis of IBD.

PROINFLAMMATORY ROLE OF IL-23 IN THE PATHOGENESIS OF IBD

Recent advances have also indicated that IL-23, mainly produced by macrophages, is one of the critical cytokines in IBD and is essential for promoting chronic intestinal inflammation^[20,21]. IL-23 and IL-12 are members of a small family of proinflammatory heterodimer cytokines, sharing a common p40 subunit covalently linked to a p35 subunit to form IL-12 or to a p19 subunit to form IL-23. IL-12R is comprised of an IL-12R β 1 and IL-12R β 2 subunit, whereas the receptor for IL-23 consists of the IL-12R β 1 subunit and a novel component termed IL-23R^[20], which is expressed predominantly on T, NK, and NKT cells and to a smaller extent, on monocytes, macrophages, and DCs. After binding to the IL-23R, IL-23 preferentially induces memory T cell activation. IL-23 exhibits some similar biological activities to IL-12, however, in comparison with IL-12 with profound induction of the Th1 immune response, as well as promotion of cytotoxic, antimicrobial, and anti-tumor responses, IL-23 is found to play a critical role in the maintenance of immune response by controlling T cell memory function and by influencing the proliferation and survival of IL-17-producing Th17 cells^[22,23]. Moreover, recent work has also shown that IL-23 could induce naive CD4⁺ T cells to secrete IL-22, indicating that IL-23 is also associated with the differentiation of naive CD4⁺ T cells^[24].

Previous studies with murine colitis models have demonstrated a requirement for IL-23 in the development of intestinal mucosal inflammation. IL-23p19 subunit knockout results in a decrease of proinflammatory cytokines (*e.g.*, TNF, IFN- γ , IL-6, and IL-17) and the presence of less intestinal mucosal inflammation^[25,26]. Moreover, *in vivo* blockade of IL-23 using anti-IL-23p19 mAb or its inhibitor STA-5326 could inhibit chronic intestinal inflammation in a colitis model and down-regulate a Th1-mediated immune response^[26,27]. Elevation of IL-23p19 transcript levels has been observed in inflamed mucosa of IBD patients, and its expression is correlated with the severity of endoscopic lesions^[28]. Recent work has demonstrated that myeloid DCs from mesenteric lymphoid nodes of CD patients, when stimulated with exogenous microbial antigens *in vitro*, produce higher levels of IL-23p19 than UC patients and healthy controls^[29].

In order to investigate the pathogenic role of IL-23 in the induction of mucosal inflammation in IBD, we have analyzed IL-23p19 expression in inflamed mucosa

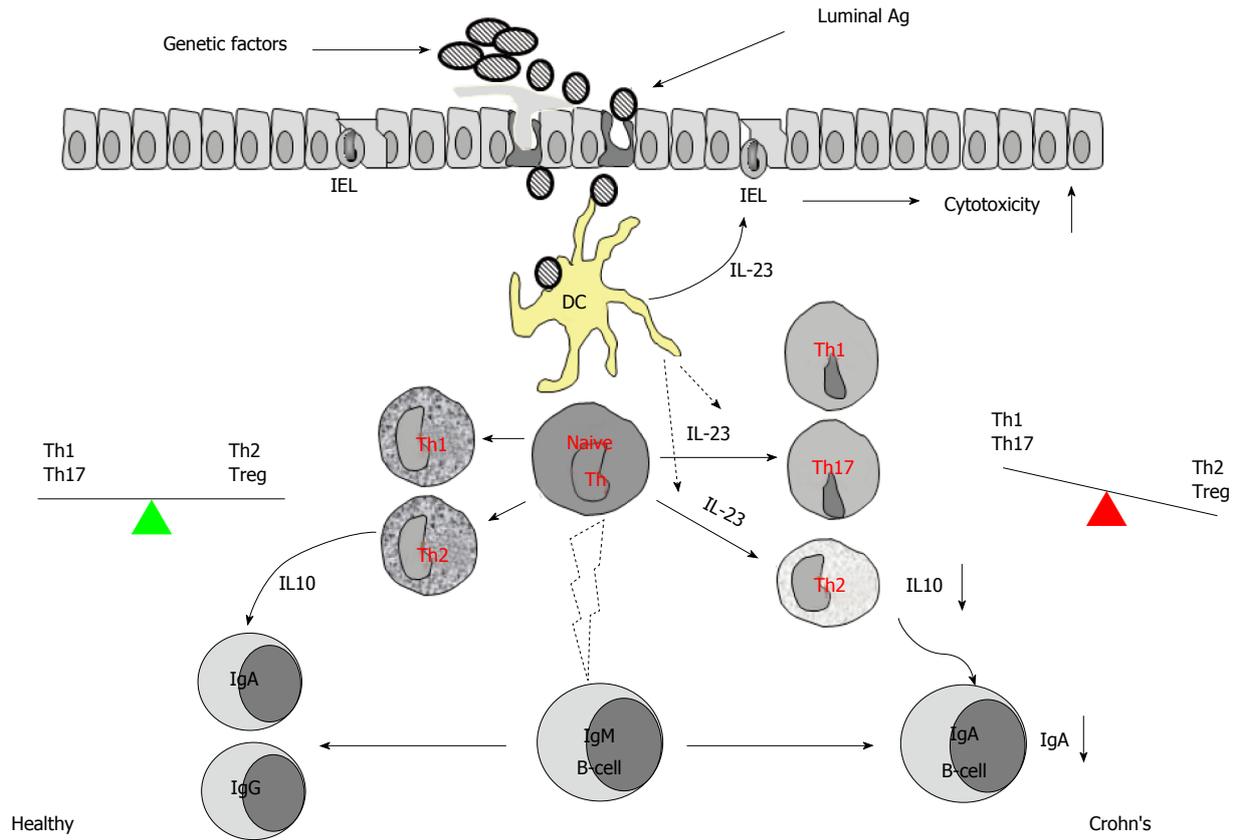

Figure 3 Overexpression of interleukin-23 in inflamed mucosa of patients with inflammatory bowel disease weakens the intestinal defensive barrier and disturbs the immune regulation in intestinal mucosa. IEL: Intestinal epithelial lymphocyte; IL: Interleukin; Th: T helper; Treg: T regulator cell; DC: Dendritic cell.

of IBD patients and its role in the induction of intestinal epithelial lymphocyte (IEL) and NK cell activation as well as Th17 cell differentiation. Expression of IL-23p19 has been observed to be increased significantly in inflamed mucosa of CD patients compared with that in UC patients and healthy controls. IL-23R cells are increased significantly in PB- and LP-CD4⁺ and -CD8⁺ T and NK cells. IL-23 could markedly promote IBD IEL and NK cell activation and cytotoxicity and triggered IBD PB- and LP-T cells to secrete significantly higher levels of IFN- γ , TNF, IL-2, and IL-17A compared with healthy controls. IL-23 promotes IBD PB- or LP-CD4⁺ T cells to differentiate into Th17 cells. These data indicate that IL-23 plays an important role in the induction of IEL, NK, and T cell activation, proinflammatory cytokine secretion, and Th17 cell differentiation^[6]. In two IBD models there is excessive accumulation of short-lived neutrophils and inflammatory monocytes in the intestine. IL-23-driven colitogenic T cell program has been found to regulate upstream hematopoietic stem and progenitor cells (HSPC)^[30]. Targeted therapy directed against IL-23 may have a therapeutic role in treatment of IBD.

Additionally, we have also elucidated the further role of IL-23 in the suppression of IL-10 in the IBD intestinal mucosa^[7]. IL-10 is an important cytokine in the induction of Th2 response that plays a crucial role in adaptive immunity *via* the induction of specific antibody

ies to eliminate the reinvasion of microbes and the absorption of microbial products. IL-10 is also one of the most effective immune regulatory cytokines contributing to maintaining the homeostasis of the body^[31,32]. Previous studies indicate that the production of IL-10 in the intestine of IBD patients is suppressed, but the underlying mechanism has not fully understood yet. Therefore, we examined the expression of IL-10, IL-23, and IgA in the surgically removed colon specimens and found that the levels of IgA and IL-10 were significantly lower, and both negatively correlated with IL-23 expression and the infiltration of inflammatory cells in the IBD mucosa. The production of IL-10 by lamina propria mononuclear cells was lower in the IBD group than the control, and these levels could be enhanced by blocking IL-23. The gene transcription of IL-10 was significantly suppressed in CD4⁺ T cells of IBD mucosa, and this phenomenon could be replicated *in vitro* by adding IL-23 in the culture of polarized Th2 cells^[7]. Thus we conclude that overexpression of IL-23 in the intestinal mucosa weakens the defensive barrier in the gut and disturbs the local immune regulation (IL-10 and Treg) (Figure 3).

POTENTIAL ROLE OF IL-25 IN THE DEVELOPMENT OF IBD

IL-25 (also known as IL-17E) is a distinct member of the

IL-17 family of cytokines, including IL-17A, IL-17B, IL-17C, IL-17D, IL-17E (IL-25), and IL-17F. IL-25 shares the receptor IL-17 receptor homolog 1 (IL-17Rh1) (also named the IL-17RB) with IL-17B, although it binds with a much higher affinity. IL-25R is a 56-kDa single transmembrane protein and is expressed in Th2 central memory cells, eosinophils, monocytes, airways smooth muscle cells, fibroblasts, and endothelial cells. Evidence has shown that IL-25 is also involved in the immune responses in gut mucosa^[33]. Previous work has demonstrated that IL-25 is constitutively expressed by intestinal mucosal T cells of mouse strains (*e.g.*, BALB/c, C57BL/6 mice) that are resistant to helminth *Trichuris muris* infection, whereas IL-25-deficient mice on a genetically resistant background fail to develop a Th2-mediated immune response or eradicate *Trichuris* infection but develop severe infection-induced intestinal inflammation. Moreover, the immunopathology in *Trichuris*-induced IL-25-deficient mice is also associated with increased expression of IFN- γ and IL-17A in the mesenteric lymph nodes and cecum^[33]. Administration of IL-25 could prevent intestinal mucosal inflammation in experimental colitis induced with peptidoglycan, 2,4,6-trinitrobenzenesulphonic acid, or oxazolone in mice. These data indicate that IL-25, which promotes the differentiation and activation of Th2 cells in gut mucosa, plays a critical role in the attenuation of destructive intestinal inflammation^[33,34].

IL-25 has been also found to be decreased in the inflamed mucosa of IBD patients and could decrease the synthesis of IL-12 and IL-23 in the CD14⁺M ϕ from the inflamed mucosa of patients with CD *in vitro*^[35]. Therefore, IL-25 may be a negative regulator of inflammatory responses in the intestinal mucosa. However, the exact role of IL-25 in the development of IBD remains to be elucidated. Recently, we have also studied the role of IL-25 in the pathogenesis of IBD^[36]. The results have demonstrated that IL-25 is significantly decreased in the sera and inflamed mucosa of patients with active IBD compared with controls. The levels of IL-25 in inflamed mucosa and sera are inversely correlated with endoscopic disease activities and CRP, respectively, in IBD. IL-25 could markedly inhibit IBD CD4⁺ T cells to produce TNF, IFN- γ , and IL-17A but promote IL-10 secretion. IL-25 could suppress the differentiation of IBD CD4⁺ T cells into Th1 and Th17 cells but did not interfere with Th2 cell differentiation. Importantly, blockade of IL-10 secretion by IBD CD4⁺ T cells markedly attenuates the inhibitory role of IL-25 in modulating both Th1 and Th17 immune responses (Figure 4). Our study provides evidence that IL-25 is a critical anti-inflammatory cytokine in the pathogenesis of IBD and may be considered as a potential therapeutic agent for human IBD^[36].

POTENTIAL ROLE OF THE TH17/IL-17 AXIS IN THE PATHOGENESIS OF IBD

IL-17 has pleiotropic activities, functions through the adaptive and innate immune system to promote im-

mune response, and plays an important role in immune responses. The identification of the IL-17 family of cytokines as well as the IL-23-mediated expansion of IL-17-producing T cells has uncovered a new subset of Th cells, designated as Th17 cells. Th17 cells originate from naive CD4⁺ T cells in the presence of TGF- β and IL-6. Th17 cell differentiation does not require IL-17. The amplification and stabilization of Th17 are provided by IL-21 and IL-23. At the same time, the ROR γ t is identified as the master key regulator and transcription factor of Th17 cell differentiation^[37,38]. The IL-17 cytokine family includes six members, IL-17A, IL-17B, IL-17C, IL-17D, IL-17E (or IL-25) and IL-17F, and act *in vitro* and *in vivo* as potent proinflammatory cytokines^[38]. IL-17A can induce the expression of proinflammatory cytokines (such as IL-6 and TNF), chemokines (such as KC, MCP-1 and MIP-2) and matrix metalloproteases, which mediate tissue infiltration and tissue destruction. It is also involved in the proliferation, maturation and chemotaxis of neutrophils^[38].

Evidence has shown that high numbers of Th17 cells are present in the colonic LP of the ileum and colon in conventionally raised mice, and that these cells are highly infiltrated in inflamed areas of colitic mice^[39,40]. Further analysis confirms that commensal gut flora contributes to the expansion of these CD4⁺ Th17 cells, leading to intestinal mucosal inflammation. In terms of mucosal immunity, the IL-23/IL-17 axis has been observed to play an important role in normal intestinal homeostasis.

To date, IL-17 and other Th17-associated cytokines (*e.g.*, IL-22 and IL-23) have been found to have protective or pathogenic effects dependent on other effective factors in local tissue. Recent work^[41] has also demonstrated that most of the transcripts for Th17-related cytokines are increased in IBD patients compared to normal controls, but more abundant in UC than in CD. In contrast, upregulation of IFN- γ mRNA is marked in CD LP CD4⁺ T cells. Up-regulation of IL-23p19 mRNA is detected in colonic mucosa from both UC and CD patients. The significance of Th17 immunity in UC is further supported by the finding that recombinant IL-23 actually enhances IL-17A production by LP CD4⁺ T cells in UC, but has a lesser effect on LP CD4⁺ T cells in CD^[42]. IL-17A is protective against dextran sodium sulfate (DSS)-induced colitis and colitis in the T cell transfer model, in which T cells are injected into lymphopenic mice. However, mice deficient in IL-17F are resistant to DSS-induced colitis. These data suggest that IL-17F, not IL-17A, is pathogenic in the gut. IL-17 may synergize with other inflammatory mediators in the gut. Recent studies have highlighted further potential heterogeneity within Th17 cell populations by demonstrating that some may even secrete IL-10^[43], a factor known to inhibit intestinal inflammation. Thus, it is possible that the actions of Th17 cells may differ dependently on other factors that may be present in the local environment. In the normal intestine, the primary function of Th17 cells may be like sentinels which contribute to maintaining epithelial barrier function, whereas

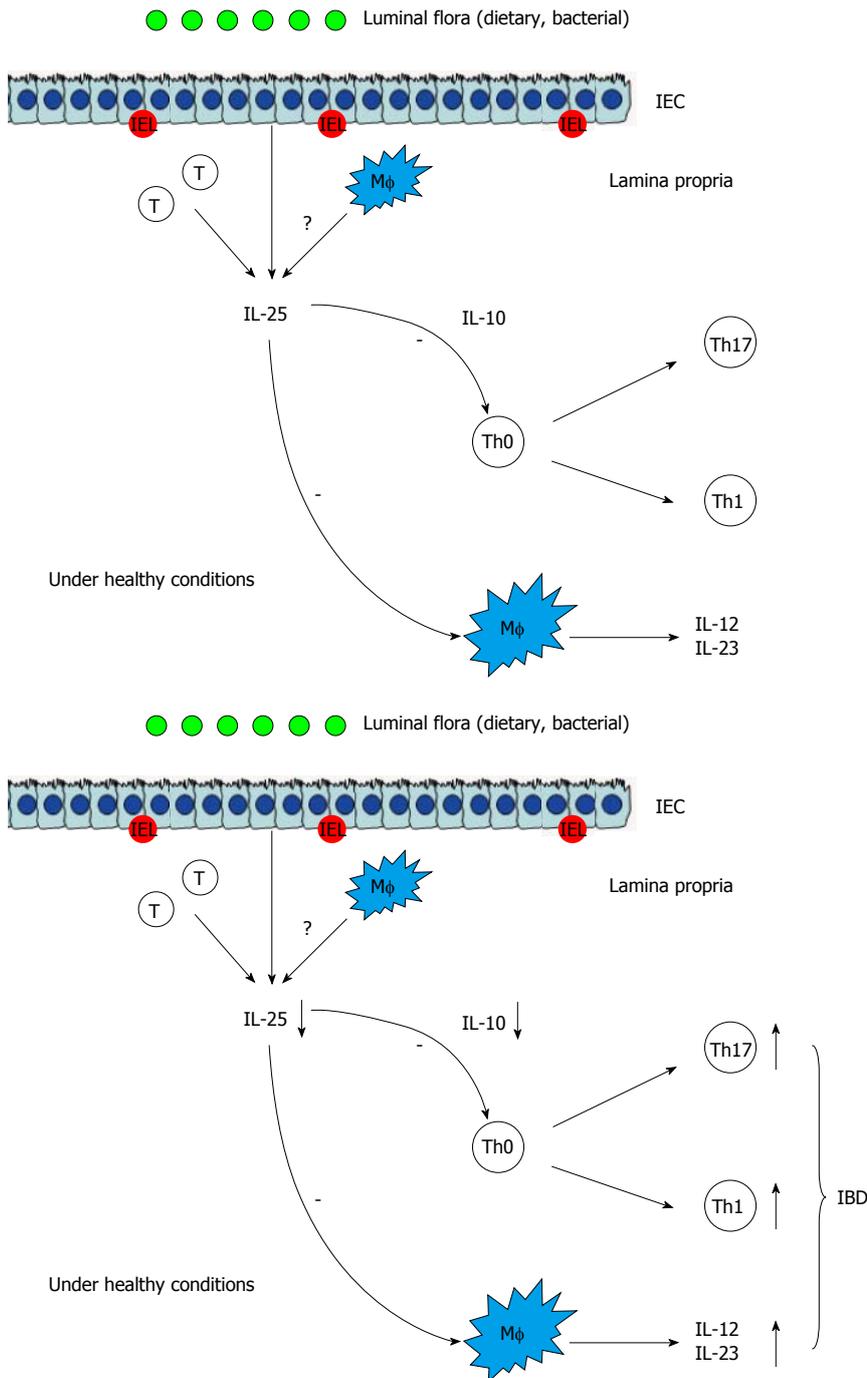

Figure 4 Inhibitory role of interleukin-25 in intestinal mucosa. IEL: Intestinal epithelial lymphocyte; IL: Interleukin; Th: T helper; Treg: T regulator cell; CTL: Cytotoxic T lymphocyte; Mφ: Macrophages; IEC: Intestinal epithelial cells; IBD: Inflammatory bowel disease.

in sites of chronic intestinal inflammation, high levels of IL-23 may activate their full pathogenic and antibacterial functions. Recently, Secukinumab (an IL-17A antibody), Brodalumab (an IL-17 receptor antibody) and two small-molecule drugs (Vidofludimus and Tofacitinib) are used in clinical trials for IBD patients, which inhibit IL-17 as part of their overall pharmacological profiles^[44].

IL-27 AND IL-35: NEWER MEMBERS OF THE IL-12 FAMILY

The IL-12 family is made up of secreted heterodimers

with some overlapping usage between family members. IL-12 (p35/p40) and IL-23 (p19/p40) are the best-known members of the IL-12 family. Other members include IL-27 (EBi3/p28) and IL-35 (EBi3/p35). Like the IL-17 family, however, a critical issue is whether these molecules are pathogenic or protective in the gut. IL-27, produced mostly by myeloid cells, is present at increased concentrations in IBD mucosa. If T cells are taken from mice deficient in the IL-27R and injected into lymphopenic mice, they induce significantly less colitis than wild-type T cells, clearly suggesting that IL-27 is pathogenic in this model. IL-27R-null mice are also less susceptible to DSS-induced

colitis, again suggesting that IL-27 is a proinflammatory mediator. In marked contrast, however, treating mice with established TNBS-induced colitis with IL-27 reduces disease and cytokine production. In humans, IL-27 has also been observed to reduce proinflammatory cytokine production in M ϕ activated with TNF^[45].

MICRORNA AND THE INTESTINAL IMMUNE HOMEOSTASIS

MicroRNA (miR) is an emerging group of short, non-coding RNAs that play an important role in regulating expression of classical genes at the post-transcriptional level. miR regulates cell proliferation, apoptosis, growth, cell differentiation, metabolism and other processes. Recently, miR in intestinal epithelial cells has been found to regulate intestinal mucosal barrier function through its important effect on intestinal epithelial cell proliferation and differentiation. Moreover, differential expression of miR in immune cells within the intestinal mucosa affects the intestinal immune homeostasis^[46,47].

In recent years, evidence has suggested that intestinal epithelial miR expression is closely related with the incidence and development of IBD^[46]. The expression of miR-192, miR-375 and miR-422b is significantly decreased in inflamed mucosa of patients with active UC, while miR-16, miR-21 and let-7 expression is significantly increased. miR-19b and miR-629 are significantly decreased in patients with active CD inflammation within the intestinal mucosa, while miR-23b, miR-106 and miR-191 are significantly increased. The abnormal miR expression will affect translation process of its corresponding target gene mRNAs, regulate gene expression and thus participate in inflammatory injury of intestinal mucosa in IBD. A recent study by Coskun *et al*^[48] provides the first evidence that miR-20b, miR-98, miR-125b-1*, and let-7e* are deregulated in patients with UC.

We have also investigated the expressions of miR10a in IBD and found that the expression of miR10a is decreased in inflamed intestinal mucosa of IBD patients. Furthermore, we have also found that TNF inhibits miR10a expression, while blockade TNF with anti-TNF mAb markedly enhances miR10a expression in the intestinal mucosa (unpublished data). Our findings, together with previous data showing that miR10a could block intestinal inflammation in mice and reduce the differentiation Th1 and Th17^[49], further prove that miR10a is involved in intestinal mucosal inflammatory response, and that targeted therapy may be beneficial for human IBD.

ROLE OF REGULATORY B CELLS

B cells are a source of inhibitory cytokines such as IL-10 and TGF- β . Depending on the signals B cells receive, pro- or antiinflammatory cytokines can be produced, and the shift towards an inflammatory or a protective/suppressive response will be induced. Specific B cell subset found to affect autoreactive responses and suggested to

have a regulatory role in autoimmune diseases is B-regulatory cells (Bregs). CD19⁺CD25⁺ B cells were the first subset of human B cells previously suggested to have a regulatory role. CD19⁺CD25⁺ B cells contribute up to 30% of all peripheral blood B cells in mice and can effectively present peptides to helper T cells. In humans, only B cells expressing high levels of CD25 (BCD25⁺) seem capable of acting as Bregs with abundant TGF- β production. However, it remains unknown how to identify Bregs with membrane markers or transcription factors. Several signals like B cell receptor (BCR), CD40 and/or Toll-like receptor (TLRs) may include. These different activation signals (alone or combined) were shown by many studies to increase regulatory functions of Bregs^[50].

Bacterial molecules have been used to stimulate Bregs. In mice, splenic B cells stimulated *ex vivo* by bacteria acquire the CD5⁺ CD1d⁺ phenotype, which is characterized by high level IL-10 expression and being capable of markedly suppressing the activity of experimental IBD. The protective subset (contributing 1% to 2% of all splenic B cells) is composed of CD5⁺CD1d(high) B cells activated *via* the TLR2/4 pathway by bacterial antigens in the gut flora. Investigations into the influence of the gut microbiota on the balance between effector B cells and Bregs may open up new therapeutic possibilities in IBD^[51,52].

ROLE AND FUNCTIONAL ALTERATIONS OF THE INNATE IMMUNITY

Innate immunity prevents pathogens from entering and spreading within the body. The intestinal innate immune system involves three lines of defense: the mucus layer, epithelium, and lamina propria. Mucus is the first line of intestinal defense, and the major constitutive proteins are mucins (MUC), with diverse isotypes in different portions of the gastrointestinal tract. CD patients show decreased MUC1 and MUC4 levels in the ileum, while MUC2, MUC5AC, MUC5B, MUC6, and MUC7 are undetectable in lesions. UC patients also show decreased MUC2 expression. As the second line of defense, the intestinal epithelium is composed of a monolayer of fast replicating polarized cells: enterocytes, goblet cells, and enteroendocrine cells. All are bound together through tight junctions that separate the body from intestinal lumen components. The membrane TLRs and cytosolic nucleotide oligomerization domain receptor (NOD) are the most important among intestinal pathogen recognition receptors. NOD2 has also been described as a negative regulator of TLR2-mediated IL-12 secretion. Some NOD2 mutations have been described in CD patients, which are associated with decreased defensin secretion by ileal mucosa Paneth cells.

Lamina propria as a third line of intestinal defense contains innate and immune cells. In IBD patients, DCs promote a robust recognition of bacterial products that might cause an immune response to commensal bacteria, provoking a loss of intestinal tolerance. Intestinal macro-

phages from IBD patients have lost the ability to maintain tolerance, mainly through increased surface CD14 content and NF- κ B transcription pathway activity, which might induce increased peripheral macrophage recruitment. Increased cytotoxic activity and elevated NK cell counts are also found in IBD patients. Crucial molecules in NK cells, such as IL-15, IL-21 and IL-23, and their cognate receptors, are elevated in the intestinal mucosa of UC patients. Moreover, in IBD the IEL activation increases, resulting in elevated production of IFN- γ , TNF and IL-2, which is associated with increased IL-23^[53,54].

Deregulated mucin expression in IBD patients might be due to the cytokine imbalance that characterizes these diseases. These molecules stimulate various transcription factor pathways, such as JAK/STAT and NF- κ B, and induce mucin secretion. The combination of TNF and IFN- γ could also decrease claudin-3, claudin-5 and claudin-7 expression, with a marked increase in paracellular permeability in rat colon. Moreover, TNF, IL-6 and IFN- γ increase apoptosis and monolayer permeability in HT-29/B6 cells. These cytokines also inhibit the wound-healing in HT-29/B6 cells. Increased apoptosis and delayed woundhealing of epithelial cells would augment monolayer permeability, and damage the epithelial barrier function^[54,55].

CONCLUSION

The exact etiology of IBD is still not completely understood, and increasing data have demonstrated that these conditions occur through an inappropriate immune response to a subset of commensal enteric bacteria in a genetically susceptible host, with disease initiated by environmental triggers. Dysfunction of the mucosal immune system evokes intestinal inflammation through the activation of both innate and acquired immunity in the gut. Among these, T cell activation and Teff/Treg imbalance play an important role in the process of inflammation. Understanding of immunopathogenesis of IBD will help us to find new ideas for diagnosis and treatment.

Abstract

Fecal microbiota transplantation (FMT) is considered to be a highly successful therapy for recurrent and refractory *Clostridium difficile* infection (CDI) based on recent clinical trials. The pathogenesis of inflammatory bowel diseases (IBD) is thought to be due in part to perturbations in the gut microflora that disrupt homeostasis. FMT restores essential components of the microflora which could reverse the inflammatory processes observed in IBD. Case reports and series for the treatment of IBD by FMT have shown promise with regards to treatment success and safety despite the limitations of the reporting. Future studies will determine the optimal delivery and preparation of stool as well as the conditions under which the recipient will derive maximal benefit. The long term consequences of FMT with regards to infection, cancer, auto-immune, and metabolic diseases are not known and will require continued regulation and study. Despite these limitations, FMT may be beneficial for the treatment of ulcerative colitis and Crohn's disease, particularly those with concurrent CDI or with pouchitis.

Key words: Crohn's; Ulcerative colitis; Microbiota; Fecal transplantation; Dysbiosis; Pouchitis; *Clostridium difficile*; Probiotic

Core tip: Advances into the understanding of the pathogenesis of inflammatory bowel diseases (IBD) have highlighted the importance of a dysbiosis in the intestinal microbiome. A perturbed microbiota with loss of colonization resistance is a main driver of *Clostridium difficile* infection and exciting new data exists that microbial restoration through the use of fecal microbiota transplantation (FMT) is highly successful. Therefore, it is logical to conclude that FMT will have therapeutic efficacy in IBD. Preliminary studies that have evaluated FMT for IBD are reviewed with an emphasis on subpopulations that may benefit the most. The limitations and unknowns for this novel therapy are also discussed.

INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease, the two main classifications of inflammatory bowel diseases (IBD) are characterized by chronic intestinal inflammation resulting in recurrent episodes of disease exacerbations with associated abdominal pain, diarrhea, weight loss and rectal bleeding. IBD remains poorly understood and medical therapies continue to be inadequate. The current mainstays of conventional therapy for these diseases include 5-aminosalicylates (5-ASAs), corticosteroids, thiopurines, and anti-tumour necrosis factor agents. However, despite continued advances in therapy, a significant number of

patients remain refractory to standard therapies. Overall, 20%-30% of patients with UC will require a colectomy. At least 50% of patients with Crohn's disease will require surgical treatment in the first 10 years of disease and 70%-80% will require surgery within their lifetime^[1].

The etiology of IBD is complex and several factors are believed to play a role in its development and progression. The host genotype is important and twin studies have shown concordance rates of 16% for UC and 35% for Crohn's disease^[2]. However, these numbers also indicate that non-genetic factors play a substantial role in the development of IBD^[3]. The most important of these is likely the intestinal microbiota (reviewed extensively in this issue of *WJG*). Humans have evolved with the microbes in the intestine which are known to provide critical functions to the host such as metabolism, digestion, development and maintenance of the immune system, and mucosal barrier function. The microbes exist in the various niches to carry out their function and are relatively stable over time^[4]. In disease states such as IBD, the microbial balance that favored homeostasis is perturbed and studies that have analyzed the composition of the gut microbiome in IBD have found a loss in the richness and diversity of the bacterial components including under representation of the anti-inflammatory phyla *Bacteroides* and *Firmicutes* and a relative plume of pro-inflammatory *Proteobacteria*^[5-7]. This shift in the composition of the microbiota ("dysbiosis") may favor the appearance of distinct pathogens that perpetuate the inflammatory response. In this regard, several studies have revealed an increase in adherent/invasive *E. coli* in the terminal ileum of patients with Crohn's disease and *Mycobacterium avium paratuberculosis* has been casually linked to Crohn's pathogenesis although a direct link has not been proven^[8]. Opportunistic microbes such as *C. difficile* may also be able to establish pathogenicity in niches that may be present in the colons of IBD patients. Whether the dysbiosis directly leads to inflammation or is a consequence of an inflammatory environment is yet to be determined. Nonetheless, antibiotics and fecal diversion have been successful in treating various forms of IBD^[9], and it is possible that restoring a healthy microbiota through Fecal microbiota transplantation (FMT) may prove to be more effective^[2].

FMT has been suggested as a therapy for IBD, given the observed intestinal dysbiosis^[10]. FMT has also been termed "fecal bacteriotherapy", "human probiotic infusion", "stool transplant," "intestinal microbiome restoration" and "fecal transfer" in the literature. FMT involves collecting stool from a healthy pre-screened donor and delivering a prepared slurry into the gastrointestinal tract of the individual with disease via nasogastric tube, EGD, colonoscopy, or enema^[10]. Multiple studies have investigated the role of FMT for the treatment of colitis and diarrhea caused by the opportunistic pathogen *C. difficile*. The accumulated data suggests that FMT is a safe and highly effective therapy for *C. difficile* infections (CDIs) refractory

to standard medical treatment with antibiotics^[11-22]. In this review, we will discuss the literature on the use of FMT for the treatment of IBD with a focus on special populations of patients with IBD who are predicted to respond to this treatment. We also discuss the limitations of FMT and remaining questions for this exciting novel therapy.

PUBLISHED EXPERIENCE WITH FMT AS A THERAPY FOR IBD

There are currently no published clinical trials on FMTs in either UC or Crohn's disease. The literature consists of various case reports and case series, mainly in UC. The first report of FMT for UC was presented by Bennet and Brinkman in 1989^[23]. Bennet, who had UC, self treated with fecal retention enemas. Six months after his experimentation, he remained symptom-free and off of medications. This report was followed by a case series, by Borody and colleagues in the same year, of 55 patients with a mixture of gastrointestinal disorders including UC, Crohn's disease (only one patient), and irritable bowel syndrome who were treated with FMT by retention enemas^[24]. They reported that 20 of the 55 patients were "cured" after one FMT and 9 had significant symptom reduction. This study was very limited and did not provide details as to how clinical outcomes were measured and which patient groups may have derived the greatest treatment benefit. Furthermore, details were not provided as to the frequency and duration of treatment or the length of follow up. The one patient with Crohn's disease was reportedly symptom free after four months after suffering from steroid refractory disease^[24]. In a later review, Borody reported that this Crohn's patient had relapsed at 18 mo^[25]. Borody followed up this report up with another case series highlighting 6 patients with UC^[26]. Each of the 6 had at least five years of disease and had either failed what was described as maximal medical therapy (steroids, 5-ASAs and mercaptopurine) or quickly relapsed upon withdrawal of medications. Each patient was confirmed to have active inflammation on colonoscopy and was negative for CDI. Prior to the treatment, each patient received antibiotics for 7-10 d in order to suppress the *Clostridia* (vancomycin 500 milligrams (mg) twice daily, metronidazole 400 mg twice daily, and rifampicin 150 mg twice daily). Each patient also underwent a one time 3 L lavage with an oral polyethylene glycol solution. These patients provided their own donors and received daily fecal retention enemas for five days. They were encouraged to retain the enemas for as long as possible (6-8 h). Each of these patients was in complete remission four months after treatment and remained off of IBD medications. In several of the patients, follow up colonoscopy revealed no active inflammation. The follow up time was variable but remission was reportedly sustained over many years (1-13)^[26]. A recent systematic review on the topic found nine articles and 26 patients (18 UC, 6 CD, 2 indeterminate) who had received FMT for management of IBD, several of which are included

in the series described above^[27]. Of these 26 patients, results were reported in 17. After FMT, 13/17 patients were able to cease all IBD medications within 6 wk and all had symptom reduction or resolution at 4 mo^[28]. It is important to note that these cases varied significantly in the route of administration, preparation of stool, and screening protocols.

Angelberger *et al*^[29] characterized the bacteria communities present both pre and post FMT in 5 patients with moderate or severe UC. They found that none of the 5 patients achieved remission by week 12 and response was only noted in one patient. In two of the patients, further deterioration of their UC was noted at 4 wk post FMT. Upon analysis of the microbial compositions, they found that the UC patients pre FMT displayed a low phylotype richness and an overrepresentation of *Enterococcaceae* and *Enterobacteriaceae* and an underrepresentation of *Lachnospiraceae*, *Ruminococcaceae* and *Bacteroidaceae* when compared to healthy donors^[29]. They found that post FMT the microbiota of the patients became similar to that of the donor, however the duration of that change was patient dependent. The one patient with a clinical response maintained a similar microflora to the donor extending to 12 wk post FMT. However, the 2 patients who experienced disease deterioration showed increased microbiota dissimilarity by 4 wk post FMT. This small study raises several important questions such as what IBD phenotypes may respond best to FMT and how many infusions are necessary to establish a healthy microbiota and a sustained clinical response. Future studies for the treatment of IBD should carefully consider whether disease severity at the time of FMT affects treatment outcome, and at what point in the IBD disease process FMT may be optimal.

FMT FOR CDI IN PATIENTS WITH IBD

The incidence of CDI continues to rise^[30]. First line treatment for CDI consists of antibiotic therapy, however recurrence rates have been reported between 15%-35%^[30]. FMTs are best studied in CDI infections refractory to standard treatment. Current literature consists of multiple case series, systematic reviews and a recent randomized controlled trial^[31]. Impressively, cure rates have been reported between 81% and 100%^[30]. CDI infections are more common in patients with IBD, with a higher prevalence among patients with UC (3.7%) and Crohn's disease (1.1%) compared with the background general population (0.45%)^[32]. While IBD itself is thought to be an independent risk factor for CDI, the increased prevalence has also been linked to immunosuppressive medications, increased antibiotic use and multiple surgeries and hospitalizations^[33]. CDI may have adverse effects on the underlying IBD and so effective therapy to eradicate the organism is necessary to promote disease remission^[33]. A recent systematic review identified eight articles that reported on 15 patients (9 UC, 6 Crohn's disease) who underwent FMT for recur-

rent or refractory CDI, however outcomes were only reported in 12 of these patients^[27]. All patients had resolution of *C. difficile* as measured by stool specific testing. Several patients were noted to have fever and abdominal pain post FMT in this cohort but no major adverse events were reported. We will await the results of future trials to verify that FMT is a safe and effective therapy for IBD patients with *C. difficile*.

UC PATIENTS WITH ILEAL POUCHES

Up to 20% of people with UC undergo an ileal pouch anal anastomosis (IPAA)^[34]. Over 60% of individuals undergoing an IPAA for UC have at least one episode of pouchitis^[35]. This complication is uncommon in those undergoing IPAA for non-UC related reasons, such as familial adenomatous polyposis suggesting that genetic and environmental factors such as the composition of microbiota play a role in the pathogenesis of pouchitis^[36]. Its development in relationship to microbiota likely has two sides: a dysbiosis which reflects changes in bacterial composition possibly at the core of the pathogenesis of UC as well as the emergence of pathogenic bacteria such as *C. difficile*^[37]. Pouchitis often responds to a course of antibiotics but may recur and require multiple courses of the same antibiotic or a switch to a different antibiotic^[34]. Various types of probiotic preparations have been demonstrated to maintain remission in pouchitis when used daily^[38,39]. Unfortunately, pouchitis becomes a chronic, refractory condition in 5%-30% of patients undergoing IPAA for UC^[40] and more effective therapy is needed. Because dysbiosis likely propagates pouchitis in IBD and bacterial manipulation with antibiotics and probiotics has proven to be successful, it stands to reason that FMT will prove to be a successful treatment for many pouchitis patients. There is currently no published literature or ongoing trials exploring this possibility.

LIMITATIONS AND UNANSWERED QUESTIONS FOR FMT

Screening

The process of screening the donor stool and what tests should be ordered prior to FMT continues to evolve. Ideally, experts from gastroenterology and infectious disease can form a consensus regarding the appropriate screening of donor stool. In our practice, we ask the donor initially about high risk sexual behaviors, whether they have been diagnosed with any gastrointestinal diseases such as IBD, colon polyps, or irritable bowel syndrome, and whether or not they have taken antibiotics within the previous 3 mo. We then screen both the donor and recipient's blood for Hepatitis A (IgG and IgM), Hepatitis B (HBsAg/Ab and HBe), Hepatitis C (Ab), HIV-1/2 (Ab and viral load), and Syphilis (TP-IgG). The donor's stool is screened for *C. difficile* (by culture), routine stool bacterial culture, *Giardia* antigen,

Cryptosporidium antigen, and test for ova and parasites. More extensive screening protocols have been used in other studies that include additionally screening the donor for strongyloides, CMV, HTLV 1 and 2, EBV and Entamoeba histolytica^[31]. Given regional and geographic differences, we recommend consulting with an infectious disease specialist and infection control in order to determine the appropriate screening tests for an individual practice setting.

Whether or not the efficacy of FMT is improved with a related donor *vs* unrelated donor is not clear at this time. One recent systematic review suggested that stool from a related donor resulted in a higher resolution rate (90.5%) for CDI than an unrelated donor (84%)^[30]. However, other studies where universal donor pools were used have yielded similar overall results^[30]. Identification of individual bacterial components within the donor microbiota which could potentially influence efficacy are being investigated^[41].

Patient preparation

Most published reviews have recommended large-volume bowel lavage before the procedure, regardless of upper or lower tract administration in order to mechanically reduce *Clostridial* organisms that are still present^[30]. This concept has never been tested formally. For recurrent *C. difficile*, reports generally have recommended discontinuing antibiotics 1-3 d prior to the FMT^[13,30], however this has also not been compared to continuing antibiotics up until the day of the procedure. At our Institution, we have patients discontinue antibiotics the night before the FMT.

Stool delivery

Another issue that will need clarification through future study is the mode by which the stool is delivered to the bowel. Although the efficacy of FMT has been shown to be similar when delivered by endoscopy, nasogastric tube, enema or colonoscopy, it is possible that one method may be superior to another in IBD. The type and location of IBD may drive this decision. Upper gastrointestinal delivery of stool may be more efficacious for patients with small bowel Crohn's disease *vs* delivery by colonoscopy for patients with colonic disease. Lastly, tolerability and relative safety of each procedure will have to be considered when deciding between upper gastrointestinal delivery *vs* lower. In this regard, belching, nausea and abdominal cramps have been reported with upper gastrointestinal administration on the day of the procedure in 8/16 patients, however these symptoms resolved upon follow up^[31]. Although no major adverse events have been reported with any intestinal administration of stool, the safety of the proposed procedure should be considered at the time of treatment. Although colonoscopy is generally considered to be a safe treatment in the setting of active IBD, the perforation rate may be increased and other modes of stool delivery

should be considered in patients with moderate or severe inflammation or stricturing disease. Lastly, it is possible that FMT delivered by retention enema is effective in a subset of IBD patients and would obviate the need for an endoscopic procedure and hospital visit.

Processing and storage

Another unanswered question is whether donor stool may be frozen and then thawed prior to FMT. This has obvious practical implications but whether or not the key components of the stool will be adequately preserved is not known. The University of Minnesota reported similar *C. difficile* cure rates among patients who received fresh *vs* frozen (minus 80 degrees Celsius from 1-8 wk) specimens ($n = 33$)^[42]. In this series, 10 patients had underlying IBD. Interestingly, only 4 patients required a second FMT for recurrent symptoms and 3 of them had underlying IBD^[42]. Stool frozen at -80 °C therefore may be equally effective for FMT as fresh stool, however the viability of organisms after exposure to atmospheric oxygen may be an important consideration. Facultative anaerobes in stool may be inactivated by oxygen and thus transplants under anaerobic conditions may be more efficacious^[4].

It is conceivable that oral preparations that mimic human stool may be manufactured in the near future. Although probiotics have yielded modest treatment effects in certain populations of IBD^[43-46], it is likely that the various probiotics lacked critical organisms and possibly other factors that help successfully restore the gut microbiota back to health.

Long term complications

Whether or not FMT may exacerbate underlying bowel disease in some patients may be an important question. A case of a UC flare after FMT for CDI was recently reported^[47]. The patient had quiescent disease for twenty years and was not on immunosuppressive medications. He developed symptoms nine days after the FMT. *C. difficile* testing was negative and sigmoidoscopy revealed the appearance of inflammation and ulceration that was not present on the FMT colonoscopy.

There is a theoretical concern for the transmission of infections that may have escaped the screening process^[48]. A recent case series reports two patients who experienced gastroenteritis only 2 d and 2 wk after FMT respectively. Both patients were found to be *C. difficile* negative by PCR but norovirus positive. The donor stool however was negative for norovirus and the authors concluded that there was not direct transmission from donor to patient.

Whether or not FMT may influence non-gastrointestinal diseases in the long term such as metabolic disease, obesity, and cardiovascular disease is not known at this time^[49-53]. This may be the reason why several regulatory agencies such as the United States Food and Drug Administration have asked for more research on FMT

before this can be recommended as a first line treatment.

Regulation

While initial reports of FMTs for IBD are promising, several unresolved issues remain. Treatment of IBD with FMTs may be considered investigational and so many health care providers may not cover the cost of the procedure (colonoscopy and stool preparation). This is the case in the United States where the Food and Drug Administration has required that providers who would like to perform FMT must file an “Investigational New Drug” application. Many patients may end up having to pay the hospital charge for this treatment out of their own funds. This burden may be greater when it is possible that patients with IBD may require several treatments. Nonetheless, it is conceivable that long term costs may be reduced if FMT leads to treatment success and the patient is able to avoid expensive medical therapies, hospitalizations, or surgeries.

CONCLUSION

FMT is now considered to be a highly successful therapy for recurrent and refractory CDI based on recent clinical trials. The pathogenesis of IBD is thought to be due in part to perturbations in the gut microflora that disrupt homeostasis. Therefore, it is logical to extend the successes of FMT in CDI to the treatment of IBD. Case reports and series for the treatment of IBD by FMT have shown promise with regards to treatment success and safety despite the limitations of the reporting. While several questions remain unanswered such as the long term consequences of FMT on the recipient, this therapy may be beneficial for the treatment of UC and Crohn’s disease, particularly those with concurrent CDI or with pouchitis. The study of the gut microbiome has opened an exciting new world in medicine raising as many questions as it seems to answer. It is nonetheless here to stay with additional data from randomized controlled trials much needed. Synthetic and multi-microbial stool substitutes are an inevitable advance that we are likely to see in the near future.

Abstract

Thiopurine analogs and anti-tumor necrosis factor (TNF) agents have dramatically changed the therapeutics of inflammatory bowel diseases (IBD), improving short and long-term outcomes. Unfortunately some patients do not respond to therapy and others lose response over time. The pharmacokinetic properties of these drugs are complex, with high inter-patient variability. Thiopurine analogs are metabolized through a series of pathways, which vary according to the patients' pharmacogenetic profile. This profile largely determines the ratios of metabolites, which are in turn associated with likelihoods of clinical efficacy and/or toxicity. Understanding these mechanisms allows for manipulation of drug dose, aiming to reduce the development of toxicity while improving the efficacy of treatment. The efficacy of anti-TNF drugs is influenced by many pharmacodynamic variables. Several factors may alter drug clearance, including the concomitant use of immunomodulators (thiopurine analogs and methotrexate), systemic inflammation, the presence of anti-drug antibodies, and body mass. The treatment of IBD has evolved with the understanding of the pharmacologic profiles of immunomodulating and TNF-inhibiting medications, with good evidence for improvement in patient outcomes

observed when measuring metabolic pathway indices. The role of routine measurement of metabolite/drug levels and antibodies warrants further prospective studies as we enter the era of personalized IBD care.

Key words: Inflammatory bowel disease; Anti-tumor necrosis factor; Infliximab; Adalimumab; Drug level; Azathioprine; Thiopurines; Antibodies; Drug monitoring; Thioguanine

Core tip: The use of thiopurine analogs and anti-tumor necrosis factor (TNF) agents in patients with inflammatory bowel diseases (IBD) has improved outcomes. The pharmacokinetics of thiopurines is variable among patients, and some do not benefit from these drugs. The manipulation and monitoring of thiopurines can potentially increase response to treatment and/or reduce the development of toxicity. The efficacy of anti-TNF drugs is also variable and several factors can modify drug clearance, including the concomitant use of immunomodulators, systemic inflammation, the presence of anti-drug antibodies, and body mass. The treatment of IBD has advanced with the understanding of the pharmacologic profiles of immunomodulating and TNF-inhibiting medications.

INTRODUCTION

Inflammatory bowel diseases (IBD) are chronic disor-

ders of the intestinal tract characterized by relapsing and remitting intestinal inflammation; Crohn's disease (CD) and ulcerative colitis (UC) are the best-recognized of these entities. The etiology of IBD is not clear, but it is thought to occur when the intestinal flora induces an exaggerated immune response in the context of genetic predisposition. Most therapeutic regimens focus on immunosuppression as the hallmark of treatment with medications including corticosteroids, purine anti-metabolites, and newer biologic agents that target specific molecules of the inflammatory cascade like tumor necrosis factor (TNF). Dramatic advances in the treatment of IBD have been seen with the availability of new drugs and our ability to tailor the treatment strategy for each patient. Drug monitoring is relevant not only when trying to achieve treatment efficacy, but also when trying to mitigate toxic side effects and optimize costs. In medicine, we usually measure levels in drugs with a narrow therapeutic range and that pose significant deleterious side effects with overdosing (*e.g.*, theophylline, cyclosporine, and lithium). With some antibiotics (*e.g.*, vancomycin), we measure levels in order to assure the patient receives the required dose to induce a therapeutic effect. Accordingly, the treatment of IBD has evolved with advances in laboratory medicine. We will review the latest evidence concerning measurement of genomic risk for metabolic side effects and levels of metabolites, drugs and antibodies used in the treatment of IBD, including thiopurines (purine anti-metabolites) and anti tumor necrosis factor (anti-TNF) agents.

THIOPURINE ANALOGS

In IBD patients, thiopurines have been successfully employed for decades. The thiopurine analogs with activity against IBD include mercaptopurine (MP) and its pro-drug azathioprine (AZA). The general consensus is that the thiopurine medications are effective at preventing relapse of quiescent disease, but not at inducing remission^[1]. They also exert a beneficial effect when combined with biologic drugs such as infliximab (an anti-TNF agent), improving rates of clinical remission and mucosal healing^[2].

These medications antagonize endogenous purines, interfering with the synthesis of DNA. They were first developed to treat leukemia in pediatric patients, but because of their observed anti-proliferative effect on T-cells, they have been successfully used to treat autoimmune disease and to prevent graft rejection after solid organ transplantation. While the exact molecular mechanism by which thiopurines exert their immunosuppressive effect is not well-comprehended, several theories have been proposed. One hypothesis suggests that 6-thioguanine (6-TGN), a metabolite of AZA, accumulates in lymphocytes and blocks the expression of inflammatory-related cytokines, including TNF-related apoptosis-inducing ligand, TNF receptor S7, and alpha-4-integrins, ultimately inhibiting the inflammatory response induced by T-cells

in the intestinal lamina propria in patients with IBD^[3].

Drug metabolism

The metabolism of AZA is quite complex, and involves many enzymatic pathways producing active, inactive, and potentially toxic metabolites (Figure 1). After getting absorbed from the gastrointestinal tract, 88% of AZA is converted to MP and methyl-nitro-thioimidazole in red blood cells (RBC)^[4]. MP can then be metabolized through three of the following competing pathways: conversion to 6-thiouric acid by xanthine oxidase (XO), methylation by thiopurine methyltransferase (TPMT) into 6-methyl mercaptopurine (6-MMP) (which is associated with potential hepatotoxicity), or conversion to thioinosine monophosphate (TIMP) by hypoxanthine phosphoribosyltransferase (HGPRT)^[5]. TIMP is subsequently converted into 6-TGN, which are thought to be desirable therapeutic metabolites of AZA/MP^[4,6]. Though 6-TGN is a favorable metabolite, high levels of this agent can result in life-threatening myelosuppression.

Measuring the thiopurine methyltransferase phenotype/genotype

Thiopurine drugs have a complex metabolism, and some metabolites may cause life-threatening toxicity, including myelosuppression and hepatotoxicity. TPMT catalyzes one of the rate-limiting pathways in AZA/MP metabolism. Because TPMT has variable activity among patients, checking TPMT activity prior to initiation of thiopurine therapy is routinely used in clinical practice and is recommended. TPMT induces the metabolism of MP to 6-MMP, "competing" with the HGPRT and XO enzymatic pathways (Figure 1). TPMT also metabolizes TIMP to 6-methyl-thioinosine monophosphate (6-MeTIMP); thus, low TPMT activity results in greater conversion of MP to 6-TGN, as less TIMP is converted to 6-MeTIMP. Measuring TPMT before prescribing AZA/MP can help predict those patients who will accumulate high levels of 6-TGN relative to 6-MMP, a profile which increases the risk of leukopenia early in the treatment course. The TPMT status of a patient may be identified by requesting the genotype or the phenotype from a commercial laboratory, with the phenotype testing being in general more clinically useful.

TPMT genotype: Studies in different racial and ethnic backgrounds have shown that most of the population (89%) are homozygous for the wild type (WT) *TPMT* gene (high TPMT metabolism), 10% are heterozygous for the WT and a low metabolic polymorphism (intermediate TPMT metabolism), and 1 in 300 are homozygous for low TPMT metabolic polymorphism (low TPMT metabolism)^[7]. While higher 6-TGN levels are associated with a better clinical response, they also increase risk of myelotoxicity with AZA/MP; therefore, determining TPMT phenotype/genotype is currently used to predict early leukopenia^[6]. Further research in this area has resulted in the identification of fourteen single nucleotide

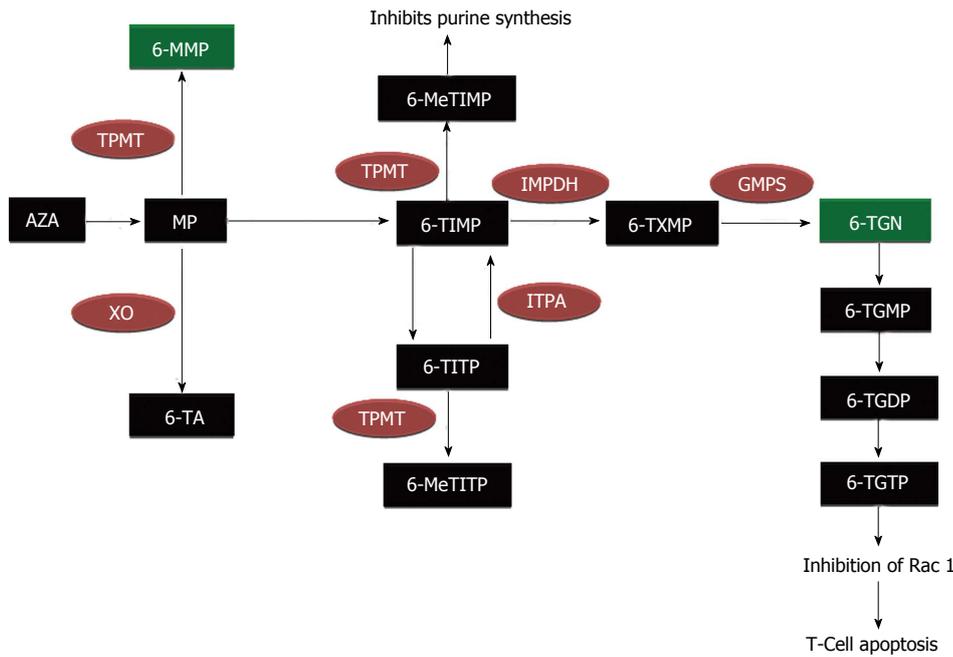

Figure 1 Metabolic pathway of azathioprine/mercaptopurine metabolism. AZA: Azathioprine; MP: Mercaptopurine; TPMT: Thiopurine methyltransferase; XO: Xanthine oxidase; IMPDH: Inosine-5-monophosphate dehydrogenase; GMPS: Guanidine- 5-monophosphate synthetase; 6-TA: 6-Thiouric acid; 6-MMP: 6-Methylmercaptopurine; 6-TIMP, 6-Thioinosine monophosphate; 6-MeTIMP: 6-Methylthioinosine monophosphate; 6-MeTITP: 6-Methyl thioinosine triphosphate pyrophosphate; 6-TITP: 6-Thioinosine triphosphate pyrophosphate; TXMP: Thioxanthosine monophosphate; 6-TGN: 6-Thioguanine nucleotides; 6-TGMP: 6-Thioguanine monophosphate; 6-TGDP: 6-Thioguanine diphosphate; 6-TGTP: 6-Thioguanine triphosphate.

polymorphisms for the *TPMT* gene that cause a diminished or absent enzymatic activity.

TPMT phenotype: As with genotype, enzyme activity (or phenotype) may also be measured and sub-divided into three major groups (high, intermediate, and low *TPMT* metabolizers). The correlation between *TPMT* genotype and phenotype varies between 65 and 89%^[8,9]. The cause of this variance is unclear, but measuring phenotype has a better predictive value for myelosuppression when compared to genotype^[8].

Select situations exist where the genotype can theoretically be more reliable than the phenotype. Because *TPMT* is measured in erythrocytes and uremia may affect the assay, measuring *TPMT* genotype and not phenotype may be reasonable when a patient has had a recent transfusion of red blood cells or has a high blood urea nitrogen, (usually in patients requiring dialysis)^[10]. Also, some medications including azathioprine itself and some diuretics may increase *TPMT* activity, but the clinical significance of this effect is not clear^[11]. Conversely, mesalamines and sulfasalazine inhibit *TPMT*, theoretically increasing the risk of leukopenia, though this claim is unproven^[12].

Monitoring thiopurine metabolites

Once the decision has been made to treat patients and at a particular dose, monitoring thiopurine metabolite levels is a clinical option. Measuring metabolites has two important applications, increasing the likelihood of treatment efficacy and reducing the risk of treatment-related toxicities. The two metabolites that are commercially available

are 6-TGN and 6-MMP.

6-TGN has been the metabolite most associated with treatment efficacy; as such, its measurement has been proposed as a strategy to optimize treatment in patients with IBD receiving AZA/MP. 6-TGN is a metabolite of TIMP, which goes through a series of phosphorylation events resulting in 6-thioguanine diphosphate. A 6-TGN level $> 230 \text{ pmol}/8 \times 10^8 \text{ RBC}$ has been correlated with clinical remission in both adults and children with IBD^[6,13]. Another study using a different assay that included only adult patients failed to show a relation between 6-TGN levels and clinical activity^[14].

The need to follow 6-TGN levels during treatment has not been well-established. In a prospective cohort study, Wright *et al.*^[15] found that patients on a stable dose of azathioprine present with variable levels of 6-TGN over time, bringing into question the value of interpreting any single 6-TGN level. The difference in outcomes among studies is unclear, but could be related to the heterogeneity in the instrument used to determine IBD activity and the use of different assays to measure the 6-TGN levels. Another added potential use for metabolite measurement is to assess adherence to medical therapy. If both 6-TGN and 6-MMP are low, it is likely the patient is not ingesting or absorbing the medication. Randomized controlled trials looking at the role of serial measurements of thiopurine metabolites and the effect of subsequent dose adjustment on outcomes are needed.

AZA metabolite measurement can also be used to help prevent drug-related toxicity. 6-MMP is a metabolite produced from MP by *TPMT*. Higher 6-MMP levels have been found to correlate with a higher risk of hepatotoxicity.

icity. Even though patients with 6-MMP levels > 5700 pmol/ 8×10^8 RBC have a three-fold increased risk of hepatotoxicity, not all patients with a high 6-MMP level will develop elevated liver enzymes, and having a low 6-MMP level does not preclude the development of hepatotoxicity^[6,16]. As with 6-MMP, some patients with very high 6-TGN levels do not develop myelotoxicity while some with low 6-TGN levels may still develop this abnormality. Thus, measuring 6-TGN and 6-MMP levels do not replace monitoring liver enzymes and blood counts. 6-TGN level measurements can also be useful to identify those patients who will not experience clinical benefit despite an optimal AZA/MP dose. Patients with normal TPMT activity and 6-TGN levels > 400 pmol/ 8×10^8 RBC who do not achieve clinical remission will likely remain refractory to treatment even if the treatment is continued for 6 more months or the dose is increased^[17].

Patients resistant to AZA/MP therapy and the use of allopurinol

Patients who fail therapy with AZA/MP may not always benefit from dose escalation. The metabolic pathways in some patients favor an increased conversion of medication into 6-MMP rather than 6-TGN. Metabolite levels confirm this phenomenon when increasing thiopurine dose in patients who are clinically not responding^[18]. This finding supports the metabolic heterogeneity that exists among the IBD population and how some patients preferentially favor particular AZA/MP metabolic pathways. The identification of these patients represents another potential use for metabolite measurement. Up to 24% of patients preferentially produce 6-MMP while maintaining low levels of 6-TGN despite increasing the dose^[18]; these patients usually have high TPMT activity, which is genetically determined and are usually labeled as “thiopurine resistant”.

In this setting, one option is to switch to another therapeutic class (methotrexate or anti-TNFs), but manipulation of the known pathways provides an alternative option to optimize therapy in these so-called “shunters”. Inhibition of TPMT could reduce the production of 6-MMP, but drugs with this effect (*e.g.*, mesalamines/sulfasalazine) have failed to reliably optimize the metabolic profile, likely due to their weak inhibitory effect on the enzyme. Another potential target is XO. This enzyme converts MP into 6-thiouric acid, which has no known biologic effect. When this enzyme is inhibited, much of the MP is shunted down the 6-TGN pathway. Allopurinol, a XO-inhibitor used in the treatment of gout, has been successfully used to shunt metabolism of AZA/MP down this more favorable 6-TGN pathway. The mechanism by which this occurs is not completely understood, as the sole inhibition of XO would not explain the rise in 6-TGN. Sparrow *et al*^[19] selected a group of patients who had a preferable metabolism towards 6-MMP and initiated therapy with 100 mg of allopurinol while reducing the AZA/MP dose by 25%-50%. After 2-4 wk on this regimen, they found that the level of 6-TGN had significantly increased while the 6-MMP level had decreased. A

subsequent study by the same group looking at clinical response in AZA/MP non-responders when starting allopurinol found that the allopurinol-immunomodulator regimen also improved disease activity^[20]. This beneficial effect was not only observed for disease activity, but also reversed hepatotoxicity, presumably by reducing the 6-MMP levels.

However, there are several issues that must be addressed when starting patients on a combination of a thiopurine and allopurinol. First, we recommend serial blood counts, checking a complete blood count (CBC) with differential weekly for the first month and monthly thereafter. Thiopurine metabolites may be checked one month after initiating therapy in order to ensure the goal of increased 6-TGN and decreased 6-MMP is achieved. If leukopenia develops, the dose of AZA/MP can be reduced.

Another proposed strategy to overcome the shunting of MP towards 6-MMP is splitting the thiopurine into twice daily dosing. A retrospective study in patients with preferential 6-MMP metabolism showed that dividing the daily dose of the thiopurine (MP or AZA) modifies how the drug is metabolized, resulting in a significant reduction in 6-MMP levels and decreasing toxicity without having an adverse impact on clinical disease activity or 6-TGN levels^[21]. The exact mechanism explaining the beneficial outcomes seen when implementing this strategy is unknown, and further studies are needed to confirm the results.

In summary, measuring TPMT activity prior to thiopurine initiation has improved the clinical care for IBD patients, both by improving treatment efficacy and by ameliorating iatrogenic toxicities. Many clinicians, including our group, also follow thiopurine metabolite levels with the intent of positively impacting patient care. The enclosed algorithm represents a logical approach to the care of IBD patients on thiopurine therapy (Figure 2).

ANTI-TUMOR NECROSIS FACTOR

Anti-TNF agents have dramatically changed the management of CD and UC. Though four anti-TNF agents are currently approved to treat IBD, we will focus on infliximab (IFX) and adalimumab (ADA), as these are the two anti-TNF drugs with commercially available assays to measure drug levels and anti-drug antibodies. IFX is a chimeric IgG1 (human-constant and murine-variable regions) monoclonal antibody consisting of human constant and murine variable regions; it is indicated for induction and maintenance of clinical remission in patients with moderate-to-severely active CD and UC^[22,23]. ADA is a recombinant fully human IgG1 monoclonal antibody, also approved for the induction and maintenance of remission in patients with CD and UC^[24,26].

These biologic therapies are of proven benefit, reducing rates of hospitalization and surgery rates while improving quality of life^[27,28]. Unfortunately, up to 50% of patients lose response to treatment (secondary non-responders) and up to 30% do not respond at all (primary

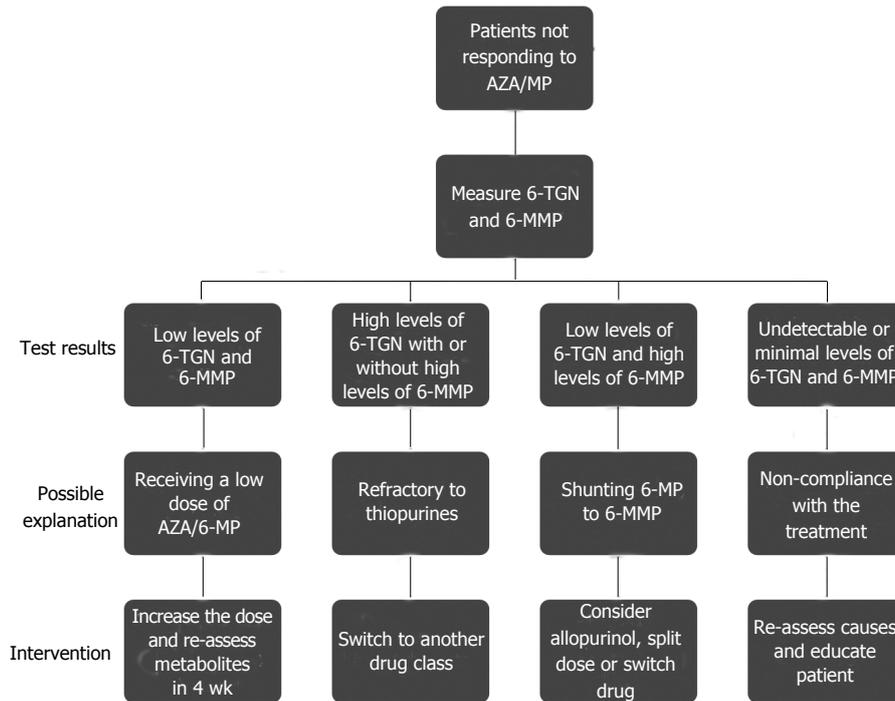

Figure 2 Algorithm with recommendation on how to manage patients that fail therapy with Azathioprine/Mercaptopurine. AZA: Azathioprine; MP: Mercaptopurine; 6-TGN: 6-Thioguanine nucleotides; 6-MMP: 6-Methyl-mercaptopurine.

non-responders)^[29]. The rationale for lack or loss of response is multi-factorial, but is likely related to the molecular structures and complex pharmacokinetics (PK) and pharmacodynamics of the medications, including the development of anti-drug antibodies. One of the proposed strategies when patients lose response to an anti-TNF is switching to another drug in the same or different class. Another strategy is to empirically increase the dose, hoping to overcome increased drug clearance. Unfortunately, this can lead to significant adverse events including hypersensitivity reactions. A third potential tactic is to measure drug levels and antibodies, trying to identify those patients who will benefit from dose escalation and those who will be best served by switching to an alternate drug class. This latter strategy has been proven to be more cost effective when compared to the former and highlights the importance and usefulness of measuring levels in these patients^[30]. Most of our collective experience has been measuring IFX levels and antibodies to IFX (ATI), but the measurement of ADA and antibodies to ADA (ATA) has recently become available commercially.

PHARMACOKINETICS OF ANTI-TNF

Within an individual patient, a linear relationship exists between anti-TNF dose and serum medication levels^[31]. However, inter-patient PK variability complicates the reliable prediction of medication levels among patients^[32,33]. Some have theorized that this inconsistency occurs as a result of differences in body mass, but variable levels are observed with drugs with weight-based dosing like IFX. The clearance of TNF-inhibitors likely also plays a role.

Anti-TNFs are monoclonal antibodies with a high molecular weight, and as is the case with other with IgGs, they are metabolized through many pathways. One of

the primary mechanisms by which anti-TNFs are cleared involves the reticuloendothelial system (RES). The main component of IgG metabolism is the Brambell receptor (FcRn), which is responsible for internalizing an antibody intra-cellularly, degrading the antigen, and then “recycling” it by releasing it back into the circulation for excretion^[31]. High circulating IgG levels may saturate the FcRn, translating into an inverse association between IgG levels and anti-TNF clearance.

Many of the mechanisms underlying variation in drug levels and clearance of TNF-inhibitors are summarized in Figure 3.

Anti-drug antibodies

The human immune system recognizes these biologic drugs as foreign antigens, creating specific antibodies that neutralize their effect. This phenomenon, known as immunogenicity, increases drug clearance and ultimately may contribute to treatment failure. Immunogenicity was first described with IFX, a chimeric antibody. Originally, it was believed that ADA would demonstrate less immunogenicity as it is a fully human antibody, but this theory was not substantiated by clinical practice findings^[33,34].

In patients with IBD, the negative effect that antibodies to IFX (ATI) and antibodies to ADA (ATA) have on clinical outcomes has been well established^[32,35-38]. ATI and ATA bind to the medication, forming an immune complex that induces drug clearance via the RES. The ability to routinely measure drug levels and anti-drug antibodies has led to an understanding of why some patients lose response to therapy.

Currently, there are several methods to measure IFX and ADA. Most studies have been performed using a solid-phase, double-antigen, enzyme-linked immunosorbent assay (ELISA). Unfortunately, this assay cannot measure

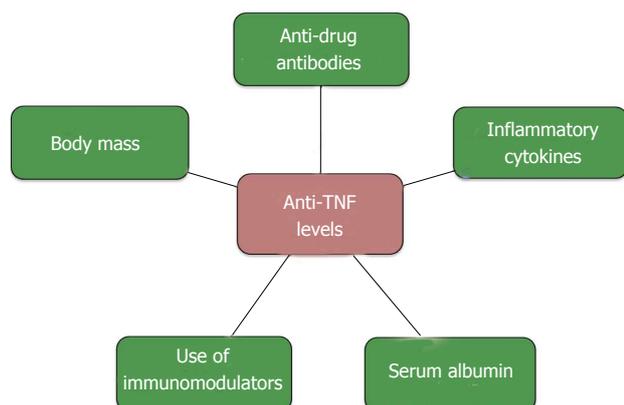

Figure 3 Variables associated with Anti-tumor necrosis factor levels. TNF: Tumor necrosis factor.

the presence of antibodies when there are detectable levels of anti-TNF. Another method is a fluid-phase radioimmunoassay, which can report antibodies irrespective of the presence of drug. A recently developed assay is a homogeneous mobility shift assay using size-exclusion high-performance liquid chromatography, which has a high sensitivity and specificity and can potentially detect all isotypes of immunoglobulin^[39]. This modality permits the measurement of antibodies to anti-TNF medications, even in the presence of detectable drug. However, most clinical studies have used the ELISA assay, which could have implications in how we interpret the available data.

Role of immunomodulators with biologic therapy

Observations from randomized controlled trials have shown that the concomitant use of immunomodulators (AZA, MP or methotrexate) and biologic medications increases anti-TNF levels^[36]. It is generally believed that this occurs by diminishing immunogenicity (decreasing the formation of anti-TNF antibodies) while simultaneously reducing the amount of systemic inflammation which, as we describe below, will negatively affect IgG levels.

The presence of ATI has consistently been associated with lower IFX levels^[36]. In an exploratory analysis of a randomized controlled trial looking at efficacy of IFX monotherapy, AZA monotherapy, and the two biologic drugs combined with immunomodulators, the authors found that at week 30 the IFX levels were 1.6 µg per milliliter for patients in the IFX group and 3.5 µg per milliliter for those in the combination therapy group ($P < 0.001$)^[40]. They also found that only 1 of 116 patients (0.9%) receiving combination therapy (compared to 15 of 103 patients (14.6%) receiving IFX monotherapy) had ATI^[40]. Studies looking at the effect of ATA on ADA levels have yielded similar results^[33,37].

Even though most studies have shown a clear association between the presence of anti-TNF antibodies and drug levels, some data have failed to support this observation. Lichtenstein *et al* looked at the influence that concomitant immunomodulators and IFX therapy had on drug levels^[41]. They reviewed the ACCENT I and II trials (effect on induction and maintenance of remission

that IFX have in CD) as well as ACT 1 and 2 (effect on induction and maintenance of remission that IFX have in UC). In contrast to the previously mentioned studies, they found that IFX levels were similar when comparing patients who did and did not receive immunomodulators, even though those patients that received immunomodulators had a higher incidence of ATI antibodies to infliximab^[41]. Of note, this report was based on a post-hoc analysis and the results should be interpreted in that context.

Disease activity and systemic inflammation

Patients with severe disease have been found to have lower levels of anti-TNF. The exact mechanisms by which disease activity and systemic inflammation affect drug clearance are not completely understood. Systemic inflammation induces the RES to increase its catabolic activity, reducing levels of IgG and albumin. Direct and indirect markers of inflammation have been used to predict IFX efficacy. For example, higher levels of CRP correlate with poor response to IFX and may predict loss of response^[32,42,43]. Also, low albumin levels are associated with lower IFX levels, which suggests that increased catabolic activity in systemic inflammation induces the Brambell receptor^[44]. As with IFX, preliminary studies looking at ADA levels showed that higher CRP levels are associated with lower ADA levels^[33,34]. In one study, a minimum ADA cut-point of 5 µg/mL best predicted elevation of CRP levels^[33].

These studies cannot prove causation but do show an association between low drug levels, high CRP, and low albumin. Severe inflammation of the mucosa also induces a protein-losing enteropathy, with a loss of drug through the intestinal lumen. A recent study that included patients going through IFX induction therapy found that even though all patients had detectable IFX in the stool, those who did not respond to treatment had a significantly higher level of fecal IFX^[45].

Body mass and composition may influence anti-TNF drug levels

Many other variables have been proposed to affect the levels of anti-TNF. One study found that body mass and gender influence the central volume of distribution of IFX (increasing with weight and male gender)^[46]. While one might suspect these results were due to the collinearity of gender and mass (as men weigh more than women), the authors tested each variable individually and concluded that each had independent influence on the central volume of distribution; this finding was attributed to the fact plasma volume is lower in women than in men. The influence of body mass on ADA levels in patients with IBD is unknown, but might play a key role as ADA does not have weight-based dosing; this also applies to other anti-TNFs approved for IBD (certolizumab pegol and golimumab).

An important distinction must be made between total body mass and body composition. For example, Bultman *et al*^[47]

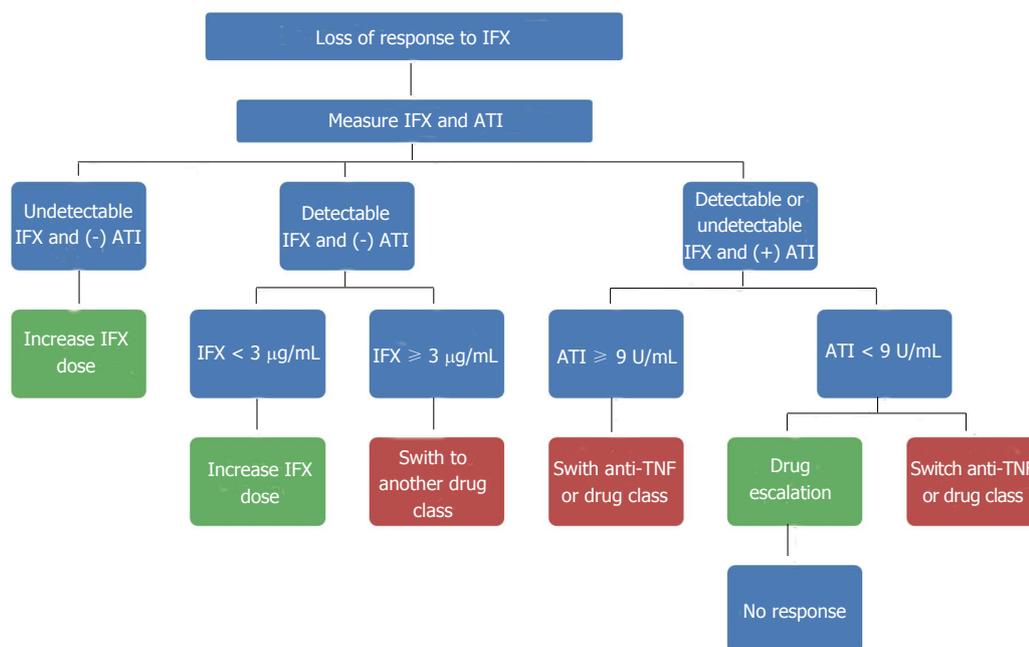

Figure 4 Approaches to patients on infliximab in the setting of loss of response. ATI: Anti-infliximab antibody; IFX: Infliximab; TNF: Tumor necrosis factor.

found that patients on ADA who required dose escalation had a higher body mass index (BMI) despite equivalent dosing of ADA given per kg of body weight. The component responsible for the increased BMI is unclear, but it may be related to mesenteric fat, an important contributor to the inflammatory response in CD^[48].

CLINICAL IMPLICATIONS OF MEASURING ANTI-TNF LEVELS AND ANTIBODIES

Many studies have shown that higher IFX levels are associated with better outcomes in patients with IBD. A detectable IFX trough level is associated with a higher rate of clinical remission, lower serum CRP levels, and an improvement in endoscopic disease activity^[32,49].

The presence of ATI has been associated with treatment failure and lower IFX levels^[50]. In a landmark study, Baert *et al*^[35] studied the immunogenicity of a group of patients with CD. They found that 61% had detectable ATI after the 5th infusion, which did not increase after subsequent infusions. This high prevalence of ATI can be explained by the fact those patients received episodic dosing (when they relapsed) and not scheduled (every 8 wk) infusions. They found that those patients with ATI >8.0 µg/mL before an IFX infusion had a shorter duration of response and a higher risk of infusion reactions^[35]. Afif *et al*^[50] looked at the clinical utility of measuring IFX levels and ATI in patients with loss of response or an incomplete response to IFX. They found that most patients with ATI did not respond to IFX dose escalation, but those with no ATIs and sub-therapeutic concentrations did benefit from a higher dose^[50].

With ADA, the experience is more limited. In an observational study, Karmiris *et al*^[37] found that lower

ADA serum trough levels were associated with drug discontinuation and the presence of ATA was associated with lower ADA levels. Recent studies have found that detectable ATA and ADA levels < 5 µg/mL are associated with higher CRP serum levels, increased endoscopic inflammatory activity, and use of steroids^[33,34]. Another recent study measuring ADA trough levels by ELISA assay showed similar results; an ADA trough of 4.85-4.90 µg/mL was the optimal cut-off value for predicting clinical remission and mucosal healing^[51].

ROLE OF ANTI-TNF DRUG MONITORING IN CLINICAL PRACTICE

Commercial assays to measure anti-TNF drug and antibody levels have been available for a relatively short time; direct cost implications for patients and/or insurers have limited their widespread clinical use despite documented efficacy in directing patient management. Knowledge of drug levels and measurements of anti-drug antibodies can help identify those patients who will benefit from dose escalation versus those who are unlikely to respond to this strategy (high titers of anti-drug antibodies or those with high drug levels but persistent intestinal inflammation). A recent study modeled both strategies and found that testing for drug levels and antibodies in patients with secondary loss of response is more cost-effective when compared to empiric drug escalation^[52].

The titer of ATI may also predict response to dose escalation, as demonstrated by a cohort of 90 patients undergoing serial IFX and ATI levels with at least one ATI positive measurement throughout the follow-up period. In 15 of those patients (28%), ATI disappeared overtime^[53]. Only 2 of those 15 patients (13%) required

discontinuation of therapy, which is quite significant as ATI may be transient and do not necessarily lead to treatment failure. However, they also found that ATI > 7.95 U/mL was associated with IFX discontinuation, which may suggest that patients with high ATI titers would not benefit from dose adjustment^[53]. Most of the available evidence includes patients on IFX, so further studies are needed with the other medications. A proposed algorithm to guide therapy in patients receiving IFX who lose response to treatment is shown in Figure 4.

An unanswered question is the potential benefit of measuring drug levels in all patients and adjusting the dose accordingly to maintain adequate levels, thereby avoiding immunogenicity. Considering low trough IFX levels are associated with immunogenicity and the fact that the dose of IFX and serum levels are not always linear, measuring drug levels even in patients with clinical response could improve outcomes. The study cited above also showed that an IFX trough level at week 14 of < 2.2 µg/mL correlated with IFX discontinuation^[53]. These results are based on a retrospective analysis and future prospective controlled studies are needed, especially considering anti-TNF levels are influenced by several variables that can fluctuate over time and among individuals.

The repeated demonstration of clinical utility and evidence for cost-effective patient care have made routine measurement of anti-TNF drug and antibody levels a regular part of our group's clinical practice. For UC, when patients tend to have a lower starting albumin level and a markedly elevated CRP, our practice has been to give IFX at a higher dose (10 mg/kg) and then check levels after induction. While this practice has yet to be validated, we have had anecdotal success in achieving remission in patients who we feel clinically merit higher induction doses. Monitoring trough drug levels after induction allows for a tapered return to lower doses and a sustained remission.

CONCLUSION

The pharmacokinetic and pharmacodynamic properties of anti-TNFs and thiopurines are complex. Considerable inter-individual variability exists due not only to differences in pharmacogenetic factors but also disease phenotype and concomitant drug therapy. Measuring drug levels, metabolites, and anti-drug antibodies may help overcome treatment failures while mitigating toxic side effects, but further randomized studies to confirm these findings are needed. The treatment of IBD has evolved with the understanding of the pharmacologic profiles of immunomodulating and TNF-inhibiting medications, with good evidence for improvement in patient outcomes observed when measuring metabolic pathway indices. The role of routine measurement of metabolite/drug levels and antibodies warrants further prospective studies as we enter the era of personalized IBD care.

Abstract

Endoscopy plays a key role in the diagnosis and treatment of patients with inflammatory bowel disease (IBD). Colonoscopy has been traditionally used in the diagnosis of IBD and helps in determination of an important end point in patient management, "mucosal healing". However, the involvement of an advanced endoscopist has expanded with innovations in therapeutic and newer imaging techniques. Endoscopists are increasingly being involved in the management of anastomotic and small bowel strictures in these patients. The advent of balloon enteroscopy has helped us access areas not deemed possible in the past for dilations. An advanced endoscopist also plays an integral part in managing ileal pouch-anal anastomosis complications including management of pouch strictures and sinuses. The use of rectal endoscopic ultrasound has been expanded for imaging of perianal fistulae in patients with Crohn's disease and appears much more sensitive than magnetic resonance imaging and exam under anesthesia. Advanced endoscopists also play an

integral part in detection of dysplasia by employing advanced imaging techniques. In fact the paradigm for neoplasia surveillance in IBD is rapidly evolving with advancements in endoscopic imaging technology with pancolonoscopic chromoendoscopy becoming the main imaging modality for neoplasia surveillance in IBD patients in most institutions. Advanced endoscopists are also called upon to diagnose primary sclerosing cholangitis (PSC) and also offer options for endoscopic management of strictures through endoscopic retrograde cholangiopancreatography (ERCP). In addition, PSC patients are at increased risk of developing cholangiocarcinoma with a 20% lifetime risk. Brush cytology obtained during ERCP and use of fluorescence in situ hybridization which assesses the presence of chromosomal aneuploidy (abnormality in chromosome number) are established initial diagnostic techniques in the investigation of patients with biliary strictures. Thus advanced endoscopists play an integral part in the management of IBD patients and our article aims to summarize the current evidence which supports this role and calls for developing and training a new breed of interventionalists who specialize in the management of IBD patients and complications specific to those patients.

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are a group of inflammatory bowel diseases (IBD) that have environmental, immunological and bacterial etiologies. The role of an endoscopist has been well defined in the initial diagnosis of these disorders, assessment of disease severity and differentiation between the two disease processes. Previous studies have reported that in 80% of CD patients, at last one surgical resection will be required within 10 years of CD diagnosis^[1,2]. Although surgical treatment is effective for CD strictures, there is invariably a high risk of recurrence of CD which may result in repeat surgery in up to 34% of patients^[1,3]. Repeated surgery can result in complications related to short bowel syndrome, requirement for total parenteral nutrition and its attendant complications. The advent of endoscopy in the management of complicated CD strictures has changed the approach to the management of anastomotic and small bowel strictures in these patients. The advent of balloon enteroscopy has helped us access areas not deemed possible in the past for dilations. An advanced endoscopist also plays an integral part in managing ileal pouch-anal anastomosis (IPAA) complications including management of pouch strictures and sinuses. Colorectal cancer (CRC) is a serious potential complication of IBD. Advanced endoscopists play an important role in detection of dysplasia by employing advanced imaging techniques to identify early and subtle neoplastic lesions^[4].

In addition, primary sclerosing cholangitis (PSC) a chronic, cholestatic disorder is seen in 2.4%-7.5% of patients with UC^[5] and about 3.4% of patients with CD^[6]. Advanced endoscopists are called upon to diagnose PSC and also offer options for endoscopic management of strictures through endoscopic retrograde cholangiopancreatography (ERCP). In addition, PSC patients are at increased risk of developing cholangiocarcinoma (CCA) with a 20% lifetime risk^[7,8]. Brush cytology obtained during ERCP and use of fluorescence in situ hybridization (FISH) which assesses the presence of abnormality in chromosome number are established initial diagnostic techniques in the investigation of patients with biliary strictures^[9]. The aim of our review is to highlight the current evidence which supports the role of an advanced endoscopist in the management of IBD and complications specific to them.

For the purpose of this article, we will discuss the role of an advanced endoscopist under various sections.

Figure 1 illustrates the various roles of an advanced endoscopist in managing inflammatory bowel disease patient.

Inflammatory bowel strictures

The Vienna Classification describes three distinct groups of CD: inflammatory, stricturing and penetrating. It also demonstrated an association between location and disease behavior. Stricturing disease is predominant in the terminal ileum and ileocolonic locations^[10]. Subsequent studies using this classification have confirmed that most patients over the course of time will develop a penetrating or stricturing complication with stricture formation being the second most common and that this change is governed by location of disease^[11,12]. Data from the TREAT (the Crohn's therapy, resource, evaluation, and assessment tool) registry suggested factors associated with stricture formation. These were CD severity at the time of event onset (HR = 2.35, 95%CI: 1.35-4.09); CD duration (HR = 1.02, 95%CI: 1.00-1.04); ileal disease (HR = 1.56, 95%CI: 1.04-2.36); and new corticosteroid use (HR = 2.85, 95%CI: 1.23-6.57)^[13].

Strictures in CD can occur *de novo*, at sites of bowel anastomosis or in the ileal pouch. Strictures are believed to be either inflammatory or fibrotic^[13]. Inflammatory strictures have the option of being treated by medical therapy. Even then, when these patients are followed, 64% of these patients require surgery. CD patients with ileocolonic disease do worse with medical therapy ($P = 0.026$) and may require surgery sooner than patients with ileal disease ($P = 0.023$)^[14]. The fibrotic strictures are largely treated surgically with either intestinal resection or strictureplasty^[15]. Although the latter has the advantage of preserving bowel length, it has still been associated with a significant operative recurrence rate of 34% during a median follow up period of 7.5 years^[16]. These results seem comparable to those from other review studies^[17,18], one of them a meta-analysis^[17], in which surgical recurrence rates have been cited as 24% (median surgical rate at 46 mo) and 23%. Younger patients tend to run an aggressive course with a shorter duration to reoperation^[16]. Moreover, an 82% rate of second operation has been reported with upto 33% patients requiring more than 2 surgeries leading to risk of developing short bowel syndrome^[19]. This means that avoidance of repeated surgeries is an important factor in considering alternative therapies. Endoscopic balloon dilation has been one such treatment alternative. Additionally, endoscopic balloon dilatation could be considered an adjunct to surgery given that it has been shown to add at least 50% efficacy to the initial surgery by prolonging the surgery free period. This was deduced after comparing interval of 6 years from surgery to first endoscopic dilation with the post dilatation surgery free period of 3 years^[20]. It also has the advantages of reduced invasiveness and bowel preservation.

Endoscopic balloon dilation

There have been several studies aimed at reporting the clinical efficacy, technical feasibility and short and long

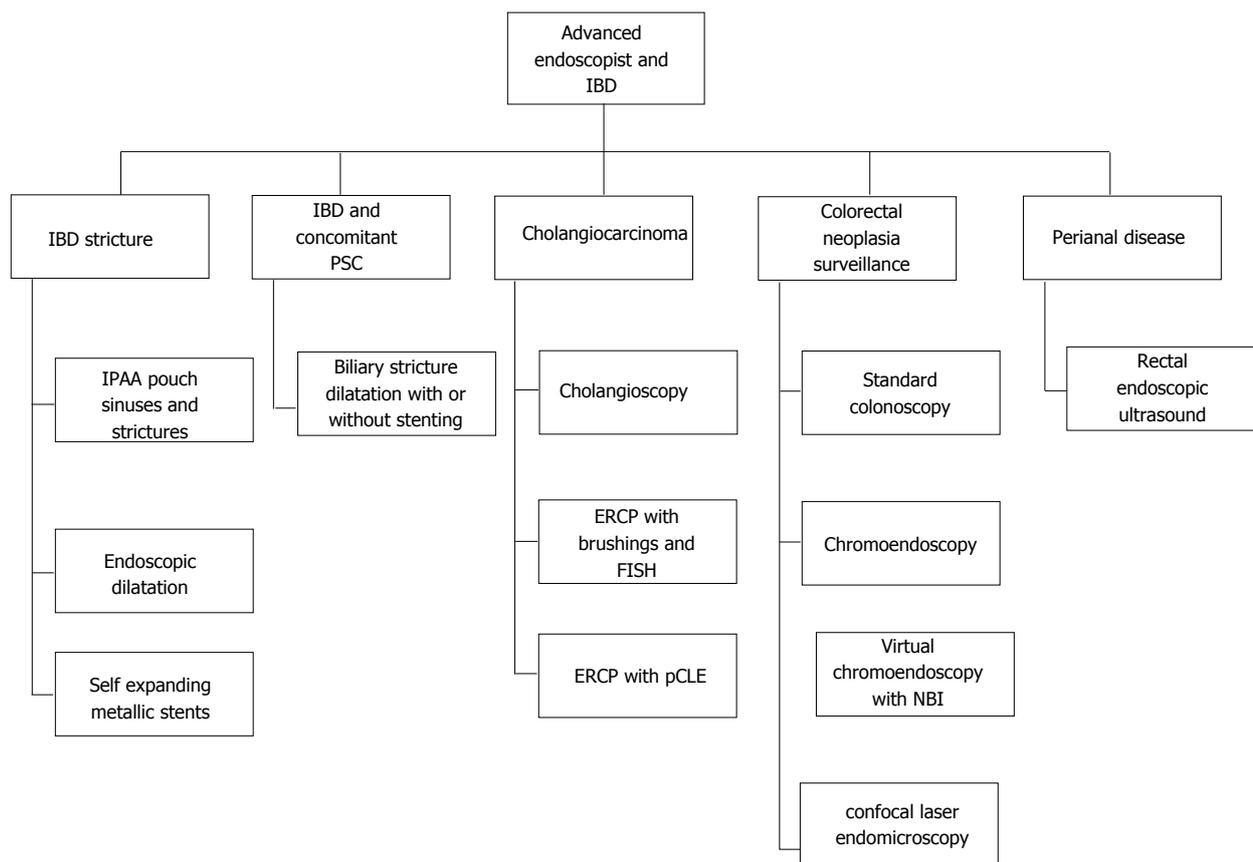

Figure 1 Figure illustrates the various roles of an advanced endoscopist in managing inflammatory bowel disease patient. IBD: Inflammatory bowel disease; IPAA: ileo-pouch anal anastomosis; PSC: Primary sclerosing cholangitis; ERCP: Endoscopic retrograde cholangiopancreatography; FISH: Fluorescence *in situ* hybridization; pCLE: Probe based confocal laser endomicroscopy; NBI: Narrowband imaging.

term results of endoscopic balloon dilatation. Almost all studies have used resolution of symptoms and/or surgery free period as outcomes. A systemic review summarized the results of important studies^[20]. Most studies included had less than 60 patients. Most of them included post-surgical strictures. The meta-analysis clearly highlighted the drawbacks with making clear conclusions from the literature because of varying caliber of endoscopic balloons used for dilation from 18 to 25 mm, different approaches that were used, number of dilatations in the same endoscopic sessions and heterogeneity concerning the duration of each single dilatation^[20]. Overall, technical success was achieved in 86% patients. The complication rates were < 5% in all studies barring two which reported a higher complication rate^[21,22]. The reasons for this have been unclear, aggressive dilatation in one of them^[21] may have been a contributing factor. The only factor that significantly affected dilatation efficacy and surgery-free follow up was length of stricture. Naïve *vs* postsurgical, steroid injection, active *vs* inactive CD were all deemed to be non significant^[20]. Importantly, endoscopic dilatation was successful in avoiding surgery at the end of the follow-up in 112 of the total 347 (67%) patients that were included in this review^[20]. If the patients who had failed for technical reasons were excluded, the success rate measured by avoidance of surgery was up to 78%^[20].

Subsequent to the meta-analysis, more studies have

been published on the efficacy of endoscopic dilation and have shown similar short (51%-89%) and long (52%-89%) term success^[23-28]. Most strictures included in these studies have been anastomotic with the exception of the Mueller *et al*^[26] study, in which 69% had *de novo* strictures. The study by Gustavsson *et al*^[27] is the largest study to date, including a total of 178 patients, and the one with the longest follow-up period (median 12 years). Most patients had either ileal or ileocolonic disease, and approximately 40% had stricturing disease at presentation. Most of the patients (80%) had anastomotic strictures. There was no difference in efficacy based on the etiology of their strictures whether anastomotic or *de novo*. Bowel perforation occurred in 1.4% of patients and use of 25 mm balloon was associated with a 9.3% complication rate, as compared to 3.5% for the other sizes ($P < 0.01$).

Another prospective single center study from Germany of 55 patients, with 74 symptomatic strictures reported their efficacy^[26]. Majority of patients in this study (69%) had *de novo* strictures. There was a 95% initial success rate, and 76% patients never required repeat treatment over the period of follow-up. 24% patients did eventually receive surgery over the follow-up period. Stricture length was the main factor that predicted the need for surgery. Interestingly, stricture location at ileocecal valve and stricture associated with fistula were significant predictors of

a negative outcome^[28]. Smoking has been reported to be a significant patient variable that negatively affects surgery free period^[29,30] and doubles the risk of recurrent stricture formation requiring a new dilatation after the first one ($P = 0.022$)^[31].

Given the high rate of stricture recurrence after dilatation, intralesional injection of medications after dilatation has been studied. A pilot study comparing intralesional steroid injection after balloon dilatation vs placebo did not find a reduction in time to redilatation^[32]. This is in contrast to a pediatric study of 29 patients that reported a significant trend of patients who did not receive intralesional steroids towards redilatation and surgery^[33]. Effect of intralesional injection of infliximab has been studied in small number of patients but consensus is lacking. Thienpont *et al*^[34] reported no significant effect of active disease at the time of dilatation or systemic medical therapy afterwards on redilatation or surgery. Thus, there is no clear evidence at this time to support the role of intralesional injection of medications following dilatation.

We routinely perform endoscopic dilatation with a 16-, 17-, and 18-mm through the scope (TTS) balloon (Boston Scientific, Inc, Boston, MA) or a 18-, 19-, and 20-mm TTS balloon with guidewire assistance. If possible, retrograde dilatation with passage of the endoscope beyond the stricture and introduction of the balloon and pulling the endoscope backward and dilating the stricture is preferred.

Endoscopic balloon dilatation with stenting

Metal stents have been reported as an effective alternative to surgery for the palliation of patients with colorectal neoplastic obstruction. Data regarding their use in treating benign naïve or postsurgical strictures in CD is limited and controversial. Recent studies that have used self expanding metallic^[35,36] and biodegradable^[37,39] stents have reported a high incidence of migration^[37,39]. On the other hand clinical success has ranged from 45% to 80%. The majority of stents in these studies were placed in postsurgical strictures.

Overall, efficacy of endoscopic dilatation in the treatment of small and large bowel strictures is promising with an acceptable rate of complications. Length of stricture and location of stricture are important considerations. We have not employed stenting in the management of IBD related strictures. We prefer the use of needle-knife for strictures which are refractory to balloon dilatation for management.

Strictures in IPAA

The role of an advanced endoscopist in managing IPAA complications mainly caters to strictures and sinuses. IPAA strictures can occur at the pouch inlet, outlet, afferent limb or pouch body. An 11-year-experience with 1005 patients after restorative proctocolectomy and IPAA reported stricture formation in 14% of patients of which the majority (97.9%) were successfully treated with digital or bougie dilatation and only 2.1% required surgery^[40]. Another large retrospective study with 1884 patient re-

ported a similar incidence (11.2%) of stricture formation but a much higher (12%) rate of surgery to salvage pouch function. Dilatation of non fibrotic strictures was more successful than fibrotic strictures ($P = 0.0001$)^[41]. A more recent study in which a cumulative of 646 strictures were dilated reported that 87.3% patients over a median follow up of 9.6 years were able to retain their pouches. It concurred that endoscopic dilatation of pouch strictures is efficacious and safe with a low rate of complications when attempted by an experienced endoscopist^[42].

Pouch sinus is typically a late presentation of an initial anastomotic leak. The most common location of a pouch sinus is the pouch-anal anastomotic site at the presacral space. Presenting symptoms include perianal pain, pelvic pressure/discomfort and/or evidence of pelvic sepsis or pouchitis, CD of the pouch, or refractory cuffitis; others may be asymptomatic. Sinus opening and sinus tract can be detected by a combined application of pouchoscopy, contrast pouchogram, examination under anesthesia and pelvic magnetic resonance imaging (MRI). Treatment usually includes incision and drainage of the chronically infected superficial sinuses^[43]. Fibrin glue injection of the sinus may be attempted^[44]. Patients with a long sinus track who fail to heal are suitable for redo pouch.

An alternative strategy that has only recently been introduced and studied at our institution is endoscopic needle knife therapy for pouch sinuses. A total of 65 patients with pouch sinuses were treated with needle-knife therapy of which 84.6% achieved a complete or partial response. Duration from colectomy to needle knife treatment and complex nature of sinuses were inversely proportional to healing of sinuses^[45].

Endoscopic ultrasonography in the evaluation of CD fistulae

Approximately, 25% of all patients with CD develop a perianal fistula, with fistulae more frequent in patients with involvement of the rectum^[46,47]. Identification of fistulae is difficult with digital rectal examination alone or even with exam under anesthesia (EUA) because perianal disease is associated with induration and scarring. Endoscopic ultrasonography (EUS) has been used in this setting to help in the evaluation of CD fistulae.

Rectal EUS is performed by introducing a radial probe into the distal rectum and anal canal while the patient is in the left lateral position^[48]. On EUS, the fistulae in the setting of CD appear as hypoechoic structures, but the presence of air or gas in the fistula tract may make the tract internally hyperechoic^[48]. An abscess in the setting of CD fistulae can also be visualized as an anechoic or hypoechoic mass in the perianal region^[48]. Some investigators have used hydrogen peroxide injection into the cutaneous fistula site to enhance visualization as it creates bubbles that appear hyperechoic and thus make the fistula easier to identify.

The accuracy of rectal EUS in the evaluation of perianal disease has been demonstrated in 3 prospective, blinded studies^[49-51]. One of these studies compared EUS to computerized tomography (CT) in 25 patients with

suspected perianal CD^[49]. Confirmation of fistulae was done at the time of surgery. EUS was found to be more accurate than CT in the evaluation of perianal fistulae (82% *vs* 24%)^[49]. In another study, rectal EUS was compared with pelvic MRI and EUA in 22 patients with CD and perianal fistulae. Rectal EUS was found to be the most sensitive modality for imaging (82%) when compared with pelvic MRI (50%)^[50]. Rectal EUS in this study was performed with only a 7-MHz linear scanning probe. Another study comparing EUS to MRI found both to be equally accurate in the assessment of CD perianal fistulae (91% *vs* 87%)^[51].

Studies have also used EUS to monitor fistula healing and/or guide treatment. A small, randomized, prospective study showed a benefit to the use of EUS monitoring for fistula healing^[52]. Thus, it seems that a team of colorectal surgeons and advanced endoscopists seem to be the future in the evaluation and management of perianal CD.

IBD with concomitant primary sclerosing cholangitis

PSC is a chronic, cholestatic liver disease characterized by inflammation and fibrosis of both intrahepatic and extrahepatic bile duct leading to the formation of bile duct strictures. An advanced endoscopist is integral in diagnosing PSC. Although magnetic resonance cholangiopancreatography (MRCP) is the initial preferred non-invasive technique to diagnose PSC, often ERCP is required to confirm diagnosis and rule out a dominant stricture. An advanced endoscopist is often called upon to manage patients with IBD and PSC who have concomitant dominant biliary stricture in the setting of PSC.

A “dominant stricture” has been defined as a stenosis with a diameter of 1.5 mm in the common bile duct or of 1 mm in the hepatic duct^[53,54]. It is a frequent finding and occurs in 36%-57% of patients during follow up^[55]. It should always raise the suspicion of the presence of a CCA. The stricturing process may cause extrahepatic biliary obstruction leading to development of symptoms. Patient with jaundice, pruritis, right upper quadrant pain and abnormal biochemical studies have been deemed appropriate candidates for therapy. The goal of therapy is to relieve biliary obstruction.

The optimal non surgical management of these dominant strictures is still debatable. Endoscopic balloon dilatation both with and without stenting has been studied. Long term stent therapy (3 mo) has been shown to have a high rate (close to 50%) of complications of cholangitis/jaundice attributed to stent occlusion^[56]. However, short term stenting (11 d) was associated with a lower rate (7%) of these complications, at the same time producing significant effects in symptom reduction and biochemical resolution of cholestasis. Additionally, 81% remained asymptomatic over a 19 mo follow up period and none of the patients had recurrence of clinical/biochemical cholestasis^[57]. Another study reported similar positive results after short term stent therapy with significant effects on resolution of symptoms and biochemical cholestasis with 80% of patients remaining re-intervention free at the end of 1 year^[58]. A randomized trial comparing balloon

dilatation and stenting has not been performed. However, a retrospective study that compared at endoscopic dilatation with dilatation + stenting reported an increased number of complications and incidence of cholangitis in the group that received both without significant difference in improvement of cholestasis^[59]. It has been suggested that the group that received both interventions may have been sicker as stenting was done only when dilatation alone did not improve biliary drainage^[60]. Moreover, half of the stents were placed percutaneously and the authors reported a significantly higher rate of complications with percutaneous placement of stents as compared to the endoscopic approach. One study aimed at assessing a survival benefit of endoscopic treatment of strictures reported a 5 years survival that was significantly ($P = 0.027$) higher over that predicted by the Mayo risk score^[61]. Indirect evidence from other studies has supported this finding^[62,63].

Overall, endoscopic therapy of strictures has been proven to be a safe and efficacious mode of treating primary sclerosing cholangitis associated strictures that helps in amelioration of symptoms and cholestasis with a low rate of complications. If stenting is considered, short term therapy is deemed best.

Surveillance for cholangiocarcinoma

Patients with PSC are at risk of developing CCA. The risk after 10 years and 20 years is 9% and 19% respectively^[64]. Patients with deterioration in functional status, worsening liver functions and/or weight loss should be evaluated for CCA. The distinction between a benign dominant stricture and CCA, however, has remained a challenge.

A cut off value of CA19-9 (cancer antigen 19-9) of > 130 U/mL in symptomatic patients has a sensitivity and specificity of 79% and 98% respectively^[65]. Its value as a screening tool in asymptomatic patients remains to be defined. CCA often presents in its advanced stage when identification of a mass lesion makes a diagnosis of CCA very likely. In early stages, however, diagnosis is difficult. A study that followed 230 patients over 6 years reported sensitivity of ultrasound, CT, MRI as 57%, 75% and 63% respectively when imaging alone was considered. The positive predictive value of ERCP, MRCP and MRCP + MRI was 23%, 21% and 23 % respectively^[66].

Bile duct brushings are the most commonly used method for tissue sampling during ERCP are now routinely obtained at the time of ERCP^[7-9]. The vast majority of extrahepatic CCA are periductal, cancers, and do not demonstrate mass lesions on imaging studies. Brush cytology obtained during ERCP is the usual diagnostic technique in the investigation of patients with biliary strictures. However the sensitivity of brushings is low for distinguishing benign strictures and CCA with a 43% sensitivity and a diagnostic accuracy of 50%-60%^[7-9].

At the time of ERCP brushings of stricture for cytology, another set of brushings for FISH are obtained in our institution. FISH probes are used to target the centromeric regions of chromosomes 3, 7 and 17 and the

9p21 band (p16). Some studies have considered positive FISH based on polysomy only, while some have considered trisomy or tetrasomy as positive too. In a recent meta-analysis from our group, we pooled all the available evidence in order to better define the utility of FISH for detection of CCA. Our unpublished observations show that any FISH positivity has a pooled sensitivity and specificity of 68% (95%CI: 61%-74%) and 70% (95%CI: 66%-73%) respectively. Thus both brushings for cytology and FISH obtained at the time of ERCP contribute significantly in diagnosing CCA in PSC patients^[9].

Recent studies have demonstrated promising results of cholangioscopy in the diagnosis of CCA. Tischendorf *et al.*^[67] prospectively studied 53 patients out of which 12 patients were found to have CCA based on tissue sampling. Patients underwent cholangioscopy in addition to ERCP, cholangioscopy was found to have higher sensitivity and significantly higher specificity, positive predictive value and negative predictive value than endoscopic retrograde cholangiography. A single center prospective study involving 36 patients and using peroral cholangioscopy and biopsy reported an overall accuracy of 89% in differentiating benign from malignant stenoses^[68].

ERCP with probe-based confocal laser endomicroscopy is an emerging technology that enables high resolution assessment of gastrointestinal mucosal histology thereby allowing examination of “optical biopsies” and exponentially expanding the scope of imaging capabilities. The examination is done *in vivo* and images are displayed in real time. A single center small case series of 15 patients and 21 dominant stenoses reported 100% sensitivity and 100% negative predictive value in excluding neoplasia^[69]. It concluded that if verified in large prospective studies, this technology could be used to risk stratify strictures in patients with PSC. Also, chromoendoscopy using methylene blue was studied for the first time in staining tissue of the bile duct^[70]. It helped identify normal, dysplastic and inflamed mucosa of the biliary tract as was subsequently proven by follow up or histology. A homogenous staining was suggestive normal tissue, absence of it on circumscribed lesions or diffuse staining predicted neoplastic or inflamed tissue^[70].

We routinely send 2 sets of brushes with PSC-related dominant strictures; one for routine cytology and the other for FISH analysis. Thus an advanced endoscopist forms an integral part of the team managing IBD patients with associated PSC and its related complications and surveillance of these patients for CCA.

IBD and colorectal neoplasia surveillance

Patients with IBD are at increased risk of CRC. Incidence of cancer has been more extensively studied in relation to UC than Crohn's. The risk in UC is increased with the duration and extent of disease. A meta-analysis reported the risk is 2% at 10 years, 8% at 20 years, and 18% at 30 years of disease^[71]. Patients with extensive colitis are at increased risk as compared to those with left sided colitis. Compared to age-matched controls, the risk begins to increase about 8-10 years after onset of symptoms. Patients

with PSC are also more predisposed to developing CRC. Earlier studies on the risk of CRC with CD have been inconclusive. It is now believed that risk of developing CRC in UC and CD is nearly identical^[72].

There have not been randomized controlled trials proving the effectiveness of surveillance colonoscopy. There have been three case series that have studied this^[73-75]. A Cochrane analysis of these studies concluded that there was no clear evidence that surveillance improves survival. There is evidence that cancer tends to be detected earlier in patients who undergo surveillance and they are likely to have a better prognosis although lead time bias may affect this apparent benefit. It stated that there may be indirect evidence that surveillance is effective at reducing death associated with IBD and that it may be acceptably cost-effective^[76].

Interval colonoscopies with random biopsies of abnormally appearing mucosa and targeted biopsies of suspicious lesions have been recommended. Newer methods aimed at detecting abnormal/dysplastic mucosa have been studied to help make this more effective. An advanced endoscopist with experience in complex mucosal imaging would play an important role in the surveillance of IBD patients for CRC. Newer endoscopic imaging modalities including high-definition endoscopy, chromoendoscopy, virtual chromoendoscopy and confocal laser endomicroscopy have the potential to significantly improve the detection and characterization of flat and subtle dysplasia, thereby setting the stage for a system of targeted neoplasia detection without random biopsies in IBD patients.

Chromoendoscopy is a dye-spraying technique that highlights the borders and surface architecture of neoplastic lesions, thereby unmasking and delineating subtle lesions and aiding in the differentiation of neoplastic and non-neoplastic tissue^[76]. Chromoendoscopy has been compared to standard-definition endoscopy for detection of neoplasia in both IBD and non-IBD patients and shown to be superior^[77]. However, careful cleansing and inspection of the entire colonic mucosal surface needs to be done to detect neoplasia^[76]. Importantly, the use of chromoendoscopy does not increase the mean procedure time and has been shown to be no better than white-light endoscopy with random and targeted biopsies^[78,79]. Chromoendoscopy described above using methylene blue has been studied in UC patients. The study included 102 patients, each of who had biopsies by different 3 techniques: standard colonoscopy with random biopsies, targeted biopsies and dye targeted biopsies in which methylene blue was segmentally applied throughout colon and abnormal mucosa that was made visible by dye spray was then biopsied. It concluded that dye targeted biopsies detected more dysplasia than random biopsies ($P = 0.001$) and more than targeted non dye biopsies. ($P = 0.057$)^[78]. The disadvantages of this technique include the cost, time consuming nature and the fact the dye does not always coat the mucosa evenly and does not allow for a detailed analysis of the subepithelial network.

Virtual chromoendoscopy technologies have also

been employed including narrowband imaging (NBI; Olympus, Tokyo, Japan), i-scan (Pentax, Tokyo, Japan), Fuji Intelligent Chromo Endoscopy (FICE; Fujinon, Tokyo, Japan) with use of selective light filters or post-image processing techniques to improve visualization of vascular structures^[80]. A recent randomized parallel group study with 112 patients randomized to get colonoscopy using either NBI or white lights reported no significant difference in detection of dysplasia^[81]. Another study involving 60 patients concluded that NBI was a less time consuming and equally efficacious method compared to chromoendoscopy to detect intraepithelial neoplasia in long standing IBD patients but had a high lesion and patient miss rate and cannot be recommended as a standard technique^[82].

Confocal laser endomicroscopy is another advanced imaging technique that permits direct histologic assessment of mucosa at the cellular and subcellular levels *in vivo*^[83]. The potential application of technology in IBD patients would be in combination with white-light endoscopy and chromoendoscopy to more accurately predict lesion histology and thus aid in decision making regarding lesion resectability in the setting of chronic colitis^[84].

Endoscopic mucosal resection (EMR) is being used for management of specific raised lesions in chronic UC patients getting surveillance colonoscopy for dysplasia. In a study, EMR was used to remove 79 flat Paris 0-II lesions with a recurrence rate of 2.4% at 3 mo with no additional lesions detected in a 4-year follow-up period^[85]. Thus management of dysplasia is emerging as a new intervention to develop in the area of IBD.

Even though considerable research has been done in the area of interventional IBD, future research is needed for better imaging techniques in the diagnosis of CCA and role of cholangioscopy in the management of PSC strictures. In addition, randomized controlled trials aimed at studying endoscopic balloon dilations and stenting in treating bowel strictures in the setting of IBD and comparing its efficacy with surgery are required.

The above review underlines the fundamental role of an advanced endoscopist in a team of IBD specialists, colorectal surgeons and hepatologists that manages patients with IBD. Further research and studies will better define the scope of the advanced endoscopist in the coming years.

Key words: Inflammatory bowel disease; Pregnancy; Biologics; Neonatal outcomes

Core tip: Inflammatory bowel disease affects people during their reproductive years. Many patients and physicians have concerns about pregnancy in inflammatory bowel disease (IBD), and are unsure about management of IBD during pregnancy. Women with IBD have similar fertility as the general population, with the exception of certain prior surgeries, and active disease. This review highlights the relative safety of medications used to treat IBD during pregnancy and breastfeeding, and summarizes the updated literature for immunosuppressants and biologics. Good control of disease and clinical remission at the time of conception increases the likelihood of having successful pregnancy outcomes, and quiescent disease during pregnancy.

From conception to delivery: Managing the pregnant inflammatory bowel disease patient. *World J Gastroenterol* 2014; 20(13): 3495-3506 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i13/3495.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i13.3495>

Abstract

Inflammatory bowel disease (IBD) typically affects patients during their adolescent and young adult years. As these are the reproductive years, patients and physicians often have concerns regarding the interaction between IBD, medications and surgery used to treat IBD, and reproduction, pregnancy outcomes, and neonatal outcomes. Studies have shown a lack of knowledge among both patients and physicians regarding reproductive issues in IBD. As the literature is constantly expanding regarding these very issues, with this review, we provide a comprehensive, updated overview of the literature on the management of the IBD patient from conception to delivery, and provide action tips to help guide the clinician in the management of the IBD patient during pregnancy.

INTRODUCTION

Inflammatory bowel disease (IBD) is a group of chronic bowel diseases, including Crohn's disease and ulcerative colitis, which can affect all aspects of a patient's life. The majority of patients with IBD are diagnosed in their adolescent to young adult years. The diagnosis of IBD and the medications and surgeries used to treat IBD come with many questions and concerns about how they can affect future education and work plans, and relationship and family plans. These questions and concerns not only affect the patient, but also the health care providers who are managing the patient. In particular, the complex

interaction between IBD and pregnancy is important, especially because any decisions regarding the management of the patient will not only affect her, but also her fetus. In addition, they will not only affect them currently, but may have long lasting effects.

The concerns regarding IBD and reproduction certainly play a central role in any decisions made by the patient and the physician caring for her. Many women with IBD choose not to become pregnant and to remain childless. This concept of “voluntary childlessness” has been documented in early studies that showed up to 30% of women with IBD (compared to 7% of the general population) had voluntary infertility^[1]. More recent studies confirm this “voluntary childlessness” continues to be an issue, with up to 18% of childless IBD patients indicating that the decision was influenced by IBD related factors^[2-4]. The five major concerns of women with IBD that have been reported by previous studies include: fertility/conception, genetics, IBD-related congenital abnormalities, medication effects on pregnant and fetus, and effect of pregnancy on IBD^[3-5]. Inadequate physician knowledge regarding reproduction in inflammatory bowel disease, and lack of comfort managing pregnant IBD patients may be contributing to the medical advice component of “voluntary childlessness” seen in IBD patients. In this review, we aim to address each of these major topics of concern, in the hopes that practitioners will be better equipped with up-to-date information to use in counseling their patients.

CONCEPTION

Fertility: what are the chances of becoming pregnant?

Women with IBD have been shown to have similar fertility as the general population^[1,2,6-9]. However, some studies report that Crohn's disease (CD) patients may have slightly decreased fertility^[10,11], especially when their disease is active^[9] or if they have adhesions from prior surgeries^[10,12]. Ulcerative colitis (UC) patients can have normal fertility, however once UC patients have had a surgery, such as restorative proctocolectomy and ileal pouch anal anastomosis, they have an increased risk of infertility up to 3-4 fold^[15-16]. It is hypothesized this increased infertility is due to tubal infertility from the adhesions and scarring^[15,16], since UC patients who have had laparoscopic IPAA have been shown to have less adhesions^[17], and lower infertility rates^[18,19]. Although there have been variable reports on the infertility rates among women with Crohn's disease and ulcerative colitis, some of these differences may be attributed to voluntary childlessness. In a recent meta-analysis of eleven studies, the authors found that in women with CD, fertility was reduced 17%-44% compared to controls, but further analysis revealed this to be linked to voluntary childlessness; they did not find any reduction in fertility in women with UC^[20].

Action point: In general, women with IBD have similar fertility rates as the general population. Previously reported infertility may be attributed to voluntary childlessness.

Women with Crohn's disease may have decreased fertility rates when their disease is active, or if have had prior surgeries. Women with ulcerative colitis who have had pelvic surgery have decreased fertility rates.

Genetics: what are the chances of offspring developing IBD?

Earlier studies supported strong genetic risks of IBD in offspring of patients with IBD up to 13 times the general population^[21,22]. When early twin studies were combined, results showed concordance ranging between 15.4% monozygote twin concordance for ulcerative colitis to 30.3% concordance for Crohn's disease^[23]. Monozygote twins are born from the same zygote, so this low concordance rate suggests there are other non-genetic influences, such as environmental factors. A recent study re-ran the Swedish twin registry, which is one of the major data sources for twin studies, and found that previous twin studies overestimated the influence of genetics in Crohn's disease^[24]. Although genetics does play an important role in the risk of developing IBD, they are not the only determinants.

Action point: Genetics play an important role in the risk of developing IBD, but women should be counseled that there are other factors involved. Their offspring will not necessarily develop IBD.

PREGNANCY

Conception and beyond: what is the effect of IBD activity on the pregnancy?

Some studies indicate that IBD, especially Crohn's disease, can be associated with an increase in adverse pregnancy outcomes, such as prematurity^[2,10,14,25-33], low birth weight^[14,25,26,28,31-32], small for gestational age^[25,28,30,33,34], congenital abnormalities^[28,31,35], miscarriages or spontaneous abortions^[11,30]. Other studies report no significant association between IBD and adverse pregnancy outcomes^[9,29,36-38]. However, the effect of IBD on pregnancy outcomes may be partially attributable to disease activity, and medications, rather than IBD alone. In addition, other demographic variables such as maternal age and smoking have been shown to be risk factors for congenital abnormalities and pregnancy outcomes such as preterm delivery, among women with IBD^[38].

A few studies concluded that disease activity did not predict adverse pregnancy outcomes in women with IBD^[1,30,32], but other studies found that active disease at the time of conception, and during pregnancy, increases the risk of adverse pregnancy outcomes, such as spontaneous abortion^[1,6,7] and preterm delivery^[37,39].

Action point: Women with IBD should be in remission before attempting to become pregnant.

Conception and beyond: what is the effect of pregnancy on IBD course?

Women with active disease at the time of conception, or

within 3 mo of conception, are more likely to have active disease during pregnancy than if their disease was in remission^[40,41]. For both ulcerative colitis and Crohn's disease, the relative risk of a woman having active disease during pregnancy if she had active disease at the beginning of pregnancy is about two-fold^[41]. Conversely, women with disease in remission at the time of conception are more likely to have quiescent disease during pregnancy^[6]. Pregnancy was reported to decrease activity of Crohn's disease in a study of 61 women^[42], but a larger study including 92 women with Crohn's disease found no statistical significant difference in disease course during or after pregnancy^[43]. Longer disease duration in Crohn's disease patients may increase the risk of relapse during pregnancy^[43]. In ulcerative colitis patients, there was a higher risk of relapse during pregnancy and in the post partum period^[43]. A large study on 543 women over 10 years reported that pregnancy was associated with a reduced number of flares in the years following pregnancy^[44].

Action point: The disease activity at time of conception tends to predict disease course during pregnancy. Ideally, women should be in remission at the time of conception.

Flares and remissions during pregnancy: which medications can be used during pregnancy?

Women who require medications to achieve and maintain remission of their IBD, should continue these medications during pregnancy. With the exception of methotrexate, which should be stopped when attempting to conceive, and withheld during pregnancy, other medications used to manage IBD have not been associated with significant adverse fetal outcomes.

Aminosalicylates [Food and Drug Administration (FDA) Class B, Asacol FDA Class C] and sulfasalazine (FDA Class B): Aminosalicylates and sulfasalazine are commonly used drugs for mild to moderate ulcerative colitis. A cohort study from Denmark found an increased risk of stillbirth and preterm birth in women prescribed 5-ASA drugs during pregnancy, but was unable to distinguish between effects of disease activity and 5-ASA^[36]. Other studies found no significant association between 5-ASA drugs and poor pregnancy outcomes^[45-51]. A recent meta-analysis reported slight but non-significant increases in congenital malformation (OR = 1.16), stillbirth (OR = 2.38), spontaneous abortion (OR = 1.14), and preterm delivery (OR = 1.35) and low birth weight (OR = 0.93) with 5-ASA medications^[51]. However, again, the results were pooled, and they were unable to differentiate which 5-ASA drug, type of disease, or disease activity. Recently there has been concern about the dibutyl phthalate (DBP) coating on certain mesalamines, as animal studies found adverse effects on development and reproductive organs^[52]. A recent study reported high mean urinary concentrations of the main DBP metabolite in a woman who used Asacol^[52]. However, there have been no reports of adverse developmental or reproductive effects on hu-

mans. In addition, DBP can be found in many commonly used medications and dietary supplements^[53].

Sulfasalazine inhibits folate synthesis, so women on sulfasalazine should be supplemented with folic acid (5 mg/d) to prevent neural tube defects^[54,55]. Sulfasalazine can also displace bilirubin from albumin, which theoretically could lead to kernicterus in the newborn child, but no cases have been reported^[55].

Action point: Aminosalicylates and sulfasalazine can be used during pregnancy, and are not significantly associated with adverse neonatal outcomes. Women on sulfasalazine should receive folic acid supplementation (5 mg/d).

Azathioprine and 6-mercaptopurine/Purinethol (FDA Class D): Although thiopurines are classified as FDA Class D drugs, because of teratogenicities in animal studies, the use of azathioprine/6-MP during pregnancy in IBD is not associated with increased risk of preterm birth, low birth weight, neonatal adverse outcomes, or congenital abnormalities^[33,49,56-60]. Disease activity rather than medication use can lead to neonatal adverse outcomes^[57]. One study reported that thiopurines increased the risk for congenital malformations when compared to healthy women, but not when compared with IBD controls^[61]. A large ongoing prospective registry of pregnancy outcomes in women with IBD exposed to immunomodulators and biologic therapy (PIANO study) has found no association with the use of immunosuppressants with congenital anomalies, abnormal newborn growth and development, or other complications^[62]. In addition, a recent review found that thiopurine use during pregnancy was not associated with low birth weight or congenital abnormalities, but was associated with pre-term birth^[63]. Infants may be exposed to a metabolite of Azathioprine, 6-TGN^[64,65], and a recent study has found that up to 60% of infants exposed to thiopurines in utero are born with anemia^[65]. In long-term (average 4 years) follow-up studies of babies exposed to azathioprine in utero, there was no increased risk of infection^[66] or development and immune function^[67]. Expert opinion is to continue thiopurine use during pregnancy to maintain remission of disease^[54,68].

Action point: Thiopurines can be used during pregnancy, and are not significantly associated with adverse neonatal outcomes.

Methotrexate (FDA Class X): Methotrexate is a teratogen and an abortifacient, and is therefore contraindicated during conception and pregnancy period. Methotrexate exposure during organogenesis (6-8 wk) may lead to congenital abnormalities, while exposure in the second and third trimesters can lead to fetal loss^[55,69]. Since Methotrexate remains in the tissue for a period of time, patients should discontinue at least 3-6 mo prior to attempting to conceive^[54,69]. Women who become pregnant while on methotrexate should seek medical attention immediately, for assessment of the fetus, and counseling

regarding options^[54,55].

Action point: Methotrexate should be discontinued at least 3 to 6 mo before conception.

Corticosteroids (FDA Class C): Glucocorticoids cross the placenta and can reach the fetus, but the placental enzymes convert corticosteroids to less active metabolites^[54,55]. Prednisone, prednisolone, and methylprednisolone are the preferred agents during pregnancy, as they are more efficiently metabolized by the placenta than dexamethasone or betamethasone^[54]. Most studies on glucocorticoid use during pregnancy have been in patients with various diseases, such as asthma. There has been a reported association of increased oral cleft in neonates exposed to glucocorticoids in utero in the first trimester, and this risk should be discussed with the patient^[54,55,69]. Overall there is no increased risk of congenital abnormalities^[50]. Budesonide has only been reported in one small study in Crohn's disease patients, and was not associated with adverse neonatal outcomes^[70].

Action point: Corticosteroids may be used to treat flares of IBD during pregnancy. There is a small risk of oral cleft in neonates exposed to corticosteroids in the first trimester.

Antibiotics: Metronidazole (FDA Class B) and Ciprofloxacin (FDA Class C) are commonly used to treat abscesses and fistulae in IBD. Animal studies showed carcinogenic effects from Metronidazole, and early studies suggested a risk of cleft lip^[55], but this has not been reported in humans^[71]. It was not associated with preterm birth (OR = 1.02, 95%CI: 0.80-1.32), low birth weight (OR = 1.05, 95%CI: 0.77-1.43), OR = congenital anomalies (OR = 0.86, 95%CI: 0.30-2.45) in a large study of 2829 singleton/mother pairs^[72]. In a small study (27 of 113 patients on Metronidazole) in female IBD patients, metronidazole was found to be safe in all trimesters of pregnancy^[49]. Previously, there was concern that quinolones increase the risk of arthropathies in the offspring. Studies have reported no significant increase in major congenital anomalies, including musculoskeletal problems from the use of ciprofloxacin^[73]. A meta-analysis of pregnancy outcomes after exposure to quinolones in the first trimester reported no increased risk of major malformations, stillbirths, preterm births, or low birth weight^[74]. However, because of the known possible effect of ciprofloxacin on bone and cartilage, it has been recommended to avoid this medication during pregnancy^[55].

Penicillins have not been shown to cause fetal malformations or adverse pregnancy outcomes, and are considered the first line therapy in pregnancy^[71]. Amoxicillin (FDA Class B) can be used to treat abscesses and complications of IBD during pregnancy.

Action point: Metronidazole can be used during pregnancy, preferably avoid use in first trimester. Ciprofloxacin

should be avoided during pregnancy due to risk of arthropathy. Amoxicillin is safe to use during pregnancy.

Biologics: Anti-tumour necrosis factor inhibitors (FDA Class B) such as Infliximab, Adalimumab, and Certolizumab, are commonly used to treat moderate to severe IBD, and fistulizing Crohn's disease. TNF- α is a pro-inflammatory cytokine that stimulates the production of prostaglandins, and increased levels are associated with preterm labor^[75]. TNF levels increase during pregnancy, as it is mainly produced by the placenta^[76]. TNF- α is important for the initial stages of pregnancy, and also for the development of the fetal immune system, and TNF deficient animals have been shown to have increased risk of immune developmental abnormalities^[77]. However, increased levels of TNF- α have been associated with preeclampsia, gestational diabetes, obesity^[76].

Initially Infliximab and Adalimumab were reported in a few cases of pregnant women with IBD^[78-84] which did not show any adverse effects. Larger observational studies, registry studies, and systematic reviews have shown its safety for use during pregnancy^[85-88]. The PIANO study has not found any increase in congenital anomalies, abnormal newborn growth and development, or other complications, among women receiving biologics^[62].

Infliximab and Adalimumab are IgG1 monoclonal antibodies, and are actively transported across the placenta, while Certolizumab is a Fab fragment of IgG1, and has not been shown to have placental transportation^[89]. This active transport of IgG1 antibodies occurs mainly in the third trimester^[81,90]. Thus it has been recommended to stop Infliximab and Adalimumab at the onset of the third trimester^[91,92]. However, in a recent study, in women with quiescent IBD, who discontinued anti-TNF therapy by week 30, Infliximab and Adalimumab were still detected in cord blood^[93]. The exact time to hold anti-TNF is now debatable, especially with Adalimumab which is given weekly or biweekly, but in high risk patients, or patients with active disease, these biologics should be continued throughout the pregnancy^[94]. Levels of Infliximab and Adalimumab have been detected in infants for as long as 6 mo^[95]. At least for the short term, children exposed to intra-uterine Infliximab develop normally, without increased infections, allergic reactions, or decreased response to vaccinations^[91]. However, infants exposed to combination of immunomodulators and biologics have been noted to have increase in infections from 9 to 12 mo of age^[62]. Thus, it is still recommended that infants exposed to intra-uterine anti-TNF therapy delay live vaccinations for at least the first 6 mo.

Action point: Anti-TNF therapies are safe to use during pregnancy. Infliximab and Adalimumab should be held after week 30, if not earlier, to decrease placental transport to the fetus. Neonates exposed to biologics during pregnancy should not have live vaccines during the first 6 mo post delivery.

Cyclosporine (FDA Class C): Cyclosporine crosses the placenta, and has not been found to be teratogenic in animal models^[96]. The majority of studies on cyclosporine in pregnancy involve post-transplant patients, which suggests an association with premature delivery and low birth weight infants^[97]. In severe ulcerative colitis flares during pregnancy, cyclosporine has been used with successful control of the disease, avoidance of colectomy during pregnancy, and no significant adverse pregnancy outcome^[98-104]. The most common side effect reported was hypertrichosis in the mother, however, in one case report, the patient developed severe hypertension and seizures 48 h post infusion^[99]. Other adverse effects of cyclosporine include nephrotoxicity and hepatotoxicity^[97].

Fulminant ulcerative colitis leading to colectomy has been associated with adverse pregnancy outcomes, with up to 49% fetal mortality and 22% maternal mortality rates in the literature^[105]. Thus, in cases of severe fulminant ulcerative colitis, in order to avoid urgent colectomy, cyclosporine may be considered.

Action point: Cyclosporine may be considered in cases of severe fulminant ulcerative colitis in pregnancy, in order to avoid colectomy during pregnancy. However, as biologics are FDA Class B, and there are more studies on Infliximab use during pregnancy, Infliximab may be the preferred first line option.

Managing relapses during pregnancy: can we use induction medications?

As already mentioned, active disease during pregnancy is associated with poor pregnancy outcomes. Since medications commonly used to treat IBD are not associated with significant adverse pregnancy outcomes, treating the mother to induce and maintain remission during the remainder of the pregnancy will lead to more beneficial outcomes. If hospitalization is required to manage an acute IBD flare, IV hydrocortisone^[103] and IV infliximab^[78,82,91,92,106] may be used for rescue therapy, as thus far, they have not been associated with significant adverse effects. One study has shown that IV cyclosporine can be used safely^[103].

Action point: Active IBD is associated with adverse pregnancy outcomes. Management of flares of IBD during pregnancy may involve the use of steroids, biologics, and possibly cyclosporine.

DELIVERY

Women with IBD were initially reported to be more likely to have a caesarean section^[2,14,25,33,34,107]. This has mainly been attributed to Crohn's disease patients, especially those with perianal disease^[14,107,108]; it has also been shown that vaginal delivery with episiotomy may be associated with subsequent perianal involvement^[109]. Larger population studies found no significant difference in caesarean section rates among IBD patients^[38], and no

risk of progression of perianal disease in Crohn's disease with vaginal delivery^[108]. Thus, the decision for caesarean section should not be made purely on the IBD diagnosis, but also obstetrical reasons.

Action point: In women with Crohn's disease with active perianal disease, caesarean section should be considered on an individual basis.

POST PARTUM

What is the risk of IBD flaring after delivery?

Some women may flare after delivery, while others fare well. A retrospective cohort study of 114 Crohn's disease patients reported more frequent disease progression after childbirth in patients who had active luminal disease prior to pregnancy^[108]. A large multi-country prospective study found higher risk of relapse in the postpartum period in women with ulcerative colitis^[43].

Action point: Ulcerative colitis patients have an increased risk of relapse after delivery. Crohn's disease patients with active luminal disease before pregnancy have a higher risk of relapse after delivery.

BREASTFEEDING

Breastfeeding physiologically may be associated with increased inflammation, as prolactin is associated with up-regulation of TNF production^[110] and increased levels are found in other autoimmune diseases such as lupus, rheumatoid arthritis^[111]. Many women with IBD choose not to breastfeed their children^[2,112]. This may be due to fears of medication effects, physician recommendation or personal choice^[112]. The effect of breastfeeding on the development of IBD is thought to be related to the hygiene hypothesis, in which breastfeeding is thought to help the neonate develop tolerance to microflora and food antigens, thus preventing immune over activation to delayed antigen exposures^[113-115].

Does breastfeeding affect IBD?

Studies investigating the effect of breastfeeding on developing IBD vary in methodology and conclusions. In one study, women who breastfeed were found to be more likely to have a postpartum flare of their disease, but this increased risk was non significant once adjusted for discontinuation of IBD medications during pregnancy^[112]. A more recent population-based study found no increased rate of disease flare in the post partum year between those who breastfed (26%) *vs* those who did not (29.4%)^[116].

Can breastfeeding affect the risk of IBD in the offspring?

Some studies find no association between breast feeding and diagnosis of IBD^[117]. However, some report that a lack of breastfeeding in infancy is associated with an increased risk of UC (OR = 1.5, 95%CI: 1.1-2.1) and

CD (OR = 1.9, 95%CI: 1.1-3.3)^[118]. More recent studies reported a protective effect of breastfeeding to decrease the odds of developing IBD^[119,120]. Two systematic reviews investigating the role of breastfeeding and the development of IBD found that breastfeeding is associated with lower risks of developing early-onset IBD^[121,122].

Which medications can be used during breastfeeding?

Aminosalicylates (FDA Class B, Asacol FDA Class C) and sulfasalazine (FDA Class B): Earlier studies have reported the rare occasion of infants exposed to 5-aminosalicylates via breast-milk developing watery diarrhea^[123], however very small amounts of drug are excreted into breast milk, making risk of toxicity and reaction very unlikely^[124-126]. Sulphasalazine has also been reported to cause bloody diarrhea in the infant exposed via breast-milk^[127], however, it has not been reported other than case reports. Sulfasalazine can have a bilirubin displacing effect leading to jaundice in the neonate, however the amount of drug transferred to the child via breast-milk is negligible to cause jaundice^[128,129].

ACTION POINT: 5-aminosalicylates and sulphasalazine can be continued during breastfeeding.

Azathioprine and 6-mercaptopurine/Purinethol (FDA Class D): Azathioprine and 6-MP can be continued during pregnancy, as described above, but there are concerns about the potential for tumorigenicity, and increased susceptibility to infections in neonates exposed during breastfeeding^[66]. Recent studies show that only very small amounts of AZA/6-MP are measured in breast milk, and negligible amounts detected in the neonate^[130-134]. In addition, the highest concentration of AZA measured in the breast milk appears during the first 4 h after consumption^[130], thus it has been recommended to “pump and dump” the first 4 h of breastmilk. Thus far, there has not been reported increase risk of infections among babies breastfed with exposure to azathioprine^[66], and it is considered safe to continue these medications during breastfeeding^[54,66,130-134].

Action point: Azathioprine and 6-MP are can be continued during breastfeeding; the first 4 h of breastmilk after consumption may be discarded to minimize the amount of drug transferred to the neonate.

Methotrexate (FDA Class X): Methotrexate crosses into the breast milk^[135] and because of its teratogenicity, it is contraindicated during breastfeeding^[136,137].

Action point: Methotrexate is contraindicated during breastfeeding.

Corticosteroids (FDA Class C): Corticosteroids do transfer to the breast milk, but in very low levels^[138,139] and because the highest levels appear in the first 4 h^[139], it is recommended to “pump and dump”^[53,139] the first 4

h after medication consumption to minimize transfer of the drug to the neonate.

Action point: Corticosteroids can be continued during breastfeeding if required to treat maternal IBD.

Antibiotics: Metronidazole is transferred into the breast milk^[139], but in minimal levels^[140] and levels decline after 12-24 h after maternal dose intake^[141]. If metronidazole is required for the treatment of active IBD, it is recommended to wait 12-24 h after metronidazole intake before breastfeeding^[55], and long term use should be avoided^[69]. Ciprofloxacin is also detectable in the breast milk in small amounts^[142,143], but short term treatment can be used if indicated^[55].

Action point: Metronidazole and ciprofloxacin can be continued for short term during breastfeeding if required to treat maternal IBD.

Biologics: As mentioned, the biologic therapies can be continued during pregnancy, and held in the third trimester. Studies have shown nil to minimal levels of infliximab and adalimumab in the breast milk and no significant adverse events have been reported in the infant^[81,143-148]. It is thought that any detectable levels in the neonate after delivery may be due to placental transfer during pregnancy^[147]. Thus, although anti-TNF therapies are can be continued during breastfeeding, further studies are required to determine the effect of infant exposure to these biological therapies on the development of their gastrointestinal immunity and systemic immune system^[89,146,148]. The preliminary results of the PIANO study have not found any association between breastfeeding and infection risk in the neonate exposed to biologic therapy^[62].

Action point: Infliximab and adalimumab may be continued during breastfeeding.

Cyclosporine (FDA Class C): Cyclosporine does cross into the breast milk, but if required for fulminant colitis, it can be used. Case reports and series of neonates exposed to cyclosporine during pregnancy and breastfeeding are mainly from the renal transplant literature, and have reported varying levels of cyclosporine in the breast milk, and relatively good outcomes in the mother and neonate^[149-153]. One case report of cyclosporine use in the management of severe ulcerative colitis while breastfeeding also reported short term good outcomes in the mother and neonate^[154]. More studies are required to determine the long term effects of neonatal exposure to cyclosporine in the breast milk.

Action point: Cyclosporine has been used to manage fulminant colitis during breastfeeding, however, infliximab is preferred due to the lack of studies for cyclosporine.

CONCLUSION

IBD affects people during an important time of their lives when they are considering family planning or are already pregnant. With the exception of Methotrexate, commonly used medications for the treatment of IBD are not associated with significant adverse pregnancy outcomes, and can be used throughout pregnancy. Good control of disease and clinical remission at the time of conception increases the likelihood of having successful pregnancy outcomes, and quiescent disease during pregnancy. There is no need to adjust medications during pregnancy, with the exception of biologics such as Infliximab and Adalimumab, which should be held during the third trimester in women who are in clinical remission. However, biologics may be continued throughout pregnancy if necessary to control disease. Induction of remission of IBD flares during pregnancy should be treated with appropriate medications, such as steroids, infliximab, and for severe fulminant colitis, cyclosporine, as active disease and fulminant colitis requiring surgery has increased risk of adverse fetal outcomes. The management of IBD in women during their reproductive years should include consideration of their family planning decisions, and education counseling regarding the overall safety of medications and the importance of medication adherence should occur prior to conception.

Abstract

Diabetes mellitus is one of the most frequent co-morbidities of ulcerative colitis patients. The epidemiological association of these diseases suggested a genetic sharing and has challenged gene identification. Diabetes co-morbidity in ulcerative colitis has also relevant clinical and therapeutic implications, with potential clinical impact on the follow up and outcome of patients. These diseases share specific complications, such as neuropathy, hepatic steatosis, osteoporosis and venous thrombosis. It is still unknown whether the coexistence of these diseases may increase their occurrence. Diabetes and hyperglycaemia represent relevant risk factors for postoperative complications and pouch failure in ulcerative colitis. Medical treatment of ulcerative colitis in patients with diabetes mellitus may be particularly challenging. Corticosteroids are the treatment of choice of active ulcerative colitis. Their use may be associated with the onset of glucose intolerance and diabetes, with difficult control of glucose levels and

with complications in diabetic patients. Epidemiologic and genetic evidences about diabetes co-morbidity in ulcerative colitis patients and shared complications and treatment of patients with these diseases have been discussed in the present review.

Key words: Diabetes mellitus; Ulcerative colitis; Diabetes complications; Inflammatory bowel diseases; Glucose intolerance; Medical therapy; Corticosteroids

Core tip: The relationship between ulcerative colitis and diabetes mellitus is intriguing, full of practical and speculative information, useful for clinical practice and basic research. Diabetes mellitus is one of the most frequent co-morbidities of ulcerative colitis and their epidemiological association suggests genetic sharing and stimulates studies for gene identification. Diabetes also shares specific complications with ulcerative colitis and represents a challenging condition in ulcerative colitis patients for the treatment of the disease, due to difficult control of glucose levels and for high risk of postoperative complications and pouch failure. All these issues have been discussed in the present review.

Glucose intolerance and diabetes mellitus in ulcerative colitis: Pathogenetic and therapeutic implications. *World J Gastroenterol* 2014; 20(13): 3507-3515 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i13/3507.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i13.3507>

INTRODUCTION

Ulcerative colitis (UC) is a chronic disease characterised by mucosal inflammation, limited to the colon. Its inci-

dence and prevalence are increasing with time in different regions around the world, with the highest annual incidence of 24.3 per 100000 persons-year, and prevalence of 505 per 100000 persons in Europe^[1].

The disease is associated with high costs, disease-specific morbidity and decreased quality of life, mostly related to complications, surgery and co-morbid diseases.

Co-morbid diseases in UC include several immune mediated diseases, such as rheumatoid arthritis, multiple sclerosis, lupus, psoriasis, hypothyroidism and diabetes mellitus^[2-7].

Among these diseases, diabetes mellitus is the most frequent condition and its association with UC has epidemiological, pathogenetic, clinical and therapeutic implications.

All these points represent the objects of the present review.

An electronic literature search was conducted using PubMed and Medline as primary sources. No time limits were specified up to the date of the search (September 2013). A comprehensive search was performed using the following search terms: “ulcerative colitis” or “inflammatory bowel diseases” and “diabetes mellitus” or “glucose intolerance”. The search was restricted to articles involving humans and those in the English language (or with an English abstract) and following identification of relevant titles, the abstracts of these articles were read to decide if the study was eligible.

The full text article was retrieved when the title and/or abstract seemed to meet the pre-defined eligibility criteria. A manual cross-reference search of bibliographies was carried out to identify articles missed in the computerised search.

DIABETES CO-MORBIDITY IN UC

Diabetes mellitus, like other autoimmune disorders, is significantly associated with UC, both in children and in adult patients. A recent large case-control study, which included more than 1200 children with inflammatory bowel disease (IBD), 488 of whom with UC, showed that UC is associated with a higher prevalence of diabetes than in controls (OR = 2.7, 95%CI: 1.1-6.6) with an overall prevalence of 2049 cases per 100000 children. Noteworthy, this association was confirmed excluding patient on treatment with anti-TNF alpha, and was the strongest among the other autoimmune conditions. It was also specific for UC, the association with Crohn's disease not being significant (OR = 1.4, 95%CI: 0.5-4)^[7]. Regarding the association between UC and diabetes, the estimates in this paediatric study were only slightly higher than those in adult studies. Indeed, few other studies examined the concomitance of autoimmune diseases among adult IBD patients without showing a significant increased risk for type 1 diabetes mellitus^[3,4] although this endocrine disorder represented the third most common co-morbid disease in UC patients (0.8%) after psoriasis (1.8%) and rheumatoid arthritis (1.1%). No study

has assessed the prevalence of type 2 diabetes mellitus in IBD, so far.

Interestingly, patients with both psoriasis and IBD showed significantly higher rates of diabetes (26.7% *vs* 11.0%) and autoimmune thyroiditis (2.1% *vs* 6.8%) and hepatitis (0.7% *vs* 6.2%) compared to individuals with psoriasis only^[8].

On the other hand, a large study made possible by the availability of the Multigeneration Register in Sweden, estimated the associations between type 1 diabetes mellitus and 33 autoimmune and related diseases in parents, offspring, siblings and twins. This study showed that type 1 diabetes in offspring was associated with 13 diseases in parents, including UC (standardised incidence ratio 1.23) and few other gastrointestinal diseases such as primary biliary cirrhosis (3.63) and celiac disease (2.73)^[9].

All these epidemiological findings suggest potential shared aetiological mechanisms for UC and type 1 diabetes mellitus. Although the aetiology for both diseases remains unclear, a large body of evidence supports the hypothesis that in genetically predisposed individuals, both host factors and environmental factors contribute to an uncontrolled immune function.

Co-morbidity among these autoimmune disorders and familial associations with several autoimmune and related diseases suggest genetic sharing and represent a challenge for gene identification.

On this regard, a recent genome-wide association study examined known susceptibility loci for IBD and type-1 diabetes mellitus in a cohort of 1689 Crohn's disease patients, 777 UC patients, 989 type-1 diabetes patients and 6197 control subjects, and identified multiple shared loci with opposite effects. In particular the study identified 1 diabetes mellitus locus (TNFAIP3) that confers UC risk and 2 UC loci (HERC2 and IL26) that confer type-1 diabetes mellitus risk^[10].

The genetic association between UC and type-1 diabetes mellitus has been also suggested by the description of a monogenic form of diabetes with the typical features of type 1 diabetes (autoantibodies to β cells, lean and young at onset of hyperglycemia, rapid disappearance of C-peptide production and insulin dependence) together with insulin resistance, which appears as a consequence of an autosomal-dominant mutation in the *SIRT1* gene. A recent case-report describes a family carrying a mutation in the *SIRT1* gene, in which all five affected members developed an autoimmune disorder: four members developed type 1 diabetes and one developed UC^[11]. It is particularly interesting to know that SIRT1 suppresses TNF α expression^[12]. Importantly, both type-1 diabetes and UC are strongly associated with this cytokine, and TNF antagonism improves both conditions^[13].

COMMON SHARED COMPLICATIONS IN DIABETES AND UC

Diabetes mellitus and UC share a number of complications, namely neurological, hepatobiliary, osteoarticular,

Table 1 Common shared complications in diabetes mellitus and ulcerative colitis

| |
|---|
| Neurological |
| Distal symmetric polyneuropathy (50% in DM and 0%-39% in UC) |
| Hepatobiliary |
| Cholelithiasis (20%-30% in DM, only after colectomy in UC) |
| Hepatic steatosis |
| Non alcoholic fatty liver disease |
| Osteo-articular complications |
| Osteoporosis |
| Vascular complications |
| Venous thrombosis (with ketoacidosis in DM, with active disease or surgery in UC) |
| Post-operative complications |
| Anastomotic dehiscence |
| Infections |
| Non-infectious complications |

DM: Diabetes mellitus; UC: Ulcerative colitis.

vascular and post-operative. It is unknown whether concomitance of both diseases for a long time increases the risk of such complications.

Although diabetic patients with mild or quiescent UC are likely to have a favourable outcome, UC patients with recurrent or steroid-refractory active disease, with consequent long term steroid treatment, could present hyperglycaemia and hyperinsulinemia and an increased risk of complications. Unfortunately, the outcome of UC in diabetic patients has not been investigated so far and no data are reported in the large therapeutic trials.

Examples of the more frequently shared complications of diabetes mellitus and UC are presented hereafter (Table 1).

Neurological complications

Neuropathy is a well known complication of diabetes mellitus. In particular, distal symmetric polyneuropathy is the most frequent form of neurological involvement, occurring in up to 50% of diabetic patients^[14]. Peripheral neuropathy is also a neurological complication of inflammatory bowel diseases^[15,16] with an incidence ranging from 0% to 39%, depending on the features of the study populations and on the criteria adopted to define the neuropathy. A population-based study showed that incident at peripheral neuropathy in IBD patients occurs late in the course of the disease^[17] and is likely due to nutritional (*e.g.*, B₁₂ deficiency), iatrogenic (*e.g.*, metronidazole neurotoxicity) and immune-mediated causes.

Hepatobiliary complications

Cholelithiasis, a well known complication of 20%-30% of patients with diabetes mellitus probably due to impaired gallbladder contraction, obesity and hyperlipidemia^[18], is also reported as a complication in UC patients, but only after colectomy, likely due to changes in bile composition and increase in cholesterol concentration in bile^[19].

Hepatic steatosis is a frequent feature of both diabetes mellitus and UC. Nonalcoholic fatty liver disease

(NAFLD) is characterized by insulin resistance and it is often associated with type 2 diabetes mellitus^[20,21]. Up to 50% of these patients may have nonalcoholic steatohepatitis^[22]. NAFLD is also frequently reported in UC patients, apart from classical risk factors such as obesity or insulin resistance^[23].

Osteo-articular complications

Diabetes mellitus-induced osteoporosis is often present in diabetic patients, probably due to changes in osteoblast function and bone formation, sustained by hyperglycemia^[24].

A high prevalence of reduced bone density is also frequently reported in UC patients due to increased bone reabsorption, not balanced by an appropriate bone formation. Long duration of disease, low body mass index, colectomy and in particular high doses and prolonged treatment with corticosteroids (cumulative use of steroids) have been recognised as risk factors for this complication and fractures^[25-27].

Vascular complications

Diabetes mellitus and UC share vascular complications, such as venous thrombosis. UC is characterised by a potential hypercoagulable state and an incidence of systemic thromboembolic events higher than in the general population, usually correlated with active disease and surgery^[28-30]. Diabetes, although most commonly complicated by arterial thrombosis, may also be complicated by venous thromboembolism, in presence of ketoacidosis^[31-33].

Post-operative complications

Diabetes mellitus is a well known risk factor of poor outcome in colorectal surgery, mainly due to the occurrence of anastomotic dehiscence^[34], infectious and non-infectious complications.

Recently, it has been found that perioperative hyperglycemia, in diabetic patients and even in patients without a preoperative diagnosis of diabetes undergoing colorectal surgery, is associated with a high rate of infectious and noninfectious complications, reintervention and mortality^[34].

Adverse outcomes may be associated with a single postoperative elevated glucose value and the risk of morbidity and mortality is related to the degree of hyperglycaemia^[35,36].

Therefore, it is not surprising that the post surgical period is one of the most important time frames for morbidity and mortality in UC patients with co-morbid diabetes mellitus.

Surgical-site infections is a major source of morbidity after colectomy for fulminant UC. A retrospective study including 59 patients operated for fulminant UC, showed that diabetes is one of the most frequent independent risk factors for surgical-site infections, along with white blood cell count, intraoperative blood loss and blood transfusion^[37]. The poor outcome of the postopera-

Table 2 Predictive risk factors for the development of diabetes mellitus and hyperglycemia in ulcerative colitis patients treated with corticosteroids

tive course in diabetic patients with UC has been also found in another large retrospective study that included 3754 patients undergoing ileoanal pouch, which showed that diabetes mellitus was an independent factor associated with the risk of pouch failure (HR = 2.31; 95%CI: 1.25-4.24)^[38].

CORTICOSTEROID-INDUCED DIABETES IN UC

IBD are immune-mediated disorders which appear in genetically predisposed subjects.

Corticosteroids are the main therapeutic agents in UC, because of multiple effects on the cellular and humoral immune system, including an inhibitory action on several pro-inflammatory cytokines and metabolites of arachidonic acid.

For more than 50 years corticosteroids, such as prednisone and methyl-prednisolone, have been used to treat IBD during the acute phase. However, more than 50% of patients do not respond to the therapy (steroid-resistance) or have a relapse after treatment discontinuation (steroid-dependence) and about half of them show side effects of variable severity^[39,40]. In most cases, the appearance and the seriousness of side effects (except from osteonecrosis and idiosyncratic reactions) are related to duration and dose of therapy.

Hyperglycemia and corticosteroid-induced diabetes are the most common systemic manifestations in IBD under steroid treatment and represent a real problem in the handling of UC patients with diabetes mellitus when relapses of the intestinal disease occur.

To date, there are few data on the incidence of corticosteroid-induced hyperglycemia or diabetes in IBD and also about the onset of acute diabetic complications, such as ketoacidosis and hyperosmolar hyperglycemic state, in diabetic patient affected by IBD, under steroid treatment. Most of our knowledge is derived from non-gastroenterological studies.

A case-control study, conducted on 55 elderly patients with active Crohn's disease compared to 66 control subjects not treated with steroids, showed that treatment with high doses of corticosteroids may increase the risk of hyperglycemia, even if the difference was not statistically significant (RR = 1.53; 95%CI: 0.54 - 4.32)^[41].

However, another case-control study that included a large number of patients (11855 cases and 11855 controls) showed that corticosteroids (prednisone or ana-

logues at a dose of 30 mg a day or more) confer a RR = 10 of hyperglycemia, compared to non treated patients^[42].

A retrospective study, including 25 patients affected by neuropathy (median age: 50 years) showed that treatment with prednisolone at a dose of 30-60 mg a day for at least 2 wk may result in a postprandial hyperglycemia, compatible with diabetes mellitus in 13 of 25 patients and demonstrated that advanced age is a risk factor for this complication^[43].

The importance of age in the onset of corticosteroid-induced diabetes is confirmed also by a cohort study conducted on a large geriatric population (median age: 75 years) that shows an increased risk of diabetes induced by oral corticosteroids (RR = 2.31; 95%CI: 2.11-2.54), compared to treatment with proton-pumps inhibitors (PPIs)^[44].

Finally, a recent literature review has confirmed that corticosteroid-induced hyperglycemia is common both in patients with and without diabetes and it has estimated an OR = 1.5-2.5 for the onset of diabetes mellitus in treated patients^[45].

Overall, the available studies, mostly conducted on patients not affected by IBD, confirm that the total dose of corticosteroids and the long duration therapy are important predictive risk factors for the development of diabetes mellitus. In addition, these studies underline that other factors, such as advanced age, high BMI, family history of diabetes or previous gestational diabetes should be considered and recommend monitoring the blood glucose level during steroid therapy (Table 2).

The possible underestimation of this condition in the handling of patient with IBD in clinical practice could be attributed to the short duration of steroids treatment and to the importance given to the fasting blood glucose only. High blood glucose levels in the short-term and in the postprandial period, should be considered for their prognostic value.

Concerning the role of the corticosteroids dose on the onset of diabetes, high doses of steroids are associated with high values of blood glucose levels and can induce diabetic ketoacidosis in patients with type 1 diabetes mellitus or hyperosmolar hyperglycemic state^[46,47].

The risk of these complications is particularly significant in diabetic patients with UC, in whom the first-line treatment is represented by corticosteroids.

TREATMENT OF UC IN DIABETIC PATIENTS

Treatment of patient with UC depends mainly on the activity and location of disease^[48,49].

Severe UC

Severe UC is characterized by bloody diarrhoea > 6 bowel movements/d and many signs of systemic toxicity (tachycardia > 90 bpm, fever > 37.8 °C, Hb < 10.5 G/dL or ESR > 30 mm/h)^[50].

Patients with severe UC should be admitted to hospi-

Table 3 Management of active severe ulcerative colitis in diabetic patients treated with corticosteroids

| Disease monitoring | Disease treatment |
|---|--|
| Regular monitoring of blood glucose level | Rehydration with saline solution Correction of blood glucose levels |
| Regular monitoring of disease activity (e.g., Disease Activity Index) | Treatment of hypokalemia Treatment of hypomagnesaemia |
| Plain abdominal X-ray | |
| Dosage of: | Consider alternative treatments |
| C-reactive protein | <i>Iv</i> cyclosporine A (4 mg/d) |
| Blood cell count | Infliximab (5 mg/kg or 10 mg/kg) |
| Electrolytes | Adalimumab (160 mg/80 mg/40 mg eow) |
| Anion gap | |
| Osmolality | Tacrolimus |
| Serum creatinine levels | Leucocytapheresis |
| Ketones | Other therapies (vedolizumab, visilizumab, abatacept, tofacitinib) |
| Urinalysis | |
| Blood gas analysis | |

tal for intensive treatment^[49].

Corticosteroids, administered parenterally (e.g., Methylprednisolone 60 mg daily or hydrocortisone 100 mg four times daily), represent the first-line treatment of severe UC. Higher doses are not more effective, but lower doses are less effective^[51]. Duration of treatment is 7-10 d, since further extension of therapy carries no additional benefit. Response to therapy reaches 67% and non-responders UC patients require a second-line treatment, represented by cyclosporine, tacrolimus, infliximab or colectomy^[52].

Steroid treatment of severe acute UC, in particular in diabetic patients, requires particular attention to hyperglycemia induced by therapy. The combination of dehydration, electrolyte imbalance (hypokalemia and hypomagnesemia), the possible presence of a septic condition and the need of total parenteral nutrition are important risk factors for hyperosmolar hyperglycemic state and diabetic ketoacidosis, the major complications of diabetes mellitus. Both these conditions are particularly dangerous and burdened by significant mortality, particularly in patient in which the state of diabetes was previously unknown.

For this reason, in patients with diabetes mellitus with severe UC, in addition to a close monitoring of bowel disease which requires clinical evaluation, dosage of C-reactive protein, blood counts and abdominal X-ray studies, a careful evaluation of the diabetes is also required, through the regular monitoring of blood sugar and various blood parameters (electrolytes with evaluation of the anion gap and osmolality, phosphorus, magnesium, creatinine, urinalysis to evaluate ketones, blood-gas analysis to evaluate arterial or venous pH), in particular in patients with basal glycaemia exceeding 180 mg/dL (Table 3).

Therapy of this condition is essentially based on rehydration with saline solution, correction of blood glucose by administering intravenous or subcutaneous insulin and treatment of hypokalemia by re-integration of potassium, bicarbonates, magnesium and phosphate

(in diabetic ketoacidosis), in close collaboration with endocrinologist. Hypokalemia and hypomagnesemia are important risk factors for toxic megacolon^[53], require a prompt correction and suggest careful radiographic and biochemical monitoring, particularly when a septic condition coexists (Table 3).

Therefore, in diabetic patients with acute severe UC, close monitoring of the patient's clinical and biochemical condition is essential, in order to timely identify the opportunity of a second line medical treatment or the possible need for surgical treatment (Table 3). However, the outcome of severe UC in diabetics is still unknown.

In diabetic patients with unstable blood glucose control, steroid treatment can be replaced by intravenous cyclosporine (4 mg/d), infliximab (5 mg/kg or 10 mg/kg at 0, 2, 6 wk and then every two months) or adalimumab 160 mg/80 mg/40 mg eow^[49]. Efficacy and safety of cyclosporine and infliximab are comparable and, in clinical practice, the treatment choice should be guided by physician and centre experience^[54]. A study by Moskovitz *et al.*^[55] showed that cyclosporine is less effective in patients treated with azathioprine and should be avoided in patients with low cholesterol or magnesium in view of the increased incidence of neurological side effects in this patient group. Furthermore, there is no scientific evidence on the effectiveness of cyclosporine in preventing colectomy^[56], while other studies have shown that Infliximab can reduce the rate of colectomy compared with placebo^[57]. So the choice should be placed on individual circumstances and the availability of drugs.

The use of tacrolimus, as an alternative to steroid therapy in diabetic patients, is generally not recommended. The tacrolimus, in fact, besides being unable to induce significant mucosal healing compared with placebo^[58], can induce long-term hyperglycemia or even diabetes, as well as hypomagnesemia and it may promote the onset of opportunistic infections^[49].

In contrast, leucocytapheresis, whose principle is based on the extracorporeal removal of leukocytes through an adsorptive system of cellulose acetate beads (Adacolumn, Otsuka Pharmaceuticals) or a polyester fibre filter (Cell-sorba, Asahi Medical Company) represents a potential therapeutic remedy with a good safety profile, serious side effects being very rare. Leucocytapheresis can be associated with any medical treatment, but the real effectiveness of this device in acute severe UC remains to be determined^[59].

Leucocytapheresis has a wide-spread acceptance in Japan, but its cost may limit its use and its future role in Europe will depend on the outcome of controlled trials^[49]. On this regard, clinical efficacy outcomes are variable, being encouraging in some studies and disappointing in others, and the answer might ultimately lie in the patients' disease status at entry. Patients with the first UC episode and short duration of disease or a fair level of intact mucosal tissue, seem to respond and can be spared from multiple drug therapy. Patients with extensive loss of mucosal tissue and those with a long history of exposure to multiple drugs, like corticosteroids, are

unlikely to respond^[60].

Other therapies such as vedolizumab, visilizumab, abatacept, tofacitinib, which are characterised by different mechanisms of action are currently under investigation and have no role in clinical practice to date^[61].

Mild-moderate UC

Treatment of mild-moderate UC depends on the site of disease.

The first line therapy of mild-moderate distal colitis is topical mesalazine and/or oral mesalazine, in once daily administration, which is as effective as divided doses. Combining topical mesalazine and topical steroids, such as beclomethasone dipropionate, also helps. Patients who fail oral/topical mesalazine and topical steroids should be treated with the addition of oral prednisolone.

In proctitis, it has been shown that topical mesalamine has a higher efficacy on symptoms and endoscopic resolution of the damage compared to topical steroids, generally using suppositories that are more appropriate than enemas. However, topical steroids may be used in substitution of mesalazine, if it is poorly tolerated, or in association with the latter. Indeed, the combination of beclomethasone dipropionate (3 mg) and mesalazine (2 mg) is able to induce an improvement in clinical, endoscopic and histologic proctitis, significantly superior to treatment with mesalazine alone^[62].

In diabetic patients with mild-moderate distal UC, systemic steroid therapy should be avoided by resorting to rectal or oral administration of mesalazine and/or beclomethasone dipropionate or to new therapies such as budesonide Multi-Matrix System (MMX), fluticasone or prednisolone metasulphobenzoate.

In treatment of extensive or distal colitis it is generally recommended, as first choice, a combination of oral and topical mesalazine^[49,63,64]. In fact, the use of mesalazine alone, although at high doses or in controlled release formulation (MMX), gives a percentage of remission of at least 41% and a partial response, not exceeding 72%. Furthermore, in many patients the occurrence of relapse of intestinal disease is not uncommon, even during an appropriate maintenance therapy with mesalazine. In these circumstances the use of systemic steroid therapy is generally recommended, even in non severe forms of colitis. In the diabetic patient, this treatment requires the same level of attention already mentioned for patients with severe colitis.

Controlled colonic release formulations of steroids and steroids equipped with low bioavailability, such as beclomethasone dipropionate, budesonide MMX, fluticasone or prednisolone metasulphobenzoate represent a potential therapeutic resource with the advantage of the absence or the minimisation of the side effects of other steroids, with respect to the suppression of the hypothalamic-pituitary-adrenal axis^[65].

Although there are no specific studies on the undesirable effects of this kind of steroids in diabetic patients with UC, it should be noted that, in both normal sub-

jects and elderly diabetic patients under dietary control, treatment with topical inhaled beclomethasone in high doses for 2 wk, did not produce significant changes in blood glucose and lipid metabolism^[66].

In addition, in both adults and pediatric patients, for whom steroid treatment of UC is the remedy of choice, the oral administration of beclomethasone dipropionate is well tolerated and induces a rapid clinical and endoscopic remission in mild to moderate UC, comparable to mesalazine^[67-69].

Budesonide MMX, 9 mg daily, is effective for the induction of remission of mild-moderate active UC. It is a novel oral formulation of budesonide that uses MMX technology to extend release to the colon, without notable increases in glucocorticosteroid-related side effects, probably due to low bioavailability and to targeted delivery of drug^[70].

In patients with UC fluticasone has negative results, but prednisolone metasulphobenzoate, by oral or topical administration, appears to be effective in active distal UC and in mild-to-moderate UC with a lower incidence of systemic adverse effects in comparison with other glucocorticosteroids^[71].

If systemic steroid treatment is necessary, the occurrence of hyperglycemia (particularly in patients with known diabetes) can be corrected or controlled by rapid-acting insulin, usually administered in the preprandial period (generally at a dose of 0.1 U/kg) or by using biguanides, such as metformin, or thiazolidinediones (also known as glitazones), drugs just approved for the treatment of diabetes mellitus type 2.

Metformin, and in particular the increase in dosage of this drug, is often burdened with gastrointestinal side effects such as nausea, vomiting, anorexia, diarrhea, abdominal pain. These symptoms are usually dose-related and occur especially at the beginning of therapy. In 3%-5% of cases, diarrhea may be persistent and cause discontinuation of the drug.

In contrast, the thiazolidinediones are oral antidiabetics with anti-inflammatory properties, potentially useful in patient suffering from UC. In particular, these drugs work by binding to the gamma sub-unit of PPAR (peroxisome receptors that trigger proliferation), receptors located inside the cell nucleus, abundantly expressed in adipose tissue and in the colonic epithelium. Experimental evidence has shown that these molecules have anti-inflammatory activity, in particular in colon and that treatment with these drugs is able to attenuate the production of inflammatory cytokines and to reduce inflammation in animal models of colitis. One uncontrolled study showed that rosiglitazone (a drug used in the United States for treatment of diabetes mellitus type 2) is able to improve moderately active colitis, refractory to treatment with mesalazine. The same group later confirmed the efficacy of the drug, compared to placebo, in a double-blind controlled study^[72,73]. Unfortunately, rosiglitazone was recently withdrawn from the market in some countries for the high risk of ischemic heart

disease and myocardial infarction, but other thiazolidinediones are on the market (such as pioglitazone) or should soon enter in the pharmaceutical reference book and could be used in diabetic patients with UC, if their efficacy in UC will be confirmed.

CONCLUSION

Diabetes mellitus is a common disorder, significantly associated with UC. Co-morbidity among these autoimmune disorders and familial associations with several autoimmune and related diseases, suggest a genetic sharing but, although some shared loci at risk have been identified, the clinical implications of this findings are still unclear.

Likewise, diabetes mellitus and UC share neurological, hepatobiliary, osteoarticular, vascular and post-operative complications. Their onset may be increased by the long-standing concomitance of both diseases. Although specific studies on this aspect have not yet been carried out, this deserves attention in clinical practice. In particular, the role of hyperglycaemia and the poor control of blood glucose level in diabetics deserve particular attention for the risk of morbidity of patients undergoing ileoanal pouch after proctocolectomy.

One of the most common and challenging problems in diabetic patients with UC is the medical treatment. Corticosteroids, the treatment of choice of active UC, may be associated with the onset of glucose intolerance and diabetes, and with the difficult control of blood glucose levels and complications in diabetic patients. Advanced age, high body mass index, family history of diabetes or previous gestational diabetes should always suggest the need of monitoring blood glucose level during steroid therapy. Likewise, rehydration, correction of blood glucose and hypokalemia in close collaboration with endocrinologists, as well as the close monitoring of the patient's clinical and biochemical conditions are essential in diabetic patients with acute UC. Moreover, the potential negative effects of metformin and the beneficial effects of thiazolidinediones on symptoms of UC in remission, should be considered.

Abstract

In recent years, a number of case reports and clinical studies have highlighted the risk of hepatitis B and C virus reactivation in patients with inflammatory bowel disease who are treated with immunosuppressive drugs. The cases of viral hepatitis reactivation that have been reported are characterized by a wide range of clinical manifestations, from viremia without clinically relevant manifestations to fulminant life-threatening hepatitis. The development and dissemination of biological immunosuppressive drugs have led to a significant increase in the number of reports of interest to physicians in a variety of clinical settings. On this topic, there have been a number of published guidelines and reviews that have collected the available evidence, providing recommendations on prophylactic and therapeutic strategies and methods for monitoring patients at risk. However, it should be noted that, to date, very few clinical studies have been published, and most of the recommen-

dations have been borrowed from other clinical settings. The published studies are mostly retrospective and are based on very heterogeneous populations, using different therapeutic and prophylactic regimens and obtaining conflicting results. Thus, it seems clear that it is desirable to concentrate our efforts on prospective studies, not conducting further reviews of the literature in the continued absence of new evidence.

Key words: Inflammatory bowel disease; Biological agents; Hepatitis B virus reactivation; Hepatitis C virus reactivation; Prophylaxis

Core tip: Our review focused on the redundancy of papers on hepatitis B virus and hepatitis C virus reactivation in patients undergoing immunosuppressive therapy. However, we emphasize that, to date, very few clinical studies have been published, and most of them were retrospective with conflicting results. Thus, it is essential to conduct prospective studies before performing additional reviews of the literature.

Hepatitis B and C virus reactivation in immunosuppressed patients with inflammatory bowel disease. *World J Gastroenterol* 2014; 20(13): 3516-3524 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i13/3516.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i13.3516>

INTRODUCTION

In recent years, a significant number of warnings have been given about the risk of hepatitis B and C reactiva-

tion in patients receiving immunosuppressive therapy in different clinical settings (oncology, hematology, solid organ transplant, rheumatology, gastroenterology, and dermatology).

In particular, a number of case reports and clinical studies have highlighted the risk of hepatitis virus B and C reactivation in patients with inflammatory bowel disease (IBD) treated with immunosuppressive drugs^[1-7].

The cases of viral hepatitis reactivation that have been reported are characterized by a wide range of clinical manifestations, from viremia without clinical relevant manifestations to fulminant life threatening hepatitis.

The risk and severity of clinical reactivation seems to be related to the type of immunosuppressive drug administered (steroids, traditional immunosuppressants, or biologics). The various reports and clinical studies on this topic describe and analyze patient populations subjected to different treatment regimens that are not comparable. Moreover, these studies have heterogeneous results and conclusions^[8-13].

The magnitude of the “reactivation” problem seems much more relevant to the hepatitis B virus (HBV) than to the hepatitis C virus (HCV). To date, many reviews comparing few clinical trials have been published on this issue. Among the clinical trials, there was only one prospective study. All of the studies were conducted in different populations with different methods and drawing varying conclusions. Furthermore, the definitions of HBV and HCV reactivations used vary significantly among these studies. Some studies have considered only the increase of viral load, while others have considered the increased viral load in association with elevated levels of aminotransferases.

While some recommendations may appear “evidence-based”, such as prophylaxis for hepatitis B surface antigen positive (HBsAg+) patients receiving immunosuppressive therapy, there are large gray areas, indicating the risk of reactivation in patients with hepatitis B core antibody (HBcAb) isolated or and HCV positivity.

As mentioned above, there is currently not enough strong evidence regarding the prevalence and clinical impact of hepatitis B and C virus reactivation in patients with IBD who are receiving immunosuppressive therapy. This finding calls for the development of prospective clinical trials that can respond to the growing demand of evidence on this issue^[14,15].

IMMUNOSUPPRESSIVE THERAPY IN IBD

The ideal therapeutic approach to IBD should be aimed at inducing and maintaining long-term clinical remission with the minimal use of steroids and surgical interventions; this end-point is particularly important for patients affected by Crohn's disease (CD).

However, about half of IBD cases show a steroid-dependent or steroid-refractory clinical course^[16,17]. Currently, a traditional immunosuppressive therapeutic regimen is indicated for these patients and is mainly represented

by the use of azathioprine and 6-mercaptopurine, even if this regimen produces a low percentage of clinical remission (50%) in the treated population^[18,19]. Other potentially effective immune-suppressors are methotrexate, cyclosporine and tacrolimus. These drugs are rarely used in this setting due to the lack of significant evidence on their efficacy and are used in clinical practice for steroid-refractory ulcerative colitis (UC), as well as anti-tumor necrosis factor alpha (anti-TNF α) agents^[20-30].

IBD patients who are refractory or intolerant to azathioprine are the main candidates for biological anti-TNF α drugs (*i.e.*, adalimumab and infliximab).

Infliximab has proven to be an effective drug in inducing and maintaining clinical remission in refractory luminal and fistulizing CD, with a remission rate of approximately 50%^[29,31-36]. The efficacy of infliximab in treating UC is less impressive than in CD. However, the ACT-1 study^[37] reported an efficacy of 39% and 20% for infliximab in inducing the remission of steroid-dependent UC at weeks 8 and 54, respectively. Furthermore, this drug can avoid the 3-mo need for colectomy in approximately 65% of patients who experience a severe attack of UC^[38,39].

At present, adalimumab, a fully human recombinant anti-TNF α antibody, is approved for the treatment of CD and UC. This drug, administered by subcutaneous injection, has been efficient in inducing and maintaining remission in CD, with a 40% remission rate at week 56^[40,41]. Therefore, similar to infliximab, adalimumab has proven to be valuable in reducing the need for steroids and surgery^[42].

In view of their high efficacy, it has also been suggested that biologics could be used in the early phases of IBD in accordance with a top-down therapeutic strategy^[43], particularly for patients with a poor prognosis and factors implicating a potentially aggressive disease (*i.e.*, young age, smoking, perianal/rectal disease in CD, extensive small bowel involvement, extra-intestinal manifestations, and steroid use at diagnosis)^[42,44-47].

PREVALENCE OF HBV AND HCV INFECTION IN PATIENTS WITH IBD

The prevalence of HBV infection varies greatly throughout the world, from the low rate of < 1% to the moderate rate of 1%-2% in Western countries, towards a much higher rate of > 8% in Asia and in most parts of Africa. The dramatic progress in controlling the spread of HBV in Western countries is prevalently due to the implementation of the vaccination and the adoption of satisfactory measures in preventing HBV transmission^[48-53].

Patients with IBD are considered at risk of HBV and HCV infection because of the frequent need for surgical, endoscopic and transfusion procedures, suggesting the existence of nosocomial transmission. On the other hand, the magnitude of this risk is unknown because there are conflicting reviews and little information on this topic.

Five studies from Italy^[8,54], France^[49], Spain^[55] and China^[51] have evaluated the prevalence of HBV and HCV infections in consecutive series of patients with IBD. Between 1997 and 1999, 332 patients affected by CD were enrolled in an Italian case-control study published in early 2000. The prevalence of HBsAg, HBcAb and HCV in this cohort was 2.1%, 10.9% and 7.4%, respectively. Ten years later, the prevalence of HBsAg and HCV was approximately 1% (Table 1) in 315, 2076 and 301 consecutive subjects in three series of French, Spanish and Italian IBD patients. HBcAb positivity was present in 8/315 (2.54%) of patients in the French study (3 HBsAg+ and HBcAb+; 2 isolated HBcAb+; and 3 HBcAb+ and anti-HBs+); in 154/2056 (7.49%) of patients in the Spanish study; and in 22/301 (7.31%) of patients in the Italian study.

Therefore, the prevalence of HBV and HCV infection in IBD patients seems to be lower than expected, similar to the general population. These results indicate that IBD patients in Western European countries should no longer be considered as a risk group for HBV or HCV infection.

However, a recent study conducted in China on 714 IBD patients showed that the prevalence of HBV infection in IBD patients was higher than reported in the control group. Indeed, the cumulative prevalence of HBsAg and HBcAb was 40.62% *vs* 27.58% in non-IBD patients. The prevalence of HCV infection was similar to that found in non-IBD patients (0.42% *vs* 0.36%).

HBV INFECTION

Mechanism of reactivation

From an immunological point of view, a hepatitis flare rarely starts during the phase of maximal immunosuppression. The majority of reported HBV reactivations matured at the time of the withdrawing or tapering of immunosuppressive therapy, when the immune system has been able to react to the viral replication and to destroy infected hepatocytes^[56].

In this perspective, any deficiency of the immune response to infections caused by immunosuppressive/chemotherapeutic drugs would play a crucial role in disease progression.

In addition, several *in vitro* and *in vivo* animal studies have demonstrated that TNF- α plays a key role in clearing HBV from infected hepatocytes. Hepatitis B viral HBx proteins sensitize the cells to apoptotic killing by TNF, which is secreted by cytotoxic T lymphocytes, together with Interferon- γ (IFN- γ). Both TNF and IFN- γ clear HBV replicative intermediates from the cytoplasm and covalently close circular DNA from the nuclei of infected hepatocytes^[57,58].

Based on these results, it is possible that the use of anti-TNF α drugs in patients with chronic HBV infections could cause an increase in viral replication, leading to liver immune-mediated damage when the inhibitory effect of therapy disappears^[59].

According to this pathogenic model, the risk of HBV reactivation is closely related to the level of immunosuppression achieved, which changes significantly based on the immunomodulatory agents used during the therapy. Stronger immunosuppression may lead to increased viral replication; consequently, a more severe clinical reactivation may occur when immunosuppressive therapy is discontinued^[56].

Immunosuppressive therapy and risk of reactivation in HBsAg positive patients

The reactivation of HBV is an important concern for patients taking immunosuppressants because of the many ways it can affect the body, from a subtle shift in serum aminotransferase levels to fulminant hepatic failure and/or death.

The reactivation of HBV infection (with liver dysfunction, including fulminant hepatitis) is a well-described complication of immunosuppression in the setting of organ transplantation or cancer chemotherapy, occurring in approximately 50% of patients for whom concomitant anti-viral therapy is not used. Mortality from fulminant liver failure after the reactivation of HBV in patients receiving chemotherapy is reported in 4%-60% of cases. The traditional immunosuppressive drugs used in the management of IBD patients include the following: corticosteroids; thiopurines: azathioprine and 6-mercaptopurine; calcineurin inhibitors; cyclosporin and tacrolimus; and methotrexate. Moreover, in the past decade, these biological agents, especially TNF α inhibitors, have been used worldwide and are particularly beneficial in the management of complex and fistulizing diseases^[19,23,31-36].

From a pathogenic perspective, the risk of HBV reactivation is closely related to the levels of immunosuppression. The use of conventional immunosuppressive drugs determines low levels of immunosuppression and does not seem to be associated with the risk of HBV reactivation; this claim is supported by the results of only one study^[9]. In a series of 332 CD patients, only 4 HBsAg positive patients were treated with conventional immunosuppressive drugs (2 with azathioprine and 2 with corticosteroids) and followed-up for at least 1 year. No influence on the clinical course of HBV infection and no episodes of viral or biochemical reactivation were observed in this series of patients over the follow-up of 12 mo.

Notably, only a few cases (4 cases) of HBV reactivation during conventional immunosuppressive therapy (prednisone and azathioprine) resulting in fulminant hepatic failure has been reported in the literature^[11,60].

In recent years, a growing number of cases of HBV reactivation among patients with IBD treated with TNF- α -inhibitors have been described. The available data are limited to a small number of single case reports and a very small series of consecutive patients^[10,12-13,60-65].

Eight case reports describe the use of anti-TNF α drugs in patients with IBD infected with HBV (HBsAg+

CD: Crohn's disease; UC: Ulcerative Colitis; IC: Inactive carrier; OC: Occult carrier; NA: Not available; CH: Chronic hepatitis; IFX: Infliximab; AZT: Azathioprine; LGE: Logarithm genome equivalent; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; HBsAg: Hepatitis B surface antigen; HBV: Hepatitis B virus; TNF α : Tumor necrosis factor alpha; LAM: Lipoarabinomannan.

inactive carriers). All were affected by CD, and 7 out of 8 did not receive immunoprophylaxis. Only one patient received lamivudine as a prophylactic treatment. Six out of 7 showed HBV reactivation with a wide range of outcomes, ranging from a modest increase in the viral load and ALT levels to fatal hepatitis. Interestingly, the only patient who received prophylactic treatment did not experience viral, biochemical or clinical reactivation during the 6 mo follow-up^[66]. The duration of anti-TNF α therapy before HBV relapse varied from a single infusion to many months of treatment, and all of the episodes of reactivation were observed in patients receiving infliximab and other immunosuppressive drugs at the same time (Table 1). No reports are available in patients using adalimumab.

Recently, Loras *et al*^[55] recorded all clinical information from IBD patients with HBV and HCV infections in 19 Spanish hospitals. HBV reactivation was observed in 9 out of 25 (36%) HBsAg+ patients. All but two cases were treated with simultaneous immunosuppressors [steroid + azathioprine (4 cases) and infliximab + azathioprine (3 cases)]. In contrast, the patients without reactivation were only treated with one immunosuppressant and/or received prophylactic antiviral treatment. In 6 out of the 9 cases (66%), HBV reactivation caused severe hepatic failure.

On the contrary, Morisco *et al*^[55] conducted a retrospective multicenter study, including 5096 patients with IBD. HBV reactivation was observed in only 1 out of 6 (16%) HBsAg+ patients undergoing immunosuppressive therapy. A combined immunosuppressive therapy had been administered in all cases of HBV reactivation (Table 2).

Immunosuppressive therapy and risk of reactivation in HBsAg negative/HBcAb positive carriers

HBsAg negative and HBcAb positive IBD patients seem to have a low risk of HBsAg seroreversion and hepatitis flares. Indeed, in opposition to the results found in other clinical settings, only one case of HBV reactivation has been described in an IBD patient^[13]. A female CD patient was treated with 25 mg/d of prednisone and infliximab for the relapse of disease after an unsatisfactory remission with conventional therapy (steroids, ciprofloxacin, metronidazole, and methotrexate). After a month of treatment with infliximab and steroids, the patient's aminotransferases increased (10 times over the upper normal limit), together with the emergence of HBsAg, hepatitis Be antibody, HBcAb, IgM HBcAb, and HBV-DNA positivity in the serum.

HCV

Immunosuppressive therapy and risk of reactivation

To date, there is no conclusive information on the safety of immunosuppressive or immunomodulator drugs in HCV among IBD patients. These patients appear to be at low risk, although long-term safety studies are needed.

There are several interesting concerns regarding immunosuppressive treatment for IBD in patients with HCV infection. For example, prednisone, which is frequently used to treat acute exacerbations of intestinal diseases, may negatively affect HCV infection by increasing the viral load^[67-69].

On the other hand, anti-TNF α drugs seem to reduce inflammation through TNF α inhibition, playing a role in the pathogenesis of HCV^[70].

Table 2 Reactivation in patients with inflammatory bowel disease undergoing immunosuppressive therapy

| Ref. | HBsAg+ | HBcAb+ | HCV+ |
|--------------------------------------|--------|--------|------|
| Loras <i>et al</i> ^[60] | 9/25 | 0/65 | 8/51 |
| Morisco <i>et al</i> ^[65] | 1/6 | 1/4 | 1/10 |
| Papa <i>et al</i> ^[54] | 0/1 | 0/22 | 0/4 |

HBsAg: Hepatitis B surface antigen; HBcAb: Hepatitis B core antibody; HCV: Hepatitis C virus.

Few studies have been performed to evaluate the safety of TNF α antagonist medications in IBD patients with HCV, and most of these are case reports or small case series^[54,55,65].

The larger series available on this topic show a low risk of hepatitis flares in these patients with a mild-moderate clinical course^[54,60,65]. Indeed, HCV reactivation was observed in 8/51 (15.7%) and in 1/10 (10%) HCV-RNA positive patients, respectively, by Loras *et al*^[60] and Morisco *et al*^[65]. All cases of reactivation had a very mild course, except for one patient, who died.

The deceased patient described by Loras *et al*^[60] and experienced severe liver failure. He died while receiving steroids. Importantly, he also had an occult HBV infection and was human immunodeficiency virus-positive.

SCREENING AND VACCINATION

Screening measures must be instituted in IBD patients. Recommendations are based on the potentially fatal consequences of HBV and HCV reactivation and the availability of safe and effective drugs to prevent these situations^[11].

HBV

The most recent guidelines of the European Crohn's and Colitis Organization (ECCO) on the management of opportunistic infections in IBD^[17] recommend that all IBD patients be tested for HBsAg, HBcAb and HBsAb to assess their infection or vaccination status; vaccination is recommended in all seronegative patients.

At present, only four studies have evaluated the HBV vaccination status of patients with IBD. Evidence of effective vaccination (positive anti-HBs and negative HBcAb) was only detected in 12%, 48.9%, 24% and 21.7% of the four cohorts of patients enrolled in Spain, France, Italy and China, respectively^[49,51,54,55]. No information about the adherence to HBV vaccination is available in the literature for other series of European patients with IBD.

HBV vaccination coverage significantly differs among European countries because the vaccination programs were started in different years and have been proposed for different target populations (newborns, adolescent and pre-adolescent subjects, only for high-risk groups, *etc.*)^[71].

As consequence, the determination of the infectious or vaccination status at the time of a diagnosis of IBD

seems to be appropriate. An administration of the vaccine in negative subjects (HBsAg, HBcAb and HBsAb negative) as soon as possible should progressively reduce the number of cases with problematic management. Improved adherence to the program of universal vaccination will reduce the need for screening in the future.

HCV

No recommendations have been proposed for HCV screening prior to starting immunomodulators by the ECCO guidelines^[72]. However, we do believe that HCV screening (including HCV antibodies and HCV-RNA if anti-HCV+) should be routinely performed upon the completion of liver function tests before starting immunosuppressive therapy. If positive, these tests should be performed again every 3 mo to carefully monitor the patient's status during immunosuppressive treatment.

With regard to the use of anti-TNF α agents, it is important to emphasize that their use should be evaluated on the basis of the clinical underlying condition of the patient. In particular, while the use of anti-TNF α in non-cirrhotic patients appears safe, it is contraindicated in patients with decompensated cirrhosis and should be used with caution in patients with compensated cirrhosis on a case-by-case basis, according to the benefit/risk ratio.

PROPHYLAXIS AND THERAPY

Several studies have reported a preventive effect of antiviral agents on hepatitis B reactivation during immunosuppression therapy, and specific recommendations were elaborated by American Association for the Study of Liver Diseases, European Association for the Study of the Liver and Association for the Study of the Liver^[59,73,74]. Nonetheless, significant questions regarding the optimal antiviral prophylaxis strategy have yet to be addressed.

The effect of prophylactic antiviral therapy on the course of HBV infection in IBD patients undergoing immunosuppressive therapy has not been studied prospectively, and, until now, only a few studies have reported a good efficacy in a short period of follow-up^[65,66]. As a result, the management strategy for these patients remains uncertain.

Lamivudine prophylaxis was suggested on the basis of its well demonstrated efficacy; however, other nucleotides/nucleosides should be preferred, especially if immunosuppressive therapy is scheduled for more than 12 mo, due to their lower propensity to provoke drug resistance. Conversely, HBsAg- HBcAb+ patients (with or without HBsAb+), given their low risk for reactivation, do not require routine antiviral prophylaxis, but only periodic monitoring (about every 3 mo) for the elevation of aspartate aminotransferase/alanine aminotransferase and HBsAg, to prove the re-emergence of HBV-DNA^[72].

Prophylactic therapy seems to be appropriate when biological therapy is scheduled, especially when combined with other immunosuppressive drugs. The role of antiviral drugs other than lamivudine, including entecavir, ad-

efovir and tenofovir, is still unknown, and further studies are needed^{175]}.

To date, there is no prophylaxis available for HCV reactivation. Interferon, which is currently the milestone of antiviral therapy for HCV, is contraindicated in IBD forms that require immunosuppressive therapy. The availability of interferon-free regimens could dramatically change this scenario.

CONCLUSION

The issue in question has increasingly gained interest over the past few years, with the emergence of a number of reports (case reports or case series) on the risk of reactivation of hepatitis in immunosuppressed patients with IBD.

The first cases reported in literature date back to the 1990s and studied onco-hematological patients who demonstrated a fulminant HBV reactivation during or after chemotherapy treatments.

In subsequent years, the development and dissemination of biological immunosuppressive drugs led to a significant increase in the number of reports aimed at reaching other clinical settings (dermatology, rheumatology, gastroenterology, *etc.*).

In particular, the use of anti-TNF α is more frequent in the treatment of steroid-dependent and steroid-refractory UC and CD, as well as in the treatment of perianal fistulizing CD or extraintestinal manifestations associated with IBD (ankylosing spondylitis, pyoderma gangrenosum and uveitis).

There have been a number of published guidelines and reviews on this topic that have collected the available evidence and provided recommendations on prophylactic and therapeutic strategies and methods for monitoring patients at risk.

However, it should be noted that, to date, very few clinical studies have been published, and most of their recommendations have been borrowed from other clinical settings. The published studies are mostly retrospective and based on heterogeneous populations, using different therapeutic and prophylactic regimens to obtain conflicting results.

In particular, the two studies with larger series are those of Loras *et al.*^{60]} and Morisco *et al.*^{65]}. The first group analyzed a population of 25 HBsAg+ and 51 HCV-RNA+ patients. Among HBsAg+ patients, 36% experienced a reactivation of the HBV, and 6 of them developed acute liver failure; however, no reactivation was observed in patients with HBsAg-HBcAb positivity. On the other hand, Morisco *et al.* showed a different result in their study. Only 1/6 HBsAg+ (16%) and 1/4 HBcAb+ isolated (25%) had viral reactivations with mild clinical courses.

The two groups of authors agreed on the low risk of HCV reactivation. The study of Morisco *et al.*^{65]} on the screening procedures for HBV and HCV in patients with IBD resized the frequency and severity of the clinical im-

pact of viral reactivation in patients with IBD receiving immunosuppressive therapy.

Today, there are still some gaps in the knowledge regarding this clinical area. Current evidence supports the assumption that the HBsAg+ patients should receive prophylactic antiviral therapy prior to initiating immunosuppressive therapy. Nevertheless, the best strategy to adopt in HCV+ or in isolated HBcAb+ patients remains unclear. In these cases, the risk of viral reactivation seems to be low, compared to the former scenario.

Thus, the current evidence suggest that it is essential to place an increased emphasis on the completion of prospective studies and to discourage further reviews of the literature until new evidence is available.

Abstract

There was estimated a higher incidence of *de novo* inflammatory bowel disease (IBD) after solid organ transplantation than in the general population. The onset of IBD in the organ transplant recipient population is an important clinical situation which is associated to higher morbidity and difficulty in the medical therapeutic management because of possible interaction between anti-reject therapy and IBD therapy. IBD course after liver transplantation (LT) is variable, but about one third of patients may worsen, needing an increase in medical therapy or a colectomy. Active IBD at the time of LT, discontinuation of 5-aminosalicylic acid or azathioprine at the time of LT and use of tacrolimus-based immunosuppression may be associated with an unfavorable outcome of IBD after LT. Anti-tumor necrosis factor alpha (TNF α) therapy for refractory IBD may be an effective and safe therapeutic option after LT. The little experience of the use of biological therapy in transplanted patients, with concomitant anti-rejection therapy, suggests there be a higher more careful surveillance regarding the risk of infectious diseases, autoimmune diseases, and neoplasms. An increased risk of colorectal cancer (CRC) is present also after LT in IBD patients with primary sclerosing

cholangitis (PSC). An annual program of endoscopic surveillance with serial biopsies for CRC is recommended. A prophylactic colectomy in selected IBD/PSC patients with CRC risk factors could be a good management strategy in the CRC prevention, but it is used infrequently in the majority of LT centers. About 30% of patients develop multiple IBD recurrence and 20% of patients require a colectomy after renal transplantation. Like in the liver transplantation, anti-TNF α therapy could be an effective treatment in IBD patients with conventional refractory therapy after renal or heart transplantation. A large number of patients are needed to confirm the preliminary observations. Regarding the higher clinical complexity of this subgroup of IBD patients, a close multidisciplinary approach between an IBD dedicated gastroenterologist and surgeon and an organ transplantation specialist is necessary in order to have the best clinical management of IBD after transplantation.

INTRODUCTION

Inflammatory bowel disease (IBD) is a complex chronic inflammatory intestinal disease with a prevalence steadily increasing during the recent years. The management of IBD is leaning towards more complex clinical situations, with possible interactions between the intestinal disease and others organ diseases. The organ recipient population is constantly increasing in the medical specialized centers in the world and it can happen that a patient with a solid organ transplantation has a recurrence of IBD. This is particularly important in the liver transplantation (LT) because there is a close pathophysiological correlation between primary sclerosing cholangitis (PSC) and ulcerative colitis (UC) before the transplant. *De novo* IBD has been reported after solid organ transplantation, with an incidence estimated ten times higher with respect to the expected incidence of IBD in the general population. Therefore, the organ recipient patient may be a new clinical “scenario” for IBD management.

The first objective of this review was to examine the studies present in the English literature (PubMed) about the natural history in organ recipient patients. In particular, we have evaluated: (1) risk of recurrent IBD; (2) risk of *de novo* IBD; (3) need for colectomy; (4) risk of pouchitis; and (5) risk of colorectal cancer. The second objective was to examine the medical therapy for active IBD after organ transplantation.

We have more knowledge of IBD clinical management after LT, but in this review we have evaluated the IBD studies after heart, renal, lung, and intestinal transplantation.

EPIDEMIOLOGY AND CLINICAL FEATURE OF IBD AFTER LIVER TRANSPLANTATION

Recurrent IBD

Singh *et al*^[1] has recently examined the studies on the natural history of IBD after LT for PSC, reporting 609 patients in 14 studies, followed approximately 4.8 years after LT (range, 1.8-7.2 years), about 31% of patients have improvement of IBD activity, 39% of patients do not have a significant change in IBD activity, and 30% of patients develop worsening IBD, requiring intensification of medical therapy and/or surgery. The estimated risk of severe IBD flare up at 5 and 10 years after LT ranged from 39% to 63% and 39% to 98%, with a median time of a flare up around 1 year (range, 0.3-8.6 years)^[2-4]. The

need of colectomy for acute IBD refractory to medical therapy is nearly 9% (range, 0%-21%)^[2-6]. Dvorchik *et al*^[7] observed a significant 3.1-fold increased risk of colectomy due to severe IBD flare up or medically refractory disease after LT compared to IBD patients who did not require LT.

De novo IBD

Wörns *et al*^[8] evaluated 44 patients with IBD after solid organ transplant (SOT) and reported the *de novo* disease: 38 of 44 (86%) cases occurred following LT (23) or combined liver/kidney transplantation (15), 4 (9%) after heart transplantation, and 2 (5%) after kidney transplantation. Riley *et al*^[9] identified 14 patients who developed *de novo* IBD in 6800 cases after liver and kidney transplantation. Twelve (86%) of the patients developed IBD post liver transplant and two (14%) were detected post kidney transplant. The authors estimated a higher incidence of *de novo* IBD after SOT than in the general population (206 vs 20 cases per 100000 persons-year). The higher prevalence of IBD post LT in the SOT patients can be related to the strong association between PSC and UC. In these patients, the 10-year risk of *de novo* IBD after LT is estimated to be 14%-30%, with median time to development of approximately 4 years (range, 1.1-7.1 years)^[2-4]. After a median follow-up of 4 years 18/86 (21%) patients who underwent LT for PSC developed IBD. Verdonk *et al*^[3] observed that the *de novo* IBD patients tended to develop disease later in post-transplant period than the patients with pre-existing IBD. Moreover, the patients with *de novo* IBD after LT respond better to medical therapy and none required colectomy.

RISK FACTORS FOR IBD AFTER LIVER TRANSPLANTATION

Clinical activity of IBD

The clinical activity of IBD at the time of LT may be a risk factor for worsening the intestinal disease after LT. In fact, a three-fold higher risk of IBD flare up after LT in patients with active IBD at the time of LT it was observed^[3].

Smoking

Joshi *et al*^[4] evaluated 110 patients underwent LT for PSC. In the multivariate analysis, active smoking at the time of transplant was the only significant risk factor for flare up of IBD post-transplantation (HR = 17; 95%CI: 2-180).

Cytomegalovirus

Cytomegalovirus (CMV) mismatch (seropositive donor, seronegative recipient and CMV infection) have not been associated with the recurrence of IBD after LT^[4,10,11]. CMV mismatch was associated with a 4.5-fold higher risk of *de novo* IBD after LT, but CMV infection is not related to *de novo* IBD post LT^[11].

Therapy of IBD after LT

The therapy with proven efficacy for active IBD may re-

Table 1 Interaction between inflammatory bowel disease therapy and anti-reject therapy in inflammatory bowel disease patients after liver transplantation

| Drug | Efficacy | | Ref. |
|-------------------|-------------|---------------------|--------------------------------------|

| Azathioprine | + | + | [2] |
| Anti-TNF α | + | | [15] [16] [13] [14] [18] |
| Tacrolimus | - | + | [2] [3] |
| Cyclosporine | + | + | [3] |
| Mycophenolate | - | + | [22] |
| Mofetil | | | [23] |

TNF α : Tumor necrosis factor alpha; IBD: Inflammatory bowel disease; 5-ASA: 5-aminosalicylates.

duce the risk of disease exacerbation post-LT (Table 1).

5-aminosalicylates (5-ASA) therapy after LT appears to be protective against the worsening disease activity of IBD, decreasing the flare up and/or colectomy risk about 80%^[3,12].

Azathioprine may reduce the risk of active IBD after transplant. In the study's Haagsma *et al*^[2], a comparison between 55 patients who received azathioprine with the 23 patients did not receive azathioprine, was performed and this showed a significantly higher IBD-free survival for azathioprine group. In particular, at 1, 3 and 5 years after LT, the IBD-free survival rates in patients receiving azathioprine were 96%, 96% and 88%, respectively; while in patients not receiving azathioprine, these value were 87%, 63% and 54%, respectively.

We have little knowledge about the use of anti-tumor necrosis factor alpha (TNF α) therapy for refractory IBD after transplant. To date, there have been only 22 patients treated with anti-TNF for relapsing IBD following LT; this number includes patients with UC, Crohn's disease, indeterminate colitis and pouchitis, treated with infliximab or adalimumab (Table 2)^[13-18]. In our study, we evaluated the efficacy and safety of infliximab therapy in a homogeneous series of four patients with refractory UC following LT, followed for a median time of 18 mo. At week 54, three patients (75%) experienced sustained improvement of IBD. Complete mucosal healing (defined as absence of lesions) was observed in one of three patients (33%). Steroid treatment was successfully withdrawn during infliximab therapy in all patients. Adverse events included only one infection by *Molluscum contagiosum*, which resolved without sequelae. No malignancies were observed in any patient following infliximab therapy. No cases of hepatic rejection were documented. Our results are in line with others studies about the efficacy and

safety of anti-TNF α therapy in patients with refractory IBD following LT, but larger studies are needed to evaluate the safety profile of biological therapy combined with anti rejection treatment.

Anti-reject therapy

Tacrolimus is the principal immunosuppressive agent in SOT, but it has been observed, in retrospective studies, that it may be associated with a four-fold higher risk of post-LT IBD relapse^[2,3]. In patients with tacrolimus for transplant-related immunosuppression, Dvorchik *et al*^[7] found that the risk of relapse of IBD at 1- and 5-year was 13% and 64%, respectively; while, in patients with tacrolimus-free regimens, the risk of IBD was 4% and 10%, respectively. The cause of a possible relationship between tacrolimus and IBD flare up after transplant is not known. IBD results from inappropriate and ongoing activation of the mucosal immune system in the presence of normal luminal flora. Immunosuppression agents may promote infections which may lead to the change bacterial gut flora and decrease the intestinal barrier function^[19]. Moreover, tacrolimus is a strong inhibitor of interleukin-2 production. Deficiency of interleukin-2 can result in T-cell dysregulation, leading to the development of intestinal chronic inflammation^[2,3].

Cyclosporine, like anti-TNF α , is the chosen drug in severe steroid refractory UC. Cyclosporine does not seem to worsen the course of IBD after transplant^[3,10]. In contrast with tacrolimus, the frequency of interleukin-2-expressing T cells was significantly higher with cyclosporine in renal transplant patients^[20]. This may explain in part the different effect of cyclosporine and tacrolimus on IBD course after transplant.

Corticosteroids are effective in acute and chronic prevention of SOT rejection as well as in inducing clinical remission in IBD. Moncrief *et al*^[21] and Navaneethan *et al*^[12] observed that prednisone therapy may favorably modify the course of IBD after LT, but this therapeutic regime is associated to important side effects.

Mycophenolate mofetil (MMF) has proven efficacy in SOT, but its role in IBD is not clear^[22,23]. Moreover, MMF is associated with enterocolitis, which can mimic a IBD flare up.

COLECTOMY POST-LIVER TRANSPLANTATION

Ho *et al*^[24] observed a prevalence of colectomy after LT about 35%. In this Scottish study 7 of 20 patients underwent colectomy with a median time of 3.4 years (range 1.5-6.3 years) following LT^[24]. The indication for colectomy was chronically active severe UC in three patients (43%), colonic dysplasia or colorectal cancer in three patients (43%) and benign stricture of colon in one patient (14%). The study in Cleveland compared 86 patients with UC and LT for PSC with 81 patients with UC and PSC who did not require LT^[25]. The necessity of colectomy was significantly more frequently in the non-LT group

Table 2 Anti-tumor necrosis factor alpha therapy for management of refractory inflammatory bowel disease after liver transplantation

| Author | Number LT patients | Clinical outcome | Endoscopic outcome | Adverse events |
|--|--------------------|------------------|------------------------|--|
| Sandhu <i>et al</i> ^[13] | 6 | Response: 67% | - | Systemic lupus erythematosus |
| Mohabbat <i>et al</i> ^[14] | 8 | Response: 87.5% | Mucosal healing: 42.9% | Colorectal cancer Oral candidiasis <i>Clostridium difficile</i> colitis Bacterial pneumonia Cryptosporidiosis Post-transplant lympho-proliferative disorder |
| Lal <i>et al</i> ^[15] | 1 | Response: 100% | Improvement: 100% | No |
| El-Nachef <i>et al</i> ^[16] | 2 | Response: 100% | - | No |
| Indriolo <i>et al</i> ^[18] | 4 | Response: 75% | Mucosal healing: 33% | <i>Molluscum contagiosum</i> |

than the LT group (76.5% *vs* 34.9%). The percentage of patients which underwent colectomy for steroid dependent/refractory disease was lower in the LT group than patients in the non-LT group (39.9% *vs* 48.4%). Regarding the possible difficulties to surgically pack the J pouch in patients who underwent LT and Roux-en-Y biliary-jejunal reconstruction, Mathis *et al*^[20] did not encounter any problems in the 13 patients operated on.

POUCHITIS POST-LIVER TRANSPLANTATION

The risk of acute pouchitis after LT for PSC ranged from 14% to 66%^[26-28]. The risk of chronic pouchitis ranged from 9.1% to 73.7%^[26-30]. Freeman *et al*^[29] observed that the risk of chronic refractory pouchitis was comparable in patients who underwent LT and those who did not. Therefore, it seems that LT does not increase the risk of pouchitis. With regard to the therapy of pouchitis after LT, Mathis *et al*^[20] evaluated 32 patients who underwent ileal pouch-anal anastomosis (IPAA) for UC and LT for PSC (in 13 patients IPAA followed by OLT). Two-thirds of the patients had pouchitis during follow-up, about half developed a chronic pouchitis that required daily antibiotic therapy. Only one patient needed a defunctioning ileostomy. Anti-TNF α therapy was used in only four IBD patients in three studies for refractory pouchitis after LT for PSC^[13,14,18]. Even though a clinical improvement was observed, the little data available does not allow us to extrapolate any conclusions about the efficacy and safety of biological therapy in patients with chronic refractory pouchitis after LT.

COLORECTAL CANCER POST-LIVER TRANSPLANT

Epidemiology

A large range with rates of risk of colorectal cancer after LT for PSC, from 0 to 31.5 per 1000 person/year, is present in literature in recent years^[4,7,21,25,31-48]. Watt *et al*^[31], reported a cumulative incidence of colorectal cancer (CRC) at 10-years post LT for PSC of 8.2% as compared to 2.6% after LT for non-PSC patients. The CRC risk in PSC patients without IBD after LT is 2.8% at 10-years. There-

fore, the combination of IBD and PSC after LT leads the patient to a higher risk in developing CRC.

Moreover, the CRC risk is increased in patients with long-standing IBD, long-standing LT and extensive colonic involvement^[32,35,45]. In fact, it was observed at 1-, 5- and 10-year, a cumulative incidence of CRC of 3.3%, 6.7%, and 11.8%, respectively, after LT. Regarding the colorectal cancer location, similarly to IBD/PSC patients before LT, the right-side colon is more frequently affected^[39]. There is no clear evidence if the age of the patients at the time of LT is associated with CRC risk^[7,33,35,45]. No significant association between clinical severity IBD and CRC risk after LT was observed^[39,45]. Regarding the use of 5-ASA or ursodeoxycholic acid in the chemoprevention of CRC, it seems that they don't change the cancer risk^[33,39].

Risk factors

The risk of CRC may increase after LT because of errors in mucosa sampling during colonoscopy or perhaps due to the immunosuppression treatment of anti-reject therapy. Loftus *et al*^[42] observed that the CRC rate was 4.4-fold higher after LT, as compared to a historical cohort patient with PSC/IBD who did not undergo LT. However, the role of LT in the risk of CRC in IBD/PSC patients still isn't clear. In fact, while Dvorchik found that LT did not significantly influence the risk of CRC, it was observed that LT may be an independent risk factor for CRC in other studies^[7,35,42,45].

Surveillance

A program of endoscopic surveillance with serial biopsies for CRC is recommended by the European Association for the Study of Liver^[49]. A colonoscopy is suggested every year in IBD/PSC patients after LT. If dysplasia colonic mucosa is found, a colectomy is advised. It has been shown to be a relatively safe procedure in specialized surgical centers^[45,46].

Management

Adjuvant pharmacotherapy with drugs like oxaliplatin has also been shown to be well tolerated in patients post-LT and hepatic graft dysfunction was not documented^[50]. Prophylactic colectomy in selected IBD/PSC patients with CRC risk factors could be a good management strategy in the CRC prevention, but it is used infrequently in

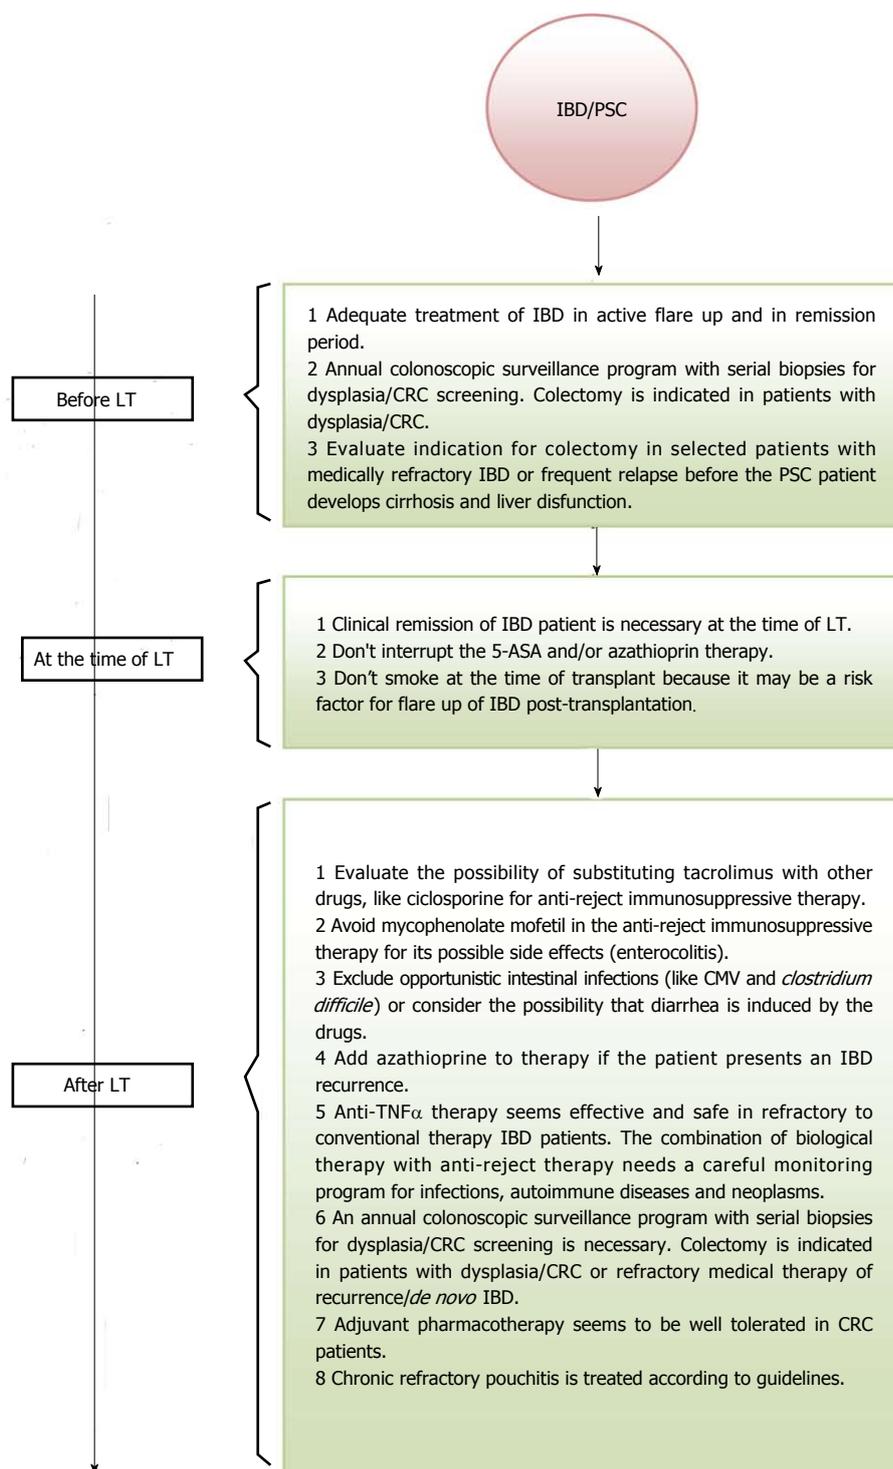

Figure 1 Clinical management of inflammatory bowel disease/primary sclerosing cholangitis patients before and after liver transplantation. TNF α : Tumor necrosis factor alpha; IBD: Inflammatory bowel disease; LT: Liver transplantation; PSC: Primary sclerosing cholangitis; CRC: Colorectal cancer; CMV: Cytomegalovirus; 5-ASA: 5-aminosalicylates.

the majority of LT centers^[45,51].

CLINICAL MANAGEMENT OF ACTIVE IBD AFTER LT

Patients who underwent LT can develop diarrhea and it is very important exclude an intestinal infection (CMV, *Clo-*

tridium difficile), or consider the possibility that diarrhea may be caused by the drugs (Figure 1). If the symptoms of active IBD are confirmed from a colonoscopy and a histological exam, the patient starts the IBD therapy. The plan of IBD therapy in the patient who underwent transplant, is similar to the therapy plan before the transplant. 5-ASA at a dose of 2.4 g per day is indicated in induction and in maintenance in the mild-to-moderate UC patients. Topical

therapy with 5-ASA and/or beclomethasone dipropionate can be useful in distal UC. Budesonide or systemic steroids are indicated in patients with mild Crohn's disease. In moderate-to-severe IBD patients the use of oral or *iv* corticosteroids are necessary. Prednisone at a dose of 50 mg per day or prednisolone at a dose of 40-60 mg per day based on the patient's body weight (60-80 kg) may be used in clinical practice. A gradual tapering of corticosteroids is recommended, for example 5 mg every week in prednisone therapy. Maintenance immunosuppression therapy with azathioprine at a dose of 2.0-2.5 mg/kg body weight per day is effective after the corticosteroid therapy. Anti-TNF α treatment could be effective and safe in refractory to conventional therapy IBD^[13,14,18]. The little experience of the use of biological therapy in transplanted patients, with concomitant anti-rejection therapy, suggests there be a higher and more careful surveillance regarding the risk of infectious diseases, autoimmune diseases, and neoplasms.

It is very important to consider the possibility of surgical treatment in patients with moderate-to-severe IBD after LT for PSC and even more so, because of the higher colorectal cancer risk. Proctocolectomy with IPAA is feasible and safe in dedicated surgical centers^[26,27].

IBD AFTER HEART TRANSPLANTATION

Three cases of *de novo* IBD after heart transplantation have been reported in 3 studies: two cases of Crohn's disease and one case of UC^[52-54]. The onset of IBD has been observed in pediatric age in two of three patients. Rakhit *et al*^[52] reported one case of Crohn's disease in 104 post-orthotopic heart transplant children. The patient developed diarrhea and rectal bleeding immediately after the transplant and IBD was diagnosed after one year. The patient continued to have flares despite immunosuppressive therapy. Harms *et al*^[53] reported a 15-year-old girl developed IBD 10 years after cardiac transplantation and presented a severe growth failure and delayed onset of puberty. The patient was found to have pan-enteric Crohn's disease and has done remarkably well following a nutritional therapy. Jüngling *et al*^[54] reported a 53-year-old patient who developed distal UC 2 years after heart transplantation. In spite of high-dose treatment with prednisolone the patient's clinical situation worsened with a progression of inflammation in the entire colon. Colectomy with ileostomy was necessary to obtain a good state of health. Three IBD cases have been observed after heart transplantation in spite of immunosuppressive therapy. Two of them have been treated with conventional medical therapy with success, whereas one IBD case required surgery with colectomy and ileostomy. No IBD patient was treated with anti-TNF α therapy.

IBD AFTER RENAL TRANSPLANTATION

A total of about of twenty-seven *de novo* IBD patients (15 UC and 11 Crohn's disease) after renal transplantation in

11 studies were reported^[9,16,54-63]. One patient presented erythema nodosum associated to IBD^[60], one patient developed colonic cancer with liver metastasis 2 years later and died^[60], thirteen (50%) patients were treated with conventional medical IBD therapy (mesalazine, corticosteroids, and azathioprine), achieving a clinical remission. Significant clinical improvement of IBD was observed with anti-TNF α therapy in three (11.5%) patients. No severe infections or graft reject were documented after biological therapy^[22,61]. Five (19.2%) patients with Crohn's disease continued to have flare up despite treatment^[9]. Five (19.2%) UC patients were refractory to therapy and required a colectomy^[9,55,56,62].

IBD AFTER LUNG AND INTESTINAL TRANSPLANTATION

The number of patients who underwent lung or intestinal transplantation is significantly lower than the patients who underwent liver, heart, and renal transplantation. This could probably be explained because no IBD cases were reported after lung and intestinal transplantation.

CLINICAL MANAGEMENT OF IBD PATIENTS AFTER HEART AND RENAL TRANSPLANTATION

The concomitant anti-reject immunosuppressive therapy can increase the risk of infectious diseases in transplanted patients. Therefore, in patients who develop diarrhea, it is very important to exclude an intestinal infection (CMV, *Clostridium difficile*). It is also necessary to exclude that diarrhea may be induced by the drugs. The onset of IBD after heart or renal transplantation could lead to a severe clinical situation for the transplanted patient. In fact, in about half of the patients, conventional IBD therapy combined with anti-reject therapy, can be non-effective. Nineteen percent of patients developed multiple recurrence on IBD in the renal transplantation group. Eleven percent of patients required anti-TNF α therapy in order to have clinical remission and in about 20% of patients required a colectomy. The LT model suggests that anti-TNF α therapy combined with anti-reject therapy could be useful in selected IBD patients with refractory to conventional therapy after heart or renal transplantation. Like in the LT, it is very important that there be a higher more careful surveillance regarding the risk of infectious diseases, autoimmune diseases, and neoplasms after biological therapy in heart and renal transplanted patients. The surgical option remains an essential treatment in complicated IBD cases which are refractory to the intensive medical therapy.

CONCLUSION

There is estimated a higher incidence of *de novo* IBD after solid organ transplantation than in the general popula-

tion. The onset of IBD in the organ transplant recipient population is an important clinical situation which is associated with higher morbidity and difficulty in the medical therapeutic management because of the possible interaction between anti-reject therapy and IBD therapy. IBD course after LT is variable, but about one third of patients may worsen, needing increased medical therapy or a colectomy. Active IBD at the time of LT, discontinuation of 5-ASA or azathioprine at the time of LT and use of tacrolimus-based immunosuppression may be associated with an unfavorable outcome of IBD after LT. Anti-TNF therapy for refractory IBD may be an effective and safe therapeutic option after LT. The little experience of the use of biological therapy in transplanted patients, with concomitant anti-rejection therapy, suggests there be a higher more careful surveillance regarding the risk of infectious diseases, autoimmune diseases, and neoplasms. Therefore, it is very important to consider the possibility of a surgical treatment in refractory severe IBD after LT. An increased risk of colorectal cancer is also present after LT in IBD/PSC patient. An annual program of endoscopic surveillance with serial biopsies for CRC is recommended. If dysplasia colonic mucosa is found, a colectomy with IPAA is advised. It has been shown to be a relatively safe procedure in the specialized surgical centers. Adjuvant pharmacotherapy has been shown to be well tolerated in patients post-LT. Hepatic graft dysfunction has not been documented after adjuvant pharmacotherapy. A prophylactic colectomy in selected IBD/PSC patients with CRC risk factors could be a good management strategy in the CRC prevention, but it is used infrequently in the majority of LT centers. About 30% of patients developed multiple recurrences of IBD and 20% of patients required a colectomy after renal transplantation. Like in the LT, anti-TNF α therapy could be an effective treatment in IBD patients with conventional refractory therapy after renal or heart transplantation. A large number of patients are needed to confirm the preliminary observations.

Regarding the higher clinical complexity of this subgroup of IBD patients, a close multidisciplinary approach between an IBD dedicated gastroenterologist and surgeon and an organ transplantation specialist is necessary in order to have the best clinical management of IBD after transplantation.

Abstract

Azathioprine is a purine antimetabolite drug commonly used to treat inflammatory bowel disease (IBD). *In vivo* it is active after reaction with reduced glutathione (GSH) and conversion to mercaptopurine. Although this reaction may occur spontaneously, the presence of isoforms M and A of the enzyme glutathione-S-transferase (GST) may increase its speed. Indeed, in pediatric patients with IBD, deletion of GST-M1, which determines reduced enzymatic activity, was recently associated with reduced sensitivity to azathioprine and reduced production of azathioprine active metabolites. In addition to increase the activation of azathioprine to mercaptopurine, GSTs may contribute to azathioprine effects even by modulating GSH consumption, oxidative stress and apoptosis. Therefore, genetic polymorphisms in genes for GSTs may be useful to predict response to azathioprine even if more *in vitro* and clinical validation studies are needed.

INTRODUCTION

Azathioprine, the 1-methyl-4-nitroimidazol-5-yl derivative of mercaptopurine, is a purine antimetabolite drug commonly used to treat inflammatory bowel disease (IBD). Despite the introduction of effective biological treatments, such as antibodies against tumor necrosis factor- α (TNF- α), azathioprine is still a mainstay for maintenance therapy of severe IBD. Azathioprine is a prodrug and requires complex conversion to active metabolites (Figure 1). The first step in this conversion is the reaction of azathioprine with reduced glutathione (GSH), to yield the prodrug mercaptopurine and a nitroimidazole derivative/conjugate of GSH. Even though this reaction can occur spontaneously^[1] the presence of the enzyme glutathione-S-transferase (GST) may increase its speed,

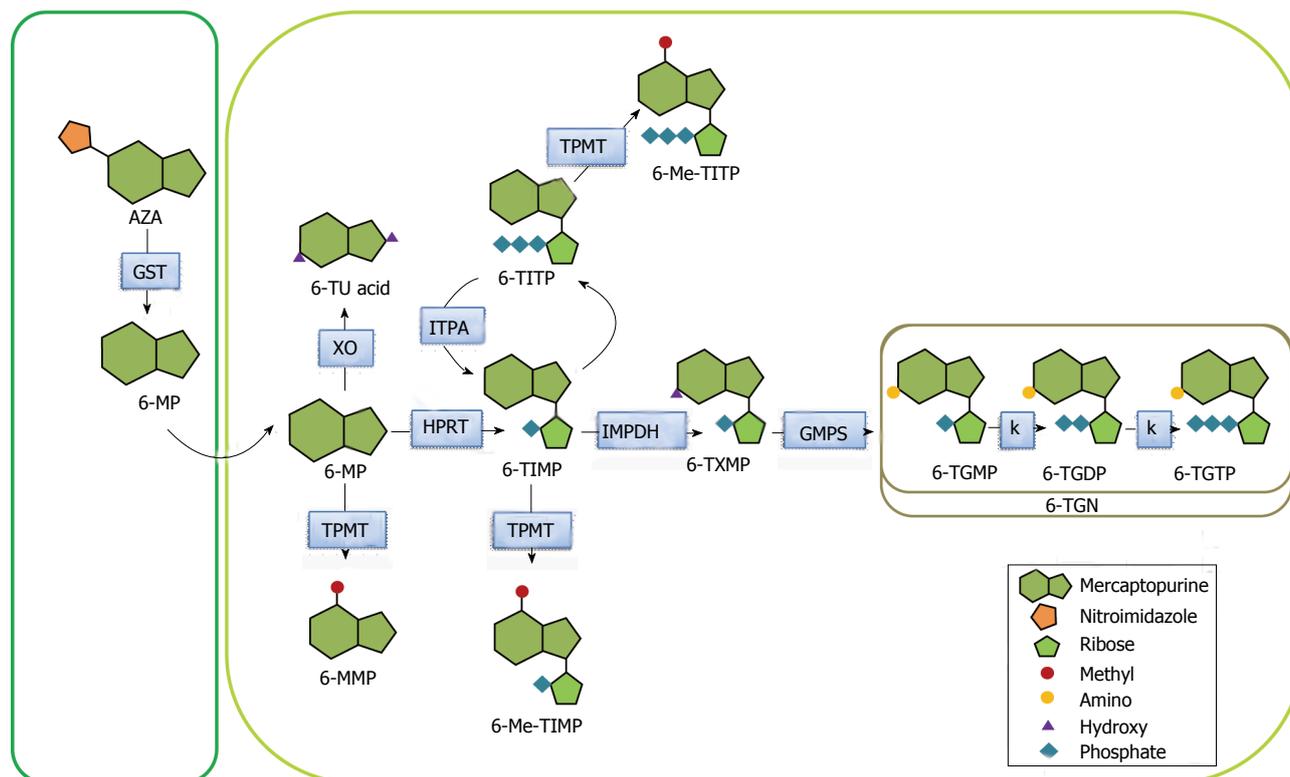

Figure 1 Metabolism of azathioprine and mercaptopurine. 6-Me-TIMP: 6-methyl-thioinosine-monophosphate; 6-Me-TIPP: 6-methyl-thioinosine-triphosphate; 6-MMP: 6-methyl-mercaptopurine; 6-MP: Mercaptopurine; 6-TGDP: 6-thioguanine-diphosphate; 6-TGMP: 6-thioguanine-monophosphate; 6-TGN: 6-thioguanine nucleotide; 6-TGTP: 6-thioguanine-triphosphate; 6-TIMP: 6-thioinosine-monophosphate; 6-TIPP: 6-thioinosine-triphosphate; 6-TU: 6-thiouric; 6-TXMP: 6-thioxanthosine-monophosphate; AZA: Azathioprine; GMPS: Guanosine-monophosphate-synthase; GST: glutathione-S-transferase; HPRT: Hypoxanthinephosphate-rybosyl-transferase; IMPDH: Inosine-monophosphate-dehydrogenase; k: Kinase; TPMT: Thiopurine-S-methyl-transferase; XO: Xanthine-oxidase.

as discussed later. Even mercaptopurine needs metabolic conversion to thioguanine nucleotides (TGNs), catalyzed by the enzymes of the purine salvage pathway. Moreover, mercaptopurine is inactivated in the liver mainly by xanthine oxidase (XO), while in the extra hepatic tissues mercaptopurine catabolism involves predominantly genes that display genetically determined polymorphic activity, such as thiopurine-S-methyltransferase (TPMT) and inosine triphosphate pyrophosphatase (ITPA). After oral administration, intact azathioprine is undetectable in blood because of extensive first pass metabolism^[2].

Mercaptopurine's cytotoxic effects are mainly related to incorporation of the active TGNs in the nucleic acids and to the consequent interference with the function of DNA processing enzymes and, to some extent, to inhibition of *de novo* purine synthesis, mainly operated by methylated precursors of TGNs.

While mercaptopurine pharmacokinetics and pharmacodynamics have been characterized extensively, the mechanism of conversion of azathioprine to mercaptopurine and its clinical implications for therapy personalization have not been completely elucidated.

EFFECTS OF GST POLYMORPHISMS ON AZATHIOPRINE EFFICACY AND METABOLISM IN PATIENTS WITH IBD

The hypothesis that patients with reduced levels of spe-

cific GST isoforms, due to genetic polymorphisms, may present decreased sensitivity to azathioprine because of a reduced enzymatic conversion of azathioprine to mercaptopurine, was tested recently by our team in young patients with IBD. The deletion of GST-M1, GST-T1 and the coding non synonymous single nucleotide polymorphism rs1695 in GST-P1 were tested. An initial study considered a cohort of 70 young patients (median age 16.2 years, 36 females) with IBD (41 Crohn's disease, 29 ulcerative colitis). Among these, 15 patients developed adverse events during treatment with azathioprine: in particular, there were three cases of bone marrow suppression, three cases of liver toxicity, seven cases of pancreatic toxicity, one case of neuropathy and one case of arthralgia; all these side effects resolved completely after the reduction or interruption of azathioprine administration: azathioprine was therefore considered the main determinant of the adverse effects. Interestingly, the candidate genetic association analysis in these patients revealed that frequency of GST-M1 deletion was significantly lower in patients that developed an adverse event in comparison to patients that tolerated azathioprine treatment with no adverse event (frequency of deletion respectively 26.7% *vs* 67.3%, $P = 0.0072$). Moreover, the incidence of mild lymphopenia (lymphocytes count under $1000/\text{mm}^3$), that was considered a marker of efficacy during azathioprine treatment, resulted associated with GST-M1 genotype: indeed, among patients tolerating azathioprine treatment

and with lymphopenia, frequency of the deletion was 28.6% in comparison to 72.9% among patients tolerant to azathioprine but that did not present this drug effect ($P = 0.032$)^[3]. Taken together, these results are in agreement with a model in which patients with GST-M1 deletion are less sensitive to the effects of azathioprine, putatively because of the contribution of this enzyme on the conversion of azathioprine to mercaptopurine. In a recent study, we evaluated the effects of GST polymorphisms on azathioprine metabolism in a cohort of 75 young patients (median age 15.2 years, 36 females) with IBD (46 Crohn's disease, 29 ulcerative colitis) tolerant to azathioprine therapy (taking azathioprine for more than 3 mo). Azathioprine metabolites were measured on samples collected from these patients using a high performance liquid chromatography assay (HPLC)^[4]: 150 measurements of azathioprine metabolites were collected. Patients with the deletion of GST-M1 tolerated a dose of azathioprine significantly higher in comparison to patients with normal GST-M1 (mean dose of azathioprine 2.1 mg/kg per day *vs* 1.8 mg/kg per day, $P = 0.022$). Moreover, the amount of active TGNs generated in patients with the deletion of GST-M1 was significantly decreased in comparison to patients with a normal genotype (mean amount of TGNs metabolites concentration for mg/kg of azathioprine: 252 pmol/ 8×10^8 erythrocytes *vs* 164 pmol/ 8×10^8 erythrocytes, $P = 0.0030$). Multivariate analysis confirmed that this effect was independent from that of other genes with a significant effect, such as TPMT, the main gene known to influence mercaptopurine metabolism^[5]. This study therefore supports a role of GST-M1 on azathioprine efficacy, mediated by an increased conversion of azathioprine to mercaptopurine. The reaction catalyzed by GST-M1 likely occurs after oral administration mainly in the intestine and the liver, modulating the amount of mercaptopurine and TGNs that are released in the main circulation.

These studies considered even the effect of GST-P1 and GST-T1 polymorphisms on azathioprine effects and metabolism but did not detect any significant association. The lack of association may be due to the tissue distribution of GST-P1 and GST-T1, which are not highly expressed in the liver, but even to the lack of specific activity of these enzymes toward the catalysis of the reaction of azathioprine with glutathione^[6]. Another study considered GST-M1 genetic polymorphisms as a candidate involved in azathioprine activation^[7]: this report considered 51 Asian patients with systemic lupus erythematosus (SLE) and the effect of polymorphisms in the ITPA, TPMT, GST-M1 and GST-T1 genes on the response to a low dose of azathioprine (0.97 mg/kg per day). Response to therapy, evaluated as a change in disease activity index, was associated with ITPA genetic polymorphism but not with the other ones. A clear interpretation of this paper results may be difficult because of the lack of data on azathioprine metabolites concentrations. However, the lack of an effect of GST-M1 on azathioprine efficacy in this study may be due to the very low dose of drug used. This study indicated that in Asian patients with SLE

the effect of ITPA might be predominant on those of TPMT and GST-M1 when azathioprine is used at very low doses; indeed, in this study even TPMT genetic polymorphism was not associated with azathioprine efficacy. It is known that in patients with Asian ancestry the frequency of variant TPMT is very low, while that of variant ITPA is increased in comparison to Caucasians^[8,9].

INVOLVEMENT OF GST IN AZATHIOPRINE MOLECULAR AND CELLULAR EFFECTS

GSTs are enzymes responsible for the inactivation of electrophilic substances, both endogenous and exogenous, by catalyzing their reaction with GSH. Human cytosolic GSTs are encoded by 17 genes and the proteins derived can be classified into 7 distinct classes based on their amino acid sequences. The most abundant GSTs in human cells are those of class P, M and A. GST-P1 is the principal isoform in most tissues, such as the small intestine and erythrocytes, but is not detectable in normal liver cells; on the other hand, GSTs M1, A1 and A2 are highly expressed in hepatocytes, while they are not expressed in erythrocytes. GST-T1 is expressed in the liver, intestine and erythrocytes even if its level of expression is lower compared to GSTs of the other classes^[6].

All the genes for these GST classes display common genetic polymorphisms that influence the activity of the enzyme in some individuals. For GST-M1 and T1, a common deletion is present in humans, so that about 50% and 20% of caucasians lack activity of these enzymes because of this genetic variant. In patients of African and Asian ancestry, frequency of GST-T1 deletion is higher than Caucasian, reaching around 50%, while frequency of GST-M1 deletion is similar^[10]. GST-P1 displays a common coding non-synonymous variant, an A-G transition at base 1578, resulting in the amino acid change I105V in the substrate binding site of the enzyme: the frequency of the variant genotype for this polymorphism in Caucasian and African is similar (13%-15%), while in Asian the percentage is lower (1%-2%)^[11,12].

Even expression of GST-A is modulated by genetic polymorphism: GST-A1 -69 C > T results in a reduced GST-A1 expression and related enzyme activity^[13,14]. The GST-A1 polymorphism shows different frequencies for the mutated genotype between Caucasian and African (respectively 17% and 11%) and Asian (1%). For GST-A2, a C-T transition at base 328, resulting in the amino acid change P110S in the electrophilic substrate binding site, occurs only in heterozygosis, at a frequency of 11% in Caucasian and 23% in Asian population^[15,16]. In the African population, the variant allele to date has not been found (Table 1). Genetic polymorphisms in GSTs, determining the interindividual variability in the activity of these important metabolic enzymes, have been related to the incidence of several pathologies, in particular oncological, and to altered sensitivity to medications, including azathioprine^[17-20].

Table 1 Glutathione-S-transferase polymorphisms and frequencies in different ethnic groups

| Gene | Polymorphisms | Caucasian | African | Asian |
|--------|-------------------|-----------|----------|------------|
| GST-M1 | Deletion | 50% | 50% | 50% |
| GST-T1 | Deletion | 20% | 50% | 50% |
| GST-P1 | rs1695 (A > G) | 13% (GG) | 15% (GG) | 1%-2% (GG) |
| GST-A1 | rs3957357 (C > T) | 17% (TT) | 11% (TT) | 1% (TT) |
| GST-A2 | rs2234951 (C > T) | 11% (CT) | 0% (CT) | 23% (CT) |

GST: Glutathione-S-transferase.

Enzymatic conversion

Azathioprine conversion to mercaptopurine can occur spontaneously^[1], even if in the presence of specific GST classes and at physiological pH values the reaction catalyzed by the enzyme may be prevalent.

Kaplowitz described an initial report on the enzymatic contribution on the conversion of azathioprine to mercaptopurine in rat liver homogenates. While at relatively high pH levels (*i.e.*, 8.0) the non-enzymatic reaction and the enzymatic one occur in similar proportions; at lower pH levels (*i.e.*, 6.5-7.4), closer to physiological values, the enzymatic reaction prevails^[21]. The same reaction has been demonstrated in homogenates of human livers: in these samples, mainly from kidney transplant donors, conversion of azathioprine to mercaptopurine was inhibited by treatment with furosemide, a GST inhibitor^[22]. Additional evidence obtained in animal models supports a significant contribution of the enzymatic conversion of azathioprine to mercaptopurine *in vivo*. Indeed, pretreatment of rats with probenecid, a GST inhibitor, determines a greater proportion of unmetabolized azathioprine in the liver and less hepatic GSH depletion. Bilirubin is also a GST inhibitor and, in a model of hyperbilirubinemic rat (Gunn rat), less hepatic GSH depletion was found during exposure to azathioprine^[23]. These observations indicate that the conversion of azathioprine to mercaptopurine *in vivo* is mediated enzymatically by the GSTs. After oral administration of azathioprine this reaction likely occurs mostly in the liver: indeed after oral administration azathioprine is undetectable in blood, while mercaptopurine appears after either oral or *iv* azathioprine administration^[2]. In addition it has been shown that after *ip* injection of azathioprine in rats, GSH was depleted rapidly in hepatocytes but not in other tissues (*i.e.*, erythrocytes, kidneys and intestine) indicating that after administration of azathioprine, the hepatic contribution to total GSH consumption may be predominant^[24].

Eklund *et al*^[6] have shown that among 14 GSTs tested, GST-A1, GST-A2 and GST-M1 displayed the highest activity on the catalysis of azathioprine to mercaptopurine; these enzymes are all highly expressed in human hepatocytes and therefore in these cells the uncatalyzed reaction of azathioprine with GSH was estimated to be less than 1% of the GST-catalyzed biotransformation. Interestingly, GST-M1 and GST-A display genetically determined variable expression levels. These differences in GST activity may result in interindividual differences in

the conversion of azathioprine to mercaptopurine. The authors suggest that individuals with high levels of GST could be particularly sensitive to azathioprine and potentially more prone to adverse effects during treatment with azathioprine, because of both increased concentrations of free mercaptopurine and of a more pronounced GSH depletion.

Oxidative damage

Considering the intracellular enzymes involved in thiopurines' metabolism, it is reasonable to suggest that these agents are able to induce oxidative stress. Indeed, it has been demonstrated that thiopurines can generate directly reactive oxygen species (ROS) in cells exposed to ultra violet light^[25,26]. Moreover, regarding azathioprine, some evidence suggest an indirect ability to induce oxidative stress, mediated primarily by GSH consumption during the metabolic conversion of azathioprine to mercaptopurine^[27,28]. GSTs, influencing the reaction of azathioprine with GSH, may influence therefore the cellular effects of azathioprine mediated by oxidative damage. Moreover, even metabolism of thiopurines by XO may generate ROS, as assessed on primary cultures of rat hepatocytes^[28]. XO, which metabolizes mercaptopurine, converting it to thiouric acid, is a well know producer of ROS, such as superoxide anion^[29], whose accumulation could worsen the oxidative stress induced by GSH depletion. Allopurinol, a XO inhibitor, has been shown to restore response to thiopurines in patients with IBD unresponsive to thiopurines and with unfavorable metabolic ratio, increasing the concentration of active TGNs and decreasing those of the methylated nucleotides, likely because of inhibition of TPMT^[30]. Cellular redox balance is largely determined by GSH. Depletion of such cellular antioxidant defenses allows the accumulation of significant amounts of ROS, as demonstrated in several systems^[31,32], which, in turn, have been suggested to act as a signal for apoptosis induction^[33]. Regarding azathioprine, exposure to this medication *in vitro* induces a rapid depletion of GSH in hepatocytes before any loss of viability. Addition of exogenous GSH or N-acetylcysteine protected against cell death. Lee *et al*^[27] suggested that oxidative stress induced by GSH depletion is able to induce mitochondrial damage, opening of mitochondrial permeability transition pore (MPTP) and rapid consumption of adenosine triphosphate. Ultrastructural analysis showed occurrence of necrosis after azathioprine exposure. The fact that, under the same experimental conditions, mercaptopurine was not able to reduce hepatocyte viability, allows suggesting that the activating steps triggered by GST and the associated GSH depletion could be a crucial step in azathioprine cytotoxicity *in vitro*.

Among the many secondary effects attributed to them, a role for ROS in mediating an anti-proliferative effect has been demonstrated. Indeed, the cellular redox balance fluctuates during cell cycle, so that the redox state modulates cell cycle progression from one phase to the next^[34]. In this scenario, significantly higher GSH content

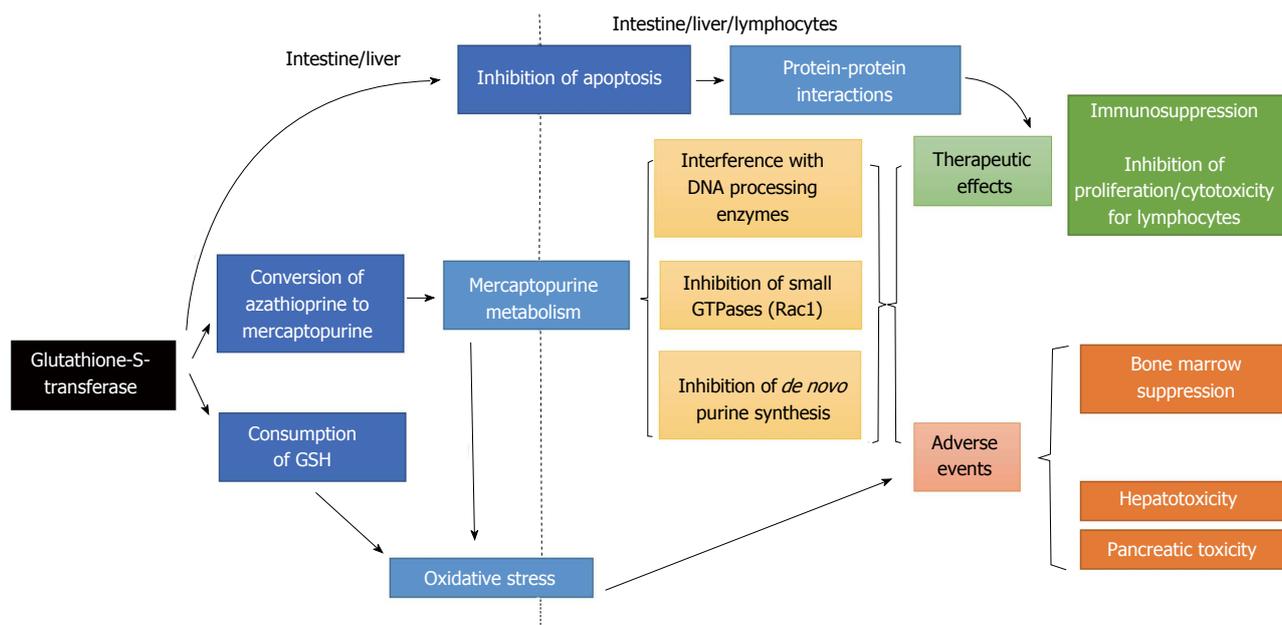

Figure 2 Schematic representation of different glutathione-S-transferase catalyzed phenomena (blue boxes) that even through intermediate events (light blue) bring or contribute to the canonical mechanisms of action (yellow), determining the therapeutic effects (green) and/or adverse events (orange). GSH: Reduced glutathione.

in the G₂ and M phases compared with G₁ were found^[35]. Hence, it is reasonable to hypothesize a role for ROS in affecting the anti-proliferative effect of thiopurines, which are cell cycle phase specific agents and especially azathioprine, which consumes GSH during its conversion to mercaptopurine.

Azathioprine half-life is very short and its therapeutic effects on lymphocytes are likely due to the metabolites produced after first pass metabolism in the intestinal and liver cells. However, azathioprine cytotoxic effects due to GSH consumption are likely to play an important role on the development of cytotoxicity in intestinal and liver cells, supporting a role in the induction of adverse events in these organ systems. However, the fact that on hepatocytes azathioprine is able to modulate a necrotic cell death through a cyclosporine-A sensitive MPTP opening, rise some doubts on the actual role of oxidative stress^[27]. Studies are still required to demonstrate if ROS could represent an alternative mechanism of cytotoxicity induced by azathioprine and its clinical relevance.

Modulation of apoptosis

Azathioprine and mercaptopurine induce apoptosis in activated lymphocytes and these effects should be crucial in determining the efficacy of these medications as immunomodulators in young patients with IBD^[36]. GSTs have been shown to modulate apoptosis and the incidence of lymphopenia during treatment of IBD patients and therefore modulation of apoptosis by GSTs may be of significant relevance as a mechanism for the role of these proteins on azathioprine effects.

GST-P1 was the first isoenzyme found to play a role in signaling pathways that control cell survival, and so far is the most important one. This regulation role is

achieved independently from the well-known conjugating activity and occurs through a physical protein-protein interaction with c-Jun N-terminal Kinase (JNK), a member of the mitogen-activated protein kinases (MAPK), with the consequent inhibition of the downstream JNK-induced apoptotic pathway. GST-M1 plays a similar role of negative regulator by physically sequestering the apoptosis-signaling regulating kinase 1 (ASK-1), a MAPK kinase kinase that activates both JNK and stress responsive p-38 kinase (another MAPK)^[37]. Stress triggers, such as heat shock or the pro-inflammatory cytokines TNF- α and interleukin 1- β , promotes the dissociation of GST-M1 from ASK1, resulting in the activation of ASK-1 and the phosphorylation-dependent activation of p38^[38]. The final cell fate (proliferation or apoptosis) depends on the strength and duration of the cellular stress.

GST-A1 has been found to suppress activation of JNK signaling by a pro-inflammatory cytokine and oxidative stress in Caco-2 cells, suggesting also a protective role for GST-A1 in JNK-associated apoptosis^[39].

The expression of GSTs of the M and A classes has been reported to drop under apoptotic conditions and their overexpression was able to block apoptosis in rat hepatocytes^[40]. GST-M1 has been reported to bind to ASK1 and inhibit apoptosis^[37].

Matsumaru *et al.*^[41] reported that depletion of cytosolic GSH could sensitize murine hepatocytes to apoptosis induced by TNF- α ^[41,42]; clinical studies have shown that TNF- α protein and mRNA levels are elevated in serum, intestinal tissue and stools of active IBD, in correlation with disease activity^[43]. Therefore, even depletion of GSH catalyzed by GST could make cells of patients with IBD particularly sensitive to the cytotoxic effects of thiopurines, potentially leading to an increased incidence

of adverse events.

CONCLUSION

It would be important that other studies validate the observation of the increased conversion of azathioprine to mercaptopurine in patients with normal GST-M1, resulting in increased sensitivity to the medication in patients with IBD, both clinically and using *in vitro* experiments. Moreover, since GSTs of the A class are highly expressed in the liver, have catalytic activity on the conversion of azathioprine to mercaptopurine and display genetically determined polymorphic activity, it would be important to evaluate the role even of variation in genes for the A class of GST on azathioprine pharmacokinetics and efficacy.

Further insights on the role of genetic polymorphisms of GST and other enzymes on azathioprine pharmacogenetics could come from the use of innovative and more sensitive methods for the measurement of azathioprine metabolites. Indeed, most of the research published so far, including the papers mentioned in this report, have characterized thiopurine metabolites in erythrocytes from patients with IBD, using HPLC methods that group all thionucleosides as TGNs or methylated nucleotides^[4,44], without distinguishing the degree of phosphorylation, which may be of relevance for thiopurines' cellular effects^[45]. Given the complexity of thiopurines' metabolism, methods with increased sensitivity, allowing to assess the nucleotides degree of phosphorylation and potentially the identification of additional relevant species, such as those based on mass spectrometry are of great interest^[46]. Moreover, these methods with increased sensitivity allow the use of very small volumes of patients' samples and this is particularly relevant for pediatric patients^[47,48].

The increasing complexity^[49] of thiopurines' pharmacogenetics has been consolidating: while TPMT is the strongest determinant of variability in the pharmacokinetics of these medications^[50], currently used in several clinical protocols to adjust treatment with thiopurines, even other genes, such as ITPA, have been shown to be of relevance^[51]. Based on the clinical and *in vitro* evidence highlighted in this paper (Figure 2), it seems that for azathioprine even GST-M1 genetic polymorphism could enter in a useful multi-locus genotype to predict patients' response to this medication. However, the association of GST-M1 with azathioprine efficacy in patients with IBD still needs to be supported mechanistically by *in vitro* studies and validated by adequately sized prospective clinical trials.

Abstract

Anemia, a common complication associated with inflammatory bowel disease (IBD), is frequently overlooked in the management of IBD patients. Unfortunately, it represents one of the major causes of both decreased quality of life and increased hospital admissions among this population. Anemia in IBD is pathogenically complex, with several factors contributing to its development. While iron deficiency is the most common cause, vitamin B₁₂ and folic acid deficiencies, along with the effects of pro-inflammatory cytokines, hemolysis, drug therapies, and myelosuppression, have also been identified as the underlying etiology in a number of patients. Each of these etiological factors thus needs to be identified and corrected in order to effectively manage anemia in IBD. Because the diagnosis of anemia in IBD often presents a challenge, combinations of several hematimetric and biochemical parameters should be used. Recent studies underscore the importance of determining the ferritin index and hepcidin levels in order to distinguish between iron deficiency anemia, anemia due to chronic disease, or mixed anemia in IBD patients. With regard to treatment, the newly introduced intravenous iron formulations have several advantages over orally-admin-

istered iron compounds in treating iron deficiency in IBD. In special situations, erythropoietin supplementation and biological therapies should be considered. In conclusion, the management of anemia is a complex aspect of treating IBD patients, one that significantly influences the prognosis of the disease. As a consequence, its correction should be considered a specific, first-line therapeutic goal in the management of these patients.

Key words: Anemia; Inflammatory bowel disease; Iron deficiency; Anemia of chronic disease; Erythropoietin

Core tip: Anemia represents one of the major causes of both decreased quality of life and increased hospital admissions among inflammatory bowel disease (IBD) patients. This paper analyses the complex etiological and pathophysiological mechanisms underlying anemia in IBD, including iron and micronutrients deficiency, effects of proinflammatory mediators and bone marrow insufficiency secondary to the disease by itself and IBD therapy. By a comprehensive review of the current diagnostic and therapeutic evidences on anemia in IBD, an state-of-the-art approach will be provided to effectively manage this challenging and common condition.

INTRODUCTION

Anemia, a frequent systemic complication in patients

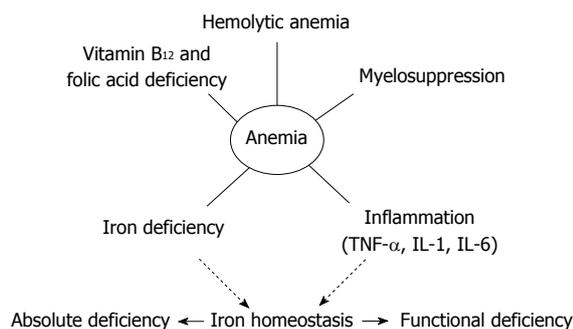

Figure 1 Pathogenesis of multifactorial anemia associated to inflammatory bowel disease. TNF- α : Tumour necrosis factor- α ; IL: Interleukin.

with inflammatory bowel disease (IBD), has a complex and multifactorial pathogenesis (Figure 1). It is considered a prototype of a combination of iron deficiency (IDA) and anemia of chronic disease (ACD), which is caused by the negative effects of an activated immune system at different levels of erythropoiesis^[1,2]. Besides IDA and ACD, metabolic disturbances, vitamin deficiencies, and various drug therapies commonly used in IBD can aggravate anemia in IBD patients^[3]. The study of anemia in these patients thus requires a specific diagnostic and therapeutic approach.

It is important to highlight that anemia has a significant impact on the disease and is one of the most frequent comorbid conditions associated with mortality in IBD patients^[4]. In addition, it also has a relevant effect on health related quality of life (QoL) and ability to work^[5,6]. The fact that it is also a common cause of hospitalization and delay of discharge^[7] only serves to underscore the need for prompt diagnosis and management of this condition.

Although the correction of anemia in IBD patients can improve the QoL and the quality of patient management, the specific diagnosis and treatment of anemia is often a low priority for gastroenterologists and has thus received little attention. A recent study showed that further diagnostic tests were undertaken in only one-third of patients with proven anemia and that 54.3% of patients diagnosed with IDA receive no iron supplements^[8,9].

This article reviews current data on the diagnosis and treatment of anemia in IBD patients. A search was conducted in the PubMed, Cochrane, MEDLINE, and Scopus libraries with the following individual and combined key words: Crohn's disease, ulcerative colitis, anemia, iron deficiency anemia, anemia of chronic disease, vitamin B₁₂ deficiency, folic acid deficiency, myelodysplastic syndrome, refractory anemia, iron supplementation, intravenous iron therapy, erythropoietin, and inflammatory bowel disease. References cited in the articles retrieved were also searched in order to identify other potential sources of information. The results were limited to human studies available in English.

PREVALENCE OF ANEMIA IN INFLAMMATORY BOWEL DISEASE

The prevalence of anemia in IBD is markedly variable, ranging from 6% to 74% in two systematic reviews^[10,11]. The more recent review calculated a mean prevalence of 17% (16% in outpatients and 68% in hospitalized patients), with anemia occurring more frequently in patients with Crohn's disease (CD) than in those with ulcerative colitis (UC)^[3,12]. This variability in the prevalence of anemia depends on different factors. First, the definition of anemia is not homogenous in the various studies reviewed. In fact, because the widely accepted World Health Organization criterion for the diagnosis of anemia [hemoglobin (Hb) below 13 g/dL in men or 12 g/dL in non-pregnant women]^[13] has been questioned due to racial differences, environmental conditions, and eating habits^[14,15], its use cannot completely reflect the real prevalence of anemia in different IBD populations. Furthermore, estimations of the prevalence of anemia often depend on the specific groups of patients studied (for example, hospitalized patients *vs* outpatients). In this sense, a study from a Swedish cohort showed that the prevalence of anemia in hospitalized UC and CD patients was higher than among outpatient populations (5% *vs* 35% and 9% *vs* 50%, respectively)^[16]. Furthermore, it is important to note that anemia has been poorly studied in pediatric IBD patients. One recent epidemiological study showed that while the prevalence of anemia was 72% at the time of diagnosis, the proportion of severely anemic pediatric patients decreased from 34% to 9% while the number of patients with mild anemia doubled after 1 year of follow-up^[17]. Finally, because Hb levels form part of a widely used disease activity index, the presence of anemia correlates directly with disease activity, which means that the prevalence of anemia may change throughout the natural history of the disease. In fact, the prevalence of mild and moderate anemia in IBD has decreased over time, reflecting improved treatment and management of the disease. However, the prevalence of severe anemia in IBD patients over the last 10 years has not decreased in the same manner^[18].

PATHOGENESIS OF ANEMIA IN INFLAMMATORY BOWEL DISEASE

Iron deficiency anemia

Iron deficiency is the most common cause of anemia in IBD patients, with a reported prevalence of up to 90%^[11]. Iron deficiency may be related to "absolute iron deficiency" due to low dietary intake and blood loss from ulcerated intestinal mucosa (especially in UC patients) along with reduced iron absorption (especially in CD localized in the upper GI tract), or it may be related to "functional iron deficiency."

Iron is an essential mineral for the function of all

body cells and is absorbed at the apical surface of enterocytes to be transported by ferroportin across the basolateral surface of the enterocyte into the circulation^[19]. In the maintenance of iron homeostasis, the peptide hormone hepcidin is a master regulator that is produced in response to iron overload or upon induction by pro-inflammatory stimuli such as lipopolysaccharide or interleukin (IL)-6. In fact, inflammatory conditions can interfere with iron absorption by causing an increase in hepcidin that inhibits ferroportin activity^[20], leading to its internalization and degradation^[21]. The inhibition of ferroportin activity blocks the transfer of absorbed iron from the enterocyte into the circulation and causes iron retention in the macrophages and monocyte cells^[22]. In addition, during inflammation other events contribute to the retention of iron in these cells, including the inhibition of ferroportin transcription by pro and anti-inflammatory cytokine action and a reduction in the half-life of erythrocytes due to oxidative stress and lipid-peroxidation, with iron recycling through erythrophagocytosis^[23]. These mechanisms all lead to “functional iron deficiency,” which means that despite an abundance of iron in the body, it is not available for erythropoiesis.

Anemia of chronic disease

The exact prevalence of ACD in IBD patients is unknown^[24], with its etiology being ascribed to altered erythropoiesis at different levels^[25]. Firstly, chronic inflammation can decrease erythropoiesis by direct action of interferon (IFN)- γ , IFN- α , tumor necrosis factor (TNF)- α , and IL-1 in the bone marrow to exert pro-apoptotic effects on erythroid burst-forming units (BFU-E) and colony-forming units (CFU-E)^[26]. Moreover, IL-1, IL-6, TNF- α , and hepcidin may decrease erythropoietin (EPO) synthesis and impair its biological activity^[1,27]. In fact, EPO levels in ACD have been found to be inadequate in some chronic disease and IBD patients^[11,28,29]. Low EPO production is due to direct inhibition of the activity of the promoter of the EPO gene by IL-1 and TNF- α , which in turn inhibits the synthesis of EPO in the kidney and acts indirectly on EPO-producer cells through cytokine-induced toxic radicals^[30]. Impairment of the biological activity of EPO means that much higher amounts of EPO are needed to restore the formation of CFU-E in the bone marrow. Cytokines can also interfere with the signaling process mediated by the interaction of EPO and its receptor and can down-regulate EPO receptors on erythroid progenitor cells^[26], thus producing cell resistance to EPO activity. Finally, the limited availability of iron for heme biosynthesis induced by “functional” or “absolute” iron deficiency and the inhibition of iron uptake into erythroid progenitors due to the blocking of the transferrin receptor by α 1-antitrypsin (an acute phase protein) negatively affect the biological functions of EPO along with cell growth and differentiation^[1].

Other types of anemia

Vitamin B₁₂ deficiency has been observed in 48% of

CD patients and in 5% of UC patients^[31] while folic acid deficiency has been noted in 67% of CD patients and in 30%-40% of UC patients^[31-33]. These types of deficiencies depend on low dietary intake as well as increased turnover of epithelial cells due to chronic inflammation in the intestinal mucosa and a reduced absorption in the intestinal tract^[34-36]. In CD, several factors influence these deficiencies, including the inflammatory involvement of ileal mucosa, the presence of fistulas, secondary bacterial overgrowth with direct consumption of vitamin B₁₂, and extensive surgical resections in small bowel segments with impaired absorption^[37]. Deficiencies in patients with UC derive from proctocolectomy and ileo-pouch anastomosis, with the prevalence of vitamin B₁₂ deficiency being affected more by surgical changes leading to impaired function of ileal receptors, reduced intestinal transit time, and secondary bacterial overgrowth than on the length of the ileal segment resected^[38].

Autoimmune hemolytic anemia (AIHA) is a rare type of anemia observed in UC patients. It can be due either to the development of antibodies with cross-reactivity with erythrocytes^[39] or to the hemolytic effect of sulfasalazine in patients with glucose-6-phosphate dehydrogenase deficiency^[40]. This association was first described in 1955 by Lorber *et al*^[41] with the most recent studies calculating that the prevalence of AIHA in UC patients is between 0.2%-1.7%, as indicated by a positive Coombs test result in 1.8% of patients studied^[40]. AIHA can occur before, after, or at the moment of diagnosing UC. Even when the potential relationship between disease activity and the occurrence of AIHA is not clear, a correlation with the extension of the disease has been demonstrated in several reports, which show a prevalence of AIHA of up to 28% in patients with extensive colitis^[40].

Anemia can also represent a late manifestation of myelosuppression in IBD patients due to several factors. Firstly, myelosuppression can be associated with myelodysplastic syndrome (MDS), with ineffective erythropoiesis and a risk of progression to acute myeloid leukemia. Some studies have shown a frequent predominance of MDS in CD with colorectal involvement; however, it should be noted that the prognosis of IBD with concomitant MSD is determined by the MSD itself^[42]. The prevalence of MDS in IBD patients has been estimated to be 0.17%, with a higher incidence in IBD patients than in the general population (170/100000 IBD patients/year *vs* 20-30/100000 of the general population over the age of 70/year)^[43]. This is probably due to a undetermined common pathogenetic mechanism, the long-term use of immunosuppressive drugs, or chromosomal abnormalities in bone marrow cells that have been observed in 67% of patients with concomitant IBD and MSD^[44,45]. These can induce the development of colitogenic monocytes, producing a large number of pro-inflammatory cytokines resistant to apoptosis upon stimulation with microbial antigens. Indeed, one of the first hypotheses about this association regarded IBD to be an extra-hematologic manifestation of MSD with a

Table 1 Laboratory findings in anemia of inflammatory bowel disease patients

| Biomarkers | IDA | ACD | Mixed anemia |
|-------------------|-----------|-------------------|---------------------|
| MCV (fL) | < 80 | Normal or reduced | Normal or reduced |
| MCH (pg) | < 27 | Normal | Normal |
| CHr (pg) | < 28 | Normal | Normal |
| C-RP (mg/dL) | Normal | > 5 | > 5 |
| ferritin (ng/mL) | < 30 | > 100 | 30-100 |
| TfS (%) | < 20 | < 20 | < 20 |
| Ferritin index | > 3.2 | < 11 | > 2 |
| sTfR | Increased | Normal | Normal or increased |
| Hepcidin (nmol/L) | Reduced | Increased (> 4) | Increased (> 4) |

MCV: Mean corpuscular volume; MCH: Mean corpuscular hemoglobin; CHr: Reticulocyte hemoglobin content; C-RP: C-reactive protein; TfS: Transferrin saturation; sTfR: Soluble transferrin receptor; IDA: Iron deficiency anemia; ACD: Anemia of chronic disease.

vasculitic process at the level of the mesenteric arteries^[46]. Alternatively, myelosuppression may represent a complication of severe UC with the development of a systemic inflammatory response syndrome, or even been a side effect of immunosuppressive drugs. There is an increasing concern about therapy-induced leukemias and myelodysplastic syndromes in patients treated with thiopurines, which are extensively used as immunosuppressants in IBD, particularly for maintenance therapy^[47]. Data from a large French cohort of patients (19486) with inflammatory bowel disease identified a relative risk of developing lymphoproliferative disorders as 5.2 for patients who were treated with thiopurines compared to those who were not^[48].

Finally, additional gastrointestinal diseases that do not usually cause bleeding should be also considered in case of iron deficiency anemia in those IBD patients who maintain disease into remission, including colon or gastric cancer or polyps, peptic ulcer, hiatal hernia with linear erosions, atrophic or *Helicobacter pylori*-associated gastritis, and celiac disease^[49,50].

DIAGNOSIS OF ANEMIA IN INFLAMMATORY BOWEL DISEASE

Basic laboratory screening for anemia in IBD should consist of hemoglobin and full blood counts (including reticulocytes to differentiate between regenerative or hypo-regenerative anemia), with a determination of erythrocyte mean corpuscular volume (MCV) to distinguish between microcytic, normocytic, and macrocytic anemia as well as a determination of mean corpuscular Hb (MCH) and reticulocyte Hb content (CHr), if available. Moreover, assessments of both the level of inflammation by means of C-reactive protein (CRP) and of iron status are required. There is no single biomarker to diagnose iron deficiency in IBD; a combination of different biomarkers is needed. In most cases, total store of body iron with serum-ferritin (or ferritin) and the iron available in the bone marrow with transferrin saturation (TfS) is sufficient to differentiate between IDA and

ACD^[51]. However, many of the laboratory measures of iron status may be unreliable in IBD patients because the inflammation influences all parameters of iron metabolism to produce “functional iron deficiency”^[52,53]. For this reason, in some cases it is essential to use other, more specific biomarkers of iron status to allow for the differentiation between predominantly IDA, predominantly ACD, and ACD combined with iron deficiency in order to provide appropriate, more effective treatment^[54] (Table 1). Further testing for causes of anemia in IBD may include tests for vitamin B₁₂, folic acid (especially erythrocyte levels, which, when available, represent the best stable marker of folic acid deficiency), haptoglobin, lactate dehydrogenase, indirect bilirubin (with Coombs test if hemolytic anemia is confirmed), and serum creatinine in order to rule out potential hemolysis or renal failure, which in itself can cause macrocytic or normocytic anemia^[51]. It should be noted that if the origin of anemia is not obvious, IBD patients should be tested for MDS, especially if normocytic and hypo-regenerative anemia are both present, carrying out a bone marrow study in selected patients.

Once a diagnosis of IBD has been established, patients in clinical remission should be screened for anemia at least every 6 to 12 mo, whereas patients with active disease should be tested every 3 mo or at even shorter intervals, depending upon their iron status^[55].

Iron deficiency anemia

Patients are considered to suffer from IDA when they present with low Hb (men < 13 g/dL, non-pregnant women < 12 g/dL), TfS < 20%, and ferritin concentrations < 30 ng/mL without any biochemical or clinical signs of inflammation. A low MCH (< 27 pg) or even better a low CHr (< 28 pg) rather than MCV (< 80 fL) have become the most important red cell markers for detecting iron deficiency in circulating red blood cells. Although MCV is a reliable and widely available measurement, it tends to be a relatively late indicator in patients who are not actively bleeding^[56]. A normal Hb level does not rule out iron deficiency and with an MCH in the lower limit of normal (normal range: 28-35 pg) or an increased red cell distribution width (RDW, normal range: 11-15), one can suspect the presence of mild iron deficiency without anemia^[57]. Although the main laboratory marker for iron deficiency with or without anemia is a low ferritin level (< 30 ng/mL) in the absence of inflammation, in the presence of inflammation a normal ferritin level (as an acute phase reactant) does not rule out iron deficiency; therefore, TfS should also be measured. “Functional iron deficiency” in inflammatory conditions should be defined by low TfS (< 20%) and normal ferritin concentration (> 100 ng/mL), whereas low TfS (< 20%) and intermediate ferritin values (30-100 ng/mL) suggest “absolute iron deficiency”^[57]. Some authors suggest a cut-off value of TfS < 16% combined with low iron value for the diagnosis of iron deficiency^[51]. Iron deficiency can also be defined by a ferritin index > 3.2 (> 2 if CRP > 5 mg/L). The ferritin index, which reflects

the iron supply for erythropoiesis, is calculated as the ratio between the soluble transferrin receptor (sTfR) and the log of ferritin^[58]. The sTfR is a truncated fragment of the membrane receptor and its levels increase when the availability of iron for erythropoiesis is low, as occurs in IDA. CHr, which measures the Hb content of reticulocytes, reflects the direct measurement of available iron for erythropoiesis and is useful for differentiating IDA from ACD. In particular, CHr has a high sensitivity and specificity for diagnosing iron deficiency and is less affected by inflammation than TfS and ferritin, but no data are available for its use in IBD^[58].

Anemia of chronic disease

Patients are considered to suffer predominantly from ACD when they present evidence of inflammation (with increased levels of serum CRP and clinical signs), an Hb concentration < 13 g/dL for men and < 12 g/dL for non-pregnant women, and a low TfS < 20%, but normal or increased ferritin concentrations > 100 ng/mL. In the presence of intermediate ferritin concentrations (30-100 ng/mL), a diagnosis of ACD combined with “absolute iron deficiency” is confirmed if the ferritin index has a value < 2 with normal CHr^[54,58-60]. Still, some cases may require supplementary testing for the differential diagnosis between IDA and ACD. It has recently been shown that hepcidin levels may replace the ferritin index for the confirmation of combined IDA and ACD if the hepcidin levels are > 4 nmol/L with a CHr < 28 pg^[61]. In fact, hepcidin levels have been found to be significantly higher in IBD patients compared with healthy controls, with a significant correlation with ferritin levels, CRP, and disease activity, whereas those of prohepcidin were observed to be significantly lower^[62]. In addition, although other hematological indices may help in the diagnosis of iron deficiency in ACD, many of them are only available in specific hematology analyzers and their precise clinical usefulness has yet to be determined. In a recent study carried out with a Beckman-Coulter LH 780, high values of RDW and low values of blood cell Size Factor were the best markers for the diagnosis of IDA, whereas both Reticulocyte Distribution Width-Coefficient of Variation (RDWR-CV) and Reticulocyte Distribution Width-Standard Deviation (RDWR-SD) were significantly correlated to disease activity and CRP levels^[63].

TREATMENT OF ANEMIA IN INFLAMMATORY BOWEL DISEASE

Iron supplementation

Iron supplementation should be considered in every patient presenting iron deficiency with or without anemia. In patients with mild to moderate anemia (Hb \geq 10 g/dL), the administration of oral iron at optimal low doses of 60-120 mg/d is the conventional approach recommended by the Centers for Disease Control and Prevention^[9,64]. Oral iron compounds are mostly available as inorganic ferrous salts, such as ferrous fumarate, ferrous

sulphate, and ferrous gluconate containing 33%, 20%, and 12% of elemental iron, respectively. A single tablet of most of these ferrous salt preparations provides a sufficient dose for the treatment of iron deficiency^[65,66]. In fact, there is no evidence to support the administration of high doses of iron in comparative trials^[65-67]; on the contrary, excessive doses may actually decrease tolerance and compliance while increasing gastrointestinal side effects, with a discontinuation of iron treatment in 20% of patients with or without IBD^[68]. Nevertheless, there are several drawbacks associated with oral iron therapy that must be taken into account. In addition to the generally low bioavailability of oral iron, intestinal absorption is further compromised in IBD patients due to an inflammation-driven blockade caused by increased hepcidin levels. For this reason, in patients with active inflammation and combined ACD/iron deficiency, intravenous administration of iron may be preferable to oral iron therapy. Moreover, when achieved, the therapeutic effect of oral iron supplementation is slow, requiring two to three weeks to obtain increased Hb concentrations and up to two months to achieve normal values. At least six months are needed to replenish iron stores completely^[69]. Moreover, non-absorbed iron salts can be toxic to the intestinal mucosa and oral iron has been shown to increase intestinal inflammation and possibly colon carcinogenesis in animal models through the production of reactive oxygen species that mediate intestinal damage and the alteration of the intestinal bacterial milieu in rodents^[70-75].

Intravenous iron therapy is more effective, has a higher response rate, and is better tolerated by patients, with a lower discontinuation rate due to adverse events than oral iron supplementations in IBD patients, as demonstrated in a recent systematic review with meta-analysis^[76]. However, it is important to highlight that of 757 articles identified, only three industry-funded articles met the inclusion criteria for this systematic review^[69,77-83]. Nevertheless, intravenous iron therapy should be considered in patients with severe anemia (< 10 g/dL), with intolerance or inadequate response to oral iron, or with concomitant erythropoietin treatment and/or presence of active IBD. It should be noted that the new intravenous iron formulations (iron carboxymaltose, iron ferumoxytol, and iron isomaltoside) reduce both the risk of free iron reactions as well as that of immunogenicity without the need for administering a test dose before starting treatment. Treatment duration is also reduced because the new formulations are safer at higher doses than traditional intravenous iron formulations (iron sucrose, ferric gluconate, and low molecular weight iron dextran). Iron carboxymaltose is the only new intravenous iron formulation approved for use in Europe that has been studied in IBD patients. Its superiority at higher standardized doses over individually calculated doses of iron sucrose has been demonstrated along with its efficacy in reducing anemia recurrence as compared to a placebo^[84-86]. After 12 wk of follow-up,

ferric carboxymaltose led to higher response rates (66.1% *vs* 54.1%), a higher proportion of non-anemic patients (72.8% *vs* 61.8%), and better treatment adherence (92.5% *vs* 79.1%) than iron sucrose, with no difference in treatment-related adverse events (13.9% *vs* 11.3%). With regard to side effects, in the ferric carboxymaltose group there were more skin and subcutaneous tissue disorders (rash, dermatitis, pruritus) and more cases of hypophosphatemia, but fewer infusion site reactions than in the iron sucrose group. The superiority of high-dose intravenous iron supplementation in IBD probably depends on the iron overload produced in the macrophages of the reticulo-endothelial system. This induces an overexpression of ferroportin, which may, in turn, by-pass the hepcidin block in ACD^[57]. Recently, an alternative dosage scheme to the traditional Ganzoni formula has been presented for ferric carboxymaltose treatment. In the new protocol, for a baseline Hb > 10 g/dL, the dose is 1.0 g for patients with a body weight < 70 kg and 1.5 g for patients > 70 kg; the corresponding total doses for serum Hb ≤ 10 g/dL are 1.5 g and 2.0 g^[84]. Phase 3 clinical trials are currently underway to evaluate the use of ferumoxytol in patients with iron deficiency anemia, including a subgroup with IBD (ClinicalTrials.org identifier: NCT01114139, NCT01114217 and NCT01114204). However, ferumoxytol may be problematic in IBD patients because it can interfere with MRI signals due to the paramagnetic nature of its iron core^[19]. In addition, a Phase 3 clinical trial of iron isomaltoside (NCT01017614) and a Phase 4 study of iron sucrose (NCT01067547) are currently being carried out on IBD patients with IDA. All treatments being tested strive to achieve ferritin concentrations > 100 µg/L, measured as early as 8 wk after intravenous iron treatment to obtain a reliable result^[55]. Considering that the recurrence of iron deficiency with or without anemia is frequent in IBD patients^[87], regular controls at 12 wk intervals are advisable so that treatment can be restarted promptly if needed.

Erythropoietin supplementation

Several studies have shown that recombinant human erythropoietin may be effective for treating ACD in IBD patients^[88-95]. In the anemia treatment algorithm, intravenous iron therapy should be considered as a first-line therapy in patients with severe anemia whereas erythropoietin treatment should be considered only in patients unresponsive to intravenous treatment, with low EPO levels, or who are unresponsive to aggressive management of IBD^[29,53,96] since EPO can be used as an adjunct therapy to control the inflammation^[97]. Recently, a prospective study on CD patients showed that EPO combined with enteral nutrition can improve the Hb levels in CD patients with a treatment success rate of 63.16% in the EPO group compared to none of the patients in the non-EPO group^[98]. When a decision has been made to administer EPO therapy, it should always be combined with intravenous iron supplementation to meet the increased demand caused by the “functional

iron deficiency” typical in IBD patients^[99].

Other treatments

Intramuscular vitamin B₁₂ continues to be the gold standard therapy for vitamin B₁₂ deficiency, especially in symptomatic patients^[100]. A dose of 1000 µg/wk for 8 wk, then 1000 µg once monthly for maintenance lifelong is recommended^[101]. No therapeutic advantages have been demonstrated for either cyanocobalamin or hydroxycobalamin in terms of serum levels during maintenance therapy^[102]. Effectiveness data for sublingual^[103,104] and intranasal^[105] routes for vitamin B₁₂ administration have revealed as promising non-invasive alternatives.

Specific treatment of IBD has been shown to gradually increase Hb levels over time, which indicates that the presence of anemia is positively associated with disease activity and disease-associated gut lesions. Some data suggest that anti-TNF-α treatment improves the anemia in a sub-group of patients with CD. In fact, patients who responded to treatment showed improvements in their anemia within 2 wk of the first infusion of Infliximab, with a parallel improvement in their CD activity index and an increase in endogenous EPO levels over time^[12]. Infliximab seems to neutralize the inhibitory effects of TNF-α on EPO production, increasing the availability of iron for erythropoiesis and reducing anemia^[30]. The drug produces these effects through various mechanisms, including reduced cytokine-induced formation of ferritin and hepcidin, with improvement of intestinal iron absorption and iron release from macrophages *via* ferroportin-mediated iron export^[21,106,107]. Moreover, Infliximab improved the proliferation of cultured BFU-E, blocking the inhibitory effects of cytokines on erythroid progenitor cells^[26]. Finally, it induced mucosal healing, thereby reducing the production of pro-inflammatory cytokines and the amount of blood loss through mucosal ulcers. Other therapies with potential for treating IBD associated with anemia include treatment with anti-IL-6, which is the major inflammation-driven inducer of hepcidin, and other new therapies that neutralize hepcidin, modify EPO and/or erythropoietin receptor sensitivity, or affect cytokines to effectively stimulate erythropoiesis.

The multi-factorial origin of anemia in IBD implies that several leading mechanisms can be simultaneously identified in a single patient, including chronic intestinal blood loss, decreased absorption capabilities of the small bowel secondary to inflammation or resection, bacterial overgrowth, and an inability of many IBD patients to tolerate the side effects of oral ferrous sulfate, among others^[108]. Each of these causative factors usually requires a specific therapeutic approach. Disease inflammatory activity and iron deficiency should be the first aspects to be restored in every patient^[109] since they are the main causes of anemia and easily identified. Although more uncommon, vitamin B₁₂ or folate deficiency, hemolytic and drug-induced anemia should also be born in mind. Effective treatment is only possible if the con-

tributing factors in a particular patient are clearly defined and corrected^[110].

CONCLUSION

Anemia is a common multifactorial complication in IBD that increases disease morbidity. Awareness on the part of gastroenterologists needs to be increased to improve the specific diagnosis and management of anemia in these patients. New generation IV iron compounds are currently available to treat iron deficiency effectively in IBD patients. Further studies are needed to establish standardized treatments to reduce the development and recurrence of anemia as well as to improve the clinical course of IBD.

Abstract

Ulcerative colitis and Crohn's disease, commonly known as inflammatory bowel disease (IBD), draw attention from specialists of various disorders, including gastroenterology, psychiatry, and radiology. The involvement of a cortical influence in the brain-gut axis as well as the interaction of the hypothalamic-pituitary-adrenal axis and the peripheral nervous system provide an initial explanation of the psychological symptoms associated with IBD. The involvement of structures the limbic system, such as the anterior cingulate cortex, the prefrontal cortex, and the amygdala, paves the way for the discovery of the mechanisms underlying depression depression, anxiety, alexithymia, personality traits, and other psychological impairments following the onset of IBD. Psychiatric therapy in IBD patients is almost as important as the gastroenterological approach and consists of pharmacological treatment and psychotherapy. Neither of the available psychiatric treatment methods is considered the golden standard because both methods have side effects, and psychotropic medication can provoke the worsening of

IBD symptoms. Thus, both approaches must be applied with awareness of the possibility of side effects. We suggest that psychiatrists and gastroenterologists work together to reach a consensus on IBD therapy to ensure success and to reduce side effects and relapse to the lowest possible rates.

Key words: Inflammatory bowel disease; Psychiatry; Treatment; Personality traits; Depression; Anxiety

Core tip: The involvement of a dysfunction of brain-gut interactions in the pathogenesis of inflammatory bowel disease (IBD) is represented by a dysfunction of the autonomic nervous system, an abnormal hypothalamic-pituitary-adrenal axis and cholinergic anti-inflammatory pathway, a deleterious effect of stress and depression, an abnormal coupling of the prefrontal cortex-amygdaloid complex, and an abnormal relation between the microbiota and the brain as pro-inflammatory factors. New investigations have provided a critical link between forebrain changes and abdominal pain independent of active disease and drug treatment, providing a potential basis for an explanation of the psychological symptoms and brain influence in the pathogenesis of IBD.

ANATOMICAL BASIS FOR THE PSYCHIATRIC CHANGES IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) results from an inap-

appropriate inflammatory response to intestinal microbes in a genetically susceptible host. In recent reports, authors^[1,2] have discussed the involvement of a dysfunction of brain-gut interactions in the pathogenesis of IBD as represented by a dysfunction of the autonomic nervous system, an abnormal hypothalamic - pituitary - adrenal axis and cholinergic anti-inflammatory pathway, a deleterious effect of stress and depression as well as an abnormal coupling of the prefrontal cortex-amygdaloid complex and an abnormal relation between the microbiota and the brain as pro-inflammatory factors. The New investigations have provided a critical link between fore-brain changes and abdominal pain independent of active disease and drug treatment because all patients examined in the morphometric evaluation were in remission and suffered from ongoing abdominal pain. Investigators observed decreased gray matter volumes in the dorsolateral prefrontal cortex and the anterior midcingulate cortex (aMCC), and the disease duration was negatively correlated with volumes in the subgenual anterior cingulate (sACC), the posterior MCC (pMCC), the ventral posterior cingulate (vPCC), and the parahippocampal cortices. The aMCC has a role in feedback-mediated decision making, and specific cognitive tasks that differentiate the aMCC and pMCC can be used to evaluate defects in Crohn's disease (CD). The sACC is an important area because it has impaired functions in major depression. Because depressive symptoms are a feature in a subset of patients with active inflammatory diseases, including IBD, treatment targeting this subregion should prove efficacious. Finally, the vPCC has a role in ongoing self-monitoring of the personal relevance of sensory stimuli, including visceral signals *via* the sACC. This pathway may be interrupted by vPCC atrophy in CD. Cingulate atrophy in CD requires the targeting of chronic pain and psychiatric symptom therapies *via* neuronal circles involved in the cingulum. These therapies include psychotherapy, guided imagery and relaxation training, analgesic dosages of morphine or antidepressants, and hypnosis. Thus, a new generation of novel treatments may emerge from drug and non-traditional therapies for CD in this formative area of research^[3,4]. Nevertheless, a certain level of caution should remain: the same areas have been found to be susceptible to changes in temporal epilepsy^[5], and it remains unclear whether the volume alterations in these areas are specific to IBD or if they overlap with other diseases.

The white matter is not spared from damage in IBD patients. The number of such lesions is significantly higher in IBD patients compared to controls (12.75 ± 19.78 *vs* 3.20 ± 2.90 , $P < 0.05$). However, there are no significant differences between UC and Crohn's disease patients with regard to magnetic resonance imaging (MRI) findings. In addition, the incidence of white matter lesions and other brain parenchymal lesions, sinusitis, and otitis-mastoiditis does not differ significantly with disease activity ($P > 0.05$ for all)^[6].

Scheid *et al*^[7] (2007) proposed the following three possible mechanisms for peripheral and central nervous system involvement in ulcerative colitis (UC): cerebrovas-

cular conditions due to thromboembolic events, systemic and cerebral vasculitis, and neuropathy and cerebral demyelination due to immune-related mechanisms. In contrast, white matter lesion is a frequent finding in patients with IBD on MRI, and the development of these lesions has been attributed to ischemic mechanisms (atherosclerotic or vasculitic) or demyelination^[8-10]. Thus, early identification of these lesions may be clinically helpful as an early indication of neurological involvement because they may represent another extra intestinal manifestation of the disease^[10].

Studies performed by functional magnetic resonance imaging for both, patients and control subjects suffering from irritable bowel syndrome, which is also a psychosomatic disease, and control subjects, rectal distention stimulation increased the activity of the anterior cingulate cortex (number of positive answers to the stimulation/total number of patients: 35/37), the insular cortex (37/37), the prefrontal cortex (37/37), and the thalamus (35/37) in most cases. In patients with inflammatory bowel syndrome (IBS), the average percentage area of regions of interest increased in parallel with rectal distention volumes in the insular cortex, the prefrontal cortex, and the thalamic region. However, only the prefrontal cortex was statistically significant ($P < 0.05$). In controls, this tendency to increase only occurred in the anterior cingulate cortex. At 120 mL rectal distention, the average percentage area of regions of interest (ROI) and the average percentage change in MR signal intensity of ROIs in the insular cortex, the prefrontal cortex, and the thalamic region were significantly greater in patients with IBS than in control subjects^[11,12].

PSYCHOLOGICAL SYMPTOMS IN IBD

There is consistent evidence that psychological factors play a role in the pathophysiology and the course of IBD and in how patients cope with IBD^[12]. One prospective study in a population-based cohort of individuals with IBD ($n = 552$) evaluated whether the presence of a stressful event and the perception of stress as well as other factors (*i.e.*, nonsteroidal anti-inflammatory drugs, antibiotics, or infections) believed to contribute to triggering flares of IBD were, in fact, associated with symptomatic flares^[13]. Subjects completed surveys on health issues every 3 mo for 1 year. In any 3-mo period, approximately 50% of subjects experienced some type of stress, and the majority of subjects reported the stresses were everyday life stresses. Family stress was the most commonly reported stress, followed by work or school and financial stress. Subjects were grouped by disease activity over time. Significantly more individuals in the persistently inactive disease group indicated they experienced no stressful events compared with individuals in the persistently active disease group. In terms of the association between variables experienced in one 3-mo period and a symptomatic flare in the next 3-mo period, only psychological factors, including the occurrence of a major life event, high perceived stress, and high negative mood during a previous 3-mo period, were significantly

associated with the subsequent occurrence of a flare. This study complements the growing evidence from experimental as well as clinical studies that stress exposure, including stressful events and perceived stress (the individual's view of his or her own level of demand relative to resources), may contribute to relapse risk in IBD^[14-18]. In fact, using multivariate logistic regression analyses of these variables, only high perceived stress (adjusted OR = 2.40; 95%CI: 1.35-4.26) was associated with an increased risk of flare. This finding speaks to the bidirectional relationship between stress and symptomatic disease. Being symptomatic may exacerbate or even incite stress, whereas being stressed may trigger symptomatic disease. Recent reports have shown that brain derived neurotrophic factor (BDNF) levels are highly dynamic in response to stress. BDNF levels not only vary across brain regions but also fluctuate rapidly, both immediately after a stressor and over the course of a chronic stress paradigm. However, BDNF alone is not sufficient to effect many of the changes observed after stress. Glucocorticoids and other molecules have been shown to act in conjunction with BDNF to facilitate both the morphological and molecular changes that occur, particularly changes in spine density and gene expression^[19].

Although discrete personality traits have been studied in IBD patients, no specific personality type matches this disease. It is recommended that future research consider the discrete personality traits observed in these patients and integrate them in such a way that the traits will be addressed to include new personality types, such as types C and D^[20,21], which are well matched with the unregulated immune and hormonal systems that are characteristics of IBD. Type C individuals are introverted, perfectionistic, sensitive, and thoughtful. Individuals with a type D personality have the tendency to experience increased negative emotions across time and situations and tend to not share these emotions with others because of a fear of rejection or disapproval. It is believed that depression and anxiety are dominant in patients with IBD^[22]. These patients also have a higher prevalence of anxiety and depressive disorders than the general population but a lower prevalence of these disorders than patients with a functional bowel disorder. The prevalence (21%-35%) is similar to that found in other patients with chronic physical illness. Depressive disorder appears to be more common in older patients and individuals with a previous history of a psychiatric disorder^[23,24]. Patients suffering from IBD take more medications than the healthy population: the use of antidepressants (OR = 1.44, 95%CI: 1.28-1.61), anxiolytics (OR = 1.52, 95%CI: 1.31-1.78), oral bisphosphonates (OR = 6.08, 95%CI: 4.56-8.11), cardiovascular medications (OR = 1.38, 95%CI: 1.24-1.54), antibiotics (OR = 4.01, 95%CI: 3.57-4.51), proton pump inhibitors (OR = 3.90, 95%CI: 3.48-4.36), and nonsteroidal anti-inflammatory analgesics (OR = 1.17, 95%CI: 1.07-1.28) is significantly more common in IBD patients than in controls. Individuals who use antidepressants, anxiolytics, or analgesics have significantly impaired health-rated quality of life (HRQOL) ($P < 0.001$)^[25].

Both depression and anxiety precede ulcerative colitis significantly more often than would be predicted from the control population's experience^[24]. The association is strongest when the two psychiatric disorders and ulcerative colitis are diagnosed in the same year, although the association between depression and ulcerative colitis is also significant when depression precedes ulcerative colitis by five or more years. Neither depression nor anxiety precedes Crohn's disease more often than expected by chance, although the study involved fewer cases with Crohn's disease than ulcerative colitis. Two prospective clinical studies of patients with IBD appear to produce conflicting results. During a 6-mo follow-up period, one study found a strong association between the change in disease activity and anxiety level and a weaker association with depressive symptoms. Changes in disease activity seemed to lead to changes in anxiety and depression. Beck Depression Inventory scores at baseline predicted the number and timing of relapses during an 18-mo follow-up period^[26,27].

Nevertheless, the origin of depression and anxiety in patients with IBD remains at least insufficiently explained. In a review of psychotherapeutic approaches to IBD, Prasko *et al.*^[28] (2010) emphasized that higher scores of neuroticism, depression, inhibition, and emotional instability are typical for many patients with chronic diseases and nonspecific for chronic gastroenterological disorders. More directly, anxiety and depression are consequences of IBD symptoms, such as frequent stools with evidence of blood, pain in the abdominal region, and bloating.

Because anxiety and mood disorders are the most common mental health concerns in the community, these disorders are usually the focus of screening efforts. The typical symptoms of anxiety disorders include high levels of physiological arousal, excessive worries about the future, avoidance of feared situations (including, in some cases, medical appointments and procedures)^[29,30], and difficulty coping with unfamiliar situations. Depression typically presents with a constellation of affective, cognitive, and somatic symptoms, including a sad or depressed mood; a loss of interest in normal activities; feelings of guilt, worthlessness, or hopelessness; difficulties with concentration; reduced energy; changes in appetite and sleep; and withdrawal from usual activities. When these clusters of symptoms persist beyond a few weeks and begin to significantly interfere with daily functioning, they are typically considered to reach a clinical threshold^[31]. The incidence of IBD in adolescents has been reported to be an increasing trend, especially in the Northern parts of Europe (Finland, Schotland)^[32-34]. According to parent reports, adolescents with IBD have more emotional, social, and thought problems and lower competence than their healthy peers^[35]. The disease disturbs adolescents' quality of life^[25,36,37], may have negative consequences for education and school functioning^[38,39], and may be a cause of difficulties in employment, such as finding or maintaining a desired job^[40-42]. Furthermore, adolescents with severe IBD have disturbed sleep and are overtired

more often than their healthy peers^[43].

Some studies have shown alexithymia to be another common personality characteristic in IBD patients. Patients with alexithymia have difficulties in recognizing and verbalizing emotions, and their ability to regulate emotions and express them to others is usually reduced^[44,45]. Numerous studies^[46-50] have shown that IBD patients have higher scores for alexithymia than controls. In a study conducted by Jones *et al*^[46] (2006), the scores of 74 IBS patients, 55 healthy control subjects, and 48 IBD patients were compared on the Toronto Alexithymia Scale. The results showed that IBS and IBD patients had higher scores on measures of alexithymia than the controls, but they did not differ from one another. In an epidemiological study, Porcelli *et al*^[50] (1999) compared 121 functional gastrointestinal disorder patients, 116 IBD patients, and a group of 112 healthy subjects using the Toronto Alexithymia Scale. Their results showed that the FGID group was significantly more alexithymic than the IBD group, and the scores of the two gastrointestinal groups were higher than the normal healthy group. Even after controlling for the influence of education, gender, anxiety, depression, and gastrointestinal symptoms, these differences remained significant. Moreno-Jiménez *et al*^[47] (2007) did not use a control group. In their sample comprising 60 UC and 60 CD patients, they attempted to address the question of which personality factors may predict HRQOL in IBD patients. They showed that difficulty in describing one's feelings was significant for predicting two dimensions of HRQOL, systemic symptoms and social functioning. Difficulty in describing one's feelings negatively predicted systemic symptoms and social functioning. Patients experiencing more difficulty in describing their feelings reported lower HRQOL. Although alexithymia may not be specific to IBD, it may lead patients to communicate their psychological distress through somatic and behavioral symptoms rather than verbal communication. This may occur particularly when patients have limited perceived social support or personality traits such as introversion. Regardless of whether alexithymia is specific to IBD, it has been reported that affected patients have greater difficulty in describing their feelings to others, poorer disease outcome, lower psychological functioning, and worse HRQOL^[12,47,51].

Adolescents with IBD have mild cognitive problems compared to the same population with juvenile idiopathic arthritis, particularly in the acute phase. Adolescent patients with IBD produced more perseverative errors than patients with non-acute juvenile idiopathic arthritis. Perseveration in the California Verbal Learning Test may be related to a momentary loss of alertness in the tiresome and long verbal memory test. However, no other differences in cognitive functioning between the study groups were detected. These findings indicate that adolescents with active IBD may have some mild problems in verbal memory but no major cognitive deficits. Prior studies in adults with IBD found deficits, particularly in verbal functioning, suggesting that in the clinical evaluation of young patients with IBD, it may be relevant to pay atten-

tion to even minor cognitive problems that may be aggravated during the growth process^[43,52,53].

PSYCHIATRIC THERAPY IN IBD

Psychiatric treatment of patients with IBD involves two types of approaches: (1) psychotropic medication; (2) psychotherapy; and (3) psychotropic medication.

Anxiety and depression, the most common psychiatric symptoms in IBD patients, are highly treatable conditions. The interventions that are the most widely used and have been evaluated the most extensively for anxiety and depressive disorders are specific pharmacological agents [particularly selective serotonin reuptake inhibitors (SSRIs), such as citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline, and the serotonin norepinephrine reuptake inhibitor (SNRI) venlafaxine] and specific psychological treatments (particularly cognitive behavioral therapies). The SSRI and SNRI medications are second-generation antidepressants that have been well established in the literature as being similarly effective for anxiety and depression^[54].

In humans, it has been observed that although antidepressants improve both the mental and somatic status of IBD patients, the low quality of available research provides significant barriers to making a definitive statement on their efficacy or lack thereof^[55]. Animal models, however, have found a positive impact of desipramine and fluoxetine on inflammation in models of IBD. When doctors' perspectives on antidepressants in IBD were examined, it was reported that gastroenterologists commonly treat IBD patients with antidepressants for pain, anxiety and/or depression, and insomnia. Gastroenterologists reported that antidepressants were successful in reducing pain, gut irritability, and urgency of defecation. In the most recent retrospective case-note audit of 287 patients, 83 (28.9%) patients had used an antidepressant at some time in their life^[56-59]. Nonetheless, the design of the study does not allow a firm statement to be made about whether antidepressants improved the course of IBD. The recent study in this area conducted by Goodhand *et al*^[60] (2012), which examined the disease course one year before and one year after the commencement of antidepressants, showed that patients reported fewer relapses and steroid treatment in the year after starting an antidepressant than in the year before. This effect was not observed in the control group. Although this report of decreased symptoms may simply reflect the report of fewer functional gastrointestinal symptoms when patients are in better psychological health^[61,62], it may also indicate an inflammation-specific benefit from antidepressants. Thus, it is clear that randomized controlled trials are justified and needed to provide a definitive answer regarding the efficacy of antidepressants in IBD.

Amitriptyline is an antidepressant drug that is widely used for the treatment of IBD and gastrointestinal disorders^[55,63]. It is effective for treating psychological and somatic symptoms in patients suffering from IBD^[55]. Other studies have shown the anti-inflammatory effects

of antidepressants by different mechanisms^[64,65]. Amitriptyline also acts on $\alpha 1$ -adrenoceptors to produce anti-inflammatory effects^[64]. Due to its effects on the inhibitory cytokine interleukin-10, amitriptyline has been reported to suppress neuroinflammation^[66]. Furthermore, antidepressants have anti-inflammatory effects by considerably decreasing the production of nitric oxide (NO) and tumor necrosis factor- α (TNF α) in microglia and astrocyte cultures at mRNA levels^[65]. They can inhibit the degradation of I κ B, the nuclear translocation of the p65 subunit of NF- κ B. Therefore, NF- κ B cannot translocate into the nucleus to bind with DNA to promote the expression of gene regions^[66]. Antidepressants can also inhibit the phosphorylation of p38 mitogen-activated protein kinase in lipopolysaccharide-stimulated microglia cells^[65]. This phosphorylation can induce the associated inflammatory gene expression to produce the proinflammatory cytokines and NO, which may be attenuated or inhibited by antidepressants^[66]. NO can also induce ROS; therefore, it can increase intestinal damage and, with cytokine production, prolong the development of IBD. Based on these studies, the NF- κ B pathway has been considered to play an important role in the inflammatory process. Therefore, investigators have hypothesized that the antidepressant-like effects of amitriptyline, *via* the modulation of this pathway, may be more effective for treating and suppressing the development of IBD through its anti-inflammatory actions^[67].

Some authors have argued that antidepressants may, in fact, cause tolerance and present problems when tapering off medications^[68,69]. Significant numbers of patients no longer need an antidepressant for their mental health problems, yet they suffer unbearable withdrawal effects when discontinuing the medication and thus remain on the treatment^[58]. Patients participating in a study by Mikocka-Walus *et al.*^[58] (2012) reported antidepressants to be a medication worth recommending to fellow IBD sufferers as long as the decision for their use was taken into consideration. Although studies exploring attitudes toward antidepressant use in larger samples or in samples recruited in primary care (and thus with possibly better-controlled IBD) are not available, studies conducted in the general population in primary care have shown a less receptive attitude toward antidepressants. For example, a survey of 1054 primary care users showed that over 20% of individuals did not disclose depressive symptoms to their doctors due to fear that antidepressants would be prescribed^[70]. Other studies have reported non-adherence to treatment with antidepressants due to patient beliefs or misconceptions about this type of medication^[71,72]. In light of these findings, the positive attitudes toward antidepressants identified in previous studies should be interpreted with caution and confirmed by larger quantitative studies with more representative IBD samples.

A systematic review of SSRIs indicated that although the medications were similar in efficacy, there were meaningful differences in their side effect profiles. These differences may guide decisions concerning the best choice for a particular patient^[73]. Nevertheless, studies report

serious adverse effects of selective serotonin reuptake drugs. Gastrointestinal side effects can be of particular concern to the IBD patient and have been reported for many antidepressant medications. These side effects are generally dose related and tend to decrease over the first weeks of treatment^[74]. Nausea and vomiting are more frequent with the one SNRI evaluated (venlafaxine) compared to the SSRIs as a group (fluoxetine, fluvoxamine, sertraline, paroxetine, citalopram; 34% *vs* 22%). Diarrhea is reported more often with sertraline than with the other SSRIs. Other side effects that have been cited as problematic when patients decide to discontinue antidepressant medication early in the course of treatment include drowsiness/fatigue (10%), anxiety (6%), headache (6%), insomnia (2.7%), and dizziness (2.7%)^[75]. Weight gain has been found to be a more significant problem with paroxetine and mirtazapine^[74], but it remains a concern with all SSRI medications^[76]. In some cases, there may be weight loss early in treatment and weight gain later^[74]. Decreased sexual functioning is a relatively common dose-related side effect of antidepressant medications and may be a concern for IBD patients, given the disease-related difficulties with intimacy and sexual functioning^[77]. It has been found that 60% to 70% of patients report reduced sexual functioning on SSRIs or SNRIs that does not improve with longer periods on the medication. Bupropion has the lowest rates of sexual dysfunction relative to other antidepressants^[76], and it is usually recommended as a substitute for SSRIs in case of side effects. Kast *et al.*^[78] (2001) reported two patients who achieved long-lasting remission of Crohn's disease while using bupropion. These investigators hypothesized that this outcome may have resulted from decreased TNF α , which is known to play a vital role in Crohn's disease. Phenzine and bupropion increase intracellular cyclic adenosine mono phosphate^[79], which, in turn, decreases TNF α . Because phenzine may cause a hypertensive crisis, bupropion is suggested to be a safer therapeutic option than phenzine. Interestingly, phenzine and other monoamine oxidase inhibitors have been noted to induce remission of rheumatoid arthritis, a disease in which, as in Crohn's disease, TNF α has a central role^[80]. Kast^[81] (2003) compared the use of bupropion and mirtazapine in patients with Crohn's disease. He speculated that both of these antidepressants have the potential to affect inflammatory responses: bupropion by lowering TNF α and mirtazapine by increasing its level. Therefore, according to the hypothesis of Kast^[81] (2003), there are theoretical reasons for recommending bupropion and cautioning against mirtazapine when treating depression in patients with Crohn's disease. Although Kast's explanations appear logical and are supported by other investigators^[82], their practical effectiveness needs to be experimentally confirmed in appropriate clinical studies^[55].

With regard to the risk of severe side effects, recent reports have raised the possibility of a greater risk of upper gastrointestinal (GI) bleeds with the use of certain antidepressants^[83-85]. Large-scale studies have found a moderately increased risk of GI bleeds with SSRIs as well as with

the SNRI venlafaxine^[86-88]. The use of acid-suppressing agents mitigated the higher risk, whereas the use of non-steroidal anti-inflammatory drugs (NSAIDs) increased the risk^[86]. The absolute risk of taking SSRIs was low, however; 2000 patients per year would need to be treated with SSRIs for one case of upper GI tract bleeding to be attributed to such drugs. The risk is higher when SSRIs and NSAIDs are taken together, with one patient in 250 experiencing a GI bleed that could be attributed to that combination^[86].

PSYCHOTHERAPEUTIC APPROACH

The first study regarding the effectiveness of psychotherapy for ulcerative colitis was conducted half a century ago^[89], but it was methodologically problematic. The effect of psychodynamic psychotherapy on patients with Crohn's disease was investigated in a randomized, multicenter study^[90]. The psychotherapeutic intervention consisted of psychodynamic psychotherapy (26 sessions) and autogenic training (17 sessions). After 2 years, relapse was not experienced by 23% of the control group and 30% of the therapy group. Twenty-nine percent of the control group and 17% of the therapy group had to undergo surgery. The therapy group had better somatic data than the control group, but this was not significant. Nevertheless, a meta-analysis was necessary for this review article given that the authors analyzed a respectable number of investigations addressing the subject of interest, such as the use of psychotherapy in IBD patients^[91,92]. Twenty-one studies were included in the analysis. Four studies did not report results in detail and could not be included in any of the pooled analyses. These 4 studies included a controlled trial on hypnosis in ulcerative colitis^[93], a trial on the effects of a multicomponent behavioral therapy package in 22 patients with IBD^[94], and a trial examining the effects of support meetings^[95].

Given its chronic nature and frequently reported poor quality of life for many patients, IBD is often associated with anxiety and depression. In addition to medical treatment, psychological intervention may be a crucial component of the treatment of IBD patients^[96,97]. Prior research has found that the disease course is gender dependent and that females may have a higher risk of disease activity relapse than males^[22,98]. Therefore, females may have more psychological symptoms. Furthermore, females more frequently become ill from Crohn's disease. Second, patients are stratified by treatment center. A distinction must be made between an academic setting and a peripheral setting. We expect that an academic hospital would treat more severe cases of IBD than a peripheral setting. Finally, the disease type is also used as a stratification factor. Previous research has found that CD patients undergo more surgical interventions and experience more disease exacerbations than ulcerative colitis patients^[99]. This finding indicates that CD is a more complex disorder than UC. In addition, CD patients report poorer quality of life and more anxiety symptoms than UC patients^[99,100]. Therefore, it is important that UC and CD patients are distributed evenly in the experi-

mental group and the waiting list control group^[101]. Of all psychotherapeutic interventions, cognitive behavioral therapy appears to be the most effective^[102]. This therapy posits that an individual's biased information processing leads to restrictive thoughts, feelings, and behaviors that can culminate in anxiety and depressive symptoms and, eventually, in psychiatric disorders. Cognitive behavioral therapy offers a well-developed intervention protocol that has been found to enhance quality of life and to decrease psychological distress. Its positive effect has been emphasized in individuals with other chronic somatic illnesses, such as chronic obstructive pulmonary disease, diabetes, and cancer^[103,104].

Cognitive behavior therapy was evaluated in an open trial of adolescents with major depression^[105,106] and a randomized controlled trial (RCT) of adolescents with subsyndromal depression^[107]. In all studies, treatment significantly reduced depression and improved global functioning. For individuals with a comorbid anxiety disorder, there was also a significant reduction in anxiety. The open trial did not find any change in illness severity posttreatment. The RCT reported a decrease in the number of individuals with moderate to severe disease posttreatment (29% pre-treatment *vs* 15% post-treatment), but the decrease was not significant. In an RCT of adults with IBD, a Spanish group reported clinically significant reductions in anxiety and depression following a structured cognitive-behavior therapy program that included components such as relaxation training, distraction, and cognitive restructuring^[108].

Reviews considering the overall effectiveness of psychological therapies for IBD patients not selected for anxiety or depressive disorders have reached a more modest conclusion: there may be some clinical benefit related to psychological functioning, with little support at this point for a significant direct impact on disease parameters^[109-111]. These studies incorporated a broad range of treatments (*e.g.*, psychodynamic therapy, supportive therapy, and cognitive behavioral therapies), some of which are not as well supported empirically. Further, the studies often involved unselected IBD patients or patients in remission with little elevated distress^[112,113], resulting in the potential for floor effects. Thus, unsurprisingly, psychological treatment is not indicated for all patients with IBD^[114]. The results of well-conducted studies imply that validated treatments should be targeted to high-risk subgroups, such as individuals with comorbid psychiatric conditions or elevated stress^[110,111]. Certainly, IBD patients may be quite susceptible to psychological treatment. Among individuals reporting high distress, there is a strong level of interest in receiving support for these concerns^[115]. A structured measure of desire for psychological care comparing patients with IBD and rheumatoid arthritis found that 2 to 3 times the number of IBD patients (31%) expressed an interest in receiving assistance compared to individuals with rheumatoid arthritis (13%)^[116]. Other indicators of receptivity included positive evaluations of treatment^[113] and low dropout rates despite the expectation of active participation^[104,106].

The appropriate choice of medication depends on many factors that are best tailored to the individual patient. Different galenic preparations are released at different sites and may have local activity [such as mesalazine (5-ASA) preparations, budesonide, or types of enemas]. The choice is influenced by the balance between drug potency and side effects, previous response to treatment (especially when considering treatment for a relapse or treatment for corticosteroid-dependent or corticosteroid-refractory disease), and the presence of extraintestinal manifestations (indicating the need for systemic therapy) or complications. Despite general agreement that treatment decisions for active Crohn's disease should be based on the site as well as the activity and behavior of the disease, the sample size is too small for statistically valid conclusions to be drawn from therapeutic trials when patients are stratified according to the site of disease^[117].

For mildly active IBD, budesonide 9 mg/d is favored because it is superior to both placebo (OR = 2.85, 95%CI: 1.67-4.87)^[118,119] and 5-ASA 4 g/d (OR = 2.8, 95%CI: 1.50-5.20)^[120], and it achieves remission in 51%-60% of individuals over 8-10 wk^[119,121-123]. Budesonide is preferred to prednisolone for mildly active CD because it is associated with fewer side effects, although a Cochrane systematic review has shown budesonide to be somewhat less effective than prednisolone (pooled OR for the five trials 0.69, 95%CI: 0.51-0.95)^[119]. For corticosteroid-related adverse effects, budesonide showed no difference from the placebo (OR = 0.98, 95%CI: 0.58-1.67)^[118,119] but had fewer side effects than prednisone (pooled OR = 0.38, 95%CI: 0.28-0.53).

When IBD is estimated as moderately active, budesonide or prednisolone are appropriate. Prednisolone is associated with a good clinical response (92% remission within seven weeks at a high dose of 1 mg/kg), but it commonly causes more side effects than budesonide^[117,124,125]. The dose of prednisolone is adjusted to the therapeutic response over a period of weeks. More rapid reduction is associated with early relapse. The consensus does not favor sole nutritional therapy, antibiotics (unless septic complications are suspected), infliximab (IFX) (until more data are available), or surgery for moderately active ileal CD as the first line therapy^[122].

Prednisolone or intravenous hydrocortisone is appropriate for the initial treatment of severe ileal CD. Azathioprine (AZA) (or mercaptopurine) should be added for individuals who have relapsed because it has a corticosteroid-sparing effect (NNT 3) and is effective at maintaining remission^[126,127]. Methotrexate should be considered an appropriate alternative if thiopurines cannot be tolerated, but it has specific contraindications, such as pregnancy. IFX is best reserved for patients who do not respond to initial therapy and for whom surgery is considered inappropriate. This does not mean that surgery takes precedence over IFX. IFX has emerged as a conservative option for cases with severe inflammatory activity, and it is in these cases that primary surgery will often be inappropriate. Surgical options should, however, be considered and discussed with the patient as part of

an overall management strategy. The stage at which IFX is introduced may change if it can be established whether early therapy changes the pattern of disease. The threshold for surgery for localized ileocecal disease is lower than for disease elsewhere, and some experts advocate surgery over IFX for disease in this location. Other experts advocate resection if medical therapy is not effective within two to six weeks. It may sometimes be difficult to distinguish between active disease and a septic complication, but antibiotics should be reserved for patients with a fever or focal tenderness or in whom imaging has indicated an abscess. Adding ciprofloxacin and metronidazole to budesonide has been shown to have no advantage over budesonide alone in active CD^[127,128].

BIOLOGICAL THERAPY

Regular infusions of IFX 5 or 10 mg/kg every eight weeks are effective at maintaining an IFX-induced response in nonfistulating CD (EL1b). Patients in a scheduled treatment strategy with regular infusions of IFX seem to fare better in many (but not all) clinical end points compared with patients in an episodic (on-demand) strategy^[129,130].

CONCLUSION

The psychopathological impact in IBD patients is evident, and the most common symptoms of depression and anxiety may affect the success of the desired gastroenterological therapy. Personality traits, cognitive impairment, and sleep deprivation are the tip of the iceberg of psychological problems in patients with IBD. The worsening of psychological problems is often followed with the same trend in GI symptoms of IBD and vice versa; that is, relapse of IBD symptomatology, such as blood in the stool, bloating, and pain, may increase psychological problems. This "vicious cycle" could be broken by involving a trained psychiatrist in the IBD treatment team. Nevertheless, some measures of precaution should be taken, such as avoiding bias in the group selection for both psychotropic medication and psychotherapy and an awareness of the possible side effects of antidepressant therapy, especially SSRIs, such as more frequent liquid stools, addiction, or sexual dysfunction problems. Finally, we suggest that psychiatrists and gastroenterologists work together to determine the final consensus of the IBD therapy to ensure success and to reduce side effects and relapse to the lowest possible rates.

Abstract

Despite the advent of biological products, such as anti-tumor necrosis factor- α monoclonal antibodies (infliximab and adalimumab), for treatment of moderate to severe cases of inflammatory bowel disease (IBD), most patients depend upon aminosalicylates as the conventional treatment option. In recent years, the increased knowledge of complex pathophysiological processes underlying IBD has resulted in development of a number of newer pharmaceutical agents like low-molecular-weight heparin, omega-3 fatty acids, probiotics and innovative formulations such as high-dose, once-daily multi-matrix mesalamine, which are designed to minimize the inflammatory process through inhibition of different targets. Optimization of delivery of existing drugs to the colon using the prodrug approach is another attractive alternative that has been utilized and commercialized for 5-aminosalicylic acid (ASA) in the form of sulfasalazine, balsalazide, olsalazine and ipsalazine, but rarely for its positional isomer 4-ASA - a well-established antitubercular drug that is twice as potent as 5-ASA against IBD, and more spe-

cifically, ulcerative colitis. The present review focuses on the complete profile of 4-ASA and its advantages over 5-ASA and colon-targeting prodrugs reported so far for the management of IBD. The review also emphasizes the need for reappraisal of this promising but unexplored entity as a potential treatment option for IBD.

INTRODUCTION

Anti-inflammatory activity of antitubercular drug 4-ami-

nosalicyclic acid (ASA) was first described by Lover in 1984. Since then, numerous clinical trials were carried out to establish its efficacy in left-sided and active/quiescent ulcerative colitis. It is 50% more potent than 5-aminosalicylic acid (5-ASA) against inflammation and does not produce 5-ASA-induced immunoallergic acute pancreatitis. 4-ASA is a stable and inexpensive alternative to 5-ASA in patients with acute pancreatitis. Despite all these positive findings, an extensive literature review surprisingly revealed few colon-targeting delivery systems for 4-ASA. The present review presents a complete profile of 4-ASA and its colon-specific prodrugs for inflammatory bowel disease (IBD).

IBD

Ulcerative colitis (UC) and Crohn's disease (CD) are two distinct idiopathic, chronic and relapsing inflammatory disorders of the gastrointestinal tract (GIT) that are grouped under the term IBD. Dysregulation of immune responses and upregulation of proinflammatory mediators are the two hallmarks of IBD that make it recurrent and nearly incurable^[1]. UC is characterized by distinct episodes of active and inactive disease in 80%-90% of patients. Repetitive cycles of active and quiescent disease with varying clinical patterns are also observed in CD^[2].

UC is one of the most common chronic inflammatory forms of IBD and is characterized by diffused mucosal inflammation, mainly limited to the large intestine and rectum. UC is characterized by diarrhea, rectal bleeding and abdominal pain. Inflammation of the rectum is common and generally extends proximally in a continuous fashion^[3]. CD is a patchy transmural granulomatous inflammation that affects any part of the GIT and has a predilection for the terminal ileum and colon^[4].

Despite the differences between UC and CD, both forms of IBD cause similar symptoms. UC is characterized by mild symptoms like progressive loosening of the stools, abdominal cramping, and diarrhea. In the severe form of the disease, patients may also experience weight loss, fatigue, and loss of appetite that may result in nutrient deficiencies, mucus in the stools, severe rectal bleeding, fever, and anemia. In CD, abdominal pain, diarrhea and weight loss are often the earliest signs; constitutional symptoms include malaise, lethargy, anorexia, nausea, vomiting and low-grade fever. CD can be complicated by the development of intestinal obstruction, fistulae and perianal disease. Fistulae develop in about one-third of patients. Perianal disease is a frequent complication of colonic and ileocolonic disease and is characterized by fissures, fistulae and abscesses^[5,6].

The pathogenesis of IBD is obscure and is considered to involve multifactorial interactions amongst genetic, immunological and environmental triggers. The key factor differentiating individuals with IBD from normal ones is their inability to downregulate the uncontrolled and chronic inflammatory state. The pathological findings associated with IBD are: an increase in certain inflammatory mediators, signs of oxidative stress, a deranged colonic milieu, abnormal glycosaminoglycan content of the

mucosa, decreased oxidation of short chain fatty acids, increased intestinal permeability, increased sulfide production, and decreased methylation. Although no single factor has been identified as the initial trigger for IBD, the etiological factors have been elucidated^[7]. However, no guaranteed curative therapeutic regimen has been developed so far.

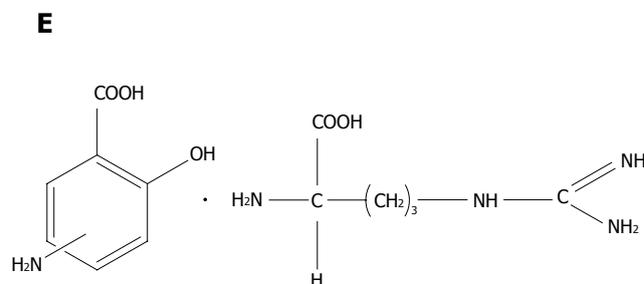

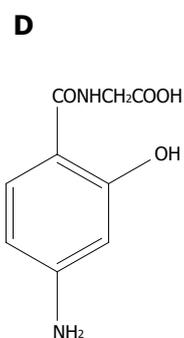

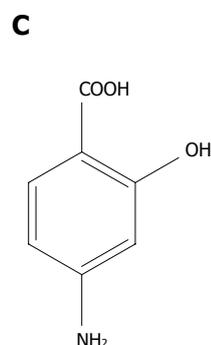

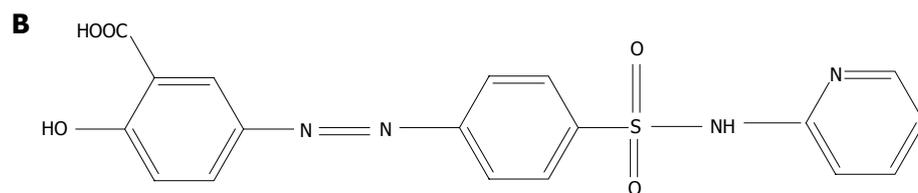

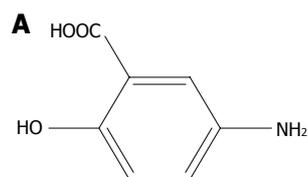

IBD THERAPY

Therapy for IBD has not seen major changes or breakthroughs during the past 4-5 decades and still revolves around the single nonsteroidal anti-inflammatory drug 5-ASA (Figure 1A) and its colon-targeting prodrug sulfasalazine (Figure 1B), followed by second-line treatment with steroids and immunomodulators, because reducing the extent and severity of colonic inflammation remains the primary focus of treatment. Antibiotics, probiotics, and nutritional supplements are used as supportive therapy. The use of anti-tumor necrosis factor monoclonal antibody (infliximab), recombinant anti-inflammatory cytokines, and related gene therapy are recent advances in the field^[8,9].

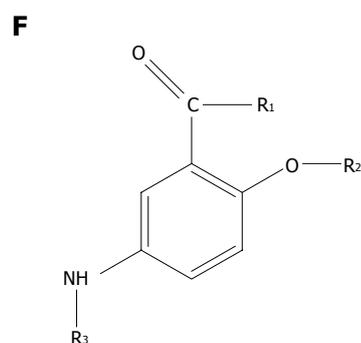

High and repeated doses of 5-ASA are necessary for maintenance and preventive therapy of IBD relapse. The majority of orally administered 5-ASA is readily and extensively absorbed from the stomach and small intestine, leaving a small amount that is transported to the colon. 5-ASA is absorbed from the upper GIT, causes many systemic side effects, and at the same time, results in poor bioavailability at the site of action, namely, the colon. Bypassing absorption in the upper GIT and targeting the delivery of 5-ASA to the colon by designing colon-specific prodrugs is the rational approach to improve the bioavailability at the site of action. The earliest reported colon-specific prodrug of 5-ASA is sulfasalazine, which is extensively prescribed for the treatment of UC. It is an azo conjugate of 5-ASA with sulfapyridine. However, its sulfapyridine part is used as a carrier and is completely absorbed through the colon and produces adverse effects such as hypersensitivity, impotency, blood dyscrasia, hepatitis, abnormal liver function tests and hepatic failure, agranulocytosis, leukopenia, thrombocytopenia, hemolytic anemia, and cyanosis^[10-12]. Although 5-ASA derivatives have an excellent safety profile, some undesirable effects may occur; the most prominent being immunoallergic acute pancreatitis^[13,14]. These side effects contraindicate the further use of all 5-ASA-containing drugs and pose a problem, because they limit treatment of acute phases of the disease to corticosteroids and relapse to immunosuppressants. 4-ASA has also been shown to be effective in IBD; in enemas or in oral formulations^[15-18].

4-ASA

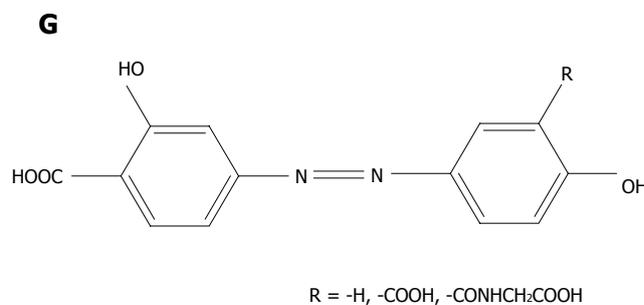

4-ASA (p-aminosalicylic acid, 4-amino-2-hydroxybenzoic acid) (Figure 1C), is a comparatively safe antitubercular agent that has been used for many years in resorbable high oral doses (ranging from 8 to 12 g/d) in multidrug-resistant tuberculosis. It has a bacteriostatic effect on

Mycobacterium tuberculosis and inhibits resistance against streptomycin and isoniazid. Chemically, it is distinguished from its position isomer 5-ASA by the position of the NH₂ group, although they share the salicylic acid backbone. Therefore, their method of synthesis is also different. 4-ASA is prepared by heating 3-aminophenol with potassium bicarbonate or ammonium carbonate under pressure, while 5-ASA is prepared by zinc/hydrochloric acid-assisted reduction of m-nitrosalicylic acid^[19]. 5-ASA is unstable and is degraded rapidly into a dark purple quinone containing tar but does not decarboxylate in the presence of moisture. However, 4-ASA is readily decarboxylated in the presence of moisture, but unlike 5-ASA, is slowly degraded into brown to purple material^[20,21]. In view of the well-recognized chemical distinction between 4-ASA and 5-ASA, it is surprising to discover that not only does 4-ASA have anti-inflammatory activity, but it is also about 50% more potent than 5-ASA.

Lover reported in animal models that 4-ASA may have anti-inflammatory properties comparable with those of 5-ASA^[22]. Numerous clinical studies have shown that 4-ASA is highly effective in the topical treatment of active ulcerative proctitis or active left-sided UC^[23]. Moreover, slow release tablets of 4-ASA are effective in active UC^[17]. 4-ASA has been suggested as an effective treatment for both active and quiescent UC. 5-ASA is well established for maintenance treatment of inactive UC. Moreover, recent studies suggest that 5-ASA may also be effective in maintaining remission in Crohn's colitis. The efficacy of 1 year maintenance treatment with oral 4-ASA (1.5 g/d, slow release tablets, *n* = 19) and oral 5-ASA (1.5 g/d, slow release tablets, *n* = 21) was compared in a randomized double-blind trial in patients with quiescent Crohn's ileocolitis. That study concluded that 4-ASA may be as effective as 5-ASA for maintenance treatment of quiescent CD and there were no differences in the severity of relapse between both treatment groups^[18]. In contrast to 5-ASA, no nephrotoxicity related to 4-ASA

has been reported. The only other study that compared these two compounds examined the response to topical treatment in left-sided colitis and showed that 4-ASA and 5-ASA were equally effective^[24].

Mechanism of action of 4-ASA

The anti-inflammatory mechanism by which the aminosalicylates exert their therapeutic action is not well established but several hypotheses have been documented. 5-ASA is a potent inhibitor of arachidonic acid metabolism, decreasing the synthesis of both leukotrienes and prostaglandins. Moreover, 5-ASA is a potent scavenger of free radicals^[25-27].

In contrast, 4-ASA does not seem to have an inhibitory effect on the lipoxygenation of arachidonic acid and is ineffective as a radical scavenger, but it is thought to act via nuclear factor (NF)-κB inhibition^[28]. Both drugs, however, inhibit *in vitro* activation of T and B lymphocytes by pokeweed mitogen in a dose-dependent manner^[29,30]. These findings suggest that the use of either drug in IBD may decrease the heightened state of lamina propria lymphocyte activation as a part of their therapeutic action^[31]. Moreover, mechanisms not affecting arachidonic acid metabolism and superoxide release may contribute to the therapeutic potential of both drugs in IBD^[32].

The most common side effects of 4-ASA include nausea, vomiting, and epigastric pain. Less frequent side effects are fever, joint pains, skin eruptions, and hepatitis; all of which may be attributed to hypersensitivity reactions^[33]. More serious side effects are seen only rarely, such as leukopenia, thrombocytopenia, and agranulocytosis^[33]. Because of the lower incidence of serious side effects, it was thought that delayed release formulation of 4-ASA at higher doses could be used in IBD with higher therapeutic efficacy than seen in previous studies. Schreiber *et al*^[18] concluded that oral 4-ASA may be as effective as 5-ASA for maintenance treatment of remission in CD. Several other studies have suggested that

4-ASA is effective in the treatment of active CD or UC; both as a topical formulation (enema) or as an oral slow-release tablet^[18].

The risk of cross intolerance reaction between 5-ASA and 4-ASA was evaluated by Gisbert *et al*^[34]. They reported three cases of 5-ASA-induced pancreatitis, with no recurrence of pancreatitis during subsequent treatment with 4-ASA enemas. They concluded that 4-ASA enemas are a safe and well-tolerated therapeutic alternative whenever 5-ASA-induced pancreatitis occurs. 4-ASA has been used in the treatment of mild to moderate UC in patients intolerant of sulfasalazine, and in the treatment of CD^[35]. It has been designated an orphan drug by the United States FDA for use in these conditions^[36].

Pharmacokinetics of 4-ASA

4-ASA is readily absorbed from the GIT. It is distributed into various tissues and fluids including peritoneal fluid, pleural fluid and synovial fluid in concentrations approximately equal to plasma concentrations of the drug. Cerebrospinal fluid concentrations of 4-ASA are reported to be 10%-50% of concurrent plasma concentrations of the drug in patients with inflamed meninges. 4-ASA is 50%-73% bound to plasma proteins. The plasma half-life of 4-ASA is about 1 h. Plasma concentrations of the drug are not substantially affected by renal or hepatic insufficiency; however, the half-lives of the inactive metabolites may be prolonged in patients with impaired renal function. 4-ASA is inactivated in the intestinal mucosa and liver primarily by acetylation. The major metabolites are N-acetyl-p-aminosalicylic acid and p-aminosalicylic acid. 4-ASA and its metabolites are excreted in urine by glomerular filtration and tubular secretion. After 2 h in simulated gastric acid, 10% of the dose of unprotected (nonenteric coated) aminosalicylic acid is decarboxylated to form m-aminophenol, a known hepatotoxin^[37].

Dose of 4-ASA

4-ASA is about 50% more potent than 5-ASA, therefore, its therapeutic dose is about 60% of the effective dose of sulfasalazine or 5-ASA on a molar basis. The recommended daily dosage of sulfasalazine is 3-4 g (6-8 tablets) for adults and 40-60 mg/kg/d (divided into 3-4 doses) for children (aged > 6 years). On this basis, a dosage regimen of 0.5-0.75 g of 4-ASA divided into two or three doses can be used^[38].

Contraindications of 4-ASA

4-ASA is contraindicated in patients who are hypersensitive to ASA or who have severe renal diseases, hepatic disease or gastric ulcers^[39].

Interactions of 4-ASA

4-ASA impairs GI absorption of rifampin, reduces rate of acetylation of isoniazid, decreases the GI absorption of digoxin, and enhances the hypoprothrombinemic effect of oral anticoagulants. Concomitant probenecid increases the serum concentration of 4-ASA, ammonium chloride increases probability of crystalluria during thera-

py, and diphenhydramine impairs its absorption.

Pregnancy

4-ASA is a FDA pregnancy category C drug.

Adverse effects of 4-ASA

The most frequent adverse effect of 4-ASA is GI disturbance including nausea, vomiting, abdominal pain and diarrhea. The acidic carboxylic group of 4-ASA is responsible for the gastrointestinal (GI) irritation. Occurrence of peptic ulcers and gastric hemorrhage is rare. Adverse GI effect can be minimized in patients by administration of the drug with food or discontinuation of the drug when symptoms are severe. Malabsorption of vitamin B₁₂, folic acid, iron and lipids is also observed. Reported hypersensitive reactions include fever, skin eruptions of various types, pruritis, vasculitis, exfoliative dermatitis, joint pain, eosinophilia, leucopenia, agranulocytosis and thrombocytopenia^[39,40].

COLON-SPECIFIC PRODRUGS OF 4-ASA

Extensive clinical studies have shown the effectiveness and safety of 4-ASA for the topical treatment of active ulcerative proctitis or left-sided UC^[23]. It presents many advantages over 5-ASA, such as: more stability, more potency, and absence of incidences of pancreatitis, but shares the same drawback of fast and extensive absorption in the upper GIT, before it reaches the colon. This is due to its weakly acidic nature (pKa 3-4), which results in its ready absorption in the upper GIT^[16]. Studies by Selby suggest that 4-ASA is a stable, inexpensive alternative to 5-ASA for the topical treatment of UC or for linking to carrier molecules for release in the colon^[24].

Many colon-specific prodrugs of 5-ASA have been cited in the literature, while the prodrug approach has been only sporadically applied for colonic delivery of 4-ASA, for reasons that are not known. The possible reason could be the steric problem of 4-ASA, due to which it cannot be linked with same polymers (*e.g.*, dextran, chitin, hydroxymethyl cellulose or synthetic polymers) as 5-ASA or to other polymers (*e.g.*, cyclodextrins) using the same methods that have been used for 5-ASA^[20].

Zhao *et al*^[41] were the first to design a colon-targeting amide prodrug of 4-ASA (Figure 1D) with the nonessential amino acid glycine for the treatment of IBD. The amide prodrug was synthesized by reacting amino and hydroxyl protected 4-ASA acyl chloride with glycine, followed by deprotection. *In vivo* experiments on rats suggested that 4-aminosalicylylglycine showed more curative effect than 4-ASA.

Wallace *et al*^[42] have patented L-arginine salts of 4-ASA and 5-ASA (Figure 1E) for inflammatory conditions of the GIT, and for irritable bowel syndrome (IBS). They claim that the salt is more effective in reducing the inflammation in the colon compared to individual drugs or L-arginine, as demonstrated from overall greater reduction in the colitis-associated edema, granulocyte infiltration, and body weight loss with enhanced free-radical scavenging and more potent antioxidant activity, thus

providing a synergistic effect. They ascribe the synergistic effect to the ability of arginine to act as a source of nitrogen for NO, which is a potent vasodilator that attenuates intestinal tissue damage^[43,44].

A US Patent describes 5-ASA and 4-ASA prodrugs as having an H₂S-releasing moiety linked via an azo, ester, anhydride, thioester or amide linkage (Figure 1F) for the treatment of IBD and IBS and chemoprevention of colon cancer^[45]. The basis for using H₂S-releasing carriers in this design is their encouraging and beneficial pharmacological profile. There is documented evidence for antinociceptive effect of H₂S in the GIT by activating K_{ATP} channels and smooth muscle relaxant activity in intestinal tissue^[46].

Based on the design of sulfasalazine and using azo bond chemistry, Zhao *et al*^[47] have reported the synthesis of prodrugs of 4-ASA with salicylic acid, hydroxybenzene and N-salicyloyl glycine (Figure 1G), aiming to target 4-ASA to the colon for management of IBD with enhanced efficacy and fewer side effects. However, we could not find any reports of activity of these prodrugs in any of the experimental models of IBD.

Oxidative stress is one of the key players in the pathogenesis of IBD causing cellular injury and colonic inflammation^[48]. Keeping this in mind, Sheng *et al*^[49] designed azo-linked colon-specific prodrugs of 4-ASA (Figure 1H) with several substituted phenols such as m-nitrophenol, salicylamide, o-chlorophenol, m-methylphenol, o-methylphenol, o-nitrophenol and o-dihydroxybenzene, possessing antioxidant properties. Their main aim was to achieve co-antioxidant effects of 4-ASA and substituted phenol that would result in higher reducibility and synergistic free-radical scavenging. These phenols were chosen on the basis of their reducibility, electronic and steric factors. 4-(3',4'-dihydroxyphenyl) azobenzene-2-acetylsalicylic acid, 4-(2'-methyl-4'-hydroxyphenyl) azobenzene salicylic acid and 4-(3'-methyl-4'-hydroxyphenyl) azobenzene salicylic acid were reported to be the compounds with maximum anti-inflammatory and antioxidant activities.

Dhaneshwar *et al*^[12] have explored mutual amide prodrug strategy for 5-ASA with several amino acids. Applying the same concept further to 4-ASA, they have reported its amide conjugates with D-phenylalanine (Figure 1I) and L-tryptophan (Figure 1G). The proposed mechanism of activation was enzymatic by the action of N-acyl amidases secreted by colonic bacteria. The amino acids used in the design were nontoxic carriers like D-phenylalanine and L-tryptophan, possessing wound healing and anti-inflammatory activities. The prodrugs furnished 86%-91% release of 4-ASA in rat fecal matter in 20 h. Their curative effect was investigated in a 2,4,6-trinitrobenzene-sulfonic-acid-induced experimental colitis model in rats. Pancreas, liver and stomach of rats were studied by histopathology for the assessment of any adverse reactions. The prodrugs were found to possess significantly superior safety profile than sulfasalazine, oral 4-ASA and 5-ASA, with comparable efficacy to sulfasalazine.

In an innovative attempt, colon-specific 4-ASA-D-

glucosamine amide prodrug (Figure 1K) was developed by Dhaneshwar *et al*^[50] out of the urgent need to search for such alternate options that would not produce 5-ASA-induced pancreatitis and sulfapyridine-induced hepatitis. The hypothesis was to offer supplementation of D-glucosamine that would suppress activation of intestinal epithelial cells, thus helping to maintain the integrity of the colonic architecture. The protective effect of this prodrug was compared with 5-ASA-D-glucosamine conjugate as well as standard drugs like sulfasalazine, 4-ASA and 5-ASA on the course of 2,4,6-trinitrobenzene sulphonic acid (TNBS)-induced colitis. The mitigating effect of 5-ASA prodrug was comparable to that of sulfasalazine, while that for 4-ASA prodrug was moderate. However, hepatitis or pancreatitis was not seen with 4-ASA prodrug^[50].

A polymeric prodrug of 4-ASA (Figure 1L) with an acrylic polymeric system and degradable ester bonds, such as hydroxy propyl methacrylate, was synthesized and evaluated for colon-targeted drug delivery by Yadav *et al*^[51]. In the first 2 h, 40.01% release was observed in rat fecal matter at pH 7.4, which was followed by sustained release of 93% over a period of 12 h. The authors propose that the developed delivery system could be useful for controlled release, prolonged transit time, and colon-targeted delivery of 4-ASA.

A macromolecular colon-targeting ester prodrug of 4-ASA with β -cyclodextrin as a promo moiety was reported very recently by Vadnerkar *et al*^[52]. Interestingly, 20%-23% release of 4-ASA was observed in the stomach and small intestinal homogenates, while the prodrug was found to be resistant to pH-dependent hydrolysis at pH = 1.2 and 7.4. Almost 68% and 92% release was obtained in rat cecal and fecal matter, respectively. The prodrug demonstrated a moderate ameliorating effect on TNBS-induced colitis as compared to sulfasalazine or 4/5-ASA administered rectally, but it was similar to that with orally administered aminosalicylates. Partial activation of the prodrug in the upper GIT homogenates causing incomplete transport of 4-ASA to the site of action could be responsible for its moderate effect. However, the prodrug was reported to be safe, producing no harmful effects on the stomach, liver or pancreas of rats^[52].

In another innovation, Suneela *et al*^[53] designed four azo prodrugs of 4- and 5-ASA using the same aminosalicylates as carriers. As known already, olsalazine is a dimer of 5-ASA, which is synthesized by coupling diazo salt of 5-ASA with salicylic acid, which upon reduction by azo reductase, generates two molecules of 5-ASA. However, the azo prodrugs reported by Suneela *et al*^[53] are different in the sense that they are prepared by coupling diazo salt of either 4-ASA or 5-ASA with 4-ASA or 5-ASA as carriers in all possible permutations and combinations. This results in prodrugs that, upon activation by azo reductase reduction, generate only one molecule of either 4-ASA or 5-ASA, while the other molecule released is a diaminosalicylic acid and not another molecule of aminosalicylate. These prodrugs were designed to target the colon affected with IBD. Due to their improved hydrophilic nature, the prodrugs had minimum absorption in the

upper GIT. The prodrugs were considerably stable when incubated in the upper GIT. Approximately 68%-91% release was obtained on incubation with rat cecal matter. Amongst the series of four prodrugs, the prodrug of 4-ASA with 4-ASA (4A-4AAz) (Figure 1M) at a dose of 53 mg/kg was found to alleviate all the quantifying markers of TNBS-induced experimental colitis in Wistar rats. Due to absence of adverse effects in the stomach, liver and pancreas, it could be a promising alternative for IBD patients intolerant to 5-ASA-induced pancreatitis and sulfapyridine-induced adverse effects observed with sulfasalazine^[53].

CONCLUSION

Despite possessing more stability and potency than 5-ASA in treating UC, without the evident risk of 5-ASA-induced pancreatitis, 4-ASA or its colon-targeted prodrugs remain unexplored and neglected when it comes to the management of IBD patients intolerant to 5-ASA. There is a need to investigate this promising compound, explore its untapped potential, and develop safe but effective systems for its targeted delivery to the colon, for better management of IBD as well as other local diseases of colon like IBS and colorectal cancer.

Abstract

Ulcerative colitis (UC) is an inflammatory bowel disease affecting large bowel with variable clinical course. The history of disease has been modified by the introduction of biologic therapy, in particular Infliximab (IFX), that has demonstrated efficacy in inducing fast symptoms remission, promoting mucosal healing and maintaining long-term remission. However, surgery is still needed for UC patients: in case of failure of medical therapy and if acute complications or a malignancy occurred. Surgical treatment is associated with a short-term post-operative mortality and morbidity respectively of 0%-4% and 30%. In this study we systematically analyzed: the role of IFX in reducing the colectomy rate, the risk of post-operative morbidity in pre-operatively IFX-treated patients and the cost-effectiveness of IFX therapy. Four of 5 analyzed randomized controlled

trials demonstrated that therapy with IFX significantly reduces the colectomy rate. Moreover, pre-operative treatment with IFX doesn't seem to increase post-operative infectious complications. By an economic point of view, the cost-effectiveness of IFX-therapy was demonstrated for UC patients suffering from moderate to severe UC in a study based on a cost estimation of the National Health Service of England and Wales. However, the argument is debated.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory disease, of an unknown etiology, affecting the large bowel. It is characterized by a contiguous mucosal inflammation

starting in the rectum and proximally progressing in continuity in the colon for a different distance. According to the Montreal Classification, which describes the maximal macroscopic extent of the disease at colonoscopy, the distribution of UC is commonly classified as: proctitis, left-sided and extensive colitis^[1-4]. Disease activity is grouped into remission, mild, moderate, or severe but the clinical course of UC is variable and can range from a long-standing remitting to a refractory or fulminant disease^[5-11]. Solberg *et al.*^[5], in a population-based cohort study of 843 patients with inflammatory bowel disease, enrolled in South-Eastern Norway and systematically followed-up at 1, 5 and 10 years after diagnosis, identified 4 different clinical patterns: (1) initial high activity to remission or mild severity (55%); (2) chronic intermittent symptoms (37%); (3) continuous symptoms (6%); and (4) initial low activity to increased severity (1%)^[12]. The main symptoms of UC are bloody diarrhea and abdominal pain, associated with urgency and tenesmus. UC is conventionally treated with a step-up approach, based on the severity and extent of the disease, including various agents such as 5-aminosalicylates, corticosteroids and immunosuppressants (including thiopurines and cyclosporine). The primary aims of medical therapy in UC should be inducing and maintaining long-term remission, achieving mucosal healing, minimizing steroid-dependence, avoiding serious complications (hospitalization and surgery) and improving patients' quality of life^[13-17]. However, standard therapy is not always able to achieve these goals and patients become steroid-dependent or experience frequent or severe relapse, with consequent increased risk of hospitalization and surgery. The history of disease has been partially modified by the introduction of biologic therapies. Infliximab (IFX) has demonstrated efficacy in inducing fast symptoms-remission, promoting mucosal healing and maintaining long-term remission^[17-20]. It is currently approved for patients with moderate to severe UC who have incomplete response, are intolerant or have any medical contraindications to corticosteroids and/or immunomodulators^[21-24]. It is also recommended as rescue therapy in severe steroid-refractory disease^[25-27] and in steroid-dependent patients^[28,29].

Surgery is still needed for UC patients, in case of failure of medical therapy, occurrence of acute complications (such as fulminant colitis, toxic megacolon and bowel perforation) or development of malignancy. Since its first description (1978), restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) represents the gold standard of surgical treatment of UC: all the colon and rectum are removed and a J pouch is created with terminal ileum and anatomized to the anal canal. This restorative operation, avoiding a permanent stoma, maintains intestinal continuity and preserves the patient's body image^[30-33]. Moreover, the introduction of minimally invasive approach significantly contributed in improving the acceptance and tolerability of this procedure^[34-37], reducing the rate of post-operative adhesions and post-operative hospital stay and improving cosmetic results^[38-41].

However, even if in skilled hands, proctocolectomy with IPAA is not without risk and is associated with an estimated short-term mortality ranged between 0% and 4% and a morbidity rate of about 30%, with an incidence of pelvic sepsis ranging from 5% to 24% and a re-surgery risk of about 16%^[42,43].

If surgery represents a definitive solution for cessation of symptoms, withdrawing medical therapies and reducing the cancer-risk, it is not free of long-term post-operative morbidity (as pouchitis, fecal incontinence, female fecundity or fertility) with a relevant impact on patients' quality of life^[44-46]. Population-based studies have reported a 10-years cumulative risk of colectomy ranging between 9%-30%, with some differences among countries. Approximately, 4% to 9% of UC patients will require colectomy within the first year of diagnosis and, subsequently, the risk of colectomy increases of 1% per year^[47-50].

It is still under debate whether, in the long-term, the biological therapies could be a valid approach for organ-sparing, rather than an expensive option to delay surgery. Aim of this review was to evaluate the real impact of biological therapy on the rate of colectomy in UC patients.

A review of the literature searching for the terms "anti-tumor necrosis factor- α (TNF- α)", "infliximab" matched with the terms "ulcerative colitis" and "surgery" was performed, using PubMed, MEDLINE, EMBASE and Cochrane databases. All relevant articles (both experimental and observational studies) in English between January 2000 and July 2013 were reviewed.

Therapy with infliximab and rate of colectomy

We identified five randomized controlled trials^[51-54], one meta-analysis^[55] and six observational studies^[56-61] following literature search. Characteristics of the studies are summarized in Table 1.

RANDOMIZED CONTROLLED TRIALS AND META-ANALYSIS

Two randomized, double-blind, placebo-controlled trials, ACT 1 and ACT 2, demonstrated the efficacy of IFX for induction (week 8) and maintenance (week 30 and week 54 for ACT1) of clinical response and remission in patients with moderate-to-severe UC, despite the use of conventional therapy^[51]. Further analysis, from ACT 1-2 open-label extension phase, focused on colectomy and hospitalization rates during follow-up to 54 wk. Compared with placebo, the cumulative incidence of colectomy through 54 wk for IFX was significantly lower (10% *vs* 17%, $P = 0.02$), with an absolute risk reduction of 7% (95%CI: 0.01-0.12, HR = 0.59). Moreover, in IFX-treated patients were recorded fewer (compared to placebo group) UC-related hospitalizations and surgical procedures per 100 patient-years of treatment (40 *vs* 20, $P = 0.003$; 34 *vs* 21, $P = 0.03$ respectively)^[52].

Previous controlled smaller studies have addressed the risk of colectomy in patients with severe UC treated

RCT: Randomized controlled trial; Pts: Patients; FU: Follow-up; IFX: Infliximab; UC: Ulcerative colitis; Y: Yes; N: Not.

with IFX as rescue therapy. In 2001 Sands reported data on 11 patients with severe steroid-refractory disease, of whom 8 treated with IFX and 3 with placebo. After 2 wk, all patients treated with placebo underwent to surgery, while only 50% of patients receiving IFX needed surgery; however, the sample size was too small to detect a statistically significant benefit^[53]. Later, 45 patients with moderate to severe UC were randomized to IFX or placebo (24 *vs* 21 respectively) both after four day from the start of corticosteroid treatment. In the placebo group more patients (14/21, 66.7%) than IFX group (7/24, 29.2%) had a colectomy ($P = 0.017$; OR = 4.9; 95%CI: 1.4-17) within 3 mo after randomization^[25]. After a follow-up of 3 years, 50% of patients in the IFX group and 76% in the placebo group had a colectomy ($P = 0.012$)^[54].

Recently, Costa *et al*^[55] presented data from a meta-analysis on the benefit of IFX in reducing hospitalization and/or major surgeries in patients with inflammatory bowel disease. They analyzed 11 studies: 5 randomized controlled trials (RCTs) and 6 observational studies. In the RCTs, IFX treatment was associated with a significant 43% odds reduction of overall major surgery risk (OR = 0.57; 95%CI: 0.37-0.88) with a number-to-treat to avoid colectomy of 11 (95%CI: 6-51) for 1.2 years. However, a not significant increase was found in pooled results from observational studies (OR = 1.43; 95%CI: 0.65-3.13). The authors concluded that this discrepancy could be explained by the heterogeneity of observational studies, including patients at high risk of colectomy due to more severe disease and refractoriness to previous treatment.

OBSERVATIONAL STUDY

The first data on the long-term risk of colectomy were reported in a study of 314 UC patients from Italy. Among them, 52 (16.5%) patients had severe UC and were treated with intravenous corticosteroids for a median of 7 days. Of 15 patients who did not respond,

11 received IFX with short-term clinical benefit and 4 underwent urgent colectomy. In the long-term follow-up, another 6 patients underwent elective colectomy for a disease relapse, with a total colectomy rate, following the acute flare-up, of 19%. The long-term colectomy risk was not different between patients treated with IFX and steroid-responsive patients (18% *vs* 11%, respectively), as IFX was able to avoid urgent colectomy, but not to reduce the risk of elective surgery^[56]. The risk of long-term colectomy in severe UC was also evaluated in a smaller Danish study of 52 UC patients. Nineteen (37%) patients had severe UC and 7 of them (37%) underwent colectomy after a median follow-up of 22 mo (range 4-57 mo). Among the remaining patients with a chronic refractory UC, the colectomy rate was 21%. The authors concluded that IFX can avoid colectomy in two-thirds of the patients with acute, severe UC, but the beneficial effect on colectomy rate in chronic, refractory UC seems less convincing^[57]. Long-term data on colectomy in UC patients treated with IFX come from referral centers studies. In the Leuven's cohort of 121 refractory UC patients (patients with acute severe attack, refractory to intravenous steroids were excluded), 21 patients (17%) came to colectomy and 68% of initial responders achieved a sustained clinical response during a median follow-up of 33 mo (IQR 17-49.8). Lack of short-term clinical benefit, high values of baseline C-reactive protein (CRP) and previous intravenous steroid or cyclosporine treatment were identified as independent predictors of colectomy^[58]. These results are similar to those reported in a French multicenter study, in which, among 191 patients who received at least one IFX infusion, 36 patients (18.8%) underwent colectomy during a median follow-up of 18 mo (IQR 8-32). Independent predictors of colectomy were: no clinical response after IFX induction, high baseline CRP value, previous treatment with cyclosporine and IFX indication for acute severe UC^[59]. Furthermore, other experience supported history of hospital admission as an independen-

dent predictor of the need of colectomy^[60,61].

Peri-operative infliximab and post-operative outcome

An increasing number of patients undergo to surgery after experienced biologic therapy. There is an emerging concern on the safety profile of IFX in the peri-operative setting in potentially pre-surgical patients. Many groups have reported their experiences for UC patients and there is not an agreement on the impact of these drugs on post-operative complications^[62-67]. The main characteristics of the studies are summarized in Table 2. Recently, Yang *et al*^[68] performed a high quality meta-analysis based on five studies, including 706 patients, who were treated with IFX before restorative procto-colectomy with IPAA. The authors did not find a strong association between pre-operative treatment with IFX and short-term infectious complications (OR = 2.24), but it was associated with a significantly increased risk of short-term overall post-operative complications (OR = 1.80). However, these results need to be interpreted with caution. The subgroup analysis was underpowered to assess the nature of these complications because of the small sample size and heterogeneity of the included studies (end-points, patients' characteristics and indication, type and timing of surgery).

Infliximab and surgery: Cost-effectiveness

An important issue of IFX therapy is its cost-effectiveness. IFX is often perceived to be an expensive treatment option for patients with IBD. Tsai *et al*^[69] made a cost-effectiveness analysis in UC patients based on a cost estimation of the National Health Service of England and Wales for the year 2006-07. At analysis of responders patients only, therapy with IFX was associated at an additional 0.753 quality-adjusted life year (QALYs) at an additional cost of £20662 compared to standard care without IFX; the estimated incremental cost per QALY gained for IFX against standard care was £27424. At analysis of remission patients, therapy with IFX derived an additional 0.387 QALYs at an additional cost of £7615 compared with standard care without IFX. The estimated incremental cost per QALY gained for IFX against standard care was £19696. The authors conclude that therapy with IFX appears to be a cost-effective treatment option for

adult patients suffering from moderate to severe UC. In a recent study, Park *et al*^[70] created a Markov model simulating 2 cohorts of 21-year-old patients with severe UC, following them until 100 years of age or death, comparing early colectomy with IPAA strategy to the standard medical therapy strategy (including IFX). In this study standard medical therapy accrued a discounted lifetime cost of \$236370 per patient; in contrast, early colectomy with IPAA accrued a discounted lifetime cost of \$147763 per patient. QALY-gained for standard medical therapy was 20.78, while QALY-gained for early colectomy with IPAA was 20.72; the resulting incremental cost-effectiveness ratio was approximately \$1.5 million per QALY-gained. So, the authors concluded that early colectomy with IPAA after diagnosis of severe UC reduce health care expenditures and provides comparable quality of life compared exhaustive standard medical therapy. Only an extremely low quality of life after IPAA could maintain the standard medical therapy strategy as the optimal management strategy in severe UC.

CONCLUSION

IFX has demonstrated efficacy in inducing and maintaining clinical and endoscopic remission in the long run. IFX can also avoid urgent colectomy in patients with severe acute UC refractory to intravenous steroids. The real impact of biological therapy on the natural history of UC is still controversial, whereas it is not clear if it allows avoidance of colectomy or rather than a delay. The median colectomy risk for UC patients treated with IFX is about 10%-20% in both RCTs and observational studies, with higher rate for patients with severe acute attack. Data from RCTs support the efficacy of IFX in reducing the risk of surgeries in the long-term, but none was designed to assess IFX effects on surgeries. Real life data from referral centers do not confirm this issue, but each study includes patients with different baseline characteristics and risks of colectomy. From these evidences, it seems that patients with more severe disease, high inflammation burden, refractoriness to intravenous steroids and/or cyclosporine and history of hospitalizations, have higher risk of colectomy. So, it is necessary for physicians taking in account the risks and the benefits of medical

versus surgical therapy, concerning about cost and side effects of medications, cost and morbidity of surgery and patients' quality of life. Prospective, specifically designed studies are necessary to assess the long-term risk of colectomy in UC patients treated with IFX.

Abstract

Recent findings demonstrate the common genetic basis for many immune-mediated diseases, and consequently, the partially shared pathogenesis. We collected these findings and reviewed the extension of these overlaps to other disease characteristics. Two autoimmune diseases were selected that also share

the specific target organ, the bowel. The etiology and immunopathogenesis of both conditions characterized by chronic intestinal inflammation, inflammatory bowel disease (IBD) and celiac disease (CeD), are not completely understood. Both are complex diseases with genetics and environment contributing to dysregulation of innate and adaptive immune responses, leading to chronic inflammation and disease. CeD constitutes a particular disease because the main environmental and genetic triggers are largely known. IBD comprises two main clinical forms, Crohn’s disease and ulcerative colitis, which most likely involve a complex interplay between some components of the commensal microbiota and other environmental factors in their origin. These multifactorial diseases encompass a broad spectrum of clinical phenotypes and ages of onset, although the clinical presentation often differs depending on childhood or adult onset, with greater heterogeneity commonly observed in adults.

INTRODUCTION

The immune system is essential for defense self against external pathogens, and to maintain homeostasis. Dysregulation between those two processes contributes to development of immune-mediated diseases. These diseases represent an important cause of chronic illness, with a consequent high impact on public health. Different diseases can be found under this term, including autoimmune and inflammatory conditions. In these cases, it is common to find a specific organ affected, as occurs in inflammatory bowel disease (IBD) and celiac disease (CeD), both involving damage of the gastrointestinal tract. The gut is highly exposed to exogenous and endogenous antigens and controlled inflammation is a key process in maintaining homeostasis. Different factors can contribute to alter this equilibrium and to disrupt health status. Decades of research have focused on identifying those contributing factors and the reason why one specific disease develops. Recent findings demonstrate the extensive overlap in the genetic basis of immune-mediated diseases, including IBD and CeD.

The present review summarizes the current knowledge of different features related to the two major clinical forms of IBD, Crohn's disease (CD) and ulcerative colitis (UC), and CeD, paying special attention to the overlaps and differences between them. These two diseases share genetic risk factors, and it would be interesting to know whether this overlap also extend to other disease characteristics in order to gain knowledge about common pathogenic mechanisms and possible shared treatments.

CeD is one of the most frequent immune-mediated diseases. In Europe and the US the current prevalence of CeD is around 1 per 100 individuals^[1,2] and a similar prevalence probably exists worldwide, although it has not been as extensively studied^[3,4]. IBD shows a lower prevalence with values ranging from 26 to 199 per 100000 individuals in CD and from 37 to 246 per 100000 individuals in UC^[5]. The prevalence of IBD is higher in developed countries and urban areas. A recent increase in the prevalence of both CeD and IBD has been described as a consequence of several factors^[6-8]. In CeD these factors include the development of more effective diagnostic tools^[9].

IBD affects both sexes similarly and the highest incidence is found between the second and the fourth decade of life. CeD seems to be more frequent in women^[10], although this depends on the age at onset^[11]. CeD can be diagnosed in individuals at any age, but it appears more frequently during childhood^[12].

The prevalence of CeD in patients with IBD is not clear. There are several cases in the literature describing the coexistence of both diseases in the same family or even in the same patient^[13-18]. However, some authors consider that this is an incidental association and the

prevalence of CeD is similar between IBD patients and the general population^[19]. In fact, CD and UC patients are not considered a risk group for routine CeD screening.

CLINICAL PRESENTATION

A wide spectrum of clinical symptoms characterizes IBD and CeD. In addition, differences in the clinical presentation can be found depending on the age at diagnosis.

IBD manifests during childhood or adolescence in at least 20% of patients. This presentation is commonly more severe and extensive than that observed in adult-onset disease^[20]. In CD, involvement of the upper gastrointestinal tract is more frequently observed at early onset^[21]. Bloody, mucous diarrhea is the almost universal hallmark of UC, although additional symptoms may be also present. The initial symptoms of CD are more subtle and varied, partly as a result of its diffuse and diverse anatomical location. The constellation of abdominal pain, diarrhea, poor appetite and weight loss constitutes the classical presentation of CD in all age groups, and is the mode of presentation in nearly 80% of children and adolescents (with or without extraintestinal manifestations). Abdominal pain is the most common single symptom at presentation^[22,23].

In CeD, the presentation may be variable, but diarrhea, which may be acute or insidious in onset, is the most common presenting symptom in children. On the contrary, mild and nonspecific gastrointestinal symptoms are common in adults with CeD, with intermittent diarrhea, diffuse abdominal pain, dyspepsia, constipation, asthenia, flatulence, bloating or abdominal discomfort being the most frequently observed symptoms. In adults, iron-deficiency anemia without response to any appropriate treatment is a frequently observed sign^[24,25].

Extraintestinal manifestations may be present in IBD and CeD. In IBD, most of the extraintestinal manifestations are shared by CD and UC. They may accompany intestinal symptoms or, less commonly, precede or overshadow them. These manifestations seem to be related to activity (relapse/remission) and location of the disease. Although children and adults may share extraintestinal manifestations, their frequency is usually different. Ocular lesions seem to be less common in young patients and a childhood-onset of IBD, particularly CD, may represent a specific risk factor for long-term morbidity from clinical osteoporosis^[26].

In CeD, extraintestinal manifestations are usually a consequence of nutrient malabsorption and may coexist with digestive symptoms. It is currently accepted that extraintestinal signs and symptoms are common and may be the only presenting manifestation, mainly in adults^[25,27].

Table 1 summarizes the main clinical features for IBD and CeD. Several overlapping characteristics can be observed. Diarrhea and abdominal pain are digestive symptoms commonly observed in both groups, but they also share several extraintestinal manifestations, as iron-deficiency anemia, short stature or osteoporosis. Some

Table 1 Main clinical features associated with inflammatory bowel disease and celiac disease

| IBD | CeD |
|---|---|
| Intestinal mucosal involvement | Intestinal mucosal involvement |
| Clinical heterogeneity | Clinical heterogeneity |
| Depending on location and severity | Depending on degree of gluten sensitivity and amount of gluten ingested |
| Symptomatic (relapses/remission) | Commonly symptomatic (early onset) |
| | Mono or oligosymptomatic (late onset) |
| Digestive signs or symptoms | Digestive signs or symptoms |
| Diarrhea (\pm rectorrhagia) | Diarrhea |
| Abdominal pain (less predominant in UC) | Abdominal distension |
| | Abdominal pain |
| | Constipation |
| | Dyspepsia |
| | Recurrent vomiting |
| | Pyrosis and regurgitation |
| | Irritable bowel syndrome with diarrhea predominance |
| Extraintestinal manifestations | Extraintestinal manifestations |
| Refractory iron-deficiency anemia | Refractory iron-deficiency anemia |
| Short stature | Short stature |
| Poor appetite | Failure to thrive |
| Weight loss (less prevalent and extreme in UC) | Dermatitis herpetiformis |
| Sexual maturation delay | Vitamin B12 deficiency |
| Pneumopathies | Neurological symptoms |
| Psychological syndromes | Menstrual disturbances |
| Joints: arthritis and arthralgias (the most common in both CD and UC) | Bleeding diathesis (malabsorption of vitamin K) |
| Ocular: acute episcleritis, uveitis, orbital myositis | Paresthesia, cramps and tetany (hypocalcemia) |
| Skin: erythema nodosum, pyoderma gangrenosum | Hepatobiliary system: hypertransaminasemia |
| Hepatobiliary system: primary sclerosing cholangitis (less predominant in CD), autoimmune hepatitis (unusual) | Osteopenia, osteomalacia and osteoporosis |
| Renal system: ureteral obstruction, hydronephrosis, urinary stones | Edema, ascites and anasarca (hypoproteinemia) |
| Vascular system: thrombocytosis, hyperfibrinogenemia, elevated factor V-VII, depression antithrombin III | Hypopituitarism and adrenal insufficiency |
| Bone: osteoporosis (less predominant in UC) | Recurrent mouth ulcers |
| Severe complications | Severe complications |
| Malnutrition with weight loss and emaciation | (In refractory CeD or in patients who do not follow a GFD) |
| Fistulae | Collagenous CeD |
| Abscesses | Ulcerative jejunitis |
| Obstruction | T cell lymphomas |
| Perforation | |
| Dysplasia and colorectal cancer | |

IBD: Inflammatory bowel disease; CeD: Celiac disease; UC: Ulcerative colitis; CD: Crohn's disease; GFD: Gluten-free diet.

differences are also observed. CeD patients can remain asymptomatic, in contrast with the symptomatic IBD patients.

The major complications of CeD, ulcerative jejunitis and intestinal lymphoma, cause more severe clinical manifestations that may resemble CD, such as acute and persistent abdominal pain, weight loss, signs of intestinal obstruction or gastrointestinal bleeding, fever or signs of marked malnutrition^[28]. It has been suggested that complicated CeD should be considered in CD patients who do not respond to immunosuppressive or biological treatments^[29].

SEROLOGY

As frequently observed in autoimmune diseases, CeD is characterized by the presence of autoantibodies, which are currently included in the definition and diagnostic guidelines for CeD^[30]. Transglutaminase type 2 (TG2) is the major autoantigen in CeD and the target antigen for

endomysial antibodies (EMA) and anti-TG2 antibodies. Therefore, those two antibodies are the most specific for CeD diagnosis. Although a high correlation exists between anti-TG2 and EMA antibodies, the highest specificity is observed for EMA, because anti-TG2 can be present in individuals with other conditions, including CD and UC. However, it is difficult to know the frequency of anti-TG2 antibodies in IBD patients because the studies developed with that aim have yielded different results, probably partially caused by the wide variety of commercial kits used^[18,19,31-35].

On the contrary, the presence of specific antibodies is not a common feature in IBD. Two major groups of serological markers have been described in these patients: those against microbial antigens and autoantibodies. Their relevance for IBD diagnosis is not as strong as for CeD, but they are useful to differentiate CD from UC patients. Among the antibodies against microbial agents, those against *Saccharomyces cerevisiae* (ASCAs) are the most extensively studied and they are related to CD. These anti-

bodies have also been described in CeD patients but they disappear after taking a gluten-free diet (GFD), which is supposedly due to the association of ASCAs with inflammation of the small bowel, and therefore, questions their specificity for CD^[36]. Regarding autoantibodies, anti-neutrophil cytoplasmic antibodies have a high prevalence in UC^[37].

ETIOLOGY

The causes underlying the development of IBD and CeD have not been completely unraveled, but both diseases show a multifactorial origin with a complex genetic and environmental involvement.

Environment

In this regard, CeD is the best-understood immune-mediated disease because the main environmental factor involved is largely known. CeD is triggered by ingestion of dietary wheat gluten or analogous proteins present in other cereal grains, mainly rye and barley.

Although gluten intake is necessary to develop CeD, other environmental factors may play a role. Infections have been related to CeD development. Specifically, rotavirus^[38] and hepatitis B and C virus infections have been observed in CeD patients^[39]. A protector role for breastfeeding at the moment of gluten introduction has also been described^[40].

Viruses have also been implicated in the origin of IBD. The hygiene hypothesis establishes that lack of early exposure to microbial agents due to severe hygienic conditions could increase the likelihood of developing autoimmune and allergic disorders, and it has been used to explain the rising prevalence of IBD observed in industrialized countries^[41]. Although to a lesser extent, this hypothesis has also been proposed for CeD^[42]. Recent genetic findings support a role of pathogens in IBD and CeD.

Other environmental factors contributing to IBD risk are smoking and appendectomy. The effect of cigarette smoking is opposite in both forms of IBD: beneficial in UC and harmful in CD^[43,44]. For appendectomy, it seems that it reduces the risk of UC^[45,46].

Vitamin D levels, diet, hormone use and stress have also been postulated as risk factors for one or both main forms of IBD, but they need to be further investigated^[47].

The environmental influence in IBD pathogenesis seems to involve complex mechanisms because its role in disease risk may be modified by other factors such as sex, geographic region, or genetic background^[47]. Moreover, environmental factors are probably influencing the natural history in addition to the origin of these diseases.

Microbiota

An altered microbiota composition seems to be a common phenomenon in intestinal inflammatory disorders. In IBD, an abnormal response to the normal commensal flora of the bowel is considered to cause the disease^[48,49]. The role of the microbiota in the pathogenesis of IBD was

first suggested by studies in mice, which showed a lack of experimental colitis in animals kept in a germ-free environment^[50]. Since then, numerous works have been published in this field. Although no final conclusions can be drawn, it is clear that no single pathogen is associated with the disease, and quantitative besides qualitative changes in the microbiota influence disease development^[51,52].

Microbiota alterations have also been related to CeD risk, again with quantitative and qualitative changes reported^[53,54]. In CeD, an altered microbial diversity depending on the clinical presentation has been recently described, with marked differences between patients showing classical gastrointestinal symptoms and those with extraintestinal manifestations^[55].

The influence of diet (including breastfeeding) and cigarette smoking or the increased risk of disease in children born by Cesarean section have been postulated to be mediated through changes in the microbiota. These changes have also been linked to the increasing incidence of IBD and CeD in recent decades.

Nowadays it is clearly accepted that the intestinal microflora differs between healthy individuals and those showing CeD or IBD. It has been claimed that those differences could be a consequence of the disease. Among other functions, commensal bacteria of the gut contribute to protection against external pathogens and participate in the maturation of the mucosal immune system, supporting their role in the etiology of these diseases. Recent genetic studies are also concordant with a causal role^[56]. Nevertheless, a complex situation exists because the microbiome can be altered as a result of infection or pathological processes.

Genetics

The genetic contribution to disease risk differs between CeD and IBD. The highest values are observed for CeD (75% of concordance between monozygotic twins)^[57], followed by CD (44%-50%) and UC (16%)^[58].

Knowledge of the genetic basis of immune-mediated diseases has dramatically increased in recent years with the advent of genome-wide association studies (GWAS). These studies analyze hundreds of thousands of common [minor allele frequency (MAF) > 5%] genetic variants (single nucleotide polymorphisms, SNPs) across the human genome, looking for variants with a different frequency between individuals showing the disease and the general population. They need high numbers of affected and unaffected individuals that provide enough statistical power to find significant associations. Initially, GWAS included around 1000 individuals with each phenotype, but this number has been increased in recent GWAS. Moreover, follow-up of the nonsignificant most associated SNPs and meta-analysis of previously published largescale studies have also been performed. Additionally, cross-disease meta-analyses that combine data of previous GWAS have been performed to identify susceptibility loci common to different immune-mediated diseases. Looking for variants shared between CD and CeD, these

studies have identified four new shared loci^[59]. New approaches to study the genetic basis of IBD and CeD include the Immunochip Project, also based on the presence of a common genetic basis for immune-mediated diseases but focused on deep replication and fine mapping^[56,60]; and the recently published high-throughput exon-sequencing of 25 GWAS risk genes^[61].

GWAS are not based on prior hypothesis determined by previously available information (*e.g.*, gene function, previous association studies, and animal models) and the studied SNPs are selected to cover a high proportion of gene variation across the genome. With this approach, unexpected genes have been identified as related to disease susceptibility. The newly identified genes point out functional pathways involved in particular phenotypes, some of them also previously unexpected.

IBD and CeD show both a complex genetic basis that is characterized by the presence of numerous common susceptibility factors contributing a small risk to disease susceptibility. In IBD, no factor seems either necessary or sufficient to develop the disease, as it is commonly observed in complex diseases. However, CeD constitutes a particular case. It is commonly accepted that the main genetic risk alleles, those coding the HLA-DQ2 or -DQ8 heterodimers, are necessary although not sufficient to develop CeD, because they are present in almost all CeD patients.

The influence of the HLA region in disease risk marks more differences between IBD and CeD. This region, located on 6p21, contains hundreds of genes with immunological functions and it is responsible for the strongest association signals observed in most immune-mediated diseases. However, HLA influence is different between IBD and CeD, and these two diseases are at opposite ends of the spectrum. HLA loci are the main genetic susceptibility factors for CeD and they are responsible for 40% of the genetic risk; in addition, their functional involvement in disease pathogenesis is well established. On the contrary, a weak and a weak-moderate association is found in CD and UC, respectively. Moreover, the HLA alleles associated with IBD are markers of still unknown HLA risk variants^[62].

Additional to the HLA region, 163 loci have been associated with IBD risk: 110 common to CD and UC, 30 specific for CD and 23 for UC^[56]. For most of the specific loci, the same direction of effect exists in the two forms of IBD and only two loci (*NOD2* and *PTPN22*) have shown significant opposite effects between CD and UC^[56]. In CeD, 40 susceptibility loci have been described^[60,61]. The number of associated SNPs is even higher, because one SNP does not always account for the risk overall attributed to one locus. The causal variant or even the genes responsible for the reported associations remain unknown for many of these regions. In CeD, the individual gene involved is known for half of the associated regions. In both diseases, independent effects of the associated variants have been reported, as well as correlation of genotypes for many SNPs with expres-

sion levels, and an important role of noncoding variants. This last observation has been recently underscored by the discovered negligible impact of rare variants (MAF < 5%) within exons^[61], until now considered as potential relevant contributors to disease risk. The different number of variants associated with IBD and CeD is probably mirroring the different sample sizes used in the studies.

The large sample sizes required by GWAS have been achieved thanks to international collaborations, but this necessary effort may overlook genetic factors associated with specific populations. A new genetic region (22q13.2) has been recently associated with CD risk in a GWAS performed in a Southern European population^[63]. This encourages us to study homogeneous groups of patients (in terms of ethnicity or clinical features) to look for new genetic susceptibility factors.

GWAS have found similar genes associated with IBD when considering childhood or adult onset^[56], although the severe inflammation that mutations in interleukin (*IL*)-10RB cause in children suffering extreme phenotypes, identified through other kind of genetic studies, must be highlighted^[64]. In CeD, studies considering the age of onset remain to be performed.

Seventy percent (113/163) of the IBD loci are shared with other complex diseases, and 12% (20) with CeD. The picture is different when the number of CeD risk regions is used as a reference; 50% of the CeD loci are shared with IBD. Independent of the real percentage, which is impossible to ascertain until scientific advances provide us with a full knowledge of the genetic basis of these diseases, the existence of a common genetic background is evident.

Despite the huge advance in the genetic basis of these chronic diseases, only 14% of the genetic variance is known in CD, 7.5% in UC, and approximately 50% in CeD. The highest values of CeD are due to the strong influence of the HLA, which accounts for 40% of the genetic variance.

IMMUNOPATHOLOGY

The model of immunopathogenesis for CeD has long been established. Dietary gluten induces innate and adaptive immune responses. The innate immune response is characterized by the gluten-induced production of IL-15, which acts on intraepithelial lymphocytes and licenses them to kill epithelial cells. This increases permeability and facilitates that gluten peptides pass through the impaired epithelial barrier into the lamina propria. In this compartment, TG2 induces deamidation of gluten-derived peptides, creating epitopes that bind efficiently to HLA-DQ2/DQ8 heterodimers on antigen-presenting cells, and thus elicits a T-cell response^[65,66].

GWAS findings suggest four main processes underlying CeD: T-cell development in the thymus, innate immune detection of viral RNA, T and B cell co-stimulation (or co-inhibition) and cytokines, chemokines and their receptors. It seems now that a specific enrichment for genes involved in natural killer (NK) cell activation

and interferon γ production also exists. Thus, besides T cells, other cell types may have special relevance in the pathological process, as B cells, NK cells or neutrophils, but the previous model of pathogenesis remains valid and basically unchanged.

In IBD, the model of pathogenesis is based on the dysregulation of the normally controlled immune response to commensal bacteria, which could be precipitated by infection or by defects in the mucosal barrier. This involves infiltration of several cells of the immune system and chemokine and cytokine production, which in turn exacerbate the dysfunctional immune response and activate either T helper (Th)1 or Th2 cells in the gut mucosa, associated with CD and less conclusively with UC, respectively^[67].

GWAS results have been crucial in advancing our understanding of IBD pathogenesis. Two major findings were the unsuspected role of autophagy and the implication of the Th17 immune response. The genes associated with CD and UC risk point to shared pathways involved in the pathogenesis of these two inflammatory conditions.

The genes shared between IBD and CeD are mainly related to the innate immune response against pathogens and to the activation of the immune system to produce inflammation, including T-cell differentiation and immune-cell signaling. Specific pathways like autophagy and Th17 response seem to be only involved in IBD. Autophagy is responsible for degradation of intracellular structures, but it is also important in removal and recognition of invasive pathogens. Its involvement in CD etiology was suggested after the association of *ATG16L1*, *LRRK2* and *IRGM* with CD risk. The implication of Th17 cells marks an important difference between IBD and CeD, because they have been associated with susceptibility to numerous immune-related diseases but not to CeD^[60,68], which is still considered to be a Th1-mediated disease. Th17 cells are involved in defense against extracellular pathogens but they act as potent inducers of autoimmunity through their involvement in tissue inflammation and are probably linked to innate and adaptive responses^[69]. *IL23R* was the first Th17 gene found in genetic association studies, but it was followed by numerous related loci: *IL22*, *IL17A*, *IL17F*, *TYK2*, *JAK2*, *CCR6* and *STAT3*.

In Figure 1, all the genes associated with IBD and CeD in large scale studies are shown. They have been grouped according to their predominant role in three major functions: innate immune response, adaptive immune response, and epithelial barrier function. All the genes with a different role or with still unknown function have been grouped as “others”. The highest number of shared genes between IBD and CeD is observed for genes involved in adaptive immunity. The specific association with UC risk for most of the loci involved in barrier function is noteworthy.

Both CeD and IBD need an environmental stimulus that activates the immune system and leads to the pathological process. The amplification of the immune re-

sponse involves release of cytokines, molecules involved in intracellular signaling, and transcription factors. GWAS have found many genes coding for products related to these processes. The initial stimulus to trigger the disease is different and it seems to be crucial in developing one or other disease, probably in combination with the genes specific for each disease.

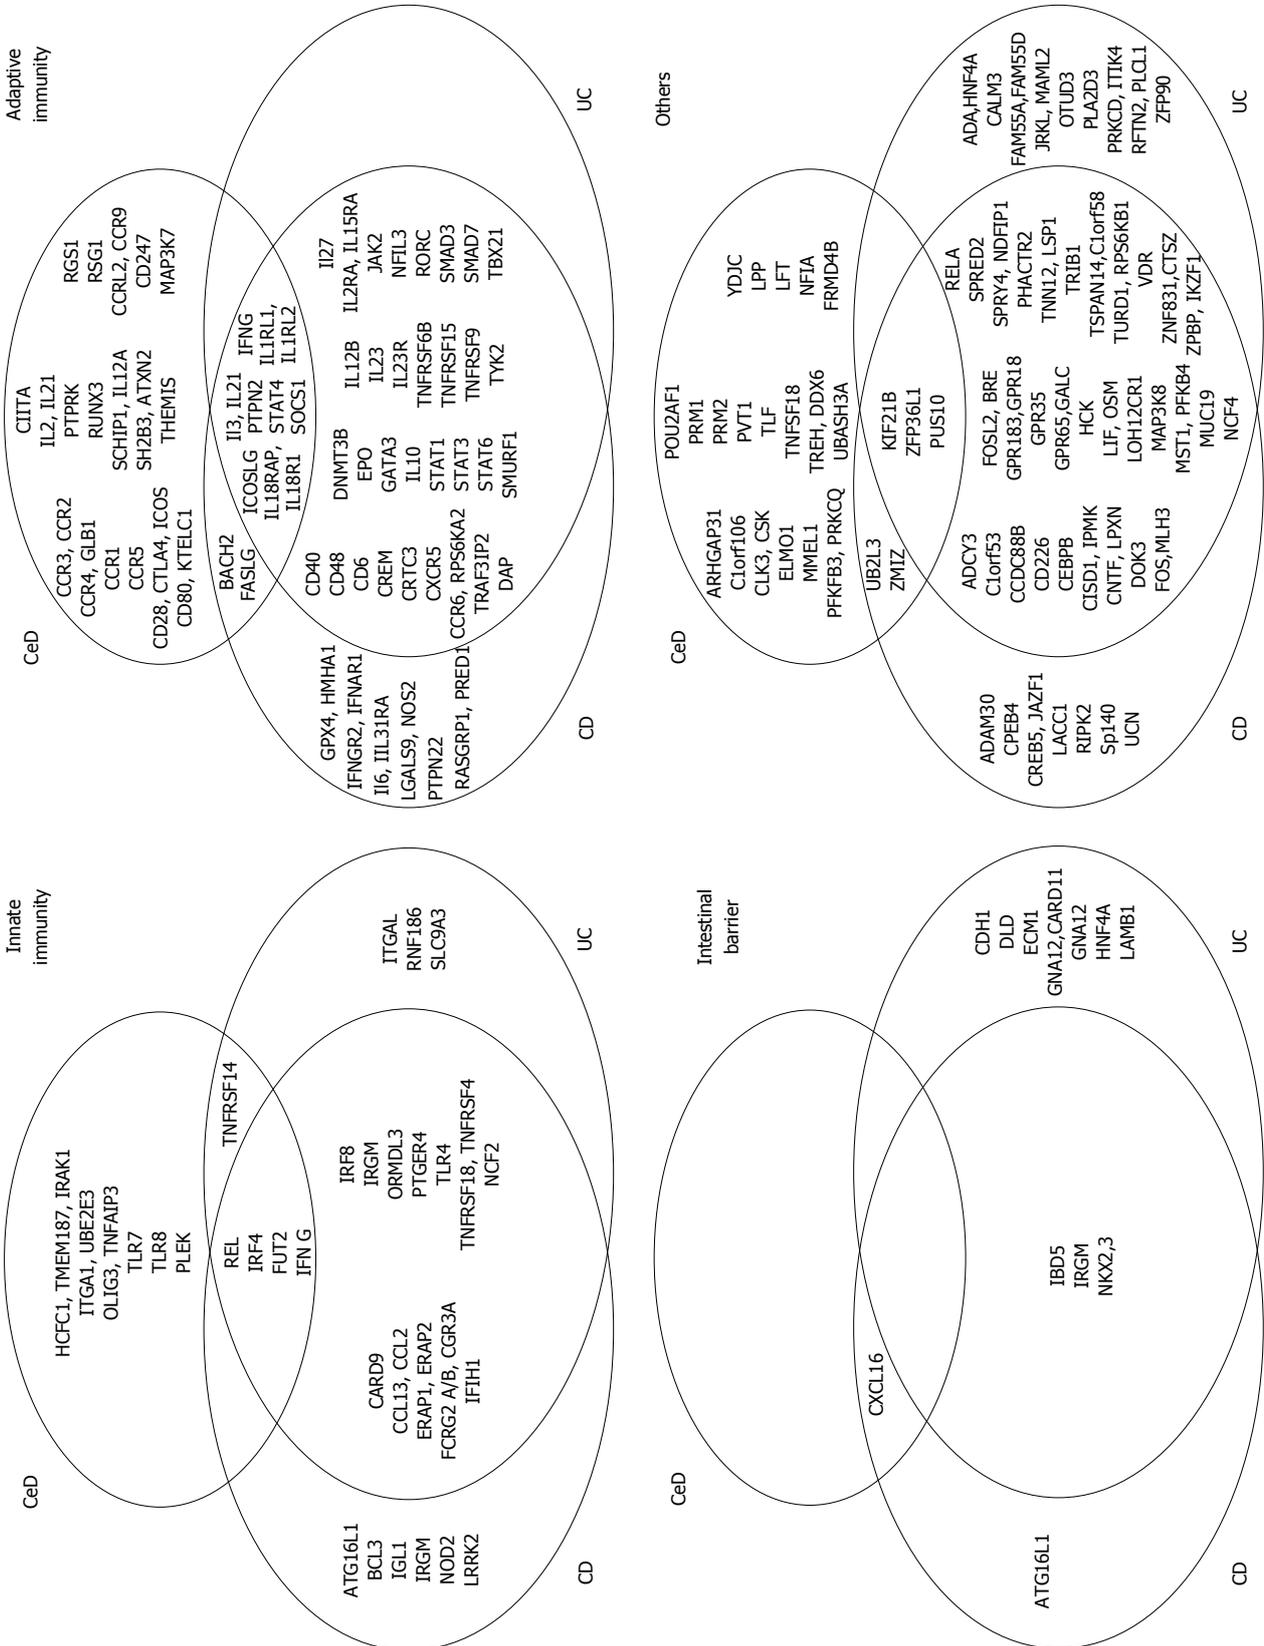

Despite the scientific revolution prompted by GWAS, some issues still hamper a direct translation to disease pathogenesis: (1) in many regions, the genetic variant or even the gene responsible for the association remain to be identified; (2) many of the proteins detected are pleiotropic, with different possible roles and with still unknown functions; and (3) the immune responses, with complex networks of interactions that include specific molecules inducing up- or downregulation of the same functional pathway depending on the microenvironment.

TREATMENT

There is no single effective treatment for all IBD patients. Therefore, different treatments are used to manage the disease, often several of them in the same individual. Conventional immunosuppressive drugs, including azathioprine, mercaptopurine and methotrexate, are the initial treatment for IBD. When the immunosuppressive therapy losses efficacy or the patient continues with active disease, alternative biological therapies based on tumor necrosis factor (TNF)- α blockade are commonly used in IBD. In recent years, infliximab and adalimumab became standardized biological therapies in IBD. Infliximab is a chimeric monoclonal IgG1 anti-TNF α and it is indicated in refractory CD^[70,71] and in acute severe UC^[72]. Despite the high efficacy of infliximab, some patients do not respond to this treatment. An alternative therapy for these patients is adalimumab, an humanized TNF- α antibody, which decreases the risk of developing antibodies^[73-75]; one of the causes of non-response to infliximab^[76]. Based on the results of genetic studies, new biological therapies are currently being tested or are already in clinical use in IBD patients^[77-80].

In CeD, treatment is a lifelong GFD. This is an effective and safe treatment, but there is a small group of patients who do not respond. Refractory CeD patients (RCeD) are defined as those showing persistent villous atrophy, crypt hyperplasia, and high levels of intraepithelial lymphocytes despite strict adherence to a GFD for > 12 mo^[81,82]. There are two categories of RCeD, depending on the presence (type I) or not (type II) of aberrant intraepithelial T cells^[83]. RCeD patients develop higher severe malnutrition combined with an increased risk for developing enteropathy-associated T-cell lymphoma^[84]. Immunosuppressive therapy, similar to that used in IBD patients and based on azathioprine, cyclosporine or anti-TNF- α , is the current treatment for RCeD^[84,85]. In the bad prognosis of RCeD, primarily type II RCeD, chemotherapy shows moderate clinical, histological and hematological efficacy^[86,87].

Figure 1 Immunopathology. Overlap between inflammatory bowel disease (IBD) [considering the two major forms Crohn's disease (CD) and ulcerative colitis (UC)] and celiac disease (CeD) for the loci identified by large scale genetic studies. Genes are grouped according to their participation in three main functional blocks: innate immunity, adaptive immunity, and intestinal barrier. All the genes with still unknown function are grouped as "others". Note that some genes can be found in more than one functional group.

New therapeutic approaches in CeD have increased in recent years. These therapies are focused on engineering gluten-free grains, decreasing the intestinal permeability by blockade of the epithelial zonulin receptor, inhibiting gluten peptide presentation by HLA-DQ2 antagonists, and inducing oral tolerance to gluten^[88].

In both disorders, a delay in diagnosis or in proper treatment carries an increased risk of future complications. However, individuals with different autoimmune diseases can present similar symptoms, which sometimes makes it difficult to establish early diagnosis and treatment.

Reconstitution of the physiological flora remains an interesting therapeutic aim for both IBD and CeD.

FUTURE PERSPECTIVES

Despite the great advances in our understanding of IBD and CeD, we are still far from being able to anticipate who will develop some of these immune-mediated conditions. Ingestion of gluten and alterations in the commensal microbiota seem to be the main environmental triggers for CeD and IBD, respectively. However, it remains to be understood what is further needed to break the tolerance in specific individuals and develop disease.

Nevertheless, current advances related to the functional pathways involved in IBD are being useful in finding new drug targets. The shared molecular pathways between IBD and CeD open new possibilities for therapy in RCeD. With the identification of the causal variants in all the associated regions new clues about disease pathogenesis will be obtained and new treatment targets will appear.

Future epidemiological studies are necessary to gain knowledge about the genetic and environmental interactions that contribute to disease development. Better knowledge of the role of pathogens will also be useful to look for new therapies or prevent disease. Although numerous factors make it difficult to study the environmental contributing factors, some genes seem to point to specific triggers. Prospective as well as retrospective studies involving individuals with alterations in those genes could be performed, which aim to advance the role of those specific environmental triggers.

The multifactorial nature of the etiology of CeD and IBD likely hides great complexity due to the interplay among all the factors involved. The role of the microbiota seems to be influenced by interaction with external pathogens, but also by host genetic factors. More research is needed in this field, which will likely contribute to identifying where the missing heritability lies and a better understanding of the immunopathogenesis.

A broad range of symptoms characterize CeD and IBD. Subgroups of patients combining their clinical features with the presence of a similar genetic profile may help to establish more homogeneous groups to perform the next steps in research.

CONCLUSION

IBD and CeD are two immune-mediated disorders with

a partially common genetic background. Overlaps between both disorders are also observed for other specific features; however, these conditions do not seem to be more strongly correlated with each other than with other immune-related disorders. The common clinical manifestations are probably a consequence of the target organ affected: the gut. Shared genetics originates the altered immune response and the inflammation characterizing both diseases. Nevertheless, comparison of these two diseases helps to understand what is specific for each disease and what is common. Common features may be useful to understand better the inflammatory processes and to look for new shared therapies.

Abstract

Patients with inflammatory bowel disease (IBD) may have an increased risk of venous thrombosis (VTE). PubMed, ISI Web of Knowledge and Scopus were searched to identify studies investigating the risk of VTE and the prevalence of acquired and genetic VTE risk factors and prothrombotic abnormalities in IBD. Overall, IBD patients have a two- to fourfold increased risk of VTE compared with healthy controls, with an overall incidence rate of 1%-8%. The majority of studies did not show significant differences in the risk of VTE between Crohn's disease and ulcerative colitis. Several acquired factors are responsible for the

increased risk of VTE in IBD: inflammatory activity, hospitalisation, surgery, pregnancy, disease phenotype (*e.g.*, fistulising disease, colonic involvement and extensive involvement) and drug therapy (mainly steroids). There is also convincing evidence from basic science and from clinical and epidemiological studies that IBD is associated with several prothrombotic abnormalities, including initiation of the coagulation system, downregulation of natural anticoagulant mechanisms, impairment of fibrinolysis, increased platelet count and reactivity and dysfunction of the endothelium. Classical genetic alterations are not generally found more often in IBD patients than in non-IBD patients, suggesting that genetics does not explain the greater risk of VTE in these patients. IBD VTE may have clinical specificities, namely an earlier first episode of VTE in life, high recurrence rate, decreased efficacy of some drugs in preventing further episodes and poor prognosis. Clinicians should be aware of these risks, and adequate prophylactic actions should be taken in patients who have disease activity, are hospitalised, are submitted to surgery or are undergoing treatment.

INTRODUCTION

The possible association between inflammatory bowel disease (IBD) and venous thrombosis (VTE) was first reported in 1936 by Bargen *et al*^[1], who described 18 patients with thromboembolic disease (predominantly venous) from among more than 1000 patients treated for IBD at the Mayo Clinic. Since that time, several publications have suggested that patients with IBD have an increased risk of VTE, including deep venous thrombosis (DVT), pulmonary emboli, portal vein thrombosis, cerebral venous sinus thrombosis, Budd Chiari syndrome and retinal vein thrombosis^[2-5]. The overall incidence rate of VTE in IBD patients has been estimated to be 1%-8%, although necropsy studies report an incidence of 39%-41%^[2-5]. One systematic review^[4] and one meta-analysis^[3] showed a higher VTE risk in IBD patients, even after correction for known prothrombotic factors such as smoking and obesity^[3]. Nevertheless, other studies, such as that of Grip *et al*^[6], show a similar risk between IBD and the background population. However, in that report, where the incidence of VTE in the IBD cohort (0.15% per year) was comparable with that of the background population, the differences in age between the groups could have affected the conclusions^[6].

It is important to stress that most of the evaluated studies were retrospective. When the IBD population was compared with other patients or healthy controls, most of the classical prothrombotic risks were not assessed, and therefore a bias could have been present. Therefore, the aim of this review was to assess the risk of VTE and the prevalence of acquired and genetic VTE risk factors and prothrombotic abnormalities in IBD.

SEARCH STRATEGY

A systematic review was conducted on published articles that assessed the risk of VTE and the prevalence of acquired and genetic VTE risk factors and prothrombotic abnormalities in IBD through a literature search of PubMed, ISI Web of Knowledge and Scopus. This search was performed in September 2013 using the following medical terms: “venous thrombosis IBD”, “acquired venous thrombosis risk factor IBD”, “genetic venous thrombosis risk factor IBD”, “coagulation IBD”, “fibrinolysis IBD”, “platelets IBD” and “endothelium IBD”. Additionally, a comprehensive search of reference lists of all review articles and original papers achieved by this method was performed to identify additional reports that could be included in the final analysis. Potential studies were initially screened by title and abstract. Potential

exclusion criteria to reduce the risk of bias and unnecessary observations included case reports on single patients, book chapters and studies exclusively on arterial thrombosis. A total of 207 articles were studied to construct this review.

RISK OF VTE IN IBD

A summary of the controlled studies comparing the risk of VTE in IBD patients with the risk of VTE in non-IBD patients is presented in Table 1.

General risk

In one of the earliest studies evaluating the incidence of VTE in IBD patients, 61 out of 7199 patients (0.84%) developed VTE during an 11-year period from January 1970 to December 1980 at the Mayo Clinic, with similar rates of VTE observed in patients with Crohn's disease (CD) and ulcerative colitis (UC)^[7]. In 2001, Bernstein *et al*^[8] published the first study on the risk of VTE in IBD in a large population-based study using health administrative data from the province of Manitoba, Canada, in which they applied validated case ascertainment definitions of CD and UC (Table 1). The incidence rate for VTE in IBD patients was 45.6 per 10000 persons-year of follow-up, and IBD patients were 3.5 times more likely to develop VTE than the controls. Similar rates of VTE were observed in CD and UC and in males and females. The highest rates of VTE were observed among patients over 60 years old; however, the highest incidence rate ratio (IRR) for VTE was among patients younger than 40 years old (IRR = 6.02, 95%CI: 3.92-9.12). In 2004, Miehsler *et al*^[9] compared the risk of VTE in patients with IBD and other chronic inflammatory diseases (rheumatoid arthritis and coeliac disease) with matched controls (Table 1). The subjects with IBD had a significantly higher risk of VTE compared with the matched controls [prevalence: 6.15% *vs* 1.62%; odds ratio (OR) = 3.6, 95%CI: 1.7-7.8], whereas the subjects with rheumatoid arthritis or coeliac disease had a risk of VTE similar to that of the controls. In 2007, the risk of VTE among 17 chronic illnesses was evaluated (Table 1)^[10]. The relative risk (RR) of VTE was nearly twofold higher in IBD patients than in the matched controls (OR = 1.84, 95%CI: 1.29-2.63), with only cancer and heart failure carrying a greater risk of VTE than IBD.

IBD, activity, hospitalisation and surgery

Some studies have shown that the risk of VTE may be higher in UC than in CD^[11,12], with other showing the opposite^[13]; however, the majority of did not show significant differences in the risk of VTE between CD and UC^[3,4,8,14,15]. A recent meta-analysis showed similar risks in patients with UC (RR = 2.57, 95%CI: 2.02-3.28; *n* = 6 studies) and CD (RR = 2.12, 95%CI: 1.40-3.20; *n* = 5 studies)^[3].

Several studies reported IBD activity in 45% to 90% of patients at the time of VTE diagnosis^[8,9,16-18]. The asso-

Table 1 Risk of venous thrombosis in inflammatory bowel disease patients relative to non-inflammatory bowel disease patients

IBD: Inflammatory bowel disease; CD: Crohn's disease; UC: Ulcerative colitis; VTE: Venous thrombosis; DVT: Deep venous thrombosis; PE: Pulmonary emboli; PVT: Portal vein thrombosis; aRR: Adjusted relative risk; aOR: Adjusted odds ratio; aHR: Adjusted hazard ratio.

ciation of VTE and IBD flares was assessed using a large primary care database from the United Kingdom (Table 1)^[19]. According to the data from this assessment, the risk of VTE was increased most prominently during a flare of IBD [hazard risk (HR) = 8.4, 95%CI: 5.5-12.8], compared with periods of chronic activity (HR = 6.5, 95%CI: 4.6-9.2) and periods of clinical remission (HR = 2.1, 95%CI: 1.6-2.9). The RR at the time of a flare, compared with a matched control, was higher during non-hospitalised periods (HR = 15.8, 95%CI: 9.8-25.5 *vs* HR = 3.2, 95%CI: 1.7-6.3). However, this finding must be interpreted with caution because the lower RR during hospitalised periods is related to a higher absolute risk (37.5 *vs* 6.4 per 1000 persons-years), and the treatment with corticosteroids in patients with active disease may also be an additional risk factor for the development of VTE. Moreover, the use of VTE prophylaxis in hospitalised patients can also contribute to a lower RR of VTE during hospitalisation. Bernstein *et al*^[20] showed higher VTE rates in hospitalised IBD

patients than in non-IBD hospitalised patients regardless of age (Table 1). IBD patients who were younger than 50 years had a higher RR than those who were older than 50 years (RR = 1.57, 95%CI: 1.42-1.72 *vs* RR = 1.30, 95%CI: 1.23-1.37)^[20]. Nguyen *et al*^[12] compared the risk of VTE between hospitalised IBD patients and randomly selected hospitalised non-IBD patients (Table 1) and reported that IBD patients had an adjusted 1.7-fold [adjusted OR (aOR) = 1.66, 95%CI: 1.33-2.06] increased rate of VTE compared with non-IBD patients. In 2011, three studies were published showing a 1.1- to 3.1-fold higher risk of VTE in hospitalised IBD patients (Table 1)^[11,21,22].

The risk of VTE in IBD was also evaluated in the surgical setting; Merrill *et al*^[23] compared the risk of VTE between patients with IBD and patients without IBD who underwent surgery in 211 hospitals participating in the American College of Surgeons National Surgical Quality Improvement Program (Table 1). The incidence of VTE was 2.5% in IBD patients ($n = 57$) *vs* 1.0% ($n = 2608$)

Table 2 Prothrombotic risk factors and abnormalities associated with inflammatory bowel disease

| |
|--|
| Acquired prothrombotic risk factors |
| Infection or inflammation, previous thromboembolism, age, smoking, malignancy, central venous catheter, surgery, trauma, immobilization, Pregnancy, drugs (oral contraceptives, steroids), antiphospholipid antibody syndrome, hyperhomocysteinemia, fluid depletion |
| Genetic prothrombotic risk factors |

| ↑ PAI-1 and TAFI |
| ↑ D-dimer |
| Abnormalities of platelets |
| ↑ Number, activation (CD40L and P-selectin) and aggregation |
| Abnormalities of endothelium |
| ↓ NO |
| ↑ vWF |

PAI-1: Plasminogen activator inhibitor 1; MTHFR: Methylene tetrahydrofolate reductase; TF: Tissue factor; AT: Antithrombin; EPCR: Endothelial cell protein C receptor; TM: Thrombomodulin; TFPI: Tissue factor-pathway inhibitor; TAT: Thrombin-antithrombin; t-PA: Tissue plasminogen activator; TAFI: Thrombin-activatable fibrinolysis inhibitor; CD40L: CD40 ligand; vWF: von Willebrand factor.

in the controls. IBD remained a significant predictor of VTE after multivariate adjustment (OR = 2.03, 95%CI: 1.52-2.70). Another interesting finding of this was the observation that the risk persisted even when procedures on small and large bowels were excluded, with IBD patients undergoing non-intestinal procedures having a 4.45-fold increased risk of VTE compared with non-IBD patients. Furthermore, in a large cohort of surgical IBD patients, bleeding disorders, steroid use, anaesthesia time, emergency surgery, haematocrit < 37%, malnutrition and functional status were identified as potentially modifiable risk factors for postoperative VTE in IBD patients^[24].

Pregnancy

The risk of VTE in IBD was also evaluated during pregnancy and puerperium. According to the Nguyen *et al.*^[14] study, based on nationwide inpatient sample data (database containing discharge abstracts from 1054 hospitals in the United States), the aOR of VTE was substantially higher in women with CD (aOR = 6.12, 95%CI: 2.91-12.9) and UC (aOR = 8.44, 95%CI: 3.71-19.2) compared with the non-IBD obstetric population, and this increased risk was independent of whether the women underwent a caesarean section (Table 1). A similar study conducted by Bröms *et al.*^[15] in Sweden also showed an increased risk of VTE in pregnant IBD patients compared with non-IBD pregnant patients but showed a lower odds ratio (aOR = 2.65, 95%CI: 0.65-10.1 for CD; aOR = 3.78, 95%CI: 1.52-9.38 for UC) (Table 1). For women with UC, the increased risk of VTE seemed to be highest during pregnancy and not during puerperium like in the general population of women giving birth.

IBD-phenotype risk factors

Several IBD-phenotype risk factors have been shown

to affect the risk of VTE. Nguyen *et al.*^[12] reported that fistulising disease was independently associated with a greater VTE risk (OR = 1.39, 95%CI: 1.13-1.70). Colonic involvement in CD patients or extensive disease in UC patients was also associated with an increased VTE risk. A study by Solem *et al.*^[17] showed that CD patients with VTE typically had colonic disease involvement (ileocolonic in 56% and colonic in 23%), and most UC patients with VTE (76%) had pancolonic disease. Nguyen *et al.*^[12] found a higher risk of VTE in CD patients with colonic-only disease that was 40% higher than the risk of VTE in those with small bowel-only disease. In UC patients, 25% experienced VTE after proctocolectomy, and VTE recurrence rates were not improved by proctocolectomy^[17].

IBD-nonspecific acquired risk factors

In IBD, several nonspecific acquired risk factors, other than those previously discussed, often increase the risk of VTE, such as oral contraceptive/hormone substitution use, smoking and drug therapy (Table 2). In most studies, at least one of the known clinical risk factors for VTE was present in approximately 20%-50% of IBD patients with VTE at the time a TE occurred^[9,16,18,25]. Approximately 30% of these patients may have two or more risk factors^[9].

PROTHROMBOTIC ABNORMALITIES IN IBD

Impact of inflammation on coagulation

Although the causes of the increased risk of VTE in IBD are not yet completely understood, most studies suggest that this risk is largely dependent on the biological and biochemical effects exerted by the activation of the inflammatory pathways (*e.g.*, cells and cytokines) in

the haemostatic system. In fact, there is now convincing evidence from clinical, epidemiological and experimental studies that inflammation and VTE are related^[5,26-28]. Many inflammatory diseases other than IBD, such as systemic lupus erythematosus, Behçet's disease, polyarteritis nodosa and polymyositis/dermatomyositis, have been associated with an increased risk of VTE in several clinical and epidemiological studies^[5,26-28]. This association appears to be the strongest when the time between the exposure and the outcome is short, *e.g.*, when the inflammatory disease was experienced recently or, more specifically, in the active stage of an inflammatory disease (flare-up)^[5,26-28]. In many inflammatory diseases, such as systemic lupus erythematosus and Behçet's disease, VTE may be part of the presentation of those diseases. VTE in IBD may complicate the differential diagnosis with other inflammatory diseases that may also lead to VTE and intestinal inflammation, such as Behçet's disease.

The impact of inflammation on coagulation has been confirmed by several experimental studies showing that inflammatory mechanisms shift the haemostatic balance to favour the activation of coagulation and, in the extremes, VTE^[27].

Tumour necrosis factor-alpha (TNF- α) and CD40 ligand (CD40L), two inflammatory cytokines, and C-reactive protein (CRP), a liver-synthesised acute phase protein, have been shown to induce the expression of tissue factor (TF) on the cell surface of leucocytes^[29,31]. Interleukin (IL)-6, an inflammatory cytokine, and TNF- α have been shown to lead to thrombin generation^[32,33]. Of the natural anticoagulant pathways, the protein C pathway and heparin-antithrombin pathway have been shown to be downregulated by IL-1 β and TNF- α ^[34,35], whereas the tissue factor pathway inhibitor (TFPI) has been shown to be inhibited by CRP^[36]. There is also evidence that CRP increases the expression of plasminogen activator inhibitor type 1 (PAI-1) and decreases the expression of tissue plasminogen activator (t-PA)^[37,38].

Inflammatory mediators, such as IL-6, increase platelet production. The newly formed platelets appear to be more thrombogenic. For example, the newly formed platelets activate at lower concentrations of thrombin^[39]. Thus, both the platelet count and platelet reactivity are increased in response to inflammatory mediators.

Some authors have proposed the term "endothelial stunning" for the endothelial dysfunction/activation that may be induced by inflammatory cytokines and may thus play a key-role in the association between inflammation and VTE^[40]. For example, CRP has been shown to induce the release of von Willebrand factor (vWF)^[41] and to reduce the production of nitric oxide (NO) by endothelial cells^[42].

As discussed above, in general for inflammatory diseases, there is also convincing evidence from basic science as well as clinical and epidemiological studies that IBD is associated with several prothrombotic abnormalities, including the initiation of the coagulation system, downregulation of natural anticoagulant mechanisms, impairment

of fibrinolysis, increase in the platelet count and reactivity and dysfunction of the endothelium (Table 3)^[43-45].

The mechanisms underlying IBD-associated prothrombotic abnormalities have been the subject of recent experimental and clinical studies. For example, Yoshida *et al.*^[46,47] showed that TNF- α and IL-1 β are both implicated in the enhanced extra-intestinal thrombosis that accompanies experimental colitis [mice with dextran sodium sulphate (DSS)-induced colitis]. The authors noted that exogenous TNF- α and IL-1 β enhanced thrombosis in the arterioles of control mice and that the enhanced thrombus formation in the arterioles of mice with DSS-induced colitis was significantly attenuated in wild-type colitic mice treated with TNF- α or IL-1 β blocking antibodies and in colitic mice deficient for the TNF- α receptor or the IL-1 receptor. The IL-6 concentrations were positively correlated with disease activity and thrombocytosis in patients with UC^[48]. Taken together, these data suggest that inflammatory cytokines such as TNF- α , IL-1 β and IL-6 may play an important role in the inflammation-mediated risk of VTE in IBD.

Abnormalities of haemostasis associated with IBD

Abnormalities of coagulation: Quantitative alterations in key sites of the coagulation cascade that favour clot formation occur in patients with IBD^[44]. These alterations include the elevation of circulating microparticles (including TF-rich microparticles)^[49,50], factor VIIa^[51], factors XIIIa and XIa^[52], factors Xa and Va^[52,53], prothrombin^[7,54-56] and fibrinogen^[56,57]. The levels of antithrombin (AT) are significantly lower in the plasma of patients with IBD^[56,58]. Reports on protein C and S deficiency in IBD are conflicting^[48,59-61]. There is also a significantly lower expression of endothelial protein C receptor (EPCR) and thrombomodulin (TM), which impairs protein C activation leading to lower effective protein C activity^[62]. TFPI levels were also shown to be reduced in patients with IBD^[63,64]. Alterations suggestive of the activation of coagulation have also been reported in IBD. These include elevated prothrombin fragment 1+2 (prothrombin F1+2), thrombin-antithrombin (TAT) complexes, fibrinopeptide A (FPA) and B (FPB)^[7,54-56] and decreased factor XIII levels^[57,65].

IBD treatment was also found to influence coagulation abnormalities associated with IBD. For example, the treatment with infliximab induced a significant decrease in the amounts of circulating microparticles in IBD patients^[49].

Abnormalities of fibrinolysis: The circulating concentration of factors involved in the lysis of clots also favours thrombosis in IBD. The plasma levels of t-PA are significantly lower in IBD patients than these levels in the general population^[66,67]. There is also a significant absolute increase in urokinase-type plasminogen activator (u-PA) activity and a decrease in t-PA activity in the inflamed mucosa of IBD patients compared with the control group^[66]. Two proteins that inhibit fibrinolysis,

VTE: Venous thrombosis; CD: Crohn's disease; UC: Ulcerative colitis; IBD: Inflammatory bowel disease; IBD-VTE: Inflammatory bowel disease with venous thrombosis; HC: Healthy controls; C-VTE: Controls with venous thrombosis; OR: Odds ratio. ¹Presented prevalence data refer to heterozygous and homozygous carrier for FV Leiden and prothrombin mutation and to homozygous carrier for the other mutations.

PAI-1^[66] and thrombin-activatable fibrinolysis inhibitor (TAFI)^[68], were found in higher concentrations in the plasma of IBD patients. Increasing levels of D-dimer, a fibrin degradation product, were also found in IBD, mainly in patients with active disease^[58]. As D-dimer is generated from cross-linked fibrin, but not from fibrinogen, and elevated plasma concentration of D-dimer indicates recent or ongoing intravascular blood coagulation.

Abnormalities of platelets: In patients with IBD, there are often increased circulating platelet numbers and platelet and leukocyte-platelet aggregates (PLAs)^[69]. Greater platelet aggregation has also been demonstrated in the mesenteric vasculature compared with non-IBD controls, supporting the hypothesis that platelet activity is stimulated in the mesenteric microcirculation^[70]. Indeed, spon-

taneous platelet aggregation or platelet hypersensitivity to low levels of aggregating agents occurs in nearly one-half of patients with IBD^[71] and appears to be independent of the disease activity^[57,71]. Such platelet hyperactivation is mediated at least partly by the CD40-CD40L pathway, a key regulator and amplifier of immune-inflammatory reactivity and inducer of TF, which initiates the extrinsic coagulation pathway. Evidence for the involvement of CD40L includes a markedly elevated expression of CD40L protein by platelets from patients with IBD and the release of larger amounts of soluble CD40L into the plasma, leading to an approximately 15-fold increase in the CD40L plasma levels^[72,73]. There are also elevated levels of CD40L in the mucosa that appear to be proportional to the degree of inflammation^[72,74]. The activation of platelets in IBD may also be mediated by P-selectin.

IBD patients have been reported to have more platelets expressing P-selectin (marker of platelet activation) than healthy controls^[69]. In the DSS model of murine colonic inflammation, colonic inflammation has been reported to be associated with an increased number of circulating activated platelets, along with the formation of PLAs, which can be inhibited by selectin blockade with fucoidin^[75].

The IBD treatment may influence platelet abnormalities associated with IBD. Infliximab significantly reduced plasma-soluble CD40L levels and eliminated CD40 from mucosal microvessels^[76], whereas IBD patients on thiopurines had fewer PLAs than those not taking them^[69]. These findings suggest that IBD treatment may influence platelet abnormalities associated with IBD.

Abnormalities of endothelium: Endothelial dysfunction has been clearly demonstrated in IBD patients and involves several aspects of endothelium biochemical physiology^[77]. In particular, such dysfunction involves an alteration in the NO and reactive oxygen species (ROS) balance, which occurs when the endothelium fails to generate NO, a potent vasodilator and anti-aggregating agent, and instead forms elevated levels of superoxide anion^[78]. Decreased NO generation may result from an acquired deficient transcription of nitric oxide synthase 2 (NOS2) in chronically inflamed IBD endothelium^[79] and from the induction, by many inflammatory cytokines (*e.g.*, IL-2 and TNF- α), of the enzyme arginase, which competes with NOS^[80]. The increased production of ROS in the inflamed endothelium may also contribute to oxidative stress in vWF molecules, which become unresponsive to proteolysis by ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13), leading to the accumulation of ultra-large vWF multimers^[81]. The latter are the most haemostatically active forms of vWF and, by favouring platelet adhesion and aggregation, may contribute to microvascular thrombosis in IBD. Increased levels of vWF were reported in IBD patients, especially in those with active disease^[58,82].

Thrombophilia and IBD

Acquired risk factors: Antiphospholipid antibodies (APLA) and hyperhomocysteinaemia are two acquired thrombophilias associated with arterial and venous thrombosis. APLA are a group of prothrombotic antibodies directed against plasma proteins that are bound to anionic phospholipids. Patients with APLA may present with venous or arterial thrombosis, recurrent foetal loss and/or thrombocytopenia. The disorder may be primary or may be associated with pregnancy or with inflammatory, post infectious and other disease states. This group of antibodies includes anti-cardiolipin (aCL), anti- β 2-glycoprotein 1 (b2-GPI) and lupus anticoagulants, each of which requires specific testing. Available studies in IBD vary in the assessment of different antibodies, types of IBD and disease activity level; therefore, the true prevalence of APLA in IBD patients remains unclear. The prevalence of aCL antibodies in IBD patients is higher

than in the control population, with an average incidence of 20%-30%, but the association with thrombosis in IBD patients is less clear^[83]. Similarly, the levels of antibodies against b2-GPI, the cofactor that mediates the binding of aCL antibodies to cardiolipin and a more specific measure of the risk associated with thrombosis, has been detected in 9% of patients with IBD compared with its absence in healthy controls^[84]. Lupus anticoagulants were not detected in a small series of 16 patients with CD^[85]. The levels of aCL antibodies and anti-b2-GPI antibodies and of lupus anticoagulants were similar in a population of IBD patients with and without current or past VTE events^[84,86]. One of the causes of the appearance of APLA in IBD may be anti-TNF- α therapy because this therapy has been associated with the development of APLA^[87,88].

Hyperhomocysteinaemia may be both a genetic and acquired abnormality. The most common genetic defect is homozygosity for a thermolabile mutant of the enzyme methylenetetrahydrofolate reductase (MTHFR)^[89]. Plasma homocysteine concentrations can also be increased by deficiencies in vitamin B6, B12 or folic acid (dietary, genetic or drug-associated)^[90]. Hyperhomocysteinaemia is an independent risk factor for atherosclerotic vascular disease, with the risk increasing in a graded fashion with increasing plasma homocysteine concentrations^[91,92]. Hyperhomocysteinaemia has also been associated with an increased risk of VTE^[93,94]. Reducing levels of homocysteine with B vitamin supplements, however, has not resulted in a reduction in the incidence of recurrent VTE or arterial thrombotic complications^[95,96]. The association of folate deficiency and hyperhomocysteinaemia has been evaluated in IBD patients. One study reported elevated serum homocysteine and low folate in 63 patients with IBD, but these levels were not observed in 183 matched controls without thrombotic complications^[97]. In a small study, fasting homocysteine levels in IBD patients with a history of arterial or venous thrombosis tended to be higher (although not significantly) than in IBD controls^[98]. Recently, Oussalah *et al*^[99] conducted a systematic review and meta-analysis to evaluate the association between homocysteine metabolism and IBD and the association between hyperhomocysteinaemia and thrombosis in IBD. The mean plasma homocysteine level was significantly higher in IBD patients compared with the controls. The mean plasma homocysteine level did not differ between patients with UC and CD. The risk of hyperhomocysteinaemia was significantly higher in IBD patients compared with controls (OR = 4.65, 95%CI: 3.04-7.09). The risk of hyperhomocysteinaemia was not higher among IBD patients who experienced thromboembolic complications (OR = 1.97, 95%CI: 0.83-4.67), suggesting that hyperhomocysteinaemia may not be a major contributor to VTE in IBD. Medication-associated folate deficiency (*e.g.*, methotrexate or sulfasalazine) may be the most common explanation for hyperhomocysteinaemia in IBD patients, although deficiencies in vitamin B6 and B12 and a MTHFR mutation may also play a role

(see below). Taken together, the current data do not support a major role for APLA or hyperhomocysteinaemia in IBD-associated VTE, but studies with a higher number of patients and a prospective design are needed.

Inherited risk factors: A summary of controlled studies on the prevalence of inherited thrombophilias in IBD is presented in Table 3. The rate of inherited thrombophilias in patients with IBD and VTE is estimated to be 15%-30%, which is similar to the rate in non-IBD patients and VTE in most studies^[6,17,25,98,100-104], although one study has reported a lower rate of inherited thrombophilias in patients with IBD and VTE^[105]. Data comparing the prevalence of inherited thrombophilias in the overall IBD population and in the general population are conflicting. Although some cohorts reported a higher prevalence in the overall IBD population^[106-109], most reported a similar prevalence^[6,16,61,102-104,109-121]. These data suggest that the role of inherited thrombophilias in VTE in IBD patients is similar to that in the general population.

The most prevalent thrombophilia reported in IBD patients is factor V mutation. Other genetic variants that have been found in IBD patients include the prothrombin G20210A mutation, deficiencies in protein C, protein S and antithrombin, the PAI-1 4G mutation, the factor XII val34leu mutation and the MTHFR C677T mutation (Tables 2 and 3). Factor V mutation increases the risk of thrombosis five- to eightfold for heterozygous carriers and 50- to 80-fold for homozygous carriers^[122]. A similar frequency of factor V Leiden was reported in IBD patients with thrombosis compared with thrombotic controls^[6,102,104] and in the overall IBD population compared with the general population^[61,109]. However, the prevalence of factor V mutation in thrombotic IBD patients has been shown to be significantly higher than that in IBD patients without thrombosis, suggesting that factor V Leiden, when present, increases the risk of IBD-associated VTE^[101,102]. Two recent meta-analyses confirmed this conclusion. In the meta-analysis of Zhong *et al.*^[123], the OR of VTE in IBD patients with factor V mutation was higher than in IBD patients (OR = 4.00, 95%CI: 2.04-7.87) and healthy controls (OR = 3.19, 95%CI: 1.38-7.36). Liang *et al.*^[124] showed a similar prevalence of factor V mutation in IBD patients and the general population (summary OR = 1.13, 95%CI: 0.87-1.46). Of note, the factor V Leiden mutation was associated with a significantly higher risk of thromboembolism in IBD patients (summary OR = 5.30, 95%CI: 2.25-12.48)^[124].

The prothrombin G20210A mutation leads to greater prothrombin plasma levels (heterozygous carriers have approximately 30% higher PT levels than healthy controls) and increases the risk of VTE approximately threefold^[122]. There is no difference in the prevalence of the prothrombin G20210A mutation between IBD patients and normal controls^[110,120], between IBD patients with thrombosis and non-IBD patients with thrombosis^[6,102] or between IBD patients with and without thrombosis^[102,104]. Protein C, protein S and antithrombin III deficiencies also

have no increased prevalence among patients with IBD, regardless of whether they have had a VTE^[52,125-127].

The factor XIII val34leu mutation is associated with a greater FXIII activation rate and leads to a 20%-40% reduction of the risk of VTE for homozygous carriers^[111,121]. A slightly greater prevalence of factor XIII (val34leu) mutation carriers in CD was found in a recent population-based study^[109], but this prevalence could not explain the greater risk of VTE in CD. Available data suggest that there is no difference in the prevalence of homozygous carriers of the factor XIII val34leu mutation between IBD patients and healthy controls^[111,116,121]. Finally, the prevalence of the factor XIII val34leu mutation was similar in thrombotic IBD patients and non-IBD thrombotic patients^[104].

The MTHFR C677T mutation leads to a 25% increase in homocysteine plasma levels in homozygous carriers^[128]. The effect of the MTHFR C677T mutation on the risk of VTE varies among studies, and a recent meta-analysis found a weak effect (20% risk increase)^[128]. The prevalence of the MTHFR C677T mutation in IBD has shown discordant results, most likely because of regional and ethnic variations in the prevalence of this polymorphism in the general population. The allelic frequency of MTHFR C677T has been reported to be higher in IBD patients than in the reference population^[119]. In a recent population-based case-control study, some differences were observed between patients with IBD and healthy controls (with a decreased number of mutant allele carriers in UC); however, these differences did not explain the excess risk of thrombosis^[109]. No difference in the prevalence of homozygous carriers of the MTHFR C677T mutation was found between the IBD patients and healthy controls in most studies^[102,104,109,110,115,116,118,119]. The prevalence of C677T homozygosity between IBD thrombotic patients and non-IBD thrombotic patients showed no significant difference^[102,104].

Several studies have demonstrated that the PAI-1 (4G) homozygosity is associated with enhanced PAI-1 expression^[129] and contributes as an additional risk factor towards the development of VTE^[130]. However, the evidence regarding the relationship between an elevated PAI-1 plasma level or PAI-1 4G polymorphism and the risk of VTE is rather conflicting. The allelic frequency of PAI-1 4G has been reported as being higher in IBD patients than in the reference population^[119]. Moreover, a recent study showed a significantly higher allelic frequency of PAI-1 4G in IBD patients with vascular complications compared with IBD patients and healthy controls^[104]. No difference in the prevalence of homozygous carriers of the PAI-1 4G mutation was found between IBD patients and healthy controls in most studies^[104,116,119]. The prevalence of this genotype does not differ in thrombotic IBD patients compared with non-IBD thrombotic patients^[104].

As in the general population, more than one thrombotic defect can occur among IBD patients with inherited thrombophilia, particularly factor V Leiden^[104,119]. A higher prevalence of the carriage of two or more throm-

bogenic polymorphisms has been found in IBD patients compared with the reference population^[119], but no significant difference has been found between thrombotic and non-thrombotic IBD patients^[104].

Taken together, these data show that genetic risk factors are generally not found more often in IBD patients than in others, suggesting that genetics does not explain the greater risk of VTE in CD and UC. However, when genetic risk factors occur, patients with IBD (compared with healthy controls) are more likely to suffer thromboembolic complications, suggesting that hereditary thrombophilia and inflammation-associated thrombogenicity have at least an additive effect for the risk of VTE in IBD.

PHARMACOLOGICAL EFFECT ON RISK FACTORS

Almost all drugs used in the treatment of IBD have been associated with abnormalities in the haemostatic system in experimental and clinical studies. Corticosteroids have been associated with both hypo- and hypercoagulating alterations^[131,132]. A meta-analysis demonstrated that dexamethasone-based chemotherapy was a risk for VTE in patients with multiple myeloma^[133]. Furthermore, in a large cohort of surgical IBD patients, the use of steroids was identified as a potentially modifiable risk factor for postoperative VTE in IBD patients^[24]. Studies of platelets from IBD patients treated with 5-aminosalicylic acid (5-ASA) agents have shown conflicting results. *In vitro*, 5-ASA significantly reduced both spontaneous and thrombin-induced platelet activation^[134]. *In vivo*, platelets from IBD patients taking 5-ASA have decreased expression levels of P-selectin, a surface marker for platelet activation^[134], and lower plasma levels of RANTES (Regulated upon Activation Normal T-cell Expressed and Secreted), a prothrombotic platelet cytokine^[135]. In contrast to these findings, a study of six patients with IBD (four with UC and two with CD) treated with 5-ASA showed no changes in platelet aggregation or fibrinolytic activity^[136]. Sulfasalazine inhibits dihydrofolate reductase leading to folate deficiency, which is a cause of hyperhomocysteinaemia (acquired thrombophilia; see above). Plasma homocysteinaemia levels have been reported to be significantly increased in patients with ankylosing spondylitis under sulfasalazine therapy^[137].

Azathioprine has been shown to inhibit platelet aggregation *in vitro*^[138]. IBD patients taking thiopurines experienced fewer PLAs than patients who were not taking them^[69]. The *in vitro* data suggest an antithrombotic effect from azathioprine and 6-mercaptopurine. Methotrexate, a folate antagonist, is a well-established contributor to hyperhomocysteinaemia (which is associated with thrombotic risk) when used in patients with rheumatoid arthritis^[139]. Nonetheless, no study associating methotrexate with hyperhomocysteinaemia is available for IBD. Cyclosporine has been associated with thrombogenicity *in vitro* and *in vivo*. *In vitro* studies showed an increased plate-

let aggregation^[138] and activation of endothelial cells^[140] induced by cyclosporine. Cyclosporine has also been associated with impaired fibrinolysis through a decrease in PAI-1 activity^[141]. The *in vitro* thrombogenicity of cyclosporine has been confirmed *in vivo* by several studies showing thrombotic events in patients taking cyclosporine^[142].

Infliximab, an antibody against anti-TNF- α , may decrease platelet activity through the downregulation of the CD40/CD40L pathway in the mucosal microcirculation^[76]. Additionally, in patients with active rheumatoid arthritis, infliximab treatment has been shown to normalise the disease-associated impairment of the coagulation and fibrinolytic systems by decreasing the levels of prothrombin F1+2 and D-dimer^[143], t-PA antigen, PAI-1 antigen and PAI-1 activity^[144]. Finally, infliximab induced a significant decrease in the amounts of circulating microparticles in IBD patients^[49]. Despite these potential anticoagulant effects of the TNF- α blockade, there are also case reports of thrombosis at several sites, such as the retinal vein, in patients under anti-TNF- α therapy^[145]. Moreover, the prothrombotic effects of anti-TNF- α therapy may be mediated by antiphospholipid antibodies (acquired thrombophilia) as anti-TNF- α therapy has been associated with the development of APLA^[87,88]. Nonetheless, a recent prospective observational cohort study of biological safety in patients with rheumatoid arthritis showed that VTE events are not increased in patients with rheumatoid arthritis who are treated with anti-TNF therapy^[146].

CONCLUSION

In IBD, there is an increased risk of thromboembolic events due to inflammation, nutritional deficiencies, hospitalisations, surgery and inherited prothrombotic factors. Moreover, beyond an increased risk, VTE may have clinical specificities in IBD. There is evidence that subjects with IBD experience the first episode of VTE early in life^[6]. In IBD, the RR of VTE is inversely correlated with age (*i.e.*, younger IBD patients have a higher RR of VTE); nevertheless, the actual incidence increases with age^[8,11,13,21]. The rate of recurrent VTE in the five years after the discontinuation of anticoagulation therapy is also increased in IBD [adjusted RR (aRR) = 2.5, 95%CI: 1.4-4.2]^[16]. Even with continued prophylaxis for VTE, the risk of recurrence of VTE in IBD patients has been reported to be 13%^[17]. Low molecular weight heparin (LMWH) has been shown to be less effective in preventing DVT in hospitalised subjects undergoing surgery for IBD than in patients with non-IBD conditions, including colorectal cancer and diverticular disease (aOR = 5.9, 95%CI: 0.9-39.7, for UC and DVT postoperatively)^[147]. Importantly, VTE appears to carry a poorer prognostic outcome for patients with IBD than for the general population. In a hospitalised cohort, the rate of VTE was not only higher in IBD subjects than in the controls, but the admissions for IBD subjects were also longer (11.7 *vs*

6.1 d, $P < 0.0001$) and were associated with higher costs (\$47515 *vs* \$21499, $P < 0.0001$) and higher mortality (aOR = 2.5, 95%CI: 1.83-3.43)^[12].

Therefore, clinicians should be aware of these risks so that adequate prophylactic actions can be taken in all IBD patients with flares, particularly in patients who are hospitalised, submitted to surgery or undergoing treatment.

and a significant number of patients undergo surgery during the disease course. Based on recent knowledge, serum antibodies are qualitatively and quantitatively associated with complicated CD behavior and CD-related surgery. Pediatric UC is characterized by extensive colitis and a high rate of colectomy. In patients with UC, high levels of anti-CBir1 and pANCA are associated with the development of pouchitis after ileal pouch-anal anastomosis. Thus, serologic markers for IBD can be applied to stratify IBD patients into more homogeneous subgroups with respect to disease progression. In conclusion, identification of patients at an increased risk of rapid disease progression is of great interest, as the application of early and more aggressive pharmaceutical intervention could have the potential to alter the natural history of IBD, and reduce complications and hospitalizations.

Abstract

The spectrum of serological markers associated with inflammatory bowel disease (IBD) is rapidly growing. Due to frequently delayed or missed diagnoses, the application of non-invasive diagnostic tests for IBD, as well as differentiation between ulcerative colitis (UC) and Crohn's disease (CD), would be useful in the pediatric population. In addition, the combination of pancreatic autoantibodies and antibodies against *Saccharomyces cerevisiae* antibodies/perinuclear cytoplasmic antibody (pANCA) improved the sensitivity of serological markers in pediatric patients with CD and UC. Some studies suggested that age-associated differences in the patterns of antibodies may be present, particularly in the youngest children. In CD, most patients develop stricturing or perforating complications,

Core tip: Application of non-invasive diagnostic tests for the diagnosis of inflammatory bowel disease (IBD) and differentiation between ulcerative colitis (UC) and Crohn's disease (CD) would be useful in the pediatric population. The combination of pancreatic autoantibodies and antibodies against *Saccharomyces cerevisiae* antibodies/perinuclear cytoplasmic antibody improved the sensitivity of serological markers in pediatric patients with CD and UC. In addition, serologic markers for IBD can be applied to stratify IBD patients into more homogeneous subgroups with respect to disease progression. With this knowledge, clinicians will be able to stratify patients accordingly with regards to the risk of disease progression, create a personalized treatment strategy, and attempt to modify disease course, thereby

improving long-term prognosis.

INTRODUCTION

Inflammatory bowel diseases (IBD), Crohn's disease (CD), and ulcerative colitis (UC) are chronic relapsing and remitting disorders of the digestive tract with unknown etiology^[1]. Previous studies suggested that IBD results from an aberrant innate and acquired immune response to commensal microorganisms in genetically susceptible individuals^[2,3]. This hypothesis is supported by the presence of antibodies directed to microbial antigens and by the identification of genetic polymorphisms, such as *NOD2/CARD15* and toll-like receptor 4 variants in CD^[4]. Besides genetic predisposition and environmental factors, innate immunity is assumed to be another major contributor to pathogenesis in IBD.

Incidence of IBD is increasing, especially in pediatric patients with CD^[5]. It is estimated that 15%-25% of IBD patients present in childhood. Recent studies showed that up to 20% of pediatric patients and 5%-15% of adult patients with colon only involvement had diagnostic difficulties if they had UC or colonic CD^[6]. Serologic markers may help to establish diagnosis of IBD and to differentiate CD from UC, particularly when they are combined. It is especially important in the pediatric population, where invasive diagnostic testing is less desirable. In CD, most patients develop stricturing or perforating complications, and a significant number of patients undergo surgery during the disease course. Pediatric UC is more often associated with pancolitis and colectomy. Besides their diagnostic significance, current knowledge suggests that serologic markers can be a valuable aid in stratifying patients according to disease phenotype and risk of complications in IBD.

Several circulating autoantibodies have been described in IBD. The two most intensively studied conservative antibodies are atypical perinuclear anti-neutrophil cytoplasmic antibodies (atypical pANCA), which are primarily associated with UC and anti-*Saccharomyces cerevisiae* antibodies (ASCA), which are primarily associated with CD^[4,7]. In pediatric IBD, sensitivity/specificity of pANCA in UC ranged between 57% to 83% and 65% to 97%, respectively, whereas in CD, ASCA showed a sensitivity/specificity in the range of 44% to 76% and 88% to 95%, respectively^[8,9]. ASCA positivity or high titers are associated with complicated CD behavior (penetrating or stenosing disease) and could be useful markers for predicting the need for surgery in adults and children^[10-12].

In pediatric studies, ASCA positivity increased with age at diagnosis^[13] and was predictive for a more relapsing disease course [OR 2.9 (95%CI: 1.33-6.33)] in CD^[14]. In addition, Trauernicht and Steiner^[15] reported that serum ASCA antibodies are associated with lower anthropometric data (lower mean weight and height Z-scores) at the diagnosis of pediatric CD. pANCA is noted for its association with the "UC-like" phenotype in patients with CD^[16,17]. Testing for ASCA and pANCA alone may have limited usefulness; therefore additional seromarkers are needed to improve the diagnosis, differentiation, and stratification of IBD, as well as prediction of disease course.

NEW SEROLOGICAL MARKERS

Crohn's disease

Antibodies to *Escherichia coli* outer membrane porin C, *Pseudomonas*-associated sequence I2, and bacterial flagellin CBir: Several antibodies against microbial components have been detected in serum samples of patients with IBD, including ones against outer membrane porin C (anti-OmpC) of *Escherichia coli*, against *Pseudomonas*-associated sequence I2 (anti-I2), and against bacterial flagellin CBir (anti-CBir1). Adherent-invasive *E. coli* has been found in ileal CD lesions, and OmpC has been shown to be required for these organisms to adhere to intestinal epithelial cells^[18,19]. I2 was identified as a bacterial sequence from lamina propria mononuclear cells of active CD patients, and was shown to be associated with *Pseudomonas fluorescens*^[20]. CBir1 is a flagellin related antigen that was initially identified in the gut flora of mice, and has the ability to induce colitis in immunodeficient mice^[21].

Approximately 50% of adult patients with CD were positive for these markers, which were insignificant in adult patients with UC and healthy subjects^[22,23]. The prevalence of anti-OmpC and anti-I2 was found to be 11% and 56% in pediatric CD, respectively^[10,13,24-28]. The occurrence of antibodies varies in children of different ages: children younger than 8 years old at diagnosis are predominantly anti-CBir1 positive and ASCA and anti-OmpC negative, while those older than 8 are more commonly both ASCA and anti-CBir1 positive^[13]. In children with CD, these strong serological responses to bacterial flagellin CBir antigens suggest that this antigen may have a potential role in the immunopathology of the disease.

Anti-glycan antibodies: The most recently described serum markers directed against microbial antigens are anti-glycan antibodies. Glycans are predominant cell surface oligosaccharides found on microorganisms, immune cells, erythrocytes, and tissue matrices. In IBD, the presence of anti-glycan antibodies results from the interaction between the immune system and the glycosylated cell wall components of such pathogens as fungi, yeast, and bacteria. Besides gASCA (which is very similar to conventional ASCA IgG), certain novel anti-glycan

antibodies were identified and associated with CD: anti-mannobioside carbohydrate antibodies (AMCA), anti-laminaribioside carbohydrate antibodies (ALCA), anti-chitobioside carbohydrate antibodies (ACCA), anti-laminarin carbohydrate antibodies (anti-L), and anti-chitin (anti-C) carbohydrate antibodies.

Anti-glycan markers are significantly increased in CD compared to UC and healthy controls^[29,30]. However, only 16.9%-30.5% of patients were positive for each of AMCA, ALCA, ACCA, anti-L, and anti-C markers in pediatric CD^[31]. Since the presence of anti-L and anti-C is low in ASCA-negative patients with CD, it has been proposed that these markers may bind different epitopes. Interestingly, the optimal cutoff values for anti-glycan markers were different in children than in adult populations in a serological study by Rieder *et al.*^[31]; strikingly lower cutoff points of gASCA, ACCA, ALCA, AMCA, anti-L, and anti-C were observed in children compared to adult patients with CD.

Pancreatic autoantibodies: Autoantibodies against exocrine pancreas (PAB) were described for the first time in 1984^[32], but the autoantigenic targets of PAB were identified only in 2009^[33,34]. The recognition of glycoprotein 2 (GP2) as a major target antigen of the droplet-like PAB (type I PAB) has been followed by the identification of CUB/zona pellucida-like domain-containing protein 1 (CUZD1) as another major antigenic target of PAB giving the reticulogranular, cytoplasmic pattern by indirect immunofluorescence (type II PAB). Both GP2 and CUZD1 are glycosylated membrane proteins residing in the acinar secretory storage granules of the pancreas. It was previously believed that GP2 is exclusively expressed by pancreatic acinar cells, but recent studies have shown that GP2 is also present as a specific membrane-anchored receptor on the microfold (M) intestinal cells of intestinal Peyer's patches, and is essential for host-microbial interaction and the initiation of bacteria-specific mucosal immune responses^[35,36]. Notably, GP2 overexpresses at the site of CD inflammation in contrast to UC^[33,37]. Respective data regarding CUZD1 expression in the intestine are sparse, with further research being needed to evaluate the relevance of these autoantibodies in CD. Combined determination of GP2 and CUZD1-specific autoantibodies by indirect immunofluorescence using recombinantly expressed human embryonic-kidney cell autoantigens represents a new method in the serological diagnosis of IBD. Discrimination between positive and negative reactions is considered to be easier in transfected cells than in primate tissues. The selective detection of anti-GP2 and CUZD1 autoantibodies by enzyme-linked immunosorbent assay (ELISA) has also been recently developed^[34].

PAB have been reported to be pathognomonic markers of CD. A prevalence of 27% to 39% of PAB was present in patients with CD, compared with only 0% to 5% in patients with UC^[38-40]. Increased prevalence of PAB has been found in unaffected first-degree relatives^[41]. Stöcker *et al.*^[38] reported that PAB could only be

determined in the serum of patients with CD. However, other studies found much higher (22%-24%) prevalence of PAB in UC^[42-44]. Although anti-GP2 only represents a small proportion of PAB seropositive cases, anti-GP2 autoantibodies are detected in about 30% of patients with CD and in 5%-12% of patients with UC^[45-47].

Ulcerative colitis

Autoantibodies against intestinal goblet cells: Serological markers have been far less extensively studied in UC than in CD. Autoantibodies against different colonic antigens have been found in patients with UC [*e.g.*, goblet cell autoantibodies (GAB)]. In previous studies, GAB has been detected in adult patients with UC, with a prevalence of 28% to 30%. In contrast, other studies suggested a much lower prevalence in both diseases^[42-44]. These conflicting results are likely due to methodological differences, such as enzyme-linked immunosorbent assay antigen substrates and the evaluation of fluorescence patterns. GAB produce mucin that has multiple functions: it serves as a lubricant, provides nonspecific protection against unwanted microbial agents, and hosts the normal bacterial flora. Through complicated and strictly regulated glycosylation, mucins act as a decoy in binding a range of different microbes and maintaining the normal intestinal flora. The significance of these antibodies, however, has not been established and thus remains unclear.

DIAGNOSTIC VALUE OF NEW SEROLOGIC MARKERS IN IBD

In diagnostic workup of IBD, a serologic test with high sensitivity and specificity is desired. The diagnostic value of the new serologic markers for IBD is limited due to their low sensitivity and presence in other conditions, such as celiac disease, autoimmune diseases, and liver cirrhosis^[48-50]. Sensitivity can be increased by the combination of different antibodies. A role for serological testing in screening for IBD was suggested by several studies, but the low sensitivity of these assays only provide a modest contribution to the identification of IBD^[8,24,51-53]. The diagnostic value of the new serologic markers in children with IBD is shown in Table 1. A retrospective study of 300 pediatric patients tested in the IBD7 panel (anti-OmpC, anti-CBir-1, ASCA, and ANCA, Serology 7, Prometheus, Sandiego, CA, United States) for the evaluation of pediatric IBD resulted in a 67% sensitivity and 76% specificity. Consequently, this panel has a limited clinical utility in screening for pediatric IBD^[53].

In pediatric CD, each anti-OmpC, anti-I2, or anti-CBir1 antibody was detected in 11%-55% of patients as a single marker. In a prospective pediatric study using combined analysis (anti-OmpC, anti-I2, anti-CBir1 or ASCA), 77% of patients with CD were positive for at least one microbial-driven antibody^[26]. Therefore this method provided modest support for the diagnosis of CD.

Single glycan markers have limited clinical value for the primary diagnostic workup for CD due to their low

Table 1 Diagnostic value of the new serological markers in children with inflammatory bowel disease

| Marker | Sensitivity | | Specificity | PPV | NPV | Ref. |
|-----------|-------------|-------------|--------------------|--------------------|--------------------|-----------------------|
| | CD | UC | | CD vs UC | | |

¹Mixed pediatric and adult cohort; ²Ulcerative colitis (UC) vs Crohn's disease (CD). ND: No data available; Anti-OmpC: Antibodies against outer membrane porin C of *Escherichia coli*; Anti-CBir1: Antibodies against bacterial flagellin CBir1; Anti-I2: Antibodies against the *Pseudomonas*-associated sequence; ASCA: Antibodies against *Saccharomyces cerevisiae*; AMCA: Anti-mannobioside carbohydrate antibodies; ALCA: Anti-laminaribioside carbohydrate antibodies; ACCA: Anti-chitobioside carbohydrate antibodies; Anti-L: Anti-laminarin carbohydrate antibodies; Anti-C: Anti-chitin carbohydrate antibodies; PAB: Pancreatic antibodies; Anti-GP2: Antibodies against glycoprotein 2; GAB: Antibodies against intestinal goblet cells; IBD: Inflammatory bowel disease; PPV: Positive predictive value; NPV: Negative predictive value.

sensitivity. From the entire panel, gASCA came out as the most accurate for the diagnosis of pediatric CD (sensitivity: 62.7%, specificity: 95.6% CD vs controls, and 88.9% CD vs UC)^[31]. With respect to the latest two novel markers, the addition of Anti-L and Anti-C to gASCA and pANCA further improved discrimination between CD and UC ($P < 0.001$) in a large pediatric and adult cohort with IBD ($n = 818, 517$ CD, 301 UC)^[30]. More specifically, nearly three-quarters of the patients with CD showed seropositivity for at least one of the aforementioned seven anti-glycan antibodies^[30,31]. Anti-glycan antibodies may be particularly important in ASCA-negative patients with CD. Rieder *et al.*^[31] found that 40.9% of ASCA-negative pediatric patients with CD were positive for at least one other anti-glycan marker, suggesting that these novel antibodies may further improve serological diagnosis for CD. Similarly, other studies found that about half of ASCA negative adult patients were positive for ALCA, ACCA, or AMCA^[29,54]. In concordance with the results published by Rieder *et al.*^[55], Seow *et al.*^[30] demonstrated that all the anti-glycan antibodies were highly specific for IBD, particularly for CD (85.4%-97.7%), and were more prevalent in CD vs UC ($P < 0.0015$). In this large pediatric and adult cohort with IBD, anti-C showed the highest specificity of 97.7, followed by ACCA at 97%, then anti-L at 96.7%. Due to the combined use of these markers, the specificity for CD increases up to 100%^[29,55].

While the specificity of PAB for CD is high, its sensitivity is low. In our study the presence of PAB was significantly higher in CD (34%) and UC (20.4%) compared with the pediatric control cohort (0%, $P < 0.0001$). Specificity of PAB was 100%; however, sensitivity was low. The combination of PAB and antibodies against ASCA/pANCA improved the sensitivity of serological markers in CD (87.4%) and in UC (79.6%); specificity was 89.3% and 93.2%, respectively^[44]. Combinations of these antibodies, particularly with ASCA, have shown

increased sensitivity; therefore, it may be recommended in the diagnostic procedure of IBD^[42,44]. Diagnostic accuracy of the combined novel antibodies with conventional serological markers in children with IBD is shown in Table 2^[44].

In a recent study, Bogdanos *et al.*^[45] observed a significantly higher prevalence of PAB compared to anti-GP2 in UC (20.6% vs 8.8%, $P < 0.003$), whereas the difference between PAB and anti-GP2 did not reach a statistically significance level in CD (38.5% vs 30.2%, $P = 0.108$), respectively. Thus, anti-GP2 testing by ELISA assay seems to be more specific for CD than for PAB testing, so it may improve the differentiation between CD and UC.

In UC, the most frequently studied serological marker is pANCA. Besides pANCA, in our study the prevalence of GAB was significantly increased in patients with UC in comparison to CD and controls (UC, 12.2%; CD, 1.9%; controls, 1.9%; $P = 0.02$). Sensitivity can be significantly increased with combinations of different antibodies. For example, pANCA and/or GAB together had a sensitivity of approximately 80% for UC^[44].

ASSOCIATION WITH IBD PHENOTYPES AND PROGNOSIS

In patients with CD at diagnosis, most patients have inflammatory type disease^[56,57]. Nevertheless, during the disease course the development of complicated behavior in the pediatric population is a common feature^[58]. In the largest pediatric cohort with CD ($n = 989$), the cumulative incidence of stricturing or penetrating complications was found to be 13%, 27%, and 38%, 1, 5, and 10 years after the diagnosis of IBD, respectively^[58]. Furthermore, small bowel disease is more frequently correlated with the development of complicated disease behavior than in isolated colonic disease. Based on these observations,

Table 2 Diagnostic accuracy of the combined novel antibodies with conventional serological markers in children with inflammatory bowel disease^[44,45]

| | Marker | Sensitivity | Specificity | PPV | NPV | Ref. | |
|-----------------------------|------------------------------|-------------|-------------|-------------|-------------|----------------------|------|

¹Mixed pediatric and adult cohort; ²Diagnostic value of antibodies against *Saccharomyces cerevisiae* (ASCA) antibodies in ulcerative colitis (UC) patients without primary sclerosing cholangitis (PSC). PAB: Pancreatic antibodies; Anti-GP2: Antibodies against glycoprotein 2; pANCA: Perinuclear anti-neutrophil cytoplasmic antibodies; GAB: Antibodies against intestinal goblet cells; IBD: Inflammatory bowel disease; CD: Crohn's disease; PPV: Positive predictive value; NPV: Negative predictive value.

a more aggressive treatment should be considered in this large subgroup of pediatric patients with CD. Consequently, the evaluation of relevant phenotype-serotype correlations may provide important prognostic information. Association of the new serologic markers with phenotype in pediatric CD is summarized in Table 3.

Antibodies directed to bacterial antigens were reported as being qualitatively (presence) and quantitatively (titer) associated with aggressive disease behavior in both children and adults^[10,26,59,60]. The first prospective pediatric study conducted by Dubinsky and co-workers demonstrated that the degree of the immune response to ASCA, anti-I2, anti-OmpC, and anti-CBir1 correlated with internal penetrating, stricturing disease, and the need for surgery in a large cohort with CD ($n = 196$). The risk of developing penetrating and/or stricturing CD was increased 11-fold in those subjects with immune responses to all four antigens (anti-I2, anti-OmpC, anti-CBir1, and ASCA) compared to seronegative cases (OR = 11, 95%CI: 1.5-80.4, $P = 0.03$). Moreover, in this study, the highest antibody sum group and quartile sum score group showed the most rapid disease progression^[26]. These initial findings were confirmed in another larger study of 796 pediatric CD patients using ASCA, anti-OmpC, and anti-CBir1^[10].

Recent studies demonstrated that seropositivity for anti-glycan antibodies was associated with early disease onset, small bowel disease, complicated disease behavior, and CD-related surgery in both adult and pediatric

CD^[4,29,30,31,54,55,61,62]. This was also found in both qualitative (number of positive antibodies) and quantitative (antibody titers) immune response. In a cross-sectional pediatric study, ALCA and anti-L had the strongest association with complications^[51]. In this pediatric population, most of the anti-glycan markers, except for ACCA and anti-C, were associated with complicated disease behavior and ALCA with CD-related surgery. Only gASCA was associated with terminal ileal disease location. Surprisingly, gASCA was inversely correlated with early disease onset in this pediatric cohort^[51], but this link was found to be positive in adult CD^[4,55,63]. This difference may arise from the distinct nature of the intestinal immune system in children.

There are conflicting results related to the association between PAB and CD phenotype in adult cohorts. Increased prevalence of PAB was observed in patients with early onset of disease, and stricturing or penetrating phenotypes^[39,40,42,43,64]. Lakatos *et al*^[42] reported an association between PAB positivity, perianal disease, and EIMs. However, in our pediatric study, we found that the presence of PAB was not associated with disease phenotype in CD^[44]. It is difficult to compare the data of these studies, since age may affect localization and behavior as well.

In some studies, the relation between anti-GP2 and CD phenotype was also evaluated. In mixed pediatric and adult cohort with CD ($n = 169$), humoral autoreactivity to GP2 and ASCA applying ELISA has been reported to be associated with ileocolonic location, suggesting a

Table 3 Association of the new serologic markers with phenotype in pediatric Crohn's disease

¹Mixed pediatric and adult cohort. Anti-OmpC: Antibodies against outer membrane porin C of *Escherichia coli*; Anti-CBir1: Antibodies against bacterial flagellin CBir1; Anti-I2: Antibodies against the *Pseudomonas*-associated sequence; ASCA: Antibodies against *Saccharomyces cerevisiae*; AMCA: Anti-mannobioside carbohydrate antibodies; ALCA: Anti-laminaribioside carbohydrate antibodies; ACCA: Anti-chitobioside carbohydrate antibodies; Anti-L: Anti-laminarin carbohydrate antibodies; Anti-C: Anti-chitin carbohydrate antibodies; Anti-GP2: Antibodies against glycoprotein 2.

role for GP2 as a receptor on M cells in intestinal Peyer's patches^[45]. Moreover, in this cohort, the presence of anti-GP-2 was associated with younger age at the onset of the disease (< 16 years), stricturing behavior, and perianal disease in CD^[45]. Similarly, Pavlidis *et al*^[46] demonstrated that patients with colonic CD do not show significant antibody reactivity against GP2 compared to those who had ileal localization; the site of GP2-rich M cells. However, a Belgian study by Op De Beéck *et al*^[65] did not find any association between anti-GP2 seropositivity and clinical phenotype in CD ($n = 164$) using the same ELISA.

In patients with UC, both anti-CBir1 and pANCA positivity correlated with the development of pouchitis after ileal pouch-anal anastomosis. In a study by Fleshner *et al*^[66], diverse patterns of reactivity to microbial antigens were manifested as different forms of pouchitis ($n = 238$, age range: 8-81 years). Anti-CBir1 positivity indicated acute pouchitis only in patients who have low-level pANCA expression, with increased incidence of chronic pouchitis only in patients who had high-level pANCA expression. In a meta-analysis by Singh *et al*^[67], the risk of chronic pouchitis after IPAA was higher in ANCA-

positive patients, but the risk of acute pouchitis was unaffected by ANCA status. These data had a significant influence on the patients' treatment in post-operative course. The studies could not demonstrate any association between the presence of GAB and clinical presentation, medical therapy, or need for surgery in patients with UC.

ASSOCIATION WITH THE RESPONSE TO THERAPY AND DISEASE ACTIVITY

Recent studies have highlighted the connection of serologic markers with biologic therapies. Previous studies demonstrated that ASCA signals do not predict response to anti-tumor necrosis factor (TNF)- α therapies in CD^[4,68]. Comparative findings were reported regarding the effect of biological agents in the behavior of anti-GP2 antibodies. Belgian investigators did not find a robust effect of infliximab and adalimumab in patients followed up for 6-44 mo^[65].

No association was detected between anti-glycan markers and the response to corticosteroids and disease activity in children with CD^[51]. Similarly, in our study, we could not find any association between serum antibodies of PAB, ASCA, and ANCA and response to therapy^[44].

Dubinsky *et al*^[69] reported that a combination of phenotype, serotype, and genotype is the best predictive model of non-response to anti-TNF α agents in pediatric patients. In this study, anti-OmpC, anti-CBir1, anti-I2, ASCA, and pANCA serum markers were analyzed. The most predictive model included the presence of three novel "pharmacogenetic" loci, the previously identified BRWD1, pANCA, and UC diagnosis ($P < 0.05$). The relative risk of non-response increased 15-fold when the number of risk factors increased from 0-2 to ≥ 3 ($P < 0.0001$)^[69].

Based on longitudinal analysis, the presence of antibodies in IBD is relatively constant during the disease course^[62,70]. However, the prevalence of ASCA, anti-OmpC, and anti-I2 has been found to be more frequent when the disease persists for a long time^[12,60]. Furthermore, disease activity, CRP levels, or response to corticosteroids does not appear to influence marker levels in longitudinal studies. Therefore, serial measurement of antibodies may not provide additional information for the evaluation of IBD^[51,70].

CONCLUSION

The correct diagnosis and classification of IBD as either CD or UC is essential for choosing the appropriate therapy. Combined application of the novel antibodies (PAB/GP2) with conventional serology markers (ASCA/pANCA) increased sensitivity. Therefore, the use of combinations may be advisable in the diagnostic work-up of selected cases. Moreover, childhood-onset CD often leads to complicated disease (stricturing or penetrating) with increasing prevalence in parallel to disease duration.

In CD, information gained from a serologic profile, both qualitatively and quantitatively, may help to determine the likelihood of a more severe phenotype. In addition, pediatric UC is associated with pancolitis and a higher risk of colectomy. In patients with UC, serologic markers are associated with the development of pouchitis after ileal pouch-anal anastomosis. With this knowledge, clinicians will be able to stratify patients regarding the risk of disease progression, create a personalized treatment strategy, and try to modify disease course, thus improving long-term prognosis. Further simultaneous prospective multicentric studies are needed to evaluate the exact prognostic role of serologic markers which may help in the individual therapeutic management of pediatric and adult IBD.

Abstract

Vitamin D deficiency is commonly diagnosed among patients with inflammatory bowel disease (IBD). Patients with IBD are at risk of low bone density and increased fractures due to low vitamin D levels, long standing disease, and frequent steroid exposures; as a result, it is well established that vitamin D supplementation in this population is important. There is increasing support for the role of vitamin D in strengthening the innate immune system by acting as an immunomodulator and reducing inflammation in experimental and human IBD. The active form of vitamin D, 1,25(OH)D₃, acts on T cells to promote T helper (Th)₂/regulatory T responses over Th₁/Th₁₇ responses; suppresses dendritic cell inflammatory activity; induces antibacterial activity; and regulates cytokine production in favor of an anti-inflammatory response. Murine and human IBD studies support a therapeutic role of vitamin D in IBD. Risk factors for vitamin D deficiency in this population include de-

creased sunlight exposure, disease duration, smoking, and genetics. Vitamin D normalization is associated with reduced risk of relapse, reduced risk of IBD-related surgeries, and improvement in quality of life. Vitamin D is an inexpensive supplement which has been shown to improve IBD outcomes. However, further research is required to determine optimal serum vitamin D levels which will achieve beneficial immune effects, and stronger evidence is needed to support the role of vitamin D in inducing disease response and remission, as well as maintaining this improvement in patients' disease states.

Key words: Vitamin D; Inflammatory bowel disease; Immune response; Inflammation; Cytokines; Supplementation

Core tip: There is support for the importance of maintaining normal vitamin D levels in inflammatory bowel disease (IBD) patients, demonstrated by its anti-inflammatory actions in the gut. A randomized controlled trial examined the impact of vitamin D supplementation on IBD outcomes and demonstrated a reduced risk of relapse in vitamin D-treated Crohn's disease patients. Furthermore, vitamin D₃ and active vitamin D have been shown to reduce clinical disease activity and improve quality of life in IBD patients. Normalization of vitamin D levels is also associated with a decreased risk for IBD-related surgery. This vitamin has therapeutic benefit in IBD patients.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic inflammatory condition of the intestine that causes abdominal pain, diarrhea, and weight loss and includes two forms, Crohn's disease and ulcerative colitis^[1]. IBD reduces quality of life and may cause financial stress by increasing disability and decreasing the capacity for work^[1,2]. The disease is complex and etiology is not completely understood; however, IBD is associated with abnormal immune responses to the body's natural intestinal bacteria^[1,2], which activate the gastrointestinal immune system. It is expected that genetic and environmental interactions play a role in the susceptibility of IBD^[1,2]. As there is currently no cure for IBD, medical therapy remains the mainstay treatment for achieving and maintaining remission^[2].

It is well-established that vitamin D plays a critical role in improving bone health and is specifically important for patients who are at risk of low bone density. Low bone mineral density is more prevalent among patients with Crohn's disease and ulcerative colitis compared to healthy controls^[3]. Long standing disease, multiple steroid exposures, and low serum 25-hydroxycholecalciferol [25(OH)D3] levels are contributing factors to decreased bone mineral density and increased fractures in patients with IBD^[3-5]. Therefore, vitamin D supplementation is essential in this high-risk group. There is, however, growing support for non-traditional actions of vitamin D including anti-inflammatory, anti-proliferative, cell differentiation, and apoptotic effects^[6]. These effects have led to examination of vitamin D in the pathogenesis of autoimmune diseases such as IBD^[6]. This review will address the regulatory role of vitamin D on immune responses and describe its relevance in regards to inflammatory bowel disease.

VITAMIN D PHYSIOLOGY

Vitamin D metabolism

Vitamin D is present in two major forms. Vitamin D2 (ergocalciferol) is present in plants, yeast, and fungi^[6,7], while vitamin D3 (cholecalciferol) can be obtained from animal sources such as oily fish and egg yolk^[6,8]. Vitamin D3 is also synthesized endogenously in the skin upon ultraviolet light exposure. Sun light exposure to the skin results in a photochemical conversion of 7-dehydrocholesterol to pre-vitamin D, which then rapidly converts to cholecalciferol. This process is self-limiting to prevent toxicity^[6,8].

Vitamin D is fat soluble and absorbed in the small intestine along with dietary fat. After incorporation into chylomicrons, it is rapidly delivered into the venous circulation^[3,4]. It is then transported by vitamin D binding proteins (DBPs) to the liver where it is converted to 25(OH)D3 by hepatic 25-hydroxylase^[6,7,9]. 25(OH)D3 is inactive, however, it is the main circulating form of vitamin D and the best indicator of vitamin D status^[6,9]. Vitamin D is primarily stored in the liver as well as in adipose

tissue. Once saturation of these tissues occur, 25(OH)D3 is released to circulate in the blood^[4], where it is predominantly bound by DBPs and albumin, leaving little in the free form^[3,7]. DBPs transport 25(OH)D3 to the kidney, where it is converted to its active hormonal form, 1 α ,25-dihydroxycholecalciferol [1,25(OH)2D3], by the enzyme 25-hydroxyvitamin D3-1 α -hydroxylase^[6,9]. It can now act on its receptor, the vitamin D receptor, in many target tissues, including the intestine, kidney, and bone, thereby altering transcription of target genes^[10,11]. In the target tissue, 24-hydroxylase catabolizes 1,25(OH)2D3 and 25(OH)D3 into their inactive metabolites, which are then excreted as calcitroic acid in the urine^[3,8,10].

The rate limiting enzyme in the metabolism of vitamin D is 1 α -hydroxylase. This enzyme is tightly regulated by plasma parathyroid hormone (PTH) and 1,25(OH)2D3. Active vitamin D production in the kidneys is directed by PTH^[4,6,8,9], which upregulates transcription of CYP27B1, the gene encoding for 1 α -hydroxylase^[9]. This results in an increased production of 1,25(OH)2D3 in the kidney. In turn, 1,25(OH)2D3 takes part in a negative feedback loop to suppress the transcription of PTH and CYP27B1, thereby decreasing production of 1,25(OH)2D3^[9]. Simultaneously, 1,25(OH)2D3 induces 24-hydroxylase production^[8,9]. This is an autoregulatory mechanism to suppress the actions of 1,25(OH)2D3^[9]. An overview of vitamin D sources and metabolism is outlined in Figure 1.

Vitamin D receptor

The vitamin D receptor (VDR) plays an important role in how vitamin D exerts its biological effects. It belongs to a superfamily of nuclear hormone receptors and is specifically activated by 1,25(OH)2D3^[11,12]. In response to 1,25(OH)2D3 binding, VDRs regulate gene transcription, thereby producing specific proteins to carry out vitamin D3 biological activity. The DNA binding domain of the zinc finger recognizes vitamin D response elements (VDREs), which are specific DNA sequences on cell-targeted genes^[11]. 1,25(OH)2D3 binding results in the formation of the VDR and retinoid X receptor (RXR) heterodimer^[12]. This complex binds to VDREs and recruits large coregulatory complexes to these specific genes through the VDR transactivation domain^[11,12]. The activities of coregulatory complexes may include nucleosomal remodeling, selective chromatin histone modification, or RNA polymerase II recruitment and initiation. All of these activities work to enhance or suppress gene expression^[11].

Multiple tissues and immune cells express VDRs and the enzymes needed to produce local 1,25(OH)2D3^[6,13-15]. This enzyme activity is regulated in a different manner compared to the enzymatic renal production of 1,25(OH)2D3; it is no longer under an endocrine feedback mechanism, but is induced by other factors^[6]. These findings have led to the examination of multiple roles of vitamin D in the pathogenesis of autoimmune diseases such as IBD^[6].

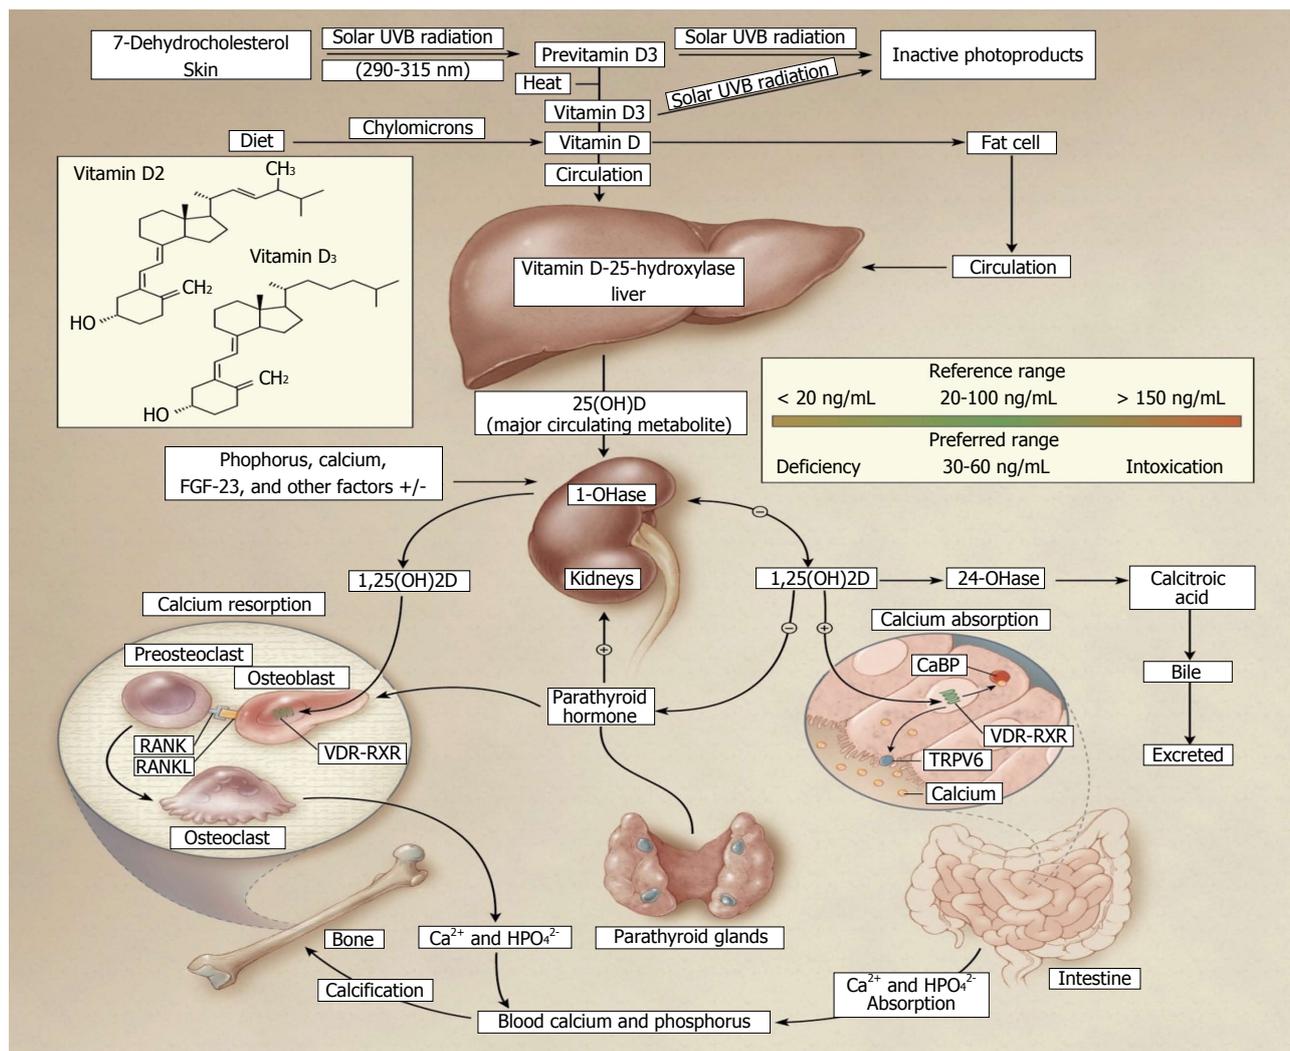

Figure 1 Vitamin D sources and metabolism^[8]. Vitamin D can be obtained either from the diet or synthesized in the skin. Under solar ultraviolet (UVB) radiation, 7-dehydrocholesterol in the skin is converted into cholecalciferol (vitamin D3). Vitamin D from the diet enters chylomicrons, which transport it into circulation. Vitamin D is stored in adipose tissue, but when released into circulation, vitamin D binding proteins direct it to the liver where it is converted into its major circulating form, 25-hydroxyvitamin D3 [25(OH)D3] by 25-hydroxylase. In the kidneys, 25(OH)D3 is converted into 1 α ,25-dihydroxyvitamin D3 [1,25(OH)2D3], the active form, by 1 α -hydroxylase. It can now exert its biological effects including calcium absorption, resorption, and bone development. Parathyroid hormone released from the parathyroid glands upregulates hepatic conversion of 1,25(OH)2D3 by stimulating 1 α -hydroxylase production; however, autoregulatory mechanisms suppress these actions through negative feedback loops. 1,25(OH)2D3 suppresses parathyroid hormone and 1 α -hydroxylase production. Vitamin D is then catabolized by 24-hydroxylase and excreted as calcitriolic acid. The recommended optimal range for vitamin D levels is 30-60 ng/mL (75-150 nmol/L). EFFECTS OF VITAMIN D ON THE IMMUNE SYSTEM

Vitamin D is important in both the innate and adaptive immune systems^[13]. Immune cells express VDRs and the enzymes necessary to convert vitamin D3 and 25(OH)D3 into 1,25(OH)2D3, wherein locally produced 1,25(OH)2D3 can exert specific autocrine and paracrine effects without producing unnecessary systemic effects^[16,17]. 1,25(OH)2D3 can modulate the adaptive immune responses by altering the actions of activated T and B cells, and it can modulate the innate immune responses by regulating macrophages and dendritic cells^[16].

Vitamin D and T-cell differentiation

It has been established that vitamin D is an immune system regulator through its role in targeting CD4⁺ cells of T lymphocytes to suppress T helper type 1 (Th1) cell driven immune responses^[17-19]. Th1 cells produce pro-inflammatory cytokines including IFN- γ , interleukin (IL)-2, and tumour necrosis factor-alpha (TNF- α), which are important for reducing intracellular infections. 1,25(OH)2D3 works to inhibit the over production of these pro-inflammatory cytokines^[19].

Overall, the main action of 1,25(OH)2D3 on T-cells is mediating T helper type 1 (Th1)/T helper type 2 (Th2) development and differentiation^[17,18]. Vitamin D3 affects

the Th1-Th2 balance in favour of Th2 cell development. The development into either Th1 or Th2 from CD4⁺ T cells is directed by cytokines^[18]. Cytokine IL-12 induces Th1 cell development whereas IL-4 induces Th2 cell development. The effects these cytokines have on the Th1-Th2 balance determines which cytokines will be produced and therefore determine the type of immune response. Th1 cells produce pro-inflammatory IFN- γ and lymphotoxin, and Th2 produces anti-inflammatory IL-4, IL-5, and IL-13^[17,18]. The increased development of Th2 is a result of direct action of vitamin D3 on CD4⁺ cells^[18], whereas the reduction in Th1 cell development is due to the effects of vitamin D3 on dendritic cells^[17,18]. Using mice Ag-specific T cells, Boonstra *et al*^[18] demonstrate that vitamin D3 increases the frequency of IL-4 producing cells *in vitro* from 8.0%-55.8%, thereby supporting a vitamin D induced Th2 profile. This study also shows that vitamin D3 increases IL-10 and IL-5 producing cells and decreases IFN- γ producing cells^[18]. The role of vitamin D in regulating cytokine production has been suggested to limit inflammatory tissue damage, but it also reduces bacterial killing. IFN- γ augments toll-like receptor (TLR) 2/1 induced expression of CYP27B1 and bacterial killing, and IL-4 depresses TLR 2/1 activation of bacterial killing^[13]. Therefore, a balanced response is important.

At the transcription level, c-maf and GATA-3 are the transcription factors relating to Th2 development^[18]. Vitamin D3 can directly target CD4⁺ cells to promote Th2 development at the level of transcription^[17,18]. *In vitro* studies show a correlation between increased expression of GATA-3 and c-maf and Th2 cytokine levels, IL-5, IL-10, and IL-4, after vitamin D3 treatment. In addition, there is a reduction in IFN- γ ^[18]. Boonstra *et al*^[18] conclude that vitamin D likely functions to diminish cell-mediated immune responses by skewing toward a Th2 phenotype, which fights extracellular infections.

Th17 cells are another vitamin D target because of their ability to produce IL-17, a pro-inflammatory cytokine. Vitamin D reduces inflammatory tissue damage by suppressing Th17 development and in doing so, reduces IL-17 production^[13]. Furthermore, 1,25(OH)2D3 increases the development of T regulatory cells by acting on naïve CD4⁺ cells. Regulatory T cells are a group of CD4⁺ T cells that have immunosuppressive properties by depressing the proliferation of other CD4⁺ T cells^[13]. Vitamin D in combination with another immunosuppressive drug, dexamethasone, has been shown to increase IL-10 producing regulatory T cells. This supports the idea that regulatory T cells located at sites of inflammation down-regulate the immune response^[19].

Research supports the immunosuppressive effect of vitamin D due to its involvement in T-cell differentiation. The evidence shows that vitamin D plays a role in maintaining a balance between the inflammatory response of Th1/Th17 cells and the immunosuppressive response

from Th2/Treg cells.

Vitamin D and dendritic cells

Dendritic cells (DCs) are antigen presenting cells (APCs) and are important in initiating CD4⁺ T cells responses^[20]. Vitamin D inhibits differentiation and maturation of human DCs *in vitro*^[20] by suppressing the IL-12 production from DCs and increasing IL-10 production^[17,20]. This is an important immunosuppressive activity as IL-12 is an important cytokine in inducing Th1 development^[17,18]. 1,25(OH)2D3 inhibits the differentiation, maturation, and immunostimulatory capacity of DCs^[21]. Canning *et al*^[21] confirm that 1,25(OH)2D3 suppresses monocyte differentiation into DCs, thereby generating immature DCs. This suppresses DC ability to stimulate T-cell proliferation.

Lipopolysaccharide (LPS) is a component of the Gram-negative bacterial wall, which induces monocytes/macrophages to produce cytokines. After LPS stimulation, DCs and monocyte-derived macrophages (MACs) have a high local 1- α -hydroxylase production of 1,25(OH)2D3, which positively modulates MAC differentiation and depresses actions of DCs and lymphocytes^[14]. This mechanism facilitates a normal immune response as some DCs still mature; vitamin D prevents over stress of this immune response that may lead to pathological effects^[13]. Vitamin D skews the development of the immune response towards a non-specific innate immune response and away from an antigen-specific immune response.

Antibacterial activity of vitamin D

As a fundamental part of the innate immune response, human monocytes have been shown to locally produce 1,25(OH)2D3, which triggers increased autophagy, an important mechanism for eliminating pathogens by antibacterial proteins^[15]. TLR expressed on monocytes recognize pathogens, and under TLR 2/1 stimulation, CYP27B1, the gene encoding for 1 α -hydroxylase, and VDR expression is upregulated^[13,15]. 1,25(OH)2D3 acts on monocytes to induce expression of the cathelicidin antimicrobial peptide (CAMP) gene (LL-37), producing a protein that enhances intracellular killing of bacteria^[13,15,22]. The CAMP gene is a direct target of the vitamin D receptor^[22]. Furthermore, nucleotide-binding oligomerization domain-containing protein 2 (NOD2), a pattern recognition receptor, has an important role in inducing antibacterial activity. NOD2 activation by muramyl dipeptide, a product of Gram-negative and Gram-positive bacteria, stimulates transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B), which induces gene expression for antimicrobial peptide defensin β 2 (DEFB2)^[13,23]. Interestingly, 1,25(OH)2D3 induces NOD2 expression in many cell types, thereby increasing cell sensitivity to these bacteria products; as a result 1,25(OH)2D3 enhances NOD2 mediated DEFB2 transcription^[13,23].

Anti-inflammatory role of vitamin D

As a part of the innate immune system, macrophages release proinflammatory cytokines and chemokines upon stimulation. This leads to an inflammatory response to protect the body from pathogenic microorganisms^[24]. TNF- α is a proinflammatory cytokine that is produced early in the course of inflammation by macrophages and lymphocytes. It is involved in autoimmune diseases, including IBD^[25]. Proinflammatory cytokines are positive for host defense, but overproduction leads to unresolved inflammation^[26]. Muller *et al*^[27] examine the effect of 1,25(OH)2D3 on LPS-stimulated human blood monocytes, and find it inhibits the release of IL-1 α , IL-6, and TNF- α . LPS binds to TLR4 on monocytes to mediate activation of mitogen-activated protein kinase (MAPK)^[26]. MAPKs are critical regulators of proinflammatory cytokine production, including IL-6 and TNF- α . 25(OH)D3 treatment has been shown to inhibit LPS-induced IL-6 and TNF- α production in peripheral blood mononuclear cells (PBMC) of healthy donors *via* upregulation of MKP-1 (MAPK phosphatase-1). MKP-1 switches off cytokine production in monocytes/macrophages after inflammatory stimuli. Interestingly, doses of 25(OH)D3 that relate to vitamin D sufficiency (> 30 ng/mL or 75 nmol/L) significantly inhibited mRNA production of these cytokines^[26].

Vitamin D analogues have also been proven to have immunomodulatory effects. Stio *et al*^[28] demonstrate the vitamin D analogue KH 1060 and a monoclonal anti-TNF- α antibody to work synergistically in significantly inhibiting PBMC proliferation and TNF- α production in healthy subjects. *In vitro* experiments using PBMCs from healthy volunteers were also able to demonstrate the effect of paricalcitol, a vitamin D analogue, in reducing both basal TNF- α and LPS-induced TNF- α ^[25].

The importance of VDRs in the inflammatory response has also been demonstrated. Chen *et al*^[24] report a more robust and prolonged production of pro-inflammatory cytokines TNF- α , IL-6, and IL-1 β in bone marrow derived macrophages (BMDMs) from VDR-/- mice compared to wild type (WT) mice after LPS exposure. This suggests a dysregulated and over sustained innate immune response in macrophages under attenuated VDR signalling. Interestingly, 1,25(OH)2D3 and its analogue, paricalcitol, have been shown to reduce LPS-induced TNF- α and IL-6 cytokines in WT BMDMs^[24].

Chen *et al*^[24] have also examined novel anti-inflammatory effects of vitamin D by investigating its microRNA-155-SOCS1 target. MicroRNAs (miRNAs) are small noncoding RNAs that control gene expression. Recently, miRNA-155 has been shown to regulate innate immune responses and TLR signaling. It targets the “suppressor of cytokine signalling” (SOCS) family of proteins, specifically SOCS1. miRNA profiling in mice cells was examined after the treatment with LPS, with or without 1,25(OH)2D3. As a result, miR-155 increased the most with LPS and was suppressed the most by vitamin D; miR-155 were elevated in VDR -/- bone marrow derived

macrophages (BMDMs) after exposure to LPS compared to the WT BMDMs; and 1,25(OH)2D3 suppressed the induction of miR-155 by LPS in these cells. Additionally, 1,25(OH)2D3 blocked TNF- α , IL-6, and miR-155 induction in human PBMCs. Overall, 1,25(OH)2D3 was found to upregulate SOCS1 through its suppression of miR-155. SOCS1 is important in the negative feedback regulation of LPS-induced inflammation and inhibits TNF- α , IL-6, and IFN- γ pathways. In the absence of VDRs, the negative feedback loop is dysregulated^[24].

Seasonal variations in serum vitamin D levels have an effect on the innate immune response. The increase in serum vitamin D levels during the summer months is associated with a significant drop in LPS-induced TNF- α (64%), IL-6 (33%), IL-1 β (59%), and IFN- γ (46%) from PBMCs in healthy individuals *in vivo* compared to LPS-induced levels during the winter months^[29]. Caution does need to be taken when considering the difference in physiological up-regulation of vitamin D levels by solar radiation and the doses of vitamin D employed *in vitro* and *in vivo*; however, this data does support how the innate immune response can be regulated by the physiological variation of serum vitamin D3 levels during the four seasons of the year^[29].

Role of vitamin D in gastrointestinal inflammation

There is support for the role of vitamin D in the immune system, particularly in reducing inflammatory responses. Recently, more studies have demonstrated the role for vitamin D specifically in gastrointestinal inflammation and suggest deficiency is associated with IBD.

The importance of vitamin D in reducing the pro-inflammatory profile of IBD patients is demonstrated by the impact of cytokine-induced apoptosis and cytokine disruption of epithelial barrier function. Epithelial apoptosis occurs as a normal physiological event in the gastrointestinal tract and the mucosal barrier function is still maintained; however, cytokine-induced apoptosis may disrupt the barrier, leading to abnormal mucosal permeability, a common occurrence among IBD patients^[30]. Bruewer *et al*^[30] address the mechanisms by which pro-inflammatory cytokines disrupt the barrier through non-apoptotic mechanisms. IFN- γ was demonstrated to reduce epithelial gate function, and the effects were increased when combined with TNF- α , resulting in intestinal epithelium paracellular permeability. The authors suggest this allows for the barrier function to quickly normalize when inflammatory cytokines are reduced^[30], stressing the importance of medical therapy in maintaining disease remission.

There is evidence to suggest that there are distinct cytokine profiles in Crohn's disease and ulcerative colitis. Papadakis *et al*^[31] report Crohn's disease to show a Th1 type of immune response with elevated IL-12, TNF- α , and IFN- γ cytokines, whereas ulcerative colitis presents with increased IL-5 secretion. Specific pro-inflammatory cytokines have been identified in the inflamed mucosa of Crohn's disease and ulcerative colitis patients such as

IL-1, IL-6, IL-8, and TNF- α ^[31]. Each of these cytokines upregulate the inflammatory cascade leading to more inflammation and tissue damage in the inflamed mucosa^[31]. Vitamin D has been shown to target these inflammatory pathways.

TNF- α is a central cytokine in the pathogenesis of inflammatory bowel disease^[31]. In the review by Papadakis *et al*^[31], they report three lines of evidence to support the importance of TNF- α in IBD. They explain that anti-TNF therapy has been very successful in treatment of IBD in humans and in animal models, and that a “Crohn’s like” phenotype is expressed in mice that over express TNF- α ^[31]. Interestingly, a vitamin D analogue has recently been shown to work synergistically with infliximab, an anti-TNF therapy used in the treatment of IBD, to reduce the cytokine TNF- α in human peripheral blood monocytes^[28]. Treatment with 1,25(OH)2D3 in the colonic tissue of IL-10 knock-out (KO) mice has also been shown to down-regulate TNF- α -associated genes in these mice^[32]. Furthermore, *in vitro* studies of CD4⁺ T-cells of healthy controls and patients with Crohn’s disease have shown that 1,25(OH)2D3 increases the production of anti-inflammatory cytokine IL-10 and decreases the production of pro-inflammatory IFN- γ , supporting a therapeutic role of vitamin D in IBD^[33].

Stio *et al*^[34] examine the effects of vitamin D on PBMCs from patients with active Crohn’s disease on infliximab, an anti-TNF therapy. After vitamin D treatment, PMBC proliferation decreased in both responders and non-responders, but to a greater extent in responders^[34]. Interestingly, vitamin D analogue treatment increased VDR expression in unresponsive patients and VDR levels did not change in responsive patients. The authors suggest infliximab induces VDR expression in the presence of vitamin D in unresponsive patients; as a result, there are differences in sensitivity to vitamin D between responders and non-responders. This suggests that VDR expression and PMBC proliferation may be useful indicators to predict response of Crohn’s disease patients to infliximab therapy^[34].

Studies have gone on to suggest that vitamin D deficiency and deficiency in its signaling pathways are contributing factors in the pathogenesis of IBD. Wu *et al*^[35] propose a mechanism by which vitamin D deficiency may cause IBD through the changes in vitamin D receptor signaling in autophagy homeostasis, including increases in TNF- α -induced autophagy. Another study by Wang *et al*^[23] examine the role of vitamin D in NOD2 expression, as NOD2 deficiency, due to mutations in its gene, has been linked to the pathogenesis of Crohn’s disease^[22]. These authors show that 1,25(OH)2D3 signaling induces NOD2 expression in human intestinal epithelial cells, thus supporting the idea that vitamin D deficiency plays a causative role in Crohn’s disease.

As discussed previously, local production of vitamin D is an important part of regulating microenvironment inflammatory profiles. DCs from healthy subjects convert 25(OH)D3 to the active form of vitamin D, 1,25(OH)2D3,

which could be important in local control of inflammation in Crohn’s disease patients^[36]. Bartels *et al*^[36] isolate peripheral monocytes from 20 Crohn’s disease patients who were vitamin D deficient, which were then matured into DCs *in vitro*. Addition of the active [1,25(OH)2D3] and inactive [25(OH)D3] vitamin D3 metabolites inhibited LPS-induced DC maturation, and supplementation changed the cytokine profile of LPS-matured DC cultures compared to those not supplemented. The production of TNF- α and IL-12 decreased, while unexpectedly, there was a trend towards reduced IL-10 and IL-6 significantly increased^[36]. DCs of Crohn’s disease patients could be exposed to LPS in the gut resulting in similar findings^[36]. Furthermore, vitamin D supplementation reduced proliferation of the entire lymphocyte population and the CD4⁺ lymphocytes; therefore, vitamin D could be protective against Crohn’s disease as inflammation in this disease can be characterized as uncontrolled lymphocyte development^[36].

While the addition of vitamin D *in vitro* changes cytokine profiles, there may be differences in the effects of vitamin D in *in vivo* studies. A study was conducted on Crohn’s disease patients who were treated with 1200 IU of vitamin D3 per day or placebo for 26 wk to assess differences in induced T-cell mediated immune function between the treatment and placebo groups during *in vivo*^[37]. PBMCs were cultured from patients of each group, and there was a significant increase in production of IL-6 in T cells from vitamin D treated patients. IL-6 significantly correlated with serum vitamin D [25(OH)D3] levels ($P = 0.02$). In the vitamin D treated patients, there was also a trend to increased IL-4 and no effect on TNF- α and IFN- γ production^[37]. There was no change in IL-10 production nor in the amount of T regulatory cells CD4⁺, CD25⁺, FoxP3⁺ T cells; however, the amount of proliferating CD4⁺ cells significantly increased. IL-6 can induce T cell IL-4 production, which may explain the increase in IL-4^[37].

There is strong evidence for a protective effect of vitamin D against IBD related inflammatory responses; however, there are mixed findings on the production of IL-6 with the treatment of vitamin D. IL-6 has been shown to increase in certain situations and decrease in others under vitamin D treatment. Interestingly, *in vitro* and *in vivo* studies examining vitamin D treatment of LPS-matured DCs and PBMCs from Crohn’s disease patients show increased IL-6 production, whereas these studies examining healthy volunteers demonstrate a decrease in IL-6 after vitamin D treatment. IL-6 has been reported to support Th17 development, which have important anti-microbial roles^[36]. Additionally, IL-6 may have anti-inflammatory roles by reducing DC maturation and increasing T cell IL-4 production^[36,37]. Therefore, vitamin D does have immunosuppressive properties; however, instead of isolating vitamin D to this effect, it may be better to suggest it is an immunomodulator that strengthens the innate immune response and depresses the adaptive immune reaction^[36], which may explain the

different actions in healthy volunteers and IBD patients who have intestinal mucosal injury.

EFFECT OF VITAMIN D IN ANIMAL MODELS OF IBD

VDR KO mice models

Vitamin D and the vitamin D receptor have been shown to have an important role in animal models of colitis. Vitamin D receptor KO mice treated with dextran sodium sulfate (DSS) to induce colitis demonstrate markedly elevated levels of a number of tissue pro-inflammatory cytokines including TNF- α , IL-12p70, and IFN- γ , and have significantly more intestinal injury, fewer intact crypts, more epithelium loss, and more inflammation. This indicates that the absence of VDRs increases the sensitivity of the intestinal mucosa to very low doses of DSS^[38], thereby increasing the susceptibility to chemical injury in the gut. This confirms a prominent role of VDR signalling in the regulation of gut inflammation^[38].

Oral intake of 1,25(OH)2D3 improves DSS induced colitis in WT mice, and there is an upregulation of anti-inflammatory cytokine IL-10 production, which may help to reduce other cytokine responses^[38]. Interestingly, rectal administration of 1,25(OH)2D3 in the WT mice is more effective than oral in regards to decreasing DSS colitis. This is justified by obtaining the same results but only injecting half the dose of vitamin D in the rectum (site of inflammation)^[38].

Vitamin D and its receptors play important roles in maintaining gut integrity and protecting the intestine from pathogenic enteric bacterial infection. Wu *et al*^[39] support the role of vitamin D in suppressing bacterial-induced NF- κ B activity in the intestine. NF- κ B is a regulator of inflammatory cytokines such as IL-6, and after bacterial invasion, VDRs inhibit its actions. Intestinal VDRs protect against bacterial infection, demonstrated by a 6-fold increase in IL-6 and more severe inflammation after a *Salmonella* in VDR-/- mice compared to VDR+/+ mice^[39]. Furthermore, after exposure to Salmonella, mice lacking VDRs had more Salmonella invasion of the intestine compared to WT^[39]. Interestingly, VDR expression increased in WT mice as a direct result of an enteric bacterial infection, indicating a role of VDR signalling pathway in responding to specific pathogenic bacteria. VDRs relocated from the surface of colonic epithelial cells to the surface of crypts as well as in the middle and bottom of the crypts after infection^[39]. Furthermore, IL-6 was undetectable in VDR+/+ mice and present in VDR-/- mice; as a result, this suggests that VDR-/- mice start with a pre-inflammatory state even before being infected^[39].

The intestinal epithelial layer contains a highly specialized immune system and physical barrier to protect against the invasion of pathogens. Intraepithelial lymphocytes (IELs) are found in the intestinal epithelial layer, and they are an important part of maintaining intestinal integrity^[40]. Specific IELs, CD8 $\alpha\alpha^+$ T cells, aid in the maintenance of gut health. VDR KO mice have fewer

CD8 $\alpha\alpha^+$ T cells in the gut, implying VDRs are important in regulating the growth and maintenance of CD8 $\alpha\alpha^+$ T cells^[40]. Moreover, VDR-/- mice have significantly reduced intestinal transepithelial resistance (TER) compared to VDR+/+ mice. TER is reduced when epithelial barrier function is compromised, making it a good indicator of this malfunction. Additionally, tight junctions and desmosomes are severely disrupted in VDR-/- colonic mucosa^[41]. The breakdown of the physical barrier that separates the host from its gastrointestinal microorganisms results in intestinal permeability and the development of IBD. These studies demonstrate prominent role of VDR signalling in maintaining the integrity of the epithelial barrier in the intestine and in its protection against IBD^[42].

Increased IL-17 production has also been reported in VDR null mice. Th17 cells are pro-inflammatory and have been associated with increased severity of IBD in animal models. VDR KO mice have significantly higher induced Th17 cell and IL-17 production compared to WT mice^[43]. Additionally, 1,25(OH)2D3-deficient T cells overproduce IL-17 compared with WT cells^[43]. Recombinase-activated gene 2 knockout mice lack mature T and B cells. When WT CD4⁺ T cells are transferred to VDR/Rag double KO mice, the colonic sections of these recipients show significantly more hyperplasia and inflammation compared to Rag KO recipients^[43]. There is an increased expression of IL-17 secreting cells in the gut and periphery of these double KO mice, suggesting VDRs on accessory cells direct Th17 development^[43].

Conversely, there are some limitations of vitamin D on host susceptibility to pathogens. While increased production of Th1/Th17 cytokines is related to the pathogenesis of Crohn's disease, Th1/Th17 responses are critical for the removal of many infectious bacteria^[44]. Examining the role of 1,25(OH)2D3 in *Citrobacter rodentium* (*C. rodentium*) infected mice, Ryz *et al*^[44] demonstrate that mice treated with 1,25(OH)2D3 have significantly increased scores for edema, goblet cell depletion, hyperplasia and infiltrating inflammatory cells compared to vehicle-treated mice^[44]. These mice also have a reduced number of Th17 T cells in their colons and decreased production of Th17 associated antimicrobial peptide TEG3 γ , which works as a host defense against infection with *C. rodentium*^[44]. This study demonstrates the potential negative consequences of vitamin D treatment. It can protect against Th17 cell driven damage, but it is important to note these responses are key in host defense against pathogens^[44].

IL-10 KO mice models

VDR/IL-10 double KO mice develop severe IBD involving all areas of the small intestine and colon and have the largest change in colon anatomy and inflammation compared to single VDR KO and IL-10 KO mice^[45]. WT mice do not express any cytokines and VDR/IL-10 double KO mice express two-three fold higher levels of IL-1 β , IL-2, IFN- γ , and TNF- α mRNA in their colons

compared to the single KO mice colons^[45]. IL-10 KO mice with normal VDR function experience a milder form of disease; thus, VDR deficiency seems to intensify IBD severity. Single VDR KO mice also express a milder form of disease; therefore, IL-10 and VDRs have a collective effect on disease severity^[45]. Furthermore, vitamin D deficiency in IL-10 KO mice enhances inflammation in the small intestine in comparison to vitamin D sufficient and vitamin D supplemented IL-10 KO mice^[46]. Evidently, vitamin D deficiency augments disease severity; however, dietary intake of vitamin D can be problematic, as few foods are high in vitamin D and weight loss is common in patients with IBD^[46]. Therefore, vitamin D supplementation to achieve and maintain sufficient levels is critical.

Trinitrobenzene sulfonic acid and DSS induced colitis mice models

Colitis can be induced in mice with treatment of trinitrobenzene sulfonic acid (TNBS). While treatment alone with calcitriol, a vitamin D analogue, significantly reduces colitis in acute TNBS colitis, treatment with both calcitriol and dexamethasone shows the best improvement in health^[47]. This is demonstrated by the study by Daniel *et al.*^[47], which showed weight gain and improvement in macroscopic, microscopic, and immunological parameters of colitis after treatment of TNBS-induced colitis with the combined therapies. Calcitriol treatment reduced Th1 mediators and increased IL-4, thereby promoting the Th2 subset^[47]. Additionally, calcitriol upregulated IL-10 and enhanced regulator T cell function, specifically transforming growth factor beta, and FoxP3 levels. Calcitriol also decreased IL-12p70 and IL-23p19 expression, which are DC mediators. As a result, calcitriol downregulates the pro-inflammatory response of intestinal DCs and counteracts Th1 action^[47].

A vitamin D analogue has been shown to provide similar results. ZK156979 is a new low calcemic vitamin D analogue, and its use in treating TNBS-induced colitis in mice results in remarkable disease improvement. Daniel *et al.*^[48] show a reduction in colitis-associated hypercalcemia and inflammation as a result of treatment of TNBS-induced colitis with this vitamin D analogue. Infiltration of inflammatory cells, neutrophils and lymphocytes, ulcerations, loss of goblet cells, and fibrosis in the colon were restored after vitamin D treatment^[48]. TNF- α and IFN- γ levels decreased, and the Th2 profile was induced with increased production of IL-4 and IL-10^[48]. This analogue effectively treats Th1 colitis.

DSS treated vitamin D deficient and sufficient mice both show increased expression of mRNAs for cytokines IL-1, IL-10, IL-17, and IFN- γ ^[49]. Both types of mice show severe ulceration, granulation, and inflammation; however, symptoms are exacerbated in vitamin D deficient mice^[49]. Vitamin D acts to protect DSS treated mice, as there is an increased expression of vitamin D activating enzyme CYP27B1 in these mice^[49] and CYP27B1 KO mice are more susceptible to colitis after DSS

treatment^[50]. Lagishetty *et al.*^[49] examine the impact of vitamin D status on antibacterial activity in DSS-induced experimental colitis. The expression of an antimicrobial protein, angiogenin-4 (Ang4), decreased in vitamin D deficient mice^[49]. Ang4 has bactericidal activity in the intestine and a decreased expression resulted in a 50-fold increase of bacterial infiltration in vitamin D deficient mice^[49]. It is worthy to note dietary restrictions in these mice resulted in 25(OH)D3 concentrations less than 50 nmol/L, which is consistent with human parameters of deficiency. The authors note that the consequences of vitamin D deficiency resulted after treatment with DSS; therefore, vitamin D deficiency may be important after inflammation has occurred^[49]. On the other hand, the expression of Ang4 was associated with vitamin D status; therefore, the authors hypothesize impaired vitamin D status may be a predisposing factor for IBD due to the regulation of enteric bacteria^[49].

Although these animal results are limited in their application to humans as chemical induced colitis in mice may not fully be representative of human IBD forms, they are important in examining treatment and disease activity outcomes. Investigation into determining whether other mouse models better replicate human IBD will be important^[50]. The differences in results between models with impaired vitamin D status as opposed to deletion of VDRs or the *CYP27B1* gene expression are also important in determining IBD susceptibility^[50].

EFFECT OF VITAMIN D IN HUMAN IBD

Geographical distribution of vitamin D deficiency in IBD

Epidemiological evidence for a role of vitamin D in IBD is seen in the geographical distribution of disease, with higher incidences and prevalence in temperate climates and lower risks in persons living near the equator^[6,51,52]. Additional environmental, lifestyle, or genetic factors that have similar associations with geographical location may play a part in the association between sun exposure and IBD^[51]; however, this “north-south” gradient in the risk of Crohn’s disease and ulcerative colitis is likely explained by the variation in sun exposure, a major determinant of vitamin D levels^[51,52], thereby strengthening the role of vitamin D in IBD.

Vitamin D deficiency has been well described in IBD patients from all over the world with varying prevalence. In Ireland, 63% of Crohn’s disease patients had 25-OH vitamin D levels < 50 nmol/L; however, using the higher cut-off to define vitamin D deficiency (< 80 nmol/L), 90% of this Crohn’s disease cohort was vitamin D deficient^[53]. The frequency of vitamin D deficiency in Canada is approximately 8% (< 25 nmol/L) with an additional 22% having insufficiency (< 40 nmol/L)^[54]. A Japanese study found that 27.3% of Crohn’s patients were vitamin D deficient (< 10 ng/mL or < 25 nmol/L) compared to only 6.7% of controls^[55]. In an IBD cohort of children, adolescents, and young adults from Philadelphia and Pennsylvania, 16% of the Crohn’s disease patients enrolled were vitamin

D deficient (< 38 nmol/L)^[56]. In a cohort study of IBD patients in Wisconsin, 49.8% of patients had levels < 50 nmol/L with 10.9% having levels < 25 nmol/L^[57]. Lastly, in London, United Kingdom, 68% of the IBD cohort was vitamin D deficient (< 50 nmol/L)^[58].

Higher 25-OH vitamin D plasma levels, predicted on the basis of a validated regression model in the Nurses' Health Study, have been shown to be associated with a lower incidence of Crohn's disease and ulcerative colitis^[59]; therefore, obtaining and maintaining optimal vitamin D levels are important, and yet, cut-off values used to define vitamin D deficiency among studies are variable. It is, however, generally accepted that vitamin D deficiency is defined as a serum 25-OH vitamin D level < 75 nmol/L^[8,60].

Risk factors of vitamin D deficiency in IBD

Many risk factors for vitamin D deficiency in IBD have been reported. Seasonal variation is evident in most studies with lower levels seen in winter months^[53,54,56,58]. Lower vitamin D levels have also been associated with longer disease duration and smoking^[53,57]. Poor health outcomes such as the need for intestinal resection, a structuring disease phenotype, the need for oral corticosteroids within 3 mo of diagnosis, and a diagnosis of pancolitis in ulcerative colitis are more prevalent in severely vitamin D deficient patients (< 25 nmol/L) compared to those with normal levels (> 50 nmol/L)^[58]. Intestinal resection may be a risk factor as the prevalence of at least one intestinal resection is significantly higher in those with vitamin D deficiency than those with adequate levels ($P < 0.05$)^[58].

The role of ethnicity as a risk factor for vitamin D deficiency in IBD has also been examined. A one year prospective study was conducted to examine the association between vitamin D levels, ethnicity, and human IBD. A significantly higher percentage of South Asian IBD patients were vitamin D deficient (< 50 nmol/L) compared to Caucasians^[61]. For both Caucasians and South Asians with Crohn's disease, an inverse relationship was found between clinical disease severity and vitamin D levels. For all IBD patients, CRP levels were inversely related to vitamin D levels; however, none of these results reached a significant association^[61]. Chatu *et al*^[58] also examine ethnicity as a predictor of vitamin D deficiency in an IBD cohort. No differences were found in median vitamin D levels among Crohn's disease and ulcerative colitis patients; however, the median vitamin D level was significantly lower in non-Caucasians (Asian and Black) compared to Caucasians. The multivariate regression analysis showed a history of IBD related surgery and ethnicity to be independently associated with vitamin D deficiency in Crohn's disease and ethnicity alone to be independently associated with vitamin D deficiency in ulcerative colitis^[58]. In an IBD cohort of children, adolescents, and young adults from Philadelphia and Pennsylvania, deficiency was more prevalent among African American subjects, Crohn's disease patients with upper gastrointestinal tract involvement, and patients with a significantly greater

lifetime exposure to glucocorticoid therapy^[56]. Other risk factors may include decreased nutrition intake due to Crohn's associated anorexia^[56,62], fear of GI discomfort from dairy due to lactose intolerance, and active disease associated with decreased physical activity resulting in reduced sun exposure^[56].

Genetic variants in the VDR and DBP have been shown to be associated with increased risk of IBD^[63,64]. Analysis of the frequency of common genetic variants in the DBP have shown the DBP 420 variant Lys to be less common in IBD patients as compared to healthy controls ($P = 0.034$)^[63]. A meta-analysis found that VDR gene polymorphisms are associated with the susceptibility to IBD. The TT genotype of TaqI was associated with Crohn's disease in Europeans (OR = 1.23; 95%CI: 1.02-1.49)^[63]. This polymorphism is a base substitution resulting in two encodings of isoleucine instead of an amino acid change. It has been suggested to result in lower VDR mRNA levels and less vitamin D/VDR inhibition on immune activation^[64]. Additionally, this variant was significantly associated with IBD in males. Furthermore, an increased risk of ulcerative colitis in Asians was significantly associated with the ff genotype of FokI on the promoter region of the VDR (OR = 1.65; 95%CI: 1.11-2.45)^[64]. This was compared to the FF genotype in Asians. The fourth finding was associated with decreased Crohn's disease susceptibility if one was a carrier of the "a" allele (Aa + aa genotypes) of ApAI (OR = 0.81; 95%CI: 0.67-0.97)^[64]. These studies demonstrate a genetic role explaining the high prevalence of vitamin D deficiency among IBD patients.

Vitamin D and disease activity

There is strong evidence to support a high prevalence of significantly lower serum 25-OH vitamin D levels among the IBD population, which have been shown to correlate with increased disease activity. Vitamin D levels have been shown to correlate negatively with disease activity assessed by the Harvey Bradshaw score^[57,61,62,64] or Crohn's disease activity index (CDAI) score^[65]. Joseph *et al*^[66] show that Crohn's disease patients have significantly lower vitamin D levels than their age- and sex-matched controls who were patients diagnosed with irritable bowel syndrome^[66]. Predictors of vitamin D status in this study were disease activity and sun exposure. In regards to severity of disease, patients with mild disease had vitamin D levels similar to the controls, but vitamin D levels were significantly lower in patients with moderate-severe Crohn's disease^[66]. As expected, lower vitamin D levels were observed in patients who had jejunal involvement of their disease^[66]. This association has also been reported in patients with ulcerative colitis. Blanck *et al*^[67] conducted a cross-sectional study and reported a larger number of patients with clinically active disease, using the six-point partial Mayo index, in the vitamin D deficient group compared to the vitamin D sufficient group ($P = 0.04$). Patients were stratified based on their vitamin D levels as either vitamin D suf-

ficient, insufficient, and deficient, and there continued to be a trend towards more active disease as vitamin D levels decreased^[67]. Furthermore, in a retrospective review of South Asian patients with IBD, patients with vitamin D deficiency appeared to have a more aggressive disease course with 14% of deficient patients requiring surgical management^[68]; therefore, optimizing vitamin D status and assessing the relationship between vitamin D treatment and disease activity is important^[68].

Despite a high prevalence of vitamin D deficiency among IBD patients, serum vitamin D levels may not always be associated with disease activity. Hassan *et al*^[69] found no association between low vitamin D levels and increased disease activity in IBD patients. Vitamin D deficiency may also be explained by the increased risk of intestinal malabsorption among the IBD population, particularly if patients have undergone small bowel resections or use cholestyramine for postresectional diarrhea. Cholestyramine reduces bile acids, which are required for vitamin D absorption^[6]. It has been demonstrated that Crohn's disease patients with quiescent disease have on average a 30% decrease in their ability to absorb vitamin D in comparison to normal subjects after supplementation with 50000 IU of vitamin D2^[70]. Furthermore, Suibhne *et al*^[53] report vitamin D deficiency to be common among Crohn's disease patients in clinical remission. Even in the summer, vitamin D deficiency among these patients continued to remain high (50%). About 40% of these patients were supplementing with vitamin D (200-400 IU), but it was not enough to maintain optimal vitamin D levels^[53]. The location of disease, disease activity, or prior resection may not be the only factors affecting vitamin D bioavailability^[70].

According to the previous studies, vitamin D status has been reported to be inversely correlated with disease activity^[57,61,62,64,67]. However, Abreu *et al*^[71] demonstrate a significant positive correlation between modified Harvey Bradshaw indices and 1,25(OH)2D3 levels in Crohn's disease patients taking corticosteroids. This correlation, however, did not exist in the patients who were not taking this drug^[71]. The increase in systemic 1,25(OH)2D3 may be a result of increased inflammation as a result of Crohn's disease^[71]. This can be explained by the expression of 1 α -hydroxylase in the intestine and increased expression of 1 α -hydroxylase in inflamed biopsies of Crohn's patients^[71]. The authors conclude that elevated 1,25(OH)2D3 is an additional risk factor for osteoporosis in this study population as they determine glucocorticoid use and high 1,25(OH)2D3 levels to be independent risk factors for low bone mineral density. They also suggest that 1,25(OH)2D3 may be a direct cause of bone loss or a surrogate marker for the type of intestinal inflammation leading to osteoporosis^[71]. The evidence from this review would support the latter. It should be noted that the previous studies measured 25(OH)D3 to determine vitamin D status, not 1,25(OH)2D3 levels.

Vitamin D supplementation in IBD

Vitamin D supplementation has traditionally been recommended in patients with IBD for management of bone disease. There is now increasing evidence for the potential immunomodulatory effects of supplementation. To date, the optimal level of 25-OH vitamin D for immunomodulatory effects is not known^[6].

Ananthakrishnan *et al*^[72] demonstrate an increased risk for IBD-related surgery in patients who have low plasma 25(OH)D levels. This association was found to be similar in both patients with Crohn's disease and ulcerative colitis. Furthermore, Crohn's disease patients who initially had a low level, which then was normalized, were significantly less likely to undergo surgery in comparison to patients who continued to maintain a low vitamin D level^[72]. A significantly lower C-reactive protein was also seen in these "normalized" patients. There was no association seen in ulcerative colitis patients, which the authors suggest may be due to a higher plasma 25(OH)D threshold in these patients to obtain any immune effects. Another explanation may be that vitamin D has a stronger interaction in Crohn's disease *vs* ulcerative colitis^[72]. Furthermore, Zator *et al*^[73] report a significant association between earlier cessation of anti-TNF therapy in IBD patients who had insufficient vitamin D levels prior to initiation of anti-TNF therapy, suggesting vitamin D may be an important adjuvant treatment aiding in the maintenance of response to this therapy. These studies denote the importance of repleting and maintaining sufficient vitamin D levels in patients who have IBD, specifically above 30 ng/mL (75 nmol/L), to reduce the risk of flares and to maintain response to IBD-therapies^[72,73].

One randomized placebo-controlled study has assessed the effectiveness of vitamin D supplementation in improving Crohn's disease activity. In comparison to the placebo, oral vitamin D supplementation of 1200 IU in adult patients with Crohn's disease in remission was shown to increase the 25-OH vitamin D levels and reduce the risk of relapse from 29% to 13% at 1 year ($P = 0.06$)^[74]. Although this difference in relapse was not statistically significant, the difference is clinically meaningful and does warrant further study. The authors did discuss the risk of type II error as an explanation for not reaching statistical significance^[74,75].

A prospective study completed by Miheller *et al*^[76] compares supplementation with active vitamin D (alfacalcidol) to non-active vitamin D (cholecalciferol) in Crohn's patients. Looking at the clinical course of Crohn's disease at 6 wk, disease activity significantly decreased in the active vitamin D group; however, there was no difference by the end of the trial at 12 mo^[76]. Active vitamin D treatment resulted in a significant decrease in CDAI scores and CRP levels, as well as improvement in quality of life scores. It has prominent short-term effects and may be due to improved immune responses^[76].

A systematic review^[75] was completed to examine the efficacy of vitamin D supplementation for treating colitis

| Ref. | n | Methodology | Aims | Intervention | Definition of improvement | Conclusions |
|--|------|---|---|---|---|--|
| Miheller <i>et al</i> ^[76] | 37 | Prospective single cohort study | Compare the effects of active vitamin D and plain vitamin D on bone health and disease status in Crohn's disease patients | Group A: 2 µg × 0.25 µg alfacalcidol (active vitamin D) daily Group B: 1000 IU cholecalciferol daily (plain vitamin D) | Assessment: Osteocalcin (OC) and beta-CrossLaps (βCL) concentrations CDAI, CRP, IBD-questionnaire (IBD-Q) Improvement: Significant decrease in OC and βCL concentrations Significant decrease in CDAI and IBDQ scores and CRP concentrations | Significant reduction in βCL and OC concentrations showed decelerated bone resorption and bone turnover in the active vitamin D group compared to the plain vitamin D group at 6 wk and 3 mo (<i>P</i> < 0.05) Significant reduction in disease activity and improved quality of life in the active vitamin D group at 6 wk (<i>P</i> < 0.05) No difference at 12 mo Decreased risk of relapse (29% to 13%) at 1 yr with vitamin D treatment, but did not reach significance (<i>P</i> = 0.06) |
| Jørgensen <i>et al</i> ^[71] | 94 | A multi-centre randomized double blinded placebo controlled trial | Assess the efficacy of vitamin D supplementation in reducing the risk of relapse in Crohn's disease patients compared to placebo | Treatment group: 1200 IU vitamin D3 + 1200 mg calcium/d Placebo group: placebo + 1200 mg calcium/d | Assessment: CDAI Improvement: Decreased proportion of patients who achieve a CDAI score of 150+ and a 70 point increase in CDAI compared to baseline | Low levels of vitamin D significantly increased risk for IBD-related surgery and hospital admissions (OR = 2.05; 95%CI: 1.53-2.75 for Crohn's disease and OR = 4.75; 95%CI: 1.21-2.52 for ulcerative colitis) Achieving normal vitamin D levels decreased risk of Crohn's disease-related surgery (OR = 0.56; 95%CI: 0.32-0.98) |
| Ananthakrishnan <i>et al</i> ^[72] | 3217 | Retrospective study | Assess the association between plasma 25(OH)D3 levels and IBD related surgeries and hospitalizations Assess changes in these outcomes after normalization of IBD patients' vitamin D levels | None | Risk of IBD-related surgery or hospitalization (OR); Improvement: Reduction in risk (OR < 1) for surgery or hospitalization | Vitamin D supplementation improved vitamin D status at 24 wk (<i>P</i> < 0.001). 78% of patients required 5000 IU/d of vitamin D3, suggesting this is an effective dose in raising serum 25(OH)D3 levels in mild-moderate Crohn's patients Vitamin D treatment significantly improved disease activity and quality of life at 24 wk (<i>P</i> < 0.001) |
| Yang <i>et al</i> ^[77] | 18 | Prospective clinical pilot study | Establish the oral dose of vitamin D3 required to achieve serum 25(OH)D3 concentrations above 40 ng/mL (100 nmol/L) in mild-moderate Crohn's disease patients Assess improvement in disease activity and quality of life after vitamin D supplementation in Crohn's disease patients | Initiated on 1000 IU per day of vitamin D3 for 2 wk. Increased dose every two wk by 1000 IU/d until achievement of serum 25(OH)D level of 40 ng/mL occurred or patients were taking a total of 5000 IU/d | Assessment: Dose of vitamin D3 and serum 25(OH)D3 levels CDAI and IBDQ Improvement: Increase in serum 25(OH)D3 levels Reduction in CDAI scores of > 70 points or achievement of CDAI score < 150, and increase in IBDQ scores | Significant improvement in raising serum 25(OH)D3 levels in mild-moderate Crohn's patients Vitamin D treatment significantly improved disease activity and quality of life at 24 wk (<i>P</i> < 0.001) |

CDAI: Crohn's disease activity index; CRP: C-reactive protein; IBD: Inflammatory bowel disease.

in humans and animals. With a primary outcome of inducing or maintaining remission of the disease, the above study by Miheller *et al*^[76] was included. The authors conclude that the inability to sustain differences in clinical outcomes with active vitamin D does not undermine the efficacy of vitamin D^[75]. It shows the additional improvement of the active form to the plain form. In comparison, Yang *et al*^[77] assessed the improvement in vitamin D status, clinical disease activity, and quality of life scores in 18 mild-moderate Crohn's disease patients who underwent vitamin D3 supplementation for 24 wk. Patients were started with 1000 IU/d of vitamin D3, and the dose was increased every two wk by 1000 IU until serum 25(OH)D3 levels were above 40 ng/mL (100 nmol/L) or the patients were taking 5000 IU/d. After 24 wk, the maximum dose of 5000 IU/d was required by 78% of patients and effectively raised serum 25(OH)D levels. The assessment of CDAI scores at 24 wk showed that 78% of patients achieved clinical response defined by a decreased CDAI score of 70 points or more. Additionally, 67% of patients were in remission and disease-specific quality of life significantly improved^[77]. Table 1 outlines the four studies examining vitamin D supplementation on IBD outcomes.

In a randomized clinical trial of children and adolescents with IBD, weekly high dose vitamin D2 (50000 IU) or daily vitamin D3 (2000 IU) were superior to daily vitamin D2 (2000 IU) in raising the serum 25-OH vitamin D level at 6 wk (25.4 ± 2.5 , 16.4 ± 2.0 , 9.3 ± 1.8 ng/mL, respectively)^[78]. Adherence may be improved with large doses, and dosing according to individual levels may achieve target levels most effectively^[3]. Recent studies have suggested that optimal targets for serum 25-OH vitamin D levels are greater than 30 ng/mL (75-80 nmol/L), with levels between 21-29 ng/mL (51-74 nmol/L) being defined as insufficient and levels < 20 ng/mL (< 50 nmol/L) being defined as deficient^[60].

CONCLUSION

Recent advances in the understanding of the effects and mechanism of action of vitamin D on the mucosal and systemic immune system and subsequently on intestinal inflammation suggests it has a role to play in the therapeutic management of IBD. Furthermore, both epidemiologic and emerging retrospective and prospective clinical evidence supports a significant beneficial role of vitamin D supplementation in patients with IBD. While the precise level of 25(OH)D3 that needs to be achieved for these therapeutic effects is unknown, it has been established that levels of 75 nmol/L or higher are generally adequate^[3,8,26,60,72]. Given the safety profile and low cost of vitamin D, its addition to the therapeutic armamentarium as a supplement to induction and maintenance therapy should be strongly considered.

Abstract

Helicobacter pylori (*H. pylori*) infection is one of the most widely spread infectious diseases in humans. It can cause chronic gastritis, peptic ulcer disease and gastric malignancies and has been associated with extra-gastric disorders. *H. pylori* elicit a chronic systemic inflammatory response which, under certain conditions, may trigger autoimmune reactions and may be implicated in the pathogenesis of autoimmune diseases. Although the pathogenesis of inflammatory bowel disease (IBD) is unknown, it is thought to result from complex interactions between environmental factors and microbiota in the gut of individuals who are genetically susceptible. Several bacterial and viral agents have been implicated in the aetiology of IBD. In theory, *H. pylori* infection could be involved in the pathogenesis of IBD by inducing alterations in gastric and/or intestinal permeability or by causing immunological derangements resulting in absorption of antigenic material and autoimmunity via various immunological pathways. Similar mechanisms may also be responsible for the co-existence of IBD with other autoimmune diseases and/or extra-intestinal manifestations. However, the epidemiological data fail to support this association. In

fact, various studies indicate that the prevalence of *H. pylori* infection is low in patients with IBD, suggesting a protective role for this infection in the development of IBD. In this report, we aim to shed light on proposed mechanisms and confounding factors underlying the potential link between *H. pylori* infection and IBD.

Key words: *Helicobacter pylori*; Inflammatory bowel disease; Ulcerative colitis; Crohn's disease; Colorectal cancer

Core tip: By gathering a large volume of published data, this review attempts to shed light on the mechanisms and confounding factors underlying the potential link between *Helicobacter pylori* (*H. pylori*) infection and Inflammatory Bowel Disease (IBD). However, whether the link between *H. pylori* and IBD is coincidental, epiphenomenal or mechanistic remains to be elucidated as there are contradictory data regarding both the causative and the protective role of *H. pylori* infection against IBD. This review provides a tool for researchers in this field to use as they perform further research to find the missing links.

INTRODUCTION

Inflammatory bowel diseases (IBDs), which includes Crohn's disease (CD) and ulcerative colitis (UC), are chronic, relapsing-remitting diseases that constitute a

growing worldwide health burden^[1-3]. Over time, these diseases may lead to intestinal damage, complications, surgical interventions, gut failure and/or disability^[4-7]. IBD is thought to result from complex and unidentified interactions between environmental factors (such as infections, medicines, tobacco, food particles) and genetic factors of the host, resulting in abnormal and/or inappropriate immunological reactions to elements of the intestinal flora. For example, Gradel *et al.*^[8] demonstrated that infection with either *Campylobacter* or *Salmonella* species predisposed individuals to subsequent development of IBD.

Helicobacter species easily colonize the gastrointestinal surface due to microaerophilic metabolism, spiral shape, and peculiar motility^[9]. Based on their location within the gastrointestinal system, they are divided into gastric *Helicobacters*, such as the *Helicobacter pylori* (*H. pylori*), and enterohepatic *Helicobacters* (EHH), which predominantly colonize the intestine and the hepato-biliary system and have been linked to chronic liver and intestinal diseases^[9]. *H. pylori* usually resides in the surface epithelium of the stomach, but *H. pylori* DNA has also been identified in both the colon^[10] and stool of infected patients^[11-13].

H. pylori is a gram-negative, spiral-shaped pathogenic bacterium that causes chronic gastritis. Peptic ulcer disease and/or gastric malignancies may develop in a small number of individuals infected with the bacterium^[9,14]. The inflammatory response of the gastric mucosa to *H. pylori* most likely reflects the combined effects of a cellular immune response that is driven by an on-going stimulation of the host's immune system by the bacterium. This results in high production of interleukin (IL)-12, leading to a T helper type 1 (Th1)-polarized response and elevated levels of Th1 cytokines^[15-18]. Products of the local immune reactions may travel to extra-gastric sites, thus linking *H. pylori* infection to the pathophysiology of a variety of extra-gastric diseases, including autoimmune disorders^[19-21]. Interestingly, however, *H. pylori* has been proposed to play a protective role against the development of certain autoimmune disorders^[21] such as asthma^[22] and type 1 diabetes mellitus^[23]. The mechanisms underlying this protective role of *H. pylori* infection is thought to be differential expression of an acute and/or chronic local mucosal inflammatory response, which may elicit a systemic release of cytokines^[24], which in turn may down-regulate systemic immune responses and suppress autoimmunity.

In IBD, dysregulation of the immune response of the host to commensal bacteria has been proposed as an important underlying pathogenetic mechanism. Increased attachment of gut bacteria to the intestinal epithelium has been documented in IBD. A Th1 immune reaction and secretion of pro-inflammatory cytokines is implicated in the pathogenesis of IBD, especially CD^[5]. Up-regulation of cell signalling molecules, such as the macrophage inflammatory protein 3a (MIP-3a), has also been documented in IBD^[25]. Some IBD patients suffer from concomitant autoimmune diseases and autoimmune-type extra-intestinal manifestations. The similarities between

the immunobiology of IBD and that of *H. pylori* infection provides background for the hypothesis that *H. pylori* infection may be implicated in the pathogenesis of IBD.

Nevertheless, there is epidemiological evidence that contradicts the association between *H. pylori* and IBD. *H. pylori* infection is an infection that occurs in underprivileged societies and its prevalence declines when environmental hygienic conditions improve. In contrast the prevalence of IBD increases in societies adapting a Western life style^[26]. Thus, it appears that there is an inverse relation between the prevalence of IBD and *H. pylori* infection. IBD is highly prevalent in the United States^[27], an area with low rates of *H. pylori* infection whereas, a steady rise in the incidence of IBD has been observed in *H. pylori* endemic regions following widespread use of therapeutic regimens to treat *H. pylori*^[28]. Although environmental changes may be the confounding factor underlying this inverse relationship, many (but not all) epidemiological studies have shown a low incidence of *H. pylori* infection in patients with IBD^[29-60]. This has led to the hypothesis that *H. pylori* infection may exert a protective role against IBD. However one can argue that it is the medication used to treat IBD that eradicates *H. pylori* and /or the IBD associated mucosal alterations that may prevent colonization of the stomach by *H. pylori*. The latter may be true, especially in IBD patients with focally enhanced gastritis (FEG) who have a particularly low incidence of *H. pylori* infection, even if they live in *H. pylori* endemic areas^[53,34,61-64].

Possible mechanisms of the potential protective role of *H. pylori* infection against the development of IBD may be alteration of the host immunologic response away from the pro-inflammatory Th1/Th17 response towards an increased T-regulatory cell immune response^[65,66]. Moreover, *H. pylori* may induce the production of antibacterial peptides that counteract potentially harmful bacteria implicated in the pathogenesis of IBD^[67] or compete with bacteria for the same ecologic niche in the upper gastrointestinal tract^[68].

CAUSAL ASSOCIATION OF *HELICOBACTER* SPECIES AND *H. PYLORI* WITH IBD

In animal models, EHH such as *Helicobacter hepaticus* (*H. hepaticus*) and *Helicobacter bilis* (*H. bilis*) have been shown to induce a persistent inflammation in the colon and cecum in immuno-deficient rodents^[69,70]. *Helicobacter hepaticus* triggers colitis in a specific pathogen-free IL-10-deficient mice through an IL-12 and interferon-gamma (IFN- γ) dependent mechanism^[69]. *Helicobacter muridarum* increases disease activity and inflammation in an acute colitis model^[71] and provokes a CD-like inflammation in severe combined immunodeficiency mice upon receipt of T cells^[72]. Accumulating evidence from gene knockout rodents also indicate that the presence of EHH worsens the severity or hastens the development of colitis^[73,74].

However, observations from human studies are con-

flicting. Several EHH species have been identified in the large intestine of patients with enteritis and / or proctitis^[75]. *Helicobacter macacae* has been linked with chronic idiopathic colitis in young rhesus monkeys^[76]. Similarly, Laharie *et al*^[77] found that *Helicobacter pullorum* (*H. pullorum*) or *Helicobacter canadensis* infection was significantly associated with CD in adults. *Helicobacter* species were found either in faecal specimens^[78] or in colonic biopsy samples^[79] of children with CD, and the prevalence of the *Helicobacteraceae* was significantly higher in children with CD (32/77, 41.5%) compared to controls (23/102, 22.5%)^[80]. A German group found *Helicobacter fennelliae* and *H. pullorum* in colonic samples of 12% of CD patients^[81]. *Helicobacter* genus PCR positivity was also significantly higher in UC than in controls (32/77 *vs* 11/59, $P = 0.004$)^[82]. *H. pylori* was isolated and detected by PCR in the intestinal mucosa of patients with UC-like CD and UC^[53,54,83]. Moreover, in another study *H. pylori* was found in faecal specimens in the majority of children with CD^[78]. In contrast, *Helicobacter* species were not detected in colonic biopsies of IBD patients in various studies^[84-88]. Additionally, no significant difference was observed in the rate of detection of *Helicobacter* species in intestinal biopsy specimens from 160 Chinese IBD patients (10%) and 80 controls (6.3%)^[57]. Furthermore, in an earlier study assessing gastrointestinal mucosal lesions in children with IBD, infection with *H. pylori* was found in only 2 of 41 children with CD (4.8%) and in 5 of 47 with UC (10.6%)^[89].

H. PYLORI AND THE NATURAL HISTORY OF IBD

It is conceivable that *H. pylori* infection may influence the clinical course of CD by triggering both specific and nonspecific immune responses in the human intestine. Phenotype modification of CD was identified in a study in which seropositive non-smoking CD patients had significantly fewer relapses and a lower risk of bowel resection compared to seronegative non-smoking patients^[90]. Moreover, serum anti-*H. pylori* IgG levels were significantly lower in subgroups of patients with fibro-stenotic and fistulising CD^[54].

There are several hypotheses regarding how *H. pylori* may influence the host immune response and thus alter the clinical course of CD. *H. pylori* infection may exert a direct damaging effect via urease and cytotoxins on the ileal or colonic mucosa^[91]. Moreover, *H. pylori* may induce an autoimmune-like reaction in the stomach with the production of anti-Lewis X and/or Y antibodies that have systemic auto reactive properties, thereby influencing the course of the disease^[92]. Another mechanism could be the induction of platelet activation and aggregation as shown in murine gastric venules which can cause the formation of microthrombi in gastric and intestinal epithelium and lead to infarction and development of ulcers^[93]. Another possibility is that *H. pylori* influences the host immune response via activation of the mucosa-associated lymphoid tissue (MALT), which may lead to a more generalized

immune response to *H. pylori* infection in IBD, contributing to the initiation or perpetuation of inflammation. In fact, Duchmann *et al*^[94] showed that bacteria-specific T cell clones are increased in inflamed intestinal mucosa of patients with IBD.

It appears that in *H. pylori* infected patients, CD is more often confined to the terminal ileum, a location that is frequently affected by complications, yet may be associated with a lower clinical disease activity^[95]. *H. pylori* infection usually occurs early in life, before the onset of CD, so it is possible that this early infection may influence disease location in these patients^[96]. As a result, *H. pylori* infection may not influence the course of the disease primarily, but may influence the location of the disease and thus secondarily alters its course.

PROTECTIVE ROLE OF H. PYLORI AGAINST IBD

Many studies have reported that the prevalence of *H. pylori* infection is lower in patients with IBD compared to controls, demonstrating an inverse relationship between IBD and *H. pylori* infection that suggests a protective role of *H. pylori* infection against the development of IBD (Table 1)^[32-34,38,39,41-46,48,49,52,55,57-59]. However this has not been confirmed by other studies (Table 1)^[30,35-37,53,56,60]. Väre *et al*^[41] found that seropositive CD patients presented at a significantly later age (40 years) compared to seronegative patients (30 years, $P < 0.001$), suggesting that the higher age of disease onset in seropositive IBD patients is the result of a protective modifier effect that *H. pylori* infection exerts on the development of IBD^[41], although this has not been confirmed by other studies^[34,42]. Furthermore, a meta-analysis of 23 studies suggested a protective role of *H. pylori* infection in CD pathogenesis, but the heterogeneity among enrolled studies and the possibility of publication bias limited the reliability of these results^[97]. The published literature on the prevalence of *H. pylori* infection in UC and CD is diverse. Various studies have found a lower prevalence of this infection in CD compared to UC^[29,31,34,41-43], whereas others have found exactly the opposite^[34,35,55]; still others have reported no difference in the occurrence of *H. pylori* between the two diseases^[30,32,33,36,37,39,48,56,57].

Moreover, the increased occurrence of *H. pylori*-negative FEG among IBD patients also confirmed the inverse association between the prevalence of *H. pylori* infection and IBD (Table 2). For example, *H. pylori*-negative chronic active gastritis was found in only 2% of patients without IBD compared to 20% of patients with IBD (CD 26%, UC 13%)^[98]. Furthermore, permanent colonization of the stomach by *H. pylori* is unusual in children with IBD^[40].

Heterogeneity among studies regarding the method of IBD and *H. pylori* diagnosis differences in study population, ethnicity and age across studies, and the possibility of publication bias may limit the certainty of the above findings. As environmental hygiene and intestinal

microbiota may be strong confounders, further mechanistic studies in *H. pylori* infection using mouse models are necessary to further define the mechanism of this negative association. Furthermore, when looking for explanations for the lower prevalence of *H. pylori* infection in IBD, some authors have suggested that treatment with sulfasalazine and other aminosalicylic compounds could be responsible for “spontaneous eradication” of *H. pylori* infection^[32,34,35,38], although their possible role has not been confirmed by other studies^[29-31,37,39,41-45,55,57,60,99]. Various studies have suggested that sulfasalazine, but not 5-aminosalicylic acid (5-ASA), could account for the lower prevalence of *H. pylori* infection^[32,34], whereas Piodi *et al*^[35] found the opposite. Ishikawa *et al*^[100] observed a lower prevalence of *H. pylori* infection in rheumatoid arthritis patients receiving sulfasalazine, whereas Taha *et al*^[101] did not find any statistically significant difference. The mechanisms of how these agents prevent *H. pylori* infection is still unknown, but prevention may be the result of a direct action against germ adhesion to the gastric mucosa or due to immuno-modulatory actions of the drugs^[30,102,103]. It has also been hypothesized that prolonged treatment with antibiotics used in IBD (especially metronidazole) could account for spontaneous eradication and lower prevalence of *H. pylori* infection. Indeed the prevalence of *H. pylori* infection was significantly lower in CD patients who had received antibiotics for ≥ 2 wk^[45] while in another study, antibiotic therapy was negatively associated with *H. pylori* infection (20.5% vs 55%, $P = 0.0001$)^[39]. Moreover, other studies have shown that prior treatment with ciprofloxacin and/or metronidazole had no influence on *H. pylori* status in IBD patients^[48,104,105].

Finally, the data on the prevalence of virulent *H. pylori* strains in IBD patients are limited. Wagtmans *et al*^[44] showed that the majority (66%) of *H. pylori* seropositive patients with CD were infected by *H. pylori* cagA (+) strains although a similar proportion of controls (69.4%) were also infected by these strains. These findings deserve further investigation as it is well known that the intense host responses, specifically to *H. pylori* cagA

(+) strains may further alter Th1- and Th2-type immune responses with subsequent induction of immune-regulatory lymphocytes^[106].

POTENTIAL PROTECTIVE MECHANISMS OF *H. PYLORI* AGAINST IBD

It is plausible to suggest that *H. pylori*, by attempting to promote its own survival, may benefit the host via a variety of mechanisms against other chronic inflammatory conditions such as IBD. Several mechanisms have been proposed to explain the inverse association between *H. pylori* and IBD. In CD, Th1 immune responses prevail, whereas in UC, Th2 or Th1/Th2 immune responses may be predominant^[5,107,108]. These altered immune responses to lumen antigens in IBD may influence the way the host responds to *H. pylori* infection. Conversely, a perpetual bacterial infection in the stomach may either alter the host immune responses in a way that may be protective or render the host susceptible to IBD. The levels of numerous cytokines, including IFN- γ , TNF, IL-1 β , IL-6, IL-7, IL-8, IL-10, and IL-18, are increased in the gastric epithelial cells of *H. pylori* infected humans compared to uninfected humans^[109-111]. After activation of Toll-like receptors by *H. pylori*, dendritic cells (DC) may activate T cells in different ways, being capable of inducing either a Th1 or Th2/regulatory T cell (Treg) response by generation of IL-12 or IL-10, respectively^[112,113]. This finding was reported by D'Elia *et al*^[114] who observed that most (64%) of *H. pylori* specific T cell clones derived from uncomplicated chronic gastritis displayed a Th2-like phenotype, producing interleukin IL-4 or IL-5 together with INF-a, whereas only one third of *H. pylori*-specific gastric T cells were polarized with Th1 effectors.

Thus, a protective role of *H. pylori* infection against IBD may be due to the ability of this microbe to down-regulate pro-inflammatory immune responses. Considering that adoptive transfer of Treg is able to prevent and/or treat colitis in various animal models, it is reasonable to suggest that these cells produced in response to *H.*

pylori infection may act in the prevention of IBD^[115-119]. *H. pylori* can induce a Treg response and down-regulate the pro-inflammatory Th1/Th17 pathway^[65,66,120-123]. The importance of Treg in the pathogenesis of IBD was illustrated by the development of spontaneous colitis in mice deficient of IL-10, a key regulatory cytokine for Treg function^[124].

Moreover, the systemic levels of type I IFN were found to be lower in *H. pylori* infection-colonized IBD patients compared to non-colonized controls^[125]. Luther *et al.*^[125] showed that prior oral administration of 20-50 µg *H. pylori* DNA ameliorated the severity of dextran sulphate sodium (DSS) induced acute or chronic colitis in mice in terms of both pathology and symptoms such as bleeding and weight loss. Thus, the protective properties of *H. pylori* DNA were attributed *in vitro* to inhibition of cytokine production by DC, which upon addition of the DNA failed to produce type I interferon and IL-12 in response to *E. coli* DNA^[125]. A protective effect of *H. pylori* colonization in mice against experimental colitis was also demonstrated by Higgins *et al.*^[126]. Mice that were colonized with *H. pylori* SS1 6 wk prior to the induction of *Salmonella typhimurium* experimental colitis, experienced markedly less severity inflammation compared to mice that were not colonized with *H. pylori*. This result could be attributed to an up-regulation of IL-10 in the mesenteric lymph nodes and suppression of the Th-17 response in the cecum of the infected mice^[126], illustrating an extra-gastric immune-modulatory effect of the bacterium, an immunological crosstalk between the upper and lower gastrointestinal tract and providing mechanistic support for the epidemiological observation of a negative association between *H. pylori* status and the risk of IBD.

Another protective mechanism may operate via the development of antibodies against *H. pylori*, which may confer an immunization-type protection against other pathogenic *Helicobacter* or even different types of microbes implicated in IBD. Although *H. pylori*-specific antibodies do not eradicate this bacterium, they seem to confer a degree of protective immunity from a subsequent *Campylobacter* infection, indicating an antigenic cross-reactivity between these two bacterial species^[127-129]. It could also be that *H. pylori* induced reduction in acid secretion indirectly affects a different type of infection that ultimately results in IBD. Indeed, variable disease phenotype during dual infection by different *Helicobacter* species has been described by Lemke *et al.*^[130] who demonstrated that *H. bilis* and *H. pylori* co-infection in mice attenuates *H. pylori* gastritis compared to those infected only with *H. pylori*.

The protective effect of *H. pylori* may simply be due to other confounding variables such as the presence of inherent genetic or environmental factors that favour *H. pylori* acquisition in some and the development of IBD in others. This scenario would fit well with the observation that IBD is associated with better hygiene, which in itself may be detrimental to *H. pylori* acquisition^[131,132]. The low prevalence of *H. pylori* infection in patients with

IBD compared to non-IBD patients strengthens the importance of the “hygiene hypothesis” in the development of autoimmunity and IBD. It suggests that inadequate microbial stimulation of gut-associated lymphoid tissue is a critical point for maturation of mucosal immunity^[133,134]. Improved access to a cleaner environment and the resulting decreased incidence of common childhood infections, including *H. pylori*, may be contributing to autoimmunity by altering susceptibility to certain diseases with an autoimmune component, such as IBD^[26].

Finally, regarding genetic factors, the CD variant of the autophagy gene ATG16L1 alters susceptibility to *H. pylori* infection with an enteric microbe in human subjects at the population level, supporting a role for altered autophagy in regulating the host response to enteric microbes in CD pathogenesis. It is interesting to speculate that due to increased susceptibility to infection, early exposure and acquisition of *H. pylori* in individuals with the ATG16L risk allele may decrease their risk for the subsequent development of IBD^[135].

ERADICATION OF *H. PYLORI* AND DEVELOPMENT OF IBD

There seems to be a rapid onset of CD after eradication of *H. pylori* infection, as illustrated by two cases^[136]. A similar experience was recently described by Jovanovic *et al.*^[137], who described the onset of gastric CD only 6 mo after *H. pylori* infection eradication. Moreover, a steady rise in the incidence of UC was reported in *H. pylori* endemic regions after successful eradication of *H. pylori* infection^[28].

It is unknown why these patients developed CD after eradication of *H. pylori* infection, but this may be due to the induction of immune responses that in turn contributed to the development of the disease. Long-term *H. pylori* infection may cause an unstable equilibrium between the Th1 and Th2 phenotype pattern; eradication of *H. pylori* infection may diminish Th2 cytokine, with sudden consequent Th1 pattern prevalence and rapid increase of pro-inflammatory cytokines^[106]. In genetically predisposed subjects, this Th1 predominant pattern may suddenly favour the onset of a typical Th1-related disease such as CD. Further studies investigating the effect of eradication of *H. pylori* on the development and natural history of IBD are warranted.

CAUSAL ASSOCIATION OF *H. PYLORI* WITH COLORECTAL CANCER?

A meta-analysis of 13 studies suggested an increased risk of colorectal cancer due to *H. pylori* infection^[138]. Kapetanakis *et al.*^[139] demonstrated the presence of *H. pylori* in malignant colonic tissue in 34 of 41 (82.9%) patients with colorectal cancer. *H. pylori* colonizing colonic tumour tissue seems to be associated with increased cell proliferation and impaired apoptotic process in malignant tissue

compared with adjacent normal colonic mucosa, thereby further contributing to colon cancer progression^[140]. Furthermore, *H. pylori* induced gastrin release can act as promoter of cell proliferation and differentiation (mainly by inducing COX-2 overexpression and PI3-kinase-mediated tyrosine phosphorylation of E-cadherin and b-catenin) in different gastrointestinal tract sites, including the colon^[141]. *H. pylori* infection is also accompanied by bone-marrow-derived stem cell (CD34+) recruitment that ultimately facilitates colon cancer progression^[142]. Finally, compared to normal gastric mucosa, *H. pylori* gastritis occurred more frequently among patients with hyperplastic polyps (OR = 1.24, 95%CI: 1.18-1.30), adenomatous polyps (OR = 1.52, 95%CI: 1.46-1.57), advanced adenomas (OR = 1.80, 95%CI: 1.69-1.92), villous adenomas or adenomas with high-grade dysplasia (OR = 1.97, 95%CI: 1.82-2.14), and adenocarcinomas (OR = 2.35, 95%CI: 1.98-2.80)^[143]. It has therefore been proposed that *H. pylori* eradication might inhibit IBD-related or non-colon neoplasia^[144].

CONCLUSION

Since the discovery of *H. pylori*, several epidemiological studies, therapeutic trials, case reports and/or *in vitro* studies have been published concerning a hypothetical damaging or protective role of *H. pylori* in the development of IBD. Whether the link between *H. pylori* and IBD is coincidental, epiphenomenal or mechanistic remains uncertain. There are contradictory data regarding both the causative and the protective role of *H. pylori* infection against IBD.

The discordance between studies may be explained by a number of confounding factors, such as variability in the power of the studies and the time periods in which these studies were conducted, geographical factors and the differences in the methods used to detect *H. pylori* infection^[145]. To be more specific, the urease breath test is more sensitive in detecting *H. pylori* than histology. Histology involves the examination of tissue samples that may be insufficient for a correct diagnosis and is more timely than serology, which also detects previous infections. Furthermore, one limitation of the studies using serology for the presence of *H. pylori* is the fact that after successful eradication of *H. pylori* infection, positive titres of antibodies normalize very slowly within several months, or even years, leading to the possibility that negative findings from *H. pylori* serology do not reflect eradication of *H. pylori* infection^[146]. Finally, from a clinical point of view, we must always bear in mind that any type of protection that exerts its influence on a general population level may not necessarily materialize in the individual patient.

In conclusion, the association between *H. pylori* infection and IBD is still controversial; however, it is worthy of further investigation, as the potential association of *H. pylori* with extra-gastric manifestations and disorders is always a very interesting and challenging research area^[147].

It is unclear whether the apparent protective effect of *H. pylori* is simply confounding due to other variables, but the effect of the presence of the live bacterium remains to be elucidated. More studies investigating the effect of *H. pylori* infection eradication on the risk of development of IBD and the natural history of IBD are needed.

Abstract

To evaluate the effects of inflammatory bowel diseases (IBDs) on human reproduction, we reviewed the current literature using a systematic search for published studies (articles and/or abstracts) without limits for English language. We searched on Medline (through PubMed), the Institute for Scientific Information, the Web of Science and the websites for the registration of controlled trials (<http://controlled-trials.com/>). Bib-

liographies of retrieved articles, books, expert opinion review articles and reviewed bibliographies from subject experts were manually searched. Titles and abstracts were screened initially, and potential relevant articles were identified and reviewed. Whenever possible, data were analyzed by comparing IBD patients *vs* healthy controls, and patients with active IBDs *vs* those with disease in remission. The effects of IBDs on female fertility, fertility in infertile couples, pregnancy and male infertility were examined separately. Patients with IBDs in remission have normal fertility. At the moment, there is no established guideline for the preservation of fertility in women with IBD undergoing surgery. Further data are needed regarding guidelines for the management of these patients. Data regarding IBDs and infertility are currently completely lacking. Considering the prevalence of intestinal pathology in young adults of childbearing age, this field is of great scientific and clinical interest, opening up important future perspectives. Another important and as yet unexplored point is the response to treatments for infertility in patients with IBDs. In particular, the question is whether the reproductive outcomes (clinical and biological) can be influenced by the IBD of one of the partners. The goals for successful reproductive outcomes in IBD population are correct counseling and disease remission. IBDs significantly affect several reproductive aspects of human (female, male, couple) reproduction. Further data are needed to develop guidelines for the clinical management of subjects of reproductive age with IBDs.

Inflammatory bowel diseases and human reproduction: A comprehensive evidence-based review. *World J Gastroenterol* 2014; 20(23): 7123-7136 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v20/i23/7123.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i23.7123>

INTRODUCTION

Inflammatory bowel diseases (IBDs) predominantly affect younger patients of reproductive age. To date, several reviews^[1-4] have been published in the English literature whose aim was to evaluate and clarify the impact on obstetric outcomes of both the IBDs themselves and the drugs commonly used to treat them. However, very little is known on the overall effect of IBDs on human reproduction.

The study of human reproduction includes not only the effects of IBDs and their treatment on pregnancy but also their effects on the menstrual cycle and hormonal patterns, on the subfertile women scheduled for ovulation induction cycles or assisted reproductive techniques (ARTs), on future reproductive potential in younger and/or adolescent women, and on male fertility, including data on semen parameters and libido/hormonal patterns.

Based on these considerations, the current study was designed to provide an evidence-based overview on the effects of IBDs on all aspects of human reproduction, including both female and male fertility, and to provide a critical synthesis useful for clinical practice.

SEARCH STRATEGY

To obtain evidence-based data and to provide evidence-based recommendations, a systematic search for studies (articles and/or abstracts), without English language limitation, was performed.

It included the combination of the following medical subject headings or keywords: “assisted reproduction techniques”, “ART”, “Crohn’s disease”, “complication”, “effectiveness”, “efficacy”, “embryo”, “endometrium”, “fertility”, “fetal”, “foetal”, “infertility”, “inflammatory bowel disease(s)”, “IBD(s)”, “intracytoplasmic insemination”, “ICSI”, “*in vitro* fertilization”, “IVF”, “libido”, “management”, “menstrual cycle”, “menses”, “neonatal”, “obstetrics”, “ovary”, “pregnancy”, “prevention”, “safety”, “semen analysis”, “sex hormones”, “sperm”, “spermatozoa”, “subfertility”, “surgery”, “therapy”, “treatment”, “UC”, “ulcerative colitis”.

We searched on Medline (through PubMed), the Institute for Scientific Information, the Web of Science, and the websites for the registration of controlled

trials (<http://controlled-trials.com/>). Bibliographies of retrieved articles, books, expert opinion review articles, and reviewed bibliographies from subject experts were manually searched. Titles and abstracts were screened initially, and potentially relevant articles were identified and reviewed.

For each issue, we analyzed mainly meta-analyses and/or randomized controlled trials (RCTs). When meta-analytic data or data from RCTs were lacking, prospective non-randomized and then cohort studies were included in the final analysis.

To construct a comprehensive review, data regarding both primary endpoints, as traditionally suggested by evidence-based medicine (pragmatic view), and intermediate endpoints, crucial to understanding the mechanisms of action (mechanistic view), were extrapolated and analyzed.

Whenever possible, data were analyzed by comparing IBD patients *vs* healthy controls, and patients with active IBDs *vs* those with disease in remission.

FEMALE FERTILITY

Women with inactive Crohn’s disease (CD) or ulcerative colitis (UC) appear to have normal fertility. In remission, female fertility seems not to be diminished. A case-control study by Elbaz *et al*^[5] showed that there was an increased need for fertility treatment of women with IBD; however, this association was no longer significant after controlling for maternal age (increasing maternal age is associated with subfertility).

In CD, fertility is normal or slightly reduced^[6-8]; older referral center studies estimated infertility rates of 32%-42%^[8-11], but community-based and population-based studies suggest infertility rates of 5%-14%, similar to that of the general population^[7]. Women with UC have normal fertility until they undergo surgery^[9,10].

Several reasons for the potentially reduced fertility in IBD women have been hypothesized. We have identified two main sources: psychological problems and surgery-related problems.

Psychological problems

Relatively few data are available regarding sexual dysfunctions in women with IBD. Moody *et al*^[12] did not find any significant change in rates of dyspareunia and overall frequency of sexual intercourse between women with IBD and matched controls. On the other hand, a mismatch of perception and reality seems to significantly affect family planning decisions in women with IBD. A recent large study^[13] was published whose aim was to evaluate whether, and to what extent, IBD patients’ perceptions of risk influence their reproductive behavior and to describe IBD patients’ specific concerns related to fertility and pregnancy. “Voluntary childlessness” was the main cause of the reduced fertility rate (number of live births per woman) reported in IBD patients^[13]. This fear of infertility was most evident in women with CD and pre-

vious surgery^[13]. In particular, IBD-related reproductive risks seemed to be overestimated by the examined subjects. The main reproductive concerns of IBD patients regarded pregnancy risks, drug-related teratogenicity or toxicity, long-term risks and IBD inheritance^[13].

Surgery-related problems

Women with active CD have decreased fertility^[6], perhaps related to the formation of adhesions caused by the disease itself and/or surgery, resulting in tubal infertility^[14]. Fertility may normalize after induction of remission in women with CD^[15]. Some surgical procedures, such as rectal excision and pouch formation, appear to have detrimental effects on male and female fertility.

In UC with ileal pouch anal anastomosis (IPAA), the ability to become pregnant is significantly reduced, probably because of the presence of post-surgical adhesions in the pelvis, secondary obstruction of the fallopian tubes or altering the normal tubo-ovarian relationship necessary for ovum capture and transport^[16-18]. Two studies that evaluated the impact of proctocolectomy with pelvic pouch or end ileostomy on pelvic anatomy, showed that 50 percent of females had complete unilateral or bilateral obstruction of the fallopian tubes^[19,20]. These studies suggested that pelvic dissection is the likely cause of adhesions and altered pelvic anatomy.

A systematic review showed that IPAA for UC results in decreased fertility^[21]. The conception rate in women with UC was 40% before IPAA and only 29% after IPAA^[21]. A meta-analysis estimated that the risk of infertility after IPAA increased by a factor of three^[22]. The high use of fertility treatments after IPAA compared with other groups illustrates the difficulty these women have in getting pregnant after surgery. Olsen *et al*^[10] found that after IPAA, 29% of children were born after *in vitro* fertilization compared with only 1% in the general population. Another study^[10] of Danish and Swedish patients found that females had significantly decreased fecundity (probability of becoming pregnant per month of unprotected intercourse) after IPAA compared with before IPAA. The data regarding fertility after IPAA do not state the number of women who voluntarily chose not to become pregnant and the impact of age on female fertility, which could greatly influence the interpretation of the results.

In a Canadian study, Johnson *et al*^[23] confirmed that the infertility rate was significantly higher in IPAA patients compared with patients managed non-operatively (38.6% *vs* 13.3%). In that study, the effect of age on the risk of becoming pregnant was investigated for all patients who attempted to become pregnant in both the IPAA and non-operative management groups. There was a negative association between advancing age and success of becoming pregnant: for each additional year of age there was a 12% decrease in the odds of becoming pregnant^[23]. Increasing age was associated with decreased reproductive ability among all females included in that study^[23].

A recent Finnish study showed that, although the probability of a women conceiving in any short time period seemed to be reduced to 47% of the average, the lifetime chance of having at least one live birth after IPAA was 80%^[24]. Thus, women with IPAA mostly suffer a reduction in the probability of conception rather than complete infertility.

Strategies are needed to improve fertility after IPAA. One possibility would be to perform sub-total colectomy/end ileostomy and delay IPAA, but this would likely be unacceptable to most females. A second strategy would be to preserve tubal patency and normal tubo-ovarian relationship. Various materials are available to prevent post-surgical adhesions in the pelvis; however, as there are no data regarding their efficacy in improving fertility, further research is needed^[25].

To date, there are no established guidelines for the preservation of fertility in women with IBD undergoing surgery. However, we believe that an effective strategy should be based on the following principles: (1) proper selection of patients with a specific clinical indication for surgery; (2) proper evaluation of the patient based on factors predictive of ovarian reserve [*i.e.*, age, anti-Müllerian hormone (AMH), antral follicle count]; and (3) surgery that is as minimally destructive of the radical pelvic anatomy as possible.

FERTILITY IN INFERTILE COUPLES

The purpose of this section is to evaluate the effects of the IBDs in the infertile couple. In particular, our attention focused on reproductive outcomes (*i.e.*, all intermediate steps and final results) of an infertile couple in which one or both partners are affected by IBDs. Both CD and UC mainly affect young adults of reproductive age. Whereas substantial data are available concerning pregnancy in young IBD women or fertility in IBD men, no study has been conducted on IBDs in infertile couples.

In the few last years, only two studies^[26,27] investigated the ovarian reserve status in CD women, as reflected by serum AMH. The first study^[26] showed that women with CD do not have severe ovarian reserve alterations compared with a control population. However, age \geq 30 years and a colonic location of the disease could be associated with an accelerated loss of follicles. Another study^[27] confirmed that serum AMH levels of reproductive-age women with CD were significantly lower compared with the controls, and the Crohn's Disease Activity Index (CDAI) and AMH were inversely correlated. Thus, these data could encourage gastroenterologists to inform CD women of the risk of delaying childbirth.

Finally, only one report^[28] described the reproductive outcome following intracytoplasmic sperm injection (ICSI) for male factor infertility associated with CD and 6-mercaptopurine (6-MP) chemotherapy. The authors^[28] reported the first successful birth after ICSI for severe oligozoospermia associated with CD.

PREGNANCY

Several recent data are available in literature on IBDs and pregnancy. However, the majority of published studies are reviews or retrospective analyses.

Effects of pregnancy on IBDs disease activity

Pregnancy seems to have a beneficial effect on IBD symptoms, especially when it occurs during disease remission. A small, but significant, decrease in the Harvey-Bradshaw index of disease activity during pregnancy, in comparison with the year preceding and following pregnancy, was observed in a retrospective analysis on women with CD^[29]. Similar results were found in a large European prospective study, showing that 74% of CD and 67% of UC patients with active disease at conception achieved remission later during pregnancy^[30].

Factors affecting remission or exacerbation of IBDs have been investigated extensively. In particular, smoking has a negative effect on the course of CD, and some authors showed that the reduced disease activity in pregnancy was partly the result of reduced tobacco smoking during pregnancy^[31]. By contrast, exacerbation of disease, particularly in the first trimester of pregnancy, could result from discontinuation of maintenance therapy.

The state of the disease at conception is a factor influencing the course of pregnancy^[32-34]. In fact, patients with active disease at conception often continue to have symptoms during pregnancy, whereas a normal course of pregnancy can be expected in patients who conceive when in remission. In a cohort study with a 10-year follow-up period, it was observed that if conception occurred during remission, the risk of a flare-up was comparable to that in non-pregnant patients with IBD. Instead, when conception occurred during an active disease period, two-thirds of patients relapsed during pregnancy and more than 60% of these patients experienced further deterioration^[35].

The course of IBD in the postpartum period remains controversial. A small prospective study reported a decrease in relapse rate in CD, as well as in UC patients, 4 years after pregnancy, in comparison with the 3 years before pregnancy^[36]. Similarly, in a large cohort study, the yearly flare-up rates decreased from 0.34 to 0.18 in UC and from 0.76 to 0.12 in CD. Two studies^[37,38] also reported reduced stenosis and resection rates in women with IBD after pregnancy. Mechanisms potentially involved could be related to the hormone relaxin, the effect of pregnancy on the immune response, as well as feto-maternal HLA disparity^[38,39]. The effects of breastfeeding on flare-up rates in IBD mothers are also controversial^[40,41].

Effect of IBDs on pregnancy/perinatal outcomes

Current data indicate that quiescent disease has minimal impact on the course and outcome of pregnancy in IBD patients, whereas patients with active disease at conception have increased rates of spontaneous abortion^[33] and a significantly increased risk of preterm delivery and low

birth weight^[32,42]. Overall pregnancy outcomes in women with IBDs (CD or UC) were similar to those of non-IBD pregnant patients^[31].

A meta-analysis^[43], including 3907 subjects, reported increased risks for preterm delivery (OR = 1.87, 95%CI: 1.52-2.31) in both CD and UC patients; low birth weight (OR = 2.82, 95%CI: 1.42-5.60) in CD but not in UC; and congenital abnormalities (OR = 3.88, 95%CI: 1.14-10.67) in UC but not in CD. A Swedish population study found 4.5% and 1.2% of children born to IBD patients had, respectively, low and very low birth weight, as compared to 2.9% and 0.6% in the overall Swedish population^[44]. Moser *et al.*^[32] additionally found an increased incidence of poor maternal weight gain during pregnancy in CD patients with quiescent disease at conception.

In both CD and UC patients, pregnancies ended more frequently with caesarean section compared with the general population^[45]. Furthermore, pregnant CD and UC patients who needed to be hospitalized had a higher risk of undergoing a caesarean section (OR = 1.72, 95%CI: 1.44-2.04 and OR = 1.29, 95%CI: 1.01-1.66, respectively) in comparison with patients without IBD^[46].

Prevention and treatment of IBDs during pregnancy

Most of the drugs used to treat IBD are not associated with increased risk of congenital anomalies or adverse effects on the fetus (Table 1). The 2010 European Crohn's and Colitis Organisation (ECCO) guidelines state "medical treatment for Crohn's disease (except methotrexate) should generally continue during pregnancy, because the benefits outweigh the risks of medication"^[46]. Moreover, as complications and adverse pregnancy outcomes mainly occur in patients with active disease, the main concern should be to achieve remission before conception and maintain quiescent disease during pregnancy. Patients who received counseling regarding the benefits and risks of drug treatment before conception and during pregnancy were more likely to remain compliant^[34].

It is generally regarded as safe to keep using aminosalicylates (ASA) during pregnancy [Food and Drugs Administration (FDA) category B drug], despite some reports noting a higher incidence of neural tube defects, oral cleft and cardiovascular defects^[47]. In a recent meta-analysis of treatment of IBD patients with 5-ASA drugs, IBD did not significantly increase the risk of congenital abnormalities (OR = 1.16), stillbirth (OR = 2.38), spontaneous abortion (OR = 1.14), preterm delivery (OR = 1.35) or low birth weight (OR = 0.93)^[48].

Several studies^[49,50] reported that sulfasalazine assumption during pregnancy does not give rise to increased rates of birth defects in women with IBD. Sulfasalazine therapy should be accompanied by extra folate supplementation, as this medication halts folate synthesis by inhibiting dihydrofolate reductase. Folic acid supplementation decreases the augmented risk of oral clefts and cardiovascular anomalies associated with folate antagonist treatment during pregnancy^[51]. Caution should be applied regarding the use of some mesalamine formulations (*e.g.*,

Table 1 Safety indications for drugs in pregnancy and breastfeeding

| | UC | ECCO rating pregnancy | ECCO rating breastfeeding | Personal observations |
|---------------------------------|----|-----------------------|---------------------------|--|
| 5-ASA (except sulfasalazine) | B | Safe | Safe | Avoid high doses for long time, asacol preparations may be switched to another mesalamine |
| Sulfasalazine | B | Safe | Safe | Folate supplements are required |
| AZA/6-MP | D | Safe | Probably safe | Discuss breastfeeding with the patient. Avoid lactation in the four hours after intake of the drug |
| Cyclosporine A | C | Probably safe | Contraindicated | Use only in severe cases of UC to avoid urgent colectomy during pregnancy |
| Methotrexate | X | Contraindicated | Contraindicated | Discontinue at least 4 mo prior to conception |
| Corticosteroids | C | Safe | Safe | Very low risk of malformations. If possible, not use for long time |
| Infliximab | B | Probably safe | Safe | Can be used safely in the first two trimesters of pregnancy. If possible, avoid in the third trimester |
| Adalimumab | B | Probably safe | No data | Can be used safely in the first two trimesters of pregnancy. If possible, avoid in the third trimester |
| Metronidazole | B | Probably safe | Best avoided | Very slight increase of cleft lip. Use only if strictly necessary |
| Ciprofloxacin | C | Probably safe | Probably safe | Use only for short periods and avoid in the first trimester |
| Thalidomide | X | Contraindicated | Contraindicated | |

5-ASA: 5-aminosalicylates; AZA: Azathioprine; 6-MP: 6-mercaptopurine; ECCO: European Crohn's Colitis Organisation; UC: Ulcerative colitis.

asacol) that contain dibutyl phthalate (DBP) as a coating agent. The use of DBP-coated medications produces measurable phthalate metabolite levels in urine. Prenatal exposure to DBP can cause congenital malformations in the male urogenital tract^[52]. Finally, the sulfasalazine metabolite sulfapyridine is secreted into breast milk. ASA are generally considered safe during lactation, although a case of bloody diarrhea in an infant has been reported^[53-55].

The use of antibiotics during pregnancy, *i.e.*, matronidazole and quinolones, should be considered with caution. Metronidazole is considered a low-risk drug during pregnancy (FDA class B). While several studies did not find an association between metronidazole treatment and birth defects^[56], a large case-control study showed an increased incidence of cleft lip and/or cleft palate in infants of mothers exposed to metronidazole in the first trimester of pregnancy^[57]. Thus, it should be limited to short-term use for the treatment of pouchitis. In addition, as metronidazole is excreted in breast milk, breastfeeding during its administration is not recommended^[56].

Quinolone antibiotics are FDA category C drugs and should be avoided because they carry an increased risk of arthropathy because of their high affinity for bone and cartilage. ECCO recommends avoiding quinolone use in the first trimester of pregnancy^[57]. Data on breastfeeding are limited, but quinolone use is probably compatible with breastfeeding^[58,59].

The recent London position statement on biological therapy for IBD states that anti-tumor necrosis factor (TNF) therapy is considered low risk and can be used in the preconception period and during the first two trimesters of pregnancy^[60]. The cytokine TNF- α not only plays a pivotal role in the inflammation process underlying IBD, but also plays physiological roles in host defense mechanisms and pregnancy. During pregnancy, TNF- α probably plays a role in protecting the fetus against teratogenic stress^[61]. Despite the role of TNF in pregnancy, treatment with anti-TNF antibodies can be considered

safe in the preconception period and the first part of pregnancy, because IgG antibodies do not cross the placenta in the first pregnancy trimester and transplacental IgG transport mainly takes place during the late second and third trimester of pregnancy^[62,63]. Maternal transfer of IgG during the last trimester of pregnancy provides the neonate with sufficient acquired immunity to defend itself while its own immune system is becoming fully functional.

The currently available TNF inhibitors (etanercept, infliximab, adalimumab, golimumab and certolizumab) are all classified as FDA category B drugs, indicating that no teratogenic effects of these drugs were observed in animal reproduction studies; however, adequate and controlled human safety data are still lacking. Transfer of anti-TNF antibodies to the fetus during the last part of pregnancy may mean exposure of the neonate in the first months after birth, raising potential concerns about infection and response to vaccines^[60].

Infants exposed to immunosuppressive drugs during pregnancy probably should be considered to be immunocompromised, as are their mothers. ECCO guidelines state that live vaccinations (BCG, rotavirus, mumps-measles-rubella (MMR) and varicella zoster) are contraindicated until exposure to immunosuppressants has been discontinued for at least 3 mo^[64]. IgA is the predominant immunoglobulin in human milk, so secretion of TNF inhibitors in milk is likely to be very limited and breastfeeding under anti-TNF treatment can be considered safe^[65].

Natalizumab is an α -4 integrin inhibitor approved for treatment of CD in the US, but not in Europe. Experience with natalizumab in the context of IBD is still limited, even if this biological compound is widely used for treating multiple sclerosis. It has received an FDA category C label. Thus, at present insufficient data are available to reach a definite conclusion on the safety of natalizumab during pregnancy and lactation.

Corticosteroids are FDA category C drugs. They are

believed to be safe throughout pregnancy at doses up to 15 mg per day^[60], whereas higher doses increase the risk of infection and premature delivery^[66]. Systemic treatment with corticosteroids during the first trimester of pregnancy was found to slightly increase the risk of oral clefts (OR = 3.35, 95%CI: 1.97-5.69), while the overall risk of congenital malformations is not significantly increased (OR = 1.45, 95%CI: 0.80-2.60)^[67].

Pregnant women are preferably treated with prednisone or prednisolone, as the bulk of these compounds are inactivated by placental 11 β -hydroxy steroid dehydrogenase, the physiological mechanism in place to protect the fetus from elevated maternal cortisol levels during pregnancy. Treatment with corticosteroids is compatible with breastfeeding^[68,69].

Cyclosporine crosses the placenta but is rapidly cleared in the neonate and has no known teratogenic effect. FDA categorizes cyclosporine in pregnancy category C for lack of controlled studies in humans; however, cyclosporine does not appear to be a major teratogen.

A meta-analysis^[58] on the use of cyclosporine in pregnancy showed that cyclosporine use in pregnancy was not associated with major malformations, but slightly decreased birth weight and duration of gestation. In IBD patients, cyclosporine use in refractory UC during pregnancy has been shown to be safe and effective. Its main use in pregnant IBD patients is the prevention of urgent colectomy in fulminant UC^[70,71].

Although a number of cases are reported where no overt adverse effects were observed in breastfed infants of mothers treated with cyclosporine, the use of this drug during lactation is generally not advised as cyclosporine is secreted in milk at high concentrations, leading to potential nephrotoxicity and immunosuppression in exposed infants^[72].

ASA and 6-MP are still designated as FDA category D drugs, indicating that increased risk for the fetus exists, but the risk must be weighed against the possible benefits of the drug. A recent Danish cohort study showed an increased risk of preterm delivery and low birth weight in women exposed to azathioprine (AZA) or 6-MP during pregnancy, but no significant increase in congenital malformations^[50].

The CESAME study^[73], a cohort study comparing IBD patients exposed to thiopurine therapy during pregnancy with women receiving other treatments or women without any drug therapy, showed that thiopurine exposure was not associated with low birth weight prematurity and congenital abnormalities, but was associated with preterm birth. Exposure in men at the time of conception was not associated with congenital abnormalities^[74]. Thiopurine treatment is generally considered a contraindication for breastfeeding.

Methotrexate has teratogenic properties and is contraindicated during pregnancy (FDA category X). Methotrexate metabolites have long tissue half-lives; therefore, its administration must be stopped 3 to 6 mo before conception^[75]. Folic acid supplementation after methotrexate

withdrawal is also recommended because methotrexate acts as a folate antagonist. Methotrexate is also contraindicated during lactation because of its potential accumulation in the child's tissues.

Thalidomide and its analog lenalidomide partly counteract the effects of TNF- α and have been used in patients with refractory CD, even if currently available systematic evidence does not clearly demonstrate the benefit of these drugs^[76]. The teratogenicity of these drugs has been well documented, indicating increased risks for limb defects, central nervous system defects, and congenital abnormalities in the cardiovascular, respiratory, gastrointestinal, and genitourinary tracts. Thus, thalidomide is absolutely contraindicated in pregnancy (FDA category X) and patients taking thalidomide are advised to use two complementary contraceptive methods^[77,78]. Although lenalidomide appears less teratogenic in animal studies, the lack of studies demonstrating its safety in humans leads to the absolute contraindication of this drug in pregnant patients or in patients wishing to become pregnant^[77,78].

Management of delivery in women with IBDs

Pregnancy should not be considered high risk in all cases of IBDs. Delivery, therefore, can be carried out in clinics of the second or third level. Only patients with active IBD necessitating steroid and/or anti-TNF treatment, patients with ileostomies, and patients with ileoanal pouches should be referred to high-risk pregnancy clinics.

Active perianal disease at the time of delivery is an indication for caesarean section, whereas patients without history of perianal disease or inactive perianal disease do not require caesarean delivery^[45]. In UC patients with IPAA, caesarean section rates of almost 50% have been reported, but the incidence of pouch-related complications was low and pouch function was found to be unrelated to the mode of delivery^[79]. However, the most recent ECCO guidelines state that the presence of an ileoanal pouch in CD patients is an indication for caesarean section^[80]. Moreover, patients with IPAA surgery in the past are always advised to have caesarean section, and we recommend that an abdominal surgeon should be present during the surgery.

MALE FERTILITY

Clinical data

Infertility in men with IBD has been relatively less studied than infertility in women with IBD. A recent European consensus states that both male and female fertility are not significantly affected in non-operated IBD patients when disease is quiescent, compared to the general population^[81]. It is important to note that IBD patients remain voluntarily childless more frequently than non-IBD controls^[82]. In a survey among 255 Australian IBD patients, fear concerning IBD heritability, side effects of the medication on the child, and medical advice given by physicians were the most important reasons for voluntary childlessness^[13].

Table 2 Effects of inflammatory bowel disease medications on erectile dysfunction, male infertility and partner's pregnancy

| | Erectile dysfunction | Infertility | Pregnancy complications | Recommendations |
|--|----------------------|--|-------------------------|---|
| 5-ASA (except sulfasalazine) | No | Single reversible case | No reports | No recommendations to discontinue prior to conception |
| Sulfasalazine | Single case | Yes, reversible, not dose dependent | One study | Switch to other 5-ASA preparations |
| AZA/6-MP | No reports | No | Controversial | No recommendations to discontinue prior to conception |
| Cyclosporine A | No reports | No | No reports | No recommendations to discontinue prior to conception |
| Methotrexate | Yes | Controversial | No reports | Discontinue 3-4 mo prior to conception |
| Steroids | No reports | No | No reports | Lack of data to discontinue |
| TNF- α inhibitors (infliximab, and only a case report for adalimumab) | No reports | Reduce sperm quality, but no infertility | No | No recommendations to discontinue prior to conception, but barrier methods during pregnancy |

5-ASA: 5-aminosalicylates; AZA: Azathioprine; 6-MP: 6-mercaptopurine; TNF: Tumor necrosis factor.

A recent systematic review^[83] on fertility in non-surgically treated IBD showed that in men with CD (a total of 493 men in two population-based and one referral center studies), there was an 18%-50% reduction in fertility compared with controls, although whether the cause was involuntary infertility or voluntary childlessness was not indicated. There was no evidence of reduced fertility in men with UC^[83].

IBD and male fertility intermediate end-points

Active disease, IBD treatment, and psychological factors affect male reproductive and sexual function^[84]. Most male IBD patients considered "maintaining remission" as important at conception^[85] and in fact inflammation has a negative effect on male fertility^[86]. Men who were in remission or who had only mild disease activity had rates of erectile dysfunction similar to those of healthy control subjects, whereas men with more severe IBD activity had higher rates^[87].

IBD and semen parameters

There are no large studies that assess semen abnormalities in IBD patients on no medication at all. Some studies suggest that factors such as disease activity and nutritional status could affect semen^[88-90]. Furthermore, there are reports of antisperm antibodies in both men and women with IBD, and these antibodies might contribute to infertility. Antisperm antibodies might be a result of the increased immunological response, caused by increased intestinal permeability, against antigens of gut microbiota possessing common antigenicity with spermatozoa^[91]. Dimitrova *et al.*^[92] showed that antisperm antibody incidence in 50 patients with ulcerative colitis was statistically significant compared with 50 healthy blood donors^[92]. A little study on 10 IBD patients (four women and six men) and reported the presence of antisperm antibodies in semen of male patients and cervical secretions of female patients at the time of ovulation^[93].

Surgery and male fertility

The most common surgery in IBD patients is IPAA.

Proctocolectomy with IPAA has been associated with sexual dysfunction in men. A large study found 1% and 2% of sexual dysfunction at 1 year and 12 years after surgery, respectively^[94]. Furthermore, 3% of men reported experiencing either retrograde ejaculation or no ejaculation 10 years after surgery^[94].

A meta-analysis of 43 observational studies that evaluated patients after IPAA found the pooled incidence of sexual dysfunction to be 3.6%^[95]. On the other hand, a study of 122 men who had undergone IPAA evaluated male sexual function using a validated index based on erectile function, orgasmic function, sexual desire, intercourse satisfaction and overall satisfaction^[96]. This study showed that, despite any negative effect on erectile function (in particular retrograde ejaculation), the other four features had a statistically significant improvement^[96]. A Dutch study confirmed that despite an elevated rate of sexual dysfunction of up to 25% in 35 men after IPAA for UC, 90% of patients were satisfied with the operation^[97].

A randomized, placebo-controlled trial of sildenafil for erectile dysfunction following rectal excision performed either for cancer or IBD in 32 men showed that post-operative sexual dysfunction can be treated successfully with sildenafil in most cases (79% of the sildenafil-treated group compared to only 17% of the group taking placebo)^[98].

There are other types of surgery beyond IPAA, for example, total colectomy with end ileostomy, colectomy with ileo-rectal anastomosis, and proctocolectomy with ileo-anal anastomosis without a pouch. The reports on sexual function after these procedures are limited, but only ileo-rectal anastomosis avoids the extensive pelvic dissection of the other procedures, which produces adverse effects on sexual function.

Medical treatments and male fertility

Table 2 shows the effects of IBD medications on erectile dysfunction, infertility and pregnancy. In the general population, medications are responsible for erectile dysfunction in up to 25% of cases^[99]. The medications used

to treat IBD rarely cause erectile dysfunction; however, antidepressants and anti-anxiety medications, frequently prescribed for patients with IBD, could cause erectile dysfunction because depressive mood negatively influences sexual function (patients with a first diagnosis of IBD had higher rates of depression than patients with diagnosis of colon cancer)^[100].

On the other hand, many drugs have been reported to impair semen parameters; sulfasalazine, methotrexate, and infliximab seem to affect sperm quality^[57]. Of note, confounding factors that could affect male fertility, such as smoking, alcohol consumption, disease status, and medication use, are not always reported in studies investigating the effects of medical treatments on male fertility. Men with IBD rarely have documented physician counseling regarding the potential effects of medication on fertility and pregnancy because gastroenterologists' lack of knowledge of the effects of medications on male fertility or a lack of documentation of their counselling practices^[101].

Except for sulfasalazine, the risk of adverse fetal outcomes of other medications must be weighed against the benefit of maintaining good health of the father at the time of conception.

The only 5-ASA medication shown to cause male infertility is sulfasalazine^[102,103]. Sulfasalazine causes reversible non-dose-dependent semen abnormalities (oligospermia, reduced motility and abnormal morphology)^[104,105] and infertility in up to 60% of men^[106]. Impaired sperm maturation and oxidative stress from the sulfapyridine constituent of the drug are thought to be the cause^[107-110]. Male fertility is restored two months after sulfasalazine withdrawal or switching to other mesalazine preparations^[111-115]. A single case of impotence was reported that was resolved after switching to olsalazine^[116]. One study found an association between sulfasalazine use in men and a higher rate of congenital malformations in their children^[106]. There is a single case report of mesalazine-induced oligospermia and infertility that reversed when the drug was stopped^[117]. Given these data, no recommendations are made to discontinue 5-ASA (except sulfasalazine) for men planning to conceive.

A study of 18 men with IBD showed that AZA did not reduce semen quality, and thus male fertility, in IBD: no changes in semen parameters were noted after 11 ± 5 mo of AZA administration or during long-term treatment (49 ± 14 mo)^[118]. In a survey of 164 male renal transplant patients, long-term therapy with cyclosporine, AZA and prednisone demonstrated no effects on fertility^[119].

The teratogenic effect of AZA and its metabolite 6-MP remains controversial. In one retrospective study, the incidence of pregnancy-related complications was significantly increased when the fathers used 6-MP within 3 mo of conception^[120]. Specifically, in men with IBD under 6-MP, congenital anomalies and spontaneous abortions were detected in 4% and 6% of cases, respectively. These data are substantially different from those ob-

served in men with IBD who were not taking this drug (no congenital anomalies and 2% of spontaneous abortions)^[120]. However, the rates of congenital abnormalities and spontaneous abortions were below those of the general population - 3% and 10%, respectively^[121]. In a Danish population-based cohort study, the paternal use of AZA or 6-MP before conception was associated with an increased, but not statistically significant, risk of congenital abnormalities^[122].

Two other studies did not observe any significant effect of preconception thiopurine exposure of the father on pregnancy outcomes. Francella *et al.*^[123] showed that there was no statistical difference in conception failures (defined as a spontaneous abortion), abortion secondary to a birth defect, major congenital malformations, neoplasia or increased infections among offspring of male patients taking 6-MP compared with controls. In 2010, Teruel *et al.*^[124] confirmed there were no significant differences in terms of unsuccessful pregnancies between the exposed group (MP 9, AZA 37) and the control group. Given these data, no recommendations are made to discontinue AZA/6-MP for men planning to conceive.

There are no data regarding the effects of cyclosporine on fertility of men with IBD. In animal models, cyclosporine A causes damage of testicular tissue and sperms^[125], but antioxidants may protect from testicular toxicity^[126,127]. In humans, the small studies conducted do not seem to suggest any association between cyclosporine and male infertility: a decrease in serum antisperm antibodies^[128,129], normal semen analysis, and successful pregnancies are described^[130]. There are no reports of adverse pregnancy among partners of men who were taking cyclosporine. No recommendations are made to discontinue cyclosporine A for men planning to conceive.

Methotrexate is the one most often associated with impotence^[131-133]. However, few data are available on the effects of methotrexate on male reproductive capability. In animal models, it causes altered spermatogenesis and degeneration of spermatocytes, Sertoli cells, and Leydig cells^[134-136]. Opinions differ in the literature on the effects of methotrexate on male fertility: the concurrent administration of other chemotherapeutic agents is a limitation^[137].

There are small studies reporting on methotrexate use with no other agents. In patients affected by psoriasis, there are cases of documented reversible sterility when the methotrexate was stopped^[138] and there are several case series that report no change in sperm quality^[139-142]. There are no reports of adverse pregnancy outcomes among the partners of men exposed to methotrexate before conception^[143]. However, the active metabolites of methotrexate can remain in cells or tissues for several months after discontinuation^[144]. Given these data, it is recommended that the drug should be discontinued at least 3-4 mo before attempts at conception for men with IBD^[145-147].

Few data are available on the effects of steroid therapy on male fertility^[118,148]: it appears there is little

impact. Although steroids may inhibit apoptosis of damaged sperm cells, they may prevent pathological excessive apoptosis, which results in oligospermia^[149]. No recommendations can be made to discontinue steroid use due to insufficient data.

There are few studies also on the effects of anti-tumor necrosis factor agents; the data do suggest, however, that these medications may impair male fertility. Infliximab may also serve to counter the negative effects of TNF- α on sperm quality^[150]: supraphysiological levels of TNF- α were seen to cause chromatin and DNA damage, and reduce sperm motility^[151]. Reports on male fertility in ankylosing spondylitis patients showed a decrease in sperm motility in patients on conventional treatment *vs* anti-TNF- α -treated patients^[152].

In a study of 10 men, infliximab increased semen volume with a trend towards decreased sperm motility and morphology, but its impact on male fertility was not reported^[153]. Villinger *et al*^[154] showed sperm abnormalities that were more pronounced in patients with active spondyloarthritis, but the sperm quality of patients with inactive disease receiving long-term TNF inhibition is comparable to that in healthy controls. Another report on four patients with ankylosing spondylitis who fathered six healthy children during infliximab treatment may provide some reassurance for male patients treated with infliximab^[155]. The data support continuation of anti-TNF treatment when IBD patients plan fatherhood^[154].

The recent Austrian evidence-based consensus on the safe use of infliximab in inflammatory bowel disease^[156] states that infliximab may lead to reduced quality by decreasing sperm motility and affecting sperm morphology, although these findings do not demonstrate that male fertility would be reduced^[157].

Infliximab treatment of men prior to planned conception does not seem to cause embryo toxicity. For anti-TNF alpha, as it is unknown whether the fetus will be affected by exposure to anti-TNF alpha through semen, the ECCO consensus on reproduction in IBD advises barrier methods during pregnancy. Data on the impact of other biologicals on male fertility are currently lacking, although there is a case report of 35-year-old father of a healthy 4-year-old child who was successfully treated for 3 years with adalimumab for ankylosing spondylitis^[158]. No recommendations are made to discontinue anti-TNF- α treatment for men planning to conceive.

CONCLUSION

IBDs significantly affect several reproductive aspects of human (female, male, couple) reproduction. Moreover, further data are needed in order to develop guidelines for the clinical management of subjects of reproductive age with IBDs. In fact, at the moment, there are no established guidelines for the preservation of fertility in women with IBD undergoing surgery. Further data are needed regarding the management of these patients.

Data regarding IBDs and infertility are currently com-

pletely lacking. Considering the prevalence of intestinal pathology in young adults of childbearing age, this field is of great scientific and clinical interest, opening up important future perspectives. Further studies should, in fact, be conducted to determine whether the treatments for infertility have an effect on the state of IBD (remission, flare-up, recurrence). Another important point as yet unexplored is the response to treatments for infertility in patients with IBDs. In particular, the question is whether the reproductive outcomes (clinical and biological) can be influenced by the IBD of one of the partners.

are many. Examples include its extreme slow growth, lack of cell wall, low abundance, and its mycobactin dependency. In this review article, data from 60 studies showing the detection and isolation of MAP by PCR and culture techniques have been reviewed. Although this review may not be 100% comprehensive of all studies, clearly the majority of the studies overwhelmingly and definitively support the role of MAP in at least 30%-50% of CD patients. It is very possible that lack of detection of MAP from some CD patients may be due to the absence of MAP role in these patients. The latter statement is conditional on utilization of methodology appropriate for detection of human MAP strains. Ultimately, stratification of CD and inflammatory bowel disease patients for the presence or absence of MAP is necessary for appropriate and effective treatment which may lead to a cure.

Abstract

Crohn's disease (CD) is a chronic inflammatory condition that plagues millions all over the world. This debilitating bowel disease can start in early childhood and continue into late adulthood. Signs and symptoms are usually many and multiple tests are often required for the diagnosis and confirmation of this disease. However, little is still understood about the cause(s) of CD. As a result, several theories have been proposed over the years. One theory in particular is that *Mycobacterium avium* subspecies *paratuberculosis* (MAP) is intimately linked to the etiology of CD. This fastidious bacterium also known to cause Johne's disease in cattle has infected the intestines of animals for years. It is believed that due to the thick, waxy cell wall of MAP it is able to survive the process of pasteurization as well as chemical processes seen in irrigation purification systems. Subsequently meat, dairy products and water serve as key vehicles in the transmission of MAP infection to humans (from farm to fork) who have a genetic predisposition, thus leading to the development of CD. The challenges faced in culturing this bacterium from CD

Key words: *Mycobacterium paratuberculosis*; Crohn's disease; Culture; PCR; Johne's disease; Inflammatory bowel disease

Core tip: The review manuscript describes the past, present and predicted future research accomplishments in the area of Crohn's disease and *Mycobacterium avium* subspecies *paratuberculosis*. This is a highly debated area and Dr. Naser's thoughts described in this review will fuel interest and discussions in inflammatory bowel disease research. The manuscript has been in preparation for a couple of years and it is of high quality.

INTRODUCTION

One of the earliest documented descriptions of Crohn's disease (CD) was described in 1769 by Giovanni Battista, an Italian physician. He described the results of an autopsy of a man who had suffered from chronic bowel movements throughout his life and subsequently died from diarrhea and fever^[1]. This may have been the first account of granulomatous inflammatory bowel disease (IBD). Several years later in 1813, Combe and Saunders observed a patient who suffered from an abnormally narrow and thickened ileum^[1] and Abercrombie had reported a case in 1828 whereby a patient suffered from an inflamed ileum (ileitis) as well as skip lesions affecting certain segments of the ascending colon and cecum^[1]. There were several medical publications made in the 20th century which provided further insight into the characteristics and features of CD. For example, some such cases were reported by Braun (1901), Koch (1903), Lesniowski (1903), Wilmanns (1905), Moynihan (1907), and Proust (1907)^[1]. In 1913 a surgeon by the name of Dalziel (1861-1924) had reported the symptoms of several of his patients that closely resembled clinical manifestations in cattle suffering from Johne's disease^[2]. He is credited as being the first scientist to hypothesize that the causative agent of Johne's disease, *Mycobacterium avium* subsp. *paratuberculosis* (MAP), may in fact be responsible for chronic intestinal inflammation observed in the intestines of humans. In 1923 Moschcowitz and Wilensky^[3] had reported four cases of young patients suffering from non-specific granulomata of the intestine. In these patients they observed what appeared to be tumor-like masses that were hard, thick, and associated with all four coats of the large intestine which caused stricture of the lumen. Based on these observations it was originally believed that these structural changes were confined to the colon. However, it was found that such lesions could also be located in the small intestine which was later seen in one patient^[4]. In fact, it is interesting to note that all four of the patients had a history of appendicitis and appendectomy.

In 1932 acknowledgement of CD as an official medical entity was as a result of an article published by Drs. Burrill Crohn, Leon Ginzburg, and Gordon G. Oppenheimer, who all worked at Mount Sinai Hospital in New York at the time. Their article entitled "Regional ileitis: A Pathological and Clinical Entity" had appeared in the *Journal of the American Medical Association* in October 1932^[5]. The title "Crohn's disease," has been coined after Dr. Burrill B. Crohn, a gastroenterologist who presented the above named paper at the annual American Medical Association in May 1932. The study described a disease that exclusively affected the terminal ileum of 14 patients from a pathological and clinical standpoint^[5]. The patients were primarily young adults of ages ranging from 17 to 52 years, but only two of them were older than 40 years^[5]. It was expressed that this was a moderately acute disease that was associated with inflammation characterized by rapid necrosis throughout the affected tissue, and by inflammation associated with scar tissue^[5]. Furthermore, it

was indicated that the disease is clinically represented by certain common symptoms similar to ulcerative colitis—fever, diarrhea, and even weight loss^[5]. Dr. Crohn *et al*^[5] also witnessed that the ulcers associated with the mucosa were accompanied by a non-uniform connective tissue reaction of the remaining walls of the involved intestine, a process which frequently leads to the narrowing of the lumen of the intestine, and this has been known to be associated with the formation of multiple fistulas. Other physicians reported of similar concurrent observations, but these reports cited the involvement of a number of different parts of the gastrointestinal (GI) tract. For instance, the first case reporting evidence of inflammation present in the colon and not just in the ileum was by Colp in 1934^[6]. His report is considered as the first case detailing of ileocolitis which described that this inflammatory process could also extend to the cecum and the ascending colon^[6]. In addition, several years later granulomatous lesions were also found in the skin^[7]. As a result, it was becoming quickly apparent that CD is a chronic inflammatory disease that can affect any region of the GI tract ranging from the mouth to the anus, the ileum being the most commonly targeted site. In 1938, Penner and Crohn observed that 8 out of 50 analyzed patients suffering from regional ileitis displayed anal fistulae as a possible complication. They were initially unaware that anal and perianal fistulae could present such a complication of ileitis^[8]. In 1952, Wells^[9] introduced the term *segmental colitis* while delivering a lecture at the Royal College of Surgeons of England. According to Wells, this condition is associated with the formation of fibrous tissue on the bowel wall leading to its increased thickening as well as the presence of ulcers of the mucosa. These ulcers have a patchy pattern of spreading and are therefore known as "skip lesions"^[9]. Most importantly this condition was observed in patients without lesions present in the ileum or jejunum. Wells presumed that segmental colitis is a form of colonic CD, but this was never acknowledged by Crohn himself^[9].

At present, research on CD has partitioned it into three categories: inflammatory, obstructive, and fistulating^[10]. The inflammatory and obstructive types tend to occur simultaneously and cause obstructions of the bowel due to thickening of the intestinal wall as a result of inflammation. The fistula types are commonly associated with erosion of the bowel walls including perianal fistulas and enteroenteric fistulas^[10]. Depending on the locations of these erosions the disease is called Crohn's or granulomatous colitis if symptoms occur in the large intestine, Crohn's enteritis if symptoms occur in the small intestine, or Crohn's ileitis if symptoms occur in the ileum^[11]. Furthermore, it has been documented that some patients suffer with inflammation of fat cells under the skin (erythema nodosum), or in large joints (peripheral arthritis)^[10]. It is important to note that CD is quite similar to another IBD known as ulcerative colitis (UC). The latter affects only the colon whereas CD can affect any region of the GI tract^[12].

WHO IS AFFECTED BY IBD?

Statistical evidence has indicated that the highest prevalence of CD and UC is in North America, northern Europe, and the United Kingdom. These diseases are beginning to rise in southern Europe, Asia, Africa, and Latin America. In fact, as much as 1.4 million persons in the United States and approximately 2.2 million individuals worldwide cope with IBD on a daily basis^[13]. However, in one epidemiological study of CD based on ethnicity, it was revealed that CD is least prevalent in African Americans, Asians, and Hispanics. The rate of prevalence for African Americans was 29.8 per 100000, for Hispanics it was 4.1 per 100000, and for Asians it was 5.6 per 100000^[14]. It has also been found that the occurrence of IBD is higher in industrialized countries such as North America and Europe *vs* under developed or developing countries. Therefore, this suggests that the pathogenesis of IBD may be caused by certain environmental factors^[15]. This indicates that genetic susceptibility alone cannot account for the prevalence of CD. In addition, the incidence and prevalence of CD is essentially equal among men and women. Unfortunately, CD is a lifelong debilitating disease which can start in early childhood and continue into late adulthood. Most cases of CD are usually reported or initially diagnosed when the patient is in his or her late teens or early twenties. Recent studies have indicated that in the last few decades the number of CD patients diagnosed before the age of 40 years has increased to 80%^[16]. This therefore emphasizes the young adult and adolescent age group as a primary target of this disease. Understanding the etiology of CD may facilitate the development of rapid and cost effective methods for disease diagnosis.

DIAGNOSIS OF CD

The most accurate and effective examination for the diagnosis of CD is a full colonoscopy along with intubation of the ileum^[17]. This type of endoscopic examination allows the physician to clearly visualize the colon, ileum, and even certain parts of the lower regions of the small intestine. Physicians can also take multiple biopsies of all the segments of the colon as well as the terminal ileum^[17]. Dye-based chromoendoscopy is an advanced imaging technique which allows for the visualization of subtle changes in the lining of the intestine. An alternative imaging method that can be utilized is capsule endoscopy, which is usually selected when there is no evidence of stricture or stenosis^[18]. Other technology detects inflammation of the distal ileum such as enhanced gadolinium magnetic resonance imaging which has been proven to be very effective in distinguishing between inflammatory diseases of the GI tract, is non-invasive, and does not produce any radiation^[19].

WHAT IS THE ETIOLOGY OF CD?

Unfortunately, the etiology or cause(s) of CD are still

unknown. However, there have been several theories that have been proposed to explain this phenomenon. For example, the leading theories suggest that CD can be caused by certain environmental factors or by a dysregulated immune response in a genetically susceptible host. Many believe a milieu of environmental factors such as diet and certain infectious agents may trigger this disease. For example, it has been found that a diet of refined sugars, fatty acids, fast foods, and minimal consumption of fruits, vegetables, and fibers can contribute to triggering the disease^[20]. Certain foods play a pivotal role in influencing the microbiome composition of the human gut. In fact, a "Westernized" diet is believed to change the microbiological environment such that there is an increased susceptibility for the development of intestinal bowel disease^[20]. Some of the infectious causative agents studied in connection with CD include viruses, yeast, and bacteria including *Escherichia coli*, *Listeria monocytogenes*, *Chlamydia trachomatis*, *Pseudomonas maltophilia*, *Bacteroides fragilis*, *Mycobacterium kansasii*, and MAP. Fortunately, it is almost universally accepted that a host genetic predisposition is critical for development of CD^[21].

In recent years, the amount of interest and research data in support of a possible infectious etiology for CD has been well noted. More specifically, the forerunner of the proposed infectious causative agents is MAP. However, there are several critics and skeptics who still discredit this theory. Therefore the goal of this review article is to shed light on this current predicament with the intention to further clarify our understanding of the pathogenesis of CD from the perspective of an infectious agent such as MAP.

MAP AND JOHNE'S DISEASE

It was in 1895 when Johne and Frothingham first identified MAP as the causative agent of chronic inflammation in the gut of a cow^[22]. Johne's disease was later coined after Johne for his work in identifying this chronic inflammatory enteric disease in cattle, but this disease has also been observed over the years in several different animals such as sheep, goats, rabbits, monkeys, and even chimpanzees^[22]. MAP belongs to the *Mycobacterium avium* complex (MAC) which consists of at least *M. avium* and *M. intracellulare*^[23]. Through DNA sequence analysis it is possible to evaluate the similarities and differences among mycobacterial strains. It has been documented that MAP shares certain sequence similarities with other strains of MAC. For example there is a 16S-23S rDNA internal transcribed spacer (ITS) that is approximately a 280 base paired region located on the rRNA operon of mycobacteria^[24]. It was found that ITS sequence analysis of MAP taken from 3 different mammalian species-bovine, primate, and human did not indicate much sequence variation between them and in 17 strains of MAC^[24]. Thus, the connection between MAP and other mycobacterial strains is observed through this highly conserved sequence similarity. In addition, mycobacteria can be broadly classified as either an environmental or parasitic

species on the basis of their epidemiological and pathological nature^[25]. Environmental mycobacteria such as the other strains of MAC can be considered as opportunistic bacteria that are found in a variety of habitats. Some of these environments include wet soil, rivers, agricultural slurry, the intestines of birds, ruminants, humans, and even within protists^[26,27].

MAP is an obligate parasitic mycobacterium that causes chronic inflammation in the gut of several mammalian species and is considered to have three major genetic differences that serve to separate it from other non-pathogenic MAC. These differences are the presence of an insertion element designated as IS900, the presence of a genetic element known as "GS", and the presence of a unique MAP gene (*hspX*) located in a specific genomic region. MAP contains a highly conserved insertion sequence (IS) or IS element referred to as IS900, which is repeatedly found in its genome approximately 15-20 times^[28]. IS900 contains 1451 base pairs and harbors neither terminal inverted repeats nor flanking direct repeats normally found in other classical IS elements^[28]. As a result, IS900 is grouped in a family of insertion elements that is specifically found in certain microorganisms. Some of these IS elements include IS901 and IS902 found in *Mycobacterium avium* subsp. *silvaticum*^[29], IS116 present in *Streptomyces clavuligerus*^[30], and IS1110 located in *M. avium*^[31]. It has been documented that the pathogenic nature of several microorganisms has been linked to the presence of IS elements^[32]. IS900 is able to take control of the translational machinery of MAP and thereby affects the expression of certain genes. It achieves this task by encoding for a putative transposase of 399 amino acids in size called p43 on one strand^[33]. On the complementary strand IS900 encodes for a very unique gene called the *hed* (host-expression-dependent) gene^[34]. This gene is quite unique in that upon entry into the MAP genome it requires a promoter, termination codon, and ribosome binding site (RBS). Previous studies have indicated that IS900 enters the genome of MAP at a specific consensus target sequence such that it is located between the RBS and start codon of the target gene in one specific direction^[33]. As a result of this alignment, the *hed* ORF comes under the control of the mycobacterium host promoter thereby allowing for the translation of the Hed protein^[33]. Thus, this is one probable explanation for how the insertion element IS900 may assist in the pathogenic phenotype of MAP compared with the other strains of MAC.

The second major genetic difference between MAP and other mycobacterial strains of MAC is that MAP contains a genetic element designated as "GS", which contains a low guanosine and cytosine (G + C) content^[35]. GS is a 6496 bp element which possesses six genes-*gsa*, *gsbA*, *gsbB*, *gsc*, *gsd*, and *mpa*^[36]. In addition, it has been found that the *mpa* gene of the GS element in MAP is a putative acetyltransferase, and has *mpa* homologues present in other microorganisms such as *oafA* and *oac* of *Salmonella typhimurium* and *Shigella flexneri*, respectively^[37-39]. Other virulence regions including "pathogenicity islands" or Pais

have been reported on MAP chromosome^[37] and have been found to be similar to a few protein-coding genes found in *Mycobacterium tuberculosis*. These protein-coding genes are *drxA*, *drxB*, and *drxC*, are located at Rv2936-Rv2938, and have been commonly associated with the pathogenic phenotype observed in *M. tuberculosis*^[38].

TRANSMISSION OF MAP TO HUMANS THROUGH COW'S MILK

The real concern for the transmission of MAP from cattle to humans is that MAP-infected cows remain asymptomatic in a lengthy subclinical phase^[39]. As a result of this, infected cows are not removed and may continue to be harvested for milk and meat, and the spread of MAP can go unnoticed through fecal matters to the rest of the herd^[40]. There have been several cases reporting the culture and isolation of MAP from the milk of subclinical or asymptomatic cows^[39].

There has been a plethora of documentation about the number of cases in several countries reporting outbreaks of human illness due to improper 'heat-treated' milk and dairy products. It has been observed that certain pathogens such as *Campylobacter* species, *Salmonella* species, *L. monocytogenes*, and even *Y. enterocolitica* have been found in pasteurized milk, powdered milk, and even cheese, thereby contaminating these products and causing human illness^[41]. Thus, it is apparent that milk can serve as a means of transmission of these pathogens. Similarly because MAP is found to a large extent in dairy herds and domestic livestock, it can be inferred that it may be present in raw milk. It is assumed that the pasteurization process will destroy any viable pathogens including MAP. However, there have been numerous case studies indicating the thermal-resistant characteristics of MAP thereby enabling its survival after pasteurization. Chiodini and Hermon-Taylor simulated pasteurization methodologies under laboratory conditions as defined by the Public Health Service, US Food and Drug Administration^[42]. They performed the high-temperature, short-time (HTST) method of pasteurization in which the milk samples were heated to 72 °C for 15 s in accordance with commercial pasteurization techniques^[43]. The results indicated that approximately 3%-5% of strains of MAP survived this process. Also, the pasteurization of MAP obtained from human tissues suspended in milk showed to have a higher survival rate (38.7% and 26.2%) than the bovine samples (8.7% and 9.0%)^[43]. Grant *et al*^[44] reported that MAP was not completely destroyed after pasteurization if it was already present in the milk at a concentration greater than 10⁴ cfu/mL. In other studies, Sung *et al*^[45] were able to statistically determine the *D* values for various strains of MAP tested which estimated that MAP can survive HTST pasteurization methods when initially present at a concentration greater than 10¹ organisms/mL of milk. However, there have been some critics who have dismissed the validity of the previous studies because they claimed that the HTST pasteuriza-

tion method performed in the laboratory setting cannot simulate commercial pasteurization conditions such as the turbulent flow of milk^[44]. For example, Stabel *et al*^[46] challenged the validity of these previous studies and reported that there was no evidence indicating the presence of viable MAP after the performance of HTST pasteurization simulated with an Armfield HTST laboratory pasteurizer. However, Grant *et al*^[44] defended the studies previously performed in the field and criticized the methodology selected by Stabel *et al*^[46]. She indicated that Stabel *et al*^[46] had frozen and sonicated MAP prior to its addition to raw milk. Grant *et al*^[44] also expressed that MAP will not under normal circumstances naturally undergo such treatments prior to contaminating milk samples. Furthermore, freezing and sonicating MAP will only make it more susceptible to heat shock. As already indicated by Richards *et al*^[47] in 1977, freezing (-70 °C) of bovine fecal samples contaminated with MAP substantially reduced the viability of MAP. Also, it was Sung *et al*^[45] who reported the decreased thermal resistance of de-clumped MAP cells compared to clumped MAP cells, thereby highlighting the changes caused by the sonication of MAP cells. It is without a doubt that milk can serve as a vehicle for the transmission of MAP from animals to humans through consumption of dairy and meat products from infected animals.

PREVALENCE OF MAP IN THE ENVIRONMENT AND IN WATER

One of the major contributors to the spread of MAP in the environment is through the feces of infected cattle. Both subclinically and clinically infected cows excrete massive amounts of MAP through their feces on various pastures and farmlands^[48,49]. This is a serious problem because it has already been documented that MAP can persist in the environment for long durations^[50]. MAP is capable of surviving in fecal matter and in the soil for up to 12 wk^[51]. Muskens *et al*^[52] conducted a study investigating whether infected cattle could transmit MAP to other animals such as sheep grazing on the same pastures. They reported that 20% (10/50) of sheep showed evidence for the presence of MAP in their tissues. Subsequently, MAP can spread and infect other animals which come in contact with infected cattle. Furthermore, the prevalence of MAP in the environment is not only due to infected cattle, but can be due to other infected animals such as rabbits and deer which can also spread MAP abundantly through their feces^[53]. Unfortunately, this is only part of the problem. In most cases the cow's fecal matter is used to make manure which is subsequently distributed across agricultural lands as fertilizer and thus contaminating ground water, rivers, and other surface bodies of water^[56]. It will be just a matter of time before the accidental host (human population) is infected with MAP. MAP has been shown to resist chlorine disinfection treatment at concentrations similar to those used to disinfect public drinking water systems^[54]. Clearly, it is apparent that water is a very

potent vehicle for the transmission of MAP to humans.

MAP CHALLENGES IN THE LABORATORY

From the outset, MAP is an obligate intracellular bacterium which presents multiple challenges in the laboratory with respect to its cultivation from tissue samples from both CD patients and even Johne's disease in animals. Unfortunately this fastidious bacterium is very slow-growing and often requires the cultures to be incubated for an extended period as much as 16 wk at a time^[55]. As a result it has become quite problematic over the years to isolate and culture it through conventional means. Furthermore, MAP has very specific growth requirements which must be met for its survival. For example, this intracellular bacillus is unable to synthesize iron-chelating compounds, and therefore its host must provide iron for MAP to survive. Furthermore, due to its high mycolic content mycobacteria can easily adapt to intracellular growth in macrophages and may even become drug resistant^[56]. In addition, MAP in CD assumes a cell-wall deficient spheroplast-like form which complicate culture requirement and void the use of the golden standard Ziehl-Neelsen mycobacterial staining test. For this reason, MAP in its spheroplastic form cannot be identified by light microscopy which adds to the challenges of confirming its presence in a laboratory setting^[57]. Due to these difficulties, MAP-specialized scientists looked towards better techniques for the detection and characterization of microorganisms. This led them to the utilization of IS900 polymerase chain reaction (PCR) for the detection of MAP and later on the development of appropriate culture media. Nevertheless, some challenges remain including standardization of the methodology, and most importantly spreading the awareness to clinicians and scientists that standard methodology is not appropriate for the detection of MAP in humans^[58].

INVESTIGATING MAP ASSOCIATION WITH CD

It was in 1913, when Dalziel (1861-1924), a surgeon at Glasgow reportedly characterized 13 cases of chronic intestinal enteritis in humans^[2]. Upon histological and clinical examination of nine patients, Dalziel specifically noticed that different parts of the gastrointestinal tract were affected: the jejunum, transverse and sigmoid colon, as well as the mid-ileum^[2]. He reported that these symptoms closely paralleled clinical findings observed in cattle suffering from Johne's disease, a chronic inflammatory disease of the gut. As a result, Dalziel speculated that *paratuberculosis*, the then known causative agent of Johne's disease, could be a potential etiological agent responsible for the observed symptoms in his patients^[2]. It was not until 1932 when Crohn's disease was first introduced as a clinical entity was it possible to connect the pathological and clinical findings described in CD to Dalziel's observations in 1913. However, much skepticism and uncertainty

persisted with respect to the etiology of Crohn's disease. Furthermore, confidence in this mycobacterial hypothesis over the years has suffered tremendously due to the substantial difficulty and failure in culturing mycobacteria from CD tissues and the reliance on methodology which were not appropriate for MAP from humans. MAP association with CD theory was revived when Chiodini *et al*^[59] in 1984 reported the isolation of uncharacterized mycobacteria from tissues of three CD patients. They proposed that the bacterium existed in a cell-wall defective form which was later characterized as MAP^[60]. Similar results were reported from studies out of David Graham and John Hermon-Taylor laboratories (discussed below). Advancements in cultural techniques and PCR assays unique to MAP by Naser's team (discussed below) fueled and renewed interest in investigating a possible etiological connection between MAP and CD.

CULTURE OF MAP FROM CD PATIENTS

In this review, data from a total of 23 peer review studies which investigated the presence of MAP in CD specimens using culture techniques were reviewed. As shown in Table 1, the results from 16 (70%) studies supported the association between MAP and CD. Only 7 (30%) studies did not support such association (Table 2). Much of the difficulty in culturing or isolating MAP stems from the fact that this fastidious organism has very specific nutritional requirements and is a very slow growing bacterium^[59,61,62]. Culture of MAP in liquid or agar-based media requires weeks to months of laboratory incubation^[22]. The presence of MAP in a cell wall-deficient spheroplastic form in humans adds additional challenges to growing it in the laboratory. Many investigators reported the recovery of MAP in a cell wall-deficient form from the tissues of CD patients at a higher occurrence than control groups consisting of non-IBD patients^[59,61-72]. Certainly,

the advent of PCR, RT-PCR and nested PCR had facilitated the detection of MAP IS900 in cultures from CD patients^[53,57,58,64,66,68,69,72]. Table 1 lists a total of 16 studies which strongly support the association between MAP and CD. The development of mycobacterial growth indicator tube (MGIT) sparked a new wave of interest led by Saleh Naser team who supplemented MGIT media with additives essential for survival of cell wall-deficient *in vitro* and restoration of the cell wall. Consequently, Schwartz *et al*^[62] reported a higher frequency of MAP in CD patients at 37% (10/27) *vs* healthy controls at 5.6% (2/36). What is truly insightful in this study is the fact that MAP was found at a higher percentage (86%) in surgically resected tissue samples than in tissue biopsies (20%) taken from CD patients^[62]. These results alluded to the supposition that MAP may in fact be located below the mucosal layer instead of found on the apical surface area^[62]. Naser *et al*^[69] further employed the same culture condition to study whether or not MAP is present in human milk. They reported the presence of MAP in 100% (2/2) of breast milk samples taken from lactating CD mothers who had just given birth, compared to 0% (0/5) of healthy lactating controls. Thus, this study provides critical evidence to support the similarity between Johne's disease and MAP infection in CD. MAP was later on detected from breast milk from additional CD patients (data not shown). Most interestingly, Naser *et al*^[58] were able to culture viable MAP from the buffy coat of blood sampled from CD patients at a significant percentage 50% (14/28). These intriguing results are further substantiated based on the fact that there was no evidence for the culture of MAP from the blood of the healthy control groups 0% (0/15). Other scientists reported the presence of MAP in 14/33 (42%) bowel-pinch biopsies of CD patients (14/33) compared to 3/33 (9%) non-IBD controls. It was Kirkwood *et al*^[66] who sought to investigate if there was an association between MAP and CD in children who were symptomatic of this disease at an early stage. They revealed that 40% (4/10) of the cultured mucosal biopsies from the CD patients contained viable MAP, whereas 0% (0/4) of the healthy non-IBD controls showed no evidence for the presence of MAP. Consequently, these findings clearly indicate the possible association between MAP and CD, and according to Kirkwood *et al*^[66] these results

imply that MAP maybe implicated with the early-onset of CD in children. Sechi *et al*^[57] also reported a particularly strong association between MAP and CD based on their population study which involved the analysis of people in Sardinia diagnosed with and without CD. According to their results it was found that MAP DNA was detected in intestinal mucosal biopsies of approximately 63% (19/30) of CD patients compared to 10.3% (3/29) of control patients.

Contrary to the above data, there have been some studies providing evidence for the dismissal of MAP as a causative agent of CD (Table 2). For example, Parrish *et al*^[73] conducted a study analyzing blood samples taken from 260 individuals who consisted of 130 CD patients and 130 healthy individuals. After culturing MAP, the results revealed that none of the CD patients 0% (0/130) as well as the healthy controls 0% (0/130) showed evidence for the presence of MAP^[73]. Only one patient was reported having a positive result by PCR^[73]. Due to the fact that MAP and MAP DNA are present in the food chain and the fact that MAP DNA has been detected in the blood of patients with CD and type I diabetes mellitus and in less frequency in the blood of healthy controls, most scientists in the field may question the protocol used in this study. In another study, Ricanek *et al*^[74] collected bowel biopsies from 321 individuals,

of which 75 of these biopsies were collected from CD patients and 135 were collected from non-IBD patients. After long-term culture of MAP it was reported that only 2.7% (2/75) of CD patients and 1.5% (2/135) of non-IBD patients showed the presence of MAP^[74]. Similarly, Kallinowski *et al*^[75] documented the inability to culture MAP from a variety of sources such as stool, sera, and even gut tissue samples. They reported that 0% (0/21) of CD patients and 0% (0/24) of healthy controls had MAP through culture^[75]. The results from these studies should not be surprising since MAP is extremely fastidious and requires specialized culture media to grow which is contrary to culture media used in these studies. Other studies which failed to detect MAP in CD have depended on traditional standard methodology designed to culture and detect bacillary MAP from Johne's disease animals or other *Mycobacterium* species. It is important that investigators realize that *M. avium* subspecies *paratuberculosis* is not the same as *M. avium* or *M. tuberculosis*. Moreover, tissue and blood specimens collected from patients with active antibiotic treatment should be used for attempts to culture MAP in the laboratory. Rarely did the studies described in Table 2 allotted to whether the subjects used in their studies had antimicrobial agents prior to submission of the specimens.

DETECTION OF MAP DNA BY PCR

A total of 52 studies investigating MAP DNA in CD have been reviewed. Table 3 lists a total of 27 studies providing evidence in support of MAP association with CD by PCR. On the contrary, Table 4 lists 25 studies which present data in contradiction of MAP-CD association.

One of the studies showing a strong connection between MAP and CD has been performed by Autschbach *et al*^[76]. They reported that a staggering 52% (52/100) of tissue from CD patients were found positive for the presence of MAP DNA compared to only 5% (5/100) of the non-IBD patients. Similarly, Romero *et al*^[77] had examined several surgical tissue samples from 20 individuals by performing nested PCR specific for the IS900 sequence. The results from Naser's lab indicated that a substantially high percentage 83% (10/12) of CD patients were positive for the presence of MAP, while a much smaller percentage 17% (1/6) of non-IBD patients were positive for MAP^[77]. In addition, there was another compelling study conducted by Bull *et al*^[63] in 2003 in John Hermon-Taylor's laboratory, which presented data in support of MAP as a causative agent for CD. Fresh ileocolonic mucosal biopsies were collected and analyzed for the presence of MAP by the performance of PCR specific for IS900. The results revealed that 92% (34/37) of CD patients were positive for the presence of MAP DNA compared to a significantly diminished number of healthy controls 26% (9/34)^[63]. In this same study Bull *et al*^[63] had cultivated MAP using MGIT cultures described by Naser *et al*^[58] and Schwartz *et al*^[62]. After twelve weeks of incubation, PCR was performed with these cultures which again indicated

NP: Not performed.

a higher frequency of CD patients 42% (14/33) positive for MAP DNA *vs* only 9% (3/33) of healthy controls^[63]. This data strengthens the support of MAP in connection with CD. Mishina *et al*^[78] analyzed mucosal specimens using RT-PCR for the detection of MAP RNA where they found MAP in 100% (8/8) of CD patients and 0% (0/2) in non-IBD. This study is of particular importance because MAP RNA was amplified (without culture) adding more support to the presence of viable MAP in CD^[78].

At the same time, many studies based on PCR techniques have failed to detect MAP DNA in CD and concluded the lack of association between MAP and CD (Table 4). For example, Sasikala *et al*^[79] indicated that 0% (0/93) of CD patients showed the presence of MAP and 0% (0/97) of healthy controls were also negative for the presence of MAP. Similarly, Rowbotham *et al*^[80] reported that none (0/68) of CD patients were positive for the presence of MAP and just 3.8% (1/26) of healthy controls had MAP. Lozano-Leon *et al*^[109] indicated the absence of MAP in the blood of 73 CD patients and 73 healthy controls. Frank and Cook in 1996 also reported the absence of MAP in both CD and control subjects^[81]. The investigators in these studies should be commended on their interest to question whether or not MAP is associated with CD, and for including impressive numbers of specimens in their studies. Due to the fact that MAP

and MAP DNA are found in the food chain including dairy and meat products as well as in drinking water, it is difficult to accept that MAP or MAP DNA is not detected even accidentally in some specimens. The methodology used in many of these studies must have lacked essential steps to recover the low abundance of MAP in CD specimens and must have not been able to reduce the laboratory loss of some MAP or MAP derivatives. Whether the loss of MAP occurred at the specimen collection level or during the analysis, it should be avoided. Tissue specimens must be collected appropriately and adequately from active ulcerated sites. Specimens should be transported promptly and appropriately by avoiding freezing and use of anti-microbial solutions. Blood should be withdrawn into tubes with anticoagulants, transported without freezing, and promptly, to avoid lysis of leukocytes and loss of MAP. DNA extraction conditions should be optimized to recover single MAP genome which is also free from PCR inhibitors such as hemoglobin. Earlier study in our laboratory suggested that MAP from CD patients contained limited IS900 copies compared to bovine MAP strains. Nested PCR consisting of two amplification rounds is necessary for sufficient detection of MAP DNA. For reasons mentioned above and other unknown factors, standard PCR based on a single amplification should not be used for detection of MAP in CD.

CONCLUSION

In this review, data has been presented in the form of tables providing evidence for and against an association between MAP and CD by PCR and culture. It was revealed that MAP can be detected and isolated from the tissues, blood, and milk of many CD patients. Based on this information, MAP is definitively involved in the pathogenesis of some CD cases even though other studies have not acknowledged this association as represented in Tables 2 and 4. It must be emphasized that much of the controversy concerning MAP and CD stems from the inconsistent methodologies that have been used in the detection and isolation of MAP, which have questioned the causal relationship between this bacterium and CD. These observed discrepancies result from the fact that the methods that were designed for the detection of MAP in animals with Johne's disease are inappropriate for the detection of MAP in humans. Consequently, the need for more sophisticated and optimized methodologies are required so that there can be accurate detection and isolation of MAP in CD patients. One such methodology has been developed in our laboratory, and success has been achieved based on key principles shown in Figure 1. Other factors that may also limit the detection of MAP in clinical samples from some CD patients include the stage of the disease, and prior treatment with antibiotics or drugs with antimicrobial activity. For example, negative detection of MAP in peripheral blood samples could be correlated with a localized intestinal CD com-

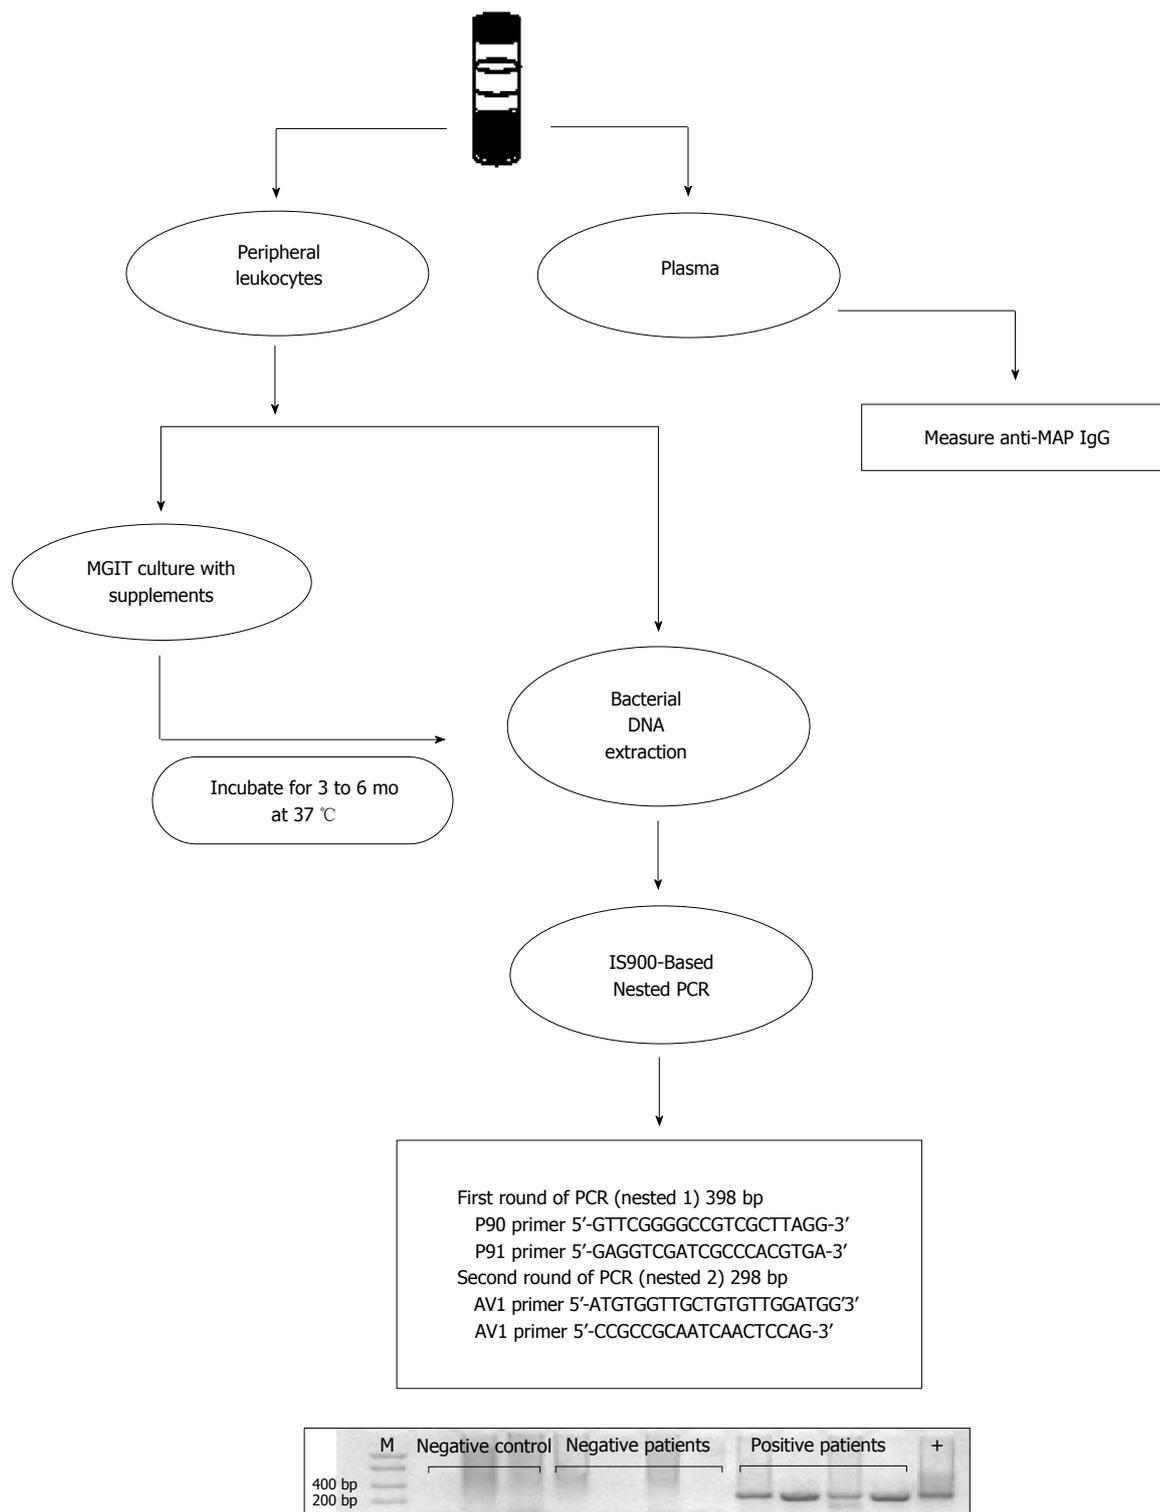

Figure 1 Schematic illustration of successful *Mycobacterium avium* subspecies *paratuberculosis* detection in clinical samples. Coded EDTA blood samples were collected from patients for investigating the presence of *Mycobacterium avium* subspecies *paratuberculosis* (MAP). Blood plasma was analyzed by measuring the concentration of anti-MAP IgG antibodies. Peripheral leukocytes were analyzed for the presence of MAP. In the first method, DNA was extracted followed by IS900-based nested polymerase chain reaction (PCR) using MAP-specific primers. In the second method a mycobacterium growth indicator tube (MGIT) liquid culture system with supplements was used to culture MAP lacking cell wall followed by 3 to 6 mo incubation and IS900-based nested PCR analysis.

pared to cases with advanced disease associated with systemic complications. The latter is most likely to lead to the presence of MAP in circulation.

Finally, it is also worth noting that it is a fact that CD

is a syndrome with multifactorial etiology. It is very possible that lack of detection of MAP in clinical samples from some CD patients may be due to the absence of MAP role in these patients. The latter statement is con-

ditional on utilization of methodology appropriate for detection of human MAP strains. Stratification of CD and IBD patients for the presence or absence of MAP is necessary for appropriate and effective treatment which may lead to a cure.

Abstract

Multiple studies have demonstrated alterations in the intestinal microbial community (termed the microbiome) in Crohn's disease (CD) and several lines of evidence suggest these changes may have a significant role in disease pathogenesis. In active and quiescent disease, both the faecal and mucosa-associated microbiome are discordant with matched controls with reduced biodiversity, changes in dominant organisms and increased temporal variation described. Mucosa-associated adherent, invasive *Escherichia coli* (*E. coli*) (AIEC), pro-inflammatory and resistant to killing by mucosal macrophages, appear to be particularly impor-

tant. AIEC possess several virulence factors which may confer pathogenic potential in CD. Type-1 pili (FimH) allow adherence to intestinal cells *via* cell-surface carcinoembryonic antigen-related cell adhesion molecules and possession of long polar fimbriae promotes translocation across the intestinal mucosa *via* microfold (M)-cells of the follicle-associated epithelium. Resistance to stress genes (*htrA*, *dsbA* and *hfq*) and tolerance of an acidic pH may contribute to survival within the phagolysosomal environment. Here we review the current understanding of the role of mucosa-associated *E. coli* in Crohn's pathogenesis, the role of the innate immune system, factors which may contribute to prolonged bacterial survival and therapeutic strategies to target intracellular *E. coli*.

Key words: Crohn's disease; Inflammatory bowel disease; *Escherichia coli*; Intra-macrophage survival and replication; Phagolysosome; Autophagy

Core tip: There is significant evidence implicating adherent, invasive mucosa-associated *Escherichia coli* (AIEC) in the pathogenesis of Crohn's disease. AIEC translocate M-cells of Peyer's patches and lymphoid follicles of the colon, and then to survive and replicate within underlying mucosal macrophages. How Crohn's AIEC resist killing and adapt to the environment within the phagolysosome to survive and grow within macrophages is still poorly understood. Here we review the current understanding of the role of AIEC in Crohn's pathogenesis, the role of the innate immune system, factors which may contribute to prolonged bacterial survival and therapeutic strategies to target intracellular AIEC.

INTRODUCTION

Crohn's disease (CD) is a chronic relapsing inflammatory bowel disease (IBD) of multifactorial aetiology, affecting any part of the gastrointestinal tract from mouth to anus. Patients typically suffer from abdominal pain, diarrhoea and weight loss which may be associated with extra-intestinal manifestations including erythema nodosum, iritis and arthritis. The intestinal pathological findings are characterised by transmural inflammation, deep mucosal ulcers, abscesses, fissures and granuloma formation^[1]. These chronic inflammatory lesions are proposed to develop due to a disrupted intestinal barrier, Paneth cell dysfunction and a disturbed innate immune response, resulting in the accumulation of antigen-presenting cells (such as dendritic cells and macrophages), lymphocytes and plasma cells within the intestinal mucosal layer^[1,2]. Pathological characteristics resemble the mucosal lesions and intestinal inflammation elicited by known enteric gut pathogens such as *Shigella* and *Salmonella* spp^[3].

CD is classically described to have a bimodal incidence with the highest rates seen in adolescents and young adults and a second peak in later years, although this has recently been questioned^[4]. It is associated with a small increase in mortality (standardised mortality ratio 1.52) but very considerable morbidity, disrupting work, study and family life^[5]. Historically approximately 80% of cases needed surgery at some time^[6] but the use of immunosuppressants and biologics has increased and is associated with a reduced 5 years risk of major surgery^[7]. The condition is more common in Europe and North America^[8]. However, incidence is rapidly increasing worldwide particularly in developed nations adopting a western style diet, as seen in Japan^[9]. Likewise, those emigrating from poor and developing nations to the West, within a few years of moving are at increased risk of developing CD presumably due to a key change in their lifestyle and environment^[10].

The gut microbiota plays an essential role in the shaping of the intestinal immune response in healthy individuals^[11]. There is now very strong evidence that both a reduction in the numbers of beneficial bacteria and increases in numbers of harmful bacteria living naturally in the gut are present in CD^[12] although it is less clear which of these changes might be causative and which might be a consequence of inflammation. Several independent groups have consistently shown changes in both the faecal and mucosa-associated microbiome in Crohn's patients and unaffected relatives^[13-15], an imbalance referred to as "dysbiosis" (Figure 1). Changes are typified by reduced biodiversity and alterations in the dominant organisms, specifically reduction in beneficial firmicutes and increase in numbers of proteobacteria [including

Escherichia coli (*E. coli*)]^[14,16,17].

There is also clear evidence to suggest that a number of lifestyle factors contribute to the dysbiosis of gut microbiota observed in CD (see Figure 1). This includes key environmental triggers such as smoking^[18], with cessation abrogating the observed dysbiosis^[19]. Also a key risk factor in CD is a intake of a "westernised" diet, high in fat and sugar, low in fruit and vegetable fibre^[20]. In a mouse model with a humanised microbiota, a switch to a high fat, high sugar diet altered the microbiome within 1 d^[21]. A similar diet has also been observed to increase numbers of Proteobacteria, such as *Bifidobacterium wadsworthii*^[22] and mucosally adherent, invasive *E. coli* (AIEC)^[23].

GENETIC SUSCEPTIBILITIES IN BACTERIAL RECOGNITION, AUTOPHAGY AND PHAGOCYTE-SPECIFIC GENES IN CD

The recent identification of genes associated with CD has been informative in improving our understanding of its pathogenesis, highlighting impairment of genetic components essential for innate immunity, intestinal barrier integrity and in microbial recognition and clearance^[24] (see Figure 1). Following on from earlier work^[25,26], Genome-wide association studies have now identified 163 IBD risk loci, 30 of which are CD specific and 110 shared between ulcerative colitis and Crohn's^[27]. Identified polymorphisms in the innate immune system of Crohn's patients include genes that are linked to processes such as pathogen recognition [nucleotide-binding oligomerization domain-containing-2 (*NOD2*)/Crohn's-associated gene identified was Caspase-recruitment domain 15 (*CARD15*) and interleukin 23 receptor (*IL23R*)] and autophagy [immunity-related GTPase M (*IRGM*) and autophagy-related 16-like 1 (*ATG16L1*)], all relevant to killing of bacteria within macrophages^[24,26].

The first *CARD15* encoding the NOD2 receptor^[28,29]. Mutations in this gene probably account for about 15% of Crohn's causation in the West although there are geographical variations with a lesser effect in northern European countries and no apparent impact on CD causation in Japan^[30]. The NOD2/*CARD15* protein is part of the innate immune system and is expressed in the cytoplasm of macrophages and Paneth cells^[31]. CD-associated mutations in NOD2/*CARD15* affect the leucine-rich domain recognising the bacterial cell wall peptidoglycan component, muramyl dipeptide (MDP), of both Gram-positive and Gram-negative bacteria. After recognition, NOD2 activates nuclear factor kappa B and induces the production and release of proinflammatory cytokines. Crohn's-associated NOD2/*CARD15* mutations are considered to be loss of function mutations with evidence for reduced production of anti-bacterial defensins by Paneth cells and for a reduced IL-8 response to MDP by macrophages^[32]. In association with NOD2/*CARD15* mutations, polymorphism in genes *SLC22A4* and *SLC22A5*,

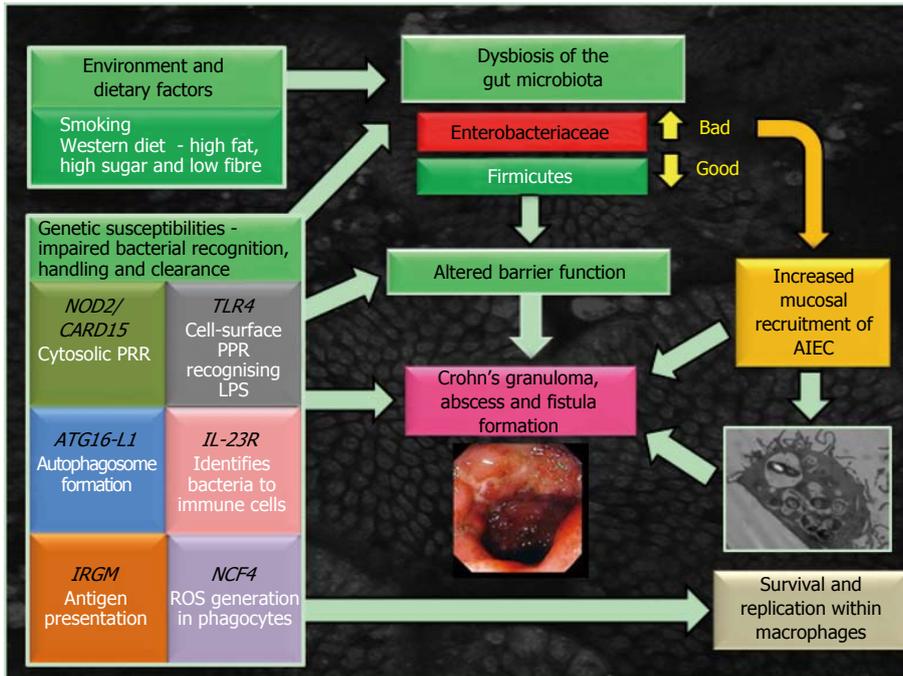

Figure 1 Model for the development of Crohn's disease. AIEC: Adherent, invasive *Escherichia coli*; ATG16L1: Autophagy-related 16-like 1; CARD15/NOD2: Caspase-recruitment domain 15/nucleotide-binding oligomerization domain-containing-2 receptor; IL-23R: Interleukin-23 receptor; IRGM: Immunity-related GTPase M; LPS: Lipopolysaccharide; *NCF4*: Neutrophil cytosolic factor-4 gene; PRR: Pathogen recognition receptor; ROS: Reactive oxygen species; TLR4: Toll-like receptor 4.

encoding the organic cation transporters OCTN1 and OCTN2 have also been identified with variants expressed in intestinal epithelial cells, T cells and macrophages^[33]. In addition, a mutation in two haplotypes of *DLG5*, encoding scaffolding protein, has also been confirmed to be associated with *NOD2/CARD15* mutations in Crohn's patients^[34].

Two other key genes associated with Crohn's are *ATG16L1* and *IRGM*^[35-37]. Both encode proteins that play a key role in autophagy, a cellular process facilitate not only disposal of protein aggregates, DNA, lipids and damaged organelles but also an integral step in the mechanism by which macrophages degrade, kill and clear invading phagocytosed bacteria (a process also termed xenophagy), including *Mycobacteria* and *Salmonellae*^[38-40].

Additional Crohn's susceptibility loci relevant to aberrant microbial recognition and handling and/or phagocyte function include toll-like receptor 4 (*TLR4*), leucine-rich repeat serine, threonine protein kinase-2 (*LRRK2*), neutrophil cytosolic factor-4 (*NCF4*) and *IL-23R*.

TLR4 is an apical cell-surface pathogen recognition receptor on intestinal epithelial cells, macrophages and dendritic cells, key in detection of lipopolysaccharide (LPS) presented on the outer-membrane surface of Gram-negative bacteria, with polymorphism of *TLR4* at D299G leading to hypo-responsiveness to LPS^[41]. *LRRK2* has been linked to CD through the association of a single-nucleotide polymorphism on chromosome 12q12^[26] and in murine studies where *LRRK2*-deficiency resulted in increased inflammation and significantly poorer clinical outcomes following administration of dextran sodium sulphate to induce colitis^[42]. The identification of *NCF4*

as a Crohn's susceptibility gene is also important^[36]. *NCF4* encodes the p40-phox subunit of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase crucial for reactive oxygen species (ROS) production by phagocytic cells in response to microbial infection, with molecular defects in NADPH oxidase already established to result in chronic granulomatous disease^[43]. Key studies show that altered neutrophil recruitment, along with an abnormal production of cytokines and reduced bacterial clearance, follow either acute trauma to the rectum and ileum^[44], or subcutaneous injection of heat-killed *E. coli* in Crohn's patients^[45]; (see Figure 2). Whilst these studies suggest macrophages may be involved in a key step of the observed immune dysfunction in CD, it is not yet clear whether this represents an inherent defect in macrophage function.

Variants of the *IL-23R* gene have also been linked to Crohn's^[46]. *IL-23R* is expressed by activated dendritic cells and macrophages, and *IL-23* can induce production of inflammatory cytokines that may contribute to intestinal inflammation^[47].

SPECIFIC BACTERIA IN THE PATHOGENESIS OF CD

There have been a number of distinctive studies that strongly favour the hypothesis that a specific bacterium plays a pivotal role in the initiation of chronic inflammation and development of CD. Early serological and culture studies suggested that *Mycobacterium avium* subspecies *paratuberculosis* (MAP), an obligate intracellular bacterium causing a chronic intestinal inflammatory disease

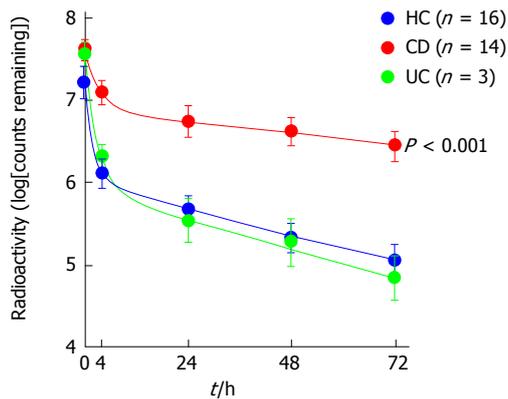

Figure 2 Patients with Crohn's disease exhibit reduced bacterial clearance of subcutaneously injected ^{32}P -labelled heat-killed *Escherichia coli* relative to healthy controls and patients with ulcerative colitis. Reproduced with permission. © 2009 Rockefeller University Press. Originally published in *Journal of Experimental Medicine* 206: 1883-1897^[45]. CD: Crohn's disease; HC: Healthy controls; UC: Ulcerative colitis.

in cattle (Johne's disease), was more prevalent in Crohn's patients^[48,49]. A study by Ryan and colleagues^[50] also confirmed the presence of MAP DNA in granulomatous lesions of CD patients. MAP-reactive CD4 T cells have also been found in patients with Crohn's^[51]. Even though, MAP has been hypothesised to be as contributing agent for Crohn's pathogenesis, there is still great controversy, and absence of conclusive evidence, to fully supporting this hypothesis^[52]. Our own studies have suggested perhaps that microbial mannan (present in yeast cell walls and Mycobacterium species such as MAP) may be a key environmental factor to suppress macrophage killing of intracellular bacteria^[53]. The shared susceptibility association of *NOD2* and *IL-23R* polymorphisms seen in both CD and Mycobacterial disease suggests MAP may yet be important in CD pathogenesis^[54].

Faecalibacterium prausnitzii may also be important with low levels strongly associated with early disease recurrence after intestinal surgery^[55]. This effect may be due to bacterial production of anti-inflammatory molecules with culture supernatant shown to reduce the severity of colitis in an animal model.

The finding of increased mucosa-associated *E. coli* in the sub-mucus niche or within the mucosa itself has proved particularly consistent in CD^[12]. Early serological studies described high antibody titres against *E. coli* in Crohn's patients compared to unaffected controls^[56] and this was later supported by immunohistochemical studies demonstrating *E. coli* antigens within macrophages in CD tissue^[57]. Many groups, including our own, have shown an increase in mucosa-associated *E. coli* in CD, both in the ileum and in the colorectum^[58-64]. We ourselves observed that aerobic culture of colonoscopic biopsies after removal of the mucus layer with dithiothreitol is often sterile in control colons whereas the colon in CD and colon cancer contains increased bacterial numbers in this sub-mucus niche, more than half of which are *E. coli*^[60], even though these organisms account for less than 1% of the faecal microbiota^[65]. Poor

correlation between site of inflammation and presence of *E. coli*^[63] and tendency to show that the same organisms can be identified from various sites within the same colon^[60,66] are compatible with the organisms having a causative role in the inflammation rather than merely colonising inflamed mucosa. Evidence for a primary pathogenic role is also given by their presence within granulomas^[67], the histological hallmark of CD, by their ability to induce granuloma formation *in vitro*^[68] and ability for similar *E. coli* to cause granulomatous colitis in dogs^[69], and potentially in cats and swine too^[70].

These *E. coli* pathovars associated with CD have been designated AIEC based on their ability to adhere to, and invade into, intestinal epithelial cell-lines, induce release of pro-inflammatory cytokines, and possess an ability to survive and replicate with intestinal macrophages^[71]. Phylogenetic analysis shows that most mucosa-associated *E. coli* isolated from the tissue of Crohn's patients belong to groups B2 and D^[65] as per extra-intestinal isolates, whereas most commensal *E. coli* strains would belong to group A^[72].

CROHN'S AIEC-HOST INTESTINAL MUCOSA INTERACTIONS

Aphthous ulcers of the "dome" or follicle-associated epithelium (FAE), overlying Peyer's patches in the distal ileum and lymphoid follicles of the colon, are likely the initial mucosal lesions occurring in Crohn's patients^[73-75], and have been observed in patients using magnifying chromoendoscopy^[76]. The FAE effectively forms the interface between the intestinal lymphoid system and the luminal environment. Specialized microfold (M) cells accounting for about 5% of cells in the FAE are optimized for antigen adherence and transport, and for immunological sampling of microorganisms^[77]. Several invasive bacteria take advantage of the transcytotic characteristics of M cells to use them to cross the gut, including *Yersinia*, *Salmonella* and *Shigella* spp^[78-80]. It was suspected that the portal of mucosal entry of AIEC was also likely through M cells^[81] and our recent studies successfully modelling M cells *in vitro*, demonstrated that Crohn's AIEC could indeed translocate through M cells (up to 20-fold compared with parent Caco2 cells) and through isolated human ileal FAE^[82]. Adhesion and subsequent translocation of AIEC across murine and human Peyer's patches, and across M cells *in vitro*, was observed to be dependent on possession of the *lpf* operon, encoding long polar fimbriae (Lpf) in AIEC^[83]. Isolates expressing *lpf* have been found to be more prevalent in Crohn's mucosae than that of non-IBD controls^[84]. *Ex vivo* studies also indicate a defective mucosal barrier to bacteria in the Peyer's patches from Crohn's patients^[85,86]. It is plausible therefore that increased bacterial load at M cells is important in the development of Crohn's. A striking correlation also exists between the age-related incidence of CD and the number of Peyer's patches in the small bowel, the latter peaking in late adolescence and then

falling away^[87].

Ileal AIEC isolates also typically express type-1 pili (FimH) on their surface supporting adherence to ileal enterocytes *via* interaction with carcinoembryonic antigen-related cell adhesion molecule-6 (CEACAM6) receptors known to be over expressed on the inflamed (but not colonic) epithelium in Crohn's^[88]. Highly glycosylated CEACAMs have also been proposed as M cell microbial receptors^[89]. It is plausible that one or more members of the CEACAM receptor family may play an important role in regulating endocytosis of CD mucosa-associated *E. coli* into host M cells. A recent study also reported that the glycoprotein 2 (GP2), specifically expressed on the apical plasma membrane of M cells among enterocytes, is recognized by FimH^[90]. By an intriguing coincidence it has also recently been found that the same GP2 protein is the epitope for the "anti-pancreatic" antibody found in CD sera^[91]. In addition, Crohn's AIEC outer-membrane vesicles (OMV), also show ability to interact with enterocyte endoplasmic reticulum stress response glycoprotein 96 receptor, increased in expression on the inflamed intestinal epithelium^[92]. These OMVs, in association with flagellin, also possess significant ability to evoke pro-inflammatory cytokine release^[93]. Colonic

mucosally associated AIEC isolates expressing afimbrial adhesin *afa* operon, more commonly associated with diarrhoeagenic diffusely adherent *E. coli*, have also been observed to be more prevalent in CD patients than in non-IBD controls^[84]. The presence of the *afa* operon correlates with diffuse adherence to, and invasion of intestinal epithelial cells^[84].

A summary of Crohn's AIEC genotype relevant to host intestinal mucosa interactions is summarised in Figure 3.

VIRULENCE FACTORS SUPPORTING CROHN'S AIEC SURVIVAL AND REPLICATION WITHIN HOST MACROPHAGES

AIEC isolated from Crohn's ileal and colonic biopsy tissue demonstrate ability to survive and replicate within phagolysosomes of host macrophages^[94,95]; see Figure 4. However, they are not unique in this ability as other pathogens are also known to survive and replicate within macrophages, including *Mycobacteria*, *Salmonella*, *Shigella*, *Coxiella*, *Brucella*, *Legionella* and *Listeria* species. Key de-

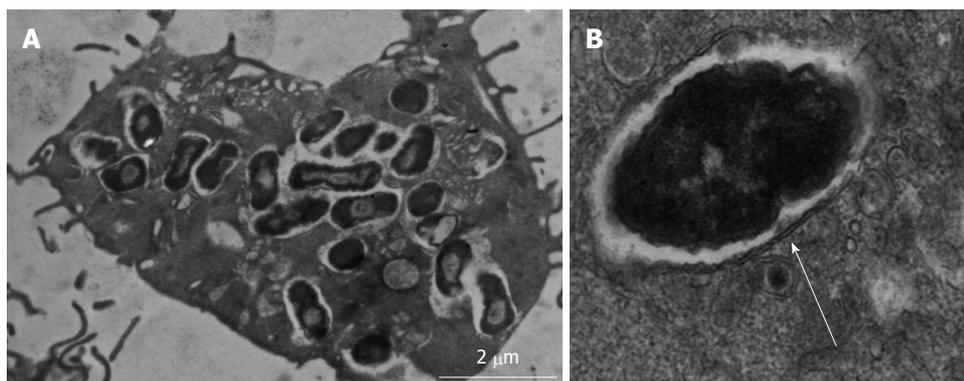

Figure 4 Transmission electron micrograph of adherent, invasive *Escherichia coli* within macrophages¹. fence mechanisms adopted by these pathogens support their resistance to killing within the low pH, low nutrient environment, high oxidative and nitrosative stress environment of the phagolysosome. For example, *Shigella* and *Listeria* are able to escape from the mature phagolysosome, *Salmonellae* can inhibit fusion of phagosome with the lysosome, whilst *Mycobacterium tuberculosis* is able to modify the intra-phagolysosome environment^[96]. Key genes supporting AIEC survival and replication within macrophages have been identified (see Figure 3) using isogenic mutants of the “paradigm” ileal AIEC LF82, including *htrA* (encoding high temperature stress protein), *dsbA* (encoding an oxidoreductase) and *hfq* (encoding a RNA chaperone important in mediating bacterial adaptation to chemical stress)^[97-99]. However, HtrA and DsbA are fairly ubiquitous in *E. coli*, and it is likely that other unidentified factors are needed to support AIEC survival within the stressful conditions of the phagolysosome.

Acid stress is the antimicrobial environment likely encountered by active enteric bacteria within the phagolysosome. *Salmonella* spp., *Shigella* spp. and *E. coli* have all been reported to possess a repertoire of low pH inducible systems that support resistance, tolerance and habituation during environmental acid stress. Likewise, AIEC certainly appear to be tolerant of the low pH intra-phagolysosome environment^[97]. *E. coli* is notable due to its possession of four known acid resistance systems. The first system requires sigma factor RpoS and the cyclic AMP receptor protein CRP, with RpoS functioning as a major environmental stress response regulator in both *E. coli* and *Salmonellae*^[100]. Deletion of RpoS from a Crohn's AIEC (strain O83:H1) has been observed to increase sensitivity of this clinical isolate to oxidative stress^[101]. The second system requires extracellular glutamate. The components of glutamate-dependent acid response are two isoforms of glutamate decarboxylase encoded by *gadA* and *gadB*, and a glutamate- γ -aminobutyric acid antiporter encoded by *gadC*^[102,103]. Murine AIEC have been observed to respond to chronic intestinal inflammation by up-regulating expression of *gadA* and *gadB*^[104]. The third acid resistance system requires is arginine-dependent utilising of arginine decarboxylase (*AdiA* and *AdiC*) an-

tiporter^[100] and the fourth is lysine dependent, involving lysine decarboxylase^[103]. In addition, *E. coli* also harbour specific mechanisms that enable them to resist high levels of ROS that form the oxidative and super-oxidative response to phagocytosed pathogens. These defensive resources have recently been found to be grouped particularly into two regulated sets of genes *soxRS* and *oxyR* regulons^[105,106].

DEFECTIVE AUTOPHAGY AND LACK OF CLEARANCE OF AIEC

ATG16L1 and IRGM function in autophagosome formation and evidence from our own studies supports a role for autophagy as an antimicrobial mechanism downstream of toll-like receptor and NOD-like receptor signalling. Activation of NOD2 by MDP induces autophagy in antigen-presenting cells (such as dendritic cells and macrophages) in a receptor-interacting serine-threonine kinase-2 dependent manner^[107]. Knock-down of *ATG16L1* and *IRGM* using siRNA approaches results in defective recognition and clearance of Crohn's mucosa-associated *E. coli* within host epithelial cells and macrophages^[108]. However, deficiency in either gene did not interfere with the replication and survival ability of other non-pathogenic, environmental, commensal, or gastroenteritis-inducing *E. coli*, suggesting a specific role for autophagy in restraining AIEC. Similarly, expression of the Crohn's variant *ATG16L1**300A in intestinal Caco2 epithelial cells impairs their ability to capture internalized *Salmonella* spp. within autophagosomes^[109] and is also associated with abnormalities in Paneth cell granule exocytosis^[110], impaired production of antimicrobial α -defensins^[111], and increased production of pro-inflammatory cytokines IL-1 β and IL-18 by macrophages in response to LPS^[112].

STRATEGIES TO TARGET INTRA-MACROPHAGE AIEC IN CD

If AIEC have a primary pathogenic role then it follows

that targeted treatment should lead to clinical benefit. This hypothesis is supported by studies in Boxer dogs which develop a granulomatous colitis following infection with an AIEC strain^[69], with subsequent clinical resolution following treatment with the 4-quinolone antibiotics, enrofloxacin^[113]. However bacterial antibiotic resistance is common both in animal and human studies and is associated with poor clinical outcome^[114]. Trials of antibiotics in the treatment of active CD have been disappointing to date with good evidence only for their use in the prevention of post-operative disease recurrence^[115,116]. A large meta-analysis recently failed to show any clear benefit for their use in maintenance of remission or in the treatment of active luminal or peri-anal disease^[117]. In some trials, early open label studies were positive only for later randomised trials to fail to show clear benefit^[118,119], which may, in part, be due to the development of antibiotic resistance. *In vitro*, quinolone-based antibiotics regimens to target intra-macrophage Crohn's AIEC isolates are effective^[95] but again single antibiotic use likely increases the risk of drug resistance, a problem highlighted by a recent study in which multidrug resistance was seen in 61.5% of Crohn's AIEC isolates^[120]. Triple antibiotic regimens are superior to ciprofloxacin mono-therapy and reduce intra-macrophage AIEC survival to 3% relative to untreated controls^[95]. Unfortunately significant drug-drug interactions occur with some antibiotics and azathioprine which have limited the use of triple combinations to date. Consequently, alternative strategies are being explored including using adjuvant agents to manipulate the phagolysosomal environment to support microbial phagocytosis.

A more promising strategy may be to alter phagolysosomal pH to aid bacterial killing within macrophages. It has already been shown that AIEC are dependent on an acidic environment for survival^[97] and that alkalinisation leads to reduced survival. Hydroxychloroquine, a weak base able to increase phagolysosomal pH, is known to improve killing of bacteria where intra-macrophage survival plays a key step in disease pathogenesis^[119]. For example, *Coxiella burnetii* the agent of Q fever, maintains an intracellular lifestyle through adaptation to survival at an acidic pH^[121,122]. *Coxiella* survival was significantly reduced *in vitro* by hydroxychloroquine treatment and this benefit translated into clinical response in a randomised trial^[123,124]. Hydroxychloroquine in combination with antibiotics, is also now standard therapy for treatment of Whipple's disease, where replication of *Tropheryma whippelii* within tissue macrophages is a central part of the pathogenesis^[125]. Similarly, our own recent studies have shown that dose-dependent enhancement of macrophage killing of Crohn's AIEC can be seen with hydroxychloroquine treatment and synergy with standard antibiotics is also observed^[126].

Vitamin D supplementation also enhances killing of intracellular AIEC in both murine and human macrophages^[127]. This may be due to enhancement of the respiratory burst but effects are likely to be multimodal with influences on several intracellular pathways. Cellular

production of the antimicrobial peptides, such as cathelicidin antimicrobial peptide (CAMP) and $\beta 2$ defensin, follows stimulation of toll-like receptors in the presence of vitamin D and conversely, vitamin D deficiency leads to impaired macrophage function due to defective defensin production^[128]. This has significance in CD, where muramyl dipeptide stimulation in the presence of vitamin D leads to increased *CAMP* expression. Furthermore, vitamin D stimulates NOD2 expression and leads to downstream $\beta 2$ defensin production^[129]. Vitamin D deficiency is common in CD with up to 70% of patients affected, even in quiescent disease^[130,131]. This now appears to have clinical consequence with several studies demonstrating a correlation between serum levels and disease behaviour. In a large prospective cohort study with nearly 1.5 m patient years of follow up, a validated method for predicting vitamin D levels was used to compare the incidence of CD in the lowest quartile relative to the highest quartile, finding the highest risk associated with the lowest Vitamin D levels^[132]. This correlation is not limited to the relative disease risk and recent studies now show a clear correlation between disease behaviour and serum concentrations. CD activity, defined both by CDAI and CRP level, has been shown to be inversely correlated with Vitamin D levels, with greatest activity seen in those with the lowest levels^[133]. Furthermore, in a retrospective study of 3217 patients, a lower likelihood of requiring surgery for Crohn's was seen with higher vitamin D levels, when using a cut off of 30 ng/mL^[134]. Given these findings we might therefore expect a clinical effect from Vitamin D supplementation. This question was addressed in a randomised double-blind placebo-controlled trial in which a trend was seen towards lower relapse rates in patients treated with 1200 U/d of Vitamin D, although this did not quite reach significance^[135]. However a significant reduction in risk of requiring surgery was seen for deficient patients who normalised their vitamin D levels with supplementation^[134]. Overall these data suggest a clinical role for vitamin D supplementation in CD although further clinical trials are required. Whilst no data yet exists for the effect of vitamin D on AIEC-macrophage interactions *in vivo*, it appears that supplementation may hold promise as a clinical strategy for targeting Crohn's mucosa-associated *E. coli*.

Smoking has long been associated with disease activity and leads to greater treatment requirements, more stricturing disease, more peri-anal disease and shorter disease free survival^[135,136]. These affects are likely to be multimodal in origin with effects seen on macrophage function, gut microbiota and vitamin D levels^[137-139]. Interventional studies clearly show benefit from smoking cessation^[140] and that this is an achievable therapeutic aim^[141]. There are some data to support a hypothesis that this may in part be due to recovery of immune cell function but to date this has not been systematically studied in CD^[142].

CONCLUSION

Based on the findings of a diversity of individual studies,

there has been accumulating evidence proving the implication of bacteria such as AIEC in the pathogenesis of CD, a chronic-relapsing IBD. AIEC have been shown to translocate M cells of Peyer's patches and lymphoid follicles of the colon, and then to survive and replicate within underlying mucosal macrophages and dendritic cells. However, the mechanism of how Crohn's AIEC resist killing process and adapt to the environment within the phagolysosome to survive and grow within macrophages without inducing cell death is still poorly understood. There is no doubt that further investigation is warranted to characterise and identify the key virulence factors relevant to AIEC phenotype, supporting current and novel, targeted treatments for future clinical benefit.

Key words: Inflammatory bowel diseases; Crohn's disease; Ulcerative colitis; Extraintestinal manifestations; Neurological disorders; Multiple sclerosis; Progressive multifocal encephalopathy; Demyelinating neuropathies; Cerebrovascular diseases; Side effects

Core tip: Extraintestinal manifestations occur in about one-third of patients with inflammatory bowel disease (IBD) and may precede the onset of gastrointestinal symptoms by many years. Neurological disorders are uncommon in IBD but they can represent an important cause of morbidity and relevant diagnostic issue. Furthermore, the use of immunosuppressant and biological therapies for IBD may also play a pivotal role in the development of neurological disorders. Hence, we review the main features of neurological complications associated with IBD, with particular reference to those related to drugs, thereby focusing on their clinical presentation and possible pathophysiological mechanisms.

Abstract

Extraintestinal manifestations occur in about one-third of patients living with inflammatory bowel disease (IBD) and may precede the onset of gastrointestinal symptoms by many years. Neurologic disorders associated with IBD are not frequent, being reported in 3% of patients, but they often represent an important cause of morbidity and a relevant diagnostic issue. In addition, the increasing use of immunosuppressant and biological therapies for IBD may also play a pivotal role in the development of neurological disorders of different type and pathogenesis. Hence, we provide a complete and profound review of the main features of neurological complications associated with IBD, with particular reference to those related to drugs and with a specific focus on their clinical presentation and possible pathophysiological mechanisms.

INTRODUCTION

Inflammatory bowel diseases (IBDs) are common causes of gastrointestinal morbidity in western countries. Extraintestinal manifestations are frequent in the course of IBD and, in some cases, may be the first manifestation of IBD, sometimes preceding the onset of gastrointestinal symptoms by many years^[1].

Among the many extraintestinal manifestations af-

fecting various organs, neurological disorders of different type and pathogenesis have been documented^[2]. Overall, the occurrence of neurological disorders during the course of IBD is uncommon^[3], but they may represent an important cause of morbidity. Neurological complications appear to be more common in men and they usually appear after IBD diagnosis, rarely coinciding with exacerbations of the underlying bowel disease^[3]. Only a few systematic studies have investigated their frequency in patients with IBD and the results have been frequently inconsistent due to differences in the methods used for case finding and outcome evaluation^[4].

One of the largest studies, performed for this purpose on 638 patients with IBD [either ulcerative colitis (UC) or Crohn's disease (CD)], found neurological disorders in 3%^[3], with another study^[5] indicating a possible increase in the prevalence of demyelinating diseases, particularly of multiple sclerosis (MS). The increasing use of immunosuppressant and biological therapies may also influence the probability of IBD-associated neurological disorders because these agents, although rarely used, may cause central nervous system (CNS) white matter lesions^[6], opportunistic infections^[7] with clinical symptoms similar to MS^[2], or JC virus (JCV)-mediated progressive multifocal leukoencephalopathy (PML)^[7].

On the basis of these considerations, it is obvious that a physician treating IBD/patients should be able to recognize unexplained neurological symptoms, consider their association with IBD, and address a proper diagnostic and therapeutic work-up, possibly with the collaboration of a consultant neurologist.

In this review, we went through the different neurological complications associated with IBD, with particular reference to those related to drugs, with a specific focus on their clinical presentation and their possible pathophysiological mechanisms^[8]. We divided the review into the following specific sections: (1) side effects of medications; (2) cerebrovascular diseases; (3) immune-mediated neurological disorders; and (4) miscellaneous.

SIDE EFFECTS OF MEDICATIONS

Biologics

Anti-tumor necrosis factor (TNF)- α drugs such as infliximab, adalimumab, certolizumab, etanercept, onercept^[9] and anti- α 4 integrin such as natalizumab and MLN020^[10], generally referred to as biologic drugs, have all been tested in the treatment of IBD, but etanercept, onercept and MLN020 have not been registered for clinical use, and thus have only had a limited exposure. Although their use has been occasionally associated with the induction or exacerbation of several neurological diseases in IBD patients^[11], the diagnosis of a possible causal relationship is usually made on the time-correlation between the use of the drug and the appearance of the neurological manifestation^[12]. In a screening study by the Food and Drug Administration on Adverse Event Reporting System (FAERS), Deepak *et al.*^[13] reported 772 distinct neurological adverse effects secondary to TNF- α inhibitor

exposure over a 10-year period. Thus, particular attention should be placed when an IBD patient on biologic therapy develops neurological symptoms, looking for a cause-effect relationship^[14]. Conversely, in patients with neurological diseases before the start of biologic therapy, a neurological consultation must be performed and possible alternative therapies, including surgery, should be considered.

PML

Because of its severity and high mortality rate, PML is the most feared neurological complication for patients treated with biologics. Although its occurrence was originally observed in patients treated with natalizumab in combination with β 1 α interferon for MS, this disease has also been reported in IBD patients treated with natalizumab only and also in very few cases undergoing anti-TNF therapy^[7]. PML is a demyelinating disease caused by the reactivation of JCV, a virus with specific tropism for glial cells in the brain^[15]. JCV may be reactivated from sites of latency in lymphoid tissues in conditions characterized by reduced immune surveillance^[16]. The explanation for the appearance of PML in natalizumab-treated patients is apparently related to both the action of JCV and to a probable increased release of infected lymphocytes from bone marrow determined by the binding of α 4 β 1 integrin with the drug^[17].

Yousry *et al.*^[18], in a review of about 3000 patients treated with natalizumab for MS, CD or rheumatoid arthritis, did not find any case of PML, thus suggesting a risk of PML of < 1 per 1000 patients treated for a mean time of 17.9 mo. The drug, at this moment, is not approved for IBD in Europe, while its use is confined to patients showing no response to anti-TNF agents in the United States. Clinicians should consider PML in the presence of visual defects (45% of all cases) and/or mental impairment (38% of all cases) such as dementia, confusion and personality changes. Indeed, cognitive impairment and behavioral changes frequently are the earliest clinical manifestations of PML^[14]. A motor weakness may also be present.

The diagnosis is confirmed by magnetic resonance imaging (MRI), which reveals white matter lesions with typical T2 and T1 signals^[18]. Cerebrospinal fluid (CSF) examination is usually normal but polymerase chain reaction (PCR) amplification of the JCV DNA is an important diagnostic tool. It is debated whether patients with IBD, similarly to what happens for MS patients treated with natalizumab, should undergo serial testing for anti-JCV antibodies before and during treatment either with natalizumab or with anti-TNF^[18]. Indeed, patients on natalizumab can be risk stratified for the development of PML based on JCV antibody status, history of immunosuppressive drug and duration of natalizumab treatment. Singh *et al.*^[14] described that all cases of natalizumab-induced PML occurred in patients who were JCV antibody positive. The seroprevalence of JCV-specific IgG in healthy blood donors is estimated to be 50% by 30 years of age and this percentage in-

creases to 60% by 70 years of age^[14]. The risk increases with duration of natalizumab therapy, particularly after 24 mo, but some cases have been reported after only 6 mo of therapy^[14].

Discontinuation of natalizumab is recommended at the first suspicion of PML^[14], and plasmapheresis is the recommended therapy to remove natalizumab, accelerate desaturation of the targeted α 4-integrin receptors and restore leukocyte transmigration^[14]. When immunosuppression is rapidly reverted in cases of natalizumab-associated PML, an exuberant immune response may occur: this condition has been termed immune reconstitution inflammatory syndrome^[14]. The response targeting JCV is evident 2-6 wk later in the CNS and it often results in paradoxical worsening of PML symptoms^[14]. High dose corticosteroids are recommended if clinical and radiographic worsening are noted several weeks after immune restoration. Despite these treatments, the clinical outcome of natalizumab-induced PML patients is poor with a reported mortality of 60% in patients with 6 mo follow-up^[14].

Posterior reversible encephalopathy syndrome and similar diseases

Zamvar *et al*^[19] described a posterior reversible encephalopathy syndrome in a 14-year-old boy affected by CD following infliximab infusion with generalized tonic-clonic seizures and visual disturbances probably caused by occipital lobe involvement. The patient recovered after drug discontinuation by which time he returned to normal.

Brigo *et al*^[20] also described a 74-year-old man with CD, without a prior history of seizures, presenting with a seizure after the second infusion of infliximab and caused by a reversible encephalopathy syndrome, an acute form of encephalopathy characterized by headache, seizures and area of increased T2 signal in the posterior quadrants of the brain on MRI^[20]. A direct correlation between seizures and infliximab treatment is likely in these cases because a sharp clinical improvement occurred 7 d after infliximab discontinuation.

Faivre *et al*^[21] described a 64-year-old woman with CD developing encephalitis associated with acute neuropathy after two infusions of infliximab. The patient had acute anterograde memory deficiency associated with epileptic episodes without infectious, vascular, tumor or toxic causes^[21]. MRI showed bilateral hippocampal hypersignals suggestive of limbic encephalitis. The clinical symptoms disappeared after infliximab withdrawal and seizures never relapsed even after discontinuation of antiepileptic drugs.

CNS vasculitis

The most common autoimmune manifestation associated with anti-TNF therapy is the development of anti-nuclear antibodies and anti ds-DNA autoantibodies without an associated clinical syndrome^[22]. A systemic lupus erythematosus (SLE)/lupus-like syndrome occurs in some of these patients and it has been named anti-

TNF-induced lupus (ATIL). This syndrome^[23] usually shows a high prevalence of anti-dsDNA antibodies (> 90%) and a low prevalence of anti-histone antibodies (57%) in contrast to what is usually seen in drug-related lupus syndromes. As in patients with spontaneous lupus, patients with ATIL may develop vasculitis. This was the case in a 53-year-old woman with ileo-colonic CD in whom adalimumab therapy was complicated by the development of SLE with CNS vasculitis. The patient showed headache, drowsiness, visual defect in her right eye associated with pleural, peritoneal and pericardial effusion 4 mo after initiation of adalimumab therapy at a dose of 40 mg subcutaneously every other week. Brain MRI showed features suggestive of cerebral vasculitis.

Ramos-Casals *et al*^[24] found 233 cases of autoimmune diseases possibly induced by TNF-targeted therapies with a prevalence of vasculitis and lupus respectively of 48% and 39%. Among the 92 patients with ATIL, CNS vasculitis was observed only in two patients (1 treated with infliximab for CD and 1 treated with etanercept for rheumatoid arthritis). In the case reported by Vannucchi *et al*^[22], the autoantibodies disappeared and the clinical picture returned to normal 6 mo after anti-TNF withdrawal.

MS

The development or exacerbations of MS^[25] or CNS demyelination are well-described neurological complications of TNF- α antagonist therapy. TNF- α antagonist might be effective for inflammatory neurological disorders such as MS because elevated levels of TNF- α have been demonstrated in serum or CSF of patients with MS^[26].

Microglia and macrophages in the CNS secrete TNF- α with a direct role in the pathogenesis and demyelination of MS^[27]. There are two forms of TNF- α : a trans-membrane protein (tmTNF) and a soluble form (sTNF); both interact with two distinct receptors, TNFR1 and TNFR2^[28]. In the first stages of MS, TNF- α is involved in demyelination, while in later stages it is fundamental for remyelination^[29]. In a double-blind placebo-controlled phase II human study of lenercept, a recombinant TNFR1 fusion protein, more lenercept-treated patients experienced exacerbations compared to placebo patients and these exacerbations occurred early, leading to early study termination^[30].

There are several case reports of the development of MS^[31] or CNS demyelination during treatment with TNF- α antagonist such as infliximab or adalimumab. The mechanisms of induction or exacerbation of MS and/or CNS demyelination are unknown. One possible hypothesis is that TNF- α has anti-inflammatory effects that may contribute to “off” signals in MS. The “on/off” balance of TNF-mediated signals is relevant to MS and the removal of TNF- α might potentiate the disease^[30]. Anti TNF- α drugs, particularly infliximab, do not appear to cross the blood-brain barrier and neutralize local TNF- α -mediated tissue injury. Nevertheless, infliximab causes enhanced permeability of the barrier increasing the activation of myelin-specific peripheral autoreactive T cells^[32]. TNFR2 function is important for the enhance-

ment of remyelination and the use of TNF- α antagonists may inhibit the tmTNF-TNFR2 axis^[33].

The Mayo Clinic reported one case of MS in 500 CD patients treated with infliximab and another patient has been reported among 651 IBD patients treated with infliximab in the Danish Crohn Colitis database; three further cases of MS were reported in Edinburgh's experience of 620 patients treated with IFX^[34]. It is unclear whether these demyelinating events are coincidental or causally associated with the use of TNF- α antagonists because the interval between the administration of anti-TNF- α agents and the appearance of symptoms varies greatly. Most researchers have reported that the average time between the beginning of treatment and the onset of neurological symptoms is about 5 mo^[35].

Demyelinating neuropathies

The proposed pathogenesis of anti-TNF α -associated neuropathies encompasses both T cells and humoral immune attacks against peripheral nerve myelin, vasculitis-induced nerve ischemia and inhibition of signaling support for axons^[11]. Most of these neuropathies improve over a period of several months after withdrawal of the drug, with or without additional immunomodulating treatment^[11].

Guillan-Barré syndrome and its variant Miller-Fisher syndrome

Guillan-Barré syndrome (GBS)^[36] and Miller-Fisher syndrome^[37] are two types of demyelinating peripheral neuropathies reported during treatment with TNF- α antagonists. GBS is a post-infectious, immune-mediated disease, generally presenting as an acute inflammatory demyelinating polyneuropathy^[36] characterized by ascending paralysis with rapid, progressive, symmetric limb weakness and areflexia.

The annual incidence is 1.5 cases/100000 and the mortality rate is about 5%. Approximately 10% of patients are still severely disabled at 1 year after diagnosis. Miller-Fisher syndrome is a rare variant of it and its main manifestation is descending paralysis affecting the eye muscles with the triad ophthalmoplegia, ataxia and areflexia^[37]. It is possible that TNF- α antibodies unmask latent infections or cause an increased susceptibility to infections triggering or worsening the autoimmune demyelinating processes^[11]. Two-thirds of GBS cases are associated with bacterial or viral infections such as *Campylobacter jejuni*, *Mycoplasma pneumoniae*, *Haemophilus influenzae*, cytomegalovirus (CMV), Epstein-Barr virus (EBV) and varicella zoster virus^[37].

It is important to remember that GBS may be an independent extraintestinal manifestation of IBD induced by vasculitis, malnutrition or vitamin deficiencies^[37]. Drug withdrawal is always suggested in the management of these patients and, in troublesome cases, cyclophosphamide or intravenous immunoglobulin is needed^[37]. Vadikolias *et al*^[38] reported a case of a 40-year-old man affected by CD developing autoimmune demyelinating

acute paraplegia 4 mo after starting infliximab therapy. Some authors suggest that search subclinical demyelinating processes before initiating anti-TNF- α therapy, particularly in young patients^[5], should become a recommended standard practice. Shin *et al*^[36] described 15 cases of GBS identified from the postmarketing database of anti-TNF (9 patients on infliximab, 5 on etanercept, and 1 on adalimumab). The symptoms were reported between 6 wk and 2 years after the start of these therapies^[36]. Thirteen patients have been subjected to regular follow-up and 12 showed a partial or complete resolution after adequate therapy for GBS^[36]. Deepak *et al*^[13], in the FAERS about neurological events in patients treated with TNF- α inhibitors, reported 153 cases out of a total of 772 with neurological manifestations related to anti-TNF- α therapy.

Lewis-Summer syndrome

Nancey *et al*^[39] reported two cases of Lewis-Summer syndrome (LSS), also called multifocal acquired demyelinating sensory and motor neuropathy, related to the use of infliximab. LSS is a rare, dysimmune, multifocal peripheral nerve disorder described for the first time in 1982 by Lewis *et al*^[40], and characterized by asymmetric multifocal and sensory involvement of the nerve roots and trunks of the upper and lower limbs. The disease should be suspected in the presence of distal, asymmetric weakness affecting the upper or lower limbs with initial sensory impairment followed by motor involvement^[39]. An electromyographic study showing persistent multifocal conduction blocks allows the diagnosis^[39]. LSS involves only peripheral nerves without any damage to central myelin^[39].

Multifocal motor neuropathy with conduction block

Barber *et al*^[41] reported one case of multifocal motor neuropathy with conduction block (MMNCB) following treatment with infliximab. This is an asymmetric motor neuropathy with diagnostic features including the presence of multifocal partial motor conduction block and the presence of blood anti-GM1 antibodies in 50% of cases. No more than 10 cases of MMNCB associated with anti-TNF therapy have been reported in the international literature. The rate of progression of demyelinating neuropathies is highly variable ranging from a few days to many years and the recovery is not always certain after drug withdrawal^[41].

Following suspicion of peripheral neuropathies related to biologic therapy, a consultation with a neurologist should always be suggested for a differential diagnosis between small fiber polyneuropathies and an axonal sensory-motor neuropathies (SM-PNs) characterized by areflexia, sensory ataxia, minor cutaneous sensory deficiency (distal dysesthesia)^[41] and variable degree of motor dysfunction.

Ischemia and inhibition of signaling support for axonal transport are the mechanisms proposed for secondary axonal loss. It is conceivable that the adverse effect

of TNF- α antagonists on peripheral nerves is cumulative and, therefore, the severity of neuropathy is proportional to the total dose of the drug received^[3]. These data emphasize the importance of long-term vigilance during the course of the treatment with TNF- α antagonists. In most cases, drug withdrawal resolves the complication^[3].

Chronic inflammatory demyelinating polyneuropathy

Some cases of Chronic inflammatory demyelinating polyneuropathy (CIDP) have been reported during anti-TNF therapy^[42,43], appearing 4-17 mo after initiation of infliximab, with the possible presence of GM2 antibodies in the serum. CIDP is characterized by weakness in the proximal and distal extremity muscle groups associated with bilateral foot drop and a stocking-glove pattern mostly localized in the lower extremities^[42]. Electrodiagnostic studies reveal progressive acquired demyelinating sensory and motor peripheral polyneuropathy. Withdrawal of the offending agent does not always reverse the immune process and chronic immunotherapy may be needed to control the inflammatory process and improve clinical outcome^[42].

Infections of the nervous system

B-lymphocyte depletion in immunocompromised patients causes meningitis by encapsulated bacterial pathogens, while T-lymphocyte depletion or impaired macrophage function cause the development of infections by intracellular pathogens such as fungi, particularly *Aspergillus* and *Nocardia*, viruses such as herpes simplex virus (HSV), JC virus (JCV), CMV, human herpes virus 6 and parasites such as *Toxoplasma gondii* (*T. gondii*)^[44].

In general, although anti-TNF agents may increase the risk of infections, even at neurological levels, and particularly for intracellular organisms, several observations indicate that the risk of opportunistic infections is greatly increased when patients are treated with more than one immunosuppressant drug. Thus, the main recommendation originating from these observations is to limit multiple immune suppression to the shortest time possible.

Patients with infections of the nervous system may present with many clinical manifestations including meningeal signs, mass lesions, encephalopathy, seizures and stroke-like presentation^[44].

CNS fungal infections

CNS infections by *Aspergillus* are usually characterized by mass lesions such as brain abscesses or by cerebral infarction, and more rarely by meningitis^[44]. *Cryptococcus neoformans* may show as subacute meningitis with fever and headache without neck stiffness. Mass cerebral lesions usually have a subacute or chronic presentation while meningitis and encephalitis have a more acute presentation. In patients with meningeal signs and/or encephalopathy, a lumbar puncture should be performed with strain culture or serology of CSF^[44]. MRI should always be performed in patients with a strong clinical suspicion

of encephalopathy. MRI should be performed and tissue biopsy sampling may be always considered^[44] in patients with cerebral mass lesions, for a differential diagnosis between tuberculosis, lymphoma and toxoplasmosis. Lumbar puncture should also be always performed in these cases because a positive EBV PCR in the CSF suggests the presence of CNS lymphoma.

Meningococcal meningoencephalitis

Majumder and Kumar^[45] described a case of a 51-year-old woman affected by CD showing meningococcal meningitis during treatment with certolizumab in clinical remission for 6 mo. Meningococcal vaccination is safe and it should always be considered in high-risk IBD patients, particularly in those subjected to biologic therapy^[46].

Listeria infection

In 2000 Morelli *et al.*^[47] described for the first time a *Listeria* infection complicating infliximab therapy in a CD patient. *Listeria monocytogenes* (*L. monocytogenes*) is a Gram-positive, rod-shaped, facultative intracellular organism. About 1%-5% of all healthy adults are asymptomatic carriers of *L. monocytogenes*. In the United States, 2500 cases/year are reported and the mortality rate is 15%-30%. Mortality of *Listeria* meningoencephalitis infection, associated with sepsis, is particularly high in pregnant women, neonates and immunocompromised subjects, where it may reach 33% of cases^[47]. Listeriosis is a foodborne infection caused by ingestion of soft cheeses, unpasteurized milk, unwashed vegetables, ready-to-eat foods such as hot dogs and cold cuts, and it may be more frequent in populations eating raw food such as those living in Africa and Asia. It is important to wash the hands and to scrub fruits and vegetables^[47]. TNF- α , produced by monocytes, macrophages, lymphocytes, and fibroblasts, has a crucial role against *L. monocytogenes* as well as all other intracellular organisms. In fact, TNF- α is crucial in host resistance against intracellular organisms by mediating local inflammation to control infection^[47]. Generally, blood culture becomes positive for Gram-positive bacilli after 32 h and lumbar puncture reveals a high percentage of polymorphonuclear leukocytes. Ampicillin and gentamicin is the treatment of choice for listeriosis^[47]. On the basis of the above considerations, it is important that patients receiving anti-TNF therapy observe safe food practices and refrain from the above-mentioned food products.

Campylobacter fetus infection

Umehara *et al.*^[48] described *Campylobacter fetus* (*C. fetus*) meningitis in a CD patient on long-term steroid therapy after only one infusion of infliximab. *C. fetus* is a Gram-negative, motile, bacterial species with a typical S-shaped rod morphology and it is particularly present in immunocompromised, pregnant women and neonates in whom it may cause endocarditis, thrombophlebitis, pneumonia, pleurisy and arthritis^[49]. The bacterium lives in the intestinal flora of cattle and sheep where it causes

spontaneous abortions^[50].

Toxoplasmosis

Young *et al*^[51] described a case of cerebral toxoplasmosis during infliximab therapy associated with low doses of prednisone, methotrexate and leflunomide in a 36-year-old woman affected by severe rheumatoid arthritis. The most important neurological symptoms were diffuse headache, slurred speech, weakness in the left arm, and a grand mal seizure. MRI imaging showed two lesions within the right hemisphere and the diagnosis of *T. gondii* infection was obtained by brain biopsy^[51]. *T. gondii* is an obligate intracellular parasite infecting up to a third of the world's population^[51]. *T. gondii* infection is acquired by ingestion of food or water contaminated with oocysts shed by cats, or by eating undercooked or raw meat containing tissue cysts^[52]. Primary infection is usually subclinical but, in some patients, cervical lymphadenopathy, ocular disease, encephalitis, myocarditis and pneumonitis may occur^[52]. The disease may be life-threatening in immunocompromised patients, and CNS involvement has been described in AIDS patients^[52], and patients receiving corticosteroid^[52] and anti-TNF- α ^[52] therapy. Lassoued *et al*^[53] described two cases of chorioretinitis related to *T. gondii* during anti-TNF therapy, with malaise, low-grade fever and visual defects as major complaints^[52]. TNF- α has an important role in the protection against *T. gondii* infection, playing a synergic role with interferon γ ^[54]. Response to treatment for toxoplasmosis occurs early and, in patients with compatible MRI of the brain, empirical treatment should be started^[51]; early response to treatment usually confirms toxoplasmosis diagnosis.

Nocardiosis

Wendling *et al*^[55] described cerebral nocardiosis during adalimumab and methotrexate therapy for rheumatoid arthritis. A 63-year-old Caucasian man showed the appearance of subcutaneous nodules in the trunk with histological diagnosis of pyogenic granulomas, pulmonary nodules upon chest radiography, and neurological signs such as headache, vertigo, cerebellar dysarthria after 8 mo combined therapy^[55]. Brain computed tomography (CT) and MRI showed two lesions with edema and a mass effect in the right parietal region and cerebellum. Surgical biopsies revealed a pyogenic abscess and the presence of *Nocardia farcinica*. Nocardiosis is caused by an opportunistic, aerobic, Gram-positive, filamentous bacterium of the order Actinomycetales. The most common species are *Nocardia asteroides*, *Nocardia brasiliensis*, and *Nocardia otitidis cavium*. This bacterium has a long incubation period^[55]. Modes of contamination include inhalation and direct inoculation through the skin^[55]. Systemic nocardiosis is defined by the presence of two or more foci of infection^[55]; the lung is the most common primary site of systemic nocardiosis (60%-80% of cases) and cerebral or other locations may occur in 20%-40% of cases. CNS involvement is responsible for the worst

prognosis with a 75% rate of mortality, particularly in lupus patients^[53]. TNF plays a role in the clearance of *Nocardia* in animal models^[55]. However, nocardiosis is rare during anti-TNF- α therapy and only eight cases^[55] have been reported among 300000 patients treated with anti-TNF agents in the United States. Anti-TNF- α may accelerate and disseminate previously undiagnosed nocardiosis, particularly when therapy comprises corticosteroids and methotrexate.

Herpes simplex infection

Herpes simplex encephalitis (HSE) has been reported in patients receiving TNF- α antagonist therapy^[56]. Also, TNF- α inhibitor therapy appears to be associated with an increased risk of herpes zoster^[57]. An increase in the risk of severe HSV infection is related to the use of TNF- α inhibitors because TNF is an important element of the innate immune response to HSV-1 encephalitis, as reported in animal models^[58]. About 95% of all cases of HSE are attributed to HSV-1 and, only occasionally, HSV-2 has been described^[59]. Bradford *et al*^[60] has identified three adults affected by HSE during monoclonal antibody TNF- α inhibitors. The patients clinically showed altered mental status, such depression or reduced affective response, slow mental processing, memory disturbances, fever, meningismus and headache. In patients receiving TNF- α the clinical manifestations may be atypical. Brain MRI shows characteristic temporal lobe involvement, CSF PCR positive for HSV DNA, and the clinical picture significantly improves after acyclovir therapy^[56]. More than 90% of adult patients with HSE have temporal lobe abnormalities on brain MRI and a positive HSV PCR at clinical presentation^[60]. Weil *et al*^[61] reported that these diagnostic tests might be initially negative in 5%-27% of patients if they are performed early in the disease course. Bradford *et al*^[61] reported that two of three patients initially had normal brain MRI and negative results for CSF HSV PCR. Recently published guidelines^[62] emphasize the need to repeat HSV PCR in 3-7 d if the results are initially negative and the clinical course is highly suggestive for HSE. Bradford *et al*^[61] suggest that in patients on anti TNF- α therapy and a clinical presentation suggestive for HSE, empirical acyclovir treatment should be performed until the result of a second PCR. The mortality of HSE at 1 year is 14%-22% and most survivors have residual neurological and cognitive deficits^[63].

Lu *et al*^[64] reported a case of Bell's palsy caused by HSV in a 43-year-old woman on adalimumab therapy (40 mg biweekly) for CD for 3 years. The patient showed small painful erythematous ulcers on her oral mucosa and lips, fever and right-sided facial palsy suggestive of Bell's palsy secondary to HSV infection. Her symptoms disappeared after 7 d treatment with three 1-g tablets/d valacyclovir, associated with adalimumab withdrawal, but symptoms recurred after rechallenge with adalimumab. Bell's palsy is an idiopathic peripheral facial nerve paralysis and reactivation of HSV may play a major role

through inflammation of the facial nerve^[65].

EBV infection

Nozaki *et al*^[66] reported one case of Epstein-Barr encephalitis during TNF- α antagonist therapy but the patient also had concurrent HIV infection. Several studies have investigated the possibility of EBV reactivation in patients treated with infliximab but no significant increased risk emerged^[67]. Lavagna *et al*^[68], in a study of 60 patients with CD treated with infliximab, did not observe any EBV viremia or any clinical manifestations of EBV infection during and after treatment. Serum EBV DNA was never found in a series of EBV-IgG-positive patients treated with TNF- α blockers^[69].

Cerebral tuberculosis

Tissot *et al*^[70] described a 40-year-old man with CD treated with infliximab monotherapy for 16 mo complicated by the appearance of neurological symptoms such as blurred vision, and motor and sensitive deficiency of the right lower limb. Clinical examination showed a papular erythematous skin lesion localized on the left lateral cervical region and multiple cervical nodes. Cerebral MRI revealed multiple ring-enhancing lesions suggestive of tuberculoma, and chest-abdomen CT showed an upper lobes alveolar syndrome and multiple abdominal lymph nodes suggestive of miliary tuberculosis. This diagnosis was confirmed by skin lesion biopsy with evidence of giant cell granuloma, and PCR for *Mycobacterium tuberculosis* in cultures of bronchial washing lavage. The patient was subjected to classical anti-tuberculosis treatment, with progressive disappearance of all cerebral lesions and complete resolution of neurological symptoms. Therapy for cerebral tuberculosis should comprise four drugs (isoniazid, rifampicin, pyrazinamide and ethambutol) for 2 mo followed by isoniazid and rifampicin for at least 10 mo^[70]. Andrisani *et al*^[71], in their experience of 92 IBD patients who were candidates for anti-TNF therapy, suggested screening for high-risk latent tuberculosis reactivation during therapy by means of Quantiferon TB-Gold (QFT-G) and tuberculin skin test (TST) because both are useful for identification of high-risk patients.

Ocular nervous disorders

Anterior optic neuropathy^[72] and retrobulbar demyelinating optic neuropathy^[73] have also been reported as possible complications of infliximab therapy. The clinician should be alert to anterior optic neuropathy when patients, during anti-TNF therapy, develop bilateral simultaneous sudden visual loss with decreased visual acuity, without pain related to eye movements, and swollen optic discs with bilateral inferior arcuate defects upon ophthalmology evaluation. Retrobulbar (posterior) optic neuropathy shows the same symptoms of anterior optic neuropathy, perhaps with monolateral visual loss, and only an ophthalmologist may obtain the diagnosis with specific tests such as visual field and flash visual evoked potentials^[73]. Risk factors such as stroke, arterial

hypertension, diabetes, atherosclerosis and hypercholesterolemia should always be ruled out^[74]. Anterior optic neuropathy generally appears early within the first three infusions of infliximab^[74]. In the study of Tissot *et al*^[70], three patients with infliximab-related anterior optic neuropathy were described; one had impaired visual loss after rechallenge with infliximab infusion, confirming the association between infliximab and optic nerve damage. To date, four cases of toxic, infliximab-related anterior optic neuropathy and 10 cases of retrobulbar optic neuritis have been described^[75]. No patients with toxic anterior optic neuropathy improved after pulsed intravenous infusion of methylprednisolone while all 10 patients with retrobulbar optic neuritis did improve^[73]. At this moment, more data are needed to evaluate the exact pathogenic mechanism and dose relationships between these ocular manifestations and infliximab^[74]. Deepak *et al*^[13], in a FAERS Study about neurological manifestations in patient on anti TNF- α therapy, reported 105 cases of optic neuritis (13.6%) in 772 patients with neurological manifestations during anti TNF- α therapy.

Steroids

Repeated or prolonged exposure to steroids may cause myopathy that needs to be differentiated from predominant involvement of large motor fibers^[75]. Steroid therapy may also produce a psychotic condition^[76]. Corticosteroid therapy increases the risk of infection in a dose-dependent fashion^[77] and corticosteroid-treated patients with intestinal disease have a relative risk of lethal and nonlethal infections of 1.4 (95%CI: 1.1-1.7, $P = 0.02$). Doses of prednisone > 20 mg/d are associated with a twofold increase in overall relative risk of lethal or nonlethal infectious complications compared with controls ($P < 0.004$). *L. monocytogenes* sepsis and meningitis have been described in adult and pediatric patients treated with high doses of steroids with or without azathioprine^[78]. The long-term use of steroids may also predispose to the development of *C. fetus* meningitis^[78].

Sulfasalazine

Sulfasalazine is still used for both CD and UC because of its low cost/effectiveness ratio. However, its use is mostly hampered by the frequent occurrence of side effects and neurological complications have also been reported.

Severe neurotoxicity leading to drug withdrawal has been reported in < 5% of patients^[79]. The neurological toxicity of the drug appears mainly to be related to folate deficiency^[80]; a typical adverse result of chronic sulfasalazine intake through different mechanisms: oxidative damage to red cells leading to hemolysis^[81]; inhibition of jejunal hydrolysis of pteroylpolyglutamates blocking absorption of dietary folates; and competition with the three enzymes (dehydrofolate reductase, serine transhydroxymethylase and methylene tetrahydrofolate reductase) mainly involved in folate metabolism. Patients with IBD are predisposed to hyperhomocysteinemia^[80],

which is considered a risk factor for cardio-cerebrovascular events, and part of this condition might be related to the folate-depleting role of sulfasalazine.

Mechanisms other than folate deficiency appear to be present in patients treated with sulfasalazine who develop neurological disorders but the pathophysiological aspects are currently unknown^[81]. Liedorp *et al*^[82] described axonal polyneuropathy occurring after 2 years treatment with sulfasalazine without blood folic acid deficiency. Mut *et al*^[83] noted a reversible encephalopathy after only 3 wk of sulfasalazine therapy, and the clinical symptoms and MRI lesions resolved completely after drug discontinuation. Gold *et al*^[84] have suggested that the drug might also be implicated in the occurrence of MS.

Methotrexate

Methotrexate is an immunosuppressant with anti-folate activity^[85]. It is highly ionized with low lipid solubility and it does not readily cross the blood-brain barrier. Methotrexate is a cell-cycle-specific agent that inhibits the enzyme dihydrofolate reductase, preventing the conversion of folic acid to tetrahydrofolic acid and thus inhibiting cell replication^[85]. Methotrexate also causes a relative excess of homocysteine determining small-vessel vasculopathy^[85]. The risk of neurotoxicity increases with higher doses.

The association between low oral weekly doses of methotrexate and the development of posterior reversible encephalopathy syndrome (PRES) has been described in only a few cases. PRES often shows nonspecific symptoms such as headache, seizures, visual disturbances including cortical blindness, altered mental status, and even coma. Seizures are present in up to 88%, visual disturbances in 60%, and headache with altered mental function in > 50% of patients. In these studies, oral methotrexate had been taken for 3-7 years before the onset of symptoms. The patient described by Hart *et al*^[85] was exposed to a total dose of 1560 mg over 4 years. Thus, the association of neurotoxicity with long-term use of methotrexate suggests a cumulative toxic effect on the blood-brain barrier. Neuroimaging, particularly MRI, is essential to obtain a diagnosis: classical lesions are symmetrical and located in the subcortical and cortical areas of the posterior circulation. The frontal lobe, brainstem, basal ganglia, thalamus, and even the spinal cord may also be involved.

Methotrexate-associated neurotoxicity is often termed as leukoencephalopathy (LEP), frequently presenting as transient seizures^[85]. Also, headache, confusion and disorientation may be present^[86]. LEP is a structural alteration of cerebral white matter in which myelin suffers the most damage. The basic pathophysiological mechanisms leading to methotrexate-induced LEP are unknown but they are multifactorial and include adenosine accumulation, homocysteine elevation, and its excitatory effect on N-methyl-D-aspartate receptor and alteration in bipterin metabolism^[85]. The white matter changes are strictly

localized to the cerebellum and this selective site may be explained by the involvement of Purkinje cell axons^[81]. Only a few methotrexate-induced white matter changes during oral treatment^[87] have been reported and most of them appeared to be related to folic acid deficiency. Chronic folic acid supplementation is thus mandatory in patients undergoing methotrexate treatment to avoid, if possible, these neurological side effects.

Metronidazole

Metronidazole is a commonly used antibiotic in the treatment of IBD, particularly in patients affected by CD^[88] with perianal involvement. Peripheral neuropathy is a well-documented side effect of the drug, reported in 21-39% of CD patients treated with metronidazole, especially in patients receiving > 1.5 g/d of the drug for > 30 d^[89]. Thus, monitoring the neurological state of the patient during metronidazole therapy is strongly encouraged^[88]. Both demyelinating and nondemyelinating neuropathies can be observed^[89]. Metronidazole-induced neuropathies are characterized by sensory manifestations with occasional ataxic features and generally are transient and resolve completely on discontinuation of medication^[14,89]. Peripheral neuropathies are one of the most frequent neurological complications described in IBD patients^[78]. The incidence of spontaneous peripheral neuropathy in IBD patients varies from 0.9%^[2] to 3.6%^[11]. These conditions are also described in other sections of this paper as side effects of biological therapies and in autoimmune nervous system disorders. Indeed, polyneuropathies in IBD may result from multiple interactions between immune-mediated disorders, nutritional imbalances, malabsorption, weight loss, vitamin deficiencies and drug-induced changes^[89]. The most important symptoms of peripheral neuropathy are paresthesia and increased threshold for temperature detection (the last sign is indicative of early neuropathy)^[88]. Axonal polyneuropathy usually is characterized by sensory loss and dysesthesia in a glove-and-stocking distribution, and decreased or absent ankle jerks with infrequent motor involvement^[84]. Small fiber nondemyelinating sensory neuropathy is characterized by subjective numbness and tingling in the absence of demonstrable abnormalities on electromyography and nerve conduction studies^[72], and may be misdiagnosed as fibromyalgia upon typically normal electrophysiological testing^[14]. IBD patients with restricted sensory involvement are usually younger than those with concomitant involvement of motor and sensory large fibers^[90]. Only some of these patients (particularly patients with CD) have been previously treated with metronidazole, and the disease progressed also after drug discontinuation, suggesting its contributory but not causative role^[76]. The physician should suspect peripheral neuropathy in cases of sensitive disturbances of the upper and lower extremities, ataxia and/or impairment of walking^[84].

Chatzkel *et al*^[91] described a 15-year-old girl affected by CD with ataxia and dysmetria 7 d after initiation of

treatment with metronidazole. Cranial MRI revealed bilateral symmetric T2/FLAIR hyperintense lesions of the dentate nuclei without contrast enhancement or restricted diffusion, and the lesions disappeared completely after drug discontinuation^[91].

Cyclosporine A

Cyclosporine A is a cyclic polypeptide that interferes with the transcription of cytokines, causing the blocking of activation and maturation of various cell types involved in cell-mediated immunity^[92]. This drug has been mostly used in severe refractory UC. Neurotoxicity is one of the major adverse events of this treatment, involving up to 25% of treated patients and including seizures, tremors, paresthesia, ataxia, motor deficits, aphasia, altered consciousness, and various degrees of visual and oculomotor disturbances^[92]. The pathogenesis of these neurological side effects is poorly understood. Cyclosporine A may rarely cause accelerated hypertension leading to progressive reversible encephalopathy syndrome^[14]; this condition is more frequent in patients with low total serum cholesterol^[14].

Irreversible bilateral optic neuropathy has also been described^[92] and two possible mechanisms have been proposed: direct toxicity to peripheral nerves, or thromboembolism leading to ischemic optic neuropathy^[93].

Cerebellar atrophy^[93] caused by cyclosporine A therapy performed despite hypomagnesemia may have its first manifestation in nystagmus. However, cyclosporine-A-induced neurotoxicity has also been described in the absence of known risk factors such as hypocholesterolemia, hypomagnesemia, previous seizure disorders and arterial hypertension^[94]. The differences in neurological side effects between oral and intravenous cyclosporine A is another matter of uncertainty^[95]. Cyclosporine A is insoluble in water and intravenous formulations are prepared in a polyoxyethylated (POE) castor oil and ethyl alcohol solution^[96]. In *in vitro* experiments, 0.1% POE castor oil determines axonal swelling and degeneration while 0.001% POE castor oil may induce demyelination. It has thus been suggested that residues of ethylene or its polymerization products might at least contribute to the neurotoxicity of intravenous cyclosporine A *in vivo*. However, the Cosmetic Ingredient Review Expert Panel has concluded that these cosmetic ingredients (POE castor oil and its derivatives) are safe in practical use^[96] and no serious neurotoxicity may be attributable to them.

Azathioprine

This drug has no specific neurotoxicity but it represents a predisposing factor to infection, particularly associated with its prolonged use. Spinal epidural abscess has been described as a complication of azathioprine therapy^[97]. Spinal epidural abscess is a rare but known neurological complication of CD^[97]; predisposing conditions are immunosuppressive therapy and the presence of intra-abdominal and/or retroperitoneal fistulas^[97]. A high index of suspicion should be raised if the patient shows back pain during or immediately after a flare of CD, with or

without neurological signs, because this condition is an alarm sign for the presence of inflamed paravertebral and spinal structures^[89]. Spinal epidural abscess represents a neurosurgical emergency in the presence of unresponsive back pain or progressive neurological deterioration such as bowel and/or bladder dysfunction. In patients with spinal epidural abscess associated with bowel fistulas and psoas abscesses determined by CD, a combined and highly specialized medical and surgical approach is needed to prevent recurrence^[98]. Prolonged antibiotic use is recommended also if cultures are negative.

Murai *et al.*^[99] reported a myelo-radiculitis determined by *Cryp. neoformans* in a UC patient on immunosuppressive therapy with azathioprine. Robineau *et al.*^[100] reported a case of HSE related to azathioprine therapy in a 28-year-old woman treated for 4 years^[100]. The diagnosis was based on the presence of photophobia, headache, asthenia and nausea associated with nuchal rigidity; lumbar puncture revealed a marked increase of lymphocytes (98%) in cerebral fluid with a detection of HSV-1 DNA determined by PCR. Intravenous acyclovir administration (15 mg/kg every 8 h) for 3 wk completely resolved this complication.

CEREBROVASCULAR DISEASES

In general, the risk of both arterial and venous thrombosis^[101], as well as of thromboembolic events, is significantly increased in IBD patients. As a consequence, thromboembolic complications have been reported in various organs, including the brain. Indeed, cerebrovascular disorders have been documented in 0.12%-4% of all IBD patients, and probably they represent the most frequently reported neurological complications^[102]. Obviously, cerebrovascular or cardiovascular events and their sequelae may be of particular severity, especially if one considers the usually young age of IBD patients. The relative risk of stroke is higher in young patients, especially women and patients with CD^[14]. Thus, a large number of studies addressing the possible underlying causes of this predisposition in IBD and proposing possible prophylactic and therapeutic strategies have been published in recent decades. As a whole, these studies suggest that active disease, even at an outpatient level, appears to be the most important predisposing factor, through many pathogenic factors activated by the ongoing inflammation. Indeed, the intimate inter-relationship between inflammation and coagulation has become clear in recent years with disease clinical and subclinical activity^[103] shown to be associated with hypercoagulability related to various factors such as qualitative and quantitative abnormalities of platelets^[104] and coagulation factors^[94], decreased anticoagulant activity^[100], hypofibrinolysis^[105], malabsorption and hypercatabolism leading to vitamin B6 deficiency^[106], endothelial changes^[102] leading also to reduced activation of protein C, dehydration, and corticosteroid therapy^[107].

The abundance of the findings showing an association between clinical activity and risk of thrombotic events has led to the introduction of antithrombotic

prophylaxis in the therapeutic guidelines of hospitalized patients with severe relapse.

However, although active disease is particularly associated with an increased risk of these complications, some cases of vascular accidents have been described during remission^[101], suggesting that IBD represents a risk factor for thrombosis. The search for a possible genetic association between IBD and carriage of factor V Leiden, G20210A prothrombin and methylene tetrahydrofolate reductase mutations has provided negative results^[102], thus suggesting that other, probably acquired although not related to inflammation, factors may indeed play a more important role. One of these factors might be hyperhomocysteinemia^[80,81], which may derive from a lack of attention to nutritional status, although in many cases the presence of subclinical inflammation cannot be ruled out. It is important to consider a higher risk in postoperative state associated with the development of arterio-arterial embolism, cardioembolism, and *in situ* cerebral thrombosis^[14].

Arterial thromboembolism

An increased risk of these complications is observed in patients with active UC and particularly in those with total colitis^[108]; even if active disease is associated with an increased risk, some cases have been described during remission^[100]. Men and women are equally affected. The cerebrovascular involvement appears to be more frequent among younger IBD patients, as reported by Houissa *et al.*^[101] who described four cases of arterial thrombosis in IBD and three of these were younger than 25 years. Intestinal inflammation may lead to increased risk for thrombosis through several pathways: by activating the coagulation cascade; decreasing anticoagulant activity; and inducing hypofibrinolysis, malabsorption and hypercatabolism with vitamin deficiencies that may lead to hyperhomocysteinemia - a well known risk factor for thrombosis^[101]. Also dehydration, immobility, sepsis, surgery and corticosteroid therapy may determine cerebral thrombosis in IBD patients^[101].

The neurological presentation of cerebral arterial thrombosis may vary from headache (95%), to mono- or bilateral paresis (43%), general or focal seizures (47%), or dysphasia (37%)^[104]. The clinical sequelae of cerebral vascular thrombosis can be devastating, especially in young patients with active and complicated IBD, leading to high mortality and disability in about 60% of cases^[101]. Conventional CT or MRI identifies the exact site of cerebral affected areas. At present, no guidelines are available for the treatment of cerebral thrombosis and stroke in IBD^[108]. Low molecular weight heparin (LMWH) is the most common drug used for the prophylaxis and treatment of vascular thromboembolism.

Given the heightened risk of thromboembolism in patients with IBD, prophylaxis with LMWH is recommended in hospitalized IBD patients, considering exacerbation of the disease^[14]. Long-term use of anti-

coagulant therapy in the treatment of arterial ischemic cerebral lesions is limited, although the presence of a hypercoagulable condition should always be considered an indication for lifelong anticoagulation with warfarin^[107]. Thrombolysis with recombinant tissue plasminogen activator, urokinase or streptokinase should also be considered in early cerebral arterial ischemic conditions (within 3 h from development of clinical symptoms) and this procedure, in expert hands, may be considered safe and effective^[109]. In selected cases, thrombectomy should also be considered^[110]. Rapid evaluation and appropriate multidisciplinary consultation are required for optimal diagnosis and management.

Venous and sinus thrombosis

Cerebral venous and sinus thrombosis is a rare condition and accounts for about 1% of all strokes^[111]. Cerebral venous and sinus thrombosis that concurrently develops with UC is rare^[111] and they may be associated with abnormalities in the coagulation system^[100]. Cerebral venous thrombosis appears to be more common in UC than in CD patients^[112], and is more commonly localized in the superior sagittal sinus and lateral sinuses^[113], although cortical venous thromboses have also been reported^[113].

All patients with UC and cerebral venous thrombosis reported in literature are young, mostly men, without other risk factors^[102]. Most patients have a pancolitis suggesting a role for increased endotoxemia and dehydration^[102] as culprits for vascular thrombosis. The most frequent symptom is headache occurring in 75%-96% of patients^[114]. The headache is often severe and diffuse and it usually precedes the appearance of neurological signs. A combination of focal defects, headache, seizures and altered consciousness is suggestive of cerebral venous thrombosis^[114], although the presenting features are variable and the condition should be considered in any IBD patients with neurological symptoms, particularly during an active phase. Cerebral infarction is a dangerous complication and it appears when the thrombosis extends from the superior sagittal sinus to the superficial cerebral veins and their tributaries^[114].

MRI studies in combination with MR venography are sensitive in identifying venous sinus occlusion^[114]. The use of local endovascular thrombolytic agents may restore the flow more frequently and rapidly than heparin alone; however, there is no evidence of the superiority of this method and the risk of hemorrhage is high^[114]. Warfarin is usually continued for at least 6 mo after a first episode of cerebral venous thrombosis, or longer in the presence of persisting predisposing factors^[114]. The theoretical risk of intestinal bleeding due to anticoagulant therapy does not appear significant in practice^[114]. Given the increased risk of thromboembolism in patients with IBD, aggressive mechanical and pharmacological deep vein thrombosis prophylaxis with LMWH is recommended in hospitalized patients^[14].

IMMUNE-MEDIATED NEUROLOGICAL DISORDERS

MS

This topic has been already treated in this paper as a possible complication of biological therapies^[25]. However, a possible spontaneous association between MS and IBD has been suspected for decades^[115]. Indeed, the estimated prevalence of MS in the general population is about 0.1%, while in IBD patients the prevalence of MS has been reported at up to 0.5%^[8,114,115], suggesting a 1.5-5-fold increase in the risk of having MS in IBD patients^[30]. In evaluating these data, however, we should bear in mind that all studies involved a limited number of patients, thus yielding low statistical power. Also, results of the studies are greatly influenced by the methods used to look for an associated disease. Indeed, Geissler *et al.*^[116] observed hyperintensity of the white matter on brain MRI in almost half of the patients with IBD free of neurological symptoms compared to only 16% of healthy age-matched controls. MS has been reported to develop either before or after the clinical onset of IBD^[116]. The nature of a possible pathogenic link between IBD and MS has not been identified, but a disturbance in functional T-cell subsets with aberrant proinflammatory activity of T helper 17 subsets has been suggested^[2]. Animal studies^[117] also suggest a link between the demyelinating lesions suggestive for MS or acute disseminated encephalomyelitis and the prothrombotic state characteristic of UC. Astrocytosis and extensive perivenular loss of myelin have been described in rhesus monkeys suffering from colitis and cerebral venous thrombosis, and it is possible to speculate that the demyelinating lesions could have been the result of perivenular edema secondary to venous blockage^[117]. Indeed, cerebral lesions in the monkey are identical to those observed in confluent leukoencephalitis and perivascular myelosis of the cerebral type; a demyelinating disease of monkeys^[118]. Whatever the mechanisms of the underlying possible association between MS and IBD, brain MRI followed by a neurological consultation for further diagnostic work-up should be organized^[2] as soon as a patient with a clinical history of UC or CD presents with an unexplained neurological symptom suggestive of MS, such as paresthesia in both arms, fingers, legs and toes, hyperesthesia of the fingertips and hyper-reflexia. Occasional, but clinically important, observations are those reporting that a demyelinating disease may be precipitated or aggravated by the use of infliximab for IBD^[119].

Cerebral vasculitis

This topic has already been treated in the chapter on complications of biological therapies^[22]. Cerebral vasculitis has been reported in association with UC^[120] and can be considered a further cause of stroke. The association between UC and Takayasu's disease, particularly in Japanese patients with an HLA-B52, DR2 haplotype, is strong^[121]. The pathogenetic process may be related

to common immune-mediated mechanisms such as T-lymphocyte mediated cytotoxicity or immune complex deposition^[121], or to a genetic susceptibility determined by patient's HLA status. The association of UC with perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA) or atypical ANCA^[122] suggests a common autoimmune etiology, but the existence of different antigenic recognitions by these antibodies in the two diseases is well established. Furthermore, UC-associated ANCA^[122] lack antigenic specificity for proteinase-3 (PR3) or myeloperoxidase (MPO) and do not have the potential for the development of systemic vasculitis or for neutrophil activation^[122]. Nevertheless, a p-ANCA (specific for MPO) positive UC patient affected by ischemic lesions in the white matter of the brain has been reported^[122].

The clinical manifestations of cerebral vasculitis are hemiparesis, hemianopsia, personality changes, headache, aphasia, seizures, coma and progressive dementia^[8]. These clinical manifestations may occur independently of the activity of the underlying bowel disease and, in some cases, they may appear even before the onset of IBD^[123]. Cerebral MRI is always abnormal^[8]. Nearly half of the reported patients have neurologic signs and symptoms developing during steroid therapy^[8].

Necrotizing angitis may show clinical manifestations similar to the acute hemorrhagic variant of acute disseminated encephalomyelitis (ADEM)^[117]. ADEM is suggested to result from a transient autoimmune response directed against myelin or other autoantigens via molecular mimicry^[117] caused by a defective epithelial barrier function in UC, leading to uncontrolled uptake of luminal antigens and stimulation of pathologic immune and inflammatory reactions^[8]. The presence of lethargy should always suggest a diagnosis of ADEM.

Autoimmune myelopathy

Lossos *et al.*^[3] reported nine UC patients with neurological disorders and six of these had peripheral nerve disorders considered as acute inflammatory demyelinating polyradiculoneuropathy^[3]. This study was limited by the absence of detailed information about CSF features and response to therapy.

Myelopathy, which may present as a slowly progressive systemic spastic paraparesis in the absence of a spinal sensory level, has been associated with UC in some case reports^[3], a link with human T-lymphotropic type 1-associated myelopathy has been proposed^[124]. This syndrome may develop without spinal MRI abnormalities^[3], an immune-mediated inflammatory origin has been suggested but a possible association with the use of medications or nutritional deficiencies cannot be ruled out^[3]. It is possible to consider this myelopathy or transverse myelitis as a part of a more widespread CNS disorder like MS or a vasculitis process as suggested by Ray *et al.*^[125].

Also, *Campylobacter jejuni* is linked to exacerbations of IBD and it may contribute to the development of autoimmune inflammatory demyelinating polyneuropathy^[121].

It is noteworthy that in the patients with generalized peripheral neuropathy, a demyelinating pattern is present in 30%^[125].

Myasthenia gravis

Myasthenia gravis (MG) is a typical immune-mediated disease in which T-lymphocyte function is abnormal, the thymus is enlarged, and circulating acetylcholine receptor antibodies are found^[126]. MG is often associated with other autoimmune disorders such as alopecia, lichen planus, vitiligo and SLE^[127]; diseases that are also observed in association with IBD. Tsuchiya *et al.*^[127] described an association between thymic abnormalities and IBD, with the presence of acetylcholine receptor antibodies^[128]. Also, the lack of age-related involution of the thymus observed in MG has also been reported in UC^[127]. T cells obtained from the thymus of patients with MG and UC have reduced ratios of suppressor (CD8⁺) to helper (CD4⁺) T cells compared with control subjects^[128].

Diplopia and ptosis of the upper eyelid in IBD patients may be an initial manifestation of MG^[129]. For the possible pathogenic association between the two diseases, intriguing observations on their therapeutic management have been reported: Finnie *et al.*^[126] reported a case of a patient with both MG and CD complicated by perianal disease whose bowel disease improved after thymectomy for severe uncontrolled MG. In contrast, Gower-Rousseau *et al.*^[130] described a patient with MG and UC in whom MG symptoms improved after proctocolectomy. Foroozan *et al.*^[129] reported a 21-year-old man with UC and binocular diplopia and ptosis due to MG; both ocular and gastrointestinal symptoms improved after plasmapheresis, azathioprine, prednisone and mestinon^[3].

Autoimmune sensorineural hearing loss

Sensorineural hearing loss is probably an immunological manifestation of IBD^[131]. The clinical manifestations of the disease are often bilateral and progressive^[132]. The hearing level is unstable with periods of deterioration alternating to partial or complete clinical remission^[132]. In general, the tendency is for gradual evolution towards permanent hearing loss^[132]. Vestibular dysfunction symptoms such as disequilibrium and postural instability may accompany auditory symptoms and these symptoms may have a sudden onset^[135].

Hearing loss generally occurs between 2 mo and 17 years after the diagnosis of UC. Hearing loss may appear during both active and remission stages of the disease and it does not have a parallel evolution. Hearing loss, if not treated, is recurrent until leading to complete deafness^[133]. A more strict collaboration with ear, nose and throat specialists should be encouraged to research this condition of autoimmune inner ear. Kumar *et al.*^[134] noted, in a controlled audiometry study, a significant sensorineural hearing loss in UC patients compared with controls. A subclinical sensorineural hearing loss may also be present in CD patients^[135].

The clinical response to steroid and immunosup-

pressive therapy suggests that an autoimmune process causes inner ear impairment^[136]. This condition is most frequently bilateral but may also be unilateral. Aggressive treatment should be started as early as possible. At present^[134], it is impossible to have detailed information about the beginning and the time-course of hearing loss because this condition is underdiagnosed. Karmody *et al.*^[133] reported that patients with hearing loss performed their first medical evaluation usually 3 years after the first clinical manifestation.

MISCELLANEOUS

Peripheral neuropathies

Polyneuropathies have previously been dealt as frequent side effects of metronidazole therapy but they may also occur as spontaneous extraintestinal manifestations of IBD. Gondim *et al.*^[89] identified 33 patients (18 with CD and 15 with UC) affected by polyneuropathies. Male sex was highly predominant (78% in CD and 75% in UC). Neurological symptoms appeared long after the diagnosis of IBD. In 33% of CD patients and 40% of UC patients, the polyneuropathy was correlated with disease activity.

In CD patients, demyelinating neuropathy was present in five patients while a nondemyelinating neuropathy was present in the other 13: small-fiber polyneuropathy (SF-PN) in two and large-fiber axonal neuropathy (LF-AN) in 11. Four patients with UC showed peripheral demyelinating neuropathies. Eleven UC patients showed nondemyelinating neuropathies: four with SF-PN and seven with LF-PN. The diagnosis of SF-PN was obtained by means of skin biopsy^[89].

Oliveira *et al.*^[4] studied 82 IBD patients (31 with CD and 51 with UC). Five CD patients (4 women) (16.1%) had SF-PN and the first symptom was sensory abnormality. Weakness was mild and mostly located in the distal legs. Neurological examination showed decreased or absent ankle jerks, and decreased distal vibration and pinprick. Ten UC patients (19.6%) had mild axonal sensory motor polyneuropathies (SM-PN). Blood B12 levels were < 200 pmol/L in two of these 10 patients, between 200-300 pmol/L in a further two, two patients had diabetes, one was affected by hypothyroidism, and positive blood rheumatoid factor was present in two^[4]. Fourteen percent of UC patients were taking steroid therapy^[4].

Oliveira *et al.*^[4] concluded that SM-PN in UC patients was more common in women, in older individuals, in patients developing the disease later in life and in subjects with a body mass index < 18.5. The authors^[4] also noted that the association with autoimmune diseases such as diabetes mellitus, hypothyroidism and positive rheumatoid factor was more frequent in UC patients with SF-PN than in CD patients.

Sassi *et al.*^[137], in a study of 102 consecutive patients with IBD, reported nine patients (8.8%) with peripheral neuropathies. Bernstein *et al.*^[138], in a large study of administrative healthcare data from the Manitoba County

between 1984 and 2003 on 8072 patients with IBD (3879 with UC and 4193 with CD), reported peripheral neuropathies in 2.4% of UC patients and 2.34 of CD patients compared to 1.35% in the general population. Peripheral neuropathies usually do not respond to treatment of the underlying IBD^[14].

Cranial nerve palsies

Cranial nerve palsies can be observed in patients with IBD. The Melkersson-Rosenthal syndrome^[139] is defined by recurrent facial nerve palsy, fissuring of the tongue, and noncaseating tissue granulomas, and it has been described in association with CD^[140]. The long intracranial course of the sixth nerve predisposes it to injury by a variety of abnormalities^[139]. Karajeh *et al*^[140] described a 27-year-old female smoker with a 12-d history of diplopia on right lateral gaze associated with retro-orbital pain before the clinical diagnosis of CD. This typical clinical presentation suggests a vascular sixth nerve palsy with a sudden onset of unilateral abduction deficit accompanied by retro-orbital pain and diplopia^[140]. It is hypothesized that microvascular ischemic demyelination of a portion of the nerve is the most likely cause of this clinical condition^[140]. This area of ischemic demyelination subsequently undergoes remyelination with clinical recovery^[140]. Complete recovery within 2-3 mo is generally observed^[140].

Optical neuropathy, as outlined above, has a clinical presentation with a bilateral optic disc swelling and it is a rare condition prevalently associated with CD^[141]. Romero Aroca *et al*^[142] reported a 27-year-old woman affected by UC and optic neuritis that resolved after mesalamine administration. Optic neuropathy may be attributed to peripapillary inflammation, optic disc ischemia, or intracranial hypertension^[142].

A local vasculitis process or a general hypercoagulability condition can determine optic nerve ischemia. Modern imaging techniques usually allow one to exclude dural venous sinus thrombosis^[113]; a serious cerebrovascular complication of IBD described in another chapter of this paper. Another clinical condition is the severe erosive arthritis of the craniocervical junction that should always be considered in IBD patients with persistent neck pain because a late diagnosis may determine severe neurological defects^[143].

Epilepsy

The association between IBD and epilepsy is uncertain^[1]. Epileptic seizure in IBD patients may be related to structural or metabolic causes^[3]. Seizures may be generalized tonic-clonic complex, simple, partial or even multiple. A MEDLINE search^[8] using “epilepsy and ulcerative colitis” as keywords found only five case reports dating back to the early 1970s. According to the literature, epilepsy appears more frequently associated with CD than with UC^[1].

Muscle disorders

Granulomatous myositis and myopathies are associated with both CD and UC patients^[144]; these manifestations usually appear during exacerbations of IBD^[145]. Orbital

myositis is a nonspecific, localized orbital inflammatory process in which one or more extraocular muscles are involved^[145]. Clinically, orbital myositis is characterized by acute pain exacerbated by eye movements; diplopia, swelling of the eyelid, conjunctival injection, and exophthalmos may also be present^[145]. The diagnosis is based on clinical history and imaging^[145]. This disease responds to steroid therapy^[146]. Orbital myositis is rare in IBD^[146]; sarcoidosis, Wegener's granulomatosis, rheumatoid arthritis and Lyme disease should be considered in the differential diagnosis^[146].

Nonspecific orbital inflammation includes histological forms that are more difficult to distinguish such as an idiopathic granulomatous and idiopathic sclerosing pseudotumor^[147]. Nonspecific orbital inflammation appears to arise from an immune reaction in the orbit secondary to a neighboring zone of inflammation or a distant autoimmune reaction^[148]. It has been associated with CD, diabetes, rheumatoid arthritis and Graves' disease^[148].

MRI is the method of choice to study the orbital region in orbital myositis because it is able to show the typical diffuse enlargement of extraocular muscles with blurred margins and to rule out other lesions such as tumor/pseudotumor infiltration, apical extension, cavernous sinus involvement and intracranial disease^[146]. Orbital myositis most commonly affects the superior recti, the medial recti and oblique muscles.

Classic migraine

The prevalence of migraine in patients with IBD remains unknown^[149]. Migraine is associated with systemic endothelial dysfunction^[150], which is also proposed as a possible pathogenic factor in IBD^[151]. Oliveira *et al*^[4] found that headache is the most common neurological complaint reported both in CD and UC patients, in 54.8% and 56.9% of patients, respectively. In most patients headache is not disabling and it is often associated with IBD relapse and treatment^[4]. Ford *et al*^[149], in a study performed on about 100 IBD patients (77% women and 23% men, 66% with CD and 27% with UC) by an ID-Migraine questionnaire^[148], noted a 30% prevalence of migraine in IBD patients. Migraine was more prevalent in CD (36%) than in UC (14.8%). In UC patients, the prevalence of migraine in women did not approach that of the general population (12.5% *vs* 18.2%), whereas the prevalence in men greatly exceeded that of the general population (18% *vs* 6.5%)^[152].

Currently, migraine is underdiagnosed in IBD patients, although it causes limited ability to work, study and perform routine activities in a high percentage of IBD patients^[146]. It is important to consider that migraine with aura may be an independent risk factor for ischemic stroke in women^[153] because they have a 13.7-fold increased risk for silent infarction in the posterior territory and 2.1-fold increased risk for deep white matter lesions^[154].

Sleep disturbances, depression and anxiety, chronic fatigue syndrome

Sleep disturbances are recognized reactions to inflamma-

tion^[155] and may represent the first response to acute inflammation^[156], although they may persist during clinical remission.

Depression and anxiety occur in IBD and they may involve sleep disturbances and asthenia^[156]. Assessment of depression and anxiety in IBD is mandatory because these conditions may contribute to the subjective perception of poor quality of life^[157]. Anxiety may be associated with more intense disease activity^[158].

Fatigue in IBD may be considered as a consequence of the disease and its treatment^[157]. Iron deficiency may cause fatigue and sleep disorders in patients with CD^[157]. Patients can express fatigue even when bowel disease is inactive^[159]. Minderhoud *et al.*^[160] showed that the fatigue score remains high during disease remission compared with normal control subjects. Lipton *et al.*^[152], in a study of French IBD patients, found that the scores obtained on the Multidimensional Fatigue Inventory in IBD patients were similar to those affected by cancer. Fatigue may be considered a part of the core symptoms of depression^[161] and the use of antidepressants may improve chronic fatigue syndrome. In summary, although chronic fatigue syndrome is frequent in IBD patients, its precise pathogenesis is not clear and this most probably reflects a multifactorial nature of the syndrome.

Restless legs syndrome

Restless legs syndrome (RLS) is a CNS disorder characterized by a compelling urge to move the legs at rest; it contributes to sleep disturbances and impaired quality of life. RLS may be primary (idiopathic and familial) or secondary to many disorders such as pregnancy, end-stage renal failure, iron deficiency anemia, rheumatoid arthritis, diabetes, Parkinson's disease, fibromyalgia, IBD^[162], gastric resection, chronic liver disease, and irritable bowel syndrome^[163]. The diagnosis of RLS must be made according to the following four criteria established by the International RLS Study Group^[164]: (1) an urge to move the legs, usually accompanied or caused by uncomfortable and unpleasant sensations in the legs; (2) the urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity; (3) the urge to move or unpleasant sensations are partially relieved by movement at least as long as the activity continues; and (4) the urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night.

Weinstock *et al.*^[162] reported a prevalence of 30% for RLS in patients with CD and noted that it appeared during or after the onset of CD symptoms, suggesting a link between CD and RLS. This association might at least partly explain the presence of both fatigue and sleep disturbances in CD patients^[161]. Patients with iron deficiency anemia are at particularly high risk of developing RLS^[165] because low brain iron concentration may play a role in altered dopamine levels, providing a unifying condition for most cases of the syndrome^[166]. In fact, inflammatory conditions such as CD cause an increased secretion of proinflammatory cytokines [*i.e.*, interleukin

(IL)-6]^[167] which in turn causes increased hepcidin production^[163], leading to iron deficiency in the CNS as a cause of RLS^[168]. Small intestinal bacterial overgrowth, which may be observed in CD patients may also cause RLS by an inflammatory state supported by IL-6 and hepcidin as in MS patients^[169]; in these cases, antibiotic therapy might be beneficial^[169].

Wernicke encephalopathy

Wernicke encephalopathy is a neurological complication determined by vitamin B1 deficiency^[170]. Hahn *et al.*^[170] have reported vitamin B1 deficiency in a young patient with CD receiving total parenteral nutrition without vitamin replacement. Larnaout *et al.*^[171] reported a CD patient with Wernicke encephalopathy under normal enteral nutrition. This patient died and autopsy revealed the following pathological cerebral lesions: hemorrhagic necrosis around the third and fourth ventricles with vascular proliferation and pericapillary hemorrhages; numerous small hemorrhagic infarctions in the central part of the corpus callosum; marked spongiosis, predominantly in the left cerebellar white matter; slight thickening of leptomeninges with some mononuclear cells; and absence of vascular thrombosis or inflammatory perivascular cuffing in the brain and spinal cord.

Vitamin B12 deficiency

Vitamin B12 deficiency due to terminal ileal disease or surgical resection in CD may cause subacute myelopathy combined with degeneration characterized by bilateral spastic paresis, loss of pressure and vibration sensation due to degeneration of the posterior and lateral columns of the spinal cord^[172].

CONCLUSION

Neurological complications of IBD, either related to drug therapy or spontaneously associated with the disease, are relatively frequent and may contribute to a high degree of morbidity and permanent damage. They are also frequently difficult to recognize and diagnose, due to their frequently unclear clinical expression. For these reasons, knowledge of the different presentations as well as of differential diagnosis and therapeutic possibilities is important for the gastroenterologist dealing with IBD patients. This paper is thus aimed at providing interested physicians with an in-depth review of the main features of neurological complications of IBD.

Abstract

To examine and evaluate recent evidence regarding the epidemiology, pathogenesis and management of colorectal cancer (CRC) development in inflammatory bowel disease (IBD)-primary sclerosing cholangitis (PSC) patients. Using the PubMed database, a literature search was conducted for relevant articles in English from the past 10 years. Relevant studies investigating PSC as a risk factor for CRC in IBD in the context of incidence and prevalence, pathogenesis, prevention and prognosis were included in this review. Recent evidence increasingly points to PSC as a significant risk factor in the development of CRC in patients with concomitant IBD. PSC may be an important risk factor for CRC in different populations worldwide. The mechanism for this increase in risk is still unclear. The efficacy of UDCA as a chemopreventive agent remains controversial. Liver transplantation does not halt the development of CRC, although there is not enough evidence to suggest that it is associated with increased

incidence of CRC. While routine colonoscopic surveillance should be performed in patients with concurrent PSC and IBD, more high-level evidence is required to support the benefits of the procedure. While many new developments have taken place in the last decade, the pathogenesis and optimal management of CRC development in IBD-PSC patients remain unclear.

Key words: Primary sclerosing cholangitis; Ulcerative colitis; Crohn's; Inflammatory bowel disease; Colorectal cancer; Liver transplantation; Ursodeoxycholic acid

Core tip: The widely accepted risk factors for malignant transformation in inflammatory bowel disease (IBD) are disease duration and extent of inflammation. Since first proposed in 1992, one increasingly recognised independent risk factor for colorectal cancer development in IBD patients is concomitant primary sclerosing cholangitis.

Original sources: Wang R, Leong RW. Primary sclerosing cholangitis as an independent risk factor for colorectal cancer in the context of inflammatory bowel disease: A review of the literature. *World J Gastroenterol* 2014; 20(27): 8783-8789 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i27/8783.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i27.8783>

INTRODUCTION

Inflammatory bowel disease (IBD) is a widely accepted risk factor for colorectal cancer (CRC). The development of CRC complicating IBD only occurs in 1%-2% of CRC cases and has been reported to account for up to a third of mortality in ulcerative colitis (UC) patients^[1].

Table 1 Summary of studies investigating colorectal cancer as a risk factor in patients with concurrent primary sclerosing cholangitis and inflammatory bowel disease

| Ref. | Location | IBD-PSC patients (n) | Colorectal neoplasms (n) | Matched controls? | Study type | Is IBD-PSC a risk for CRC? |
|------|-----------------|----------------------|--------------------------|-------------------|---------------|-----------------------------|
| [24] | The Netherlands | IBD (126) | CRC (16) | No | Retrospective | Yes |
| [9] | Belgium | IBD (107) | CRC (10) | No | Retrospective | Yes |
| [12] | Sweden | IBD (152) | CRC/Dys (3) | No | Retrospective | No |
| [31] | Germany | IBD (120) | CRC (7) | No | Prospective | Only with dominant stenosis |
| [28] | Argentina | UC (39) | CRC (7) | Yes | Prospective | Yes |
| [30] | United States | UC (50) | N/S | Yes | Retrospective | No |
| [32] | Sweden | CD (28) | CRC/Dys (9) | Yes | Retrospective | Yes |
| [33] | United Kingdom | CD (35) | Dys (1) | No | Retrospective | No |

UC: Ulcerative colitis; CD: Crohn's disease; Dys: Dysplasia; N/S: Not specified; CRC: Colorectal cancer; PSC: Primary sclerosing cholangitis; IBD: Inflammatory bowel disease.

Established risk factors for malignant transformation in IBD include disease duration and extent^[2-4], family history of CRC^[5,6], and concomitant primary sclerosing cholangitis (PSC).

PSC is a chronic syndrome of unknown aetiology. PSC is characterised by destruction and stenoses of intrahepatic and extrahepatic biliary ducts by inflammation and fibrosis, leading to cholestasis. As the disease progresses, portal tract fibrosis and biliary cirrhosis may develop, which may ultimately lead to death from hepatic cirrhosis and failure^[7]. Besides CRC, PSC has been associated with other malignant conditions, including cholangiocarcinoma^[8,9], pancreatic carcinoma^[10], gallbladder cancer^[11], hepatobiliary cancer^[12], and hepatocellular carcinoma^[10,13].

The incidence of PSC may be increasing, possibly due to earlier recognition and increasing index of suspicion^[14]. The mean age of PSC diagnosis is 40 years, and the median survival time from diagnosis to death or liver transplantation is approximately 12 years^[15]. PSC has a slightly male predominance^[16]. Currently, the only definitive long-term treatment of PSC is liver transplantation^[7].

The association of PSC with UC is stronger than with Crohn's disease (CD). The prevalence of concurrent PSC in UC patients is up to 8%, compared to only 1% to 3% for CD^[17,18]. Evidence suggests that this figure varies according to the extensiveness of disease; the prevalence of PSC is approximately 5.5% in patients with pancolitis, but only 1% in those with distal colitis^[18,19]. Overall the prevalence of PSC is approximately 10% in CD and 80% in UC^[19,20]. Broomé *et al.*^[21,22] first proposed the association of PSC and CRC in UC patients in 1992 with a cumulative risk of 50% at 25 years of developing CRC in UC = PSC patients.

The suggestion that PSC is an independent risk factor for CRC in IBD patients is one that has widely debated. Currently, no explanation of how PSC increases the risk of CRC in IBD patients has been agreed upon. Numerous literature reviews, including a meta-analysis conducted in 2002^[23], have evaluated earlier research concerning this topic. This review aims to evaluate research within the last decade and examine recent evidence concerning epidemiology, pathogenic mechanisms

and management strategies of CRC development in IBD-PSC patients.

RESEARCH

A literature search was conducted using the PubMed database for relevant articles from January 2002 until January 2014. The keywords used were: primary sclerosing cholangitis, colorectal, cancer, neoplasia, carcinoma, inflammatory bowel disease, Crohn's disease and ulcerative colitis. Relevant studies investigating PSC as a risk factor for CRC in IBD in the context of incidence and prevalence, pathogenesis, prevention and management, and prognosis were included in this review. Articles not written in English, review articles and published abstracts were not included.

EVALUATION OF EVIDENCE

Since the initial proposal in 1992 by Broomé *et al.*^[21], recent research continue to support concurrent PSC as a key risk factor in the development of CRC in IBD. The studies evaluated in this section are summarised in Table 1. Many studies now recognise PSC as just an important risk factor for CRC development as previously established risk factors such as duration and extent of IBD.

Early studies of PSC patients were characterised by small cohorts, small statistical power and disparate measurable outcomes. The increasing awareness of the link between PSC and CRC has allowed larger and better designed studies to be conducted. A retrospective Dutch study in 2009 investigated 211 PSC patients. Of that cohort, 60% had concurrent IBD. The risk of CRC development was 14% at 10 years and 31% at 20 years in PSC patients with concurrent IBD, compared with a steady risk of 2.3% in patients without concurrent IBD ($P < 0.01$)^[24]. The study also found that the majority of CRCs were located in the right colon, proximal to the splenic flexure, a result that has been confirmed by numerous other studies^[25,26]. The same group went on to confirm this finding in a subsequent study, where the majority (67%) of IBD-PSC patients that developed CRC had tumours in the right-sided colon ($P < 0.01$) in contrast to patients with IBD alone. Based on this finding, a differ-

Table 2 Summary of studies investigating the efficacy of ursodeoxycholic acid a chemopreventive agent in primary sclerosing cholangitis patients with concurrent inflammatory bowel disease

| Ref. | Location | UDCA (n) | CRN incidence UDCA (n) | No UDCA (n) | CRN incidence no UDCA (n) | Study type | Is UDCA chemopreventive? |
|------|---------------|----------|------------------------|-------------|---------------------------|---------------|------------------------------|
| [36] | United States | 29 | 3 | 23 | 8 | RCT | Yes |
| [37] | United States | 28 | 3 | 92 | 13 | Retrospective | No |
| [38] | Sweden | 37 | 13 | 40 | 15 | RCT | No |
| [39] | United States | 25 | 9 | 31 | 3 | RCT | No-high dose UDCA |
| [40] | Germany | 120 | 7 | N/A | N/A | Prospective | No-short term; yes-long term |

CRN: Colorectal neoplasm (dysplasia and cancer); RCT: Randomised controlled trial; N/A: Not applicable; UDCA: Ursodeoxycholic acid; PSC: Primary sclerosing cholangitis; IBD: Inflammatory bowel disease.

ence in pathogenesis of CRC may occur in patients with PSC and concurrent IBD, compared to patients with IBD alone^[27].

Other studies have also evaluated the cumulative risk of CRC development in the long-term. Fevery *et al*^[9] studied 200 PSC patients in a long-term, single-centre study in Belgium, where 60% of the cohort had concomitant IBD. The cumulative incidence for the diagnosis of CRC after IBD diagnosis was found to be 2% in 5 years, 7% in 10 years and 15% in 20 years. Additionally, the median age of CRC diagnosis was 49.5 years, leading the authors to conclude malignancy to be the major cause of early mortality in patients with PSC.

Terg *et al*^[28] prospectively recruited a Latin American PSC cohort from 1333 patients with UC. The prevalence of PSC was 2.9% and the cumulative risk of CRC after 10 and 20 years in these patients was 11% and 18% respectively, compared to 2% and 7% in UC without PSC ($P < 0.01$). Hence, it was confirmed that patients with UC and PSC indeed have a higher risk of CRC. An Asia-Pacific Consensus Group consisting of representatives from a host of countries, including India, China, Philippines and Australia published a paper in 2010 outlining various findings in UC patients in these countries. There was consensus on the statement that PSC associated with UC is less prevalent in the Asia-Pacific region compared to Western nations, though the level of evidence on this finding was classified as fairly weak. There was also some consensus on the statement that PSC in the setting of UC significantly increased the risk of development of CRC^[29].

Some studies have not confirmed PSC as an independent risk factor of CRC in IBD. A 2006 case-control study investigating predictive and protective risk factors associated with CRC in UC patients did not find PSC to be significant^[30]. A Swedish population-based cohort of 199 PSC patients revealed that while the disease was associated with a four-fold increase in mortality compared with the general population (SMR = 4.20, 95%CI: 3.01-5.69), the researchers unexpectedly could not confirm that PSC or PSC with concurrent IBD was associated with a higher incidence of CRC and colorectal dysplasia compared with the general population^[12]. This cohort of patients was diagnosed from 1992 to 2005, which is relatively recent compared with other large-scale studies of PSC patients with cases recruited from

the 1980s^[24]. This led the researchers to postulate that the lowered incidence of CRC in this cohort was a result of better management of IBD in recent years^[12].

Studies have also disease subtypes in the prediction of CRC. A prospective study of 171 PSC patients being treated with ursodeoxycholic acid (UDCA) found that IBD coexisting with dominant ISC bile duct stenosis had an increased CRC incidence, whereas IBD without dominant stenosis had no effect on the incidence of carcinoma ($P < 0.05$). The authors did not speculate whether this observation was a result of the interaction between dominant stenosis and IBD, or whether it was to do with UDCA treatment^[31].

While the risk of CRC is established for UC-PSC patients, studies have also evaluated their association with CD. The overall risk of CRC development in CD-PSC is not as strong as UC-PSC. Lindström *et al*^[32] studied the development of CRC in 28 patients with both PSC and CD, compared to controls with CD only. They found PSC to be a risk factor for development of CRC and dysplasia in CD (OR = 6.78, 95%CI: 1.65-27.9), but the study was limited by its small cohort and retrospective design. Another retrospective review of 166 PSC-IBD patients did not find an increased risk of CRC or dysplasia in CD^[33].

PREVENTION OF CRC

The cause of the increased risk of CRC in PSC is largely unknown. Studies have evaluated whether the risk of CRC can be reduced. Strategies such as colonoscopic surveillance, UDCA and liver transplantation have been investigated as potential methods of preventing the development of CRC.

UDCA

The chemopreventative effects of UDCA against CRC in IBD-PSC patients remain controversial. UDCA is a synthetic, hydrophilic bile acid that purportedly prevents the carcinogenic effects of secondary bile acids in the colon^[34,35]. A summary of recent data concerning the efficacy of UDCA is presented in Table 2.

A randomised, placebo-controlled trial evaluated the effect of UDCA on CRC and colorectal dysplasia in patients with concurrent UC and PSC^[36]. Colorectal neoplasia developed in 10% of the patients assigned to the

UDCA group compared to 35% of the patients assigned to the placebo group (RR = 0.26, 95%CI: 0.06-0.92). Wolf *et al.*^[37], however, reported that the incidence of CRC and colorectal dysplasia was not significantly different between patients treated with UDCA and patients that were not, but the UDCA patients did report a lower mortality rate ($P < 0.05$).

A long-term, randomised placebo-controlled trial of IBD-PSC patients prescribed UDCA *vs* placebo followed-up patients for more than 10 years yielded no difference in the CRC rate between the UDCA (13%) and placebo (16%) groups. There also was no significant difference in cancer-free survival between the two groups^[38]. Another long-term, randomised placebo-controlled trial assessed the effects of high dose UDCA (28 to 30 mg/kg per day) on the development of colorectal dysplasia and CRC in UC-PSC patients. The study found that UDCA had an adverse effect on neoplasia development where high dose UDCA significantly increased development of colorectal dysplasia and CRC compared to control (HR = 4.44, 95%CI: 1.30-20.1)^[39].

Some studies have attempted to reconcile these conflicting findings. In a prospective cohort study conducted by Rudolph *et al.*^[40], the trend of colorectal carcinoma development in patients treated with UDCA was observed to increase up to 6 years after the start of treatment, plateaued between 6 to 9 years, and after treatment for more than 9 years (up to at least 12 years) no further colorectal carcinomas developed. This finding, together with others, suggests that the effects of UDCA in UC-PSC patients may not be straightforwardly beneficial or non-beneficial, and that longer term, placebo-controlled trials are needed to provide evidence for or against UDCA as a chemopreventative agent. Lower doses of UDCA have been used to avoid possible adverse events.

A recent meta-analysis reporting 177 cases of CRC in 763 patients with PSC-IBD failed to demonstrate significant protective association between UDCA use and CRC with OR = 0.81, 95%CI: 0.41-1.61. However, a significant chemopreventive effect was found on the risk of advanced neoplasia defined as CRC and/ or high-grade dysplasia (OR = 0.35, 95%CI: 0.17-0.73). Low-dose UDCA (8-15 mg/kg per day) did significantly reduce CRC (OR = 0.19, 95%CI: 0.08-0.49)^[41]. Another meta-analysis of a similar dataset showed similar results^[42].

Liver transplantation

Currently, liver transplantation remains the only effective treatment of PSC with end-stage liver disease. It follows that liver transplantation in PSC may offer prevention against CRC development by improving PSC status, however, the evidence is largely contrary.

A study from the United Kingdom identified 152 patients with PSC following liver transplantation. Of these patients, 5.3% developed CRC, of which all of them had concurrent IBD with an intact colon. The cumulative risk of CRC development in IBD-PSC patients was calculated to be 14% at 5 years and 17% at

10 years. The risk of developing CRC in PSC patients without IBD was 0% at 10 years^[43]. Another study from the Cleveland Clinic found that coexistent IBD and PSC had a colorectal neoplasia incidence rate of 34% following liver transplantation, very similar to the incidence in matched IBD-PSC controls without liver transplantation (30%). However, the rate of colorectal neoplasia in IBD-PSC patients following liver transplantation was higher than if liver transplantation was performed for non-PSC indications (34% and 0%, respectively; $P < 0.05$)^[44].

In a large-scale study, Dvorchik *et al.*^[45] identified 192 patients with both PSC and IBD, and found no increase in the risk of CRC in these patients ($P < 0.001$). van de Vrie *et al.*^[46] conducted a retrospective study of patients having had liver transplantation for PSC, and concluded that transplantation was not adversely affected by IBD, nor was the course of IBD different after liver transplantation. High incidence rates of CRC remain following liver transplantation for PSC according to a recently published meta-analysis. The incidence rates of CRC were 5.8 per 1000 person-years but increased to 13.5 per 1000 person-years in those with an intact colon at the time of transplantation. A long duration of IBD and extensive colitis were confirmed as risk factors for CRC but specific transplant-related factors that may increase CRC risk were not identified^[47]. Overall, the evidence suggests that liver transplantation does not offer protection against CRC in PSC patients with concomitant IBD, and that post-liver transplantation patients are just as likely to develop CRC as non-transplanted patients. However, there is a lack of evidence to suggest that liver transplantation is an added risk factor for CRC development in IBD-PSC patients.

Surveillance

With increasing evidence conferring the increased risk of CRC in IBD-PSC patients, the importance of colonoscopic surveillance after the diagnosis of PSC in IBD patients has been stressed. The general consensus is that routine surveillance colonoscopy and random biopsies should be performed one to two years post PSC diagnosis in IBD patients^[48-51].

Despite these recommended guidelines, research show that scheduled colonoscopy is rarely performed in UC-PSC patients. A Canadian study followed up IBD-PSC patients for five years, and found that only 36% of the expected annual surveillance colonoscopies were conducted. 33% of patients did not undergo a single colonoscopy, and 11% of patients developed colorectal dysplasia or CRC during the follow-up period^[52]. Another study of 771 patients with an ≥ 8 years history of UC found the prevalence of annual surveillance amongst UC-PSC patients to be 38.5%, higher than that of the total study population (24.6%)^[53]. A recent study from the Mayo Clinic showed that the rate of colorectal neoplasm (dysplasia and carcinoma) discovery within two years of diagnosis of coexisting IBD and PSC (21.5 per 100 patients) was similar to rate of discovery within eight to ten years (20.4

per 100 patients)^[54]. This finding supports current guidelines for annual colonoscopic surveillance for IBD-PSC patients, starting from when concurrent PSC and IBD are diagnosed.

Rationale is lacking for the benefit of annual surveillance in IBD-PSC patients in the form of grade A supporting evidence, and current guidelines have been mainly based on expert opinion and retrospective studies. Little research has been done in the form of controlled trials to compare the rate of CRC diagnosis and prognosis between patients that undergo routine colonoscopy and those that do not. Data are unavailable that surveillance offers any prevention against CRC development or reduction in CRC mortality.

MECHANISMS OF PATHOGENESIS

Currently, the pathogenic mechanisms for the increased risk of CRC in UC-PSC patients remain unknown. One hypothesis suggests bile acids as the key culprit. PSC and other cholestatic conditions typically exhibit impaired hepatic excretion of bile acids, which may result in colonic build-up of secondary bile acids^[55]. Bile acids have long been suspected as a carcinogen in human gastrointestinal cancers. Studies in animal models have shown secondary bile acids to cause DNA damage and promote cell mutation^[56]. The observed increase in prevalence of CRC in the right proximal colon, where secondary bile acid concentrations are the highest suggests the role of bile acid in carcinogenesis^[25-27]. The strongest evidence for this hypothesis comes from the beneficial role of UDCA. Ursodeoxycholic acid modifies the bile acid pool to reduce levels of the secondary bile acid deoxycholic acid, thereby purportedly reducing the carcinogenic potential of bile acid^[57]. However, the preventative role of UDCA remains controversial, and similarly the role of bile acids in the development of CRC is also still up for debate.

Long-standing inflammation is a recognised risk factor in CRC development in IBD patients^[4]. Studies have shown that coexisting IBD in PSC patients often exhibit milder clinical courses. Patients often require less use of steroids, immunomodulators and surgery, and have reduced disease activity or even asymptomatic disease^[22,58]. Primary sclerosing cholangitis may be associated with a milder subclinical IBD for many years before diagnosis^[4,19] and hence have had longer disease duration than apparent, increasing their risk of CRC development and requiring surveillance to commence immediately upon diagnosis of PSC^[4].

CONCLUSION

Recent evidence increasingly points to PSC as a significant risk factor in the development of CRC in patients with concomitant IBD. Data suggest that the risk of CRC development can reach up to 30% at 20 years after diagnosis of concurrent IBD and PSC. PSC may be an important risk factor for CRC in different populations

worldwide. The mechanism for this increase in risk is still unclear. Various methods to prevent CRC development have been extensively investigated. The efficacy of UDCA remains controversial, and more longer term randomised placebo-controlled trials are needed. Liver transplantation does not halt the development of CRC, although there is not enough evidence to suggest that it is associated with increased incidence of CRC. Patients with concurrent PSC and IBD should be educated about the risk of CRC, and while routine colonoscopic surveillance should be performed, more high-level evidence is required to support the benefits of the procedure.

While many new developments have taken place in the last decade, the pathogenesis and optimal management of CRC development in IBD-PSC patients remain unclear. Further research in these directions will lead to better insight into the relationship between IBD, PSC and CRC.

Abstract

Inflammatory bowel disease affects a substantial number of women in their reproductive years. Pregnancy presents a number of challenges for clinicians and patients; the health of the baby needs to be balanced with the need to maintain remission in the mother. Historically, treatments for Crohn's disease (CD) were often discontinued during the pregnancy, or nursing period, due to concerns about teratogenicity. Fortunately, observational data has reported the relative safety of many agents used to treat CD, including 5-aminosalicylic acid, thiopurines, and tumor necrosis factor. Data on the long-term development outcomes of children exposed to these therapies *in utero* are still limited. It is most important that physicians educate the patient regarding the optimal time to conceive, discuss the possible risks, and together decide on the best management strategy.

Key words: Pregnancy; Drugs; Inflammatory bowel disease; Crohn's disease; Breastfeeding

Core tip: Patients should be encouraged to postpone conception until their Crohn's disease (CD) is in remission. Monitoring of nutritional status remains important in patients with small bowel CD; folic acid, vitamin D and vitamin B12 may all need to be supplemented. Most drug treatments are safe in pregnancy, based on observational data, including 5-aminosalicylic acid, thiopurines, anti-tumor necrosis factor, and anti-integrins. Methotrexate should be avoided due to its teratogenicity. Cesarean section is only indicated from a CD perspective in women with active perianal disease at the time of delivery; all others can have a normal vaginal delivery.

INTRODUCTION

In recent years, great advances have been made in the management of inflammatory bowel diseases (IBD)^[1]. Nevertheless, many questions arise for physicians and patients when women with IBD consider pregnancy. In this situation, an understanding of the nutritional, pharmacological and diagnostic considerations is important for treating physicians to minimize harm to the fetus, while ensuring the mother's disease remains in remission^[2,3].

FERTILITY IN CROHN'S DISEASE

Fertility issues, risk of the disease in off-spring, and the impact of both the disease and medication on mother

Table 1 Food and Drug Administration drug administration categories for the use of medications in pregnancy

| Category | Observations |
|----------|---|
| A | Controlled studies both in humans and in animals have shown that there is no risk during the first trimester and the possibility of fetal harm is remote |
| B | Studies in animals have shown no risk to the fetus. However, no controlled studies have been carried out in pregnant women. In addition, studies in animals have revealed adverse effects which were not confirmed in pregnant women in the first trimester |
| C | There is no record of controlled studies in humans. Studies in animals have shown adverse effects. Moreover, studies in humans and animals showing that the benefit may outweigh the risk have not been validated |
| D | Evidence of risk for the fetus |
| X | Studies in animals and humans have shown fetal abnormalities, so these drugs are contraindicated |

and child can all create fear in many patients wanting to have a child^[2]. Some factors may influence the fertility rate in patients with Crohn's disease (CD); these include active disease and/or malnutrition, and drug-induced oligospermia in male partners^[4]. Active CD in the colon or the terminal ileum or even surgery such as proctocolectomy with ileoanal anastomosis (colitis) have been associated with lower fertility rates^[4-6]. The psychological burden of disease may also play a role; in perianal CD, low fertility has been attributed to dyspareunia, decreased libido and depression in some women^[7].

Sulfasalazine is associated with infertility in men; in 80% of cases sperm motility is reduced and morphology is changed. Such effects are not reversible with the administration of folic acid, but they may reverse two months after the end of the sulfasalazine treatment^[8,9]. In contrast to these data, megalazine, which is also a 5-ASA, and immunosuppressants such as azathioprine, do not appear to affect spermiogenesis in patients^[10].

EFFECTS OF INFLAMMATORY DISEASE ON PREGNANCY AND PREGNANCY EFFECTS ON INFLAMMATORY DISEASE

Even though most pregnant women with IBD may be classified as having high-risk pregnancies, the course of the disease in this group usually does not present major complications. The rate of premature births in this specific group is frequently double that in women without inflammatory disease^[3]. The risk of congenital malformation in the general population ranges from 1% to 4.8% and there is no current evidence of an increased risk for CD patients^[11]. Conversely, miscarriage is more frequent in women with IBD (above 35%), especially in those with active disease. The natural risk of fetal loss after 16 wk is approximately 1%, which is similar to the risk of healthy women^[12]. Some studies have shown that women with active CD are more likely to bear children with low birth weight (less than 2500 g)^[13].

The influence of pregnancy on the course of the disease is closely related to the disease status at the time of delivery *i.e.*, active or inactive. This status will determine the behavior of the disease itself, the clinical course, and the response to drug therapy^[7]. Some studies show that 70% of women with active disease have worsening or persisting symptoms during pregnancy, whereas the

risk of relapse in women who do not have active disease at conception is similar to women who are not pregnant^[14-25]. A recent meta-analysis of these studies concluded that the risk of active disease during pregnancy is higher in women who conceive when their disease is active^[26].

THERAPEUTIC DRUGS AND THEIR SAFETY DURING PREGNANCY AND BREASTFEEDING

Studies conducted in the last decades with women who underwent treatment during their pregnancy provides reassuring data for the specialist as well as for the patient both during the pregnancy and while breastfeeding. The Food and Drug Administration (FDA) classification for drugs according to their known or potential teratogenicity is reviewed in Table 1. Table 2 shows the safety of medications commonly prescribed for IBD during pregnancy.

Sulfasalazine and 5-aminosalicylic acid (category B)

5-aminosalicylic acid (5-ASA) is considered safe up to doses of 3 mg/d. Above this dose, the risk is considered uncertain^[8-10]. Studies show that sulfasalazine and 5-ASA in doses below 3 g/d do not increase the risk of congenital malformation, premature birth and miscarriage in patients with CD or ulcerative colitis (UC). A post-marketing study showed that of 55 pregnant women who used megalazine in doses of 1.6 to 4 g/d, three had fetal malformations, however, these data were not different from those found in the general population, which suggests that there is no greater risk of malformations with megalazine use^[9].

Azathioprine and 6-mercaptopurine (category D)

Thiopurines (azathioprine and mercaptopurine) both cross the placental barrier and can be identified in the umbilical cord blood, however, serum level in the baby is not significant. Animal studies showed the occurrence of cleft palate and skeletal and urogenital abnormalities in rats, and historical retrospective studies associated thiopurines with teratogenic effects in 5% of cases and the risk of preterm birth in 3%, in addition to the effects of low fetal weight and myelotoxicity^[4].

More recent observational studies did not observe a

Table 2 Safety of medications prescribed for inflammatory bowel disease during pregnancy

| Safe to use when indicated | Limited data but used when clinically indicated | Contraindicated |
|----------------------------|---|-----------------|
| Mesalamine | Olsalazine | Methotrexate |
| Sulfasalazine | AZA/6 MP | Thalidomide |
| Balsalazide | Ciprofloxacin | |
| Corticosteroids | Metronidazole | |
| TPN | Biologics | |
| Loperamide | Cyclosporine | |

TPN: Total parenteral nutrition; AZA: Azathioprine MP: Mercaptopurine.

higher risk of these events in women with IBD. A recent prospective study of 30 children, performed by de Meij *et al.*^[15], evaluated the effect of azathioprine on the uterus in relation to quality of life, psychosocial development and an increased risk of infection, and showed that this drug did not directly influence these factors when compared to children who had not undergone this therapy. The American Academy of Pediatrics recommends that breastfeeding mothers should not take immunosuppressants, as these drugs induce immunosuppression in children^[16,22]. Most studies report that the most common adverse effect in pregnant women is related to low weight and miscarriage^[4].

Antibiotics

Metronidazole and ciprofloxacin are often administered in the treatment of patients with IBD, especially perianal CD. Metronidazole is classified as Category B, and short-term use (7-10 d) is considered safe in pregnancy. In contrast, extended use in the third month of pregnancy has been associated with fetal cleft palate and cleft lip, and therefore prolonged use during pregnancy is contraindicated^[4]. Ciprofloxacin is Category C, as quinolones act on the cartilage and in humans they can cause arthropathy and skeletal abnormalities of the fetus^[27]. For this reason, they are not recommended for children under 18 or for pregnant or breastfeeding women.

Corticosteroids (category C)

Corticosteroids (prednisolone) cross the placental barrier, however, they represent a very small risk when used in the first trimester of pregnancy. Studies carried out in animals have shown that these drugs may increase the risk of cleft palate and cleft lip when administered in the first trimester^[25]. Glucocorticoids should be administered with care and both blood pressure and blood glucose should be monitored due to their ability to induce gestational hypertension, diabetes, membrane rupture and preterm delivery.

Cyclosporine/tacrolimus (category C)

Cyclosporine and tacrolimus are both calcineurin inhibitors occasionally used in the management of CD. Both are category C, and can be employed in the treatment of fulminant colitis; their teratogenic action has not yet

been proven. Doses above 25 mg/kg per day can induce renal damage in the fetus in animals and their use in humans requires serum monitoring of renal function and blood pressure because both drugs cross the human placenta, however, there are conflicting reports on this point^[26].

Thalidomide (category X)

Thalidomide is rated as category X (FDA) for pregnant women due to its potential teratogenic effects. It is contraindicated in this population.

Methotrexate (category X)

This drug has also been classified as category X. It is clearly teratogenic and should not be considered for use in pregnant women and in women who want to conceive. Patients who are taking this medication should be instructed to delay conception for three to six months after its cessation. It can cause growth retardation and even mental retardation, among other effects.

Infliximab (category B)

Infliximab is a chimeric used in the treatment of CD and UC. It is known to cross the placental barrier after the second trimester, similar to all IgGs. Maternal and embryonic toxicity and increased teratogenicity have not been observed. Infliximab can be detected in high concentrations in the newborn up to 6 mo after delivery, but the clinical significance of this finding is unknown^[19]. Caution with any type of live vaccine in this group of infants during the first 6 mo is necessary, particularly if the infant received anti-tumor necrosis factors (TNFs) during gestation. There were no lethal cases of TB in three-month-old children who received BCG^[19].

Adalimumab (category B)

Considered by the FDA to be a category B drug, adalimumab has been approved for CD in induction, remission and maintenance phases. It exhibits similar behavior to infliximab, also crossing the placental barrier in the third month of pregnancy. There are few data on its use by pregnant women, and related birth defects have been reported, however, further studies are needed. Waage *et al.*^[20] conducted a review study of 126 women who had been subjected to treatment with adalimumab and no increased risk of congenital malformation was observed. Recent studies have indicated dose adjustments during pregnancy to reduce maternal exposure. It has been specifically recommended that the last dose should be given between 34 and 36 wk of gestation^[16].

Certolizumab pegol (category B)

Certolizumab is a Fab fragment of a monoclonal antibody linked to a polyethylene glycol chain. It is used during CD in remission and maintenance and it is known to cross the placental barrier throughout the pregnancy at a low level. In a recent study (PIANO), no increased risks in pregnant women administered certolizumab were ob-

Table 3 Classification of the drugs concerning the fetal risk according to Food and Drug Administration

| Drugs | Recommendation |
|-------------------------------|--|
| Adalimumab | Pregnancy (low risk) |
| Category B | Breastfeeding (probably compatible) |
| Azathioprine/6-mercaptopurina | Pregnancy (low risk) when used in low doses and as mono-therapy |
| Category D | Breastfeeding (it is recommended to breastfeed 4 h after taking the drug) |
| Balsalazide | Pregnancy (low risk) |
| Category B | Breastfeeding (probably compatible) |
| Certolizumab | Pregnancy (low risk) |
| Category B | Breastfeeding (probably compatible) |
| Ciprofloxacin | Pregnancy (not recommended due to skeletal muscular dysfunction) |
| Category C | Breastfeeding (compatible) |
| Corticosteroids | Pregnancy (risk of adrenal insufficiency, premature rupture of membrane, in the first trimester although there is little risk of cleft palate) |
| Category C | Breastfeeding (probably compatible) |
| Cyclosporine | Pregnancy (no congenital abnormalities have been noticed) |
| Category C | Breastfeeding (contraindicated) |
| Infliximab | Gestation (low risk when administered as mono-therapy) (increased risk of infection when used in combination with azathioprine) |
| Category B | Breastfeeding (probably compatible) |
| Mezalazine | Pregnancy (asacol showed low risk of teratogenicity in animal models) |
| Category B | Breastfeeding (both probably compatible) |
| Asacol (category C) | |
| Methotrexate | Contraindicated in both conditions |
| Category X | |
| Metronidazole | Pregnancy (used in the first trimester increases the risk of cleft palate) |
| Category B | Breastfeeding (toxic) |
| Olsalazine category (C) | Pregnancy (limited risk) |
| | Breastfeeding (probably compatible) |
| Rifaximin | Pregnancy (animal studies show teratogenicity) |
| Category C | Lactation (its safety is unknown) |
| Sulfasalazine | Pregnancy (low risk if administered in conjunction with folic acid) |
| Category B | Breastfeeding (probably compatible) |
| Tacrolimus | Pregnancy (no increased risk described) |
| Category C | Breastfeeding (contraindicated) |
| Thalidomide | Contraindicated in both conditions |
| Category X | |

served^[21]. In addition, when breast milk was analyzed, it was noted that from 3 to 6 d post-birth, serum levels of the drug were not detected. Thus, it seems that this drug is safe in this phase^[21].

Golimumab

Golimumab is a completely human monoclonal antibody which aims to block anti-TNF. It is administered subcutaneously and was approved in May, 2013 by the FDA for the treatment of severe ulcerative colitis. To date, there are no reports on the use of this drug in pregnant women^[24].

Natalizumab (category C)

Natalizumab was recently approved for induction and maintenance treatment of CD in patients who do not respond to therapy with anti-TNF- α . Individual studies are necessary to prove that its use can be recommended for pregnant women. In a recent study with natalizumab, no increase in abnormalities were noted in pregnant women who had received the drug. A similar result was found in the PIANO study^[22]. However, most studies did not consider the drug to be safe enough to be used

during pregnancy; thus, it is contraindicated^[23].

DRUGS AND THEIR SAFETY DURING PREGNANCY AND BREASTFEEDING

It is important to bear in mind which drugs can be used during pregnancy and lactation. These drugs are shown in Table 3. In general, 5-ASA derivatives are considered safe (EL 3b, RGB) as well as corticosteroids (L4, RGC). A low concentration of these steroids has been noted in breast milk. To minimize the effects of these drugs it has been suggested that mothers can breastfeed 4 h after their ingestion. The thiopurines are excreted in small amounts in milk, and are also considered safe. However, more studies are needed to fully confirm the safety of these drugs (EL 4, RGC). All anti-TNFs are also excreted in small amounts in the milk and there are few studies regarding the effects on children who are or were breastfed and consequently received these medications (EL5, RGC). Metronidazole and ciprofloxacin are also excreted in breast milk and are not considered appropriate during breastfeeding as their safety is unknown and these agents should, if possible, be avoided. Studies on tacrolimus

are limited and its safety is unconfirmed. Drugs such as thalidomide, methotrexate and cyclosporine are contraindicated as they have been found in breast milk and are consequently considered unsafe.

ENDOSCOPIC METHODS DURING PREGNANCY

Endoscopy, colonoscopy, retosigmoidoscopy and cholangiography are considered safe during pregnancy according to ECCO Statement 7G (EL4, RGC). However, caution is required in relation to these procedures and there must be a strong indication for these procedures to be carried out in the second trimester (EL5, RGD). Techniques for hemostasis are safe, but should be performed with caution (EL3, RGC).

RISK OF THROMBOEMBOLISM IN HOSPITALIZED PREGNANT WOMEN

Many studies have considered the increased risk of venous thromboembolism in pregnant women. This increased risk was noted in the first six weeks of the post-natal period, and is even higher in pregnant women with inflammatory bowel disease. The use of low-molecular-weight heparin is considered important to prevent this event and should be considered especially in women who have been or will be hospitalized (EL3 RGB).

CONCLUSION

Due to the current knowledge on inflammatory bowel disease, it is thought that the majority of drugs administered during pregnancy are safe for both the mother and the fetus. However, guidance in this group of patients (mothers-to-be) and control of disease activity before conception are essential for the prevention of miscarriage or premature birth. Most drugs are also safe for breastfeeding.

Abstract

Studies across medical disciplines have shown gaps in the care recommended in evidence based guidelines and the care actually delivered. Quality improvement projects using systematic audit and feedback interventions such as quality measures, will become increasingly important tools to address these gaps in care. These gaps are also apparent in the care of patients with inflammatory bowel disease. Multiple organizations, including the American Gastroenterology Association and the Crohn's and Colitis Foundation of America, have developed programs designed to implement quality measures to improve the care of inflammatory bowel disease (IBD) patients. Early results show promise of improving quality, but numerous barriers remain. Gastroenterologists need to be aware of these processes to provide the highest care possible to patients with IBD. We review the existing literature on approaches to quality improvement and their potential application and barriers when applied to IBD care.

QUALITY OF CARE AND USE OF QUALITY MEASURES

Quality in medical care has been defined by the Institute of Medicine as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge"^[1]. Another description of quality care has also been called the triple aim, which is summarized as improving the experience of care, improving the health of populations and reducing per capita costs of healthcare^[2]. The current healthcare system is undergoing a shift from a fee for service model to a performance based model. This change will occur over the next few years and will likely change how we practice medicine. Integral to this shift from a fee for service to a performance based system is the concept of quality. To this end, different systems have been developed to improve quality and quantify that improvement.

Clinical practice guidelines are one of the current methods of improving the quality of care. They are developed through review of the literature and evidence based consensus, yet many of these recommendations have not translated into clinical practice. Despite development and distribution of numerous guidelines, gaps persist between recommended care and provided care. McGlynn *et al*^[3] evaluated a broad sampling of the United States population by randomly sampling patients, as part of the Community Tracking Study. Patients were sampled by telephone for any healthcare encounters in the preceding 2 years and then the investigators reviewed their medical charts for performance of specific quality measures. They found that 54.9% of quality measures were being met and little difference existed between provision of acute care, preventative care or chronic disease care. Similarly, gaps have been observed in specialty care. Calvin *et al*^[4] reviewed the compliance of physicians with prescription of beta blockers and angiotensin-converting-enzyme inhibitors or angiotensin receptor blocker's according to evidence based guidelines to patients with congestive heart failure. They found that only 63% of physicians were compliant with these guidelines and interestingly 37% of patients were noncompliant with evidence based prescription medication. These results highlight the obstacles to delivery of quality care, which requires the participation of the physician and the patient. Kanwal *et al*^[5] examined the adherence, to quality measures for ascites and cirrhosis among practitioners in the VA healthcare system. Though variation existed for individual quality measures, they found only 33.2% of patients received all recommended care. Absence of comorbid conditions, treatment by a gastroenterologist and care received at an academically affiliated hospital were correlated with higher rate of adherence to quality measures. These studies showed the limitation of passive guideline distribution to effect patient care and that more targeted interventions are needed to improve the quality of patient care.

METHODS TO IMPROVE QUALITY OF CARE

Audit and feedback systems are among the most effective interventions for quality improvement. In audit and feedback interventions, a provider's performance is measured and the results of their performance are shown to the provider with the intention of highlighting areas of deficiency and encouraging a change in practice. A systematic review of audit and feedback studies showed modest gains when feedback was provided in a timely manner and in written format^[6]. Audit and feedback is one of the underlying principles behind quality and performance measures. Quality measures are sets of quantifiable processes and outcomes defined by evidence based medicine and expert consensus to reflect high quality care for a specific disease. In contrast to clinical practice guidelines, which provide only passive dissemination of recommendations, quality and practice measures incorporate audit

and feedback to the provider, which may include external or financial incentives for adherence. However, audit and feedback interventions are limited by the type of data readily available for auditing. Current quality measures are therefore limited to processes or outcomes with available administrative or billing data, which may fail to capture the breadth of quality of care provided. Audit using manual chart review are more comprehensive, however are too time consuming to be used in routine practice. Use of standardized templates embedded in electronic medical records or use of information retrieval techniques from plain text medical records, such as natural language processing, are being developed. These approaches may expand the ability to quantify processes and outcomes beyond administrative data.

To have meaningful and long-term impact in clinical outcomes, quality measures need to be systematically integrated in clinical care, involving multidisciplinary teams and open access to share best practices. One approach to implement quality measures is the Donabedian model of structure, process, and outcome improve quality of care^[7]. Structure involves identifying the practice or system level factors that may influence how care is delivered. These include organizational structure (multi-disciplinary models), support staff numbers and qualifications and certifications for excellence in disease care^[8]. A process is defined as the actions required to move through the defined health care structure, including how patients interact with clinic staff and how diagnostic tests are performed. Outcomes are the effects of the health care delivered and may be either process measures (*i.e.*, if a vaccination was administered), or outcome measure (*i.e.*, colon cancer). Consideration of all of these components will identify not only what needs to be measured, as in quality measures, but what the components of a high quality care organization will require and how patients interact with that organization.

Systematic integration of quality measures has been used effectively in other disciplines of medicine to improve patient care. The Cystic Fibrosis Foundation's Quality Care Initiative provides an example of a successful intervention using quality measures in a chronic disease with a meaningful improvement in clinical outcomes. The initiative began as a collection of over 100 centers that provide cystic fibrosis (CF) care. After developing quality measures, which included weight, forced vital capacity and mortality they implemented a transparent system of audit and feedback. Outcomes were shared across all participating centers through regular meetings to review these outcomes and processes that result in improved outcomes. Since it was created, they have managed to improve the median age of death among CF patients from 27 years to 37 years^[9]. In cardiology, the Northern New England Cardiovascular Disease Study Group, which is a collaboration of multiple sites, has worked to improve several cardiovascular disease outcomes. Over a 2 year period, they achieved a 24% reduction of in-hospital mortality related to coronary artery bypass grafting^[9]. Taking these

examples, we can see how influencing particular processes in a collaborative and continuous way is able to affect meaningful clinical outcomes.

QUALITY OF CARE IN INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is very similar to the previously mentioned diseases of coronary artery disease, CHF, cirrhosis and CF, in that it is a chronic medical condition with a growing impact on the healthcare system. Kappelman *et al*^[10] examined the annual cost of IBD by review of administrative claims data. Their results showed Crohn's disease and ulcerative colitis (UC) mean annual costs were \$8265 and \$5066, respectively. When examined based on costs incurred inpatient, outpatient or medications related, costs were relatively equally distributed.

Despite numerous guideline publications addressing IBD care, gaps remain in the care provided and recommended. Reddy *et al*^[11] examined this gap in IBD patient care by reviewing the medical charts of patients referred to their tertiary referral center. They found that patients with active disease were receiving suboptimal dosing of current medications (64% for mesalamine) or were given medications, such as steroids, for prolonged periods of time without attempting steroid sparing agents (77%). Wagnon *et al*^[12] also showed, through a mailed survey study, that the screening and treatment for osteoporosis was highly variable between high (52%) and low volume centers (16%). In a retrospective study of adherence to colorectal cancer screening in ulcerative colitis patients, Velayos *et al*^[13] found that only approximately 25% of patients received adequate screening. These observations show that gaps in IBD care exist and implementation of quality improvement in IBD projects could have a meaningful impact.

QUALITY OF CARE INTERVENTIONS IN IBD

One of the first attempts to adopt quality improvement projects in IBD started in the United Kingdom after an audit in 2006 showed variation in the quality of care delivered to IBD patients. This group developed a set of quality measures addressing both structural measures and process measures centered on delivery of better patient care^[9]. The Improve Care Now (ICN) consortium in the United States is a collaboration between pediatric gastroenterology centers to develop quality measures regarding IBD. Prospective data is aggregated in a central database and used to generate weekly audit and feedback reports for the participating centers. These reports are reviewed by the sites and modifications are made to processes to improve outcomes. Involvement in this program has resulted in an increase in remission rates from 55% to 75% over the past few years^[9].

In Sweden, Rejler *et al*^[14] developed a quality improvement framework, consisting of demographic data, disease

characteristics, prior surgeries and medications, quality of life and measures to assess time from referral to scheduled appointment with a specialist, to a local community to measure its ability to record pertinent patient data. They found a lower prevalence of anemia than expected, a lower prevalence of surgeries than expected and overall good access to care. Parker *et al*^[15] measured the effect of a simple vaccination questionnaire prior to a clinic visit on the quality metric of vaccination compliance. They found significant improvement in the compliance with influenza vaccine before (54%) and after implementation of the questionnaire (81%).

In adult gastroenterology practice, the American Gastroenterology Association (AGA), in association with the American College of Gastroenterology and Crohn's and Colitis Foundation of America, has worked to develop a set of quality measures for IBD. The IBD measures (Tables 1 and 2) have been developed through collaboration of the AGA and the Crohn's and Colitis Foundation of America (CCFA) through two separate panels. The IBD performance measures are now part of the Centers for Medicare and Medicaid Services pay for performance program, Physician Quality Report Service (PQRS)^[16]. As physicians submit data to this system, they are currently eligible for reimbursement incentives and beginning in 2015 penalties will be applied to reimbursement if not meeting particular standards^[9]. This vividly shows the shift towards performance based care, which will shape the near future of our healthcare system. The CCFA has developed a separate IBD quality measure set using RAND/DELPHI panel consensus and reflect expert consensus of the available literature for the specific purpose of quality improvement rather than financial incentives^[17].

The PQRS IBD measure set has also been adopted by the Bridges to Excellence (BTE) program, which is being implemented through the Digestive Health Recognition Program by the AGA. BTE works by providers selecting 25 consecutive patients seen within a 12-mo period who have an IBD diagnosis. From each chart, specific metrics must be extracted, entered through a web portal and submitted to a third party for adjudication. Each metric is weighted and if a provider achieves a threshold number of points, they will be awarded BTE recognition for 2 years^[9]. Many third party payers are reviewing this system and considering incorporating this into incentives for reimbursement.

FUTURE DIRECTIONS AND POTENTIAL BARRIERS

While the quality measures for adults with IBD are a first step towards improving care, systemic and multidisciplinary approaches will be needed to affect meaningful and durable practice change. The CCFA, in collaboration with leaders from the ICN, have started a feasibility study to develop such a project. This pilot will be performed in both academic and community practices and is designed to study the best ways to implement IBD quality measures

Table 1 American gastroenterology association inflammatory bowel disease performance measures^[16]

| Performance measures | |
|----------------------|--|
| IBD characteristics | |
| | Type |
| | Anatomic location |
| | Activity |
| Preventive care | |
| | Corticosteroid sparing therapy |
| | Bone loss assessment |
| | Influenza immunization |
| | Pneumococcal immunization |
| | Smoking screening and cessation assessment |
| Testing | |
| | Latent tuberculosis testing prior to anti-TNF therapy |
| | Assessment for Hepatitis B prior to anti-TNF therapy |
| Inpatient care | |
| | <i>Clostridium difficile</i> testing in patients with new onset diarrhea |
| | Venous thromboembolism prophylaxis |

IBD: Inflammatory bowel disease; TNF: Tumor necrosis factor.

in adult gastrointestinal practices. As in the ICN, this project will involve individual reporting of quality measure and sharing of knowledge between sites to improve the overall care delivered to adult patients with IBD.

However several barriers to implement quality improvement in IBD still exist. Although success in improvement of remission rates have been observed in ICN, the structure and processes of care may not translate into adult practices. For example, in contrast to pediatric care of IBD or CF, care for adults with IBD is decentralized with many patients receiving care from non-referral centers. The differences in practice patterns between providers in academic and community gastroenterologists have been previously described in IBD. Esrailian *et al*^[18] performed a survey study comparing diagnostic and treatment decisions for IBD among community and academic-center affiliated gastroenterologists. They mailed surveys with clinical vignettes and asked for structured responses. They found overall agreement between groups regarding diagnostic measures, but found variation in treatments recommended both between and within groups. This suggests that heterogeneity exists both between community and academic groups and within these groups regarding therapeutic options. Spiegel *et al*^[19] also examined this issue in a national survey study comparing the responses of community gastroenterologists and UC experts. They found dramatic differences regarding both diagnostic evaluation and treatment decisions, though the vignettes were developed to address controversial issues in UC management. Other related, but distinct issues, are the differences between care endpoints in pediatric and adult practices. While nutrition is important in adult patients with IBD, outcomes assess growth and height may be less relevant in adults. These are some of the limitations to be addressed prior to wide adoption of quality improvement projects can occur in adult gastroenterology practices.

Table 2 Crohn's and Colitis Foundation of America inflammatory bowel disease process measures^[17]

| Process measures | |
|--------------------|---|
| Treatment | |
| | If anti-TNF therapy is considered, then test for tuberculosis with skin testing or interferon gamma release assay |
| | If anti-TNF therapy is considered, then assess for latent hepatitis B virus |
| | Consider steroid sparing agent, if steroids needed at 10 mg (of more) daily for > 16 wk |
| | Test for <i>Clostridium difficile</i> if a patient presents with new symptoms of diarrhea |
| | If planning to start 6-mercaptopurine or azathioprine, then test for thiopurine methyltransferase and dose accordingly |
| | If a patient is hospitalized with severe colitis and does not improve after 3 d of IV steroids, flexible sigmoidoscopy with biopsies should be performed to check for CMV infection and surgery consulted |
| Surveillance | |
| | If a patient with UC has low grade dysplasia in flat mucosa, then procto-colectomy or repeat surveillance in 6 mo should be offered |
| | If a patient has extensive UC or Crohn's disease involving the colon for 8-10 yr, then surveillance colonoscopy should be performed every 1-3 yr |
| Health maintenance | |
| | If a patient is on immunosuppressive therapy, then vaccinations for influenza and pneumococcus should be offered, as well as education regarding avoidance of live vaccines |
| | If a patient has Crohn's disease, smoking status should be assessed and smoking cessation recommended |

TNF: Tumor necrosis factor; UC: Ulcerative colitis.

Another limitation to wide spread adoption of quality improvement interventions will be the time and financial constraints placed on physicians to implement the proposed quality improvement systems. Currently, physicians are faced with many pressures for their time and the possible addition of new processes could lead to unexpected adverse outcomes such as patient selection or new deficiencies in care areas not addressed in quality measures. A related issue involves the cost of establishing this system and the structure needed to provide continuous quality improvement. Illustrating this, the ICN network has shown an improved outcome of remission after implementing many process measures, but the program remains expensive and difficult to continue funding^[9]. Potential means to address these barriers are through innovations in bioinformatics. Development of integrated templates with automated data extraction of relevant clinical data into databases or information retrieval from plain text in EMR notes *via* natural language processing are possible means of accurately and efficiently gathering the data necessary for audit and feedback. Further work in these areas is required.

CONCLUSION

The system of quality measures and measurement of outcomes in IBD suggests many benefits regarding out-

comes. Several quality improvement programs have been established in IBD to develop the fundamental concepts and strategies for future quality improvement initiatives. Much has been learned from studying other chronic conditions, including CF and cardiac diseases, which can be applied to future quality initiatives within the field of IBD. Limitations remain to developing these systems and their implementation, and ongoing studies are needed to identify which outcomes should be used and how to accurately and efficiently provide feedback to providers. Overall, the healthcare system is moving towards a performance based model and as gastroenterologists we should be leading the development of potential measures and appropriate outcomes to help deliver the best care possible to our patients.

Abstract

Ulcerative colitis (UC) is a chronic disease characterized by diffuse inflammation of the mucosa of the colon and rectum. The hallmark clinical symptom of UC is bloody diarrhea. The clinical course is marked by exacerbations and remissions, which may occur spontaneously or in response to treatment changes or intercurrent illnesses. UC is most commonly diagnosed in late adolescence or early adulthood, but it can occur at any age. The incidence of UC has increased worldwide over recent decades, especially in developing nations. In contrast, during this period, therapeutic advances have improved the life expectancy of patients, and there has been a decrease in the mortality rate over time. It is important to emphasize that there is considerable variability in the phenotypic presentation of UC. Within this context, certain clinical and demographic characteristics are use-

ful in identifying patients who tend to have more severe evolution of the disease and a poor prognosis. In this group of patients, better clinical surveillance and more intensive therapy may change the natural course of the disease. The aim of this article was to review the epidemiology and demographic characteristics of UC and the factors that may be associated with its clinical prognosis.

Key words: Ulcerative colitis; Incidence; Prevalence; Risk factors; Predictive factors

Core tip: Ulcerative colitis has gained importance over the past few decades due to its increasing incidence rate worldwide. This condition is a chronic disease that affects quality of life, and it can lead to death if not treated properly. Over the past few decades, advances in treatment have provided benefits for patients, including a reduction in mortality. Due to phenotypic variability, different therapeutic modalities may be used. It is important to recognize the factors associated with a more severe clinical course so that clinical decisions can be made as early as possible.

Epidemiology, demographic characteristics and prognostic predictors of ulcerative colitis. *World J Gastroenterol* 2014; 20(28): 9458-9467 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i28/9458.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i28.9458>

INTRODUCTION

Ulcerative colitis (UC) is a chronic disease that is characterized by diffuse inflammation of the rectal and colonic mucosa. UC involves the rectum in 95% of cases and may be extended continuously and circumferentially to more proximal parts of the large intestine. The clas-

sic clinical symptom of UC is the presence of bloody diarrhea. The clinical course is characterized by periods of remission and exacerbation, which may occur either spontaneously or in response to treatment^[1].

The incidence of inflammatory bowel disease (IBD) has increased in several regions of the world in recent decades, especially in developing nations. Evidence indicates that there is an interaction between genetic and environmental factors in the etiology of the disease^[2]. Several studies have shown that certain clinical and demographic characteristics may be associated with different phenotypes and a poor prognosis in UC.

The identification of patients who tend to have more severe evolution of UC is important so that intensive treatments may be started earlier, with the goal of reducing complications and mortality.

The aim of this article was to review the epidemiology and demographic characteristics of UC and the factors that have been associated with poor prognostic outcomes.

EPIDEMIOLOGY AND DEMOGRAPHIC CHARACTERISTICS

Incidence and prevalence

The occurrence of UC worldwide has increased over the past few years. In contrast to the developed countries of North America and Western Europe, where the incidence of UC has plateaued or even decreased^[3,4], publications show that the number of cases has increased in developing countries, such as those in Latin America, Asia and Eastern Europe^[5-7]. Despite the increased incidence in these places, there are still differences in UC incidence and prevalence in different regions of the world. The incidence rate of UC may vary from 0.5 to 31.5 per 100000 people each year, depending on the studied population^[8].

The prevalence is lower in developing countries. In Asian populations, for example, the prevalence ranges from 5.3 to 63.6 per 100000 people^[9,10], whereas in North America, it ranges from 37.5 to 238 per 100000 people^[11]. In addition to the gradient between the occurrence of UC in the West and in Asian countries, it has been noted that in Europe, although there are exceptions, there is also a geographical gradient for the incidence of IBD, with higher rates in the north and a lower frequency in the south^[12]. Similarly, Sonnenberg *et al.*^[13] suggested a greater frequency of IBD in the northern United States compared with the south of the country. In Latin America, the prevalence of UC also appears to be variable. A study conducted in Puerto Rico suggested that the prevalence of UC is 12.53 cases per 100000 people^[5]. Victoria *et al.*^[14] concluded that the prevalence of UC in a southeastern region of Brazil has been increasing in recent years and that during the period from 2001 to 2005, the prevalence was 14.81 cases per 100000 habitants.

Mortality

According to previous studies, the mortality rate of pa-

tients with UC was higher in the first half of the twentieth century. Beginning in the mid-1950s, despite the ongoing increase in incidence, it appears that there has been a drop in the number of deaths, possibly due to the usage of corticosteroids and sulfasalazine and the optimization of surgical techniques^[15]. Despite this progress, data published in the 1980s showed that mortality in UC was higher than in the general population^[16]. Fortunately, overall, individuals with UC currently have mortality rates similar to or only slightly higher than the rate in the general population^[17,18]. This outcome may have been a consequence, among other factors, of the increased use of immunosuppressive therapy in recent years. However, when considering only the UC population, it is clear that mortality is higher in certain subgroups, and especially in newly diagnosed patients and in patients with extensive colitis^[17].

In meta-analyses of population-based cohort studies reported by Jess *et al.*^[20], five of 10 studies reported on UC-related mortality. The authors reported that among patients with UC, the mean percentage of deaths ascribed to UC itself was 17% (range 11% to 30%). In this subgroup of patients, the most common causes of death were colorectal cancer (CRC) (mean 37%, range 24% to 44%) and surgical or postoperative complications (mean 44%, range 17% to 100%). The remaining causes were primarily related to severe disease, *i.e.*, toxic megacolon, intestinal perforation, intestinal infarction, myocardial infarction secondary to anemia and end-stage liver disease due to primary sclerosing cholangitis. Additionally, the authors concluded that compared with general population, patients with UC are at an increased risk of dying of gastrointestinal diseases (OR = 2.5; 95%CI: 1.9-3.2; $P < 0.001$), nonalcoholic liver diseases (OR = 4.0; 95%CI: 2.5-6.5; $P < 0.001$), pulmonary embolisms (OR = 4.0; 95%CI: 1.5-8.7) and respiratory diseases (OR = 1.6; 95%CI: 1.3-2.0; $P < 0.001$), counterweighted by decreased mortality from pulmonary cancer (OR = 0.3; 95%CI: 0.1-0.9; $P = 0.04$). The overall mortality rate due to malignancy was not increased in UC, although there was a trend toward more frequent CRC (standardized mortality ratio = 1.9; 95%CI: 1.0-3.8; $P = 0.07$). The mortality rate due to hematological malignancy, and specifically leukemia and non-Hodgkin's lymphoma, were not increased^[17].

In an Australian study performed in 401 patients with UC, Selinger *et al.*^[19] concluded that the major causes of death were circulatory ($n = 42$; 44.2%), malignant ($n = 22$; 23.2%), digestive ($n = 11$; 11.6%) and respiratory ($n = 7$; 7.4%) diseases. Mortality from circulatory diseases was significantly more common in UC than in the general population [44.2% *vs* 33.8%; $P = 0.0001$; RR = 1.38 (95%CI: 1.11-1.72)], mainly due to ischemic heart disease [24.2% *vs* 15.9%; $P = 0.04$; RR = 2.04 (1.45-2.85)]. Death from cholangiocarcinoma occurred nearly 15 times more often among patients with UC than in the general population [4.3% *vs* 0.3%; $P < 0.0001$; RR = 14.28 (95%CI: 5.40-37.80)]. Fatal CRC was more frequent in UC than in

the general population [6.3% *vs* 2.7%; $P = 0.047$; $RR = 2.36$ (95%CI: 1.09-5.14)]^[19].

A Danish cohort study of 36080 patients with UC was performed by Jess *et al*^[20]. The authors reported that the overall risk of dying, compared with the risk in the general population, was high in the first year after UC diagnosis ($HR = 2.43$; 95%CI: 2.31-2.57) and then rapidly declined to a constant level of approximately 1.1 after 2 years. The risk of dying from infectious diseases, cardiovascular diseases, gastrointestinal disorders with or without the inclusion of IBD or CRC remained significantly increased in the long term, with HR estimates of 1.64 (95%CI: 1.24-2.17) for infectious diseases, 1.11 (95%CI: 1.01-1.21) for cardiovascular diseases, 1.26 (95%CI: 1.07-1.48) for gastrointestinal disorders other than UC and 1.47 (95%CI: 1.23-1.76) for CRC^[20].

Age

In recent decades, although there has been an increased incidence of UC in different age groups, the majority of patients with UC are in the age group of 30-40 years at diagnosis^[11]. It has been observed that the average age at diagnosis is usually slightly higher in Asian countries compared with Western countries^[21].

Certain publications indicate that a second incidence peak occurs in an older age group^[22,23]. A study by Souza *et al*^[24] in southeastern Brazil showed that there was a trend toward a second peak of new hospital admissions due to UC in the age group of 60-69 years old. However, there is no consensus in the literature regarding the existence of this second peak^[11].

Although UC is less common in children, recent studies have shown that the number of UC cases has increased in pediatric patients and adolescents. In Scotland, for example, in recent years, an increased incidence of UC in the age group under 16 years was observed. Comparing the periods 1990-1995 and 2003-2008, incidence rates increased from 1.59/100000 per year (95%CI: 1.28-1.94) to 2.06/100000 per year (95%CI: 1.70-2.47; $P = 0.023$)^[25]. In a recent publication, Pant *et al*^[26] demonstrated that in the United States, between 2000 and 2009, the number of hospitalizations of pediatric patients with UC increased from 4171 to 7127 per year. Lindberg *et al*^[27] suggested that the increased frequency of disease is more significant during puberty and adolescence than during childhood. The authors demonstrated that in recent years, although the incidence has increased in the age group of 11-15 years, this rate has remained stable in children under 10 years of age.

Gender

Most UC studies have shown a male predominance or an equal distribution between genders^[11,21]. In the past, Italian investigators have even suggested that polymorphisms in an enzyme involved in the signal transduction of insulin (cytosolic low-molecular-weight protein tyrosine phosphatase) could increase predisposition to the development of Crohn's disease (CD) in women and of

UC in men^[28]. However, this hypothesis was refuted in a more recent study by a group of Spanish investigators^[29]. Moreover, in contrast to the cited studies, other authors have found a high female incidence of the disease^[30]. In a recent publication describing 35404 cases of IBD, Beteridge *et al*^[31] reported a female predominance among patients with UC ($RR = 1.35$; 95%CI: 1.32-1.39).

PREDICTORS OF PROGNOSIS

Family history

Although a family history of UC is a risk factor for developing the disease, it does not seem to be a negative prognostic factor in patients with UC^[32,33].

In a prospective study, Henriksen *et al*^[34] found a 10.1% incidence of a family history of IBD among 454 individuals with UC. The authors concluded that although the group with a positive family history had further exacerbations of the disease in five years, there was no significant difference in drug therapy or indication for colectomy. In a retrospective study in 411 children with a diagnosis of IBD, 244 (59.4%) of whom had UC, Roma *et al*^[35] concluded that children with familial IBD had an earlier onset of disease compared with those with sporadic IBD. However, this difference had no significant impact on the clinical phenotypes, course and/or outcome of disease. Kuwahara *et al*^[36] obtained clinical data for 46114 UC cases. The present age and the age at disease onset were lower among patients with UC who had a family history than among those without a family history. However, the clinical course of patients with UC was not affected by family history.

Environmental factors

Patients with IBD have a genetic predisposition to the development of such diseases. It appears, however, that this predisposition alone is not sufficient for the onset of inflammation. The current belief is that genetically predisposed patients, when in contact with environmental factors, develop an inadequate immune response that ultimately causes inflammation of the gastrointestinal tract^[37]. Over time, many studies have attempted to support the hygiene hypothesis, although the data are conflicting, and well-designed prospective studies are needed^[38]. Until then, among the studied factors, only smoking and appendectomy have a well-defined influence on the risk of developing UC.

In contrast to what happens in CD, smoking is a protective factor against the development of UC. In a meta-analysis, Calkins concluded that the risk of non-smokers developing UC is approximately three times higher than that of smokers ($OR = 2.9$; 95%CI: 2.6-3.2)^[39]. Moreover, among patients with UC, those who do not smoke have a less favorable evolution of the disease over time^[40]. Aldhous *et al*^[41] concluded that five years after diagnosis, a decrease in the extent of UC was more common in smokers than in groups of former smokers and non-smokers. Smoking seems to be a protective factor against

colectomy (OR = 0.57; 95%CI: 0.38-0.85) and against the development of CRC (OR = 0.5; 95%CI: 0.2-0.9)^[42,43].

Appendectomy influences the emergence of IBD and is considered to be a risk factor for the development of CD^[44]. Conversely, in one of the first studies on this topic, Rutgeerts *et al.*^[45] concluded that appendectomy protects individuals against the emergence of UC. While studying the reason for this protection, Matsushita *et al.*^[46] suggested that the appendix plays an important role in the pathogenesis of UC. In a meta-analysis, Koutroubakis *et al.*^[47] concluded that performing an appendectomy reduced the chance of developing UC by 69% (OR = 0.31; 95%CI: 0.261-0.373). Certain studies have also suggested that appendectomy might influence the clinical course of UC by reducing the rate of recurrence of the disease and the need for immunosuppression and colectomy^[48-50]. However, the data are still conflicting, and the influence of appendectomy on the clinical course of UC needs to be further investigated in prospective studies.

The intestinal microbiota plays an important role in homeostasis and immune system functioning. Currently, it is believed that different environmental and genetic factors can promote changes in that microbiota. The formation of a pathogenic microflora in genetically predisposed individuals is associated with changes in epithelial function, dysregulation of the immune function of the gastrointestinal tract and persistent intestinal inflammation^[51]. Future studies may indicate which environmental factors are associated with the formation of an abnormal microbiota and whether these changes are only the cause or also be consequences of the changes introduced by IBD.

Nutritional factors

Knowledge about nutrition and nutritional status is not only important for the multidisciplinary team that treats patients with IBD but also for the patients themselves, who may have a wide range of questions regarding how nutrition affects their quality of life and the evolution of the disease^[52].

Nutritional deficiencies occur in 20% to 85% of patients with IBD, and protein-energy malnutrition is the most common^[53,54]. Although malnutrition is often related to CD, studies have shown similar rates of malnutrition between patients with CD and patients with UC^[55,56]. Malnutrition in these patients is associated with a poor quality of life and infection and with increased in-hospital mortality, length of stay and financial costs^[55,57,58]. It is noteworthy that body mass index (BMI), an indicator commonly used to define nutritional status, has several limitations^[59]. Jahnsen *et al.*^[60] reported that despite finding higher BMI values in patients with UC than in those with CD, lean body mass was not higher than in controls. Furthermore, a higher percentage of fat mass in patients with UC contributed to their increased weight. Therefore, BMI itself has adverse implications for the course of UC^[61,62].

Overweight or obese patients with UC have higher

rates of colectomy than do eutrophic patients^[63], an increased need for permanent ileostomy, longer hospital stays, higher rates of incisional hernia after ileoanal pouch anastomosis^[64,65], an increased risk of nonalcoholic fatty liver disease^[66] and thromboembolism^[67] and increased inflammation of the colon^[61]. Increased body weight has also been associated with an early loss of response to infliximab in IBD^[68]. In contrast, a study conducted by Markel *et al.*^[69] did not find any association between preoperative BMI and infectious complication in a post-operative wound in children with UC. In this group, 78% of patients were overweight (BMI > 25) at the time of surgery.

Age at diagnosis

The influence of age at diagnosis on the clinical course of UC is another controversial issue. Therefore, the Montreal classification of UC, in contrast to the classification of CD, does not include age at diagnosis as a criterion. So far, there is no convincing evidence that the creation of subgroups according to age at diagnosis would affect the clinical course of UC patients^[70].

Certain authors have evaluated the influence of age at diagnosis on the clinical evolution of patients with UC. Riegler *et al.*^[71] evaluated 1705 patients with UC in Italy and reported that younger patients had a greater need to use corticosteroids and a higher incidence of diarrhea and weight loss at diagnosis. An important study on the clinical course of UC (IBSEN study), conducted by Norwegian investigators, prospectively evaluated patients with UC for 10 years. Based on multivariate analysis, the authors found that the risk of colectomy in patients with an age at diagnosis of 50 years was 72% lower than in patients under 30 years old (HR = 0.28; 95%CI: 0.12-0.65)^[72]. The hypothesis of a milder and less aggressive clinical course in patients with an older age at diagnosis was corroborated by other recent studies^[73,74]. In contrast, other studies found no significant differences in prognosis when comparing groups with different ages at diagnosis^[75,76].

Extent of disease

According to the Montreal classification, based on location, UC can be classified into three different subtypes: proctitis (when inflammation is restricted to the mucosa of the rectum), left colitis (when inflammation extends beyond the rectum and to the splenic flexure) and extensive colitis (when inflammation reaches the mucosa proximal to the splenic flexure)^[70]. The most frequent location of UC may vary between different studies. Left colitis was most frequent in studies conducted in France (extensive colitis: 19.1%; left colitis: 52.3%; proctitis: 28.7%) and Portugal (extensive colitis: 28%; left colitis: 52%; proctitis: 21%)^[3,77]. In Asia, it appears that more patients have inflammatory processes limited to the mucosa of the rectum, as demonstrated by Ng *et al.*^[78] (extensive colitis: 31%; distal colitis: 32%; proctitis: 37%). In a study from southeastern Brazil that evaluated patients

diagnosed with UC in the period from 1980-1999 and in which the applied classification was different from the Montreal classification, the results were similar to those found in the Asian population. The occurrence of extensive colitis was detected in 28.3% of cases, whereas the frequencies of left and proctosigmoiditis were 29.7% and 32.4%, respectively^[24].

Furthermore, the extent of the disease in each patient is not fixed over time. In this context, it is important to emphasize that in patients with proctitis or left colitis, the inflammatory process may progress to more proximal segments of the colon. This phenomenon may require greater clinical surveillance and even changes in the therapeutic regimen. In a study by Alkim *et al*^[79], for example, the progression of inflammation to the more proximal segments of the colon occurred in 16.1% of patients with proctitis. The percentage was even higher in a study by Park *et al*^[80], which showed that in 5 and 10 years, there was proximal progression in 44.7% and 60% of patients, respectively, with proctitis or left colitis.

The extent of UC influences the clinical course and prognosis of the disease. Patients with extensive colitis are more likely to be subjected to more intensive therapies or even colectomy^[79,81]. In a retrospective study, Lee *et al*^[82] demonstrated that the extent of disease is a factor that is independently associated with resistance to therapy with aminosalicylates (HR = 1.46; 95%CI: 1.01-2.10; $P = 0.04$). A Canadian study showed that left colitis (OR = 8.67; 95%CI: 1.79-41.87; $P < 0.001$) and extensive colitis (OR = 14.08; 95%CI: 3.12-63.60; $P < 0.001$) are also associated with more frequent usage of immunosuppressive drugs in patients with UC^[83].

Whereas patients with proctitis do not seem to be at an increased risk of developing CRC compared with the general population, individuals with left or extensive colitis have a higher propensity to evolve this complication^[84-87]. In a recent study, Manninen *et al*^[85] concluded that patients with UC are at an increased risk of developing dysplasia and CRC compared with the general population (OR = 1.99; 95%CI: 1.14-3.25). The authors also noted that this risk is even higher in patients with extensive colitis (OR = 3.09; 95%CI: 1.5-5.75). Similar data were found in a recent meta-analysis, which described the risk of CRC in patients with UC as higher than in the general population (OR = 2.4; 95%CI: 2.1-2.7). Again, the risk was even higher in patients with extensive colitis (OR = 4.8; 95%CI: 3.9-5.9)^[86]. The most recent data on the evolution of CRC risk over time are conflicting. Whereas certain authors have shown a tendency to stabilize the risk^[88,89], Jess *et al*^[90] showed a reduction in the period from 1979 to 2008. The authors suggested that this reduction occurred as a result of advances in therapeutic approaches to UC. Further studies are needed to evaluate the behavior of the risk of CRC in UC over time.

Disease activity

Clinical and laboratory characteristics that are consistent with greater disease activity at diagnosis have been shown

to be important prognostic factors in patients with UC. The stratification of disease activity is important both in the choice of treatment modalities and in the assessment of prognosis. Lennard-Jones *et al*^[91] evaluated 56 variables among patients with active UC in 181 hospital admissions. The authors concluded that fever, tachycardia, the number of evacuations and serum albumin level are important predictors of treatment failure and the need for colectomy. Those patients who had persistent fever and more than 8 stools per day in the first 24 h of hospitalization had a 4-5 times higher chance of becoming refractory to medical treatment and needing surgery. Carbonnel *et al*^[92] evaluated factors associated with the failure of intravenous steroid therapy in hospitalized patients with active UC. The authors found that the risk of treatment failure was higher in patients meeting the criteria for severe disease in the classification of Truelove and Witts (RR = 2.26; 95%CI: 1.11-4.61). Lau *et al*^[83] reported that more than 10 evacuations per day and the presence of blood in the stool at diagnosis were associated with greater usage of immunosuppression in patients with UC. Furthermore, Travis *et al*^[93] concluded that patients with severe colitis who were hospitalized for more than 3 d and who persisted in having more than 8 stools per day and an elevated C-reactive protein level (> 45 mg/L) had a higher chance of colectomy. In a cohort study that evaluated the prognosis of patients during the first ten years of the disease, Solberg *et al*^[72] concluded that anemia, an elevated erythrocyte sedimentation rate and fever at diagnosis were associated with a greater need for colectomy over time.

Endoscopic exams allow the direct evaluation of lesions of the intestinal mucosa in patients with UC. The severity of the lesions usually reflects clinical disease activity and may help to identify patients who are more likely to evolve worse disease behavior over time^[92]. In a recent study, Canadian investigators found that the presence of moderate to severe endoscopic lesions was associated with an increased need for immunosuppression^[83]. Carbonnel *et al*^[94] demonstrated that patients admitted with active UC who had extensive and deep ulcerations (severe endoscopic activity) had a greater need for colectomy than did those with moderate endoscopic activity. Rutter *et al*^[95] demonstrated that there is a close relationship of the degree of endoscopic activity (OR = 2.54; 95%CI: 1.45-4.44; $P = 0.001$) and histological activity (OR = 5.13; 95%CI: 2.36-11.14; $P < 0.001$) with the risk of developing CRC in patients with UC.

Several studies have considered fecal markers, and especially lactoferrin and calprotectin, as useful tools for the assessment of disease activity in UC and the response to treatment^[96-98]. Recently, studies have shown that calprotectin and lactoferrin are also useful as predictors of clinical relapse in UC^[99,100]. A study conducted by British investigators, who evaluated patients admitted with severe UC who needed intravenous corticosteroids, showed that a higher average concentration of fecal calprotectin was associated with an increased rate of colectomy^[101].

Extraintestinal manifestations

The manifestations of UC may not be restricted to the colon and rectum. A variable percentage of patients may also have abnormalities in other organs and systems. Joint, skin, liver, eye and hematologic manifestations are common in patients with UC. Extraintestinal manifestations have been shown to be associated with a greater extent of disease and a worse prognosis^[102]. Lakatos *et al*^[103] conducted a study with 619 patients with UC who were followed for 25 years. The authors concluded that the presence of extraintestinal manifestations was associated with greater extent of disease. In the pediatric population, a recent study of Gower-Rousseau *et al*^[104] concluded that the presence of extraintestinal manifestations in pediatric patients with UC increases the risk of colectomy (HR = 3.4; 95%CI: 1.2-10.0; *P* = 0.02).

Individuals with UC and primary sclerosing cholangitis (PSC) have a different phenotypic behavior compared to patients with UC only. In this group of patients, the presence of PSC is associated with increased occurrence of extensive colitis and CRC^[105-107]. In a meta-analysis performed by Soetikno *et al*^[108], the presence of PSC in patients with UC increased the risk of dysplasia and CRC (OR = 4.79; 95%CI: 3.58-6.41). Kornfeld *et al*^[109] reported that the cumulative risk of individuals with UC and PSC to develop CRC was 25%, 33% and 40% at 10, 20 and 30 years from diagnosis of UC, respectively.

Serological markers

Anti-*Saccharomyces cerevisiae* antibody (ASCA) and perinuclear anti-neutrophil cytoplasmic antibody (p-ANCA) were the first serological markers of IBD identified. The presence of a positive ASCA is more associated with CD, and p-ANCA is more associated with UC^[110]. Over the past several years, however, these two serum markers not only became markers used to differentiate both IBD forms but also appeared to have prognostic implications. There is evidence that the presence of ASCA is associated with severe and refractory CD, whereas p-ANCA positivity in patients with UC seems to be associated with resistance to treatment^[111,112]. This association has been reinforced by other recent publications. Ferrante *et al*^[113] demonstrated that the usage of infliximab in patients with UC and p-ANCA+/ASCA- is more associated with a suboptimal early clinical response (OR = 0.40; 95%CI: 0.16-0.99; *P* = 0.049). In a study in a pediatric population with IBD, Dubinsky *et al*^[114] concluded that the presence of a positive p-ANCA was independently associated with a primary non-response to anti-TNF α in UC patients.

Papp *et al*^[115] found no association between ASCA, anti-laminaribioside carbohydrate antibody (ALCA), anti-chitobioside carbohydrate antibody (ACCA), anti-mannobioside carbohydrate antibody (AMCA) or anti-outer membrane porin C (anti-OmpC) and different phenotypes of UC.

There are only few studies on the role of antinuclear antibodies in UC. In a study in 97 patients with UC, Barahona-Garrido *et al*^[116] concluded that the presence of

antinuclear antibodies is associated with an increased risk of steroid dependency (OR = 3.9; 95%CI: 1.4-14.9; *P* = 0.033).

CONCLUSION

The global prevalence and incidence of UC have increased in recent decades. The increase in the number of new cases has been more evident in developing countries. Nevertheless, the mortality rate of UC has decreased over time, and currently, mortality in patients with UC is similar to or slightly higher than that in the general population. Environmental factors appear to be associated with the pathogenesis of UC. Among these factors, smoking and appendectomy have been considered protective against the development of UC. Moreover, evidence suggests that smoking and appendectomy are associated with less severe forms of UC and seem to confer protection against colectomy. Inversely, a greater extent of disease and higher disease activity are associated with a worse prognosis. Additionally, one should be attentive to the occurrence of nutritional deficiencies and extraintestinal manifestations, especially PSC, as well as to the presence of positive p-ANCA. The influence of age at diagnosis on the clinical course of UC is controversial, and therefore, further studies are needed to better evaluate this issue. Thus, based on current knowledge, it appears that demographic and clinical characteristics are useful to identify patients who tend to have more severe evolution of the disease. Earlier identification may allow more intensive therapeutic measures to be adopted earlier in the management of such patients.

Key words: Ulcerative colitis; Mucus; Infection; Bacteria; Etiology

Core tip: Long-term or even life-long medication bothers patients with ulcerative colitis (UC). Existing treatment ignores the cause of UC, so establishing the etiology of UC is the key to resolving this problem. UC can be viewed as a polymicrobial infection that is characterized by a sustained broken mucus barrier with subsequent bacterial migration toward the mucosa and proliferation of complex bacterial biofilms on the epithelial surface. Regulation of mucus secretion and viscosity, suppression of bacterial biofilms, probiotics and immunostimulation should be increasingly considered to treat UC.

Ulcerative colitis as a polymicrobial infection characterized by sustained broken mucus barrier. *World J Gastroenterol* 2014; 20(28): 9468-9475 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i28/9468.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i28.9468>

Abstract

To reduce medication for patients with ulcerative colitis (UC), we need to establish the etiology of UC. The intestinal microbiota of patients with inflammatory bowel disease (IBD) has been shown to differ from that of healthy controls and abundant data indicate that it changes in both composition and localization. Small intestinal bacterial overgrowth is significantly higher in IBD patients compared with controls. Probiotics have been investigated for their capacity to reduce the severity of UC. The luminal surfaces of the gastrointestinal tract are covered by a mucus layer. This normally acts as a barrier that does not allow bacteria to reach the epithelial cells and thus limits the direct contact between the host and the bacteria. The mucus layer in the colon comprises an inner layer that is firmly adherent to the intestinal mucosa, and an outer layer that can be washed off with minimal rinsing. Some bacteria can dissolve the protective inner mucus layer. Defects in renewal and formation of the inner mucus layer allow bacteria to reach the epithelium and have implications for the causes of colitis. In this review, important elements of UC pathology are

INTRODUCTION

Ulcerative colitis (UC) belongs to a subgroup of inflammatory bowel diseases (IBDs), is characterized as chronic inflammation, and has become a global health threat^[1,2]. High disease-recurrence rates, long-term or even life-long medication bothers patients with UC^[3-5]. Existing treatment ignores the cause of UC, and is unable to cure UC, which is why patients need long-term medication; therefore, establishing the etiology of UC is the

Table 1 Interaction of mucus and bacteria

| Effect of mucus on bacteria | Effect of bacteria on mucus |
|---|---|
| Limits the direct contact between the host and bacteria | Maintenance of the mucus layer is stimulated by bacterial fermentation products |
| Serves as a source of nutrients for bacterial growth | Mediate the expression of MUC2 |
| Contributes to the selection of the species-specific colon flora | Dissolve the protective inner mucus layer |
| Contains several proteins that limit bacterial growth and penetration | |

key to resolving this problem. Important elements of IBD pathology are thought to be genetics, the intestinal microbiome, the gut mucosa, and the mucosa-associated immune system^[6,7]. Studies using dextran sulfate sodium (DSS) models of colitis also suggest that the key contributors in disease pathogenesis include alteration in the mucosal barrier integrity and function^[8,9]. The human gastrointestinal tract is a vast surface inhabited by a complex and diverse community of micro-organisms^[10], and the intestinal mucus is an efficient system for protecting the epithelium from bacteria by promoting their clearance and separating them from the mucosal immune cells, thereby inhibiting inflammation and infection^[11]. UC is an immune-mediated disorder that results from an abnormal interaction between colonic bacteria and mucosal immune cells in a genetically susceptible host^[12]. In this review, UC is thought to be a polymicrobial infection characterized by sustained broken mucus barrier.

ROLE OF MUCUS AND BACTERIA IN UC

The gastrointestinal tract is covered by a layer of mucus that protects the epithelium from luminal antigens and provides lubrication to advance the bolus^[13]. A well-developed mucus barrier and not the epithelial cell layer is the first line of defense against a variety of enteric pathogens^[14,15]. Leukocytes migrate into and patrol within the mucus layer, executing the surveillance function without any collateral damage. The sticky outer mucus surface offers the opportunity for probiotic strains to grow and build protective interlaced layers, preventing bacterial accumulation and microcolony formation on the colorectal surface^[16,17]. Before bacteria can adhere and invade the mucosa, they must first traverse the mucus barrier^[17]. The inflammation takes place only after the mucus barrier is broken and the defense is overwhelmed. UC is caused by a weakening in gut barrier, mainly due to increased infiltration of gut bacteria and the resultant recruitment of neutrophils and formation of crypt abscess^[18]. Understanding the role of mucus and bacteria and their interaction will help us to establish the etiology of UC more clearly (Table 1).

Role of mucus in UC

Mucus production and secretion is a continuously ongoing process with a renewal of the inner protective mucus in the distal colon within an hour. Rapid renewal of the mucus barrier prevents microbial contact with the epithelial cells. Alteration of the adherent mucus barrier is a predisposing factor for early onset of epithelial cell dam-

age in DSS colitis^[19]. Sulfation of the mucins is significantly reduced in UC patients, and suggest that colonic mucins plays an important role in maintaining the normal physiological function of the colon and the possible role of mucus in the pathogenesis of UC^[20]. Phosphatidylcholine (PC) accounts for > 70% of total phospholipids within the intestinal mucus layer, and the mucus PC content is reduced by about 70% in UC^[21]. MUC2 is the major mucin in the large intestine^[22,23], which is secreted by goblet cells, and the expression of it correlated with the activity of disease and the extent of the inflammatory process in the large intestine^[24]. Individuals with UC have decreased numbers of goblet cells and reduced mucus thickness at presentation^[25], and goblet cell abnormalities play an etiological role in UC. DSS models of colitis were characterized by depletion of goblet cell and adherent mucin^[19]. In UC, the cooperation of aberrant expression of Hes1 and the disappearance of caudal type homeobox 2 (CDX2) caused Hath1 suppression, resulting in goblet cell depletion^[26], and the present study suggests that Hes1 is essential for Hath1 gene suppression via Notch signaling. Gersemann *et al*^[27] also pointed that in UC, the protective mucus layer, acting as a physical and chemical barrier between the gut epithelium and the luminal microbes, is thinner and in part denuded as compared to controls, and this could be caused by a missing induction of the goblet cell differentiation factors Hath1 and KLF4, leading to immature goblet cells. This goblet cell differentiation in UC can lead to defects in renewal and formation of the inner mucus layer and may enable the luminal microbes to invade the mucosa and trigger the inflammation^[16,27,28]. So we can easily reach the conclusion that understanding the regulation of goblet cell differentiation and the intestinal mucus turnover and renewal of the inner protective mucus layer is important for novel ways to improve treatment of UC^[16,21].

Role of bacteria in UC

UC is a multifactorial disease that is dependent on host genetics, environment, immune response and intestinal microbiota. The dysregulation of the gut microbiota plays an important role in the pathogenesis of UC^[29]. The immunoregulatory function of the intestinal microbiota consists of priming the mucosal immune system and maintenance of intestinal epithelial homeostasis. Epithelial barrier dysfunction brings about increased bacterial translocation through the lamina propria^[30,31]. Ineffective bacterial clearance leads to excessive Toll-like receptor (TLR) stimulation, secretion of proinflammatory cytokines and activation of innate and T-cell-mediated

immune responses. TLR-2 can bind a wide range of ligands, including lipoteichoic acid from Gram-positive bacteria, bacterial lipopeptides and glycolipids, and fungal β glucan (zymosan). TLR-4 can bind lipopolysaccharide from Gram-negative bacteria. Flagellin has innate qualities through its repetitive structures that are able to bind TLR-5, and also is a polypeptide that is internalized, processed and presented by professional antigen-presenting cells (APCs). Thus, the earliest phases of an immune response are dependent upon the recognition and interpretation of the antigenic composition of the milieu by T cells and APCs as revealed by innate and adaptive immune responses. TLR-9 is able to recognize bacterial DNA^[32,34], and the stimulation of TLR-9 causes activation of nuclear factor- κ B signaling, and leads to immune response and mucosal inflammation. These features could help to explain the mechanism of UC.

Defects in renewal and formation of the inner mucus layer allow bacteria to reach the epithelium and have implications for the causes of colitis^[28]. Neutrophils and mononuclear cells infiltrate the lamina propria and activate nuclear factor- κ B translocation, which in turn increases proinflammatory cytokines such as interleukin (IL)-1 β , IL-6 and tumor necrosis factor- α , and inhibits the production of anti-inflammatory cytokines such as IL-10^[35]. *Fusobacterium varium* (*F. varium*) was present in the colonic mucosa of a high proportion (84%) of UC patients^[36] and contribute to the clinical activity in UC^[37]. *L. crispatus* CCTCC M206119 strain is involved in exacerbation of intestinal inflammation in DSS-colitis mice, and may interact directly with colonic epithelial cells or lamina propria mononuclear cells after disruption of the mucosal barrier and balance of gut flora by DSS administration. *Campylobacter* spp.^[38], *Escherichia coli*^[39-41], *Enterohepatic Helicobacter*^[42,43], and *Bacteroides ovatus*^[44] are also responsible for the induction of intestinal inflammation.

However, not all the bacteria promote inflammation; *Pediococcus acidilactici*^[45], *Lactobacillus* spp.^[45], and *Bacteroides* spp.^[46] show a variety of beneficial immunomodulatory effects in UC. Their products, rather than live bacteria, may be capable of inducing immunoregulatory effects, and may restore the dysregulated functions of immune cells^[47]. Some recent studies have demonstrated that TLR signaling in intestinal sites can also inhibit inflammatory responses and maintain colonic homeostasis^[48,49].

Effect of mucus layer on bacteria

The mammalian gastrointestinal tract harbors a vast microbial ecosystem, known as the microbiota. Gut microbiota includes around 1000 different species and > 15000 different strains of bacteria, for a total weight of about 1 kg. The luminal surfaces of the gastrointestinal tract are covered by a mucus layer composed mainly of mucins, which are high-molecular-weight glycoproteins characterized by extended serine, threonine, and proline-rich domains in the protein core^[50]. This layer is a biochemically complex medium, rich in carbohydrates, antimicrobial peptides and other proteins, as well as lipids and electro-

lytes^[51]. The inner mucus layer normally acts as a barrier that does not allow bacteria to reach the epithelial cells and thus limits the direct contact between the host and bacteria^[52]. The mucus layer covering the gastrointestinal tract also has been reported to serve as a source of nutrients for bacterial growth. Thus, its presence influences intestinal colonization by attracting bacteria that have the ability to survive and multiply within the mucus layer^[53,54]. We have also found that the numerous O-glycans on the MUC2 mucin serve as nutrients for the bacteria as well as attachment sites, and as such, probably contribute to the selection of the species-specific colon flora^[44]. Overproduction of MUC2 may alter adherence and invasion of *Shigella dysenteriae* into human colonic epithelial cells. At the same time, the mucus also contains several proteins that limit bacterial growth and penetration, such as the antibacterial proteins and IgA^[10,20]. These are important for the assembly and stability of the microbiota.

Effect of bacteria on mucus

The mucus barrier, however, can be compromised by environmental or genetic factors as well as specific pathogens such as *Serpulina*, *Fusobacterium*, *Enterobacteriaceae*, or *Gardnerella*. These bacteria can specifically form adherent biofilms on the epithelial surface, compromising the mucus barrier and allowing migration of other indigenous bacteria into the mucosa. The commensal bacteria in the colon live and thrive in the outer loose mucus layer, and can dissolve this layer^[55]. Nevertheless, the association of the microbiota with the mucus is not well understood and requires further investigation.

The importance of bacterial exposure to produce a functional mucus barrier is demonstrated by germ-free animals in which the inner mucus layer is thin^[56], but can be restored by exposure to bacterial components^[56]. Maintenance of the mucus layer is also known to be stimulated by bacterial fermentation products^[57]. In conclusion, the bacteria can influence mucus production^[56]. Proteins secreted by probiotic bacteria of antimicrobial substances can enhance the mucosal barrier function and compete with enteropathogens for adhesion sites^[58,59]. The composition of short-chain fatty acids in the intestine is determined by the composition of the microbiota, and butyrate can mediate MUC2 mRNA *via* activator protein-1 and acetylation/methylation of histones at the MUC2 promoter. The microbiota can also mediate MUC2 mRNA^[58], and MUC2 can potentially be modulated in several other ways either during infection, such as at the level of gene expression, or even at the level of secretion into the intestinal lumen. Each regulatory step may influence the biological function of MUC2, which in turn influences how the host responds to enteric pathogens^[16]. MUC2 is reportedly overexpressed in response to bacterial components, such as lipopolysaccharide or lipoteichoic acid, in cultured intestinal or airway epithelial cells and also bladder epithelial cells^[13,60].

Bacteria can also dissolve the protective inner mucus layer, potentially triggering colitis. MUC2 is the

major colonic secretory mucin. We found that bacteria can produce proteases capable of dissolving the inner protective mucus layer by specific cleavages in the MUC2 mucin and that this cleavage can be modulated by site-specific O-glycosylation. However, because of O-glycosylation, the mucin domains are highly resistant to proteases and are not expected to be cleaved by proteases^[52]. However, MUC2 glycosylation can still be metabolized by intestinal commensal or pathogenic bacteria, serving as an energy source, suggesting a role in intestinal microbiota selection^[20,61]. The 980-amino-acid-long C-terminal part of MUC2 has two cleavage sites. One is localized to the NR2QA sequence within the VWD4 domain where the cleavage site is surrounded by numerous cysteines that are involved in disulfide bond formation. The second cleavage site is localized prior to the first cysteine in the MUC2 C-terminal VWD4 domain. The enzyme secreted by *Entamoeba histolytica* can dissolve the guanidinium-chloride-insoluble mucus gel that we now know is the major constituent of the inner firm mucus layer^[10]. *Porphyromonas gingivalis* also secretes a protease as an active enzyme to cleave MUC2, and this enzyme was isolated and identified as Arg-gingipain B. *Citrobacter rodentium* colonizes the outer mucus layer in high numbers, lacks a functional flagellum and is thus non-motile, and therefore likely utilizes specific mucinases or glycosidases to digest mucin in order to overcome the mucus barrier^[16,20].

CHANGES OF BACTERIAS IN UC

The intestinal microbiota of IBD patients has been shown to differ from that of healthy controls; abundant data indicate that the microbiota in IBD patients changes in both composition and localization^[62,63], and the changes are not a product of colitis, which has previously been reported^[64]. These support an integrative view of microbial ecology relevant to IBD^[65], and butyrate-producing bacteria could be important to gut homeostasis^[66,67]. The diversity of fecal microbiota is significantly lower in UC patients. *Bacteroides*^[68], *Clostridium* subcluster XIVab^[66], *Lactobacillus* spp.^[67], *Akkermansia muciniphila*^[69] and *Clostridium leptum*^[70] are decreased in UC patients, and the number of *Enterococcus*^[68], *Escherichia coli*^[71], *Actinobacteria*^[72], *Proteobacteria*^[73] and *Campylobacter ureolyticus*^[73] are higher in UC patients than in healthy subjects. Sulfate-reducing bacterium levels are also raised in UC^[74], and are crucial for induction of DSS colitis in mice. Some research has proposed that *F. varium* might be one of the elusive pathogenic factors in UC^[6]. Data also showed that the amount and composition of bacteria clearly differed between the mucus layers in animals not treated with DSS, with significantly higher loads of bacteria in the outer mucus layer^[75], and *Lactobacillus crispatus* CCTCC M206119 strain is involved in exacerbation of intestinal inflammation in DSS-colitis mice^[76]. Recently, we also found that small intestinal bacterial overgrowth was significantly higher in IBD patients as compared to controls^[35]. Despite the requirement

of commensal bacteria for normal intestinal function, an abnormal host response to commensal bacteria has been implicated as a crucial factor in the pathogenesis of IBD^[77,78]. Recent research has shown that some commensal and pathogenic bacteria are closely related to UC, but it is difficult to draw a definitive conclusion in evaluating the role of microflora in pathogenesis of UC, and to find specific micro-organisms associated with the pathogenesis of UC.

USE OF PROBIOTICS IN UC

Bacteria are closely related to UC, and recently some studies have investigated the use of probiotics in UC^[47,79,80]. Probiotics contain viable organisms; sufficient amounts of which reach the intestine in an active state, thus exerting positive health effects^[81]. Their mechanisms of action are still unclear, but several have been postulated to contribute to the anti-inflammatory effect of probiotics in the gut, including competitive exclusion of pathogens. Probiotics may potentially alter the intestinal microbiome exogenously or provide an option to deliver microbial metabolic products to alter the chronicity of intestinal mucosal inflammation^[82]. Bifidobacteria and lactobacilli produce harmful substances for Gram-positive and Gram-negative bacteria, and they compete with pathogens (*i.e.*, *Clostridium*, *Bacteroidetes*, *Staphylococcus*, and *Enterobacter*) for cell adhesion^[83,84]. Production of antimicrobial agents (*e.g.*, IgA) and organic acids, modulation of lymphocyte and dendritic cell function^[85,86], enhancement of the epithelial barrier function, modulation of the membrane permeability and mucosal immune system, and keeping pathogens away from the intestinal mucosal surface are also included. Probiotics have been investigated for their capacity to reduce the severity of UC (Table 2). The efficacy of VSL#3 (*Bifidobacterium breve*, *Bifidobacterium infantis*, *Bifidobacterium longum*, *Lactobacillus paracasei*, *Lactobacillus acidophilus*, *Lactobacillus plantarum*, *Lactobacillus bulgaricus*, and *Streptococcus thermophilus*) in UC patients has also been demonstrated^[94-96]. Also, some natural anti-inflammatory effects have recently been shown for *Lactobacillus salivarius*, *L. plantarum*, *Lactobacillus casei* Shirota, *Lactobacillus reuteri* and *Bifidobacterium* based on experimental colitis models^[76,97-99].

CONCLUSION

UC is mainly due to increased infiltration of gut bacteria and the resultant recruitment of neutrophils and formation of crypt abscess^[18], and can be viewed as a polymicrobial infection that is characterized by a sustained broken mucus barrier with subsequent bacterial migration toward the mucosa and proliferation of complex bacterial biofilms on the epithelial surface. Regulation of the mucus secretion and viscosity, suppression of bacterial biofilms, probiotics and immunostimulation should be increasingly considered to treat UC and evaluated in the future^[17].

Table 2 Probiotics have undergone investigation for their capacity to reduce the severity of ulcerative colitis

| Probiotics | Method | Conclusion |
|--|---|--|
| <i>B. infantis</i> 35624 ^[87] | Oral administration of <i>B. infantis</i> 35624 for 6-8 wk is taken by patients with ulcerative colitis | This microbe can reduce systemic pro-inflammatory biomarkers in UC |
| <i>L. reuteri</i> ATCC 55730 ^[88] | Mild to moderate UC were received an enema solution containing 10 (10) CFU of <i>L. reuteri</i> ATCC 55730 for 8 wk, in addition to oral mesalazine | In children with active distal ulcerative colitis, rectal infusion of <i>L. reuteri</i> is effective in improving mucosal inflammation and changing mucosal expression levels of some cytokines involved in the mechanisms of inflammatory bowel disease |
| <i>B. breve</i> strain ^[89] | Mild to moderate UC ingested 1 g of the probiotic powder [10 (9) CFU/g] three times a day, and 5.5 g of GOS once a day for one year | Administration of live <i>B. breve</i> strain Yakult and GOS can improve the clinical condition of patients with UC |
| <i>L. delbruekii</i> and <i>L. fermentum</i> ^[90] | Mild to moderate UC were treated with sulfasalazine 2400 mg/d with a probiotic preparation (which contained powder with 10 (9) CFU of <i>L. delbruekii</i> and <i>L. fermentum</i> , for eight consecutive weeks | Oral supplementation with probiotics could be helpful in maintaining remission and preventing relapse of UC |
| <i>L. casei</i> DG ^[91] | Mild left-sided UC were received oral 5-ASA and rectal <i>L. casei</i> DG | Manipulation of mucosal microbiota by <i>L. casei</i> DG and its effects on the mucosal immune system seem to be required to mediate the beneficial activities of probiotics in UC patients |
| <i>EcN</i> ^[92] | Moderate distal UC were randomly assigned to treatment with either 40, 20, or 10 mL enemas ($n = 24, 23, 23$) containing 10 (8) <i>EcN</i> /mL ($n = 20$). The study medication was taken once daily for 2, 4, 8 wk | <i>EcN</i> is a well tolerated treatment alternative in moderate distal UC |
| <i>B. longum</i> ^[93] | The probiotic group ingested one daily capsule consisting of <i>B. longum</i> 2 × 10 (9) CFU | Patients with UC on probiotic therapy experienced greater quality-of-life changes than before |

B. Infantis: *Bifidobacterium infantis*; *L. Reuteri*: *Lactobacillus reuteri*; *B. Breve*: *Bifidobacterium breve*; *L. Delbruekii*: *Lactobacillus delbruekii*; *L. Fermentum*: *Lactobacillus fermentum*; *L. Casei*: *Lactobacillus casei*; *EcN*: *E. coli* Nissle; *B. Longum*: *Bifidobacterium longum*; CFU: Colony-forming units; GOS: Galacto-oligosaccharide; 5-ASA: 5-aminosalicylic acid; UC: Ulcerative colitis.

Abstract

The intestinal immune system maintains a delicate balance between immunogenicity against invading pathogens and tolerance of the commensal microbiota. Inflammatory bowel disease (IBD) involves a breakdown in tolerance towards the microbiota. Dendritic cells (DC), macrophages (M Φ) and B-cells are known as professional antigen-presenting cells (APC) due to their specialization in presenting processed antigen to T-cells, and in turn shaping types of T-cell responses generated. Intestinal DC are migratory cells, unique in their ability to generate primary T-cell responses in mesenteric lymph nodes or Peyer's patches, whilst M Φ and B-cells contribute to polarization and differentiation of secondary T-cell responses in the gut lamina propria. The antigen-sampling function of gut DC and M Φ enables them to sample bacterial antigens from the gut lumen to determine types of T-cell responses generated. The primary function of intestinal B-cells involves their secretion of large amounts of immunoglobulin A, which in turn contributes to epithelial barrier function and limits immune responses towards to microbiota.

Here, we review the role of all three types of APC in intestinal immunity, both in the steady state and in inflammation, and how these cells interact with one another, as well as with the intestinal microenvironment, to shape mucosal immune responses. We describe mechanisms of maintaining intestinal immune tolerance in the steady state but also inappropriate responses of APC to components of the gut microbiota that contribute to pathology in IBD.

INTRODUCTION

Dendritic cells (DC), macrophages (MΦ) and B-cells comprise heterogeneous populations of cells, known as “professional antigen-presenting cells (APC)” due to their specialization in antigen presentation. APC are critical for initiating, maintaining and shaping T-cell mediated immune responses. DC are unique in their ability to drive primary T-cell responses (reviewed in^[1,2]), but MΦ and B-cells can polarize effector T-cell responses^[3-5]. All three types of APC also have other critical roles in both innate and adaptive immunity; at intestinal sites, a combination of these functions and crosstalk between APCs enable them to be critical for maintenance of immune homeostasis in the gut.

The gastrointestinal tract is in contact with a huge amount of antigens, including a diverse commensal microbiota, food antigens and also potentially pathogenic microbes. As effector cells of both innate and adaptive immune responses, DC, MΦ and B-cells are central to not only maintaining protective immunity against pathogens but also preventing inflammatory intestinal immune responses against the microbiota and food antigens (tolerance). The microbiota is recognized by pattern recognition receptors (PRRs) on all three types of APC, including Toll-like receptors (TLRs; reviewed in^[6]). Similar effector functions to those involved in protective immunity against pathogens are engaged during inappropriate inflammatory responses against harmless antigens, such as those seen in inflammatory bowel disease (IBD). IBD, including Crohn’s disease (CD) and ulcerative colitis (UC), is thought to result from a dysregulated intestinal immune response to the gut microbiota^[7] resulting in a breakdown in mucosal tolerance. Given the huge antigenic load in the normal healthy intestine, APC in the steady state maintain a tolerogenic or hyporesponsive state, giving these cells crucial roles in maintaining mucosal homeostasis. In this review, we discuss the different roles of the three “professional” APC: DC, MΦ and B-cells, in intestinal immune tolerance and inflammation, and how these APC interact with one other to shape their function and contribution to mucosal immune homeostasis.

ANTIGEN PRESENTING CELLS AND INTESTINAL HOMEOSTASIS

Dendritic cells

DC stimulate primary T-cell responses and determine whether these T-cell responses generated are immunogenic (*e.g.*, against invading pathogens) or tolerogenic (*e.g.*, against commensal bacterial antigens)^[1,2]. The primary function of intestinal DC is to transport antigens into secondary lymphoid tissue [mesenteric lymph nodes (MLN) and Peyer’s patches (PP)] and subsequently generate antigen-specific intestinal T-cell responses. Intestinal DC from the gut lamina propria (LP) transport intestinal bacterial antigens into MLN^[8,9] and are essential for inducing oral tolerance to food antigens^[10].

Intestinal DC in the steady state are generally hyporesponsive^[11] and maintain immune tolerance in the gut by generation of tolerogenic T-cell responses^[12,13] towards food antigens and commensal bacteria, preventing unnecessary inflammation and hypersensitivity. Although distinguishing DC from MΦ in the gut can be difficult, intestinal DC in mice can be identified as CD11c^{hi}MHC Class II⁺CX3CR1⁺F4/80⁻ cells and further subdivided into DC subsets expressing combinations of CD11b, CD103 and CD8α^[14]. Although previous studies suggested a subset of DC exist expressing CX3CR1, the receptor for the chemokine fractalkine, mononuclear phagocytes in the gut mucosa expressing CX3CR1 also express the pan-MΦ marker F4/80 and tissue macrophage marker CD68^[15]. Subsequent studies confirmed that all CX3CR1^{hi} cells in the gut are indeed MΦ^[16]. DC can also be distinguished from MΦ in both mice and humans on the basis of CD64 expression, with DC being CD64^[17].

Several intestinal DC subsets contribute to regulatory T-cell (T-reg) generation in mice. These include CD8α⁺ DC that promote T-reg generation in the presence of transforming growth factor (TGF)-β^[18,19], and CD103⁺ DC. CD103 (αE integrin) is expressed by the majority of DC in the murine intestinal LP^[20]; these DC are migratory and travel to the MLN *via* the afferent lymph^[21-23]. In the steady state, this constitutive migration of CD103⁺ DC from the LP to the MLN establishes T-cell responses specific for harmless luminal antigens, and is essential for the establishment of oral tolerance^[10,13,21,24]. The ability of CD103⁺ DC to synthesize retinoic acid (RA)^[25,26], which enhances generation of gut-homing T-reg at the expense of Th17 cells^[25-28], is one of the key mechanisms by which CD103⁺ DC participate in immune tolerance in the gut. Human studies indicate DC from MLN maintain some of the unique tolerogenic properties of murine intestinal CD103⁺ DC^[21,29]. Furthermore, CD103⁺ DC from the LP in both mice and humans express indoleamine 2,3-dioxygenase (IDO), an enzyme involved in the ability to drive T-reg development, is required for the establishment of immune tolerance in the gut^[30]. Plasmacytoid DC (pDC) are also key participants in oral tolerance^[31] likely to be due to their expression of IDO.

Intestinal CD103⁺ DC can be subdivided into two major subsets; CD103⁺CD11b⁺ and CD103⁺CD11b⁻ DC^[32]. CD103⁺CD11b⁺ DC stimulate Th17 and Th1 cell differentiation^[33,34], whilst CD103⁺CD11b⁻ DC can drive Th1 polarisation and IFNγ-production from CD8⁺ T-cells^[34,35]. However, other studies have shown both CD103⁺ subsets can generate T-reg responses^[36]. Interpretation of the regulatory function of these intestinal subsets is further complicated by the fact that mice lacking either CD103⁺CD11b⁺^[33,37] or CD103⁺CD11b⁻ DC^[38] have normal numbers of intestinal FoxP3⁺ T-reg. CD103⁺CD11b⁺ intestinal DC are also potent inducers of both Th17 and Th1 responses, even in the absence of overt stimulation^[35], and a subsequent study using comparative analysis of transcriptomes determined that CD103⁺Sirpα⁺ DC in the human gut are related to murine

CD103⁺CD11b⁻ DC (and human blood CD141⁺ DC), whilst human intestinal CD103⁺Sirpα⁺ DC were related to murine CD103⁺CD11b⁺ DC (and human blood CD1c⁺ DC). In this study, both these human intestinal DC subsets were able to induce Th17 cells, with only CD103⁺Sirpα⁺ supporting induction of T-reg^[39].

MΦ

Intestinal MΦ have various innate functions that enable them to contribute to both immune tolerance *via* selective inertia and contribute to protective immune responses and inflammation in other circumstances^[15]. Tissue MΦ do not usually migrate to lymphoid tissue, but can contribute to adaptive immune responses by presenting processed antigen to effector T-cells *in situ* in the LP^[3,4]. Although intestinal MΦ share expression of MHC Class II, CD11c and CD11b with DC, F4/80, CD68 and CD64 can be used to identify MΦ in the gut. It has also now evident that all CX3CR1^{hi} mononuclear phagocytes are MΦ^[16], although a subset of inflammatory, migratory CD103⁻ DC expressing intermediate levels of CX3CR1 has recently been identified^[23].

Resident intestinal MΦ express low levels of co-stimulatory molecules including CD80, CD86 and CD40^[34-38], and like intestinal DC, are hyporesponsive to stimulation by TLR ligands^[12,35,39,40] in the steady state. MΦ in the gut also contribute to maintaining intestinal immune tolerance by constitutively producing the anti-inflammatory cytokine interleukin (IL)-10^[39,40]. Perhaps the most striking role for intestinal MΦ in maintaining mucosal homeostasis is their role in generation and maintaining survival of T-reg. F4/80 knockout (KO) mice do not develop tolerance or antigen-specific CD8⁺ T-reg normally after being fed soluble antigen^[41]. MΦ secretion of IL-10 plays a key role in maintaining FoxP3 expression on T-reg under inflammatory conditions, essential for maintaining regulatory activity and suppressing colitis^[42]. Furthermore, tolerance induction following feeding with protein antigens in mice was associated with expansion and differentiation of FoxP3⁺ T-reg by IL-10-producing CX3CR1⁺ MΦ in the mucosal LP^[4].

Intestinal CX3CR1⁺ MΦ have recently been subcharacterised; CX3CR1^{hi} MΦ in the steady state represent regulatory MΦ that are resistant to TLR stimulation and produce IL-10 constitutively, whilst a smaller population of cells expressing intermediate levels of CX3CR1 represent cells partially differentiated from Ly6C⁺CCR2⁺ monocytes into regulatory CX3CR1^{hi} MΦ. These CX3CR1^{int} cells represent TLR-responsive, pro-inflammatory MΦ that accumulate during experimental colitis due to arrested differentiation^[16]. This study demonstrated that both resident regulatory MΦ and inflammatory MΦ at intestinal sites are both derived from the same (Ly6C⁺CCR2⁺) precursor, but are at different phases of differentiation.

B-cells

The role of B-cells in intestinal inflammation and im-

mune homeostasis have been underappreciated. B-cells perform several immunological functions; arguably their main function is antibody production, but B-cells also function as APC and secrete cytokines. At intestinal sites, B-cells follow a distinct differentiation pathway and are specialized in IgA production as differentiated plasma cells^[43]. Most intestinal plasma cells secrete IgA^[5]; in the gut lumen, secretory IgA (sIgA) acts as a barrier to protect the epithelium from pathogens. Within the gut lumen, sIgA interacts with intestinal antigens including the intestinal microbiota, food antigens and self antigens^[44]. In such a manner, sIgA limits access of intestinal antigens into the bloodstream, and is able to control the intestinal microbiota^[5]. The sIgA system in the gut is tightly integrated with both innate and adaptive immune mechanisms, contributing towards intestinal immune homeostasis. For example, sIgA can limit innate responses against commensal bacteria^[45] whilst also functioning to influence adaptive T-cell responses^[46]. Several regulatory compounds involved in intestinal tolerance also promote IgA secretion, including IL-10, TGFβ and RA^[43].

The antigen-presenting function of B-cells enables them to interact with T-cells directly to polarize effector T-cell responses^[47] (although they are not capable of inducing primary responses). Several disease models demonstrate that IL-10 produced by B-cells is important for the generation of mucosal T-reg^[48-51]. However, IL-10 produced by DC and MΦ is also important in T-reg generation^[42,52], and alone is not sufficient to induce T-reg directly; cognate T-cell/B-cell interactions are also required, mediated by co-stimulatory molecules CD80 and CD86^[53,54].

IL-10-producing B-cells with suppressive capacity are known as regulatory B-cells (B-reg) and can suppress experimental colitis^[55-57]. A subset of B-reg can also produce regulatory cytokine TGFβ in response to antigenic stimulation^[58-60], demonstrating an important role for B-cells in avoiding inappropriate responses to the intestinal microbiota and food proteins. Indeed, functional impairment of this subset of TGFβ-producing B-cells is associated with food allergy pathogenesis^[58-60]. It has recently been demonstrated that a subpopulation of B-cells carries the integrin α_vβ₆ (not endogenously expressed) which is able to convert latent TGFβ into its active form. These cells also expressed CX3CR1, had high levels of TGFβ, generated T-reg, suppressed T-cell activation and inhibited food allergy symptoms^[61]. This study suggests CX3CR1⁺ B-cells carrying α_vβ₆ may represent the TGF-β producing B-reg described in the studies above.

INAPPROPRIATE ANTIGEN-PRESENTING CELL RESPONSES TO MICROBIOTA AND INFLAMMATION

Despite playing essential roles in intestinal immune tolerance, APC are likely to be of fundamental importance in the pathogenesis of T-cell mediated inflammation in the

gut; all APC can influence T-cell responses directly and can secrete both pro- and anti-inflammatory cytokines. IBD is thought to result from a dysregulated immune response and breakdown of tolerance to the gut microbiota^[7,62,63]. The intestinal microbiota is essential for development of colonic inflammation in most murine models of colitis^[64], although in the steady state the gut microbiota functions to reduce bacterial trafficking to MLN by mononuclear phagocytes to downregulate inflammatory responses and autoimmunity^[65]. Analysis of the intestinal microbiota of IBD patients demonstrates decreased biodiversity, with decreased proportions of Firmicutes but increased proportions of Gammaproteobacteria^[66]. It is currently unclear whether intestinal dysbiosis in IBD patients contributes to or is a consequence of inflammation but the interplay between the host and the microbiota actively shapes intestinal homeostasis and contributes to IBD pathology. This provides a role for all APC in IBD pathogenesis due to their bacterial recognition properties *via* PRR expression. The ability of DC and M Φ to sample antigens from the gut lumen, and ability of B-cells to produce sIgA that modify immune responses to luminal antigens suggests APC play important roles in dysregulated immunity in IBD. Expression of TLRs on DC^[67,68], M Φ ^[69-71] and B-cells^[72] are upregulated in animal models of colitis and human IBD, potentially contributing to enhanced or inappropriate responses to luminal bacterial antigens.

Intestinal dendritic cells in gut inflammation

As the only cells capable of driving primary T-cell responses^[73], intestinal DC would be expected to play an important role in T-cell dominated inflammatory diseases at intestinal sites, such as IBD. For example, animal models of colitis provide strong evidence that interactions between the intestinal microbiota and intestinal DC are essential for IBD pathogenesis^[63,74]. Activated DC accumulate throughout the LP and MLN in colitis^[75-77]; intestinal DC present during inflammation may be derived from newly recruited precursors^[78], although it is likely that tissue-resident *in situ* DC can also generate inflammatory responses. Therefore, intestinal DC are likely to play both protective and pathogenic roles in intestinal immunity, fitting with their functional plasticity in their ability to generate either inflammatory or tolerogenic immune responses. In murine DSS-induced colitis, DC ablation during DSS administration ameliorated disease manifestation, but colitis was exacerbated if DC were ablated before DSS treatment^[79]. In a T-cell transfer model of colitis induced by CD45RB^{hi}CD4⁺ T-cells, transplanted T-cells formed aggregates with sub-epithelial CD11c⁺ DC in the MLN^[80]. Furthermore, colitis was associated with increased CD11c⁺ DC in MLN, and blocking OX40-OX40L interactions between DC and T-cells prevented the development of colitis^[81]. In human IBD activated DC also accumulate at sites of intestinal inflammation^[82-84]. Some human studies have shown an increase in number and maturation of DC within inflamed IBD tissue^[85], but others suggest en-

hanced recruitment of immature DC into inflamed tissue associated with increased expression of chemokine CCL20 in the intestinal epithelium^[86]. CCL20 may therefore regulate attraction of DC (and T-cells) in IBD.

The specific microenvironment of the gut, including microbes, various types of intestinal cells such as epithelial cells, and active cellular mediators can dynamically shape the properties and functions of DC. For example, human blood DC express both skin and gut homing markers; however, they lost homing marker expression when cultured *in vitro*. Conditioning of human enriched blood DC with colonic biopsy extract induced a gut-homing phenotype and a homeostatic profile, mediated by retinoid acid and TGF β , respectively^[87]. In UC patients, circulating DC displayed a reduced stimulatory capacity for T cells and enhanced expression of skin-homing markers CLA and CCR4 on stimulated T cells that were negative for gut-homing marker β 7; and this dysregulation of DC could be partially restored by probiotic bacterial strain *Lactobacillus casei* Shirota^[88].

Bacterial recognition by dendritic cells and gut-homing

An important function of DC is their ability to imprint homing properties on T-cells and B-cells, in order to localize immune responses to a particular tissue^[89-92]. Murine intestinal DC specifically imprint gut-homing molecules α 4 β 7 and CCR9 on T-cells and B-cells from different sources, thus targeting lymphocytes to intestinal tissue^[89-91]; this gut-specific imprinting property of DC is confined to the CD103⁺ “tolerogenic” intestinal DC subset. T-cells imprinted with gut-homing capacities in such a manner are T-regs, linking gut-homing with intestinal immune tolerance. Furthermore, CD103⁺ DC induce B-cell class switching to IgA-producing cells with known tolerogenic properties, alongside imprinting gut-homing properties^[20,93,94]. These functional properties of CD103⁺ DC are dependent on RA and TGF β ^[39,95,96]. A loss of CD103⁺ DC from inflamed murine intestine has been reported^[97,98], suggesting the increased DC infiltrates in colitis/IBD represent alternative inflammatory DC subsets. Further evidence to link gut-homing and intestinal immune tolerance was provided by studies showing that expression of gut-homing markers α 4 β 7 and CCR9 on T-cells is essential for induction of oral immune tolerance in mice^[99]. Both CCR9 and α 4 β 7 expression on DC also confer tolerogenic properties^[98,100,101], and a loss of α 4 β 7⁺ DC impairs induction of IL-10-producing T-regs and accelerates T-cell mediated colitis^[98].

MyD88 is an essential intracellular signaling adapter for most TLR signals^[102], which are induced in APC following bacterial recognition. MyD88-dependent TLR signaling in DC specifically enables them to imprint gut-specific homing properties *via* an increased RA synthesizing capacity^[103]. In this study, TLR stimulation was sufficient to educate extraintestinal DC with gut-homing imprinting capacity providing a crucial role for the microbiota in shaping gut DC function in intestinal homeostasis. Although it is unclear whether the intestinal dysbiosis in

IBD patients is a cause or a result of intestinal inflammation^[66], it is likely that such alterations in bacterial populations will have knock on effects on gut DC function in tolerance and immunity, perhaps disrupting the delicate balance that is maintained in the healthy gut and further contributing to pathology.

Intestinal macrophages and B-cells in inflammation

Intestinal MΦ and B-cells can contribute to adaptive immune responses by presenting processed antigen to effector T-cells *in situ* in the LP^[3,4,47], and polarizing effector T-cell responses, thereby providing a role for MΦ and B-cells in IBD pathogenesis. Properties of intestinal MΦ are strikingly different in inflammation compared with the steady state. Under inflammatory conditions, MΦ infiltration into intestinal sites of inflammation occurs; these MΦ express high levels of TLRs, co-stimulatory and inflammatory receptors^[35,37,69,104], and produce large quantities of pro-inflammatory cytokines and mediators^[104-108]. Inflammatory MΦ in the murine intestine are derived from Ly6C⁺ monocytes; CCR2 is essential for recruitment of these Ly6C⁺ monocytes to sites of inflammation and in an inflammatory context, these monocytes upregulate expression of TLR2 and NOD2, suggesting an enhanced responses to the microbiota and bacterial products^[70]. Although this study actually suggests these inflammatory monocyte precursors develop into CX3CR1⁺ regulatory DC, concurrent studies have shown Ly6C⁺CCR2⁺ monocytes differentiate into regulatory CX3CR1^{hi} MΦ but that in colitis, there is accumulation of inflammatory Ly6C⁺CX3CR1⁺, TLR-responsive, pro-inflammatory semi-mature MΦ arising from arrested differentiation^[16]. The upregulated expression of TLRs on both inflammatory monocytes and macrophages during intestinal inflammation strongly suggests interactions of these cells with the microbiota and bacterial products play a key role in IBD.

B-cells can also present antigen to effector T-cells in the LP, but their unique antibody-secreting function enables B-cells to directly control the intestinal microbiota *via* sIgA^[5]. Due to the regulatory function of IgA in contributing to maintenance of epithelial barrier function^[109,110], aberrations in the mucosal IgA system are likely to be part of IBD pathogenesis. However, IgA has been reported to play a pathogenic role in the pathogenesis of other gut-based inflammatory disorders, including Coeliac disease^[111]. Although production of sIgA directly links B-cells to immune regulation and homeostasis, their role in IBD is unclear due to their other cytokine- and chemokine-producing functions. Intestinal B-cells in IBD are increased^[112] and highly activated, producing chemokines including Eotaxin-1, leading to acute eosinophilia^[113]. Furthermore, a loss of anti-inflammatory IL-10 production by B-cells in IBD has been reported^[114] alongside unusual B-cell morphology^[115], changes in DNA methylation^[116] and other B-cell gene alterations^[117]. However, the role of B-cell in IBD pathogenesis is unclear and warrants further investigation.

ANTIGEN-PRESENTING CELL CROSSTALK

As established, DC, MΦ and B-cells have critical roles both in maintaining mucosal immune tolerance to the gut microbiota and food antigens, but also in driving inflammatory responses that can be protective in healthy individuals, but detrimental in IBD. Although each type of APC exhibits unique functions allowing them to participate in gut immunity, with knock on effects on adaptive T-cell responses, APC can also interact with one another to directly shape immune responses generated. DC in particular are at the centre of virtually all multi-cellular signalling networks underlying intestinal immune homeostasis^[118].

Activation of intestinal B-cells by dendritic cells and macrophages

The interplay between innate immunity and B-cells at the intestinal mucosal interface play a key role in maintaining mucosal immune homeostasis^[119]. Although DC are usually described for their ability to prime T-cell responses, DC can also directly activate B-cells^[120,121], present unprocessed antigens to B-cells^[122,123] and influence the differentiation and survival of antibody-secreting cells^[124]. Intestinal DC release powerful B-cell stimulating factors including BAFF and APRIL^[125,126]; pDC in particular induce IgA production by B-cells in the gut, independently of T-cells, in this manner. In the steady state, this process is dependent on stromal cell-derived type I IFN signalling^[127]. Macrophages also release BAFF at levels sufficient to potently induce B-cell proliferation^[128]. BAFF and APRIL promote survival of B-cells and plasma cells but also activate IgA production^[129-134]. Intestinal DC and MΦ also produce IgA-inducing cytokines including IL-10 and TGFβ^[39,118,135]. Some intestinal DC can also produce IL-6, which is a cytokine implicated in the differentiation of IgA class-switched B-cells into IgA class-switched plasma cells^[124,136]. Alongside directly shaping B-cell responses, gut DC induce expression of gut-homing receptors CCR9 and α₄β₇ by B-cells^[94].

RA is essential for induction of gut-homing receptors on B-cells^[94], as is the case for T-cells^[137]. The IgA promoting effects of gut DC is at least partially dependent on RA and TGFβ^[94,138,139] and intestinal MΦ also secrete RA/TGFβ^[39]. A key question that remains unanswered is whether intestinal MΦ can also imprint tissue homing properties on B-cells and directly promote IgA class switching, properties that are both dependent on the presence of RA. Secretion of RA by intestinal DC and MΦ is dependent upon their expression of retinal dehydrogenases, which are critical for RA synthesis^[25,137-139]. The expression of these enzymes by intestinal DC is restricted to CD103⁺ DC^[25,140], and CD103⁺ intestinal DC do indeed promote IgA synthesis by gut-homing B-cells^[138]. Studies have since demonstrated that follicular DC also promote IgA generation in the gut in response to bacterial stimuli, and express key factors for B-cell mi-

Table 1 Summary of information available regarding classification of gut antigen-presenting cells, primary functions of gut antigen-presenting cells and their effects on T-cells, tolerogenic and inflammatory properties of antigen-presenting cells at intestinal sites, and effects of immunomodulation of gut antigen-presenting cells by the microbiota

| Classification | Dendritic cells | Macrophages | B-cells |
|---------------------------------|---|--|---|
| | Mice: CD11c ^{hi} MHC Class II ⁺ CX3CR1 ^{med} F4/80 ⁻ CD64 ⁻ . Subsets based on CD11b, CD103 and CD8 α expression Humans: HLA-DR ⁺ Lineage cocktail (CD3/CD14/CD16/CD19/CD34). Subsets based on CD103, CD11c, CD1c, CD141 and CD123 expression | Mice: CD11c ⁺ MHC Class II ⁺ F4/80 ⁺ CD68 ⁺ CD64 ⁺ CX3CR1 ^{hi} Subsets based on levels of expression of CX3CR1. Ly6C ⁺ in inflammation Humans: HLA-DR ⁺ CD11c ⁺ CD64 ⁺ CD68 ⁺ Some CX3CR1 expression | CD19 ⁺ CD20 ⁺ CD79a ⁺ Immature B-cells: ⁺ CD20 Plasma (antibody secreting) cells: CD38 ⁺ CD138 ⁺ |
| Primary function | Antigen sampling Migration to secondary lymphoid tissue and stimulation of naïve T-cells to generate primary T-cell responses | Antigen sampling Phagocytosis of apoptotic cells, bactericidal activity, production of anti-inflammatory IL-10 | Antibody secretion as differentiated plasma cells (mainly IgA in the gut) |
| Effects on T-cells | Determine whether primary T-cell responses are immunogenic or tolerogenic, imprint gut-homing receptors on T-cells during stimulation | Contribute to effector T-cell responses <i>in situ</i> in the lamina propria, including expansion and differentiation of T-regs <i>via</i> IL-10 production | Contribute to effector T-cell responses <i>in situ</i> in lamina propria and also induce differentiation of T-regs <i>via</i> both IL-10 production and direct interaction |
| Tolerogenic properties/subsets | CD103 ⁺ CD11b ⁻ DC generate RA for T-regs/IgA secretion by B-cells, and imprinting gut-homing properties on lymphocytes. CD8 α ⁺ DC and pDC generate T-reg Gut DC in general are hyporesponsive to TLR stimulation | CX3CR1 ^{hi} M Φ produce IL-10 critical for T-reg generation Hyporesponsive to TLR stimulation | IgA production limits immune responses against commensal bacteria Regulatory B-cells produce IL-10, induce differentiation of T-regs and also produce TGF β |
| Inflammatory properties/subsets | TLR ^{hi} gut DC in IBD likely to contribute to enhanced inappropriate responses to the microbiota Infiltrates of CD103 ⁻ DC in inflammation CD103 ⁺ CD11b ⁺ can polarise inflammatory Th17 responses | TLR ^{hi} M Φ in colitis and IBD also likely to contribute to enhanced inappropriate responses to the microbiota Ly6C ⁺ CX3CR1 ⁺ inflammatory macrophages arise from arrested differentiation in colitis | TLR ^{hi} B-cells enhanced in IBD Eotaxin-1 producing B-cells enhanced in IBD CD15 ⁺ B-cells with functional surface IgM enhanced in IBD |
| Modulation by gut microbiota | Direct modulation by microbiota Commensal bacteria can induce iNOS ⁺ TNF ⁺ DC that promote IgA responses Commensal bacteria induce regulatory cytokine production by DC, such as IL-10 and TGF β , and also regulatory mediator RA | Direct modulation by microbiota CX3CR1 ⁺ M Φ directly sample luminal antigens; this process is dependent on the microbiota | Indirect modulation by microbiota DC and M Φ sampling commensal bacteria induce IgA production by B-cells <i>via</i> BAFF and APRIL release, and production of IgA-inducing cytokines IL-10 and TGF β |

TGF β : Transforming growth factor beta; TNF: Tumor necrosis factor; DC: Dendritic cells; M Φ : Macrophages; IL-10: Interleukin 10; T-reg: Regulatory T cells; TLR: Toll-like receptors; pDC: Plasmacytoid DC; RA: Retinoic acid; HLA: Human leukocyte antigen; IBD: Inflammatory bowel disease.

gration and survival. However, this process is dependent on the presence of exogenous RA^[141].

Regulatory effects of DC/B-cell interactions are not restricted to induction of IgA production by B-cells; B-cell conversion into immunosuppressive B-cells (regulatory B-cells) is partially dependent on DC production of RA^[142]. However the *in vivo* effects of intestinal DC and M Φ on conversion of gut-specific regulatory B-cells is unknown. Crosstalk between intestinal DC and B-cells can also lead to active immunity as well as regulatory immune responses; murine CD11b⁺ CD11c⁺ DC from the small intestine lamina propria express TLR5 and respond to flagellin from flagellated bacteria by inducing IgA⁺ plasma cells and antigen-specific Th17 and Th1 subsets to generate protective immunity^[138]. Crosstalk between gut DC/M Φ is bidirectional; immunoglobulins secreted by B-cells can have a direct effects on DC differentiation and activation^[143,144], though this process at intestinal sites has not been described in detail.

Role of the gut microbiota in antigen-presenting cell crosstalk

In response to pathogenic bacteria or the commensal

microbiota, APC contribute to both innate and adaptive immune responses that can be either immunogenic or tolerogenic through TLR stimulation^[11,145]. TLR-dependent activation of DC in particular can determine protection or immune tolerance that maintains immune homeostasis at intestinal sites^[146,147]. Commensal bacteria can induce intestinal iNOS⁺/TNF⁺ DC that, in the intestinal lamina propria, promote IgA responses by releasing BAFF and APRIL in response to nitric oxide^[148]. These DC may also enhance IgA responses in Peyer's patches by upregulating expression of TGF β receptor type II on follicular B-cells^[148]. IgA-inducing cytokines including IL-10 and TGF β are secreted by DC and M Φ in response to microbial TLR ligands^[118,156]. Gut DC also produce RA and IL-6 in response to microbial TLR ligands^[94,136] which have direct effects on both B-cell secretion of IgA and imprinting gut-homing markers on B-cells^[94], as mentioned above.

Non-migratory APC expressing CX3CR1, likely to be M Φ ^[15], continuously sample antigens by extending transepithelial projections without disrupting tight junctions^[149]; CX3CR1⁺ APC may be able to directly present commensal antigens to subepithelial B-cells^[43,47]; Murine

intestinal APC initiate production of commensal reactive IgA by presenting commensal bacterial antigens to B-cells^[9,150]. It is likely that CX3CR1⁺ APC transfer antigen to CD103⁺ migratory DC prior to DC migration to secondary lymphoid tissue to prime tolerogenic T-cell responses towards the microbiota^[15]. Commensal bacteria play a critical role in antigen sampling by CX3CR1⁺ APC as antibiotic treatment reduces the number of transepithelial projections^[145,151]. However, it has recently been shown that CX3CR1^{hi} cells can migrate to MLN and traffic *Salmonella* antigen to induce T-cell responses and IgA production in the absence of MyD88 or following antibiotic treatment^[65]. In this study, MyD88-dependent recognition of commensal bacteria in the gut reduced bacterial trafficking to MLN by CX3CR1^{hi} APC to down regulate excess inflammation and autoimmunity.

A subset of intestinal pDC expressing TLR7 and TLR9 are capable of producing high levels of type I IFN^[152] which in turn promotes not only maturation and differentiation of myeloid DC, but also class-switching of antibodies produced by B-cells^[153] (Table 1).

CONCLUSION

DC, MΦ and B-cells are professional APC that are fundamental components of both the innate and adaptive immune system in the gut; their plasticity allows these cells to function in an environment where they are constantly exposed to the commensal microflora and food antigens, but can also be exposed to harmful pathogens. Intestinal APC are individually specialized to perform specific functions but their role in shaping both primary and secondary T-cell responses, including generation and differentiation of T-regs, highlights their importance in intestinal immune homeostasis and IBD pathogenesis. APC function in the gut is in turn directly shaped by the microbiota. Furthermore, crosstalk between APC is essential for intestinal immunity and tolerance. Clarification and a better understanding of the functions of intestinal APC subsets, especially in humans, may provide novel therapeutic targets for manipulating mucosal immunity and tolerance, leading to new and more effective treatment for IBD.

Abstract

Restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA) has become the surgical treatment of choice for many patients with medically refractory ulcerative colitis (UC) and familial adenomatous polyposis (FAP). UC patients with IPAA (UC-IPAA) are, nevertheless, susceptible to inflammatory and noninflammatory sequelae such as pouchitis, which is only rarely noted in FAP patients with IPAA. Pouchitis is the most frequent long-term complication of UC-IPAA patients, with a cumulative prevalence of up to 50%. Although the aetiology of pouchitis remains unclear, accumulating evidence suggests that a dysbiosis of the pouch microbiota and an abnormal mucosal immune response are implicated in its pathogenesis. Studies using culture and molecular techniques have detected a dysbiosis of the pouch microbiota in patients with pouchitis. Risk factors, genetic associations, and serological markers suggest that interactions between the host immune response and the pouch microbiota underlie the aetiology of this idiopathic inflammatory condition. This systematic review focuses on the dysbiosis of the microbiota

that inhabit the pouch in UC and FAP patients and its interaction with the mucosal immune system. A meta-analysis was not attempted due to the highly heterogeneous microbiota composition and the different detection methods used by the various studies. Although no specific bacterial species, genus, or family has as yet been identified as pathogenic, there is evidence that a dysbiosis characterized by decreased gut microbiota diversity in UC-IPAA patients may, in genetically predisposed subjects, lead to aberrant mucosal immune regulation triggering an inflammatory process.

Key words: Pouchitis; Inflammation of the ileal pouch; Microbiota; Bacteria; Microbiome; Ileal-pouch-anal anastomosis; Ulcerative colitis; Crohn's disease; Inflammatory bowel disease

Core tip: This is a systemic review assessing the relationship between the microbiota that inhabit the ileal-anal pouch following restorative proctocolectomy in ulcerative colitis and familial adenomatous polyposis patients and the inflammatory response that can occur. A meta-analysis was not attempted in view of the highly heterogeneous microbiota composition and the different detection methods utilized. Although no specific bacterial species, genus, or family has as yet been identified as pathogenic, there is evidence that dysbiosis and reduced bacterial diversity of the microbiota found in ulcerative colitis patients who have undergone restorative proctocolectomy may, in genetically predisposed subjects, lead to aberrant mucosal immune regulation triggering an inflammatory process.

INTRODUCTION

About 20%-25% of patients with ulcerative colitis (UC) require a colectomy at some point in their lives, and in most cases the operative surgical procedure chosen is a restorative proctocolectomy (RPC) with ileal pouch-anal anastomosis (IPAA)^[1,2]. Diseased colonic/rectal tissue is removed during the procedure, and transanal fecal continence is maintained by creating an ileal pouch. Although effective, inflammation of the ileal pouch (pouchitis) is a common complication, with almost 50% of patients experiencing an acute episode within 5 years and about 5% of those going on to develop chronic inflammation^[1-5]. The cumulative incidence of pouchitis in patients who undergo an IPAA for familial adenomatous polyposis (FAP) is much lower, ranging from 0% to 10%^[6]. Reasons for the higher frequency of pouchitis in UC remain unknown.

Common clinical symptoms in patients with pouchitis include increased bowel movements, abdominal pain/cramping, urgency, incontinence, generalized fatigue/malaise, fever, and, occasionally, bloody stools. The diagnosis of pouchitis is based on assorted clinical, endoscopic, and histologic findings, including endoscopic and microscopic evidence of inflammation of the ileal pouch^[7]. In the absence of evident signs of inflammation of the terminal ileum, fecal lactoferrin, or calprotectin (mucosal inflammation markers) can help to distinguish pouchitis from irritable pouch syndrome^[8]. Once diagnosed, disease activity can be quantified using the pouchitis disease activity index (PDAI), which takes into consideration clinical findings, histology, and laboratory parameters^[9].

Histological features of pouchitis can also be non-specific, including acute inflammation with polymorphonuclear leukocyte infiltration, crypt abscesses, and ulceration in association with a chronic inflammatory infiltrate^[7,10]. A discrepancy between endoscopic and histologic findings, possibly linked to sampling errors, has been noted in patients with pouchitis^[11,12]. Morphological alterations of the epithelium lining the ileal pouch, characterized by flattening and a reduced number or complete disappearance of the villi leading to villous atrophy (colonic metaplasia), normally develop within 12-18 mo after ileostomy closure^[10,12]. Although a causal association has not been proven, once colonic metaplasia has developed in the pouch, pouchitis may occur^[13].

In accordance with Mahadevan and Sandborn's definition, the pattern of pouchitis is classified as infrequent (1 or 2 acute episodes), relapsing (3 acute episodes), or continuous. Recurrent pouchitis is defined, according to this classification, as relapsing (more than two episodes) or chronic^[13]. Chronic pouchitis is usually refractory to medical therapy and/or requires maintenance therapy, and may lead to pouch excision and permanent terminal

ileostomy^[13]. Risk factors linked to pouchitis include extensive UC^[2,14], backwash ileitis^[14], extraintestinal manifestations, chiefly primary sclerosing cholangitis^[15-17], being a non-smoker, and regular use of nonsteroidal anti-inflammatory drugs^[18,19].

Genetic polymorphisms in interleukin-1 receptor antagonist (IL-1Ra) or the presence of perinuclear neutrophil cytoplasmic antibodies^[20] have also been associated with pouchitis. Although definitive proof is still lacking^[21], indirect evidence from clinical practice supports the hypothesis that the pouch microbiota (*i.e.*, a microbial imbalance) plays an important role in the pathogenesis of pouchitis^[22,23]. It has been seen, in fact, that mucosal inflammation is localized in the area of the gut characterized by the highest bacterial concentrations^[24] and is limited to the mucosal surface^[25]. Short-term, oral antibiotic therapy (*i.e.*, metronidazole or ciprofloxacin)^[4,26] has been reported to be an effective treatment for both pouchitis and pre-pouch ileitis in up to 87.5% of patients^[27,28]. Probiotics have also been shown to reduce disease relapse and the risk of disease onset^[29]. Findings on risk factors, genetic associations, and the serological markers of pouchitis all seem to point to the conclusion that host immune responses and pouch microbiota interactions trigger this idiopathic inflammatory condition^[30].

SEARCH STRATEGY

Inclusion and exclusion criteria

Studies focusing on the analysis of the gut microbiota following IPAA in patients with UC or FAP were eligible for inclusion. Studies examining pouch disease were also included, with microbiota analysis being carried out in at least 10 patients. Studies or case reports dealing exclusively with operative or postoperative management or referring to fewer than 10 patients following IPAA were excluded. Studies reporting on partial analysis of the microbiota or on patients with anastomosis for Crohn's disease (CD) were also excluded. Only studies providing information on analysis of the entire bacterial microbiota were included. Whenever publications reporting on overlapping patient data were being considered, only the most complete and recent set of data were included.

Search strategy

With the assistance of a clinical librarian, two researchers (Angriman I and Scarpa M) consulted Medline, the Embase Medical Database, the Cochrane Database of Systematic Reviews, and the Cochrane Central Register of Controlled Trials (CENTRAL) for studies concerning ileal pouches carried out between January 1978 (publication date of the first manuscripts on RPC) and October 2013. The keywords and Medical Subject Headings (MeSH) used were "pouchitis OR chronic pouchitis OR acute pouchitis OR inflammation of the ileal pouch AND microbiota OR bacteria OR microbiome". Only clinical studies in English, Dutch, Spanish, German, French, and/or Italian were considered. A manual cross-reference

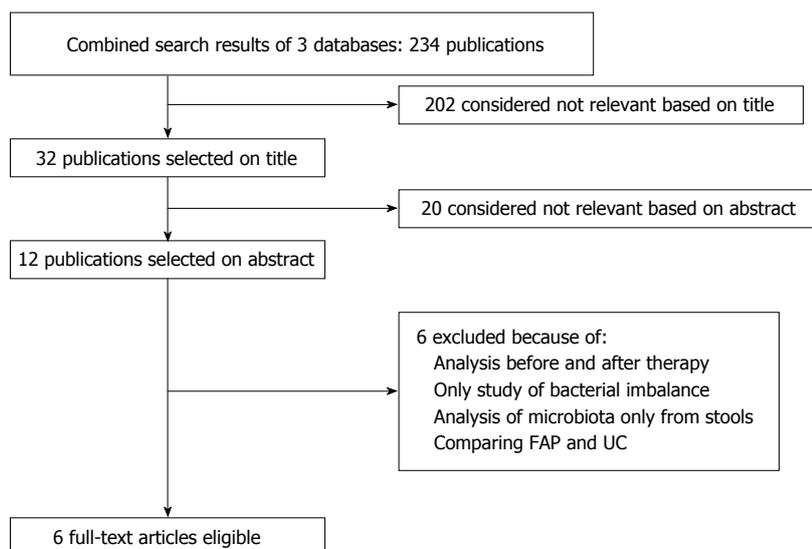

Figure 1 Flow diagram of literature review, eligibility determination, and inclusion in the systematic review and meta-analysis. FAP: Familial adenomatous polyposis; UC: Ulcerative colitis.

search for qualified papers was also carried out to identify additional relevant articles, and the resulting studies that were compatible with the inclusion criteria were evaluated independently. Unpublished data or findings published in abstracts were not taken into consideration. A negotiated agreement was reached between the two researchers whenever there was discordance regarding study inclusion.

Data extraction

Only data from original articles were extracted using a preformatted sheet with spaces for the following parameters: demographic data, pouchitis symptoms, presence of GI bleeding, frequency of bowel movements, abdominal pain, PDAI score, and endoscopic and histological diagnoses (Figure 1).

STATISTICS

Review Manager 4.2 software (The Cochrane Collaboration, Copenhagen: The Nordic Cochrane Centre, 2003) was used for all statistical analyses. A meta-analysis was not attempted due to the highly heterogeneous microbiota composition and the different detection methods used.

POUCH BACTERIOLOGY AND POUCHITIS

The composition of the bacterial microbiota in the terminal ileum differs significantly from that found in the colon^[31,32], and there are likewise significant differences in the microbial composition of the luminal and mucosal compartments of the gut^[33]. Moreover, it is known that the gut microbiota profoundly influences the intestinal mucosa and gut-associated lymphoid tissue^[34]. Although the microbiota that colonizes the mucosal surface usually exercises beneficial trophic, immunomodulatory, and anti-inflammatory effects, an “imbalanced” microbiota can damage the mucosa by producing toxins or triggering ab-

normal immune responses^[35]. Alterations in the intestinal mucosal-associated microbiota have, in fact, been linked to the pathogenesis of several gastrointestinal inflammatory disorders.

Many of the studies concerning the microbiota after IPAA that were carried out prior to the formulation of PDAI in 1994 show inconsistencies in their definition and diagnosis criteria, as well as in the distinction between acute and chronic pouchitis^[9]. In addition, the majority of studies focusing on the pouch microbiota also used culture methods, despite 60%-80% of gut bacterial species being unculturable^[36,37]. Variability in the use of fecal or mucosal samples further contributed to the discrepancies in findings noted in many of these studies.

It is well-established that, within the first year after ileostomy closure, the overall composition of microbiota shows similarities with that of the colon^[38,39]. A number of studies using fecal cultures to evaluate the microbiota of pouches in UC and FAP patients^[40,41] produced conflicting results with regard to the ratio of anaerobic bacteria to aerobic bacteria, total bacterial counts, and sulfate-reducing bacteria^[42] in the pouchitis and in non-pouchitis patients. The high grade of variability in these kinds of studies may be due to the daily variability of stool composition in relation to diet. Moreover, the high frequency of bowel movement in IPAA patients may enhance this variability.

The mucosal-adherent microbiota, which is in close contact with the gut mucosa, has recently been shown^[37,43] to be distinct from the luminal and fecal ones, which are made up of free-living or particle-attached cells. The differences in community structure are probably linked to a number of factors, such as differential substrate availability (mucus *vs* undigested dietary residues), oxygen levels, and host-microbe interactions. In particular, mucosa adherent microbiota may be influenced by drugs. The close proximity of the mucosal-adherent microbiota to the

gut epithelium suggests that these bacteria may be more relevant than the luminal microbiota in the pathogenesis of inflammatory bowel disease (IBD), since they, as well as their excreted products, probably have direct contact with the host^[37]. Moreover, since they live in a mucous environment their populations are more protect, and thus more constant.

The ideal microbiota analysis probably would examine both the fecal and mucosal-adherent microbiota. In fact, fecal microbiota may give a rough but more complete idea of whole bowel microbiota, while mucosa adherent bacteria directly cross-talk with the host and are more likely to be involved in the pathogenesis of pouchitis.

Knowledge about the complexity and diversity of the gut microbiota underwent a radical revision when 16S rRNA techniques were introduced^[31,32], with 16S rRNA gene sequencing results representing gene copy number rather than true bacterial counts. Possibly biased by differential DNA extraction and PCR amplification rates, the methodology represents, nevertheless, the best available option, and is considered the “gold standard” for the analysis of gut-associated complex microbial communities^[44]. Some studies used molecular techniques to show that microbiota that inhabit the ileal-anal pouch differ from that of the normal large intestine. UC pouches with or without pouchitis appear to harbor particularly more unusual microbes. Proteobacteria, which normally account for only a small proportion of the microbiota in the healthy colon^[31] and were found to make up 20% in IBD patients^[32], comprised up to 90% (median = 66.6%) in UC-IPAA patients in one study^[45]. That same study also showed lower than normal proportions of *Bacteroidetes*, *Lachnospiraceae* and *Ruminococcaceae*. A comparison of the two study cohorts revealed that the UC-IPAA patients had increased proportions of the phylum *Proteobacteria* and decreased levels of *Bacteroidetes* with respect to the FAP-IPAA patients.

Consistent with a reduced bacterial diversity observed in both CD^[46] and UC^[47,48], another study demonstrated that there is a significantly lower bacterial diversity in UC-IPAA patients, with or without pouchitis, with respect to FAP-IPAA patients^[49]. However, only minor compositional differences were detected in the microbiota of UC patients with active pouchitis with respect to those with no disease history. The authors of that study hypothesized that dysbiosis predisposes UC patients to pouchitis either by increasing the likelihood of immune system stimulation or by reducing microbiota diversity, which may itself be sufficient to stimulate the immune system, leading to mucosal inflammation. The observation that VSL#3 administration increases bacterial diversity and thus reduces relapse risk^[50] supports the second hypothesis. Zella *et al.*^[45] demonstrated that the microbial environment in the pouches of UC-associated, healthy UC and FAP patients is distinctly different. Using 16S ribosomal gene-based Terminal Restriction Fragment Length Polymorphism (TRFLP) data, those investigators identified significant differences in fecal and mucosal

bacterial communities in the three patient cohorts. Broad differences in TRFLP profiles were further analyzed using DNA sequencing, which revealed multiple significant variations in specific bacterial genera in the pooled fecal bacterial DNA samples in the UC and FAP groups.

Tannock *et al.*^[51] demonstrated that bacteria uncommonly present in the stools of humans in general and in FAP patients in particular comprised about 50% of the microbiota of patients with pouchitis when antibiotic-treated (CP-off = asymptomatic), and that antibiotic treatment reduced the proportion of the unknown bacteria in their feces. Chronic or recurrent pouchitis was therefore found to be associated with microbiota containing bacteria not commonly associated with human feces or FAP pouches. The uncommon bacteria constituting a large proportion of the CP-off but not of the untreated CP-on (symptomatic) microbiota were found to be members of the *Caulobacteraceae*, *Sphingomonadaceae*, *Comamonadaceae*, *Peptostreptococcaceae* and *Clostridiaceae*. At least some of these groups could theoretically be linked to the pathogenesis of pouchitis. The investigators also noted a wide diversity in the clostridial operational taxonomic units in the CP-off microbiota, presumably denoting particularly favorable conditions in the pouch for the expansion of clostridial populations. The authors concluded that *C. perfringens* may play a role in the etiology of pouchitis in some patients.

Although it is not clear if reduced biodiversity causes, perpetuates, or is a result of IBD, other studies have also demonstrated a quantitative and qualitative (biodiversity) reduction in the representation of the Firmicutes phylum, particularly clostridial cluster IV members, in the feces of CD patients. This phylogenetic group contains several butyrate-producing bacteria, such as *Faecalibacterium prausnitzii* (*F. prausnitzii*). Butyrate and other short chain fatty acids are considered important energy sources for colonic epithelial cells, have anti-inflammatory properties, and improve the intestinal barrier function of epithelial cells. A reduction in butyrate-producing bacteria in the colon or pouch might then have an overall detrimental effect on the gut mucosa^[52-56]. Indeed, although *F. prausnitzii* was not detected in chronic pouchitis stool microbiota, low levels were found in FAP and normal pouch feces. Members of the *Lachnospiraceae*, some of which produce butyric acid, were depleted in chronic pouchitis microbiota in FAP and normal pouches (average 33.61% and 21.86%, respectively). The authors reported that normal and FAP pouches showed similar proportions of *Lachnospiraceae* and clostridial cluster IV, indicating that measures of these bacterial groups in the microbiota could be useful biomarkers of pouch health.

In a recent study, we reported that the *Enterobacteriaceae*, *Streptococcaceae*, *Enterococcaceae*, and *Bacteroidaceae* were the most frequent strains of cultivable bacteria adherent to the pouch mucosa, while *Lachnospiraceae*, *Fusobacteriaceae*, *Veillonella*, *Staphylococcaceae*, *Bifidobacteriaceae*, *Eubacteriaceae*, *Bacillaceae*, *Moraxellaceae*, *Burkholderiaceae* and *Corynebacteriaceae* were the least frequent ones. Although

their incidence in the pouch mucosa was similar in the chronic pouchitis and normal pouch groups, we detected a significantly higher incidence of *Clostridiaceae spp.* in the chronic/recurrent pouchitis group compared to that of the normal pouch. The presence of *Clostridiaceae spp.* was found to be an independent predictor of chronic/relapsing pouchitis^[57] at multiple logistic regression analysis. In another study, we found that patients with a clinical diagnosis of pouchitis had a significantly reduced level of *Enterococcaceae spp.* (including bacteria strictly adherent to the pouch mucosa and in the pouch mucous) *vs* those without a clinical diagnosis. Total *Enterobacteriaceae spp.* and *Streptococcaceae spp.* counts in the mucosa were also decreased in patients with clinical pouchitis compared with patients with “healthy” pouches. Our findings indicate that *Bacteroidaceae spp.* and *Clostridiaceae spp.* are more frequently associated with microscopic inflammation of the pouch mucosa and may therefore play a pathogenic role in pouchitis. *Enterococcaceae spp.*, as well as possibly *Enterobacteriaceae spp.* and *Streptococcaceae spp.*, may instead play an active role in maintaining immunologic homeostasis within the pouch mucosa, with low levels feasibly favoring the development of pouchitis^[58].

Zella *et al.*^[45] similarly noted an overall increase in fecal *Clostridium spp.* in UC-associated pouchitis with respect to that in FAP patients. They also noted a reduction in *Bacteroides spp.* in the inflamed pouch with respect to FAP pouches, confirming that a mucosal and luminal dysbiosis exists in pouchitis not only when compared to the healthy UC pouch but also to a non-IBD one.

The overall decrease in the Bacteroidetes phylum in the inflamed pouch is consistent with several studies that included data on the molecular analysis of intestinal microbiota in both CD and UC^[47,59,60]. In line with previous reports, those studies also found that healthy UC pouches differed significantly from FAP ones, leading to the hypothesis that an alteration in the ileal pouch microbiota may be exclusive to the UC disease state, with or without inflammation. In particular, since Bacteroidetes may play a key role in maintaining gut health, a relative reduction in this population may favor inflammation^[45]. In addition, those authors found a significant increase in clostridia, namely among the *Clostridium*, *Lachnospiraceae*, and *Roseburia* genera, in the inflamed pouch. *Roseburia* are flagellated commensal inhabitants of the colon. Flagellin has been shown to induce proinflammatory gene expression by activating toll-like receptor 5 (TLR5); subjects with TLR5 polymorphisms and low levels of anti-flagellin antibodies may be protected from developing CD. Present in 50% of CD and 6% of UC patients, high levels of anti-flagellin antibodies, specifically anti-CBir1 antibodies to flagellin of *Clostridium spp.*, may be associated with the development of pouchitis^[61,62]. Additionally, the mucin-degrading *Akkermansia* genus of the Verrucomicrobia phylum was significantly more prevalent in pouchitis. There are several theories regarding the role of mucin in protecting the intestinal epithelium in IBD, with mutations, alterations, and degradation of mucins being

associated with CD and UC^[63-66].

In conclusion, studies using molecular techniques to analyze the microbiota have confirmed that there is dysbiosis of the pouches of UC-IPAA patients; there are, however, conflicting results with regard to differences in the abundance of particular species and phylotypes associated with pouchitis and in the degree of community diversity of the pouch microbiota (Table 1). As dysbiosis of the gut microbiota could be a pathogenic prerequisite for the idiopathic development of gut inflammation, this would explain the higher frequency of pouchitis in UC-IPAA with respect to FAP-IPAA patients. Although dysbiosis is found in the UC pouch, it may not be the single cause leading to inflammation, but rather a predisposing factor.

POUCH IMMUNE RESPONSES TO BACTERIA

While some investigations have failed to identify a specific microbe as a causative agent^[23], others have stated that they believe sulfate-reducing bacteria, such as *Clostridiaceae spp.*, *Enterobacteriaceae spp.* and *Bacteroidaceae spp.*, might be implicated in the pathogenesis of pouchitis^[67-71]. Our group recently observed that *Clostridiaceae spp.* adherent to pouch mucosa are associated with chronic/relapsing pouchitis while *Enterococcaceae spp.* and possibly *Enterobacteriaceae spp.* and *Streptococcaceae spp.* may play a role in maintaining immunologic homeostasis within the pouch mucosa, with low levels of these bacteria favoring the development of acute pouchitis^[57,58]. Deregulated mucosal cell immunity toward the microbiota also seems to be implicated in the pathogenesis of pouchitis. Epithelial and immune cells within the intestinal mucosa recognize conserved microbial structures, known as pathogen-associated molecular patterns (PAMPs), through membrane-bound and cytoplasmic receptors [so-called pattern recognition receptors (PRRs)], which, when activated, trigger intracellular signaling pathways to elicit a variety of stereotyped (so-called innate) immune responses^[72].

Fragments of bacterial peptidoglycan (the main component of the bacterial cell wall) can, for example, serve as PAMPs that bind to the PRR toll-like receptor 2 (TLR2), while bacterial lipopolysaccharides (LPS; found in the outer membrane of gram-negative bacteria) can serve as PAMPs that bind to TLR4. Binding of these conserved bacterial structures to TLRs triggers a number of intracellular signaling cascades which, through NF- κ B and protein kinase activation, lead to the transcription of a series of genes^[73]. In macrophages this activation results in the expression of several pro-inflammatory cytokines [including interleukin (IL)-1 β , tumor-necrosis factor (TNF)- α , and IL-6], chemokines, adhesion molecules, leukotrienes, nitric oxide, and production of reactive oxygen species, while in dendritic cells it enhances major histocompatibility complex class II and co-stimulatory molecule expression favoring subsequent antigen-specific, T-helper cell activation^[74,75]. FAP: Familial adenomatous polyposis. *E. coli*: *Escherichia coli*; LH-PCR: Length Heterogeneity Polymerase Chain Reaction.

PAMPs modulating the release of a number of biologically active molecules profoundly influence the function and integrity of the intestinal mucosa.

Experimental findings indicate that these mechanisms are activated in pouchitis. In a recent study, Toyama *et al.*^[76] reported that TLR-2 and TLR-4 were greatly up-regulated in the mucosa of active pouchitis, while TLR-3 and TLR-5 expression was barely detectable in the normal ileum and not detectable at all in pouch mucosa with or without inflammation. We confirmed in a recent study that high mucosal TLR-2 and TLR4 mRNA levels are associated with chronic/relapsing pouchitis^[57].

Epithelial cells are also equipped with various antimicrobial peptides that act rapidly to kill a wide range of microorganisms. Defensins are an important class of antimicrobial peptides, which are small cationic arginine-rich peptides with a molecular weight of 3-5 kDa expressed exclusively in Paneth cells (α -defensins) or generally in intestinal epithelial cells (β -defensins)^[74,75]. They are classified as α - and β -defensins depending on the position of three intramolecular disulfide bridges between cysteine residues. The α -defensins include the human neutrophil peptides 1-4, as well as epithelial human defensin 5 (HD-5) and human defensin 6 (HD-6). α -defensins, which may act as chemokines, have a wide variety of antimicrobial activities^[77-79]. HD-5 and HD-6 are the major antimicrobial peptides of the small intestine, and their expression is increased in the colonic mucosa of IBD patients in the form of metaplastic Paneth cells^[80,83]. In contrast with enteric α -defensins, human β -defensin 1 (HBD1) and other members of the β -defensin family appear to be expressed by most epithelial cells of the small and large intestines. HBD-1 is expressed constitutively, while HBD-2 and HBD-3 expression require NF- κ B activation^[84]. Microbes or their products could be involved in defensin deregulation in normal pouches after surgery and in the presence of pouchitis^[85]. A recent study reported that defensins are up-regulated in response to bacterial PAMPs or cytokines^[86]. The increase in HBD-2 and HBD-3 in pouchitis may thus reflect mucosal damage and infection^[85]. The interplay between the microbiota adherent to the pouch mucosa, the mucosal innate immune system, and defensin expression may thus contribute to the pathogenesis of pouchitis.

Some evidence suggests that there is a disruption in the host-gut microbiota homeostasis^[67-71] associated to (or even caused by) the deregulation of the innate immunity machinery within the ileal mucosa^[73,76]. In fact, in recent studies, we observed that *Enterococcaceae* spp., *Enterobacteriaceae* spp. and *Streptococcaceae* spp. may play an active role in maintaining immunologic homeostasis within the pouch mucosa, as low levels seem to favor the development of acute pouchitis^[21]. The presence of *Clostridiaceae* spp. adherent to the pouch mucosa and the high TLR-2 and TLR-4 mRNA expressions were, moreover, associated with chronic/relapsing pouchitis^[57].

CONCLUSION

Accumulating experimental evidence indicates that dysbiosis of the ileal-anal pouch microbiota and deregulation of the mucosal immune system play an important role in the pathogenesis of pouchitis. While its diversity was reduced, only minor compositional differences were found in the microbiota of UC patients with active pouchitis with respect to that in subjects without disease history. However, there are no studies in the literature which have analyzed the direct impact of pouchitis therapy on pouch microbiota. The most likely hypothesis is that dysbiosis predisposes UC patients to pouchitis by increasing the likelihood of immune system stimulation or by reducing microbiota diversity, which is itself sufficient to induce unbalanced activity of the immune system leading to mucosal inflammation. The failure to identify a particular bacterial species associated with pouchitis concurs with clinical experience indicating that antibiotics with a very different spectrum of antimicrobial activity are equally effective in pouchitis. Some investigators have recently shown that many patients with the form that is refractory to empirical antibiotic treatment have antibiotic resistant coliforms, and microbiological testing has been able to predict an effective antibiotic regime for those patients^[87]. Together with other findings, this suggests that antibiotic therapy is effective in pouchitis as it reduces the total gut microbial load, and therefore the stimulus to the immune system rather than eliminating a specific disease-activating bacterial species. Although the connection between dysbiosis of the microbiota and aberrant immune responses remains unclear, alterations in the mucosal immune system support the hypothesis that dysbiosis plays an active role in inducing and maintaining persistent inflammation. The dysbiosis in UC-IPAA patients, characterized by reduced diversity of the microbiota, may lead to aberrant mucosal immune regulation triggering the inflammatory processes in genetically predisposed patients. Secondary effects on the function of the epithelial membrane barrier and defensin overexpression could subsequently worsen dysbiosis and favor the chronic activation of mucosal immune responses^[88].

Abstract

Many placebo controlled trials and meta-analyses evaluated the efficacy of different drugs for the treatment of inflammatory bowel disease (IBD), including immunosuppressants and biologics. Their use is indicated in moderate to severe disease in non responders to corticosteroids and in steroid-dependent patients, as induction and maintenance treatment. Infliximab, as well as cyclosporine, is considered a second line therapy in the case of severe ulcerative colitis, or non-responders to intravenous corticosteroids. An adequate dosage and duration of therapy with thiopurines should be reached before evaluating their efficacy. Methotrexate is a valid option in patients with Crohn's disease but its use is confined to patients who are intolerant or non-responders to thiopurines. Evidence for the use of methotrexate in ulcerative colitis is insufficient. The use of thalidomide and mycophenolate mofetil is not recommended in patients with inflammatory bowel disease, these treatments could be considered in case of failure of all other therapeutic options. In patients with moderately active ulcerative colitis, refractory to thiopurines, the use of tacrolimus is considered an alternative to biologics. An increase of the dose or a decrease in the interval of administration of biological treatment could be useful in the presence of an incomplete clinical response. In the case of primary failure of an anti-tumor necrosis factor

alpha a switch to another one should be considered. Data on the efficacy of combination therapy are up to now insufficient to consider this strategy in all IBD patients. The final outcome of the treatment should be considered the clinical remission, with mucosa healing, and not the clinical response. The evaluation of serum concentration of thiopurine methyl transferase activity, thiopurine metabolites, biologic serum levels and anti-biologic antibodies could be useful for the management of the treatment but it has not been routinely applied in clinical practice. The evidence of high risk development of lymphoma and cutaneous malignancies should be considered in patients treated with immunosuppressants and biologics for a long period.

Key words: Inflammatory bowel disease; Optimization; Immunosuppressants; Biologics; Crohn's disease; Ulcerative colitis

Core tip: The clinical expression of inflammatory bowel disease (IBD) is heterogeneous with different clinical courses, so it is not easy to find the best therapy for all patients. In recent years the goals of the therapy for IBD patients have evolved from symptomatic control to altering the course of disease by achieving a "deep remission". Many trials have evaluated the efficacy of immunosuppressants and biologics in achieving clinical and endoscopic remission but the optimization of these treatments is still a debated point. We propose some recommendations about the correct use of immunosuppressants and biologics for the treatment of IBD, based on the current evidence.

Optimization of the treatment with immunosuppressants and biologics in inflammatory bowel disease. *World J Gastroenterol* 2014; 20(29): 9675-9690 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v20/i29/9675.htm> DOI: <http://dx.doi.org/10.3748/wjg.v20.i29.9675>

INTRODUCTION

Inflammatory bowel disease (IBD) refers to 2 chronic inflammatory disorders of the gastrointestinal tract: Crohn's disease (CD) and ulcerative colitis (UC). The clinical expression of IBD is heterogeneous, especially in CD, with a wide spectrum of patterns and different clinical courses, so it is not easy to find the best therapy for all patients. The course of IBD is characterized by phases of relapse and remission and the main goal of the therapy is to achieve and maintain disease remission. In recent years the goals of therapy for IBD patients have evolved from symptomatic control to altering the course of disease by achieving a "deep remission". This is defined as the contemporary presence of sustained clinical remission, complete mucosal healing and normalization of serological activity indexes (C-reactive protein and erythrocyte sedimentation rate). Many trials have evaluated the efficacy of different drugs for the treatment of CD and UC, including immunosuppressants and biologics. Although recent guidelines have been published to direct the clinicians on the correct management of IBD^[1-3], up to now the optimization of treatment with immunosuppressants and biologics is a debated point. However, nearly half of the IBD guideline recommendations are based on expert opinion and the guidelines are not frequently updated^[4]. We propose some recommendations about the correct use of immunosuppressants and biologics for the treatment of CD and UC, based on the current evidence.

CROHN'S DISEASE

Immunosuppressant therapies

Although the efficacy of corticosteroids in active CD is clear, their use is not indicated in maintaining treatment and the long-term therapy is associated with serious adverse consequences^[5]. To avoid the long term use of corticosteroids many studies have investigated the efficacy of immunosuppressants, including thiopurines, methotrexate (MTX), tacrolimus, thalidomide and mycophenolate mofetil (MMF) for the treatment of active and quiescent CD.

Thiopurines

6-mercaptopurine (6-MP) and its prodrug azathioprine (AZA) are purine analogues able to reduce cell proliferation and with immune modifier properties. The efficacy of thiopurines for the treatment of active CD is controversial. In a meta-analysis^[6] evaluating 8 trials on AZA and 6-MP therapy in patients with active CD, a higher response rate was observed in patients treated with thiopurines compared with patients treated with placebo. The time of peak response in the included trials ranged from 9 wk to more than 26 wk; the minimum period for an adequate response was found to be more than 17 wk. A more recent meta-analysis^[7], including 5 trials, showed no significant efficacy of thiopurines in active CD. The discrepancy between the results of the two meta-analyses is probably due to the exclusion, in

the second one, of trials evaluating the outcome after 17 wk of follow up. This discrepancy confirms that a longer time of treatment gives a greater chance of obtaining a positive result. Based on these data the use of thiopurines as a single therapy is not recommended in active CD but a combination with corticosteroids could be useful while waiting for the slow time of action of thiopurines. Unfortunately treatment with thiopurines is sometimes associated with the occurrence of side effects that preclude their use. In these cases the discontinuation of treatment causes a complete resolution of the symptoms. Some of these side effects are severe, including suppression of white blood cells, pancreatitis and hepatitis, but other side effects could be mild, such as nausea, abdominal pain and fever. In the presence of a mild side effect during AZA use a trial of 6-MP is recommended because half of the intolerant patients tolerate a switch to 6-MP. A study was conducted to assess the long term outcomes of 6-MP treatment in patients with AZA intolerance. Fifty-two per cent of included patients tolerated 6-MP. In particular 6-MP was more tolerated in patients with hepatotoxicity and arthralgia/myalgia during AZA treatment. Less evident was the switching advantage in patients with hematologic and pancreatic toxicity^[8]. The role of thiopurines in CD is more important in the maintenance period, particularly in steroid-dependent CD, to induce early steroid sparing. A meta-analysis, including 7 placebo controlled trials, evaluated the efficacy of thiopurines in quiescent CD. AZA and 6-MP were effective in maintaining remission and inducing steroid sparing, but higher doses of AZA (2.5 mg/kg daily) were more effective than lower doses^[7,9]. According to these data the dosage of 2.5 mg/kg daily is suggested to optimize the treatment with thiopurines.

The efficacy of immunosuppressants was also evaluated in fistulizing CD. Eleven placebo controlled trials on the efficacy of immunosuppressants and antibiotics in fistulizing CD have been included in a meta-analysis. The analysis showed that both immunosuppressants and antibiotics were able to significantly reduce the number of open actively draining fistulas by at least 50% from the baseline. The incidence of severe adverse events was higher in patients treated with immunosuppressants than in patients treated with placebo ($P = 0.037$)^[10]. Regarding the maintenance treatment a questionable point is how long treatment with thiopurines should be continued. A meta-analysis showed that stopping thiopurine treatment increases the risk of relapse at 6, 12 and 18 mo. A clear benefit of continuing thiopurines for at least 18 mo was observed^[11]. In a trial of Lémann *et al.*^[12] patients who discontinued AZA after more than 3 years of efficacious treatment had a higher probability of relapse compared with those who continued it. According to the ECCO guidelines^[1] in patients treated with thiopurines as maintenance treatment, discontinuation may be considered after 4 years of remission. Benefit and risks of continuing them should be considered case by case.

A question related to the long term treatment with immunosuppressants is the reported high risk of lymphoma

and cutaneous malignancies. Patients with IBD treated with thiopurines alone or in combination with anti-TNF α had an increased risk of developing lymphoproliferative disorders^[13-15]. Many lymphomas associated to immunosuppressive therapy in IBD patients seem to be related to a loss of control of Epstein-Barr virus (EBV) infection. Young males seronegative for EBV are at risk for fatal forms of primary EBV infection, with lymphoproliferation. This incidence could be limited avoiding the treatment with thiopurines in this subgroup of patients^[16,17].

Hepatosplenic T cell lymphoma (HSTCL) is another rare, lethal form of lymphoma^[15]. Patients at risk are typically young men, treated for prolonged periods with thiopurines in combination with anti-TNF- α . The risk of HSTCL can be limited by avoiding prolonged combination therapy in young males. Concerning the risk of cutaneous malignancies, an increased risk of non-melanoma skin cancers (NMSC) has been reported in patients treated with thiopurines. This risk persists in patients previously exposed to thiopurines, suggesting a definite impact on carcinogenic events^[18-20]. In a retrospective study, 26403 patients with CD and 26974 patients with UC were matched with non-IBD controls. The incidence of NMSC was higher among patients with IBD compared with controls and thiopurine use was associated with NMSC, as was biologic use among patients with CD^[18]. Another prospective cohort study evaluated the incidence of NMSC among 19486 patients with IBD. The authors showed that ongoing thiopurine treatment and past thiopurine exposure were risk factors for NMSC. These patients should be protected against UV radiation and receive lifelong dermatologic screening^[19]. In a third study^[20], 9618 IBD patients were followed up and matched with 91378 controls. At the end of the study a diagnosis of basal cell skin cancer was made in 1696 individuals and a diagnosis of squamous cell skin cancer in 341 patients. IBD patients had an increased risk for basal cell skin cancer, compared with controls. Among patients with IBD, the use of thiopurines increased the risk of squamous cell skin cancer compared with controls. In order to explain the interindividual variability in efficacy and toxicity, the importance of measuring serum concentrations of thiopurine metabolites, 6-thioguanine nucleotide (6-TGN) and 6-methylmercaptopurine (6-MMP), has been recently proposed. Furthermore thiopurine methyltransferase (TPMT), that is one of the enzymes involved in the thiopurine metabolism, has been measured to predict the tolerability of thiopurines. A decreased TPMT activity has been related with myelotoxicity, whereas a high activity of TPMT has been related with thiopurine ineffectiveness. Low TPMT activity and high 6-TGN concentrations have been related to therapeutic success.

A prospective study was conducted to compare the 6-TGN levels in active IBD patients with those in patients in clinical remission. One hundred patients were included (41 with an exacerbation, 59 in remission). Twenty-six of the 41 patients (63%) with active disease and 24 of the 59 patients (41%) in clinical remission had

a 6-TGN level below the therapeutic cut-off level of 235 pmol/ 8×10^8 erythrocytes ($P = 0.04$)^[21]. Recent studies suggest that too low 6-TGN and too high 6-MMP nucleotide concentrations can be reversed by a combination therapy of allopurinol and thiopurines. In a study a dose-escalation of allopurinol was performed in 11 IBD patients with low 6-TGN and/or elevated 6-MMP concentrations, treated with AZA. Adequate 6-TGN concentrations were achieved with a combination of 25 mg allopurinol and 50 mg AZA in one patient and with 50 mg allopurinol and 50 mg AZA in nine patients. The 6-MMP concentrations were normalized immediately in all patients. The authors concluded that combination therapy with 50 mg allopurinol and 50 mg AZA daily is efficacious in IBD patients with inadequate thiopurine metabolite concentrations to optimize AZA therapy^[22].

The results of a recent prospective study do not support the capability of TPMT activity or 6-TGN to predict treatment outcome and no serum threshold value was identified to adjust the thiopurine dose. A total of 113 IBD patients treated with thiopurines were included. The TPMT activity was determined at inclusion (> 5 U/mL required) and thiopurine metabolites were periodically monitored. At the end of the study no cut-off point with worthwhile sensitivity/specificity was found. Eight patients showed thiopurine-related toxicity that could not be linked to TPMT activity or 6-TGN levels^[23].

Up to now the use of thiopurine metabolites has not been applied in clinical practice. A survey performed to evaluate the extent to which IBD gastroenterologists are utilizing thiopurine metabolism in practice showed that TPMT evaluation was performed by only 30% of gastroenterologists before AZA initiation. In patients on thiopurine therapy, 6-TGN and 6-MMP levels were determined by 54% and 44% of gastroenterologists respectively and 81% did not recheck metabolite levels after dose escalation or reduction^[24].

Methotrexate

Despite the wide use of thiopurines in the management of both CD and UC, approximately 20% of patients are intolerant and 30% are refractory to AZA/6-MP. An alternative immunosuppressant in these cases is MTX, an inhibitor of dihydrofolate reductase. Based on the results of 3 small studies^[25-27], where the efficacy of oral MTX was compared with placebo or 6-MP, MTX was considered ineffective in the treatment of active CD. A placebo-controlled trial^[28] compared the efficacy of intramuscular MTX (25 mg once weekly) with placebo. After 16 wk of therapy, 39% of patients were in clinical remission in the MTX group, compared with 19% of patients in the placebo group. The authors supported the efficacy of intramuscular MTX in active CD, although a higher rate of adverse events was reported with respect to placebo, including dyspepsia, alopecia, myelosuppression, increase in transaminase levels, abdominal pain, headache and arthralgia. To avoid some of these adverse events folic acid given routinely the day after MTX injection is recom-

mended. Furthermore, the teratogenic effect of this drug must be considered when it is started.

The efficacy of MTX in quiescent CD was observed in a trial^[29] in which MTX (15 mg weekly) intramuscularly was compared with placebo. After 40 wk of treatment, relapse occurred in 35% of patients treated with MTX and in 61% of patients treated with placebo. However in another two studies^[25,26] the superiority of MTX with respect to placebo, 5-ASA or 6-MP was not confirmed. Up to now the use of MTX in CD is confined to patients who are intolerant or non-responders to thiopurines.

Tacrolimus

Several studies, but not randomized controlled trials, evaluated the efficacy of oral or intravenous tacrolimus in the treatment of active luminal CD. Six of these studies, including a total of 70 patients, have been systematically reviewed^[30]. The duration of treatment varied from weeks to years. A total of 31 treated patients (44.3%) achieved a complete remission at the end of the studies. Eight studies evaluated the efficacy of tacrolimus in patients with perianal CD^[31-38]. Data were available for 49 patients with perianal disease who were treated with oral or intravenous tacrolimus and for 8 patients treated with topic tacrolimus. Among the patients treated with oral or intravenous tacrolimus 14 patients (28.6%) achieved remission and 19 patients (38.8%) achieved a partial response. Regarding the topic treatment, in a placebo controlled trial 8 patients with perianal CD were stratified according to ulcerating or fistulizing disease. A benefit in the ulcerating group was observed. No benefit was reported in the fistulizing group^[36].

Thalidomide

Thalidomide, originally used to treat morning sickness, had been withdrawn from the market because of its teratogenic effect. Subsequently immunomodulatory properties of thalidomide have been discovered as inhibitors of TNF- α synthesis. Thus in recent years its use was proposed for a few diseases including CD. No published randomized controlled trials on thalidomide efficacy in adult CD patients are available. In one trial^[39] the efficacy of its analogue lenalidomide was evaluated. In this study, 89 patients were included and randomized to receive 25 mg of lenalidomide daily, 5 mg of lenalidomide daily or placebo. At the end of the study the rate of clinical remission in both treatment groups was not significantly different from the placebo group. Other data come from uncontrolled studies. In a study^[40] 25 patients with luminal and fistulizing CD were treated with thalidomide. At the end of the study 6 out of 8 patients treated for luminal disease and 9 out of 11 patients treated for fistulizing disease achieved clinical response after a median follow-up of 12 mo. The 4 patients treated for both luminal and fistulizing disease had a fistula response and 3 of them had also a luminal response. The authors concluded that thalidomide was an effective treatment in patients with refractory luminal and fistulizing CD. Other encouraging

results come from the pediatric population. In a study^[41] 28 patients (young adults and children) with refractory moderate to severe IBD (19 CD, 9 UC) received thalidomide (1.5-2.5 mg/kg daily). Remission was achieved in 21 out of 28 (75%) patients (17 with CD, 4 with UC). In a recent small study^[42] 12 children, non-responders to previous drugs including AZA/6-MP, MTX and biologics, received thalidomide as rescue therapy. After 6 mo a significant improvement was observed in terms of symptoms, corticosteroid use, hospitalizations, laboratory values, fistula closure and surgery. Unfortunately a high rate of adverse reactions was reported during treatment with thalidomide, including peripheral neuropathy, dizziness and allergic reaction.

Based on these data the use of thalidomide can be proposed only in patients with active CD, refractory to conventional immunosuppressants and biologics, as rescue therapy. However given its teratogen nature and the high probability of side effects, its use for maintenance therapy is difficult to justify. However contraception should be recommended in woman with CD during thalidomide treatment. Up to now there are no recommendations for the use of thalidomide in CD. However it could have a role in the treatment of children with active CD despite immunosuppressive treatment.

Mycophenolate mofetil

MMF is an immunosuppressant largely used for the prevention of solid organ transplantation rejection. It is an antimetabolite similar to AZA and its use has been proposed in the management of autoimmune diseases, including psoriasis^[43], rheumatoid arthritis^[44] and IBD^[45,46].

A retrospective study^[47] assessed the efficacy and tolerance of MMF in 20 patients with CD who were intolerant or non-responders to AZA and/or MTX. The authors reported only 20% success with MMF and 25% intolerance. A study^[48] compared the efficacy of MMF with AZA in 45 patients with active CD, 15 treated with MMF and 30 with AZA over a period of 1 year. All patients who completed the 12 mo of treatment (77% AZA, 60% MMF) achieved remission but MMF patients had almost twice as many flare-ups (80% *vs* 47%) with respect to AZA patients. The authors concluded that both drugs were effective in inducing remission, AZA was more effective in maintaining remission but the onset of therapeutic effect was delayed less under MMF than under AZA. A randomized trial^[49] compared the efficacy of AZA plus corticosteroids with MMF plus corticosteroids in 70 patients with active CD. The authors observed a significant reduction in clinical activity with MMF plus corticosteroids compared to AZA plus corticosteroids. In patients with more severe CD, MMF plus corticosteroids caused a significant suppression of clinical activity earlier than AZA plus corticosteroids with few adverse effects.

Based on these data, although AZA is still the immunosuppressant of choice in the treatment of IBD, MMF may have a role for steroid-dependent patients refractory to other immunosuppressive therapies. Up to now there

are no recommendations for the use of MMF in CD.

biological therapies

In recent years the use of biologics has changed the management of IBD. The efficacy of anti-TNF α molecules (infliximab, adalimumab and certolizumab pegol) has been largely investigated in the treatment of active and quiescent CD, with good results^[50,51]. Up to now infliximab and adalimumab have been approved for the use in CD in many countries. These two anti-TNF α are both equal options in patients with moderate to severe steroid-refractory or steroid-dependent disease and in patients who are non responders or intolerant to immunosuppressants. Their use is also indicated in the case of complex perianal disease, in combination with surgical therapy. Furthermore, in presence of axial arthropathy (sacroileitis and ankylosing spondylitis) the efficacy of anti-TNF α treatment has been well established, as well as in the case of peripheral arthritis, non-responder to sulfasalazine^[1,2]. Certolizumab pegol is not approved in the European Union but in the United States and Switzerland it has the same indications as infliximab and adalimumab.

Two meta-analyses^[50,51] confirmed the efficacy of anti-TNF α antibodies in inducing and maintaining remission of luminal CD. Some studies evaluated the efficacy of these drugs in a subgroup of patients with steroid-dependent CD. Regarding infliximab, the study by Lémann *et al.*^[52] was planned to treat patients with steroid-dependent CD. These patients received infliximab 5 mg/kg or placebo at weeks 0, 2, and 6. All patients were treated also with AZA/6-MP for 52 wk. Among the 113 enrolled patients, the steroid-free remission rate was higher in the infliximab group than in the placebo group (75% *vs* 38%, $P < 0.001$ at week 12 and 40% *vs* 22%, $P = 0.04$ at week 52). Regarding adalimumab, data on steroid-dependent patients could be taken from a subgroup analysis of the CHARM study^[53]. At week 26, 19% of patients treated with adalimumab (40 mg every other week) achieved a sustained corticosteroid-free remission compared with 3% of patients treated with placebo ($P = 0.006$). At week 56, 29% of patients treated with adalimumab achieved a sustained corticosteroid-free remission compared with 5% of patients treated with placebo ($P = 0.001$). Recently the long term efficacy of adalimumab in steroid-dependent CD patients has been evaluated in a long-term open label extension of the CHARM study. After 4 years of follow up 16% of patients taking corticosteroids at baseline were in corticosteroid-free remission^[54]. A prospective observational study including 110 steroid-dependent CD patients reported clinical data on the efficacy and prognostic factors of response to adalimumab in corticosteroid-dependent CD patients. At week 6, 100 patients had a clinical benefit (91%), 50 of these (45.5%) were in steroid-free clinical remission, the other 50 (45.5%) achieved a clinical response. Nine patients (8.1%) did not achieve a clinical benefit and only one patient discontinued adalimumab due to intolerance. At the end of the follow-up (mean 14.6 \pm 10 mo, range

2-47 mo) 89 patients (80.9%) had a clinical benefit, 18 of these achieved a clinical response (16.4%), 71 were in complete remission (64.5%) and 11 discontinued adalimumab (10%) due to lack of efficacy or severe side effects. At multivariable analysis only a higher induction regimen was related to remission at week 6. At the end of the follow-up, none of the variables were associated with remission^[55]. All the 110 patients treated in this study have been followed up for a further 24 mo. At the end of the follow up (mean 38.6 \pm 8.6 mo) 54 patients (49%) were still on maintenance treatment with adalimumab with significant clinical benefit; 56 patients stopped treatment because of ineffectiveness (35), side effects (15) or mucosal healing (6). Mucosal healing was reported in 15 out of 60 patients who underwent colonoscopy (25%). At univariable analysis a lower induction regimen (80/40 mg) was associated with a best response to infliximab ($P < 0.001$, OR = 6, 95%CI: 1.01-35.91) while 160/80 mg induction regimen was associated with a lower risk of surgery with respect to 80/40 mg ($P = 0.04$, OR = 0.311, 95%CI: 0.969-0.998)^[56].

The advantage of biologics with respect to thiopurines is the more rapid effect. After 4 wk of treatment most of the treated patients show a clinical benefit^[57,58]. However from 17% to 21% of patients treated with infliximab develop antibodies directed against the murine sequences of infliximab molecule during the treatment, with immediate-type hypersensitivity reactions. Intravenous hydrocortisone premedication reduces antibodies to infliximab but some patients discontinue the treatment because of side effects, despite premedication and schedule treatment. Adalimumab, that is a recombinant human monoclonal antibody containing only human peptide sequences, has been proposed as an effective option in patients who had showed a previous allergic reaction to infliximab^[59]. Furthermore some patients treated with infliximab experience a loss of efficacy over time. In the Gain study^[60] 22% of CD patients with loss of response or previous intolerance to infliximab achieved remission with adalimumab. Based on these data, in the case of primary failures, loss of response or intolerance to infliximab, adalimumab can be used as a second line treatment. On the other hand the effectiveness of infliximab as a second line therapy after adalimumab failure has also been evaluated in CD patients. In a recent study 15 patients who discontinued adalimumab for loss of response (5), adverse events (3) or partial response (7), were treated with infliximab. After infliximab therapy all the patients who had discontinued adalimumab due to loss of efficacy or adverse events obtained a clinical response, but 2 of them developed adverse events. None of the patients who discontinued adalimumab due to partial response reached remission with infliximab^[61]. Up to now no trial has compared the efficacy and safety of infliximab and adalimumab in CD patients, thus the only factor that can guide the choice of one of the two biologics as first line therapy is the route of administration (subcutaneous for adalimumab and intravenous for infliximab). This should

be discussed with the patient and the choice of treatment should be made case by case. In the case of patients with primary failure to one anti-TNF α a switch to the other one should be considered. However, in the case of failure of one anti-TNF- α , before switching to the other one, an increase in dose or a decrease in the interval between infusions has been proposed. In a study, 54 out of 108 CD patients treated with infliximab received a dose intensification, defined as an increase in infliximab dose, a decrease in interval, or both, at 30 mo from initial infusion. At 30 mo 69.1% of patients were event-free from an interval decrease, 48.5% from a dose increase, and 45.7% from any dose intensification. Of the 54 patients who received a dose intensification, 75.9% were able to obtain and maintain a clinical response^[62]. In another prospective study 14 CD patients, initially responders to adalimumab, experienced a relapse. All patients were then treated with adalimumab 40 mg weekly for 12 wk before returning to adalimumab 40 mg every other week. Nine out of the 14 CD patients achieved a clinical response (1) or remission (8) 3 mo after reinstating the standard dosage^[63]. Also, in the CHARM study^[53] the dosage of adalimumab could be escalated to open-label treatment with 40 mg weekly in patients with continued non response or recurrent flare. A total of 140 out of 854 enrolled patients completed the study on open-label adalimumab 40 mg weekly.

Two questionable points regarding biological therapy are: when to start and when to stop the treatment?

Some studies supported an early use of biologics in CD. In a randomized, controlled trial^[64] early combined infliximab and thiopurines treatment was more effective than a conventional step-up approach at 6 and 12 mo. Furthermore a subgroup analysis of the CHARM study^[65] showed a higher remission rate at 26 and 56 wk in patients with disease duration < 2 years with respect to patients with disease duration > 5 years. These data are not enough to confirm that an early treatment with biologics can improve patient outcomes. Therefore, a widespread early use of biologics in all CD patients cannot be recommended^[1,2] but in patient subgroups with a predicted disabling course^[66] (extensive disease, severe rectal disease, young age, severe perianal disease, steroid need at diagnosis) early introduction of biologics can be considered.

Regarding long term treatment, adalimumab was able to maintain remission for up to 4 years in patients who responded to induction therapy^[54] and long-term treatment with infliximab seems to have a safe maintenance efficacy^[67]. Despite these promising results the duration of biological therapy over 1 year is recommended only after a careful evaluation on a case-by-case basis and should be discussed with each patient^[1,2]. Some prospective studies^[68,69] showed that mucosal healing after biological therapy predicts a prolonged remission. Based on this observation a colonoscopy evaluation in patients receiving long-term anti-TNF- α therapy could guide the choice of treatment duration.

Recently pharmacokinetics and inter-individual variability of clearance and immunogenicity of biologics have

been evaluated to explain their efficacy and tolerability. Antidrug antibodies (ADA) impacted the clearance of infliximab and trough levels have been shown to correlate with clinical remission. In CD patients high trough levels of infliximab were associated positively with sustained clinical response, low C-reactive protein (CRP) levels and endoscopic improvement^[70]. In the SONIC trial, steroid-free remission at weeks 30 and 46 was more frequent in patients with high infliximab trough levels. Furthermore concomitant immunosuppressive therapy was shown to increase the trough levels of infliximab^[71]. In the AC-CENT trial a complete fistula healing was achieved in 64% of CD patients with high infliximab trough levels and in 25% of patients without detectable trough levels^[72]. In another study, in patients with infliximab levels below 12 mg/mL at mid infusion, a dose increase produced a response in 25 out of 29 patients and was more effective than changing to another anti-TNF- α agent^[73]. However the definition of therapeutic thresholds is still unclear. In a large series of 532 CD patients treated with infliximab from various trials a trough level of 3 mg/mL discriminated inflammatory activity^[74]. A cut-off of 3 mg/mL was associated with steroid-free remission in the SONIC trial^[71].

For adalimumab, pharmacokinetic-efficacy relations are less clear. In the CLASSIC trials correlations between adalimumab serum levels and remission rates were weak during induction and absent during maintenance therapy^[75]. In an observational cohort study^[76] a relationship between adalimumab serum trough levels and remission or response rates was not demonstrated.

Regarding the ADA evaluation, it seems to be the most important variable associated with low infliximab trough levels and low efficacy. The appearance of antibodies to infliximab (ATI) has been associated with loss of response and infusion reactions. In a study^[77], 73% of patients with loss of response to infliximab and all patients who developed infusion reactions showed ATI positive.

The occurrence of human antichimeric antibodies (HACA) was also inversely correlated with clinical response and positively correlated with infusion reactions^[78,79]. Premedication with glucocorticoids seems to reduce significantly the HACA levels^[77]. In a study it was observed that in 65% (11 out of 17) of patients initially positive for HACA, antibodies disappeared during maintenance treatment with infliximab but only in those with a clinical response^[80]. Furthermore the addition of immunosuppressants to infliximab therapy seems to restore the efficacy in patients positive for HACA^[81]. As for thiopurine metabolites up to now the utilization of biologic serum levels or ADA have not been routinely applied in clinical practice.

ULCERATIVE COLITIS

Immunosuppressant therapies

According to the ECCO guidelines^[3] patients with steroid-dependent UC should be treated with thiopurines.

The evidence to support the use of MTX in UC is insufficient. In patients with severely active UC, non-responder to intravenous steroids, the use of cyclosporine or infliximab is recommended.

Thiopurines

The efficacy of AZA in active UC was evaluated in two controlled trials, at the dosage of 2-2.5 mg/kg daily^[82,83]. A meta-analysis^[7] of these trials was conducted and a trend towards the benefit of AZA compared with placebo was observed but this did not achieve any statistical significance (RR = 0.85, 95%CI: 0.71-1.01, $P = 0.07$). In these two trials the efficacy of AZA was also investigated in quiescent UC. The meta-analysis of these trials showed a statistically significant benefit of AZA compared with placebo in preventing relapse (RR = 0.60, 95%CI: 0.37-0.95, $P = 0.03$)^[7]. In a study^[84] the efficacy of AZA was investigated in a subgroup of patients with steroid-dependent UC, comparing it to mesalamine. Seventy-two patients were randomised to receive AZA (2 mg/kg daily) or mesalamine (3.2 g daily), in addition to prednisolone (40 mg daily) for 6 mo. At the end of the follow up AZA was significantly more effective than mesalamine at achieving clinical and endoscopic remission with steroid sparing. More recently an observational cohort study was conducted in 42 patients with steroid-dependent UC treated with AZA (2-3 mg/kg daily) over a 3-year period. In this study AZA showed sustained efficacy for maintenance of clinical remission off steroids. Furthermore patients with earlier UC were those who most probably had sustained steroid-free remission at the end of 12 mo while on AZA^[85]. Considerations regarding the best dosage and the best duration of therapy with thiopurines are similar to the treatment for CD.

Methotrexate

Data on the efficacy of MTX in UC comes from small prospective studies where different doses and routes of administration have been used, with inconsistent results^[26,86,87]. A placebo-controlled trial showed no benefit of oral MTX at the dosage of 12.5 mg per week in UC patients^[86]. A study^[26] compared the efficacy of oral MTX at the dosage of 15 mg weekly with 6-MP (1.5 mg/kg daily) and mesalamine (3 g daily) in 72 steroid-dependent patients (34 UC and 38 CD). After 30 wk a significantly higher remission rate was observed in UC patients treated with 6-MP (78.6%) with respect to patients treated with mesalamine (25%) but no statistical differences were observed between patients treated with MTX (58.3%) with respect to patients treated with mesalamine. With regard to maintaining remission, after 76 wk UC patients treated with 6-MP presented significantly higher remission rates with respect to the other 2 groups. More recently a retrospective study^[88] evaluated the efficacy and safety of MTX in 131 patients with IBD (99 CD, 32 UC) intolerant or non-responsive to thiopurines. In UC patients clinical response occurred in 78% of patients refractory to AZA/MP and in 65% of pa-

tients intolerant to thiopurines. MTX was well tolerated in a majority of individuals. Based on these data there is insufficient evidence to support the use of MTX in UC as an alternative to thiopurines.

Tacrolimus

In patients with severely active UC not responding to intravenous corticosteroids a second line therapy with tacrolimus, as well as with ciclosporin or infliximab may be appropriate^[3]. A placebo controlled trial evaluated the efficacy of tacrolimus in 60 patients with moderate or severe UC. Patients were treated with a high concentration (10-15 ng/mL) of tacrolimus, a low concentration (5-10 ng/mL) of tacrolimus or placebo. At week 2, a clinical improvement was observed in 68.4% of patients treated with high concentration of tacrolimus and in 10% of patients treated with placebo ($P < 0.001$). Clinical remission was observed in 20% of patients treated with a high concentration. In the open label extension, 55.2% of all patients had a clinical improvement at week 10. The optimal target range appears to be 10-15 ng/mL. The incidence of side effects in the tacrolimus group was significantly higher than in the placebo group ($P = 0.043$). The most common event was finger tremor^[89]. A more recent placebo controlled trial was conducted on 62 patients with steroid-refractory UC. A response rate of 50% was reported in patients treated with oral tacrolimus compared to 13.3% in patients treated with placebo ($P = 0.003$) after 2 wk of treatment. Rates of mucosal healing were higher in the treatment group respect to the placebo group (43.8% *vs* 13.3%, $P = 0.012$), but the rates of clinical remission were not significantly different (3 out of 30 *vs* 0 out of 30, $P = 0.238$)^[90]. A retrospective review of 130 steroid refractory patients with moderate to severe UC showed that 94 patients (72%) had achieved remission after 3 mo of follow up and that the addition of thiopurines correlated significantly with remission rates^[91]. However another retrospective study on 32 refractory UC patients revealed that only 4 out of 30 steroid-dependent patients were able to discontinue steroids after a median follow-up of 29 wk and 12 out of 32 patients underwent colectomy^[92]. The efficacy of rectal tacrolimus ointment has been analysed in a small study on 8 patients with steroid dependent proctitis refractory to immunosuppressive and infliximab treatment. After 8 wk of therapy 6 out of 8 patients had achieved remission^[93].

A recent prospective study investigated the efficacy of topical tacrolimus in the treatment of refractor pouchitis. Ten patients with antibiotic-refractory pouchitis were treated for 8 wk with a tacrolimus enema. The mean pouchitis disease activity index score decreased from 15.9 ± 0.8 to 7.8 ± 0.8 during 8 wk of treatment ($P < 0.01$) but endoscopic healing was not achieved^[94].

Cyclosporine

A second line therapy with cyclosporine is indicated in the case of severe UC, which does not respond to 3-5 d of intravenous steroids. If no improvement is observed

within 4-7 d a colectomy is recommended. Two placebo controlled trials investigated the efficacy of cyclosporine in the treatment of severe UC^[95,96]. In the first study^[95] 30 patients with severe UC were randomized to intravenous cyclosporine at the dosage of 4 mg/kg daily or methylprednisolone at the dosage of 40 mg daily. After 8 d responders were treated with the same medication orally, in combination with AZA. After 8 d, 8 out of 15 patients (53%) who received methylprednisolone had a response compared with 9 out of 14 (64%) receiving cyclosporine. In non-responders, 3 out of 7 methylprednisolone patients and 1 out of 3 cyclosporine patients improved when both treatments were combined. At 12 mo, 7 out of 9 patients (78%) initially controlled with cyclosporine maintained their remission compared with 3 out of 8 (37%) initially treated with methylprednisolone.

In the second study^[96] 20 patients with severe UC, non-responders to 7 d of intravenous corticosteroids, were treated with intravenous cyclosporine (4 mg/kg daily) or placebo. Nine out of 11 patients (82%) treated with cyclosporine had a response within a mean of 7 d compared with 0 out of 9 patients who received placebo ($P < 0.001$).

Unfortunately the use of cyclosporine is associated with important adverse effects that are mainly dose dependent. A controlled trial investigated the additional clinical benefit of 4 mg/kg over 2 mg/kg intravenous cyclosporine in the treatment of severe UC. Seventy-three patients were included. After 8 d response rates were 84% in patients treated with 4 mg/kg and 86% in patients treated with 2 mg/kg. Furthermore short-term colectomy rates were 13% in patients treated with 4 mg/kg and 9% in patients treated with 2 mg/kg. The authors concluded that high-dose cyclosporine has no additional clinical benefit over low dose in the treatment of severe UC^[97]. Up to now 2 mg/kg daily has become the standard dose used in current clinical practice.

A study assessed the long-term colectomy-sparing effects and safety of cyclosporine in 71 patients with severe UC. Sixty out of 71 patients (85%) responded to intravenous cyclosporine and were discharged on oral cyclosporine. Of these 60 patients, 26 were transitioned from cyclosporine to 6-MP. Cumulative colectomy rates for the entire cohort were 39% at 1 year, 42% at 2 years, and 46% at 5 years. In the sub-group of patients maintained with 6-MP only one patient required a colectomy; whereas colectomy was carried out in 76% of patients who were not transitioned from cyclosporine to 6MP. In conclusion concomitant 6-MP therapy was associated with a reduced risk of colectomy (OR = 0.01, 95%CI: 0.001-0.09, $P < 0.0001$) on long-term follow-up. Side effects were noted in two-thirds of the patients, the majority of which were mild. The authors concluded that transition to oral thiopurines after intravenous cyclosporine was useful in preventing a future colectomy^[98].

Mycophenolate mofetil

As for CD, also for UC - data on the efficacy of MMF

come from small, uncontrolled, retrospective studies, in which patients with IBD and not only UC were included. A retrospective study^[99] evaluated the efficacy of MMF (1-2 g daily) in patients with IBD, only 7 of them with UC, treated over a 3-year period. Thirty-nine patients (32 CD and 7 UC), intolerant or non-responders to AZA, were identified. During the study period 40% of patients (a total of 16 patients, only 4 with UC) achieved remission and complete steroid withdrawal, 30% could not tolerate the drug, and 30% did not respond. An open-label prospective and uncontrolled 6 mo trial^[100] on the efficacy of MMF (2 g daily) in combination with steroids was conducted in 24 IBD patients (11 CD, 13 UC). Only 10 out of 24 patients achieved remission after 3 mo. All but one CD patient had relapsed by the end of the study. The authors concluded that MMF at the dosage of 2 g daily was unable to induce and maintain remission for a period of 6 mo in 23 out of 24 chronic active IBD patients. A retrospective study^[101] reported the results on the efficacy of MMF in 70 patients with IBD (51 CD, 19 UC) over a 5-year period. Seventeen of the 70 patients (24.3%) had a sustained steroid-free remission for 33 mo. Treatment with MMF was discontinued in 53 patients, 17 because of side effects and 36 because of non response to the treatment. A more recent study^[102] was conducted in 14 patients with IBD (9 CD, 5 UC) intolerant or refractory to conventional medical therapy who received MMF (500-2000 mg bid). Of the 11 patients who were not in remission at baseline, 7 out of 11 (63.6%) achieved remission after 8 wk. All 3 patients in remission at baseline maintained their remission. At 6 mo 64.3% patients were in remission. Of 12 patients followed for 12 mo, 8 were in remission (66.7%).

As for CD patients, MMF may be considered an alternative immunosuppressant therapy in steroid-dependent patients with UC, refractory to AZA/6-MP. Up to now there are no recommendations for the use of MMF in UC.

Biologic therapies

The use of anti-TNF α in UC patients is recommended in the case of severe UC that is refractory to steroids^[103,104] after exclusion of other causes of persistent symptoms such as coexistent cytomegalovirus or *Clostridium difficile* infection. Furthermore steroid-dependent UC patients, refractory or intolerant to thiopurines, can be treated with biologics. Also in patients with UC, as well as in CD patients, in the presence of axial arthropathy the efficacy of anti-TNF α treatment has been well established, as well as in the case of peripheral arthritis, not responding to sulfasalazine^[3].

A Cochrane meta-analysis on infliximab in moderate to severe UC, refractory to corticosteroids and/or immunomodulators, showed that infliximab was more effective than placebo in inducing clinical remission^[105]. Two placebo-controlled trials evaluated the efficacy of adalimumab in patients with moderately active UC despite conventional therapy^[104,106]. In one of these studies^[104]

adalimumab was compared with placebo in patients naïve to biologics. At week 8, clinical remission was observed in 18.5% of patients in the adalimumab group compared with 9.2% in the placebo group ($P = 0.031$). In the second study^[106] 40.3% of the included patients had been previously treated with infliximab. Clinical remission was achieved in significantly more patients receiving adalimumab than placebo at week 8 (16.5% and 9.3%, $P = 0.02$) and week 52 (17.3% and 8.5%, $P = 0.01$). The authors observed that the clinical remission rates in the adalimumab group were higher in patients who were naïve to anti-TNF α therapy at baseline. Other studies reported a benefit of adalimumab in patients with active UC previously exposed to infliximab with up to 27% of clinical remission in the short term^[107-109].

An Italian multicentre study reported data on the effectiveness of adalimumab in a cohort of 88 UC patients, retrospectively reviewed. Clinical remission rates were reported in 17%, 28.4%, 36.4% and 43.2% of the patients at 4, 12, 24 and 54 wk respectively. Twenty-two patients required colectomy. Clinical remission and low C-reactive protein at week 12 predicted clinical remission at week 54. Previous immunosuppressant use was associated with a lower probability of clinical remission at week 54 and with a higher rate of colectomy^[110].

Golimumab, a fully human monoclonal anti-TNF- α antibody, has been recently approved by the United States Food and Drug Administration for inducing and maintaining clinical remission in patients with moderate to severe UC. The efficacy of golimumab induction therapy has been evaluated in a trial on 1064 patients with UC. Patients were treated with golimumab at the dosage of 100 mg and then 50 mg, 200 mg and then 100 mg, 400 mg and then 200 mg, or placebo. The rates of clinical response at week 6 were 51% and 54.9% among patients treated with 200 mg/100 mg and 400 mg/200 mg golimumab, respectively, *vs* 30.3% among patients treated with placebo ($P \leq 0.0001$). The rates of clinical remission and mucosal healing were significantly greater in both golimumab groups than in the placebo group ($P \leq 0.0014$). The rates of serious adverse events were 6.1% and 3.0% in the placebo and golimumab groups, respectively^[111].

In a subsequent trial the efficacy of golimumab as maintenance therapy was evaluated. Patients who responded to induction therapy with golimumab ($n = 464$) were treated with placebo or golimumab (50 or 100 mg) every 4 wk through week 52. Patients who responded to placebo in the induction study continued to receive placebo. Non responders in the induction study received 100 mg of golimumab. At weeks 30 and 54, a higher percentage of patients who received 100 mg of golimumab were in clinical remission and had mucosal healing (27.8% and 42.4%) compared with patients who received placebo (15.6% and 26.6%; $P = 0.004$ and $P = 0.002$, respectively) or 50 mg of golimumab (23.2% and 41.7%, respectively)^[112].

Regarding the maintenance treatment, according to the ECCO guidelines^[3] in patients responding to anti-

TNF α both maintaining remission with thiopurines and anti-TNF α are considered appropriate. In patients with severe UC, responding to intravenous steroids, ciclosporin or infliximab, thiopurines should be considered to maintain remission. However, in patients responding to infliximab, continuing infliximab is also considered appropriate. The prior failure of thiopurines favours maintenance with anti-TNF- α therapy. According to the Italian guidelines^[2] 1 year scheduled treatment with infliximab is indicated in patients who have responded to infliximab induction. In patients who are thiopurine naïve, maintenance therapy with thiopurines may be a valuable option as maintenance treatment. The duration of therapy over 1 year should be evaluated case-by-case.

In severe UC infliximab is considered a second line salvage therapy before colectomy, such as ciclosporine^[2,3]. A small randomised controlled study showed that a single dose (5 mg/kg) of infliximab was an effective salvage therapy in patients with severe UC refractory to intravenous corticosteroids. Colectomy rates at 3 mo were significantly lower in patients receiving infliximab than placebo (7 out of 24 *vs* 14 out of 21, $P = 0.017$)^[113]. The authors observed that patients with a less active disease who were randomised after 5-7 d of intravenous corticosteroids seemed to benefit more than patients with more severe disease randomised at day 3. A retrospective Italian study^[114] then suggested that patients receiving a single infusion were more likely to require a colectomy at 2 mo than those who receive more infusions.

Other studies reported variable results^[115,116]. A placebo controlled trial showed a colectomy rate at 3 years of 50% in patients with severe UC treated with infliximab with respect to 76% in patients treated with placebo ($P = 0.012$)^[117].

The impact of preoperative infliximab use on the rate of surgical interventions and on post-surgical complications in patients with IBD was investigated in a meta-analysis. Twelve studies (8 on UC, 3 on CD and 1 on both UC and CD) were included in the analysis. In comparison with control groups, infliximab neither decreases the rate of colectomy nor increases the rate of infectious complications. However thrombotic events, ileal pouch complications, sepsis and anastomotic leaks were increased in patients treated with infliximab. On the other hand patients treated with biological therapies have a more severe disease and most of the time are refractory to other therapies. Thus it is possible that the postsurgical complications in these studies were associated with the severity of the disease and not with the treatment^[118].

A questionable point is what is the best second line rescue therapy in severe UC: infliximab or ciclosporine? Up to now no randomised trial showed clear advantages of one strategy over the other. A retrospective study compared 2 cohorts of patients receiving infliximab or ciclosporine as a rescue therapy. A lower immediate colectomy rate was reported in the ciclosporine group^[119]. At the end of the study the risk of colectomy was 11.2

(95%CI: 2.4-53.1, $P = 0.002$) at 3 mo and was 3.0 (95%CI: 1.1-8.2, $P = 0.030$) at 12 mo in infliximab treated patients, in comparison with cyclosporine treated patients.

Another retrospective study^[120] compared 2 historical cohorts of severe UC patients treated with cyclosporine (35 patients) or infliximab (30 patients). At 3 mo the colectomy rate was 28.5% in the cyclosporine group and 17% in the infliximab group ($P = 0.25$), at 12 mo the colectomy rate was 48% *vs* 17% ($P = 0.007$). At the end of the follow-up the colectomy rate was 60% *vs* 30% ($P = 0.04$). A high level of C reactive protein ($P = 0.04$), an extensive disease ($P = 0.01$) and no AZA treatment ($P = 0.001$) were related to the risk of colectomy.

In the CYSIF trial^[121] 111 patients with severe UC despite 5 d of intravenous corticosteroids were randomized to receive intravenous cyclosporine (2 mg/kg daily for 8 d) followed by oral cyclosporine (4 mg/kg daily) or infliximab (5 mg/kg at weeks 0, 2 and 6), followed by oral AZA. At day 7, 85% of patients responded to treatment in both groups. At day 98 treatment failure was reported in 60% of patients treated with cyclosporine compared with 54% of patients treated with infliximab ($P = 0.49$), with a colectomy rate of 18% in the cyclosporine group respect to 21% in the infliximab group ($P = 0.66$).

Regarding the evaluation of biologics serum levels or ADA in UC, in patients with UC infliximab serum levels were correlated with albumin serum levels^[122]. Patients with high serum albumin have a prolonged infliximab half-life and increased efficacy. Furthermore in UC patients the colectomy rate was significantly higher in the case of undetectable infliximab trough levels^[123]. In a post hoc analysis from the ACT I and ACT II studies higher infliximab concentrations were associated with an increased clinical remission and mucosal healing. The highest proportion of patients in clinical remission was observed in patients with serum levels of infliximab between 2.4 and 6.8 mg/mL at week 30^[124].

As for CD also in UC - biologics serum levels or ADA have not been routinely applied in clinical practice.

COMBINATION THERAPY IN IBD

Some studies supported the efficacy of combination therapy with biologics and thiopurines both in CD and UC. A trial compared the efficacy of induction treatment with infliximab plus AZA/6-MP to AZA/6-MP alone in steroid-dependent CD patients^[52]. At the end of the study, combination therapy was more effective than thiopurines alone. Furthermore a higher remission rate was observed in the subgroup of patients naive to AZA/6MP. In patients with previous thiopurines failure the difference between infliximab and placebo was not statistically significant. In another study^[70] combined immunosuppressive therapy with infliximab and AZA was able to obtain a higher steroid-free remission rate with respect to monotherapy with infliximab or AZA. Patients with moderate to severe CD were treated with infliximab, AZA or a combination therapy with the 2 drugs. After

26 wk 57% of patients assigned to combination therapy achieved a steroid-free remission, compared with 44% of patients assigned to infliximab alone and 30% of patients assigned to AZA alone. However the greater efficacy of combination therapy was observed mainly in patients with normal value of CRP and absence of endoscopic lesions at baseline.

Regarding UC, a recent trial^[125] suggested that in steroid-refractory patients with active UC a combination therapy with AZA and infliximab was more effective than either monotherapy. At week 16 clinical remission was achieved in 24% of patients receiving AZA, in 22% of patients received infliximab and in 40% of patients receiving combination therapy ($P = 0.032$ for combination therapy *vs* AZA monotherapy and $P = 0.017$ for combination therapy *vs* infliximab monotherapy).

These data are up to now insufficient to consider combination therapy efficient in all IBD patients. Furthermore, it is still being debated whether combined immunosuppressive therapy increases the long term toxicity. In clinical practice the use of combination therapy should be reserved for patients who do not respond to monotherapy.

The evidence of higher incidence of hepatosplenic T cell lymphoma in young men treated with combined immunosuppressive therapy^[126,127] should avoid prolonged combination therapy in young males. The recent observation that most of the lymphomas associated with immunosuppressive therapies in IBD patients were due to a loss of control of EBV infection leads to a recommendation of avoiding the use of thiopurines in patients seronegative for EBV^[128].

CONCLUSION

The use of immunosuppressive therapy, with conventional immunosuppressants or biologics, is indicated in the case of moderate to severe disease not responding to corticosteroids and in steroid-dependent IBD patients, as induction and maintenance treatment. Cyclosporine, infliximab and tacrolimus are considered a second line therapy in patients with severe UC not responding to 3-5 d of intravenous corticosteroids. The choice of biologics instead of immunosuppressants in the case of steroid-dependent IBD patients is guided by the severity of the disease, the presence of complex perianal disease in patients with CD or the concomitant extra-intestinal manifestations. Furthermore the recent observation that patients seronegative for EBV and treated with immunosuppressants have a higher risk of lymphomas, should lead to avoiding treatment with thiopurines in this subgroup of patients. The slow onset of action of thiopurines precludes their use as a single therapy in active IBD patients but they can be used in combination with corticosteroids. When treatment with thiopurines is chosen, adequate dosage and duration of therapy should be reached before evaluating their efficacy. The evaluation of serum concentration of thiopurine methyl transferase

activity and thiopurine metabolites could be useful for the management of the treatment but up to now it has not been routinely applied in clinical practice. The use of thalidomide and MMF is not recommended in IBD patients, the decision to use them might only be made on a case by case basis after failure of all other options including optimization of anti-TNF α therapies and surgical strategies.

Regarding biological treatment, dose intensification could be useful in the presence of incomplete response. In the case of primary failures to one anti-TNF α , a switch to the other one should be considered. In cases of intolerance to infliximab, the use of adalimumab as a second line treatment is recommended. Data on the efficacy of combination therapy are up to now insufficient to consider this strategy in all IBD patients. Furthermore the evidence of higher incidence of hepatosplenic T cell lymphoma in young men treated with combined immunosuppressive therapy means prolonged combination therapy should be avoided in these patients. As for immunosuppressants also for biologics - the evaluation of biologic serum levels and antibiologic antibodies could be useful for the management of the treatment but it is not routinely applied in clinical practice.

The final outcome of the treatment should be considered the clinical remission, with mucosa healing and not the clinical response.

Considering the evidence of high risk of cutaneous malignancies in patients treated with immunosuppressants and biologics for a long term period, lifelong sun protection and periodical dermatological screening should be recommended for these patients.

Abstract

Over the past decade there has been a dramatic change in the treatment of patients with Crohn's disease and ulcerative colitis, which comprise the inflammatory bowel diseases (IBD). This is due to the increasing use of immunosuppressives and in particular the biological agents, which are being used earlier in the course of disease, and for longer durations, as these therapies result in better clinical outcomes for patients. This, however, has the potential to increase the risk of opportunistic and serious infections in these patients, most of which are preventable. Much like the risk for potential malignancy resulting from the use of these therapies long-term, a balance needs to be struck between medication use to control the disease with minimization of the risk of an opportunistic infection. This outcome is achieved by the physician's tailored use of justified therapies, and the patients' education and actions to minimize infection risk. The purpose of this review is to explore the evidence and guidelines available to all physicians managing patients with IBD using immunomodulating agents and to aid in the prevention

of opportunistic infections.

INTRODUCTION

Patients with one of the inflammatory bowel diseases (IBDs), Crohn's disease (CD) or ulcerative colitis (UC), are at an increased risk of infection, which is partly inherent to the diseases themselves, but may also be due to the therapies used in their management. The pathogenesis of IBD is potentially secondary to an inappropriate in-

nate immune response to normal colonic flora and this may result in the lack of an appropriate immunological response to potential pathogens^[11]. In the more severe cases of IBD, patients may suffer from concurrent malnutrition and can need radical surgical procedures, which can further compromise the patients' immunological responses^[2]. The drugs required for disease control, such as the corticosteroids, immunological modulators like the thiopurines, methotrexate and cyclosporine, as well as the anti-tumor necrosis factor alpha (TNF α) medications, also have as their primary function the inhibition, and control, of immune system activity. Therefore, these can further reduce the immunological responses resulting in an increased risk of opportunistic infection.

The prevalence of opportunistic infections in IBD, however, is difficult to assess as this can vary markedly between countries but as they may result in mortalities within the IBD patient population their avoidance is of great importance^[3-6]. As an example, the background risk of tuberculosis (TB) in Spain is high at 21/100000, where it is considered endemic and the risk of infection can increase by up to 90-fold in IBD patients receiving an TNF α medication^[7]. By contrast there is a much lower background prevalence of TB in countries like the United States at 6.8/100000^[8] and 0.9/100000 in the non-indigenous Australian-born population^[9]. The risk to both the general population, and the immunosuppressed IBD patient, is thus vastly less in these countries and was demonstrated in an Australian and New Zealand study examining the prevalence of serious infections in IBD patients receiving a TNF α agent where not a single patient suffered from either primary, or reactivated TB, despite 3 patients receiving TB chemo prophylaxis due to a positive Quantiferon gold test prior to the initiation of TNF α therapy^[9].

While there is much concern regarding the TNF α drugs, as they may result in reactivation of granulomatous infections, particularly TB^[10], there is frequently less emphasis given to the other immunomodulating medications and whether they should also be regarded with caution, especially when used in combination with the TNF α therapies. The future of IBD medicine is, however, moving towards more biological medications (certolizumab, golimumab, natalizumab and vedolizumab) and the use of combination therapies. The risk to benefit ratio of these medications for the IBD patient thus needs to be continually assessed and monitored in order to give the best outcomes, much like the balancing act required to maintain IBD remission while minimizing the risk of cancers in these patients^[11].

Many infections have been associated with the use of the IBD medications, however, some may be specifically due to the mechanisms of action of individual medications^[12]. Patients on the thiopurine agents appear to be at greater risk of developing viral infections like cytomegalovirus (CMV), Epstein Barr virus (EBV) and varicella zoster virus (VZV), which is thought to be secondary to the effect of the thiopurine metabolites on T cells lead-

ing to the induction of apoptosis^[12]. By contrast, macrophage function is primarily affected in patients receiving a TNF α agent and it has clearly been documented that these medications reactivate TB and thus a meticulous screening program is required for these patients prior to undergoing these therapies^[10].

There is thus a definite risk of infections other than TB with the use of the IBD medications, but overall they appear to be uncommon. In the Australia and New Zealand study only 2.2% of the patient population receiving TNF α therapy suffered a serious opportunistic infection. Almost half of these cases, however, were on a combination of immunosuppressive therapies^[9]. This is similar to the findings of one of the first studies investigating opportunistic infection rates undertaken at the Mayo Clinic. This investigation demonstrated that the use of steroids, thiopurines and infliximab all impact on the rate of opportunistic infections in IBD. It noted that steroid use alone increased the risk by 2.6 fold (95%CI: 1.4-4.7) but this, however, increased further to 12.9 fold (95%CI: 4.5-37.0) when 2 or more of these drugs were used in combination^[13].

Despite how rare an opportunistic infection may be, however, the difficulty is in recognizing and treating them once they have occurred and the fact that they can result in significant morbidity and mortality. Prevention is thus certainly regarded as much better than cure in these situations. The prevention of opportunistic infections is, therefore, both the patient's and treating physician's primary goal and can be achieved through the use of multiple modalities that include vaccinations, chemoprophylaxis and education of the patients and clinicians. Each of these factors is vital for the successful implementation of appropriate guidelines for the best patient management^[14].

DEFINITION OF IMMUNOSUPPRESSION

An immunocompromised patient is someone in whom there is defective phagocytic, cellular, or humoral immunity, which leads to an increased risk of opportunistic infection and/or infective complications^[15,16]. While the presence of active IBD can itself lead to an increased risk of infections, independent of immunomodulating drugs, secondary to loss of the intestinal mucosal integrity, the IBD patient is not considered as immunocompromised *per se*. IBD patients are thus considered as being immunosuppressed primarily as a result of the therapy they receive and/or from the presence of malnutrition^[16,17]. The ECCO Consensus guidelines outline the various IBD therapies, which classify a patient as being immunocompromised and include the following: (1) treatment with steroids (prednisone or its equivalent of > 20 mg/d, or 2 mg/kg per day if < 10 kg, for 2 wk or more, and within 3 mo of stopping); (2) treatment with therapeutic doses of a thiopurine or discontinuation within the 3 mo preceding; (3) treatment with methotrexate or discontinuation within the preceding 3 mo; and (4) treatment with a TNF α agent or discontinuation within the preceding 3 mo^[16,17].

| History | Examination | Investigations |
|--|-----------------------|--|
| Previous travel or living in tropical areas, future travel | Any active infections | Full blood count and differentials |
| Bacterial, viral or fungal infections | Dental examination | C-reactive protein |
| Risk of latent or active TB including country of origin, potential contacts, previous treatments | Pap smear | HCV, HBV and HIV serology (including HBV sAb if history of vaccination against HBV) |
| Immunization status | | Stool cultures |
| | | EBV, CMV and VZV serology |
| | | Quantiferon gold assay, or tuberculin skin test (depending on local guidelines) for TB screening |

Figure 1 The patient pre-inflammatory bowel disease therapy work up. HIV: Human immunodeficiency virus; HBV: Hepatitis B virus; HCV: Hepatitis C virus; TB: Tuberculosis; CMV: Cytomegalovirus; EBV: Epstein Barr virus; VZV: Varicella zoster virus.

VACCINATIONS

Understanding the role of vaccination in the IBD population is crucial for the patient, specialist and primary care physicians involved in patient care. As advances in medical therapies lead to healthier patients with a better quality of life, focus must shift from treating infection to maintaining well-being in our patients by the prevention of disease. Vaccination is one of those vital, but frequently forgotten, areas in infection prevention. Patients with IBD are at risk of the same vaccine-preventable illnesses as the general population, and since most IBD patients will be diagnosed after they have completed their childhood immunization schedules, and most will require immunosuppression therapy at some stage in their lifetime, the opportunity should be taken to explore each patient's immunization status at the time of the diagnosis of their IBD^[15].

The institution of immunosuppressive and biological therapies also impact on which vaccinations a patient is allowed to receive and can also impact on the patient's response to vaccination with some studies demonstrating a lower response rate to vaccination once on these agents^[18,19]. There is usually only a small window of opportunity in which to vaccinate the patient prior to the institution of treatment with an immunomodulatory agent. This must be taken advantage of in order to achieve the best possible patient outcomes. To date it is clear that the vaccination rates in the IBD populations are suboptimal and these need to be improved^[20-23] and as there are now clear published international guidelines created to increase physician awareness of this issue and to improve vaccination rates and outcomes in the IBD population^[16].

What to do at diagnosis

At the initial diagnosis, or first presentation, of an IBD patient, a thorough history, clinical examination and panel of blood investigations should be performed prior to commencing any immunosuppressive, or biologic, therapy. This should include a history of previous, and current, infections including viral [VZV, herpes simplex virus (HSV), human immunodeficiency virus (HIV), hepatitis B virus (HBV) and hepatitis C virus, EBV and CMV], bacterial (TB, pneumococcal and urinary tract infections) and fungal infections. A detailed vaccination and travel history is also crucial in further determining what vaccinations need to be recommended, boosted or checked. Figure 1 summarizes the patient pre-IBD therapy work up and Table 1 summarizes the vaccination recommendations based on current guidelines and evidence.

Once a patient is on a immunocompromising medication, inactivated vaccinations only are recommended and these are suggested in guidelines for immunocompromised patients who do not have an increase risk of infectious complications^[24]. Live attenuated vaccinations need to be avoided in these patients (Table 1) as there is a risk that the administration of live vaccines to immunocompromised persons may result in adverse events, or vaccine-related disease, due to unchecked replication of the vaccine virus or bacteria. This is particularly noted for the measles-, mumps-, rubella^[25,26] and VZV-containing vaccines^[27] and for Bacille Calmette-Guérin (BCG) vaccine^[28,29]. The risk of disease, however, varies for different vaccines and for different individuals so caution is required for the use of vaccination in the setting of immunocompromise. In significantly immunocompromised persons the use of almost all the live vaccines are contraindicated.

The live attenuated vaccinations include yellow fever, oral polio, BCG, measles-mumps-rubella, typhoid Ty21a, VZV, live attenuated influenza virus and herpes zoster (Centre for Disease Control, 2009). Ideally a patient should not be receiving an immunomodulating medication for at least 3 mo prior to vaccination and in the case of steroids, the patient should avoid use for at least a month. If a live vaccine must be given to an IBD patient, the recommencement of an immunomodulatory medication should be withheld for at least 3 wk^[16].

RECOMMENDED VACCINATIONS - INACTIVE VACCINES

HBV vaccination

IBD patients who have less than 10 IU/L hepatitis B surface antibodies (anti-HBs) should be vaccinated against HBV according to the standard schedule (3 doses at 0, 1 and 6 mo) regardless of if they are immunosuppressed or not. When HBV vaccines are administered to a young healthy population, there is a > 95% protective seroconversion rate^[30-32]. Yet studies in the IBD populations have revealed much lower rates of detectable anti-HBs post vaccination (33%-36%)^[20,33], which could be attributable to

Table 1 Vaccines recommended in immunocompromised inflammatory bowel disease patients

| Infectious disease | Vaccine type | Recommendation |
|-----------------------|-------------------------------------|---|
| Influenza | Inactivated trivalent virus | Recommended annually |
| Pneumococcal disease | 23-valent purified capsular antigen | Recommended 5 yearly |
| Hepatitis B virus | Recombinant peptide | Recommended standard or double dose schedule |
| Human papilloma virus | Quadrivalent vaccine | In women according to local guidelines, standard schedule |
| Tetanus-Diphtheria | Toxoid | Recommended in vaccinated patients 10 yearly |
| Measles-Mumps-Rubella | Live attenuated | Contraindicated |
| Varicella zoster | Live attenuated | Contraindicated |
| Yellow fever | Live attenuated | Contraindicated |
| Cholera | Oral live | Contraindicated |
| | Oral killed | Use with caution |
| Poliomyelitis | Oral live attenuated | Contraindicated |
| | Injectable inactivated | Recommended |
| Meningococcal | Conjugated polysaccharide | Authorised yet not recommended |
| | C polysaccharide combined | Authorised yet not recommended |
| Tuberculosis | BCG live vaccine | Always contraindicated |

BCG: Bacille Calmette-Guérin.

an older age group^[33] but also the use of biological therapy^[18,34]. The use of a thiopurine medication, however, appears to have no negative impact on the efficacy of HBV vaccination but this may need further investigation^[18].

Due to the significantly lower response rates to standard HBV vaccination in IBD patients, some studies have suggested a modified dosing regimen that doubles the standard antigen dose, given at 0, 1 and 2 mo. This was noted to result in 60% of the IBD patients having hepatitis B surface antigen levels > 10 IU/L^[18]. Comparison between this and the standard vaccination regime has been studied in IBD where 148 patients were vaccinated with either the standard, or double dose, protocol with an anti-HBs of > 10 IU/L considered a successful response^[35]. The seroconversion rate in the standard protocol group was 41% compared to a 75% seroconversion in the double dose protocol group. The advantage of the double dosing protocol was seen regardless of the use of immunosuppressive treatments and also was noted for achieving higher titres of anti-HBs with levels > 100 IU/L.

Considering the variability of HBV seroconversion, the best time to offer immunization is at the time of diagnosis prior to commencement of any immunomodulator therapy. Serological testing should then be undertaken after completion of the vaccination schedule (1-3 mo after the last dose) to determine if immunity was conferred^[16,31,32]. If the standard protocol fails to achieve seroconversion, an additional vaccine can achieve a successful antibody response in between 25%-50% of patients and a complete second three-dose course has been shown to be successful in between 40%-100% of patients in non-IBD population studies^[31,36].

Debate has also occurred around the ideal anti-HBs titre that should be reached post-vaccination in the IBD population. Post-vaccination anti-HBs titres of > 10 IU/L is considered to have conferred protection against infection in healthy subjects. This is long-term protection and relies on immune memory. In the immunocompromised patient, however, protection may be primarily reli-

ant on the amount of circulating antibody rather than the immune memory. Thus titres > 100 IU/L in the United Kingdom are now considered as the new cut-off point for the vaccination to be considered as successful in the immunocompromised patient^[32,37]. If these titres are not achieved after the 3-dose schedule, a 4th dose is then administered, or repetition of the full 3-dose series.

Influenza virus vaccination

Annual vaccination against influenza is recommended in IBD patients from the time of diagnosis^[16]. Immunosuppressed patients have a higher risk of complications secondary to the influenza virus and there is greater associated morbidity and mortality^[38]. The inactivated trivalent influenza vaccine comprises two type A subtypes (H1N1 and H3N2) as well as type B subtype. Studies have demonstrated mixed efficacy of the vaccine in the immunosuppressed population, mostly in paediatric IBD patients, which have demonstrated poor seroprotection results^[39-42]. However, more recent data in adult IBD patients have demonstrated adequate seroprotection rates without exacerbation of intestinal disease^[43]. Regardless of these findings, however, in most cases the immune response is adequate to warrant ongoing annual vaccination.

Pneumococcal vaccination

Streptococcus pneumoniae is the most common bacteria responsible for pneumonia and sepsis. IBD patients are also at increased risk of invasive pneumococcal sepsis^[17,20]. Vaccination with the 23-valent strain is thus recommended to be administered every 5 years in the IBD population^[16].

Again, as seen with other vaccines, effectiveness of this vaccine is diminished in patients on immunomodulating therapies, especially in combination, and therefore it should, ideally, be administered prior to commencement of such treatments^[44]. Considering that the vaccine comprises 23 antigens to mount an immune response too, some degree of protection can be achieved and, therefore, it is considered worthwhile.

Human papilloma virus vaccination

The human papilloma virus (HPV) is the most common sexually transmitted infection^[45]. This virus is oncogenic and can lead to cervical dysplasia with progression through to carcinoma^[46,47]. While data is lacking of a clear link with this risk being heightened and the use of immunosuppression, and biological therapies, there is a theoretical risk of HPV-associated tumours in prolonged and combination immunosuppressing IBD therapy. Vaccination against HPV in IBD is thus advisable in the appropriate populations (young women ageing from 12 years to 26 years old) according to the local guidelines^[16,48].

Tetanus and diphtheria

It is recommended that the general population should receive the tetanus, diphtheria and acellular pertussis vaccine every 10 years. This also holds true for patients with IBD. If the vaccination history is dubious then this should occur early within the IBD patient's course of treatment^[16,49].

LIVE ATTENUATED VACCINES**Measles-mumps-rubella vaccination**

Childhood immunizations against measles, mumps and rubella should be included in the initial history taking of the new IBD patient. In most developed countries there is a low risk of acquiring these infections as an adult due to herd immunity^[50]. The evidence to support administration of the combined vaccine in patients prior to immunosuppressive therapy institution is also lacking and thus this is currently not a recommended vaccination by the ECCO guidelines.

Varicella vaccination

If patients with IBD have no history of having had varicella infection in childhood, serology should be checked and vaccination considered. Varicella infection in adults is more severe than in children, can be fatal and particularly severe if the patient is immunocompromised^[51]. Unfortunately, this vaccination is a live vaccine, and thus IBD patients who are varicella naïve and are already immunosuppressed should not receive it. If, however, the patient is known not to be immune to varicella prior to IBD therapy, a 2-dose schedule should be given at least 3 wk prior to commencing an immunosuppressive medication^[16]. Careful consideration of patients who might be at greater risk of varicella infection, such as children, teachers or health care workers, should guide the clinician in this decision.

CHEMOPROPHYLAXIS

Antibiotic prophylaxis has been a commonly used therapy in immunosuppressed patients to prevent opportunistic infections and the best example of this in IBD is for suspected latent, or active, TB. The TNF- α agents should be avoided in patients suspected of having latent, or ac-

tive, TB until treatment for TB has been commenced and has been in effect for at least 4 wk in order to avoid reactivation of TB, or according to local guidelines^[52-55].

Prophylaxis for *Pneumocystis jiroveci* with trimethoprim-sulpha-methoxazole^[12] should also be considered in patients on combination immunomodulatory regimes, usually when they are receiving the combination of 3 agents that includes steroids^[12,16,56], or in patients with low lymphocyte counts ($< 600/\mu\text{L}$)^[57]. Alternative agents are aerosolized pentamidine, dapsone and atovaquone^[58]. Data is lacking in this area and should be considered closely by the clinician on a case-by-case basis.

HSV

IBD patients with frequent and or severe recurrent HSV disease can be given oral anti-viral therapy to control these infections^[16]. Considering most infections with HSV are mild and self-limiting, chemoprophylaxis is not recommended in IBD patients commencing immunomodulators. If HSV infection, however, disseminates during immunosuppressing therapy, then treatment with high dose antivirals and cessation of immunosuppressors is recommended^[16].

HBV infection

HBV is a very common infection worldwide and is well known to reactivate in patients receiving immunosuppressive medications. This can result in significant morbidity and mortality, from liver function tests derangement through to fulminant hepatic failure and death unless anti-viral prophylaxis is given. This treatment strategy in preventing HBV flares is well established in patients with HBV-HIV co-infection and chronic HBV infected patients receiving systemic chemotherapy^[59] and is becoming increasingly important in IBD patients particularly on combination immunomodulatory therapy and on the biologics^[60]. There have been several case reports of fatal HBV flares in patients with IBD on immunosuppressant drugs^[61-64] drawing concerns that the TNF alpha drugs may be involved in regulating HBV replication^[65]. Patients who test positive for HbsAg should go onto anti-viral prophylaxis prior to commencing any immunosuppressive therapy. This is regardless of a detectable DNA viral load or not. Most recent guidelines suggest treatment with either entecavir or tenofovir over lamivudine due to fewer issues with developing viral resistance to these agents however most studies have been focused on lamivudine prophylaxis to date^[59].

HIV infection

Prior to highly active anti-retroviral therapy (HAART), immunosuppressive agents, especially the anti-TNF drugs were contraindicated in HIV-infected IBD patients. Now that viral replication can be controlled and immune reconstitution achieved with the use of HAART, both the immunosuppressive and biologic agents can be used to treat IBD in patients who have a CD4⁺ T lymphocyte count $> 500/\mu\text{L}$ ^[66,67]. In those patients who are not on

HAART, but require immunosuppressive or biologic agents, then initiation of HAART should take priority, especially if CD4⁺ T cell counts are < 500/ μ L.

EDUCATION

Patients need to be educated on how to recognize early symptoms of an opportunistic infection and to act quickly to get the required treatment if they are immunocompromised. Fever tends to be the most reliable, and sometimes the only, symptom for heralding the development of an opportunistic infection^[68] and IBD patients should always seek medical advice and/or review should they be experiencing this, especially in combination with other symptoms and the use of immunomodulator therapies. In these circumstances, a thorough history, examination, and septic work up should be performed by the clinician to help isolate the source of infection and guide therapy. Of course fever can also be a sign of a flare and thus this should also be considered.

If the suspicion for an infective cause of a fever in the context of digestive symptoms is high, then vigilance to exclude infection should be the priority, rather than the escalation of IBD therapy. Stool cultures that also examine for *Clostridium difficile* (*C. difficile*) toxin and ova, cysts and parasites should be performed. It must also be noted that a single stool culture may only exclude 66% of infections. Multiple stool cultures are thus recommended particularly for the excluding of *C. difficile* infection^[69]. *C. difficile* is an increasing problem in immunocompromised patients and current estimates suggest that approximately 10% of IBD patients will develop symptomatic *C. difficile* infection at some point during the course of their lifetime^[69]. This is important as it can lead to higher rates of colectomy and mortality.

If stool sample results are negative, an urgent colonoscopy or flexible sigmoidoscopy with colonic biopsies should be considered to assess for CMV colitis. This diagnosis is made on histological examination of biopsies taken at the interface of ulcers. Serum CMV PCR can also be performed but is not specific for active CMV disease^[70].

CONCLUSION

In an era of increasing use of immunosuppressing medications in IBD and for longer durations, together with advocacy of the use of combination therapy, patients and their doctors need to be more vigilant about prevention and detection of opportunistic infections. IBD patients are at the same risk for vaccine-preventable illness as the general population. As IBD therapy can affect vaccine efficacy, then vaccination should be considered early in the course of disease and ideally prior to the commencement of any immunocompromising medication. The challenge for doctors is to balance the medical management of IBD, knowing the risks of individual therapies, and recognizing that prevention of opportunistic infections is as

of equal importance. This usually requires the best use of one of the most precious commodities a doctor has with their patient, time.

Abstract

Ulcerative colitis and Crohn's disease are the major phenotypes of the idiopathic inflammatory bowel disease (IBD), which afflicts millions of individuals throughout the world with debilitating symptoms, impairing function and quality of life. Current medications are aimed at reducing the symptoms or suppressing exacerbations. However, patients require life-long medications, and this can lead to drug dependency, loss of response together with adverse side effects. Indeed, drug side effects become additional morbidity factor in many patients on long-term medications. Nonetheless, the efficacy of anti-tumour necrosis factors (TNF)- α biologics has validated the role of inflammatory cytokines notably TNF- α in the exacerbation of IBD. However, inflammatory cytokines are released by patients' own cellular elements

including myeloid lineage leucocytes, which in patients with IBD are elevated with activation behaviour and prolonged survival. Accordingly, these leucocytes appear logical targets of therapy and can be depleted by adsorptive granulocyte/monocyte apheresis (GMA) with an Adacolumn. Based on this background, recently GMA has been applied to treat patients with IBD in Japan and in the European Union countries. Efficacy rates have been impressive as well as disappointing. In fact the clinical response to GMA seems to define the patients' disease course, response to medications, duration of active disease, and severity at entry. The best responders have been first episode cases (up to 100%) followed by steroid naive and patients with a short duration of active disease prior to GMA. Patients with deep ulcers together with extensive loss of the mucosal tissue and cases with a long duration of IBD refractory to existing medications are not likely to benefit from GMA. It is clinically interesting that patients who respond to GMA have a good long-term disease course by avoiding drugs including corticosteroids in the early stage of their IBD. Additionally, GMA is very much favoured by patients for its good safety profile. GMA in 21st century reminds us of phlebotomy as a major medical practice at the time of Hippocrates. However, in patients with IBD, there is a scope for removing from the body the sources of pro-inflammatory cytokines and achieve disease remission. The bottom line is that by introducing GMA at an early stage following the onset of IBD or before patients develop extensive mucosal damage and become refractory to medications, many patients should respond to GMA and avoid pharmacologics. This should fulfill the desire to treat without drugs.

INFLAMMATORY BOWEL DISEASE

The idiopathic inflammatory bowel disease (IBD), which includes ulcerative colitis (UC) and Crohn's diseases (CD) is an immune disorder characterized by inflammation of the gastrointestinal tract in genetically susceptible individuals when exposed to environmental risk factors^[1]. Therefore, IBD has long been thought to have a genetic basis and involves response of the immune mechanisms to certain environmental agent(s). The development of IBD among monozygotic twins and an increased incidence in countries undergoing rapid Westernization highlight the relevance of genetic predisposition together with environmental factors in disease pathogenesis and incidence^[2]. What all these mean is that in patients with IBD, the intestinal immune profile becomes dysregulated showing exaggerated response to triggers that would have been insignificant in an individual without genetic susceptibility factor.

However, it is clinically relevant to bear in mind that whereas UC is confined to the colon and the rectum (large intestine), CD may affect any part of the gut from the mouth to the perianal region. Most commonly CD affects the distal ileum and the colon; up to 65% of CD patients present with small intestinal involvement. Both UC and CD are debilitating chronic health disorders that afflict millions of individuals throughout the world with symptoms, which impair function and quality of life.

Further, the human intestine is host to thousands of bacterial species, collectively referred to as the intestinal microbiota or microflora^[3]. While it is understood that the presence of this microbiota is essential for human

health, this relationship may become unbalanced, and translate into development of UC or CD^[3,4]. Accordingly, both clinical and experimental observations indicate that IBD flare-ups are triggered by a combined loss of the so-called intestinal barrier function and a dysregulated immune response to the intestinal microbiota^[3,5].

A multitude of clinical manifestations represent the expression of IBD. These include diarrhoea, rectal bleeding, abdominal discomfort, fever, anaemia, and weight loss. Both UC and CD tend to run a remitting-relapsing course affected by diverse factors mentioned above. The severity of UC is often presented by a clinical activity index (CAI), which is described by several authors^[6-9]. Another, but complementary parameter is endoscopic activity index (EI), which is a true reflection of mucosal damage or otherwise mucosal remission^[10] calculated according to Rachmilewitz^[6] or the Mayo scoring method^[7]. Further, disease activity in CD, which is the other phenotype of IBD is assessed by the well known CD activity index (CDAI)^[11]. A CDAI of < 150 reflects remission. The authors of this review (Tanaka T, Ohmori T, Sawada K, Yamamoto T, Hanai H) are gastroenterologists and routinely evaluate patients by both CAI and endoscopy/colonoscopy with greater reliance on endoscopic evaluation^[10]. Therefore, in this article, our endeavours were supported by the diagnostic power of colonoscopy to identify patients with an active flare of IBD who were identified as the most likely responders to selective, but therapeutic removal of circulating myeloid lineage leucocytes (granulocytes and monocytes/macrophages) by extracorporeal adsorption as a non-pharmacologic treatment intervention. This strategy is known as GMA, which stands for adsorptive granulocyte and monocyte apheresis, described later. In Figure 1 colonoscopic photographs from the colonic mucosa of a healthy human subject and from patients with UC are presented. The mucosa is the surface through, which nutrients and water from the food in the intestine are absorbed into the blood stream. Accordingly, healthy mucosa has a well developed vascular network for adequate absorption of water and nutrients. However, in patients with IBD, the vascular patterns may become invisible or lost due to inflammation or ulcers, seen in Figure 1. As the mucosal layer is involved in the absorption of nutrients and water from the gut, during severely active IBD, absorption of nutrients and water is seriously impaired. Extensive and deep ulcers together with near total loss of the mucosal tissue are not uncommon in patients with severe IBD even in the presence of conventional medications. This condition is debilitating, the patients may suffer from weight loss. For example unabsorbed food and water will pass as watery diarrhoea, or bloody diarrhoea (due to bleeding ulcers). Patients with deep ulcers and extensive loss of the mucosal tissue are not likely to respond to any drug based medication or even to therapeutic depletion of myeloid leucocytes by GMA, they have fulminant UC (disease persists in the presence of optimal medication) and often must opt for resection of the affected gut segment. Needless to say that only an

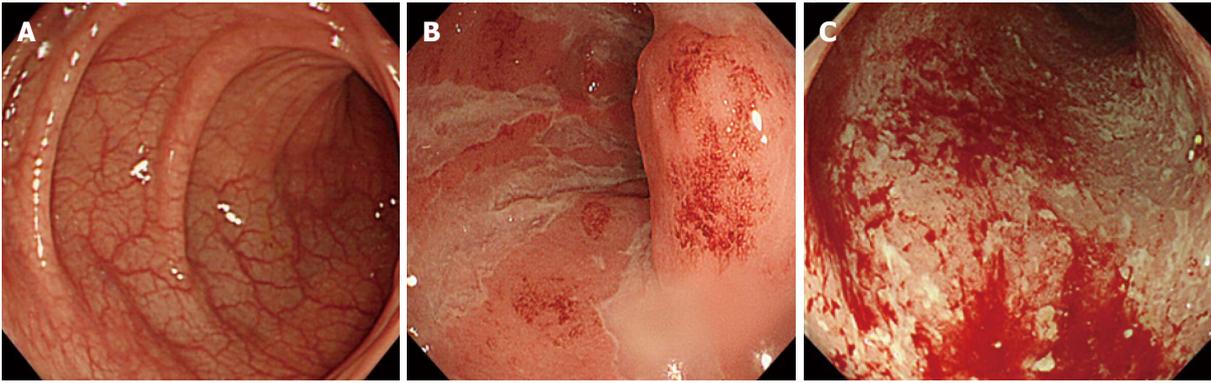

Figure 1 Colonoscopy images. A: Colonoscopy showing normal mucosa with visible vascular patterns in a healthy, non-inflammatory bowel disease (IBD) individual; B: During strong inflammation in a patient with IBD, visible vascular patterns are lost; C: Inflammation can lead to ulcerated mucosa and contact bleeding. Both mucosal inflammation and ulcers lead to inadequate absorption of water and nutrients from the gut. The affected patients may lose weight and become anaemic due to bloody diarrhoea, which if untreated can be very debilitating.

initial diagnostic colonoscopy can identify such patients as non-responders to drug based interventions so that the patient can opt for surgical intervention at an early stage. This should significantly shorten morbidity time and help to avoid futile use of medical resources.

THERAPEUTIC OPTIONS FOR PATIENTS WITH IBD

However, currently available medications aid in the induction and maintenance of remission by targeting various points along the disordered immune pathway implicated in IBD flare ups^[12-17]. Despite these seemingly advances, knowledge on the precise cause of IBD is inadequate at present. Accordingly, up to now drug therapy has been empirical rather than based on a sound understanding of disease aetiology. While drug therapy initially appears effective in the majority of patients, it comes at the cost of serious side effects^[18-20], which add to the disease complexity. First-line medications for exacerbation of IBD include 5-aminosalicylic acid or sulphasalazine in combination with a corticosteroid together with azathioprine (or 6-mercaptopurine) and nutritional support for some patients^[6,16,17]. Treatment failure in patients with severe disease has often been an indication for surgical intervention in many steroid refractory patients^[14,21] although in recent years, cyclosporin A (CsA) has been introduced for corticosteroid refractory UC^[8,9,15]. Despite being moderately effective in this clinical setting in reducing surgery rate, there remain serious concerns over long-term efficacy and toxicity of CsA^[20]. The development of new anti-tumour necrosis factor (TNF)- α antibodies like infliximab and adalimumab represent progress, but there is concern about safety and long term efficacy of biologics. However, this is not to say that drugs have no place in the treatment of IBD. In fact, no one can deny the role of medicines in the elimination of most diseases that our ancestors were left defenseless against. Instead, in this review, our endeavour has been to present clinical evidence and thera-

peutic outcomes supporting the idea that many patients with IBD can be treated without drugs, but by targeted apheresis.

CYTOKINES AND INFLAMMATORY BOWEL DISEASE

As stated above, the precise cause of IBD is not fully understood at present, and currently available medications do not eradicate the fundamental cause. Therefore, it should be logical to identify known exacerbating factors as therapeutic targets. In line with this thinking, patients with active IBD show elevated cytokine expression, aberrant antigen-antibody complexes, T-cell anomalies, and an increased numbers of granulocytes and monocytes/macrophages (myeloid lineage leucocytes)^[22,23], which show activation behaviour^[24,25], and prolonged survival^[26]. The interaction between neutrophils and macrophages is thought to induce a state of chronic inflammation, which contributes to the perpetuation of IBD. Additionally, the chronic nature of IBD means that afflicted individuals need life-long drug therapy and this can lead to refractoriness^[18] and drug-related adverse side effects^[19]. However, it is now widely known that IBD is exacerbated and perpetuated by the so-called inflammatory cytokines including TNF- α , interleukin (IL)-1 β , IL-23 and others^[27-29]. Accordingly, patients with active IBD respond to anti-cytokine antibodies, notably, to anti-TNF- α biologics^[30,31] albeit having known serious side effects^[32-34]. Nonetheless, the clinical response to anti-TNF biologics has validated the role of this cytokine as an exacerbating factor in dysregulated immune profile. Further cytokines like TNF- α , IL-1 β and others are produced by patients' own cellular elements, notably by the myeloid lineage leucocytes^[24,25,35,36]. Hence, elevated circulating myeloid lineage leucocytes appear logical targets of therapy by selective leucocytapheresis we introduced as GMA above. In this article, we have reviewed the latest developments in therapeutic leucocytapheresis to treat IBD with the Adacolumn GMA.

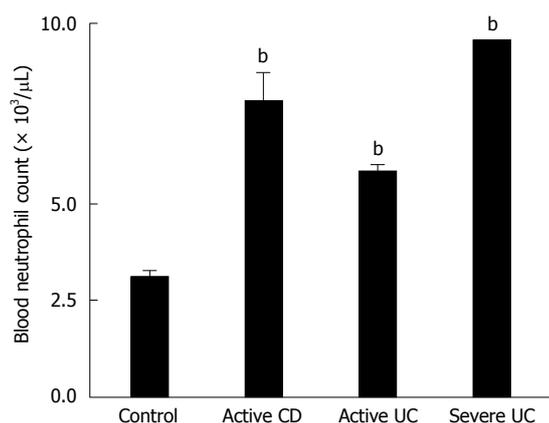

Figure 2 Blood neutrophil (granulocyte) counts in healthy controls and patients with inflammatory bowel disease. This figure shows a very marked elevation of neutrophils during active inflammatory bowel disease (IBD). Additionally, in patients with IBD, neutrophils show activation behaviour and increased survival time in the circulation^[26,36] as well as within the mucosal tissue^[25]. ^b $P < 0.01$ vs control group. UC: Ulcerative colitis; CD: Crohn's disease.

EVOLUTION OF APHERESIS AS A THERAPEUTIC PRACTICE

The word “apheresis” means to take away or to remove, clean from disease causing elements. In the modern time, apheresis means an extracorporeal medical technique for selective removal of components of the blood to achieve a therapeutic effect. Thus apheresis is an extracorporeal therapy. In classical sense, the most basic practice in apheresis involves passing of a patient's blood through a medical device where removal of components takes place; it is a kind of bloodletting. In the early 20th century, dialysis^[37], and centrifugation^[38] were introduced for selective depletion of soluble elements^[37] or blood cells^[38] to achieve therapeutic effects. Even in today's biologic based therapy targeting a pathologic cytokine, chemokine or an adhesion molecule, apheresis is considered as a non-drug strategy to manage diseases for which there is no effective drug based medication like removing toxic substances from the plasma, which threaten well-being^[39,40]. Strategies that selectively remove plasma components or blood cells as therapeutic interventions have generally been safe, and not associated with any major side effect in a significant number of patients^[39-41]. Recently, apheresis has been considered as an effective alternative to drug therapy or as an adjunct to conventional medications to enhance drug efficacy with potential to reduce standard medication dosage like the GMA trials in patients with IBD where corticosteroids were avoided or were tapered to a minimum^[41-44].

However, today's selective removal of constituents of circulating blood to achieve a therapeutic effect by apheresis is reminiscent of the rather crude technique of bloodletting (phlebotomy) and its therapeutic application at the time of Hippocrates (460-377 BC) in Ancient Greece. Bloodletting was widely practiced as a major therapeutic intervention in the Ancient civilization of Egypt from where it expanded to Ancient Greece and

other parts of the world. The perception then was that disease reflected presence of disease-causing substances in the blood and bloodletting was to expel the pathologic agents. Bloodletting was routinely and extensively practiced for diseases like inflammation, fever, hypertension, and other undiagnosed diseases, its most high profile patient was the first US president, George Washington (reviewed in ref^[45]). Bloodletting as a major medical practice was subsequently popularized by Claudius Galen (129-203 AC), a Greek physician who practiced in Rome and became a well respected authority in medicine for over 1500 years. In the late 19th century, bloodletting under a more modern name, phlebotomy was popularly used to treat conditions like haemochromatosis, polycythaemia vera and others. It may just be the folly of the past, but it is difficult to imagine that this procedure would have been so widely practiced for such a long time if it had not been associated with efficacy.

Even in this era of modern medicine and if we consider IBD, and innovations in biologic therapy, it is clinically relevant to bear in mind that drug therapy by its very nature, involves adding a foreign substance or substances to the body system and although initially may be effective, but potentially can lead to the disease becoming drug dependent or drug refractory (body' reaction to a foreign substance). Hence, a therapeutic strategy based on a non-drug intervention, a correction or support of body's natural processes like GMA^[41-53], if effective has an unrivalled advantage over drug based medication.

TARGET LEUCOCYTES FOR THERAPEUTIC GMA

For an extracorporeal intervention like GMA to be a novel non-drug therapeutic option, it should selectively deplete leucocytes, which in patients with IBD are thought to contribute to the disease pathogenesis. For example, patients with active IBD are found to have compromised lymphocytes^[42,47,54] in the presence of elevated and activated granulocytes and monocytes/macrophages^[46,48] seen in Figure 2. Additionally, certain sub-populations of lymphocytes like the CD4(+)/CD25(+) phenotype, known as the regulatory T-cells (Treg) have essential immunoregulatory function and therefore, are indispensable to the host^[55-61]. Based on these understandings, the Adacolumn for GMA is designed to spare lymphocytes, seen in Figure 3, and boost Treg phenotype^[48,61]. The column is filled with specially designed cellulose acetate beads of 2mm in diameter as leucocytapheresis carriers^[22]. As shown in Figure 3, the carriers remove from blood in the Adacolumn most of the granulocytes, monocytes/macrophages together with a significant fraction of platelets^[23,48]. Surprisingly, the procedure has been associated with a sustained increase in absolute lymphocyte counts following a course of GMA^[22]. The increase in lymphocyte counts includes the Treg phenotype, CD4(+)/CD25(+)^[61]. The mechanisms for sparing lymphocytes are briefly described here and illustrated in Figure 4. Patients with IBD may

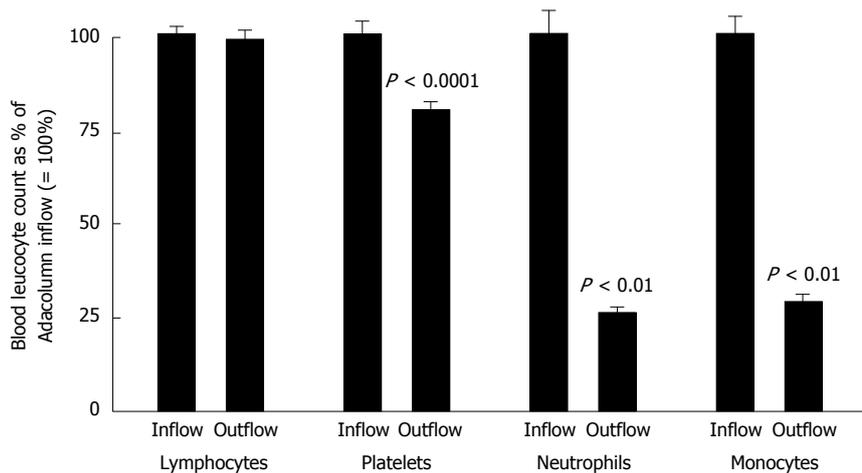

Figure 3 Selective depletion of myeloid lineage cells (neutrophils, monocytes and platelets) by adsorptive granulocyte and monocyte apheresis with the Adacolumn in patients with inflammatory bowel disease. In each case, the column inflow count was expressed as 100% and the column outflow count (return to patient) was expressed as a percentage of the inflow count taken 30 min (peak fall) during a 60-min granulocyte and monocyte apheresis (GMA) session. The data serve as a solid basis for the argument that GMA selectively depletes granulocytes, monocytes/macrophages together with a significant fraction of platelets, but spares lymphocytes^[22,23,48,117].

have immune complexes (IC) in their plasma^[23,62,63]. Cellulose acetate adsorbs immunoglobulin G (IgG) and IC from the plasma^[23,62,63]. Upon adsorption, the binding sites on IgG and IC become available for the fragment crystallizable gamma (Fc γ) receptors (Fc γ R) on myeloid lineage leucocytes^[23,62,63]. Further, cellulose acetate with adsorbed IgG and IC generates complement activation fragments including C3a and C5a^[23,63]. The opsonins C3b/C3bi and others derived from the complement activation fragments also adsorb onto the carriers and serve as the binding sites for the leucocyte complement receptors, CR1, CR2, CR3 (Mac-1, CD11b/CD18). Hence, leucocyte adsorption to the GMA carriers in the Adacolumn is governed by the opsonins, Fc γ R and the leucocytes complement receptors^[23]. The expressions of these sets of receptors are common features of myeloid lineage leucocytes. Lymphocytes are not known to express complement receptors except on small subsets of B, T and natural killer (NK) cells. Similarly, Fc γ R are not widely expressed on lymphocytes except on small populations of CD19⁺B cells and CD56⁺NK cells^[62]. These basic phenomena proceed well on the carriers and lend GMA selectivity (Figure 4). Further, to our knowledge, there is no published data showing elevated peripheral lymphocytes in patients with active IBD and in one of the best controlled studies on lymphocytapheresis in IBD, Lerebours *et al*^[64] selectively depleted circulating lymphocytes in patients with CD. At the end of an 18-mo follow-up, the clinical outcome in the lymphocytapheresis group was 21% inferior to that of the control group. This well planned controlled clinical trial^[64] rules out therapeutic benefit from removing lymphocytes in patients with IBD.

CLINICAL EFFICACY RATES FOR GMA IN UC PATIENTS

Hitherto, a large number of articles mostly from Ja-

pan^[65-77], and Europe^[78-91], but also from the United States^[92-96] have described the efficacy of GMA in patients with IBD. The clinical application of GMA with the Adacolumn began following a pioneering multicentre clinical trial by Shimoyama *et al*^[41] described below under steroid sparing effects of GMA. Since then, GMA has been widely applied in Japan and in the European Union (EU) countries to treat patients with IBD. Efficacy rates have been both striking^[42-44] as well as disappointing^[92,93], reflecting patients' diverse demographic features prior to GMA. Further, the authors of this review regularly apply GMA to treat patients with IBD for longer than a decade. Based on our experience, the best responders are first episode cases who are often drug naïve and have a short duration of IBD^[52], followed by steroid naïve patients^[42,50,53,75]. Efficacy rate in first episode cases has been as high as 100%^[52] and in steroid naïve cases over an 85%^[42,50]. Likewise, recently, Yokoyama *et al*^[74] reported that the most appropriate time to apply GMA therapy in patients with UC was immediately after a clinical relapse. The authors found that the best responders were those with a short duration of active disease^[74]. However, patients with deep mucosal lesions and extensive loss of the mucosal tissue at the lesion sites^[52,53,82,93] together with those who have a long duration of active UC and exposure to multiple conventional drugs including corticosteroids when the UC has become refractory to medications are not likely to benefit from GMA^[49,52,92,93]. These are clinically relevant findings because patients who responded to GMA have a better long-term clinical outcome by avoiding corticosteroids during their first active UC phase^[70], while knowing GMA non-responders should help to save medical cost by avoiding futile application of GMA. Figure 5 shows clinical remission rates in typical cohorts of patients with active UC. As shown, the remission rate for patients with the first UC episode has been 100%^[52]. All these first episode cases were steroid naïve with a short (< 4 mo) duration of UC.

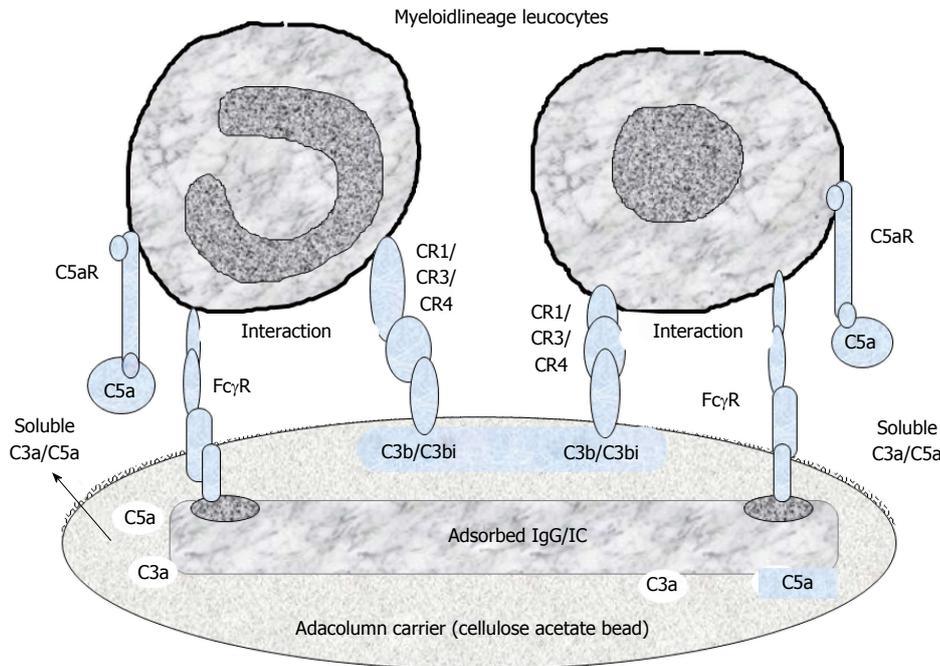

Figure 4 A tentative illustration of the mechanisms, which mediate the selective adhesion of myeloid lineage leucocytes to the granulocyte and monocyte apheresis cellulose acetate carriers. The first event is adhesion of plasma immunoglobulin (IgG) and immune complexes (IC) to the carriers, which serve as the binding sites for the fragment crystallizable gamma receptor (Fc γ R) on myeloid leucocytes. Then complement activation (helped by IgG and IC) generates C3a, C5a, C3b/C3bi fragments. Of these C3b/C3bi (opsonins) adsorb onto the carriers and serve as the binding sites for the complement receptors (CR) on myeloid leucocytes. Adhesion of leucocytes results in the release of interleukin-1 receptor antagonists, hepatocyte growth factor, soluble tumour necrosis factor receptors, all with therapeutic effects (Figure 13). Modified from Reference^[23].

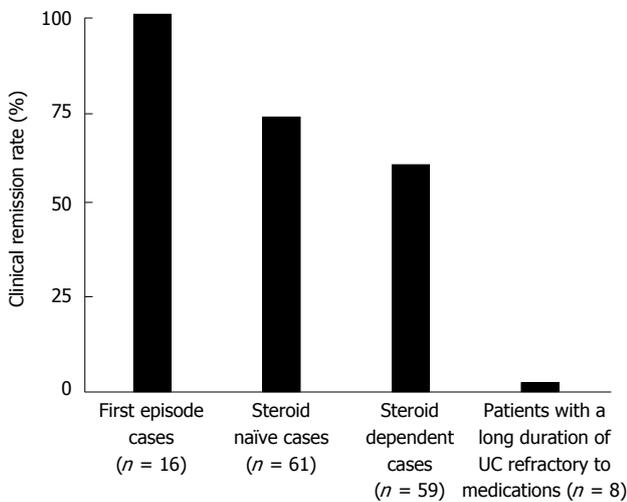

Figure 5 Clinical remission rates in typical cohorts of patients with active ulcerative colitis. The remission rate for patients with the first ulcerative colitis (UC) episode was 100%. All these first episode cases were steroid naïve with a short (< 4 mo) duration of UC; both steroid naïve and short disease duration are granulocyte and monocyte apheresis (GMA)-responder features. Accordingly, the remission rate in corticosteroid naïve cohort looks better than for steroid dependent cohort. GMA non-responder patients had deep ulcers with near total loss of the mucosal tissue at the lesion sites, a long duration of UC, and exposure to multiple drugs; a few were candidates for colectomy^[42,49,52].

GMA non-responder patients had deep ulcers with near total loss of the mucosal tissue at the lesion sites, a long duration of UC, and exposure to multiple drugs^[49,52]; a few were candidates for colectomy^[49,52]. Further, sustainabil-

ity of GMA induced remission has been good^[50,53,69,75,87]. Patients who relapse respond well to another course of GMA therapy^[87]. Regarding remission rates, Tanaka *et al*^[49] reported an efficacy of 73.8% based on CAI in a cohort of 61 steroid naïve patients. Similar efficacy rate has been reported by Hanai *et al*^[50].

GMA SPARES CORTICOSTEROID

In the first pivotal study by Shimoyama *et al*^[41] mentioned above, the steroid sparing effect of GMA was unequivocally demonstrated. In a multicentre setting^[22,41], 105 patients with active UC while on prednisolone (PSL) were randomly assigned to GMA ($n = 53$) or to PSL ($n = 52$). As seen on Figure 6, at entry, in the PSL group, the steroid dose was increased to induce remission, while patients in the GMA group received GMA, at one session per week over five consecutive weeks as remission induction therapy. As seen on the figure, PSL dose was then tapered in line with disease improvement or remission. At the end of the trial, 21 patients (44.2%) in the PSL group and 31 patients (58.5%) in the GMA group were in remission. The results of this study suggested that GMA has significantly better efficacy as compared with the conventional corticosteroid and can spare patients from steroids. Likewise, in a later study by Hanai *et al*^[44], the authors randomly assigned 69 patients with corticosteroid dependent moderately severe UC (at the time of relapse) to GMA ($n = 46$) or to PSL ($n = 23$).

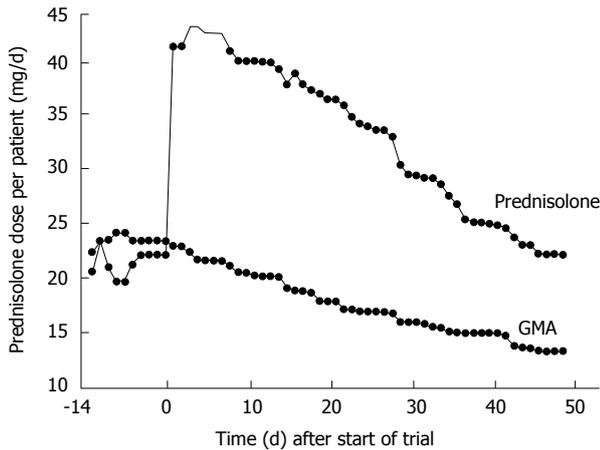

Figure 6 Steroid sparing effect of granulocyte and monocyte apheresis. In this trial, 105 patients with active ulcerative colitis while on the corticosteroid prednisolone (PSL) were randomly assigned to granulocyte and monocyte apheresis (GMA) ($n = 53$) or to PSL ($n = 52$). In the PSL group, the steroid dose was increased at entry to induce remission, while patients in the GMA group received GMA, at one session per week over five consecutive weeks. PSL dose was then tapered in line with disease improvement or remission. At the end of the trial, 21 patients (44.2%) in the PSL group and 31 patients (58.5%) in the GMA group were in remission. Therefore, GMA showed significantly better efficacy than PSL and spared patients from steroids^[22,41,44].

At entry, the mean dose of PSL was 12 mg per day per patient in both groups. As remission induction therapy, in the GMA group, patients were given up to an 11 treatment sessions over 10 wk, while in the PSL group, the mean dose of PSL was increased to 30 mg per day per patient. At week 12, an 83% of the patients in the GMA group were in clinical remission *vs* 65% of the patients in the PSL group. Further, during the 12 wk of treatment, the cumulative amount of PSL received per patient was 1157 mg in the GMA and 1938 mg in the PSL group. This study provided further support for GMA as an effective adjunct to standard drug therapy of moderately severe UC with significant corticosteroid sparing effect. They reported steroid related adverse side effects in a significant number of patients, while for GMA, side effects were flushing and transient lightheadedness in a small number of patients.

GMA FOR CHILDREN OR ADOLESCENTS WITH UC

In children and adolescents with IBD, conventional drugs like salicylates, thiopurines, corticosteroids or the new anti-TNF- α biologics may adversely affect the patients' growth and development. Therefore, GMA as a non-drug therapeutic intervention, if effective in this clinical setting is unrivalled by any currently known drug based medication. With this in mind, Tomomasa *et al*^[76] were the first to apply GMA to children who had active UC. In that study, 12 children, age 5 to 15 years, all with active UC refractory to corticosteroids were given one GMA session per week for 5-10 consecutive weeks. In 8 patients, clinical symptoms improved after two GMA

sessions. Normal body temperature, stool frequency, and disappearance of blood in stool were seen after 24.3 ± 11.5 d. The endoscopic index improved from 2.6 ± 0.3 to 0.4 ± 0.2 . One patient who initially responded developed bloody diarrhoea later and 2 cases remained unchanged. The dose of steroid was tapered during GMA therapy by 50%. No serious adverse effect was observed. This study showed that GMA was effective and well tolerated in children with active UC refractory to corticosteroids.

Very recently, Tanaka *et al*^[75] reported good efficacy and safety outcomes for GMA in children and adolescents with active IBD, all corticosteroid naïve, which is a GMA responder feature. In a single centre setting, a total of 24 consecutive children and adolescents, age 11-19 years were given mesalazine or sulphasalazine as a first-line medication. Seventeen patients relapsed or did not respond to the first-line medications, and received GMA at 2 sessions in the first week, and then weekly, up to an 11 sessions. Patients who achieved a decrease of at least 5 points in the CAI score were to continue with GMA, while non-responders were to receive 0.5 to 1.0 mg/kg per day PSL plus additional GMA sessions similar to GMA responder cases. At entry and week 12, patients were clinically and endoscopically evaluated, allowing each patient to serve as her or his own control. In this study, 7 patients achieved remission with the first-line medications and did not receive GMA. Five patients did not respond to the first 5 GMA sessions and received PSL plus GMA, while 12 patients responded to the first 5 GMA sessions and received additional sessions. At entry, the average CAI was 14.1 ± 0.4 , range 11-17, and the average endoscopic index was 9.2 ± 0.3 , range 7-11. The corresponding values at week 12 were 2.1 ± 0.2 , range 1-4 and 2.4 ± 0.2 , range 1-4. PSL was tapered to 0 mg within 3 mo in the 5 cases who did receive PSL in combination with GMA. This study is the closest one can expect to clinical practice rather than to clinical trial. With the strategy they applied, all 24 consecutive patients achieved clinical remission, most with endoscopic remission as well^[75]. The authors' conclusion states that in growing patients with active UC refractory to first-line medications, GMA induced clinical remission and mucosal healing, while in non-responders to GMA monotherapy, addition of a low dose PSL enhanced the efficacy of GMA and tapering of the PSL dose soon after remission was not associated with UC relapse. Avoiding corticosteroid at an early stage of UC should ensure better long-term clinical course^[70,75].

GMA IN PATIENTS WITH CD

So far, this review has focused mainly on the efficacy of GMA in patients with active UC. This is because IBD in the colon or in the rectum is strongly affected by neutrophils^[50,54], while the role of myeloid lineage leucocytes in the small intestinal IBD lesions has not been defined yet. Nonetheless the majority of CD patients have colonic lesions, and therefore, GMA seems to produce signifi-

cant efficacy in most patients with active CD^[85,97,98]. Additionally, as described for UC, patients with severe CD refractory to currently available pharmacologicals may not respond well to GMA^[93]. Perhaps most IBD physicians in the West are not fully aware that unlike Europe where there is no striking difference in the prevalence of UC and CD, in Japan, the prevalence of UC is more than 3 times higher than that of CD. Accordingly, the first Adacolumn multicenter study in Japan that led to reimbursement approval was in patients with active UC^[22,41]. This is why most GMA papers from Japan are on studies in patients with UC. However, subsequently, a clinical trial in patients with CD refractory to conventional medications was undertaken^[98], and led to reimbursement approval for patients with CD in Japan. However, the first study in CD was reported by Matsui *et al.*^[97], on 7 patients who were refractory to standard medications, each patient received 5 GMA sessions over 5 consecutive weeks. Five of 7 patients achieved remission. It is clinically relevant to mention here that the only 2 GMA non-responders in Matsui's study had primarily small intestinal lesions. Subsequently, Fukuda *et al.*^[98] reported an efficacy rate of 52% by applying 5 GMA sessions to each of 21 patients with severe CD. However, it is imperative to elaborate that the patients Fukuda *et al.*^[98] included had received conventional medications including 2 wk of optimum nutritional therapy (a routine treatment for CD in Japan) and only patients who remained with a high CDAI score received GMA. Therefore, 52% remission rate in a cohort of patients with severe and medication refractory CD was very encouraging. Further, Domènech *et al.*^[85], treated 12 steroid dependent patients with CD. The remission rate was 70%. Finally, Muratov *et al.*^[79] treated 7 patients with CD who had relapsed while on optimum conventional medication and a few on biologics. The median CDAI decreased from 290 at weeks 1 to 184 at week 7 and to 128.5 (remission level) at 12 mo. It is clear from the aforementioned reports that up to now, only very complicated and severe cases of CD have received GMA therapy.

EFFECTIVE DOSAGE OF GMA

The evolution of modern medicine has relied on the outcomes of clinical trials to determine the dosage of drugs with maximum efficacy margin and minimum adverse side effect. Fortunately for GMA, which is a non-drug treatment strategy, reliance on clinical trial outcomes has been less demanding or at least lack of it has not caused serious concern partly because of its good safety profile, and partly for the fact that GMA removes from the body instead of adding to it. Accordingly, unlike drugs, loss of efficacy, dependence and refractoriness are not likely. Nonetheless, it is a basic requirement to know the most effective frequency and the number of GMA sessions for patients with mild, moderate or severe IBD as this can help to save time and cost. The reality is that up to now GMA treatment has been an empirical practice. Some institutes administer 2 GMA sessions per week in the

first 2-3 wk and then 1 session per week up to 10 or 11 sessions^[50,52]. Hanai *et al.*^[50] reported that although patients with steroid naïve UC responded well to 5 GMA sessions, steroid refractory patients with severe UC responded better to 10 sessions. In contrast, Suzuki *et al.*^[42,52] administer 2 GMA sessions per week and cease when CAI decreases to 4 or less (clinical remission level); patients who do not improve after several sessions are classified as non-responders^[52]. These treatment regimens are all contrary to the initial clinical trials in which 5 GMA sessions over five consecutive weeks were applied^[22,41]. Regarding duration of one GMA session, Kanke *et al.*^[66] found that 90 min was significantly better than the routinely applied 60 min per GMA session. Likewise, Yoshimura *et al.*^[73] increased the processed blood volume from the conventional 1800 mL per GMA session to over 3000 mL per session. In this study, the efficacy rate in the higher processed blood volume group was significantly greater than in the 1800 mL per session group^[73]. In a prospective multicentre study, Sakuraba *et al.*^[99] found that intensive GMA at 2 sessions per week induced remission in shorter time and at a significantly higher rate when compared to weekly GMA. The authors assigned 112 patients with moderately active UC to 2 groups. Group 1 patients received one GMA session per week, while group 2 patients received 2 sessions per week, up to 10 sessions in both groups. The remission rate in group 1 was 46.7%, while in group 2 was 73.1%. Further, the mean time to remission was 28.1 d, in group 1 and 16.3 d in group 2. In spite of these outcomes, there is evidence to suggest that the efficacy of GMA is time dependent. Recently, Yamamoto *et al.*^[100] administered one GMA session per day over 5 consecutive days. There was no safety concern, but the efficacy rate was very much less than in the 5 GMA sessions reported by Shimoyama *et al.*^[41]. As reviewed above, in patients with active IBD, large numbers of myeloid lineage leucocytes in the colonic mucosa are seen in biopsies^[49,53] or by measuring a specific neutrophil protein^[101]. The infiltrated neutrophils may take several weeks to clear in spite of CAI showing clinical remission^[102]. Additionally, the immunomodulatory actions of GMA are time dependent. In line with this assertion, in rheumatoid arthritis patients, there was a sustained increase in CD4⁺ T-lymphocytes up to 12 wk following the last GMA session^[22]. Similarly, there was a striking down-modulation of the inflammatory chemokine receptor CXCR3 on leucocytes several weeks after the last GMA session^[23]. Clearly further investigations are warranted for establishing the optimum frequency and duration of GMA session.

TREATMENT COST

In a comprehensive study, Panés *et al.*^[78] estimated the treatment cost for patients with UC in the EU countries for conventional medications and GMA. The average annual cost per patient treated with conventional medications was estimated to be 6740€, while the cost for GMA was 6959€, which is very close to the conventional medi-

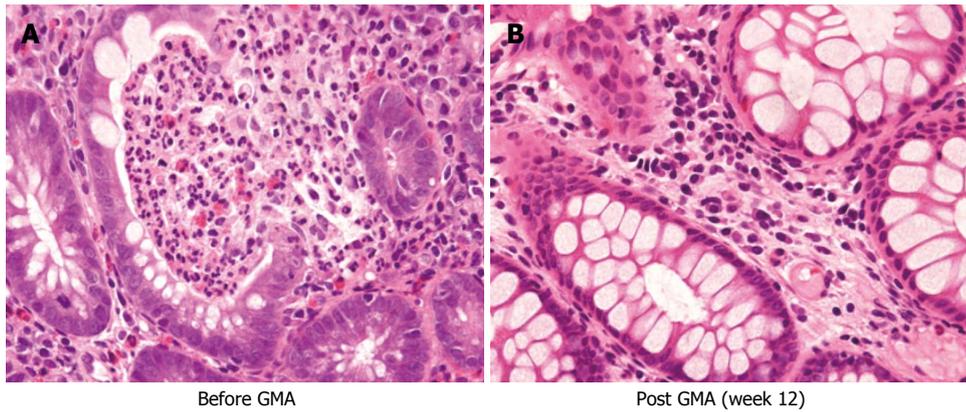

Figure 7 Typical immunohistochemical images taken from colonic biopsy specimens in a patient with total colitis in active stage (A) and following remission (B). This figure shows that the mucosal tissue is densely infiltrated by myeloid lineage leucocytes and granulocyte and monocyte apheresis has reduced the concentration of these leucocytes in the mucosa. The specimens seen in this figure are from a 60-year-old male with moderately severe ulcerative colitis and corticosteroid naïve, baseline clinical activity index, 13.

cations. In contrast, for steroid-dependent patients, the average annual cost was 6059€ for conventional medications and 11436€ for GMA. Further, this study found that the efficacy rate in patients who achieved clinical remission with GMA was 22.5% higher than for conventional therapy. The authors concluded that incorporating GMA in the therapeutic management of patients with moderate-to-severe UC, GMA is cost-effective and the extra cost is compromised by GMA's safety profile when compared with drug therapy.

GMA REDUCES MUCOSAL CONCENTRATION OF MYELOID LINEAGE LEUCOCYTES

As reviewed above, one pathologic feature of active IBD is presence of a large number of granulocytes and monocytes/macrophages in the colonic mucosa^[49,53]. In clinical settings, GMA is applied as an extracorporeal procedure to reduce the excess and activated myeloid lineage leucocytes from patients' systemic circulation. One could logically argue that removal of the leucocytes from the circulating blood should lead to depletion of these cells in the colonic mucosa where they are believed to exacerbate and perpetuate IBD^[25,27,36]. Figure 7 shows typical immunohistochemical images taken from colonic biopsy specimens in a patient with total colitis in active stage and following GMA induced remission. The figure shows that the colonic mucosal tissue is densely infiltrated by myeloid lineage leucocytes with the formation of crypt abscess and GMA has reduced the concentration of these leucocytes in the mucosa. It is relevant to mention here that the images seen in Figure 7 are typical for IBD lesions in the large intestine because similar images are uncommon in biopsies from small intestinal IBD lesions found in most patients with CD. It might be equally true to say that CD patients with the active IBD lesions confined to the small intestine may not be the right candidates for GMA therapy^[97].

COLONOSCOPIC FEATURES OF GMA RESPONDER AND NON-RESPONDER PATIENTS

As reviewed above, several studies have reported that any patient with a fair level of intact colonic mucosa is a potential responder to GMA. With this in mind, in the authors' hospitals, all patients receive endoscopic evaluations and the evaluation is used to treat or not to treat a patient by GMA. However, as stated above, by applying GMA at an early stage^[70], most first episode cases respond^[52], and we do not have many drug refractory patients with badly damaged mucosal tissue. Even patients with a near equal CAI score may have very different mucosal damage status, indicating that CAI per se does not reflect the full extent of mucosal damage in patients with IBD^[49]. Figure 8 shows typical colonoscopy features of patients who may respond well to GMA and be spared from drug based medications. These two cases were from a subgroup of patients who were identified as responders by colonoscopy. These cases were steroid naïve with severe UC based on clinical evaluation (CAI > 14) without endoscopy, nonetheless good responders to GMA because, firstly, the mucosal tissue was preserved and secondly, the patients were not exposed to multiple drugs prior to GMA. The photographs show complete restoration of the mucosal vascular patterns post GMA. Almost all such cases readily respond to GMA. Without colonoscopy, clinical evaluation would have identified these patients as having severe UC, a potential candidate for steroid therapy. However, such responders to GMA without corticosteroids should have good long-term clinical course^[70].

In contrast, Figure 9 shows colonoscopic features of GMA non-responder patients. Here, colonoscopy photographs from two typical GMA non-responder patients at entry and at week 12 are presented. The colonoscopy images at entry revealed deep and extensive colonic lesions with virtually no mucosal tissue left at the lesion sites.

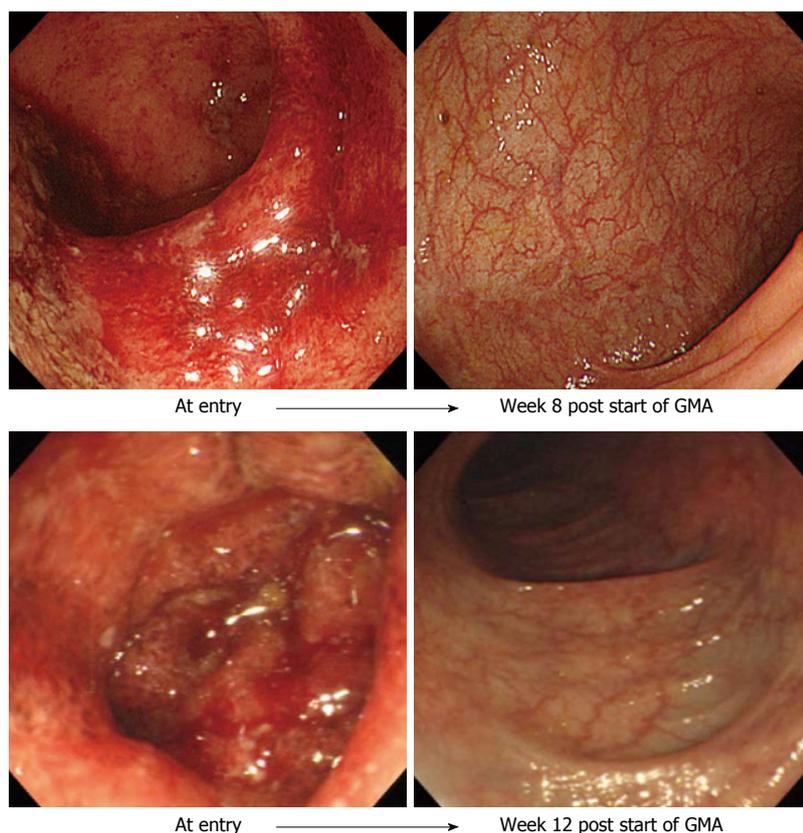

Figure 8 Typical endoscopic features of patients who may respond well to granulocyte and monocyte apheresis and be spared from drug based medications. These cases were from a subgroup of patients who have been identified as good responders by colonoscopy. These patients were steroid naive with severe ulcerative colitis (clinical activity indices > 14), yet good responders to granulocyte and monocyte apheresis (GMA), firstly because the mucosal tissue was preserved and secondly, the patients were corticosteroid naive at the time of relapse. The photographs show complete restoration of the mucosal vascular patterns at post GMA.

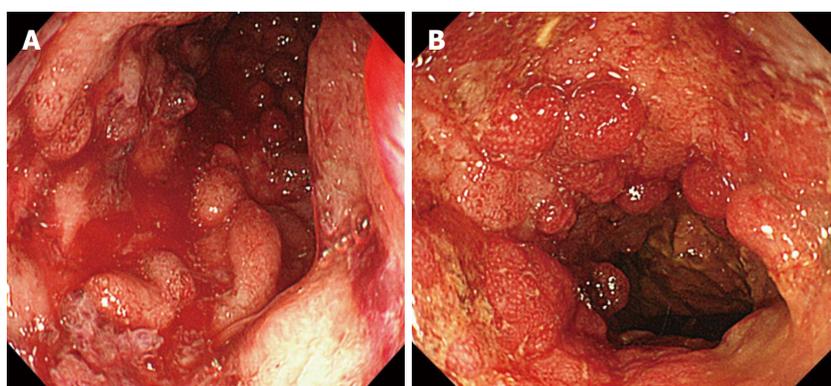

Figure 9 Colonoscopy images showing deep and extensive colonic lesions together with inflammatory polyps and contact bleeding. Typical colonoscopic images from patients with severely damaged mucosal tissue (A), granulocyte/monocyte apheresis non-responders (B). However, most patients with the entry mucosal damage seen in this figure are medication refractory and unlikely to respond to granulocyte and monocyte apheresis, some opt for colectomy.

However, no patient with the entry mucosal damage seen in this figure is likely to show any significant fall in CAI, a few may have fulminant UC, candidates for surgery.

TREATMENT OF PYODERMA

GANGRENOSUM ASSOCIATED WITH IBD

Pyoderma gangrenosum (PG)-like skin lesions are seen in up to 2% of patients with IBD and can be a major

cause of pathological and psychological morbidity^[103]. It is interesting that PG and psoriatic skin lesions are reported to be good responders to GMA^[103-107]. To our knowledge, most treated cases have responded well and yet, it all happened by chance^[103]. A patient with IBD associated PG was treated for IBD, but the response of pyoderma lesions was more striking than anything expected from GMA. The young patient had very stressful deep refractory lesions over a long period of time (Figure 10). The lesions fully remitted after 10 GMA sessions^[103].

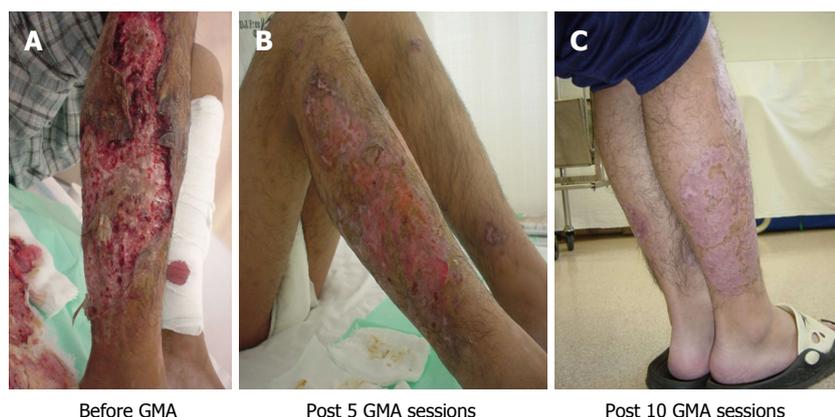

Figure 10 Pyoderma gangrenosum lesions. Pyoderma gangrenosum lesions associated with Crohn's disease (A), partially re-epithelialized after 5 granulocyte and monocyte apheresis (GMA), sessions (B), fully re-epithelialized after 10 GMA sessions (C)^[103].

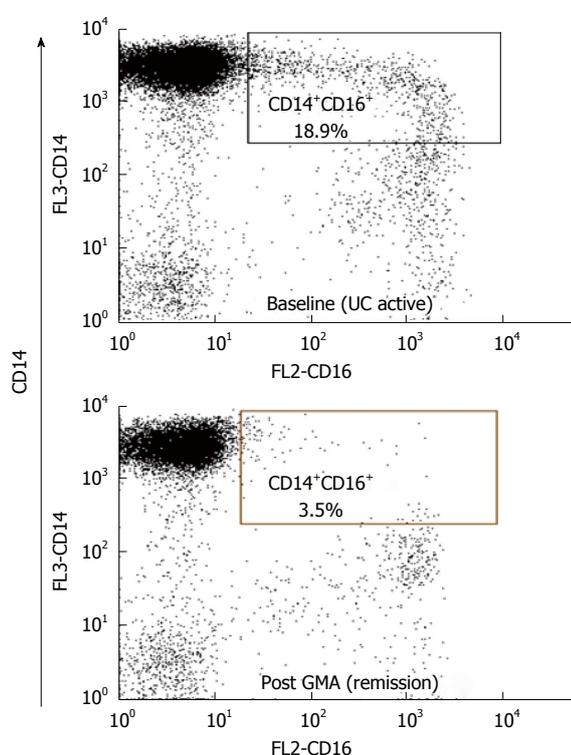

Figure 11 Typical flow cytometry outputs. Flow cytometry showing immunophenotyping of elevated pro-inflammatory CD14(+)CD16(+)DR(++) monocytes in a patient with inflammatory bowel disease and depletion of these tumour necrosis factor-producing leucocytes by granulocyte and monocyte apheresis (GMA). In this patient, an 18.9% of monocytes were identified as CD14⁺CD16⁺ phenotype in active ulcerative colitis (UC) stage and this was reduced to just 3.5% when the patient achieved remission following a course of GMA therapy. Normal level is < 8%^[109].

Subsequently, other authors independently reported cases of pyoderma or psoriatic skin lesions responding well to GMA^[104-107]. The mechanism associated with the efficacy of GMA in these conditions is not very clear, but the chemokine receptor, CXCR3 is known to have an active role in the initiation and perpetuation of inflammatory skin lesions and is strongly down-modulated by GMA^[23]. This action of GMA, if duplicated by follow-up studies can serve as a major break-through in our efforts to understand the mechanisms of clinical efficacy of GMA in

these clinical settings.

SPECIFIC IMMUNOLOGICAL EFFECTS

The CD14⁺CD16⁺ monocyte phenotype is known to be pro-inflammatory as a major source of TNF^[108] and shows dramatic expansion in inflammatory conditions. Accordingly, Hanai *et al*^[109] reported elevated CD14⁺CD16⁺ monocytes in patients with IBD and a very marked depletion of these TNF-producing monocytes by GMA. This monocyte sub-set was depleted to levels seen in healthy persons^[109]. In Figure 11, typical effect of GMA is shown by flow cytometry. This action of GMA should significantly alleviate inflammation in patients with dysregulated immune profile. Additionally, as reviewed above, GMA has been associated with a sustained increase in circulating lymphocytes^[20] including the CD4(+)CD25(+) Treg phenotype^[61]. In spite of this, the clinical efficacy associated with a course of GMA is unlikely to reflect its effects on peripheral leucocytes per se. It is inferred that additional mechanisms of actions might follow a course of GMA. As seen in Figure 4, leucocytes that bear the FcγR and complement receptors adhere to the GMA carriers^[23,62]. The adsorbed leucocytes release an array of substances both toxic and non-toxic, but anti-inflammatory as well, which reach the patients' circulation *via* the column outflow that returns to patients. Among these, cytokines, C3a and C5a are of short half-life and may not reach the patients' circulation in fully active form. Hanai *et al*^[110] reported a significant increase in the column outflow blood levels of soluble TNF receptors I and II known to neutralize TNF without invoking TNF-like actions^[111].

Further, GMA-related suppression of inflammatory cytokines (TNF-α, IL-1β, IL-6 and IL-8) released by peripheral leucocytes has been reported^[112]. In in-vitro settings, exposure of human blood to the GMA carriers caused the release of significant amounts of IL-1 receptor antagonist (IL-1ra) and hepatocyte growth factor (HGF)^[113], seen in Figure 12. The release of these substances (albeit very small) should proceed inside the Adacolumn during GMA in clinical settings and reach the patients' circulation *via* the column outflow line. IL-

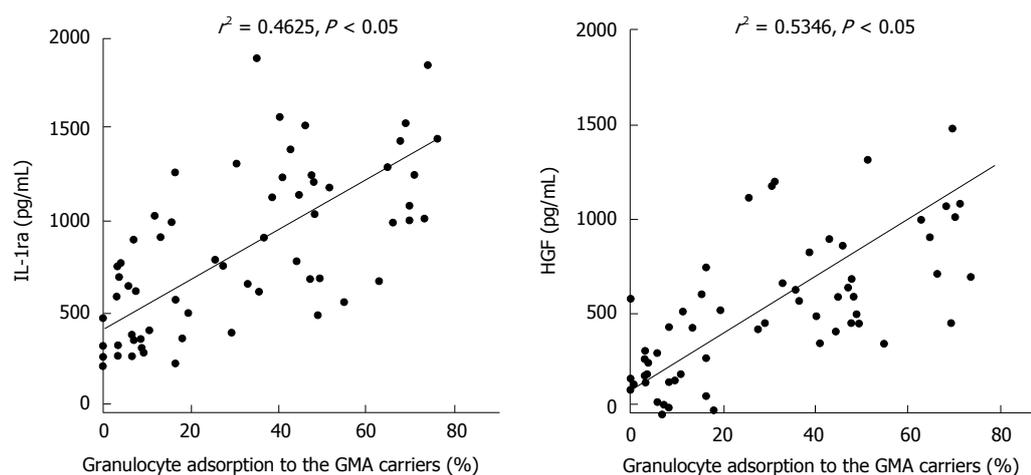

Figure 12 Adsorption dependent release of interleukin-1 receptor antagonist, and hepatocyte growth factor from myeloid lineage leucocytes (granulocytes and monocytes) in *in-vitro* setting. Hepatocyte growth factor (HGF) is known to promote ulcer healing and cell regeneration, while interleukin-1 receptor antagonist (IL-1ra) is strongly anti-inflammatory^[113]. GMA: Granulocyte and monocyte apheresis.

1ra is known to control intestinal inflammation^[114], while HGF is believed to promote epithelial cell regeneration, an essential step in ulcer healing^[115]. Further, examinations of mucosal biopsy specimens suggested that GMA suppresses cytokine profiles within the mucosa^[79,116]. A wary reader may wonder why this is possible with a system that impacts peripheral blood leucocyte counts. One answer could be that GMA reduces the number of leucocytes that are destined for the mucosa, partially by depleting them (Figure 3) and partially by down-modulating the adhesion receptors on the remaining leucocytes^[117]. Muratov *et al*^[79] found a marked decrease in tissue interferon (IFN)- γ or TNF- α positive leucocytes in clinical responders after GMA. In parallel, significantly lower levels of IFN- γ producing leucocytes were detected in peripheral blood. IFN- γ positive T-cells in pretreatment biopsies completely disappeared or decreased in post-treatment biopsies sampled 2 wk after the last GMA session in responders and appeared to predict the maintenance of long-term remission, up to 12 mo. However, our view is that the impact of GMA on the CD4(+)CD25(+) Treg^[61] reviewed above is potentially very interesting in patients with dysregulated immune behaviour in whom, the immune system is in a state of exuberant activity. In Figure 13, the immunological actions of GMA in patients with IBD are summarized based on published findings. In addition to adsorption of elevated and activated myeloid lineage leucocytes to the GMA carriers, the column outflow blood is a potential source of anti-inflammatory substances.

PUTTING EVERYTHING TOGETHER

IBD is a debilitating chronic, life-long health disorder, affecting millions of individuals with symptoms, which impair function and quality of life. The aetiology of IBD is not precisely understood at present, and therefore, hitherto drug therapy has been empirical rather than based on a sound understanding of disease mechanism(s). This empirical approach to medication might be a major fac-

tor for refractoriness and adverse drug effects. Indeed, adverse drug side effects become additional morbidity factors in many patients on long-term medications. Although, the fundamental cause(s) of IBD is not well known, but the exacerbating factors like TNF- α and other inflammatory cytokines are known and have been targeted. Bearing in mind that inflammatory cytokines are generated by the patients' own cellular elements including myeloid lineage leucocytes, it seems logical to apply GMA and deplete the elevated and activated myeloid lineage leucocytes. When the elevated cytokine producing leucocytes are depleted, the patients' immune system should be able to adjust itself to a more normal function or at least drug efficacy could be better. As GMA removes from the body instead of adding, it has not been associated with dependency, refractoriness, and safety concern. However, let's not forget that efficacy outcomes with GMA in patients with IBD have been impressive as well as disappointing. A review of the clinical experience indicates that GMA responders and non-responders define patients' past disease course, severity and response to medications. This is to say that IBD patients present with diverse clinical and endoscopic disease severity levels, long or short duration of IBD, and a history of exposure to medication (or otherwise). Hence, their clinical response to medical interventions or to GMA can be complete remission, partial response or no response at all. Regarding GMA, it has been found that first episode cases together with steroid naïve and patients with a short duration of active IBD, but without extensive loss of the mucosal tissue respond well and are spared from additional pharmacologic interventions. Additionally, GMA responder patients have good long-term disease course. Therefore, if this strategy is adhered to at an early stage during the development of IBD, there should be fewer drug-refractory or cases with badly damaged mucosal tissue that are medication or GMA non-responders. GMA is not a rescue therapy in patients in whom drug therapy has failed, while disease severity is worsening, but rather
