IPDs are defined as movement preserving devices, but they are not explicit in this action for many reasons: (1) Their implantation puts the lumbar spine in a kyphotic posture so that it cannot move in a physiological

way. In light of this, the movement cannot be intended as preserved; (2) The movement of the spinal motor unit depends greatly on the articular masses, the inter- and supraspinous ligament and the muscles of the posterior tension band, and all the components of the spinal motor unit tend to degeneration; for these reasons, all IPDs are not capable of controlling the movements in all three directions of the space and substituting all the components of the motor unit, so they cannot be defined as dynamic stabilization[28-35,43-46,50]; and (3) The materials and biomechanical concepts of construction of these devices are not fully respectful of the biological characteristics of human tissues[28-35,43-46,50-63].

Different considerations have to be made for interspinous fusion devices (IFD) (Aspen, Axle, *etc*). Described in the past, this technique has been brought to the fore in the last few years with the development of new spinous-anchoring devices whose aim is an interspinous bone fusion.

The main goal of IPD is motion preservation, while IFDs have a different root concept: if the substrate of lumbar stenosis is the hypermotion, the only way to stop the degeneration is to block it; this goal is achieved through the bone fusion. So IFD's aim is not motion preservation but bone fusion and the immobilization of the metamere. These devices have a double function, related to their possible association with TLIF interbody fusion[38-42].

### *Stand-alone*

Spinous process fusion of a spinal motor unit occurs after placement of the device in distraction or in neutral position. If the device is implanted in distraction, the biomechanical alteration persists because the axial load is altered, but the pathological segment is stabilized by the osseous fusion. The degenerative process can progress towards the adjacent segments with the development of an adjacent segment disease.

### *TLIF interbody fusion*

In my opinion, this is the best use for IFD. This surgery is recommended in cases of monolateral radiculopathy with foraminal stenosis due to facet hypertrophy. The surgical procedure includes artrectomy to perform a TLIF and complete decompression of the foramen and the nerve root, associated with the implant of a device in neutral position (not in distraction)[38-42].

This technique offers several advantages: (1) The execution of a TLIF allows performing a monolateral decompression and the insertion of an anterior intersomatic cage. The cage, in relationship with its width, can restore the physiological lumbar lordosis and leave the sagittal balance of the lumbar spine unaltered; (2) The insertion of the cage in the TLIF technique allows a higher fusion rate than the one obtained in a PLIF technique, in relationship with the most anterior position of the cage and of the width of the cage itself; (3) The insertion of the device in neutral position stabilizes the segment in its physiological position without distracting the segment; and (4) This procedure allows performing a circumferential fusion with an exclusively posterior and monolateral approach, preserving muscular insertions and the posterior tension band.

Recently, these devices have gone through an evolution, with the creation of expansion devices and cardanic compression devices that allow the distraction and the compression of the segment during the surgical procedure. These new devices allow modelling the orientation of the segment towards compression, increasing the pressure on the cage and assuring a better interbody fusion.

## INDICATIONS AND LIMITS

The surgical conditions in which restricted and non restricted IPD are recommended are fully described in the literature: foraminal and/or central stenosis, soft stenosis, I grade spondylolisthesis (actually debated), low back pain, black disc[64-69].

In the last few years, many authors have reported the high rate of surgical revision and symptom recrudescence in patients who have had these devices implanted[28-35,43-46,50]. In my opinion, from the literature review and my personal experience, surgical indications for the use of these interspinous devices are basically absent: (1) In foraminal stenosis, their only action is to accelerate the segmental degenerative process; (2) In central stenosis, they have no indication because their action is not resolutive for claudication, with its gold standard treatment the central decompression obtained with laminectomy; (3) In spondylolisthesis they are not indicated because the shear stress acting on the disc is high and the slippage would be augmented[28-35,43-46]; and (4) In low back pain due to micro-instability and in black disc conditions these devices would not be implanted because they do not reduce micro-instability but increase it, overloading the disc and augmenting pain.

In my opinion, interspinous devices have no clinical indication at the moment.

Interspinous stabilizers generating fusion, such as IFD, have a small range of surgical indications instead: monolateral or bilateral foraminal stenosis without evidence of spondylolisthesis in X-ray dynamic projections. These implants, which in my opinion have to be associated with TLIF and be inserted in neutral position or in slight compression, can allow the decompression of the stenotic nerve root with the TLIF technique, explicit in a slight compression supporting a contact between cage and endplates to promote a better intersomatic osseous fusion and promoting an interspinous and intersomatic osseous fusion, blocking the segmental degenerative process, responsible for the pathology and the symptoms[64-77].

## COSTS

The costs of the device and its surgical revision should

not be underestimated. In a 2012 review concerning the post-op status of IPD, Epstein *et al*[74] reported a 11.6%-38% complication rate, 4.6%-85% reoperation rate and a 66.7%-77% incidence of poor outcomes. Furthermore, the cost of every single device is very high. So, high cost, high rate of complications, reoperation rates and poor outcomes make the choice of implantation of an IPD really controversial. In light of the points expressed previously, I think that IPD can be summarized as follows: highly expensive and poorly effective[64-69].

## CONCLUSION

Dynamic neutralization systems should be studied, built and then implanted in order to preserve spinal biomechanics. The preservation of the physiological characteristics of the spine should particularly be aimed towards the whole motor unit (disc, facets, posterior tension band, ligaments) intended to be responsible for the segmental movement. IPD, as they are conceived today, do not seem to respect the biomechanical characteristics of the motor unit, accelerating the degenerative process and worsening the pathological process at the root of the clinical symptoms of patients. So this kind of device does not seem to have a definite and correct clinical indication at the moment. The IFD with their main aim as the treatment of the root of the pathological condition (instability) have a restricted range of clinical indications and their use can definitely be a source both for the patient and the surgeon. It is important to underline that these implants must not become a trend but only a weapon in the surgeon's hands and, as with every weapon, is extremely dangerous in wrong hands. So the spinal surgeon is the only one who can decide when to use it and must know in detail the effects of this weapon to use it correctly with no damage for the patient.

## ACKNOWLEDGMENTS

The author wants to thank Professor R Delfini, MD, PhD, Chief of Neurosurgery A, University of Rome "Sapienza" and Dr. N Marotta, MD, PhD, neurosurgeon from Neurosurgery A, University of Rome "Sapienza".

## Abstract

Tumoral calcinosis (TC) has long been a controversial clinico-pathological entity. Its pathogenesis and genetic background have been gradually unravelled since its first description in 1943. According to the presence or absence of an underlying calcifying disease process, TC has been divided into primary and secondary varieties. Two subtypes of the primary variety exist; a hyperphosphatemic type with familial basis represented by mutations in GalNAc transferase 3 gene (*GALNT3*), *KLOTHO* or Fibroblast growth factor 23 (*FGF23*) genes, and a normo-phosphatemic type with growing evidence of underlying familial base represented by mutation in *SAMD9* gene. The secondary variety is mainly associated with chronic renal failure and the resulting secondary or tertiary hyperparathyroidism. Diagnosis of TC relies on typical radiographic features (on plain radiographs and computed tomography) and the biochemical profile. Magnetic resonance imaging can be done in difficult cases, and scintigraphy reflects the disease activity. Treatment is mainly surgical for the primary variety; however, a stage-oriented conservative approach using phosphate binders, phosphate restricted diets and acetazolamide should be considered before the surgical approach is pursued due to the high rate of recurrences and complications after surgical intervention. Medical treatment is the mainstay for treatment of the secondary variety, with failure warranting subtotal or total parathyroidectomy. Surgical intervention in these patients should be kept as a last resort.

**Key words:** Tumoral calcinosis; Primary; Secondary; Calcification; Surgical excision; *FGF23*; *GALNT3*; *KLOTHO*; Phosphate binders

**Core tip:** This review of literature on tumoral calcinosis, describes the current understanding of the pathogenesis and classifications of this relatively rare clinico-pathological entity. It discusses the different current diagnostic modalities and treatment options.

## INTRODUCTION

Tumoral calcinosis (TC) is a rare clinical and histopathologic syndrome characterized by calcium salt deposition in different peri-articular soft tissue regions[1,2]. It mainly manifests in childhood or adolescence as painless, firm, tumour-like masses around the joints that may lead to joint function limitations specially when large in size[1,3,4].

Regions most commonly involved by this pathology are soft tissues of peri-articular upper limb (shoulder and elbow) and hip regions. Still; spinal[5-7], temporo-mandibular joint[8,9], metacarpals/metatarsals[10], and popliteal

space[11] involvement has also been reported.

## HISTORICAL REVIEW

The term "tumoral calcinosis" was first stated by Inclan *et al*[3] in 1943 for a disease characterized by large juxta-articular lobular calcified masses without visceral or skin calcifications in patients showing normal serum calcium and phosphorus levels. The characteristic pathological features of these lesions were the presence of multiple cysts filled with calcified deposits lined by histiocytes, giant cells, and xanthomatous histiocytes. Earlier, Giard[12] and Duret[13] reported a similar condition in the European medical literature in 1898 and 1899, respectively. This disease process was a subject of Teutschlaender[14,15] studies from 1930 to 1950, known as the Teutschlaender disease in the European literature by that time[16].

Since its first description by Inclan *et al*[3], the term tumoral calcinosis has been widely used in the literature and has been sometimes broadened to include other conditions resulting in similar clinico-pathologic features, or even imprecisely used to describe any massive collection of peri-articular calcifications[17]. In this article, we are aiming at reviewing pathogenesis of the disease and the current diagnostic and treatment options.

## ETIOLOGY, PATHOGENESIS AND CLASSIFICATION

Etiology of TC remains uncertain despite the several theories that have been proposed. In 1996, Smack *et al*[18], retrospectively reviewed 122 cases of TC ending in a proposed pathogenesis-based classification as follows: (1) Primary normo-phosphatemic TC. Normo-calcemia and normo-phoshpatemia are the hallmark of this entity. The majority of patients present before the 2$^{nd}$ decade of life and almost half of them live in tropical or subtropical regions. It is usually characterized by solitary calcifications. Although Smack *et al*[18], mentioned that there was no evident familial pattern in this entity, recent literature showed growing evidence of familial basis for this type of pathology, involving mutations in the gene encoding for SAMD9 protein[19]; (2) Primary hyper-phosphatemic TC. Normo-calcemia and hyper-phosphatemia are the hallmark of this entity. This type usually presents during the first and second decades[17,20] with predominance in people of African descent (some authors suggested confining the term TC to this variety)[17]. Genetic predisposition is a feature of this type of TC where hyperphosphatemia arises due to reduced urinary phosphate excretion caused by recessive mutations in GalNAc transferase 3 gene, *GALNT3*, and *KLOTHO*, that causes the inactivation of *FGF23*, a phosphoturic hormone[21-24]; and (3) Secondary TC. Chronic renal failure (CRF) is the most common identifiable condition in this entity.

The histology of the TC lesions in these 3 groups is identical. The reason behind this similarity has not yet been resolved[25]. This classification although bringing clarity to the diagnosis of TC and being widely propagated in the literature is still facing some debates[17] including the dissociation between the lesion and it's underlying etiology resulting from dealing with the term as a clinico-pathological description rather than a separate disease entity as described by Inclan *et al*[3].

Although Smack *et al*[18] described this classification as a pathogenesis based one, they actually classified the condition according to the presence or absence of underlying disease associated with calcification and the biochemical profile of the patients rather than actual pathogenesis of the lesions.

A stepwise approach to the pathogenesis of TC lesions has been proposed[26]. Although this approach has been described for the familial type of TC, it has been later enlarged to contain the other types of this pathology as a common pathway, which eventually results in the formation of the characteristic TC lesions[25] as follows: (1) Minimal repetitive trauma leading to hemorrhages in the peri-articular tissue initiating a foamy histiocytic response. Traumatic Injury preceding the development of TC lesions has been frequently reported specially in the normo-phosphatemic variety[18]. Trauma in the form of chronic pressure has also been accused[27]. The presence of hemosiderin pigment near TC lesions fortifies this theory[28]; and (2) A reparative process is initiated which together with friction forces, lead towards neobursae formation. However, an interplay between multifactorial calcification process and collagenolysis due to proteolytic enzymes produced from disintegrating histiocytes prevents functional bursae and bone formation. This results in the characteristic lesions of TC, representing the active stage of the process[26].

This multifactorial calcification is initiated by elevated calcium phosphorus product with hyper-phosphatemia as the overwhelming component. This hyper-phosphatemia can be explained by genetic mutations in the *FGF23*, *GALNT3* or *KLOTHO* gene resulting in inactivation of the phosphaturic protein *FGF23* in the primary hyperphosphatemic variety. In the secondary type, this hyperphosphatemic state is explained by the association with secondary hyperparathyroidism resulting from CRF. On the other hand, in the primary normo-phosphatemic variety, transient hyper-phosphatemia is the proposed mechanism. This transient hyper-phosphatemia is either produced locally due to tissue injury leading to release of phosphate from injured cells into extracellular space specially when injury involves muscles (main phosphate store in soft tissue), or induced by excessive oral or rectal use of a phosphate-saline laxatives[25,29]. This hypothesis still needs to be augmented. Figure 1 shows a schematic illustration of the pathogenesis of the different types of TC.

Finally, calcified debris fills the loculi leading to bone formation with arrest of bursae forming activity and decline in collagenolysis activity, ending in fibrosis that surrounds the TC lesions. Here, the lesions become rela-

tively quiescent[26].

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis of TC involves differentiating the condition from its mimics and further classifying it into one of the aforementioned categories.

Patients with TC usually present with multiple or solitary swellings related to the joints, discomfort, pain, and joint movement limitation[28,30] most commonly affecting the hip, elbow, shoulder, foot, and wrist[17]. Growth of such lesions is mostly slow and progressive in nature over several years[31]. Sometimes, ulceration of the overlying skin occurs with superadded secondary infection[32,33]. Huge bilateral cases of TC though rare, have been described in the literature[34].

Diagnosis of TC is mainly based on imaging modalities. *Plain radiographs* show the typical appearance of amorphous, multilobulated and cystic calcifications in a peri-articular location[17]. Computed tomography helps in determining the extent and relations of individual lesions, and as a guide for surgical planning. It usually shows cystic loculi with fluid-fluid levels caused by calcium layering giving rise to "the sedimentation sign"[35]. In other instances, the lesion may appear homogenous denoting decreased activity in the quiescent stage[36,37]. Erosion or osseous destruction by adjacent soft-tissue masses is consistently absent; another hallmark of this pathology[17]. Magnetic resonance imaging shows inhomogeneous high signal intensity on T2-weighted sequences with two patterns frequently observed; diffuse lower-signal-intensity pattern, or nodular pattern with alternating areas of high signal intensity and signal void. The lesions appear inhomogeneous with low-signal intensity on T1-weighted sequences[37].

Scintigraphy using radiolabeled phosphate compounds (technetium-99m methylene diphosphonate) is of great value in detecting multiple lesions, newly-forming lesions, bone marrow affection, and for monitoring therapy reflecting the activity of the lesions. Ultrasonography can also be of value in detecting loculated fluid collections, thus helping in determining the disease activity[17,37,38].

Other conditions including calcinosis universalis, calcinosis circumscripta, calcific tendonitis, synovial osteochondromatosis, synovial sarcoma, osteosarcoma, myositis ossificans, tophaceous gout, and calcific myonecrosis can confuse both the radiologists and the clinicians regarding the nature of these lesions. This can be resolved through combining typical radiological features of TC with the serum biochemical profile (including serum calcium level, serum phosphorus levels, renal function tests , serum parathormone level and 1,25-dihydroxy-vitamin D levels)[17,38]. Detailed family, drug and past history should also be obtained.

It should be emphasized that connective tissue diseases should be excluded before settling the diagnosis as primary TC specially in the setting of normal calcium and phosphorus levels. This can be achieved with a negative antinuclear, anti-Smith, anti-centromere and anti-scleroderma antibodies profile[17].

Although biopsy is better avoided for fear of infection[34]. It may still be done in difficult cases to settle the diagnosis[39]. Histopathological examination of TC lesions after biopsy or surgical excision shows certain characteristic morphologic features differentiating it from other calcifying processes. This includes formation of the characteristic compartments, which contain liquid chalky content together with calcifications. Such compartmentalized configuration frequently remains even in the quiescent stage[25].

## TREATMENT MODALITIES

Treatment of TC should be tailored according to the type of the lesion, stage of the pathology together with the

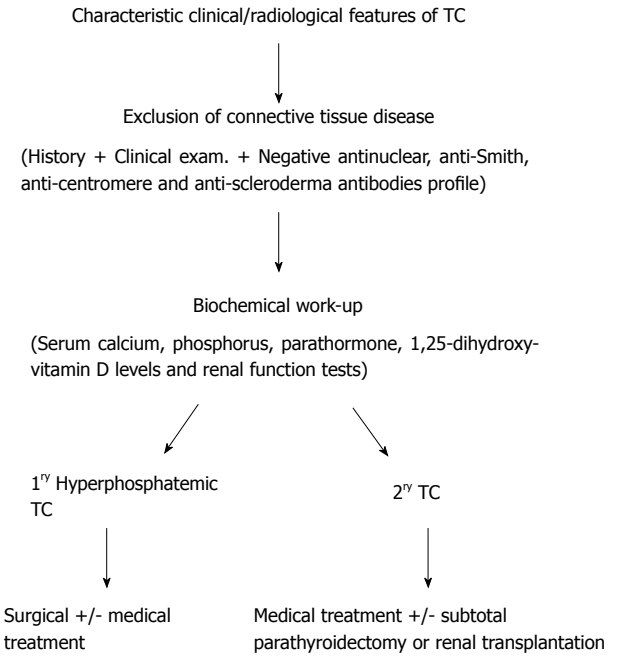

**Figure 2 Schematic diagram showing the diagnostic and treatment approach for tumoral calcinosis.** TC: Tumoral calcinosis.

site, size and relations of the lesion, as well as symptoms of the patient.

Considering the primary variety, primary treatment is early surgical excision[40]. However, the high rate of recurrence warrants repeated excisions[2,33]. During surgery, TC lesions show a cystic nature with white and yellow chalky material formed by calcium hydroxyapatite crystals, calcium carbonate and calcium phosphate[18]. The presence of a hyper-vascular region beyond the periphery of the calcified mass as proven by angiography raises the possibility that a wider surgical resection margin may lead to fewer recurrences. Confirmation of this theory is however, still needed[41]. Slavin *et al*[26], reported that immobilization after resection may also have a role in decreasing new lesion formation in the adjacent tissues.

Huge lesions may require extensive surgical excision and reconstruction[42]. Relations to important neurovascular structures may be challenging, resulting mostly in partial excision and rapid recurrence. However, partial excision of large symptomatic lesions can be helpful providing significant pain relief[43,44]. Indications for surgical excision also include recurrent infection, ulceration, and functional impairment[34,45].

According to a literature review done by King *et al*[45], surgical complications of TC excision include postoperative prolonged drainage which can lead to delayed wound healing and sinus tract formation, secondary infections caused by chronic wound problems specially with extensive disease or incomplete resection, and recurrence, which is frequent after incomplete excision and usually has a faster rate of growth.

Medical treatment through phosphate depletion (dietary deprivation of phosphorus and phosphate binding chelating agents such as oral aluminium hydroxide has shown variable success rates in both normo- and hyper-phosphatemic cases[10,33,46]. The combination with acetazolamide to induce phosphaturia may have a valuable synergistic effect in lowering hyper-phosphatemia[47,48]. In-view of the high rate of recurrence after surgical excision, medical treatment in the primary variety could be reasonably considered before the surgical approach, especially in the hyper-phosphatemic entity.

From a pathogenetic point of view, medical treatment during the active stage maybe superior to surgery which is usually doomed with recurrence in this stage. On the other hand, surgical treatment may be more effective in the relatively quiescent stage where encapsulation occurs and hinders the ion exchange process leading to failure of phosphate depletion treatment[26]. Some authors advocate a combination therapy that includes surgical excision and medical treatment as a necessity in some resistant cases[49,50]. Alternative treatment modalities including the administration of steroids, diphosphonates, or calcitonin and radiation therapy have not proven to be effective[2,3,51-53].

On the other hand, treatment of secondary TC (end stage renal disease-related, hemodialysis-related TC) is mainly medical. Surgical excision is associated with more profound complications (infection, fistula formation) aggravated by the patient medical condition, together with the persistence of the etiology[34]. Surgical interventions or biopsies should be kept as a last resort in these patients. Medical treatment includes calcium and phosphorus restricted diets, dialysates, and phosphate binders (except aluminium containing binders). Several other medical treatments including Vinpocetine, Sodium thiosulfate, intravenous Pamidronate, have been used in treatment of the secondary variety of TC with variable success rates[54-58].

Given the underlying secondary or tertiary hyperparathyroidism in most of these patients, subtotal or total parathyroidectomy is the next logical step in the setting of medical treatment failure. This approach has demonstrated significant response[59-61]. Kidney transplantation may also be considered. Figure 2 shows a schematic diagram of the diagnostic and treatment approach for TC.

## CONCLUSION

In view of growing understanding of the pathogenesis of TC and evidence of the familial origin in the normo-phosphatemic, an agreement regarding the clinico-pathological entities to which the term TC should be coined should be sought. Such an agreement may necessitate preserving the term for the familial type of the condition including its two variants after exclusion of underlying disease process, or at least limiting the secondary variant to conditions sharing the same pathogenesis on ultrastructural level. This should be propagated to radiologists, clinicians and pathologists in order to avoid a misleading imprecise diagnosis. The exact diagnosis of TC relies on

typical radiologic features and biochemical profile, with the exclusion of connective tissue diseases. Treatment plans should be tailored to individual cases. Generally, conservative treatment is better considered prior to the surgical approach in primary patients, reserving surgical excision to patients with disabling symptoms. In secondary cases, medical treatment in the mainstay. Treatment failure warrants parathyroidectomy, and surgical excision should be the last resort in these cases.

## Abstract

The prevalence of type 2 diabetes mellitus (T2DM) has risen in recent decades, and cardiovascular disease remains the leading cause of death in this population. Several clinical trials have demonstrated the benefit of tight control of risk factors on the incidence and mortality of cardiovascular disease. However, in clinical practice, few patients achieve the therapeutic goals. The current diagnostic procedures for subclinical cardiovascular disease in T2DM patients have not been shown to improve prognosis or mortality, probably because they do not categorize cardiovascular risk. Thus, clinical practice guidelines do not systematically recommend screening for subclinical atherosclerosis in these patients, although it is known that patients with extracoronary atherosclerosis, microangiopathy and poorly-controlled cardiovascular risk factors are at high risk for cardiovascular disease. Improvements in the reliability of diagnostic tests, with fewer side effects and better cost efficiency, may better help to stratify cardiovascular risk in this group of patients, and further evaluation on this topic should be considered.

**Key words:** Cardiovascular disease; Type 2 diabetes mellitus; Cardiovascular risk

**Core tip:** The prevalence of type 2 diabetes mellitus (T2DM) has risen in recent decades, and cardiovascular disease remains the leading cause of death in this population. Several clinical trials have demonstrated the benefit of tight control of risk factors on the incidence and mortality of cardiovascular disease. The current diagnostic procedures for subclinical cardiovascular disease in T2DM patients have not been shown to improve prognosis or mortality, probably because they do not categorize cardiovascular risk. Improvements in the reliability of diagnostic tests, with fewer side effects and better cost efficiency, may better help to stratify cardiovascular risk in this group of patients, and further evaluation on this topic should be considered.

## INTRODUCTION

The prevalence of type 2 diabetes mellitus (T2DM) is rising dramatically in industrialized countries[1]. According to the National Health and Nutritional Examination Survey, 19.7 million Americans had diagnosed diabetes, representing 8.3% of the adult population, and an additional 8.2 million were undiagnosed[2]. In Europe, population studies report a T2DM prevalence of 13.8%, although many cases are undiagnosed[3]. Cardiovascular

disease is the leading cause of mortality and morbidity in this specific population and is responsible for most of the increased health care costs[4]. Traditionally, T2DM has been considered a coronary risk equivalent[5]. Although this topic is the subject of debate[6-10], there is unanimous agreement that strict control of cardiovascular risk factors in T2DM patients reduces the incidence of cardiovascular disease[11].

T2DM is often associated with several other cardiovascular risk factors. Therefore, cardiovascular prevention in these patients should be multifactorial. Studies assessing the impact of multifactorial risk factor intervention obtained substantial improvements compared with those evaluating single risk factor interventions[12,13].

The effectiveness of a multifactorial intervention was demonstrated in the Steno-2 study, where patients with T2DM and microalbuminuria were randomized to intensive or conventional multifactorial intervention over 7.8 years. A target-driven, long-term, intensified intervention aimed at multiple risk factors, particularly through low-density lipoprotein (LDL) cholesterol lowering and blood pressure control, achieved a 50% reduction in vascular events in this specific population[11].

In addition, many of the benefits of controlling risk factors in patients with T2DM disappear when control ceases, at a similar rate as the benefits are obtained[13-15]. For example, in the UKPDS study, patients with newly-diagnosed T2DM who presented an increase in blood pressure levels during follow-up almost immediately had an increase in the risk of cardiovascular episodes[14]. Furthermore, intravascular ultrasound studies have shown that coronary atherosclerosis regression is more difficult to attain in patients with diabetes than in those without[16], and therefore prevention and early treatment of the disease are essential.

The proportion of patients achieving therapeutic goals in cardiovascular risk factors in clinical practice[17] is very low, mainly in those at high cardiovascular risk, as is the case of patients with T2DM. In this respect, only 28% of T2DM patients reach a blood pressure level < 140/90 mmHg, and 22% less than 130/90 mmHg. Of greater concern is the fact that among known hypertensive patients, 40% did not follow a specific therapeutic strategy. Regarding lipid goals, only 35% of T2DM patients reached on LDL cholesterol concentration below 100 mg/dL. Another alarming fact is that 62% of patients requiring lipid-lowering therapy do not receive pharmacologic treatment[18].

Given the poor risk factor control in clinical practice, it is essential to evaluate strategies for early diagnosis of cardiovascular disease in T2DM patients, especially since the disease is often asymptomatic and has worse prognosis in these subjects than in non-diabetics[19]. A substantial percentage of patients with T2DM have silent myocardial ischemia, and these patients are at greater risk for cardiovascular events[20]. Therefore, the diagnosis of silent coronary disease may help to identify subjects at very high risk and consequently aid the implementation of more aggressive risk reduction strategies in this subgroup of patients.

Recent American Diabetes Association (ADA) guidelines[17] recommend only advanced or invasive cardiac tests in the presence of typical or atypical symptoms or abnormal baseline electrocardiogram (ECG). The rationale for not indicating screening tests in asymptomatic patients at high cardiovascular risk is simply because these patients are already supposed to be being treated to attain strict metabolic goals, although as previously stated, this is not so in the majority of cases[18]. Moreover, we must take into account that technologic progress renders diagnostic techniques increasingly sensitive and less invasive and thus their applicability may vary in the short-mid term. Therefore, we considered it of interest to carry out a review of factors that may predispose to silent cardiovascular disease in T2DM and of diagnostic tests that can be considered in selected cases.

## RISK FACTORS FOR CARDIOVASCULAR DISEASE IN T2DM PATIENTS

The expert consensus published by the ADA in 2007[21] defines asymptomatic T2DM patients as being at high risk for myocardial ischemia if they display any of the characteristics shown in Tables 1 and 2.

### *Evidence of other atherosclerotic vascular disease*

Atherosclerosis is a systemic process, and patients with T2DM have a greater atherosclerotic burden at any level of the arterial tree[22,23]; therefore, involvement of only one vascular territory is highly unlikely.

Screening for peripheral arterial disease (PAD) is widely accepted and has been extensively implemented in clinical practice. Thus, patients diagnosed with T2DM require an annual evaluation of their feet, including inspection, examination of sensitivity and palpation of pedal pulses and a questionnaire addressed to identify intermittent claudication. Periodic determination of the ankle-brachial index is also recommended[17]. Ninety per cent of patients with established PAD have coronary atherosclerosis on angiography[24]. In accordance with this observation, the presence of PAD is a predictor of symptomatic coronary artery disease, with a relative risk of 6.6 (95%CI: 2.9-15)[25]. Studies in patients who have suffered a stroke showed an 18%-38% prevalence of asymptomatic heart disease[26-28]. Thus, patients with extra-coronary atherosclerosis are at high risk of coronary involvement, and therefore screening strategies should be considered along with aggressive treatment of cardiovascular risk factors.

### *Microalbuminuria*

Microalbuminuria and chronic kidney disease are clearly associated with cardiovascular disease. The incidence of coronary heart disease or cardiac death 5 years after kidney failure diagnosis is 40%[29], and the age-adjusted hazard ratio for the development of coronary heart dis-

**Table 1 Clinical characteristics of diabetic patients with increased risk of coronary heart disease**

| Novel cardiac risk factors |
| C-reactive protein |
| Homocysteine |
| Lipoprotein(a) |

ease is 1.66 (95%CI: 1.24-1.92) when microalbuminuria is present, and may rise to 2.84 (95%CI: 1.80-4.46) in the case of macroalbuminuria[30]. Although the pathophysiologic explanation for this association is not fully understood, factors associated with the development of microalbuminuria or renal failure, such as a nocturnal rise in blood pressure, increased lipoprotein(a) and homocysteine levels or elevation of inflammatory markers and insulin resistance could play a role.

In any event, multiple observational studies confirmed this association, and thus patients with T2DM and any renal impairment stage should be considered at high risk for asymptomatic coronary artery disease.

### ECG

Baseline ECG is a rapid, cheap, simple and accessible method of screening for coronary heart disease. The finding of pathologic Q waves, ST-segment changes or left bundle branch block requires further testing to evaluate coronary artery disease in these patients, who should no longer be classified as "asymptomatic". Unfortunately, the number of cases detected with a baseline ECG alone is very low.

The exercise stress test is widely available in most hospitals and provides useful information regarding the ST-segment abnormalities suggestive of ischemia, although it does not constitute a very powerful marker of prevalent or incident coronary heart disease[28,31]. In patients with T2DM, sensitivity for detecting coronary artery disease is 47% and specificity 81%[32]. In addition to low sensitivity, the exercise stress test may have a limited role in diabetic patients who are typically deconditioned, overweight and possibly ataxic from peripheral neuropathy. In some studies, over 50% of subjects are not able to complete the exercise stress test[33].

Exercise capacity is probably a more relevant factor, since decreased exercise capacity has been linked to increased mortality and cardiovascular events in healthy people[34] and in patients with T2DM, with an odds ratio for coronary heart disease of 2.21 (95%CI: 1.41-3.46)[35].

**Table 2 Key messages**

| |
|---|
| Cardiovascular disease is the leading cause of mortality in patients with T2DM |
| Control of cardiovascular risk factors has been shown to significantly reduce the incidence of cardiovascular disease in T2DM patients |
| Control level of cardiovascular risk factors in patients with T2DM in clinical practice is poor |
| Systematic screening of cardiovascular disease has not been shown to improve the prognosis of patients with T2DM |
| In patients with atypical symptoms or ECG abnormalities, cardiovascular disease screening is warranted |

T2DM: Type 2 diabetes mellitus; ECG: Electrocardiogram.

### Autonomic neuropathy

Systematic screening for autonomic neuropathy at the time of T2DM diagnosis[17] is recommended; however, it is probably the most underdiagnosed chronic complication of diabetes. It is usually associated with other microvascular complications such as retinopathy or nephropathy, and its major clinical manifestations include resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, sudoriparous dysfunction and hypoglycemia unawareness. In patients with at least one microvascular complication it may be indicated to perform a Valsalva or deep breathing test to assess the presence of cardiac autonomic neuropathy.

Since 1962, it has been assumed that patients with T2DM may have coronary episodes with few or no symptoms, and this has been attributed, at least in part, to possible cardiac denervation due to neuropathy[36]. As previously mentioned, the presence of diabetic autonomic neuropathy is a significant predictor of coronary ischemia[37]; conversely, between 65% and 92% of diabetic patients with myocardial ischemia have autonomic neuropathy[38,39]. Thus, in all T2DM patients, but especially those with other cardiovascular risk factors, it is important to perform routine screening for autonomic neuropathy. Patients with diabetic autonomic neuropathy should undergo cardiac evaluation before initiating more intense physical activity than their usual.

### Retinopathy

As in other microangiopathic complications, the presence of retinopathy is also related to the incidence of coronary artery disease in these patients[40,41]. In this regard, after adjusting for age, body mass index, waist circumference, smoking status, lipids, glycosylated hemoglobin, T2DM duration and treatment, the odds ratio for the development of heart disease was 3.75 (95%CI: 2.0-7.4) in men and 3.81 (95%CI: 2.2-7.3) in women with proliferative retinopathy or who had received laser therapy[41]. Statistical significance was also maintained after adjustment for the presence of hypertension and nephropathy. In accordance with these results, the relative risk for the prevalence of symptomatic coronary artery disease in patients with established retinopathy was 1.98 (95%CI: 1.44-2.74)[42].

### Traditional risk factors

Typically, patients with T2DM have other classic associated cardiovascular risk factors such as hypertension or dyslipidemia which increase their cardiovascular risk. Therapeutic intervention for these factors contributes to a reduction in vascular risk[11]; however, previous studies demonstrated that in clinical practice it is very difficult to achieve the therapeutic goals for these risk factors recommended by clinical guidelines[18].

On the other hand, previous studies suggested that traditional cardiac risk factors are not associated with abnormal stress tests in asymptomatic diabetic patients[37]. The Detection of Ischemia in Asymptomatic Diabetics (DIAD) study concluded that markedly abnormal myocardial perfusion results occurred with equal frequency among patients with two or more and less than two risk factors.Thus, the presence or absence of major cardiovascular risk factors is not a suitable parameter to determine which T2DM patients require screening for asymptomatic coronary artery disease.

## SCREENING TESTS

No validated algorithm for the screening of asymptomatic coronary artery disease in T2DM patients has been established. In this respect, choice of the diagnostic procedure will depend on the available scientific evidence, experience in each center and degree of coronary heart disease suspicion, based on the variables mentioned previously. The scientific evidence on the available diagnostic procedures for coronary heart disease: echocardiography, myocardial perfusion imaging and computed tomography for coronary calcium, will be reviewed.

### Echocardiography

Resting echocardiogram is not routinely recommended in normotensive patients since its sensitivity and specificity for coronary heart disease detection are low[43]. Severe changes in contractility are more typical of the acute phase of myocardial infarction; moreover, segmental wall abnormalities do not exclusively constitute an ischemic etiology, since they may also be present in patients with non-ischemic heart diseases.

Therefore, resting or stress echocardiography after exercise or dobutamine is not routinely recommended in asymptomatic T2DM patients since no studies have provided data on its benefits. The usefulness of this test is limited to patients with known coronary heart disease to assess reversible ischemia, myocardial viability and risk stratification.

### Myocardial perfusion imaging

Single-photon emission computed tomography after exercise or pharmacologic administration is one of the most widely performed screening tests in asymptomatic T2DM patients. The presence of a fixed or reversible perfusion defect is associated with a three-fold increased risk for cardiovascular episodes in patients over 60 years of age[44]. In the DIAD study, participants with type 2 diabetes and no symptoms of CAD were randomly assigned to be screened with adenosine-stress radionuclide myocardial perfusion imaging (MPI) or not to be screened and be prospectively followed for a mean period of 5 years. Patients with a normal/low-risk scan showed an annual cardiovascular event incidence of 0.4% compared with 2.4% in those with a moderate to large perfusion defect[45]. Therefore, if the benefits of this test, which is minimally invasive and of acceptable cost are considered, it should probably be recommended as a first-line diagnostic procedure for silent myocardial ischemia in T2DM patients.

### Computed tomography

The use of Multi-detector computed tomography (CT) as a noninvasive assessment of the coronary artery tree is becoming more frequent in addition to angiographic methods in patients with or without T2DM diabetes who have had an acute myocardial infarction.

In asymptomatic patients or in those with mild symptoms the assessment of coronary artery calcium (CAC) is most commonly used, which is a specific marker of atherosclerosis. It can be visualized and measured noninvasively by computed tomography. The quantity of calcium within coronary arteries is typically scored as the area affected on the scan, multiplied by a weighting factor depending on the Hounsfield unit density of the calcium deposits[46]. Given the radiation exposure, careful patient selection for this test is mandatory. Coronary calcification in men $< 40$ years of age and in women $< 50$ years of age is infrequent; therefore, CT scanning is generally not recommended in these age groups. Several studies have shown the coronary artery calcium score to be valuable in identifying patients at high risk of inducible myocardial ischemia[47,48]. These studies consistently observed that the likelihood of ischemia in patients with a calcium score $\leqslant 100$ is negligible, whereas the probability of inducible ischemia in those with a score of $\geqslant 400$ is relatively high, even in oligoasymptomatic patients[49].

The presence of CAC is predictive for future cardiovascular events in both asymptomatic diabetic individuals and in nondiabetic subjects. However, for every increase in CAC, there is a greater increase in the mortality rate for diabetic than for nondiabetic subjects[50]. Moreover, diabetic patients with low CAC scores (Agatston Score $\leqslant$ 10) had a low prevalence of inducible myocardial ischemia and a low cardiovascular event rate[49,50]. Therefore, assessment of CAC might be useful in identifying diabetic individuals with a low risk of silent myocardial ischemia. Nevertheless, the use of CAC scoring for risk stratification in asymptomatic diabetic patients is not currently endorsed by the ADA recommendations[17] since there is insufficient evidence of the long-term benefits of early diagnosis.

## CAN EARLY DIAGNOSIS OF CARDIOVASCULAR DISEASE IMPROVE CARDIOVASCULAR OUTCOMES?

Despite all this evidence, the possible benefits of early

detection of cardiovascular disease in asymptomatic T2DM patients have not been confirmed in randomized trials. In the DIAD study, the cardiac event rates were not significantly reduced by MPI screening for myocardial ischemia[45]. Additionally, observational studies have shown that, on occasions, alterations in the coronary arteries of these patients can become spontaneously reversible[51]. Finally, studies comparing intensive medical treatment with revascularization procedures showed similar results[52,53]. Therefore, from a clinical and cost-benefit point-of-view, there is not enough evidence at present to recommend screening in these patients.

However, it should be taken into account that these studies were conducted in asymptomatic patients diagnosed early with cardiovascular disease. Therefore, both patient compliance and the intensity of monitoring by the physician were higher than those observed in real life, and this fact may have influenced the results. On the other hand, the DIAD study found a six-fold increased incidence of cardiac events in patients with moderate to large perfusion defects compared to those with a normal/low-risk scan[45], which supports the hypothesis that screening for asymptomatic coronary disease can be useful even though the low prevalence could have influenced the statistical power to demonstrate the possible benefits, including cost-benefit.

## DIAGNOSTIC STRATEGY

In the absence of categorical scientific evidence to date, the sequence of tests to be performed in high-risk patients is not established. In this sense, after performing a baseline ECG, the availability of technical and financial resources, and experience in each center can play a role in choosing the most appropriate diagnostic management. Overall, the most common recommendation is to start with a resting ECG and then a myocardial perfusion imaging by SPECT, although the increasingly widespread and cheap use of multi-detector CT can change this trend in the coming years.

## CONCLUSION

Systematic screening for cardiovascular disease in asymptomatic patients with T2DM is not recommended since there is insufficient evidence at present that the benefits of early detection outweigh the costs and side effects of the different diagnostic tests. However, as mentioned previously, this situation may change in the near future given the advances in reliability and efficiency of the different diagnostic tests.

Professionals responsible for the medical care of patients with T2DM should focus on optimizing the control of cardiovascular risk factors and evaluate, only in selected cases, the need to further investigate the presence of cardiovascular disease.

## Abstract

Diffuse idiopathic skeletal hyperostosis (DISH) is a non-inflammatory disease characterized by calcification and ossification of soft tissues, mainly enthesis and spinal ligaments. The clinical presentation primarily includes spinal involvement-induced pain and range of motion. Although rare, life-threatening gastrointestinal, respiratory or neurological events or severe morbidity due to bone compression on the adjacent structures may develop. There is a limited amount of data on DISH-related events in the literature. In recent years, comorbid metabolic disorders are of great interest in patients with DISH. The early diagnosis of these conditions as well as rare entities allows an effective multidisciplinary approach for the treatment of DISH. In this article, we review extraskeletal symptoms and associated comorbidities in patients with DISH.

**Key words:** Diffuse idiopathic skeletal hyperostosis; Swallowing; Respiratory symptoms; Neurological symptoms; Comorbidities

**Core tip:** Although diffuse idiopathic skeletal hyperostosis (DISH)-related skeletal symptoms are well-established, limited data on extraskeletal signs and comorbidities are available. In this article, we review extraskeletal symptoms and associated comorbidities in patients with DISH in the light of the literature.

## INTRODUCTION

Diffuse idiopathic skeletal hyperostosis (DISH) is a non-inflammatory disease characterized by calcification and ossification of soft tissues such as ligaments, tendons and fasciae with an unknown etiology[1]. The prevalence which increases with age[1] has been reported to be 2.8% and 2.6% in men and women aged ⩾ 40 years, respectively[2]. The diagnosis is based on the presence of involvement of at least four contiguous thoracic vertebral segments, preservation of intervertebral disc spaces, and the absence of apophyseal joint degeneration or sacroiliac inflammatory changes[3].

Clinical manifestations of the disease vary depending on the involvement site. It may also present asymptomatically. The axial skeleton is the most commonly affected site at 70%. Thoracic involvement is the most common manifestation of DISH, while the cervical spine is minimally involved[4,5]. In addition, DISH is not limited to axial skeleton involvement. Other anatomical structures affected by the disease include the pelvis, patella, calcaneus bone or olecranon[5]. The majority of symptoms occurs due to altered biomechanics of the skeleton, leading to pain, stiffness and restricted range of motion (ROM) of the axial or peripheral joints. Moreover, respiratory, gastrointestinal and neurological symptoms may develop

due to bone compression of the adjacent structures[6,7]. The incidence of metabolic disorders, such as metabolic syndrome, diabetes and obesity, has been reported to be increased in patients with DISH[8]. Therefore, it is of the utmost importance that symptoms other than pain and limited ROM and comorbidities should be identified and a multisystemic therapy should be tailored for each patient. In this article, we review extraskeletal symptoms and associated comorbidities in patients with DISH.

## SWALLOWING AND RESPIRATORY SYMPTOMS

Cervical involvement has been reported to be 75% in patients with DISH[9]. Cervical osteophytes are usually asymptomatic[10]. The swallowing function is primarily affected in cases of symptomatic manifestations. The size and location of the bone spurs may vary. In the presence of upper cervical spine involvement (C3-4), laryngeal functions are mostly affected[11]. However, spasm or obstruction of the esophageal sphincter may occur in the presence of distal involvement[12]. McCaffrey showed that there was no relationship between the size of the bone spurs and severity of the symptoms[13]. Dysphagia is the most common complaint in these patients. Dysphagia typically results from esophageal compression by the osteophytes exerting a mass effect[14], recurrent laryngeal nerve injury-related neuropathy[15], and esophageal fibrosis and inflammation secondary to osteophyte irritation[16]. As the incidence of DISH increases with age, dysphagia should be considered particularly in the elderly[17].

Furthermore, tracheal compression of the giant osteophytes may lead to acute or progressive airway obstruction. Caminos *et al*[18] reported a case admitted with acute onset respiratory failure and diagnosed with DISH. The patient suffered from shortness of breath in the supine position. Cervical lateral X-ray revealed a large osteophyte which compressed the trachea. The authors concluded that DISH should be kept in mind particularly in elderly patients with unexplained respiratory distress[18]. In another study, Nelson *et al*[19] reported three cases requiring tracheotomy due to acute airway obstruction. Gokce *et al*[20] also described a case of DISH with postoperative stridor and respiratory distress due to cricoarytenoid joint fixation and right vocal cord paresis following total knee arthroplasty. Respiratory distress was reported to be induced by venous compression, nerve compression, cricoarytenoid joint fixation, post-cricoid ulceration and edema[21].

In a study including 204 patients with DISH between 1980 and 2009, Verlaan *et al*[8] reported dysphagia and airway obstruction in the study population. However, the authors found no relationship between age and the degree of dysphagia or airway obstruction. One or more of the imaging studies including cervical X-ray, barium swallow, computed tomography (CT), laryngoscopy and magnetic resonance imaging (MRI) were performed.

As DISH is mostly seen in the elderly, endoscopic inspection of the upper gastrointestinal system is critical in the differential diagnosis of malignancies. However, caution should be exercised during endoscopy with a gentle pressure. Otherwise, iatrogenic pharyngoesophageal perforation may occur[22]. Non-surgical treatments include dietary modification (fluid and soft food intake), antireflux medications, gastroprotectants and percutaneous endoscopic gastrostomy tube placement[8]. On the other hand, surgical treatment options are anterolateral, lateral or transpharyngeal resection of the ossification. Also, spinal decompression, discectomy and spinal fusion are additional surgical procedures. There are no statistically significant differences in the sex, duration of symptoms, and the number of affected vertebrae between surgically and non-surgically treated patients[8]. However, a higher number of younger patients with severe symptoms were primarily operated on. Respiratory and swallowing functions were improved in most patients following surgery[8].

## NEUROLOGICAL SYMPTOMS

Neurological symptoms which are rarely seen include decreased flexibility of the spine and narrowed spinal canal-related myelopathy due to anterior and posterior longitudinal ligament calcification[23]. Myelopathy is often associated with narrowing of the lower cervical vertebral canal[23]. Lumbar spinal canal stenosis was also reported in the literature[24]. The craniocervical junction is rarely involved. It is mainly caused by atlantoaxial dislocation or pseudoarthrosis between the spinal process of the axis and the posterior tubercle of the atlas[25]. In addition, there is a case of DISH with retro-odontoid pseudotumor-induced progressive myelopathy in the literature[26]. Retro-odontoid pseudotumors can be defined as lesions caused by inflammatory granulation or reactive soft tissue hypertrophy from chronic atlantoaxial subluxation. These patients may present with post-traumatic neurological symptoms[26]. Eser *et al*[27] described a surgically-treated case of central cord syndrome after a minor trauma. The patient had no cervical dislocation or fracture. However, MRI demonstrated spinal cord edema and myelomalasic segments. Koizumi *et al*[28] reported another case of myelopathy due to multilevel cervical canal stenosis. Such patients may suffer from spinal fractures and neurological deficit after a minor trauma. These fractures can be easily overlooked since they progress to a neurological deficit over time with a limited initial clinical presentation. This can be attributed to the fact that the mortality rate of DISH patients with spinal fractures has been reported to be nearly 20%[29]. Vengust *et al*[30] reported a case of DISH in whom post-trauma fracture dislocation developed at the third and fourth cervical vertebrae. Respiratory failure was triggered by vocal cord paralysis due to laryngeal nerve entrapment at six months[30].

In addition to neurological complications, the incidence of stroke was reported to be increased in patients with DISH[31]. In a study including a total of 90 patients, 45 with DISH and 45 with cervical spondylosis, MRI

revealed a higher incidence of infarction in patients with DISH. Magnetic resonance angiography also showed a higher incidence of major cerebral artery stenosis and occlusion in these patients. Based on these data, the authors concluded that patients with DISH had an increased risk for stroke as well[31]. In another report, a 53-year-old case with DISH was admitted with motor and sensory polyneuropathy[32]. It was associated with the metabolic disturbance in this patient population. Moreover, another case with DISH presenting with thoracic outlet syndrome-associated findings is available in the literature[33].

## MISCELLANEOUS SYMPTOMS

Other symptoms of DISH include dysphonia, weight loss, odynophagia, reflux disease, snoring, aphonia, choking, pharyngeal perforation, difficult intubation and aspiration pneumonia[8].

## DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS-ASSOCIATED METABOLIC COMORBIDITIES

The relationship between DISH and metabolic status has been shown. The incidence of DISH is higher in patients with diabetes, hypertension, hyperlipidemia, hyperinsulinemia, metabolic syndrome or obesity[34]. Vezyroglo *et al*[35] determined that metabolic abnormalities occurred in 70% of patients diagnosed with DISH and 45% in the control group. Hyperlipidemia and hyperuricemia associated with diabetes have been found frequently in patients diagnosed with DISH. Combined metabolic features of diabetes mellitus and dyslipidemia, diabetes mellitus and hyperuricemia, or diabetes mellitus and dyslipidemia and hyperuricemia were shown to be the main risk factor for DISH[35]. Mader[35] reported that patients diagnosed with DISH have a higher metabolic syndrome rate than the control group. Eckertova *et al*[36] reported that non-esterified fatty acids, insulinogenic index and insulin/C-peptide ratio decrease in patients diagnosed with nondiabetic DISH. These patients have identified impaired pancreatic beta-cell stimulation and increased hepatic insulin extraction. Eckertova *et al*[36] suggested that if these conditions persist for a long time, it might lead to a decreased ability of insulin to maintain a normal serum glucose level and consequently to insulin resistance which is highly prevalent in symptomatic DISH patients.

## DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS-ASSOCIATED CARDIOVASCULAR COMORBIDITIES

It has been reported that hypertension, atrial fibrillation, left ventricular hypertrophy and peripheral arterial disease increased[10,37,38] in patients diagnosed with DISH. Mader *et al*[16] reported that the 10 year coronary heart disease risk of patients with DISH is significantly higher than the control group. Zincarell *et al*[39] suggest that DISH prevalence was found to be 30.3% in patients with severe cardiovascular disease. A lot of studies reported that DISH carries a risk for stroke and cerebrovascular diseases.

## Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) is an endoscopic procedure with high frequency of accidental symptoms, and particularly some patients who develop and aggravate pancreatitis due to the procedure may need treatment of surgery or die. Various attempts were performed so far to prevent post-ERCP pancreatitis, however, it is impossible to completely prevent pancreatitis at this time because there are various factors for occurrence of post-ERCP pancreatitis. One of the most frequent causes of post-ERCP pancreatitis is considered to be congestion of pancreatic juice associated with duodenal papilledema after examination or treatment. Recently it is often reported that use of a pancreatic duct stent may prevent occurrence of pancreatitis which occurs because of an increased inner pressure of the pancreatic duct caused by congestion of pancreatic juice associated with duodenal papilledema. However, there are some patients who develop pancreatitis even if treated with the pancreatic duct stent, thus further clarification of the pathology and advancement of the prophylactic method will be needed.

**Key words:** Endoscopic retrograde cholangiopancreatography; Post-endoscopic retrograde cholangiopancreatography pancreatitis; Pancreatic duct stent; Pancreatic stenting

**Core tip:** There are some patients who can avoid occurrence of post-endoscopic retrograde cholangiopancreatography pancreatitis (ERCP) pancreatitis by pancreatic duct stenting. However, it is impossible to prevent all post-ERCP pancreatitides by pancreatic duct stenting, and further examination will be needed.

Sakai Y, Tsuyuguchi T, Yokosuka O. Clinical usefulness and current problems of pancreatic duct stenting for preventing post-ERCP pancreatitis. *World J Clin Cases* 2014; 2(9): 426-431 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i9/426.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i9.426

## INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) plays a very important role in diagnosis and treatment for pancreatic and biliary tract diseases. Post-ERCP pancreatitis is the early accidental symptom which occurs most frequently after ERCP. Although its frequency differs depending on the treated patients, procedure performed, definition of pancreatitis, or the investigation method, it is generally reported to occur in about 4.5% of treated patients based on the results of the large scale prospective studies[1-7] (Table 1). Although many cases of post-ERCP pancreatitis are alleviated by admission and treatment for a few days, some are aggravated, and about 0.04% need surgery and about 0.03% die[1,2,4,5]. Prophylaxis of post-ERCP pancreatitis is the great task which has not been resolved yet since introduction of ERCP, and various attempts have been performed. As one of such attempts, pancreatic duct stent is used to prevent occurrence of pancreatitis caused by duodenal papillede-

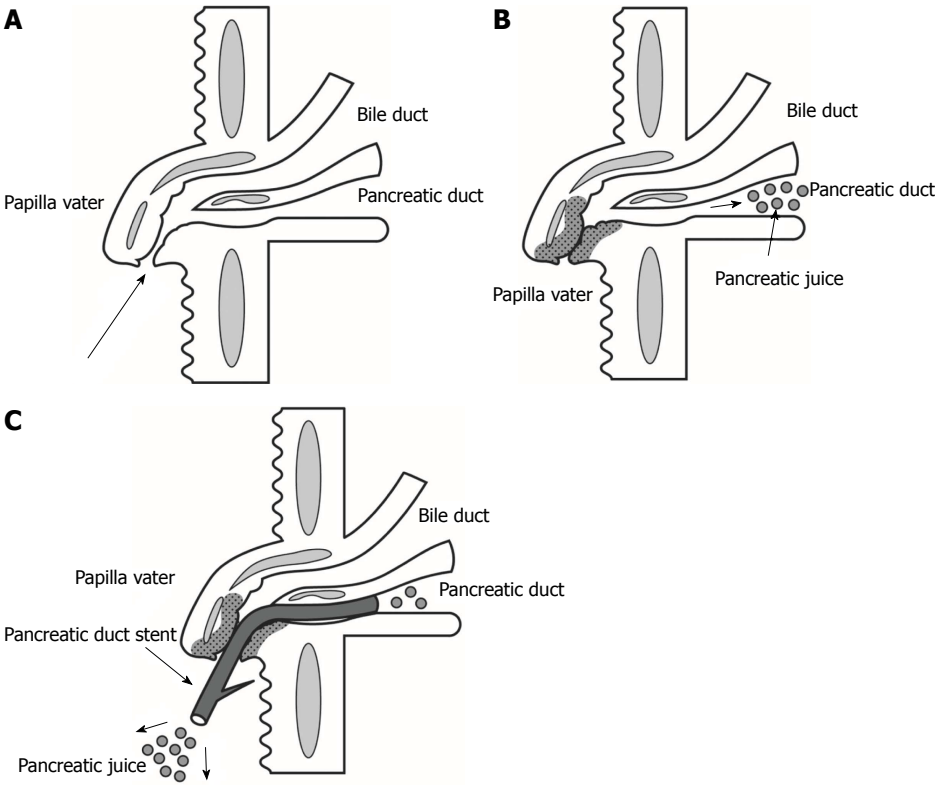

**Figure 1 Pancreatic duct stenting for preventing post-endoscopic retrograde cholangiopancreatography pancreatitis.** A: Duodenal papilla before cannulation is performed; B: Duodenal papilledema occurs by frequent cannulation manipulation; C: Pancreatic duct stent is placed to regulate the passage of pancreatic juice.

ma due to the procedure, and its usefulness is frequently reported. In this article, we will describe the usefulness and problems of pancreatic duct stenting aiming at prophylaxis of post-ERCP pancreatitis.

## PATHOGENIC MECHANISM OF POST-ERCP PANCREATITIS

Post-ERCP pancreatitis is considered to occur due to various factors. The factors are broadly classified into five categories: (1) Increased inner pressure of the pancreatic duct by congestion of pancreatic juice caused by postoperative papilledema; (2) Mechanical irritation such as damaged pancreatic duct due to deep insertion of the catheter into the pancreatic duct or insertion of the device such as the guidewire; (3) Hydrostatic injury such as increased inner pressure of the pancreatic duct due to frequent pancreatography, manometry, or reflux water of pancreatoscopy; (4) Chemical injury due to infusion of the contrast medium or intestinal juice into the pancreatic duct; and (5) Thermal injury due to papilledema by radiofrequency radiation or thermal damages of the pancreas itself. Among them, one of the most frequent causes may be congestion of pancreatic juice associated with papilledema after examination or treatment[1,4,8]. There is a mechanism that congestion of pancreatic juice increases viscosity of pancreatic juice, aggravates obstruction of discharge of pancreatic juice, decreases the outflow of pancreatic juice into the small intestine, and promotes secretion of pancreatic juice from the pancreatic acinar cell through increased cholecystokinin production. Through these processes, congestion of pancreatic juice is further aggravated, and eventually brings about activation of trypsinogen into trypsin within the acinar cell, and develops pancreatitis[8].

## REPORT ON PANCREATIC DUCT STENTING TO PREVENT POST-ERCP PANCREATITIS

Although the pathogenic mechanism of post-ERCP pancreatitis has not been sufficiently clarified, various factors may be involved[1-6]. One of the pathogenic mechanisms of post-ERCP pancreatitis includes obstruction of discharge of pancreatic juice caused by papilledema or spasm of the sphincter of Oddi associated with the procedure. In order to regulate the passage of pancreatic juice for prophylaxis of post-ERCP pancreatitis, the pancreatic duct stent is used (Figure 1). Past articles comparing the pancreatic duct stenting group and non-pancreatic duct stenting group for prophylaxis of post-ERCP pancreatitis are shown[8-26] (Table 2). Review by RCT revealed that five of eight articles describe that post-ERCP pancreatitis occurred less in the stenting group with significant difference. Of other eleven articles, five articles describe that post-ERCP pancreatitis occurred less in the stenting group with significant differ-

ERCP: Endoscopic retrograde cholangiopancreatography pancreatitis.

ence. In seven articles of nine articles without significant difference, incidence of pancreatitis tends to be low in the pancreatic duct stenting group, thus pancreatic duct stenting is considered useful for prophylaxis of post-ERCP pancreatitis. Interestingly, as reported by Tsuchiya *et al*[18], even if p-value of incidence of pancreatitis does not reach the value with significant difference, amylase value has become significantly low after ERCP in the stenting group. According to the review by Tsuchiya *et al*[18], there were significantly less patients with abdominal pain in the stenting group, and there were no serious patients, which may be the effect of stenting. In addition, in the review of Sakai *et al*[23], incidence of abdominal pain and postoperative amylase value are significantly low in the pancreatic duct stenting group, which is validly thought to be the effect of the pancreatic duct stent, taking into consideration that the background factors of both groups do not vary.

## INDICATION AND PROBLEMS OF PROPHYLACTIC PANCREATIC DUCT STENT

The risk factors of post-ERCP pancreatitis include young female, history of post-ERCP pancreatitis, recurrent pancreatitis, sphincter of Oddi dysfunction (SOD), and uncomplicated chronic pancreatitis as patient factors, and difficulty in insertion into the biliary duct, pancreatography, incision of the opening of the pancreatic duct, endoscopic papillary balloon dilation, and precut papillotomy as procedure factors[1-6] . However, it is hard to say it necessary to perform pancreatic duct stenting for all these patients, and it is necessary to select candidate patients for pancreatic duct stenting. Since pancreatic duct stenting regulates the passage of pancreatic juice, occurrence of occlusive pancreatitis is expected to be prevented. The procedure to indicate pancreatic duct stenting based on the past reports or theoretical thought includes: (1) Pancreatic duct guidewire-indwelling method or implementation of precut papillotomy from the opening of the pancreatic duct in patients with difficulty in insertion into the biliary duct, which may lead to papilledema[20,22,23,25]; (2) After endoscopic removal of duodenal papilla[17]; (3) Endoscopic sphincterotomy for SOD [13]; (4) Invasive procedure against pancreas such as the cytological diagnosis of pancreatic juice or biopsy of the pancreatic duct; and (5) Indwelling of the thick biliary duct stent instead of endoscopic sphincterotomy.

As for whether it is necessary to indwell the pancreatic duct stent in young females who are identified as the risk factor of post-ERCP pancreatitis or in patients with history of post-ERCP pancreatitis when there is no erroneous pancreatography or erroneous insertion of the guidewire, currently there is no clear evidence. Prophylaxis of pancreatitis by pancreatic duct stenting is frequently reported for patients with difficulty in insertion into the biliary duct. According to the past report, pancreatic duct stenting leads to less incidence of pancreatitis[20,22,23,25], which is a good indication when considering to regulate the passage of pancreatic juice. However, discussion will be needed as to indication of pancreatic duct stenting in patients with difficulty in insertion into the biliary duct. It may be possible to perform pancreatic duct stenting in the comparatively stable situation in patients who underwent erroneous pancreatography or erroneous insertion of the guidewire into the pancreatic duct or in patients who underwent pancreatic duct guidewire-indwelling method which is the procedure performed by indwelling the guidewire in the pancreatic duct of patients with difficulty in inserting into the biliary duct. However, there remain patients with difficulty in pancreatic duct stenting. We give an example that in the case of patients who underwent pancreatography and had difficulty in advancing the guidewire caudally due to flexion or stenosis of the pancreatic duct or patients with difficulty in cannulation both into the biliary duct and pancreatic duct, although insertion into the biliary duct has become possible through precut papillotomy, it is still difficult to identify the opening of the pancreatic duct. If approach to the pancreatic duct in such patients for pancreatic duct stenting is attempted and failed, a possibility to induce or aggravate pancreatitis becomes high. Thus, discussion may be still needed as to timing or subjects or implementation judgment of pancreatic duct stenting in the patients with difficulty in insertion into the biliary duct.

What stent should be used is examined. Currently, there is no definite information regarding material quality, diameter, length, or shape of the stent. The stent is used only for drainage of the papillary edge, thus it is not always necessary to use a long stent, and those 3-4 cm in length are often used[18-26]. The stent with the flap in one duodenal side having no flap within the pancreatic duct (Figure 2) or one with the pig tail in the duodenal side having no flap within the pancreatic duct is expected to be spontaneously dislodged later after being indwelled. The stent with the flap in the pancreatic duct side is unlikely to deviate or be aberrant after stenting, however, it is necessary to perform endoscopy for removal several days later (Figure 3). Although currently it is difficult to set the strict term, if the pancreatic duct spontaneous dis-

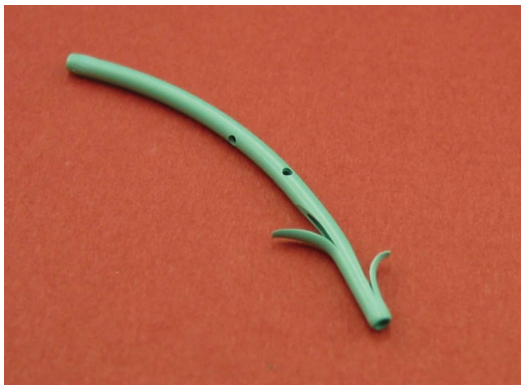

**Figure 2 Pancreatic duct stent with the flap in one duodenal side having no flap within the pancreatic duct (Pancreatic duct stent: Geenen®-COOK): Spontaneous dislodgement type.**

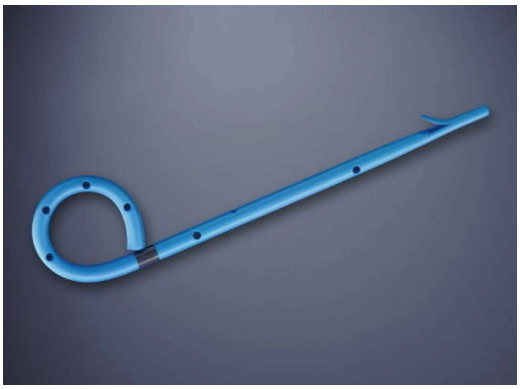

**Figure 3 Pancreatic duct stent with the flap in the pancreatic duct side (Pancreatic duct stent Zimmon®-COOK).**

lodgement stent indwelled is not spontaneously dislodged for a long time after stenting, there is a possibility that the stent is aberrant within the pancreatic duct, or pancreatitis occurs due to stent occlusion. Therefore, it should be endoscopically removed similarly to the pancreatic duct stent with the flap within in the pancreatic duct. It is important that the stent fits the shape of the pancreatic duct, and in the case of Z-shape pancreatic duct it is better to perform stenting beyond flexion depending on the case, and a long stent 7cm or greater is used in some cases. However, the longer stent tends to straddle the flexed portion of the pancreatic duct at the pancreas head, thus the stent made of the flexible material with high tracking ability is needed. The shorter spontaneous dislodgement stent less than 3cm may be dislodged after the procedure, thus attention should be paid. As for stent diameter, although the thicker stent gives impression of excellent drainage efficiency, to the contrary, such a stent blocks the thinner branches of the pancreatic duct causing pancreatitis, or it is suggested that the stent itself may give mechanical irritation to the pancreatic duct[27]. For the thin stent with a diameter of 3Fr. or 4Fr., 0.018-0.025 inch guidewires are available[27]. Therefore, the guidewire has no resilience in inserting the pancreatic duct stent, and its insertion is difficult in some cases. Hereinafter multi-center RCTs on what pancreatic duct stent should be used is expected to be performed.

Furthermore, there is a problem that pancreatic duct stent should be inserted into what patients by doctors with what experience. Most of reports so far are performed in the expert centers, and even in such facilities, failure rate of insertion of the pancreatic duct stent is reported to be 5%-10%[9,13,28]. Freeman reported that failure of insertion of the pancreatic duct stent is very dangerous, and two thirds of patients develop moderate to severe pancreatitis[29]. Thus, Fazel *et al*[15] described that insertion of the pancreatic duct stent for prophylaxis

of post-ERCP pancreatitis should not be performed by doctors with less experience. Since pancreatitis, when being aggravated, may lead to fatal subsequence, pancreatic duct stenting should be performed by doctors with sufficient experience, and even the doctors with sufficient experience should perform with sufficient attention for stenting.

## CONCLUSION

In order to prevent post-ERCP pancreatitis, pancreatic duct stenting is considered useful. However, there are patients who fail to prevent post-ERCP pancreatitis. Development of complete prophylactic methods of post-ERCP pancreatitis is expected in the future.

## Abstract

For patients with metastatic or locally advanced eyelid and periocular carcinoma not amenable to surgical excision, targeted therapies have shown efficacy with better tolerability compared to cytotoxic chemotherapy. Overexpression of epithelial growth factor receptor was found in squamous cell carcinomas. Vismodegib targets the mutation in the hedgehog pathway identified in basal cell carcinoma and basal cell nevus syndrome. Targeted therapies provide a novel and potentially effective treatment alternative for patients with eyelid carcinoma not amendable for surgery, including those with metastatic, locally advanced disease, advanced age, and significant comorbidities. High cost, need for long-term treatment, and toxicity are relative limitations.

**Key words:** Vismodegib; Periocular basal cell carcinoma; Sonic hedgehog; Epithelial growth factor receptor inhibition; Periocular squamous cell carcinoma

**Core tip:** Targeted therapies provide a novel and potentially effective treatment alternative for patients with eyelid carcinoma not amendable for surgery, including those with metastatic, locally advanced disease, advanced age, and significant comorbidities. High cost, need for long-term treatment, and toxicity are relative limitations.

## INTRODUCTION

Eyelid malignancies have been reported with yearly incidence as high as 15.7 cases per 100000 individuals in the United States[1]. The most common type of eyelid carcinoma is basal cell carcinoma (BCC), accounting for 86% to 96% of all cases, followed by squamous cell carcinoma (SCC), 3.4% to 12.6%, sebaceous carcinoma (SebCa), 0.6% to 10.2%, and melanoma, less than 1%[1-3]. Distant metastasis from eyelid carcinoma is not common, reported in up to 6% of squamous cell carcinoma[4]. Furthermore, the integrity of the eyelids are essential for protection and function of the globe making locally advanced disease difficult if not impossible to resect completely without disruption of globe function.

Traditional cytotoxic chemotherapy for treatment of metastatic or unresectable disease targets all rapidly dividing cells, whether cancerous or not. This results in an unfavorable toxicity profile. With the discovery of the common mutations in BCC and SCC, drug therapies targeted

against these mutations can potentially block only the growth of cancer cells and thus lead to less wide spread toxicity. In addition, many of these targeted therapies are administered orally rather than by the intravenous route. The ease of administration and lower toxicity generates momentous interest in these new classes of drugs.

## EGFR INHIBITION IN SQUAMOUS CELL CARCINOMA

Epithelial growth factor receptor (EGFR), also known as HER-1 or ErbB-1, is a transmembrane protein with an extracellular receptor domain for multiple ligands, including EGF, TGF-alpha and epiregulin, and an intracellular kinase domain with tyrosine autophosphorylation site[5]. Upon activation, the EGFR forms homodimer with another EGFR or heterodimer with another ErbB family receptor. Multiple pathways can be activated by these dimer formations, including RAS/RAF/MEK/MAPK, PI3K/AKT and STAT. The resultant effect of EGFR activation in both normal and malignant human skin is severe epidermal disorganization and invasion[6].

Squamous cell carcinoma has been shown to have overexpression of EGFR. In a series of 13 metastatic SCC of the skin, all showed strong expression of EGFR whereas normal skin close to the tumor had weak EGFR expression that was limited to the basal layer of the epidermis[7]. EGFR overexpression has been found in up to 78% (25 of 32) of cutaneous SCC cells and 62% (13 of 21) of actinic keratoses (AKs)[8]. In conjunctival SCC, EGFR had either moderate or strong expression of EGFR on all (5 out of 5) epithelial cell of conjunctiva[9]. Furthermore, *EGFR* numerical aberration was found 77% (27 out of 35) SCC and 52% (13 out of 25) of AKs[8]. Analysis of 3 lymph nodes of metastatic SCC all showed amplification of 7p12-13, location of EGFR gene[10].

EGFR expression level is also shown to be associated with metastasis in 45 cases of head and neck SCC[11]. In 25 cases without metastasis, only 9 (36%) showed strong expression for EGFR, compared to 11 of 14 cases (79%) with metastasis[11].

## EFFICACY OF EGFR INHIBITORS

Cetuximab (C225, Erbitux) is a chimeric mouse-human IgG1 monoclonal antibody that primarily competitively inhibits EGF binding at the same affinity as the natural ligand[12]. It was approved for use by the Food and Drug Administration (FDA) on March 1, 2006 for locally or regionally advanced head and neck cancer SCC (HNSCC) in combination with radiation therapy or as single agent for recurrent or metastatic HNSCC after failing platinum-based therapy. It was the first EGFR inhibitor studied in clinical trials and to be approved by FDA. In vivo study with A431 model epidermoid carcinoma cells had shown that even in the presence of EGF, cetuximab completely inhibits the activation of EGFR[13]. It is also able to induce dimerization of EGFR and down regulation and further activation by ligands[14]. In a phase 2 study of 36 patients with unresectable (locally advanced or metastatic) SCC of the skin with confirmed strong or moderate expression of EGFR in the primary tumor, the overall tumor response rate was 69% (95%CI: 52%-84%) base on intent-to-treat and 81% (95%CI: 63%-93%) base on actual treatment received[15]. Cetuximab was given as an intravenous infusion at 400 mg/m$^2$ dose followed by weekly 1-hour infusion at a dose of 250 mg/m$^2$. The median number of infusion received during the 48-week study was 15 (range 1 to 47 infusions)[15]. There is currently no published study on the effect of cetuximab compared to or in combination with standard cytotoxic chemotherapy. However, in a study of 424 head and neck squamous cell carcinoma (HNSCC) randomized to high dose radiation with or without cetuximab has shown superior median survival (54 mo *vs* 28 mo) with the addition of cetuximab[16].

Gefitinib (ZD1839, Iressa) was the first orally administered EGFR inhibitor shown to selectively inhibit EGFR tyrosine kinase activity through blockage of autophosphorylation[17]. Gefitinib was approved in 2003 as monotherapy for non-small cell lung cancer (NSCLC), but the approval was amended to only in patients who had previously benefited from the drug due to lack of survival benefit especially when compared to erlotinib. In vitro incubation of gefitinib with EGF and cutaneous SCC cells showed a dose-dependent reduction in EGFR and MAPK phosphorylation between $IC_{50}$ of 0.02 and 0.2 μm[18]. In 22 patients with locally aggressive or recurrent cutaneous SCC, neoadjuvant use of gefitinib 250 mg per day showed overall response rate of 45.5% (95%CI: 24.4%-67.8%) and 2-year overall survival of 72.1% (95%CI: 55.4%-93.9%)[19]. Of the 4 patients who showed complete response in this study, all were alive and were disease free at last follow-up[19]. In addition, 3 of these 4 patients with complete response showed pathologic complete response with no evidence of SCC in their resected surgical tissue[19]. There is currently only 1 case report of use of gefitinib as primary treatment for metastatic cutaneous SCC of the foot showed maintained clinical response for 30 mo and an additional 12 mo with the addition of sirolimus[20].

Erlotinib (OSI-744, Tarceva) is similar to gefitinib in that it inhibits EGFR activity through reduction of autophosphorylation causing cell cycle arrest at G1 phase; however, it does this through competitive inhibition with ATP[21]. FDA first approved its use on November 18, 2004, for treatment of patients with locally advanced or metastatic NSCLC after failure of at lease one prior chemotherapy regimen. It was later approved for use in locally advanced or metastatic pancreatic carcinoma in combination with gemcitabine and most recently as first-line therapy for metastatic NSCLC in the presence of EGFR mutation. To our knowledge the use of erlotinib in cutaneous SCC has only been investigated in one phase

1 study of erlotinib plus radiation therapy after surgical resection. The 2-year overall survival was 65% with median time to recurrence of 10.5mo (range 1 to 14 mo) in the 15 Stage III cutaneous SCC patients included in this study[22]. Palliative treatment of metastatic cutaneous SCC with erlotinib has been reported in multiple case reports with initial tumor response[23-25]. In phase 2 studies of locally advanced HNSCC, the addition of erlotinib to cisplatin and 70Gy of radiation showed improved clinical response rate, 52% compared to 40%, however, this was not statistically significant, $P = 0.08$[26].

## USE OF EGFR INHIBITORS FOR ORBITAL AND PERIORBITAL SCC

EGFR expression has been shown in 5 patients with conjunctival SCC as moderate or strongly expressed in both in situ and invasive components of SCC[9]. In contrast, study of periocular sebaceous carcinoma showed lower intensity of EGFR expression with only 2 (11%) of 19 patients showing 3+ intensity of staining[27].

Our group has also reported good clinical and radiological tumor response to EGFR inhibitors in three patients who presented with locally advanced cutaneous SCC of the periocular skin with orbital extension[25, 28]. Two of the three patients were treated with cetuximab at the standard dosage of 400 mg/m$^2$ followed by 250 mg/m$^2$ weekly and the third was treated with erlotinib 150 mg daily. One of the patients treated with cetuximab had involvement in the cavernous sinus, Meckel's cave, trigeminal tract and infraorbital nerve and showed improvement in motility and sensation after 4 weeks of treatment. This patient's tumor was also analyzed for 182 cancer-related genes and found to have EGFR P753S mutation along with *CDKN2A* mutation, *MYC* amplication and *TP53* mutation[28].

## SIDE EFFECTS OF EGFR INHIBITORS

The most common side effect of EGFR inhibitors is skin toxicity in the form of an acne-like rash, papular and/or pustular follicular eruption, in 32% to 78% of patient with a median time to onset of 14 d[7, 19]. Interestingly, the presence rash as a side effect during treatment was significantly correlated with higher overall response rate, median overall survival and progression-free survival in patients treated with erlotinib for NSCLC[29]. The lower incidence of acne-like rash with gefitinib is believed to be due to its attenuation instead of complete blockage of EGFR tyrosine kinase. Instead, toxicity from gefitinib is most commonly diarrhea and fatigue before rash[19]. Erlotinib is also associated with mucositis (87%), esophagitis (40%)[22], and ocular side effects including trichomegaly leading to corneal ulceration[30], conjunctivitis and ectropion[31]. Discontinuation of EGFR inhibitors due to toxicity varied from 9% with gefitinib[19], 11% in cetuximab[7], and 13% in erlotinib[22].

## COST OF EGFR INHIBITORS

Cetuximab costs from $2.94 per milligram in Switzerland to $6.73 per milligram in the United States[32]. At the dosage used in the phase 2 clinical trials, the cost would be approximately $28000/m$^2$ or for an average white male the cost of the course of cetuximab would be approximately $37500. Cetuximab is approved in Europe and Asia, specifically Japan, and available in central and south America as well. In comparison, Iressa costs on average $79 per 250 mg tablet[33] and Tarceva cost on average $100 per 150 mg tablet[34], or cost of $2370 and $3000 per month, respectively. Iressa and Tarceva are both available in Europe and Asia in addition to the United States.

## PTCH1 GENE AND BASAL CELL CARCINOMA

Basal cell carcinoma (BCC) has been linked to disruption in the Hedgehog (Hh) signaling cascade, a pathway important during embryogenesis but normally inactive in the adult[35, 36]. Patched-1 (Ptch-1) is a transmembrane receptor that normally has inhibitory effects on downstream receptor Smoothened (Smo)[37]. When Ptch-1 is activated, upon binding by Hh protein, the constitutive inhibition on Smo is reversed and produces angiogenesis and cellular proliferation in tumorigenesis[38]. Specifically, expression of the downstream product GLI1 in basal cells is proposed to induce formation of BCC[39]. Mutations both in PTCH-1 and Smo have been identified in basal cell nevus syndrome and sporadic basal cell carcinomas[35,36,40,41]. Additionally, continued signaling of the Hh pathway is needed for sustained growth of established BCCs in the mouse model[42].

## INHIBITION OF HEDGEHOG PATHWAY IN BCC

Vismodegib (GDC-0449, Erivedge) is a first-in-class small molecule oral Hh signaling pathway inhibitor approved January 2012 for the treatment of locally advanced or metastatic BCC. Vismodegib directly binds to and inhibits Smo[43]. Vismodegib's inhibition at this point in the cascade prevents formation of GLI1 and therefore targets BCCs related to both constitutively activated Smo mutations and mutations in the upstream PTCH-1. Hedgehog gene expression was reduced by 90% at 1 month after vismodegib treatment in *in vivo* studies[44]. Biopsy samples from patients treated with vismodegib showed decrease in GLI1 expression by more than two folds after treatment compared to baseline[45].

At a dose of 150mg daily, vismodegib has shown no dose-limiting toxicities in Phase 1 trials[43,45,46]. Initial Phase I trial of 68 patients with advanced BCC and medulloblastoma compared doses of 150 mg/d to 270 mg/d and 540 mg/d and demonstrated no increase in steady

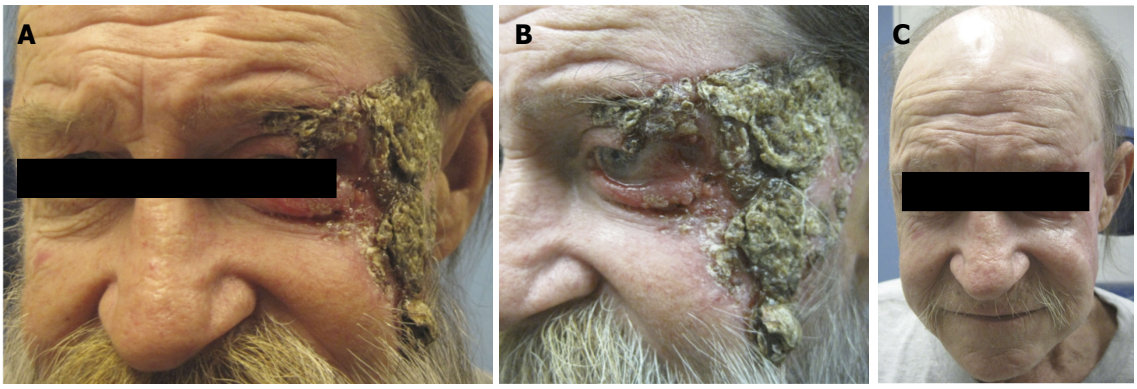

**Figure 1 A 55 year-old man with locally advanced neglected basal cell carcinoma.** A-B: The lesion involves the left lateral canthus, upper and lower eyelids, left temple and midface; C: After 29 wk of vismodegib 150 mg daily, there is significant resolution of clinically visible tumor. The only surgical intervention that the patient had undergone at this point was reconstructive surgery to repair the left lower lid cicatricial ectropion *via* a lateral tarsal strip procedure, a lateral tarsorrhaphy and full-thickness skin graft.

state plasma concentrations associated with vismodegib efficacy with higher doses[43,45]. In the cohort of patients from the phase I trial, overall response was shown in 18/33 patients (55%) with locally advanced or metastatic BCC, 2/18 demonstrating complete response and 16/18 demonstrating partial response[45].

A phase 2 trial of 33 patients with metastatic BCC and 63 patients with locally advanced BCC also showed tumor response when given 150 mg of vismodegib daily for a mean duration of 10 mo[47]. Investigators found a 30% objective response rate in the group with metastatic basal-cell carcinoma as defined by a decrease of 30% or more in the dimension or complete resolution of ulceration. The overall objective response rate in the group with locally advanced BCC was 43% with 21% of these patients demonstrating a complete response. By independent review, none of patients in the metastatic cohort had complete response, 10 (30%) patients had partial response and disease progression was noted in 1 (3%) patient with metastatic disease.

Vismodegib has also demonstrated promise in treatment of basal-cell nevus syndrome. Tang *et al*[44] demonstrated reduction of existing BCC tumor burden and prevention of new BCC in patients with basal-cell nevus syndrome. The vismodegib treatment group had a per-patient average rate of 2 per year while the placebo group had a rate of 29 per patient per year. The investigators also found a greater decrease (-65%) in the size of existing basal cell carcinomas in the vismodegib group compared to the placebo group (-11%). There was no progression of tumors in the treatment group during vismodegib administration and no signs of resistance to the drug during the study. The response was so significant in the treatment arm that the DSMB (Data Safety Monitoring Board) discontinued the study after the first interim analysis. Biopsies sampled from sites of flat-appearing, clinically-regressed basal cell lesions showed residual tumor in 1/6 samples (17%)[44]. Although discontinuation of vismodegib led to expected return of BCC at original sites, significant decrease in the incidence of new surgically eligible BCCs was noted even after cessation for several mo; 0.69 new lesions per month in the treated group compared to 2.4 per month in the placebo group.

## VISMODEGIB FOR ADVANCED PERIOCULAR BCC

The use of vismodegib specifically for periocular BCC was first reported in a review by Yin *et al*[48] in which some of the patients treated with vismodegib in our practice at MD Anderson Cancer Center were highlighted. In this report, a 30-year-old male patient with advanced basal cell nevus syndrome and numerous large BCCs throughout his periocular and facial region including all four eyelids, experienced near complete resolution of his periocular lesions after 16 wk of treatment with durable response during the more than 2 years of follow-up. Subsequently Gill *et al*[49] highlighted the results of vismodegib in 7 patients with advanced periocular or orbital BCC for a mean duration of 11 wk. With the study's mean follow-up duration of 7.3 mo, two out of seven patients (29%) had complete regression, 2 out of 7 patients (29%) had partial clinical regression greater than 80%, and 2 out of 7 patients had partial clinical regression less than 35%, and 1 patient progressed.

The histologic effects of vismodegib on a single case of periocular BCC was demonstrated by Kahana *et al*[50] in a patient with recurrent orbital BCC. After 5 mo of vismodegib, the patient opted for surgical excision due to drug side effects. The surgical specimen showed lack of Ki-67 expression, a marker for proliferation, and mitotic index < 1%.

The use of vismodegib in the periocular region can yield impressive responses in patients with locally advanced disease that would otherwise need major disfiguring surgery such as orbital exenteration or would experience loss of major parts of their face during surgical resection. An example of impressive response in a recent such patient in our practice is shown in Figure 1.

## SIDE EFFECTS OF VISMODEGIB

Adverse reactions to vismodegib of any grade are reported in 86% to 100% of patients during treatment[46,47,49]. The most common adverse events associated with vismodegib use are mild to moderate nausea, alopecia, dysgeusia, anorexia, and muscle spasms[44-47] In the phase I trial by Tang *et al*[44] 27% of patients receiving vismodegib had stopped the drug due to these averse events by 8 mo, increasing to 54% cessation a year later. Resolution of dysgeusia, muscle cramps and regrowth of hair was noted within 3 mo after cessation of therapy. No serious adverse events or dose-limiting toxicities have been observed with the recommended 150 mg dosage[43,46].

## COST OF VISMODEGIB

The cost of vismodegib (Erivedge) is set by Genetech at $7500 monthly or $250 per capsule[51]. Besides the United States, vismodegib is also approved in Switzerland, United Kingdom, the EU, Australia, Israel, South Korea, Mexico and Ecuador.

## CONCLUSION

The treatment of surgically unresectable eyelid and periocular carcinoma is no longer limited to radical disfiguring surgery or the use of high dose radiation therapy with its feared ocular toxicity. The use of drugs that target sonic hedgehog or EGFR pathways for advanced cutaneous carcinomas of the periorbital region should be viewed as palliative but can be associated with long-term and durable response and may be an option for older individuals who would otherwise need radical surgery with significant morbidity. Although specific published data on use of these agents for eyelid or periocular carcinomas are currently limited to few case reports, these relatively new drugs should be further studied for their efficacy in locally advanced BCC or SCC of periocular region. Correlation of response to mutational profile of each tumor would be intriguing and should be further evaluated. These newly available treatments should be considered only in patients with locally advanced unresectable or metastatic disease, multiple tumors, advanced age or multiple comorbidities. Future treatment strategies to decrease the duration of treatment with Hedgehog inhibitors or EGFR inhibitors and the use of these drugs in the neoadjuvant setting before surgery may be interesting to explore as a means of decreasing morbidity associated with periocular surgery.

## Abstract

**AIM:** To study a service model that enables a clinic to be open to all members of the community, irrespective of their ability to pay.

**METHODS:** Sampling methodology was used to gather information in two phases, with the city of Indore as the target region. In the first phase, dental professionals were surveyed to gather the cost of the facility, land and equipment and the cost of sustaining the practice. In the second phase, the residents of Indore were surveyed to collect information regarding their oral health problems and their expenditure for the same. Assessing the current situation, the questions to answer are related to the issues of dental health care access problems and the resources required, human and financial.

**RESULTS:** (1) People younger than 20 years of age form a large proportion (43%) of the population of the city and also a large proportion (54%) of people who visit dental clinics; (2) Dental caries are commonly found in the population younger than 20 years of age and mobile teeth in those older than 50 years of age; (3) Dental caries and mobile teeth are almost equally found in people of the age group 20-50 years old; (4) A significantly large proportion of those older than 50 years old have had all their teeth extracted; and (5) A significantly large proportion of the 20-30 years of age group has had no teeth extracted.

**CONCLUSION:** The model which we propose works well for low income patients; however, it places a lot of extra burden on the higher income group. A lot of effort can be put into generating revenue from other sources, including events and donations.

**Key words:** Dental clinic; Dentist; Dental health; Population; Dental treatment

**Core tip:** One of the primary reasons for the challenges faced by dental health care in a developing country like India is that when primary health care systems were being implemented, dental health care was not included. Also, although expenditure on health care systems form a significant percentage of the gross domestic product (nearly 5%), it is very small compared to the total population of the country. On top of that, the amount of money spent on dental health care is less compared to some other nations. This has left dental health care in India far behind other health services. The following are some of the challenges faced by dental health care in India: (1) expensive treatment; (2) imbalanced distribution of clinics; (3) unawareness; (4) skewed population to dentist ratio; and (5) changing disease pattern and treatment needs. People in developing regions suffer from different types of dental diseases, which are curable with treatment but not affordable by most people. In this study, a service model

was developed that enables a clinic to be open to all members of the community, irrespective of their ability to pay.

To explore and develop a model to maintain and build upon a dental clinic open for all in developing regions, with a primary focus on India. *World J Clin Cases* 2014; 2(9): 439-447 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i9/439.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i9.439

## INTRODUCTION

In developing nations such as India, 70% of people live in rural areas and nearly 35% of population is below poverty line. In 2004-2005, around 39 million (30.6 and 8.4 million in rural and urban areas, respectively) of Indians fell into poverty as a result of out of pocket expenditures each year[1,2]. People do not have funds for eating, let alone dental and other medical health care. The impact of health expenditures are greater in rural areas and in poorer states where a greater proportion of the population live near the poverty line[2]. The total expenditure on health was estimated to be 4.13% of the gross domestic product (GDP) in 2008-2009, with public expenditure on health at 1.10% of the share of GDP[3]. Private expenditures on health have remained high over the last decade[4]. A greater proportion of resources are directed towards urban-based services and higher level services, with 29.2% of public expenditures (both central and state) allocated to urban allopathic services compared to 11.8% of public expenditures allocated to rural allopathic services in 2004-2005. This imbalanced allocation is compounded by the private sector's bias toward higher level curative services which, determined by market forces, tends to be centered in wealthier urban areas[5]. Most public health facilities lack efficiency, are understaffed and have poorly maintained or outdated medical equipment. In addition to the lack of funds and poor infrastructure, India faces a shortage of medical staff for these facilities, especially in rural regions where access to medical care is limited. Thus, it is important to build a model clinic that does not attempt to segregate the poor but is open to all with a sliding-fee schedule to make dental care affordable for the poor and uninsured.

### What do we mean by developing regions?

Development of a country is measured with the help of statistical indexes, such as per capita income (GDP), life expectancy, the rate of literacy, educational attainment, etc. The UN developed the *Human Development Index* (HDI)[6], a standard mean of measuring human development. Thus, it helps to determine whether a country is a developed, developing or underdeveloped country.

A developing country has a low standard of democratic government, industrialization, social programs and human rights guarantees. In other words, it can be said that a developing country has an undeveloped or developing industrial base and an inconsistent varying HDI. However, countries that have more advanced economies than other developing nations but have not fully demonstrated the signs of a developed country are called newly industrialized countries. Countries that have sustained good economic growth over a long period of time and have a good economic potential are termed emerging markets. India falls under this category of big emerging markets, the target of this study.

### Why India

Over the years, the Indian economy has grown a lot but differences between the rich and poor have widened. In India, the government and private sector provide health care jointly. The poor who were not able to afford expensive medical treatment earlier are still not able to afford it. Since oral health care is still in the developing stage in India, it is expensive compared to other medical treatments, putting it out of the reach of the common man. Private sector hospitals are primarily motivated by profit, thus leaving a majority of population unattended to with public health institutions as the only hope for such underprivileged people. Since these people form a large chunk of the Indian population (over 35%), the cost of treatment becomes all the more important.

### Challenges to dental health care in India

One of the primary reasons for the challenges faced by dental health care in India is that when primary health care systems were being implemented, dental health care was not included. Also, although expenditure on health care systems forms a significant percentage of the GDP (nearly 5%), it is very small compared to the total population of the country. On top of that, the amount of money spent on dental health care is much less compared to some other nations. This has left dental health care in India far behind other health services. The following are some of the challenges faced by dental health care in India.

**Expensive treatment:** The increasing cost of oral healthcare that is paid as "out of pocket" payments makes oral healthcare unaffordable for a growing number of people. The number of people who could not seek oral care because of a lack of money increased significantly between 1986 and 1995 and the proportion of people unable to afford basic oral healthcare has doubled in the last decade. Over 20 million Indians are pushed below the poverty line every year because of the effect of out of pocket spending on health care[7].

**Imbalanced distribution of clinics:** In India, up to 80% of the population lives in rural areas without any access to dental health care[8]. Community oriented health programs are seldom found in rural areas. For any type of dental health care, they need to go to urban areas, thus

**Table 1 Demographics of Indore**

| Variable | *n* (%) |
|---|---|
| Population | |
| Total | 2465827 (-) |
| Males | 1289352 (53) |
| Females | 1176475 (47) |
| Rural | 735464 (29.7) |
| Males | 379624 (15.3) |
| Females | 355840 (14.4) |
| Urban | 1730363 (70.3) |
| Males | 909728 (36.9) |
| Females | 820635 (33.4) |
| Age Distribution | |
| < 10 yr | 538943 (21.8) |
| 10-20 yr | 524116 (21.2) |
| 20-30 yr | 460948 (18.6) |
| 30-50 yr | 625071 (25.3) |
| > 50 yr | 309070 (12.5) |

compounding the cost of treatment, which makes them unwilling to go for treatment.

**Unawareness:** It has been found that 30% of population were unaware of the ideal ways of avoiding tooth decay, gum diseases and oral cancer[9]. Only a small number of people go to a dentist on a regular basis or even in a medical emergency.

**Skewed population to dentist ratio:** The current dentist to population ratio in India is 1:10000[10] in urban and 1: 2.5 lakh in rural areas[11]. This is a significant improvement from the 1980s when it was 1:80000. However, with the geographical imbalance of the situation of dental colleges, the ratio varies significantly in rural and urban areas.

**Changing disease pattern and treatment needs:** The effectiveness of preventive dentistry is leading to a change in the disease pattern as well as people becoming more aware and concerned about dental health care. Although this number is small it is increasing, thus it has led to a decrease in demand for tooth extraction to an increase in demand for conservative modalities, such as root canal treatment. This puts a lot of pressure on an already stressed out system to introduce different specializations in postgraduate courses.

### *Fundamental causes of high cost of treatment*

The cost of treatment is one of the major concerns of the Indian population, forcing them to avoid treatment if at all possible. The following are some of the major reasons for the high cost of dental treatment in India: (1) a skewed dentist to population ratio, leading to a high demand for care; (2) rapidly changing technology and the cost to keep up with it; (3) more remuneration for qualified professionals; (4) high demand for better care; and (5) a large aging population needing special attention.

### *Objectives of the study*

**Primary objective***:* The primary objective is to explore and develop a model to maintain and build upon a dental clinic open for all in the developing regions, with a primary focus on India.

**Secondary objective:** The secondary objectives are: to study the challenges in dental health care in India; to study the cost of setting up and maintaining a dental health care clinic; to study the common dental ailments prevailing in Indian patients; and to study the needs of different types of patients.

## MATERIALS AND METHODS

### *Methodology*

The underlying challenge to our study was to understand how to achieve a balance between providing dental care to low income patients and financial stability of the clinic. Thus, factors that affect patient care revenue, including the start-up and maintenance cost, needed to be assessed. This sequence of steps was followed to achieve this goal: (1) in assessing the current situation, the questions related to dental health care access problems and human and financial resources required need to be answered; and (2) the need to envision the desired solution and define what is to be achieved.

All our studies and surveys were carried out in the city of Indore, the most populous city in Madhya Pradesh, with a population of about 3600000[12]. Its population is a mix of low and high income. Although there are no specific data regarding the income of people in Indore, a survey of the population of Madhya Pradesh indicated that 38% of the urban population[13] lives below the poverty line. Thus, assuming that this data can be extended to the population in Indore, this number is a significantly large proportion of the population. There are four dental colleges and several public and private dental clinics around the city.

### *How do we assess the needs for such a clinic?*

As a first step, the needs of a dental clinic were determined. The assessment considered the following factors: (1) population demographics: collecting information regarding poverty, age and insurance is helpful to provide a perspective about the underlying population as dental disparities occur in many population subgroups. This information is available in the 2001 census of India[14] (Table 1); (2) dental needs of the target population; (3) accessibility of current dental care resources for the target population, including availability and utilization of public and private dental care units; and (4) community perceptions of the need for dental care resources.

In order to determine the dental needs of the people of Indore and status of the current dental health care in the city, a survey at four medical hospitals and several dental clinics was conducted to collect responses from 40 dentists across the city. The survey included a questionnaire (Table 2) to be filled in by the dentist.

The survey was carried out to identify the dental

health care needs and problems of different age groups and to identify the minimum level of care needed to be provided at the clinic.

The following section summarizes the results of the survey.

## RESULTS

Tables 3-6 and Figures 1-2 contain an average of the responses received from various sources for questions 1–7 in the survey (Table 2). The results from the data are: (1) people < 20 years of age form a large proportion (43%) of the population of the city and a large proportion (54%) of the people who visit dental clinics; (2) dental caries is the most widespread dental disease (or ailment) faced by the population < 20 years of age; (3) mobile teeth is the most wide spread disease (or ailment) faced by the population > 50 years of age; (4) dental caries and mobile teeth are almost equally found in people in the 20-50 years of age group and together they form the most widespread disease (or ailment) in the age group; (5) A significantly large proportion of the > 50 years age group has had all their teeth extracted; and (6) a significantly large proportion of the 20-30 years age group had no teeth extracted.

Based on these results, the following level of service to be provided at the clinic was identified.

### *Basic oral health care service*

Services are provided early in the disease process which

**Table 6 Percentage of different age groups**

| Age group | % |
|---|---|
| Different age groups who had all their teeth extracted | |
| < 10 yr | 3 |
| 10-20 yr | 4 |

limits the disease from progressing further. These include diagnostic procedures, simple restoration of diseased teeth, early treatment of periodontal disease and many surgical procedures needed to treat oral pathologies.

### *Preventive oral health services*

These include the services which prevent the onset of the dental disease process.

### *Methodology for expenses of a dental clinic*

The next step was to estimate the expenses of a dental clinic. We conducted another survey (Table 7) to estimate start up and operational cost of a dental clinic. This survey was conducted with the suppliers for each of these

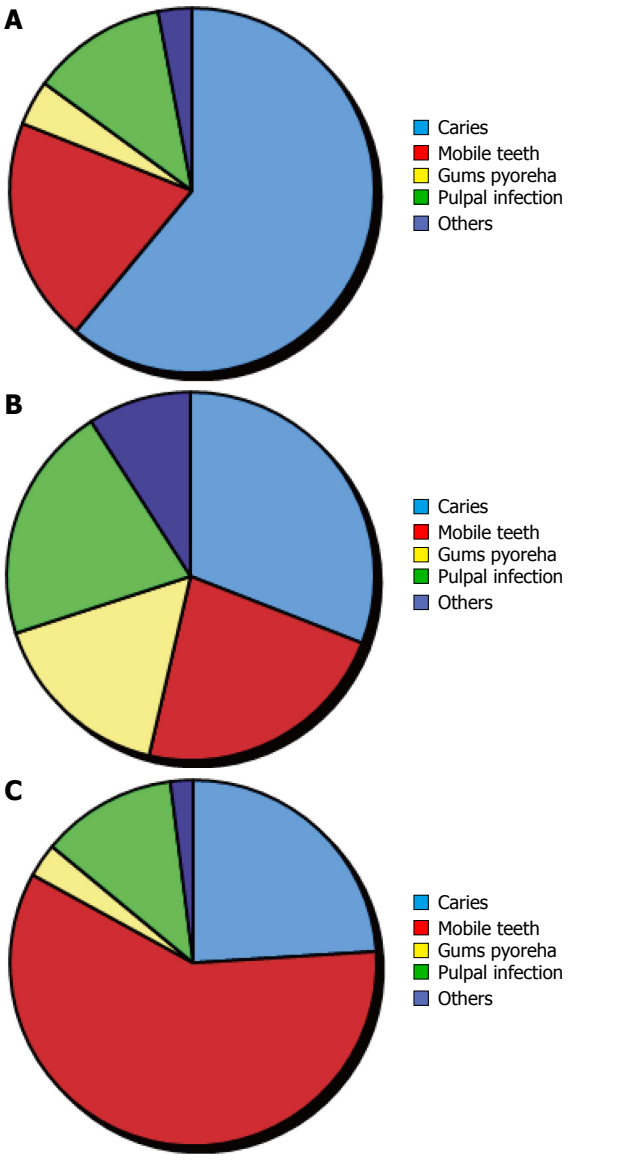

**Figure 2 Percentage distribution.** A: Percentage distribution of children < 20 year of age with the following diseases or dental ailments; B: Percentage distribution of people between 20-50 years of age with the following diseases or dental ailments; C: Percentage distribution of people over 50 years of age with the following diseases or dental ailments.

commodities to determine the costs and dentists were asked about average operational costs. Table 8 summarizes the result of the expense survey.

The equipment reserve fund is the money set apart for buying expensive equipment in the future. The list of essential dental equipment (Table 9) was determined from a list of the supplies and instruments from a dental clinic in Indore. As well as these dental instruments and supplies, a dental chair is also present at the clinic.

### *Methodology for revenue from all source*

In order to design a sliding fee model, the expected revenue from the clinic should be known in order to be able to sustain the clinic. Thus, a survey was conducted (Table 10) to determine the revenue from the clinic from sources at all the hospitals and clinics where the first survey

**Table 7 Questionnaire to determine expense of a dental clinic**

| Expense | Cost |
|---|---|
| Start-up costs | |
| Construction (or remodeling cost) | |
| Dental equipment cost (including supplies and instruments) | |
| Furniture | |
| Record filling system | |
| Phone / intercom system | |
| Computer / data / billing | |
| Operating Expenses | |
| Dental assistant | |
| Billing Clerk (or Secretary or Receptionist) | |
| Clinical supplies | |
| Office supplies | |
| Equipment maintenance | |
| Housekeeping | |
| Laundry | |
| Communications | |
| Equipment reserve fund | |

was conducted. Table 11 contains the results of dental clinic revenue survey.

### *Do we need a mobile or fixed dental clinic?*

While calculating the expense of a clinic, we observed that the initial cost of starting the clinic was a major component (nearly 66%). Thus, the question was asked if it was necessary to have a fixed dental clinic or if a mobile clinic was sufficient, thus reducing the initial start-up cost. Mobile clinics are used to serve small pockets of patients scattered over a geographic area. The greatest advantage of such a clinic is that initial cost of setup is low but the future cost of maintenance is high and the life of a mobile facility is shorter than a fixed facility. One of the aims of the open-to-all clinic is to provide care to as many people as possible so as to maximize the revenue, which would be otherwise difficult in a mobile clinic. Thus, it makes more sense to have a fixed facility that can serve a large number of people.

### *How to determine the patient charges?*

Once we had determined the expenses and revenue of a dental clinic had been determined, the next step was to develop a sliding fee model for patient charges, which was our initial goal. However, to build such a model we still needed information such as the average number patients from different income groups who visit dental clinics (Table 12). Another survey was conducted to determine this and the results are presented in Table 13.

After gathering all the relevant data, a sliding fee model that can be used for a dental clinic in India was developed. Figure 3 shows a graph from the G20 report[15] on poverty and inequality, showing the distribution of population and their income. It can be seen that less than one-fifth of the population lies below the two dollar (Rs. 100) line and around 1% lies below the one dollar (Rs. 50) line. The maximum percentage of the population earns close to Rs. 300-350 (per day).

**Table 8 Result of dental clinic expenses survey**

| Expense | Cost |
|---|---|
| Start-up costs | |
| Construction (or remodeling cost) | Rs. 1205000 |
| Dental equipment cost (including supplies and instruments) | Rs. 924500 |
| Furniture | Rs. 45900 |
| Record filling system | Rs. 12500 |
| Phone /intercom system | Rs. 9300 |
| Computer/data/billing | Rs. 35200 |
| Total start-up costs | Rs. 2232400 |
| Operating expenses | |
| Dentist | Rs. 750000 |
| Dental assistant | Rs. 24000 |
| Billing clerk (or secretary or receptionist) | Rs. 5000 |
| Clinical supplies | Rs. 107900 |
| Office supplies | Rs. 12500 |
| Equipment maintenance | Rs. 21400 |
| Housekeeping | Rs. 13600 |
| Laundry | Rs. 26700 |
| Communications | Rs. 24000 |
| Equipment reserve fund | Rs. 10000 |
| Total operating expenses | Rs. 995100 |
| Total expenses | Rs. 3227500 |

The per visit charge for patients was determined, which was taken as the basis for providing a discount to the low income group. This had to be greater than the average per visit charge we estimated from our survey in order to sustain the clinic financially. The extra amount of money being charged to the high income group will help to subsidize the fees for the low income group. The population was then divided into five different groups on the basis of their income: (1) low income group, earning < Rs. 100/d; (2) lower-middle income group, earning > Rs. 100 but < Rs. 300/d; (3) middle income group, earning > Rs. 300 but < Rs. 400/d; (4) higher-middle income group, earning > Rs. 400 but < Rs. 1000/d; and (5) higher income group, earning > Rs. 1000/d.

Well off patients (including the higher middle and higher income group) constitute a significant proportion of the population that visits dental clinics (Table 13) and is nearly thrice as large as the low income patients that visit dental clinics. So, in order to provide X% discount to the lower income group, X /3% more is charged to the higher income group. The baseline charge of Rs. 400 per visit is fixed. It was estimated that the low income group would form approximately 10% of the total patients, lower middle income group nearly 16%, middle income nearly 35%, higher middle income nearly 22% and higher income nearly 17% of the total population. Discounts are now provided to various income groups (Table 14).

The bottom line in establishing various discounts is that the weighted sum of the discount and proportion of the population that group forms should not be negative if the clinic is to be sustained financially. The sliding fee schedule is used by totaling the full fees, multiplying the discount factor and subtracting to determine the charge to the patient. Note that the negative discount for the higher income group means that they have an extra fee

| Total revenue (all sources) | Rs. 1060500 |

compared to the other income groups. There are fees for cases that would not be discounted in the case of a very high cost of treatment to the higher income group or giving a very large discount to a lower income group.

## DISCUSSION

These dental clinics address dental access problems and barriers in several ways and should be distributed throughout the state in urban and rural locations. They will serve communities for many years and maintain adequate hours of practice. Such dental clinics provide the most common dental services and, when additional services are needed, referrals to dental colleges are made. The clinic treated low income patients living below the poverty line at a very low cost and also treated low middle and middle income group patients with a sufficient discount. Because most of the clinics are located within facilities that provide oral health care service at very low cost, especially for the low income group, patients might perceive them as being more accessible and familiar. This assistance and familiarity will reduce important nonfinancial access barriers. These dental clinics will offer a variety of oral health outreach and educational programs designed to reach broader groups and expand the oral health message, possibly preventing further dental problems.

**Table 12 Questionnaire to determine patient visits at a dental clinic**

| Variable | Value |
|---|---|
| Patient Visits | |
| Total number of patient visits: | |
| Well off patients[1] | |
| Low income patients[2] | |
| Patients with insurance | |
| Per patient visit charge | |

[1]Well off patients are way above the poverty line and have no money constraints on the cost of treatment; 2low income patients are either below the poverty line or belong to a middle class that cannot afford expensive treatment.

**Table 13 Summary of patient visit survey**

| Variable | Value | % |
|---|---|---|
| Patient visits[1] | | |
| Total number of patient visits: 3550 | | |
| Well off patients[2] | 2610 | 74% |
| Low income patients[3] | 940 | 26% |
| Patients with insurance | 284 | 8% |
| Per visit patient charge | 350 | - |

[1]All visits are expressed per year; [2]Well off patients are way above the poverty line and do not have any money constraints on the cost of treatment; [3]Low income patients are either below the poverty line or belong to a middle class that cannot afford expensive treatment.

**Table 14 Discounts to different income groups**

| Income group | Discount |
|---|---|
| Lower income | 75% |
| Lower-middle income | 50% |
| Middle income | 12.50% |
| Higher-middle income | 0% |
| Higher income | -75% |

In this study, it was found that the middle and higher income group constituted a significant portion of the population who visit the dental clinic, about thrice as large as the low income group, according to the result of survey given in Table 13. So, by giving 1/3% of discount to low income group, a better oral health service is provided for them (Table 14). The almost 75% discount to the low income group and 50% discount to lower middle income group allows problem free thinking in approaching oral health care. A slightly higher fee is charged to patients with insurance to increase revenue and reduce the burden on the higher income group patients. The study limitations are that the higher income group is charged an extra fee compared to other income groups.

One of the important aims of developing such a clinic was to provide dental care to low income populations who have poor access to health care. However, it should not be forgotten that a clinic is of no use if it cannot keep its door open. The more inclusive a clinic seeks to be in providing access, the greater the risk of operating in the red because of uncompensated care. By the same token, the more a clinic limits uncompensated care, the greater its risk of limiting access to dental care for people with low income. Thus, it is always important to achieve a balance between the two. The model which we have proposed in Table 14 works well for low income patients in terms of providing them dental care at low and affordable cost; however, it places a lot of extra burden on the higher income group, which may not be acceptable to them. In this case, effort can be put into generating revenue from other sources, including events and donations.

## COMMENTS

### Background

This model has been used to open a dental clinic in a developing region in India, providing access irrespective of the patient's ability to pay. So far, however, no such survey has taken place before opening a dental clinic in which both lower income and higher income group are considered.

### Research frontiers

The model given is good for giving dental care at low and affordable cost to the low income group but it places an extra burden on the higher income group which may not be acceptable to them.

### Innovation and breakthroughs

This is a pioneering study in which the authors used sampling methodology for a survey conducted in two phases. The first phase was to ascertain the cost of the facility, land and equipment and the cost of sustaining the practice. In the second phase, a survey of the residents of Indore was carried out to collect information regarding their oral health problems and their expenditure for the same.

### Applications

In developing regions like India, this model may have success for people with low income and the extra burden on the higher income group can be distributed by generating funds by events and donations.

### Terminology

GDP: Gross Domestic Product; HDI: Human Development Index.

### Peer review

The paper is acceptable in its current form.

## Abstract

**AIM:** To investigate the relationship between upper esophageal sphincter abnormalities achalasia treatment

**METHODS:** We performed a retrospective study of 41 consecutive patients referred for high resolution esophageal manometry with a final manometric diagnosis of achalasia. Patients were sub-divided by presence or absence of Upper esophageal sphincter (UES) abnormality, and clinical and manometric profiles were compared. Correlation between UES abnormality and sub-type (*i.e.*, hypertensive, hypotensive or impaired relaxation) and a number of variables, including qualitative treatment response, achalasia sub-type, co-morbid medical illness, psychiatric illness, surgical history, dominant presenting symptom, treatment type, age and gender were also evaluated.

**RESULTS:** Among all 41 patients, 24 (58.54%) had a UES abnormality present. There were no significant differences between the groups in terms of age, gender or any other clinical or demographic profiles. Among those with UES abnormalities, the majority were either hypertensive (41.67%) or had impaired relaxation (37.5%) as compared to hypotensive (20.83%), although this did not reach statistical significance ($P$ = 0.42). There was no specific association between treatment response and treatment type received; however, there was a significant association between UES abnormalities and treatment response. In patients with achalasia and concomitant UES abnormalities, 87.5% had poor treatment response, while only 12.5% had favorable response. In contrast, in patients with achalasia and no UES abnormalities, the majority (78.57%) had good treatment response, as compared to 21.43% with poor treatment response ($P$ = 0.0001). After controlling for achalasia sub-type, those with UES abnormality had 26 times greater odds of poor treatment response than those with no UES abnormality ($P$ = 0.009). Similarly, after controlling for treatment type, those with UES abnormality had 13.9 times greater odds of poor treatment response compared to those with no UES abnormality ($P$ = 0.017).

**CONCLUSION:** The presence of UES abnormalities in patients with achalasia significantly predicted poorer treatment response as compared to those with normal UES function.

**Key words:** Upper esophageal sphincter; Achalasia; Motility; Dysphagia; Esophageal disorders

**Core tip:** Our study highlights how the presence of

Upper esophageal sphincter (UES) abnormalities in patients with achalasia significantly predicted poorer treatment response as compared to those with normal UES function, irrespective of the type of treatment received or achalasia sub-type. We believe this finding is novel and represents an opportunity to more fully characterize upper esophageal sphincter pathology in a clinical context.

Mathews SC, Ciarleglio M, Chavez YH, Clarke JO, Stein E, Roland BC. Upper esophageal sphincter abnormalities are strongly predictive of treatment response in patients with achalasia. *World J Clin Cases* 2014; 2(9): 448-454 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i9/448.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i9.448

## INTRODUCTION

Esophageal manometry has primarily been used to evaluate disorders of the esophageal body and lower esophageal sphincter. The introduction of high resolution esophageal manometry (HREM) has allowed the additional ability to assess the function of the upper esophageal sphincter (UES). While a wide spectrum of abnormalities such as alterations of resting UES pressures and impaired relaxation have been described in association with various motility disorders, the current Chicago Classification for manometric disorders[1] does not comment on UES findings. In addition, these abnormalities are often interpreted as incidental findings with no clearly defined clinical significance[2].

Manometric abnormalities of the UES have been documented in numerous settings, including as a function of aging[3-6]. They have also been reported in association with specific motility disorders and symptoms including achalasia[7-10], dysphagia[11-13], Parkinson's disease[14-16], oculopharyngeal muscular dystrophy[17], cricopharyngeal bar[18], globus[19], Zenker's diverticulum[20], and scleroderma[21]. However, the relationship and role of UES abnormalities in the context of motility disorders, specifically achalasia, remain unclear. While prior studies have demonstrated manometric UES abnormalities in achalasia[7-10], its clinical relevance and effects on therapeutic outcomes has not been fully characterized and remains poorly understood[22].

We hypothesized that UES abnormalities in association with achalasia may have significant clinical implications and may be useful as a predictor of treatment response. The primary aim of this study was therefore to assess the frequency and type of UES abnormalities in patients referred for HREM with a manometric diagnosis of achalasia. The secondary aims were to further characterize the correlation of specific UES abnormalities with achalasia sub-type and clinical characteristics and to additionally assess for differences in treatment response based on the presence or absence of UES abnormality.

## MATERIALS AND METHODS

### Subjects and study protocol

We performed a retrospective study of consecutive patients from October 2011 to November 2012 who underwent high resolution esophageal manometry at the Johns Hopkins Center for Neurogastroenterology and were subsequently diagnosed with Achalasia (Type Ⅰ, Ⅱ, or Ⅲ) defined as based per the current Chicago Classification. Patients with a manometric diagnosis that was consistent with achalasia were subsequently sub-divided into those with normal and abnormal UES function. Primary indications for HREM in these patients included dysphagia, atypical chest pain, cough, belching, globus, regurgitation, nausea and vomiting. The study protocol was approved by the John Hopkins University School of Medicine Institutional Review Board (IRB). Our protocol was in compliance with the Health Insurance Portability and Accountability Act (HIPAA).

### Manometric protocol

Manometric studies were performed with the patients in the supine position after a minimum 6 h fasting period. A solid-state high-resolution manometer was used for all data collection (ManoScan360 High Resolution Manometry System, Sierra Scientific Instruments, and Los Angeles, CA). The manometric catheter has an outer diameter of 4 mm and 36 circumferential pressure sensors spaced 1 cm apart. The system is calibrated to record pressures between -20 and 600 mmHg, with fidelity of 2 mmHg. The catheter was positioned so that at least 2 distal sensors were in the stomach and 2 proximal sensors were located above the UES. The manometric protocol included a 5-min baseline recording, followed by 10 wet swallows of 5 cc water.

### Manometric data analysis

All manometry studies were analyzed using ManoView software (*Sierra Scientific Instruments*) and were appropriately corrected for thermal sensitivity of the pressure-sensing elements using thermal compensation. The esophageal pressure topography plot of each swallow in the HRM study was subsequently analyzed based on the current Chicago Classification scheme[1]. Sub-classification of achalasia was defined based on the scheme put forth by Pandolfino *et al*[23] after the introduction of Chicago Classification: Type I representing classic achalasia with minimal esophageal contractility and low intraesophageal pressure, type Ⅱ representing absent peristalsis and panesophageal pressure elevations, and type Ⅲ representing lumen-obliterating esophageal spasm.

### Definition of UES pressure and abnormalities

UES pressures were measured throughout the study prior to each of the 10 wet swallows and abnormalities recorded included: hypotensive upper esophageal sphincter pressure, hypertensive upper esophageal sphincter pressure, and impaired UES relaxation. UES resting pressure

during the first 5 min of the study (while establishing the baseline), was excluded from our study. While there is some discrepancy in the literature regarding normal UES baseline values, normal ranges were established based on a prior study that sought the UES pressures in 73 healthy subjects. The normal range was defined by the 5$^{th}$ and / or 95$^{th}$ percentile value of the parameters found[24]. Based on these values, our patients were divided into those with normal UES function and abnormal function including: impaired UES relaxation (residual pressure > 12 mmHg), hypertensive resting UES pressure (> 104 mmHg), and hypotensive resting UES pressure (< 34 mmHg). While there is currently no well-established normal range for UES pressure, for the purposes of this study, we used the normal ranges (as referenced above) put forth by GIVEN imaging for their high resolution esophageal manometry ManoView software (*Sierra Scientific Instruments*).

The frequency of UES abnormalities and sub-type of UES abnormality present (*e.g.,* hypotensive, hypertensive, or impaired relaxation) was evaluated in this population of patients with achalasia. Additionally, we looked at the association between sub-types of achalasia *(e.g.,* Ⅰ, Ⅱ, or Ⅲ) and the presence of specific UES abnormalities. In addition, clinical and demographic profiles were also examined and correlated with type of UES abnormality present including dominant presenting symptom, age, gender, race, co-morbid medical illness, psychiatric illness, and surgical history.

Lastly, we sought to determine whether or not the presence of an UES abnormality was predictive of either treatment received or treatment response in our patient population. Types of treatment included: endoscopic pneumatic dilation (PD), targeted endoscopic botulinum toxin (Botox) injections to the lower esophageal sphincter, medical therapy (*e.g.,* calcium channel blockers), Surgical myotomy with fundoplication, and Per Oral Endoscopic Myotomy (POEM). The majority of patients underwent surgical (*e.g.,* Heller myotomy) or endoscopic myotomy (*e.g.,* POEM) for definitive treatment. Only those patients deemed "higher risk" for invasive procedures were treated with PD, pharmacotherapy or LES botox injections. All treatment decisions were made by the primary gastroenterologist who evaluated the patient and discussed treatment options which each individual at the time of a clinical office visit. Also of note, individual therapeutic options were decided by the gastroenterologist and patient independent of the presence of a UES abnormality on their manometry study.

Treatment response was defined qualitatively by patients as being either "favorable" or "poor," as based on significant improvement in post-treatment dysphagia rates and other primary associated symptoms (*e.g.,* regurgitation, weight loss, chest pain) with satisfactory improvement in symptoms and/or Eckardt score. This response was assessed in each individual patient by a gastroenterologist during a clinical office visit. A single gastroenterologist subsequently reviewed charts to document outcome data; this individual was blinded to the presence or absence of UES abnormalities.

### Statistical analysis

Counts and percentages are reported. Fisher's exact test was used to investigate the association between presence of UES abnormality and categorical variables of interest. Age was compared using a two-sample *t*-test. A multivariate logistic regression model was used to assess the relationship between presence of UES abnormality and treatment response, while controlling for the type of achalasia, given that Type Ⅱ achalasia is known to have the best treatment response. Two-sided *P*-values $\leqslant 0.05$ were considered statistically significant. All analyses were conducted using SAS v. 9.3 (SAS Institute; Cary, NC).

## RESULTS

A total of 41 patients with a diagnosis of achalasia were identified during the study period, of which 24 (58.5%) had an upper esophageal sphincter abnormality present on their HREM. There were no significant differences between the groups in terms of age or gender. When comparing individuals with no UES abnormality to individuals with UES abnormality, there were no significant differences in terms of age or gender [mean age 55.81 *vs* 53.32 ($P = 0.6492$) and 53.94% male *vs* 50.00% respectively ($P = 1.0000$)]

Among those patients with UES dysfunction present, the majority of those with abnormalities had a hypertensive basal UES pressure (41.67%) followed by impaired UES relaxation (37.5%) and a hypotensive basal UES pressure (20.83%). Patients with achalasia were also significantly more likely to have either a hypertensive UES resting pressure or have impaired UES relaxation as compared to having low UES basal pressures (20.83% *vs* 79.17%, $P = 0.004$).

The majority of our cohort with UES abnormalities had type Ⅱ achalasia (Type Ⅱ 65% *vs* Type Ⅰ 20 % *vs* Type Ⅲ 15%), which was also the case in patients with no UES abnormalities (Type Ⅱ 56.25% *vs* Type Ⅰ 18.75% *vs* Type Ⅲ 25%). There was no significant association seen between sub-type of achalasia and the presence or absence of UES abnormality ($P = 0.8916$).There was no significant association between type of achalasia and subtype of UES abnormality (*e.g.,* hypertensive, hypotensive, or impaired relaxation, $p = 0.3345$) (Table 1).

There were no significant differences observed between presence or absence of UES abnormality and type of treatment that patients received (*e.g.,* endoscopic dilatation, endoscopic Botulinum toxin injections, medical therapy, POEM, or surgical myotomy) ($P = 0.40$). Similarly, there was no association when examining therapeutic treatment response when each treatment was compared individually (endoscopic dilatation, $P = 0.69$; endoscopic Botox, $P = 0.63$; medical therapy, $p = 0.21$; POEM, $p = 1.00$; surgical myotomy, $P = 0.08$). Additionally, there was no association between type of UES abnormality and specific treatment type of received ($P = 0.79$) (Table 2).

**Table 1 Distribution of upper esophageal sphincter abnormality by achalasia sub-type**

| Type of achalasia | UES abnormality | | | *P*-value |
|---|---|---|---|---|
| | Hypertensive (%) | Hypotensive (%) | Impaired relaxation (%) | |
| Type Ⅰ | 22.22 | 50 | 0.00 | 0.3345 |
| Type Ⅱ | 55.56 | 50 | 85.71 | |
| Type Ⅲ | 22.22 | 0 | 14.29 | |

UES: Upper esophageal sphincter.

With respect to treatment response, patients with achalasia and a UES abnormality present had a significantly poorer treatment response as compared to those with no UES abnormality present. Specifically, in patients with achalasia and a concomitant UES abnormality, 87.5% rated their treatment response as poor, while only 12.5% rated it favorable ($P < 0.0001$). In contrast, in patients with achalasia and no UES abnormality present, only 21.43% reported a poor treatment response while the majority (78.57%) rated it favorable ($P = 0.0001$) (Table 3). However, individual UES abnormality type was not significantly associated with treatment response ($P = 0.70$). In addition, after controlling for achalasia sub-type, those with UES abnormality had a 26 times greater odds of poor treatment response than those with no UES abnormality ($P = 0.0099$). Similarly, after controlling for treatment type, those with a UES abnormality present had a 13.9 times greater odds of poor treatment response compared to those without ($P = 0.0173$). There was no significant relationship observed when comparing treatment response with achalasia sub-type ($P = 0.2163$).

There was no significant association between initial dominant symptom presentation (dysphagia, chest pain, GERD, globus sensation, hiccups, or "other" dominant symptom) and presence or absence of UES abnormality ($P = 0.87$). Similarly, when examining these symptoms individually, there was no association between presence of UES abnormalities with any primary symptoms (dysphagia, $P = 0.7289$; chest pain, $P = 1.000$; GERD, $P = 0.5598$; globus sensation, $P = 1.000$; hiccups, $P = 1.0000$; other dominant symptom, $P = 1.000$).

The relationship between underlying medical co-morbidities with presence of absence of UES abnormalities was also assessed, and no significant associations were observed (diabetes, $P = 0.2072$; scleroderma, $P = 1.0000$; asthma, $P = 1.0000$; stroke, $P = 0.4146$; dementia, $P = 0.4146$; gastroparesis, $P = 1.0000$; achalasia, $P = 0.4328$). Additionally, we found no association between psychiatric disorders and presence or absence of UES abnormalities (psychiatric disorders, $P = 0.7364$; depression, $P = 1.0000$; anxiety, $P = 0.6293$; other psychiatric disorders [including bipolar disorder and schizophrenia], $P = 1.0000$). There was also no significant association observed between history of prior esophageal or other relevant surgeries and presence or absence of UES abnormality (History of any prior surgery, $P = 0.752$; larynx surgery, $P = 1.0000$; esophageal surgery, $P = 0.3725$; spine surgery, $P = 0.5024$; all additional surgeries, $P = 1.0000$).

## DISCUSSION

The pathophysiology of disorders affecting the upper esophageal sphincter is incompletely understood. The advent of solid state, high resolution esophageal manometry has improved our understanding and ability to evaluate the UES and pharyngeal region. In the present study, upper esophageal sphincter abnormalities were not only a frequent finding in patients with achalasia, but additionally were useful in predicting treatment response. The association of UES abnormalities with treatment response remained even after adjusting for type of treatment received. Interestingly, among patients with achalasia, UES abnormalities were more common than normal UES function in this population. Further, the presence of UES abnormalities in patients with achalasia significantly predicted poorer treatment response when compared to those with normal UES function, irrespective of the type of treatment received or the sub-type of achalasia that was being treated. Similar to prior studies, the present study also demonstrated that in patients with UES abnormalities, Type Ⅱ achalasia was the most common sub-type[24-26]; however, there was no association observed between sub-type of achalasia and presence of UES dysfunction.

Malhi-Chowla *et al*[22] previously reported that UES abnormalities are a common incidental finding on manometric studies, even in the absence of abnormal radiographic signs or upper esophageal sphincter symptoms. These authors concluded that routine UES manometry with esophageal manometry was therefore not always useful, particularly when UES dysfunction was not suspected clinically. In contrast to their findings, with our assessment of clinical outcomes in a large group of patients with achalasia, the present study provides direct evidence that UES abnormalities may be clinically relevant, specifically in predicting treatment response in individuals with achalasia. As a result, our findings suggest a direct association between UES dysfunction and poorer outcomes in this patient population, and further provide support for careful manometic UES evaluation even when a motility disorder with a predominantly lower esophageal pathology (*i.e.,* achalasia) is suspected.

The finding that UES abnormalities in achalasia is strongly predictive of poorer treatment response suggests that this sub-population with UES dysfunction may have more severe disease with potentially more extensive and further proximal esophageal involvement. While prior studies have suggested that UES abnormalities appear to be associated with achalasia and other esophageal motility disorders[11-21], none of those studies directly assessed clinical significance or response to treatment.

Better treatment response in patients with type Ⅱ achalasia has been well described in several studies[26-28]. It is additionally well known that patients with type Ⅲ

**Table 2 Type of treatment received based on upper esophageal sphincter abnormality sub-type**

| Treatment | UES abnormality | | | *P*-value |
|---|---|---|---|---|
| | Hypertensive (%) | Hypotensive (%) | Impaired relaxation (%) | |
| Pneumatic dilatation | 0 | 25 | 11.11 | 0.3967 |
| Endoscopic botox treatment | 25 | 0 | 22.22 | |
| Medical therapy | 0 | 0 | 22.22 | |
| POEM | 12.5 | 0 | 11.11 | |
| Surgical myotomy | 62.5 | 75 | 33.33 | |

UES: Upper esophageal sphincter.

**Table 3 Treatment response based on presence of upper esophageal sphincter abnormality**

| Treatment response | No UES abnormality | UES abnormality | *P*-value |
|---|---|---|---|
| Favorable | 78.57% | 12.50% | < 0.0001 |
| Poor | 21.43% | 87.50% | |

UES: Upper esophageal sphincter.

achalasia have the worst response to all therapies. However, even after controlling for type of achalasia, our results still demonstrated that treatment response was significantly better in all types of achalasia without UES abnormalities as compared to patients with concurrent achalasia and UES dysfunction. In other words, UES dysfunction appeared to independently predict treatment failure and normal UES function independently predicted better treatment response, irregardless of achalasia subtype.

UES dysfunction in achalasia has previously been described, specifically with impaired UES relaxation reported as the most common abnormality among patients with achalasia. Yoneyama *et al*[10] compared the UES manometric characteristics of 15 patients with diagnosis of achalasia as compared to 10 healthy volunteers and concluded that UES relaxation in patients with achalasia is incomplete. In the present study, we found a very high frequency of concomitant UES abnormalities among patients with achalasia (54%). Further, these individuals with UES abnormalities were more likely to have either impairment of UES relaxation or a hypertensive resting pressure as compared to being hypotensive. Although achalasia classically spares striated muscle, both prior literature and the results of the present study demonstrate a high frequency of upper esophageal sphincter involvement in this specific patient population.

In exploring what may account for this finding, it is plausible that increased UES pressure represents a compensatory or protective effect toward inadequate esophageal clearance in achalasia. Prior studies have also reported a reflexive hypertensive upper esophageal resting pressures after intraesophageal distension[29]. These investigators proposed that this may be a result of the UES serving as a dynamic barrier to esophagopharyngeal reflux and subsequent bronchial aspiration. Another possibility is that a neural feedback mechanism exists between UES relaxation and tension in the esophageal wall, such that increased resting pressure in the esophageal body transmits directly to the UES.

A paradoxical increase in UES pressure may also result from the loss of inhibitory neurons more proximally in patients with achalasia who may have more extensive esophageal involvement. A subset of patients with achalasia may also have more significant vagal involvement with Wallerian degeneration in the vagal fibers that supply the esophagus. In this context, the presence or severity of UES abnormalities may potentially be useful as a predictor to treatment response in achalasia. It is also possible that UES dysfunction in achalasia is simply a reflection of more severe disease and may reverse with treatment. In fact, prior studies have demonstrated that UES abnormalities disappear after pneumatic dilation[13], suggesting that reversal of UES dysfunction may be used as one of the predictors of treatment response. Lastly, although it is generally believed that the upper third of the esophagus, is composed primarily of striated muscle, this may not necessarily be the case in all individuals. Interestingly, in one autopsy study, smooth muscle fibers in the circular muscle up to the level of the upper esophageal sphincter were found in 45% of specimens[30].

Our study is the first to directly report on the potential clinical significance of UES abnormalities in treatment outcome in patients with achalasia; however, the authors acknowledge that there were significant limitations to the present study. First, this was a retrospective analysis which inherently limits the ability to draw causative conclusions. However, given the limited literature on UES abnormalities and clinical outcomes in patients with achalasia, it adds significant value in identifying key areas of further study in a larger, prospective evaluation. Another limitation is that treatment response was based on subjective evaluation by the patient of improvement in primary symptoms (and Eckardt scores were not assessed in all patients), which was collected by chart review based on the assessment of the clinical provider. A more objective measure such as a pre and post-treatment Eckardt score, barium esophogram, or repeat manometric study would have provided more objective outcome data; however, this was not possible given the retrospective nature of the study. In addition, further correlation with presence or resolution of UES abnormality post proce-

dure would have been ideal, but this was not feasible in this retrospective setting. Nevertheless, our subjective measure was able to reliably demonstrate a significant clinical difference. It is also important to note that this study took place at a tertiary care/motility referral center. Consequently, the results of this study may not be as generalizable to the general patient population. However, the demographics and presentation profile of our patient population appear largely similar to those in non-academic settings. Lastly, given that UES findings are not routinely reported on esophageal manometry studies and not formally included in any manometry classification systems at this time, it is likely that some studies that were interpreted as "normal," actually had UES abnormalities present. Thus, this study may even under-represent the true frequency of UES dysfunction among patients with achalasia.

In conclusion, our study illustrates that upper esophageal sphincter abnormalities in patients with achalasia have significant value in predicting treatment outcome. Our findings not only suggest a direct association between UES dysfunction and poorer outcomes in this population, but additionally provide support for manometic UES evaluation in all patients referred for HREM in whom an esophageal motility is suspected. Further, large scale studies are needed to determine whether specific UES abnormalities have additional prognostic value and may also clarify the underlying pathophysiologic mechanism driving the poorer outcomes seen in our study. Prospective evaluation is also needed to further delineate the underlying mechanism and natural history of UES dysfunction in achalasia in order to optimize therapeutic treatment modalities.

## COMMENTS

### Background

High resolution esophageal manometry has allowed the ability to assess the upper esophageal sphincter (UES). However, UES abnormalities are often interpreted as incidental findings with no defined clinical significance.

### Research frontiers

The way in which UES abnormalities impact clinical outcomes in achalasia is unknown. We hypothesized that UES abnormalities have clinical significance and may predict treatment response in patients with achalasia.

### Innovations and breakthroughs

The authors found that UES abnormalities were associated with worse treatment outcomes in achalasia patients. Prior studies do not focus on specific clinical outcomes.

### Applications

These results, in combination with future studies, could aid in identifying which patients are more likely to succeed with achalasia treatment and could further direct treatment of UES conditions.

### Terminology

UES refers to the upper esophageal sphincter.

### Peer review

This manuscript assesses the function of UES in patients with achalasia. It is interesting. Manuscript is well written and easy to follow.

## Abstract

Calcification of the pericardium is a relatively rare finding and often has an uncertain etiology. Incidental findings of pericardial calcification may increase due to widespread application of cardiac computed tomography for the assessment of coronary atherosclerosis in the appropriate clinical setting using coronary artery calcium scoring and/or coronary angiography. Pericardial calcification alone is asymptomatic and is neither necessary nor sufficient for the diagnosis of pericardial constriction. Its presence may suggest of diffused pericardial scarring and consequently, its pathological involvement with pericardial constriction. Calcification of the pericardium must be evaluated with full clinical knowledge to facilitate an accurate diagnosis and an appropriate therapy when required. Our objective is to present a case of asymptomatic pericardial calcification and to discuss the importance of its clinical implications.

**Key words:** Pericardial calcification; Constrictive pericarditis; Cardiac computed tomography

**Core tip:** Pericardial calcification is rare but may be found more often due to the widespread use of cardiac computed tomography for the assessment of coronary atherosclerosis. Pericardial calcification can be seen in the absence of constrictive physiology and therefore, it should be evaluated with full clinical knowledge.

Nguyen T, Phillips C, Movahed A. Incidental findings of pericardial calcification. *World J Clin Cases* 2014; 2(9): 455-458 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i9/455.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i9.455

## INTRODUCTION

Calcification of the pericardium is relatively rare and often has an uncertain etiology[1]. Incidental findings of pericardial calcification may increase in the asymptomatic subjects due to the widespread use of cardiac computed tomography for coronary artery calcium scoring (CACS) with and without contrast cardiac computed tomography angiography (CCTA) for the assessment of coronary atherosclerosis. Although detecting pericardial calcification may have important clinical implication for confirming the diagnosis of constrictive pericarditis, its presence should be evaluated with full clinical knowledge to facilitate an accurate diagnosis and an appropriate medical management when it is required. Avoiding inaccurate diagnosis of constrictive pericarditis based only on the presence of calcium in an asymptomatic subject relieves patient's concern and prevents unnecessary, expensive diagnostic testing.

## CASE REPORT

A 58-year-old Caucasian man with hypertension, hyperlipidemia but nonsmoker, and no remarkable history of heart disease, presented to cardiology clinic for cardiovascular risk assessment. He denied chest pain,

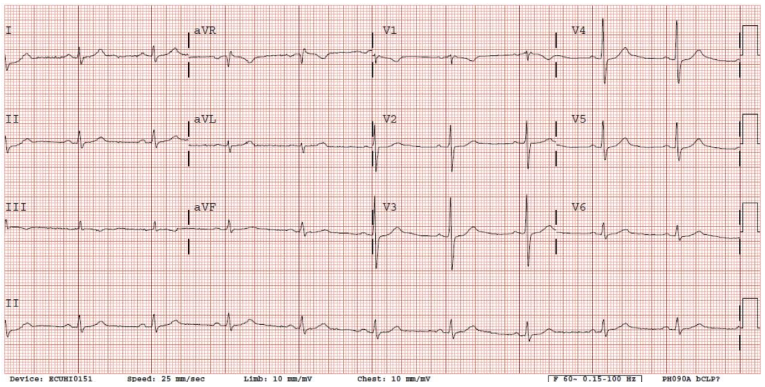

**Figure 1 Electrocardiogram showed sinus bradycardia with a heart rate of 59 bpm and RSR' in V1.**

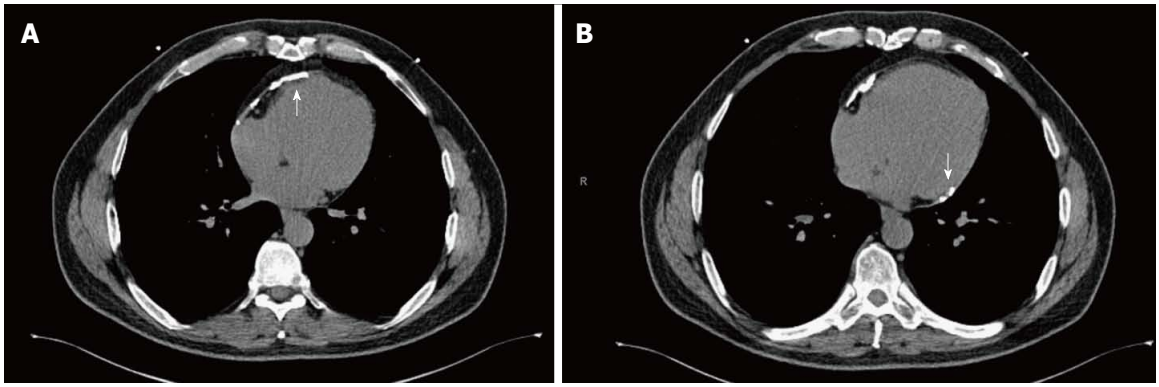

**Figure 2 Non-contrast cardiac computed tomography for coronary artery calcium scoring showed moderate pericardial calcification mostly involving anterior (A) and inferobasal (B) portion of the pericardium.**

shortness of breath, palpitation, or dyspnea on exertion. He weighed 97 kg with a body mass index (BMI) of 29 kg/m$^2$. Physical examination revealed a blood pressure of 138/85 mmHg, pulse of 59 bpm, and respiration rate of 16 breaths per minute. Lungs were clear to auscultation. There was no jugular venous distention. Normal heart sounds, no S3 or S4, no murmurs, and no rubs. No hepatomegaly or extremity edema. Electrocardiography (ECG) showed sinus bradycardia with a heart rate of 59 bpm and RSR' in V1 (Figure 1). Due to his intermediate cardiovascular risk, he underwent non-contrast cardiac computed tomography for CACS for further risk stratification, which showed a low Agatston score of 25.5. This study also revealed an incidental finding of moderate pericardial calcification, mostly involving the anterior and inferobasal portion of the pericardium with no pericardial effusion (Figure 2). Transthoracic echocardiogram showed grade II left ventricular diastolic dysfunction with pseudonormalization pattern, normal valves and normal biventricular size and systolic function. Exercise ECG stress testing demonstrated no evidence of exercise-induced myocardial ischemia at adequate heart rate, achieving 13 metabolic equivalents.

## DISCUSSION

Calcium deposit does not form in a healthy pericardium, but tends to be prominent in the fibrous and scarring pericardium in response to inflammation[1]. Historically, tuberculosis pericarditis is frequently reported as the primary cause of pericardial calcification. More recent cases of pericardial calcifications have been thought to be "idiopathic" and are likely to represent a sequelae of viral pericarditis. Other major known causes include trauma, cardiac surgery, radiation, connective tissue diseases and malignancy[2].

Pericardial calcification alone is asymptomatic. Signs and symptoms are secondary to associate processes such as constrictive pericarditis, which is typically insidious in onset and develops weeks to decades after an episode of pericarditis or chest trauma[3]. Patient usually present with signs and symptoms of right heart failure or low cardiac output including hepatomegaly, ascites, bilateral leg edema, exertion dyspnea, orthopnea, fatigue, elevated JVP, hepatojugular reflux, Kussmaul's sign, and pulsus paradoxus[2,3].

Evaluating patients with symptomatic pericardial calcification or a high suspicion of constrictive pericarditis may involve multiple imaging modalities. Electrocardiogram may show decreased QRS voltage and flattened T waves[2]. On chest radiographs, calcification may be seen as curvilinear opacities follow expected pericardial contour located predominantly over right atrium and ventricle, diaphragmatic surface, and atrioventricular grooves[4,5]. Computed tomography (CT) scan is useful to define pericardial disease and to distinguish coronary,

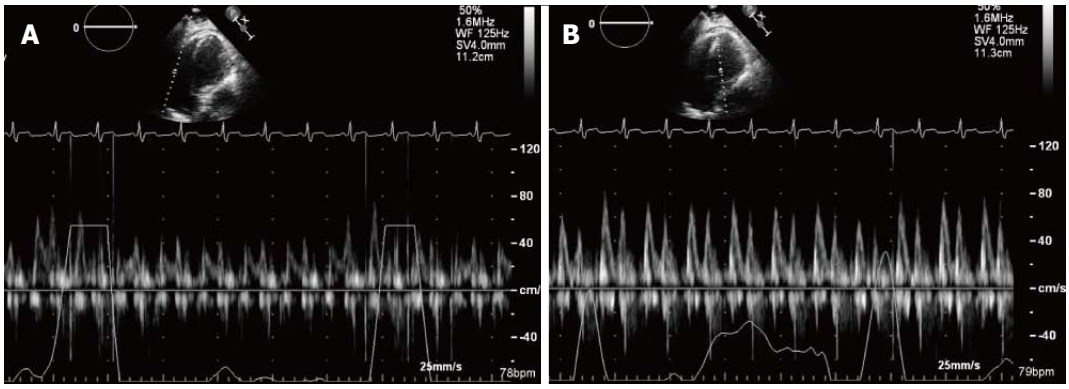

**Figure 3 Apical four chamber view of transthoracic echocardiogram and pulse wave Doppler's recording.** A: Tricuspid valve inflow in a patient with constrictive pericarditis; B: Mitral valve inflow in a patient with constrictive pericarditis. Note with inspiration, the E-wave velocity of mitral valve inflow decreases significantly. This reflects the hemodynamic changes in constrictive pericarditis, resulting from the lack of intrathoracic pressure transmission to the cardiac chambers and the exaggerated ventricular interdependence.

pericardial, myocardial, and intraluminal calcification. In many cases of constrictive pericarditis, CCTA signs of pericardial constriction will be presented and help to confirm the diagnosis. This includes global or focal pericardial thickening (> 4 mm) or calcification, tube-like configuration of ventricles, narrowing of atrioventricular groove, and sinuous appearance of the intraventricular septum[6]. CCTA scan may also shows enlargement of atriums, and enlargement of SVC (> the diameter of descending aorta) and IVC (> twice the diameter of descending aorta)[6]. Magnetic resonance imaging can accurately demonstrates pericardial thickening and provides additional functional analysis of constrictive physiology. Similarly, echocardiogram may demonstrate pericardial thickening or echogenic shadowing from calcium, and an enlargement of one or both atrium, IVC and hepatic veins[3]. Respiratory variation of $\geqslant$ 25% of early mitral inflow velocity is a well-recognized echocardiographic feature of constrictive pericarditis, which does not exhibits in those with restrictive cardiomyopathy[7]. Right heart catheterization (RHC) provides documentation of the hemodynamics of constrictive physiology and assists in discriminating between constrictive pericarditis and restrictive cardiomyopathy. RHC demonstrates preserved *x* descent and a prominent *y* descent, elevated right atrial pressure and right ventricular end diastolic pressure. Left atrial and left ventricular pressures are usually elevated. The equalization of diastolic pressures of all chambers (within less than 5 mmHg) with impaired diastolic filling pattern is a hallmark of constrictive physiology[3]. In our case, pericardial calcification was discovered incidentally without imaging findings suggestive of constrictive physiology. An example illustrating respiratory variation of mitral and tricuspid inflow velocity of a patient with constrictive pericarditis is shown in Figure 3.

The 2010 Appropriate Use Criteria for Cardiac Computed Tomography found that CACS use is appropriate in asymptomatic, intermediate-risk CHD patients, and this unanimous advocacy by the American College of Cardiology Foundation could have a significant impact on therapeutic decision-making and intervention[8]. In our case, pericardial calcification was discovered incidentally on non-contrast cardiac CT for CACS for further coronary artery risk stratification. Our patient has an in intermediate 10-year risk (17%) for hard CHD events such as myocardial infarction and CHD death, using the Framingham risk scoring[9]. As detailed in the 2010 ACC/AHA Guideline for assessment of cardiovascular risk in asymptomatic adults, CACS use is appropriate for evaluating this patient's elevated risk for future cardiovascular events[10]. Ultimately, the goal of our assessment is to refine targeted preventative efforts based on patient risk.

Although detecting and recognizing pericardial calcification on chest radiography and other imaging modalities such as CT, and echocardiography may have important clinical implications, it requires further investigations and multimodal cardiac imaging in expediting the diagnosis. Pericardial calcification is thought to occur after extensive scarring of the pericardium, and the fibrotic change in the pericardium may produce pericardial constriction. However, asymptomatic pericardial calcifications may be increasingly encountered by the use of cardiac computed tomography[1,11]. In a study of 1812 consecutive patients underwent electron-beam tomography for CACS, Hunold *et al*[12] found that approximately 1% (17/1812) had pericardial calcification without sign of pericardial constriction on the echocardiogram. Approximately 30% of patients with calcified pericardium may have signs and symptoms of constrictive pericarditis, and up to 50% of patients with constrictive pericarditis demonstrate pericardial calcification on plain chest radiographs[1,5]. Hence, the absence of calcification does not exclude constrictive pericarditis.

Due to the increase use of CACS and CCTA for the assessment of coronary atherosclerosis, incidental findings of pericardial calcification may become increasingly apparent, with or without significant clinical implications. The presence of pericardial calcification may suggest of diffused pericardial scarring and raises concerns for secondary associated processes and complications such as

pericardial constriction. However, a thickened pericardium or calcification per se is not diagnostic of constrictive pericarditis. Pericardial constriction can occur without pericardial thickening or calcification, and calcification can be seen in the absence of constrictive physiology. If constriction is strongly suggested on clinical contexts, it should only be undertaken after careful consideration to establish or exclude the diagnosis. Calcification of the pericardium must be evaluated with full clinical knowledge to facilitate an accurate diagnosis and an appropriate therapy when required.

## COMMENTS

### *Case characteristics*

A 58-year-old Caucasian man with hypertension, hyperlipidemia but nonsmoker, and no remarkable history of heart disease presented to cardiology clinic for cardiovascular risk assessment without having any symptoms.

### *Clinical diagnosis*

Lungs were clear to auscultation. Normal heart sounds, no S3 or S4, no murmurs, and no rubs. No hepatomegaly or extremity edema.

### *Imaging diagnosis*

Non-contrast cardiac computed tomography for coronary artery calcium scoring revealed a low agatston score of 25.5 and incidental finding of moderate pericardial calcification.

### *Differential diagnosis*

Pericardial calcification with and without constrictive pericarditis.

### *Treatment*

Monitoring for signs and symptoms of pericardial constrictions is sufficient for asymptomatic pericardial calcification.

### *Related reports*

Incidental pericardial calcification is rare but may become more apparent due to the widespread application of cardiac computed tomography.

### *Experiences and lessons*

Calcification of the pericardium must be evaluated with full clinical knowledge to facilitate an accurate diagnosis and an appropriate therapy when required.

### *Peer review*

Pericardial calcification is an occasional finding in patients undergoing computed tomography (CT) scan for coronary artery assessment or calcium score. Its clinical meaning remains unsettled and unless causing pericardial constriction, does not require any therapeutic intervention. In this manuscript, moving from the observation of a patient with pericardial calcification, authors address this fortuitous and serendipitous finding in patients undergoing CT scan for other purposes. The manuscript is interesting and minor changes would improve its readability.

## Abstract

Iliopsoas abscess (IPA) is an uncommon infection. The clinical presentation is usually insidious. Most patients present with nonspecific symptoms, leading to difficulty in prompt and accurate diagnosis. Delay in diagnosis can lead to complications, such as sepsis and death. Tattooing has become more popular over the recent years and has been associated with tattooing-related and blood-borne infections. We present two related cases of methicillin-resistant Staphylococcus aureus IPA after tattooing and review the epidemiology, etiology, clinical features, and management of IPA.

**Key words:** Iliopsoas abscess; Methicillin-resistant Staphylococcus aureus; Intravenous drug abuse; Tattooing; Primary iliopsoas abscess; Secondary iliopsoas abscess

**Core tip:** Iliopsoas abscess (IPA), a collection of pus in the iliopsoas compartment, is classified as primary or secondary depending on the source of infection. While immunocompromise and intravenous drug abuse are the most common known risk factors for primary IPA, tattooing may represent a novel risk factor as well. We present two related cases of methicillin-resistant Staphylococcus aureus IPA after tattooing and review the epidemiology, etiology, clinical features, and management of IPA. Maintaining a high clinical suspicion for this condition in patients with risk factors is important for prompt and accurate diagnosis and prevention of complications, such as sepsis and death.

## INTRODUCTION

Iliopsoas abscess (IPA) is a collection of pus in the iliopsoas compartment[1]. The unique anatomy of the psoas muscle predisposes it to infections by both direct extension and hematogenous spread[2]. The close proximity of the psoas muscle to sigmoid colon, jejunum, appendix, ureters, aorta, renal pelvis, pancreas, iliac lymph nodes, and spine makes it susceptible to contiguous spread of infections from these organs[3]. The abundant vascular supply of the muscle predisposes it to hematogenous spread of infections from occult sites[4]. The insidious onset and occult characteristics of IPAs can cause diagnostic delays and result in high mortality and morbidity[2].

## CASE REPORT

A 48-year-old female with past medical history of gastroesophageal reflux disease and migraines presented with 4 d of abdominal and back pain, dysuria, nausea, and vomiting. She denied alcohol use, but admitted to cigarettes (34 pack-years) and previous intravenous (IV) drugs (most recent use 2 mo prior to presentation). Vitals included temperature of 98.3 degrees Fahrenheit, heart rate 103 beats per minute, blood pressure 138/84 mmHg, and respiratory rate 28 per minute. Physical exam was unremarkable. Laboratory data revealed a white blood cell

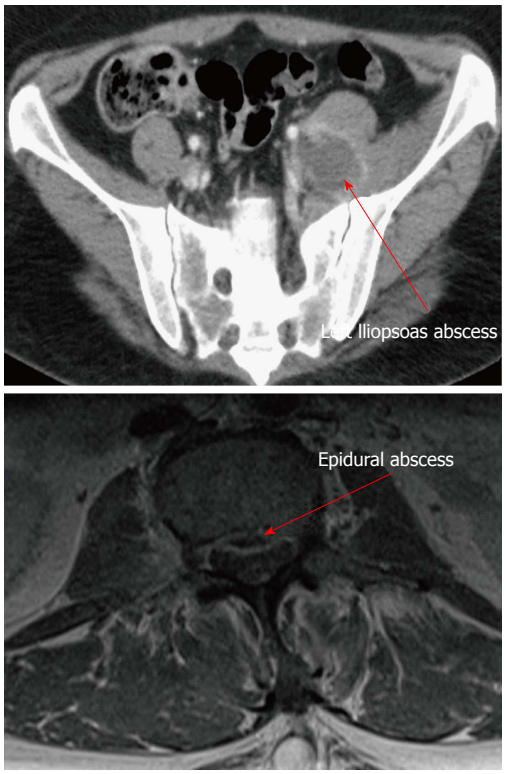

**Figure 1 Above: left iliopsoas abscess on contrast-enhanced computed tomography scan, below: epidural abscess on magnetic resonance imaging.**

count (WBC) of 34.6 × $10^3$ cells per microliter, 92.8% neutrophils, 2% bands, hemoglobin of 12.4 g per deciliter, sodium of 135 mmol per liter, chloride of 97 mmol per liter, blood urea nitrogen (BUN) of 19 mg per deciliter, AST of 53 IU per liter, and ALT of 42 IU per liter. Urinalysis revealed cloudy urine with pH of 5.5, specific gravity of > 1.030, > 25 squamous epithelial cells, 11-17 WBC, 9-15 red blood cells, moderate bacteria, positive nitrites, negative leukocyte esterase, 2+ bilirubin, and 3+ urine protein, blood, and ketones. Urine toxicology screen was positive only for tricyclic antidepressants. Viral hepatitis panel was positive for Hepatitis C antibody. Human immunodeficiency virus (HIV) serology was negative. Initial blood gram stain revealed gram positive cocci in clusters, blood cultures grew methicillin-resistant *Staphylococcus aureus* (MRSA), and urine culture remained negative. Vancomycin was initiated.

Transthoracic echocardiogram did not show evidence of endocarditis. Computed tomography (CT) of abdomen and pelvis with IV contrast revealed abscess formation in the left posterior paraspinal muscles with retroperitoneal extension along the left iliopsoas and pelvis (Figure 1). Follow-up magnetic resonance imaging (MRI) of lumbar spine with and without contrast showed epidural abscess spanning the lumbar spine along the anterior epidural compartment (from T12 to S1), a small epidural abscess in the left posterolateral epidural compartment in the sacrum, left psoas abscess, left retroperitoneal abscess, left paraspinal abscess, a tiny intra psoas abscess on the right, and inflammatory changes in the right posterior paraspinal muscles without an associated abscess (Figure 1). Neurosurgery did not recommend surgical intervention. Interventional radiology performed CT-guided aspiration of the left paraspinal and left psoas abscesses, draining 14 and 15 milliliters of purulent material, which grew MRSA.

**Figure 2 Home-made tattoo placed on the patient's back by her husband with shared equipment.**

Interestingly, patient's husband was also admitted to the same hospital at the same time and diagnosed with IPA due to MRSA. Our patient gave further history that her husband had used the same ink and equipment to tattoo his own arm and her back (Figure 2). Shortly afterwards, he had developed a superficial infection at his tattoo site which resolved prior to admission. Of note, comparison of MRSA isolated from our patient and her husband revealed identical sensitivities to antibiotics, suggesting the same strain (Table 1). Our patient was eventually discharged with outpatient IV antibiotics. At discharge, she was stable and afebrile with negative blood cultures and normal WBC.

## DISCUSSION

IPA is an uncommon infection[5]. There are two types of IPA: primary and secondary[2]. Primary IPAs are caused by hematogenous or lymphatic spread of bacteria, usually from occult distant sources[4]. While *Staphylococcus aureus* is responsible for the majority of primary IPAs[6], infections from other organisms such as *Streptococci*, *Escherichia coli*, *Enterobacter*, *and Salmonella* have also been reported[7,8]. Risk factors for primary IPAs include IV drug use (IVDU), HIV/acquired immune deficiency syndrome, active malignancy, diabetes mellitus, receipt of steroids or chemotherapy, and renal failure[2,5]. Secondary IPAs result from local extension of adjacent sources of infection[5]. Risk factors for secondary IPAs include inflammatory or neoplastic diseases of the bowel, kidney, and spine, such as crohn's disease, appendicitis, spinal pathology, trauma, or instrumentation in the groin, lumbar, or hip areas[3,4]. While secondary IPAs caused by *Staphylococcus aureus* have been reported[5], they are thought to be predominantly caused by enteric organisms, such as *Escherichia coli*, *En-*

**Table 1 Antibiotic sensitivities of methicillin-resistant staphylococcus aureus isolated from iliopsoas abscesses of both the wife (Patient 1) and the husband (Patient 2) reveal identical strains**

| Antibiotic | Patient 1 | Patient 2 |
|---|---|---|
| Ciprofloxacin | Resistant | Resistant |
| Clindamycin | Sensitive | Sensitive |
| Daptomycin | Sensitive | Sensitive |
| Erythromycin | Resistant | Resistant |
| Gentamicin | Sensitive | Sensitive |
| Inducible Clindamycin | Sensitive | Sensitive |
| Levofloxacin | Intermediate | Intermediate |
| Linezolid | Sensitive | Sensitive |
| Minocycline | Sensitive | Sensitive |
| Moxifloxacin | Sensitive | Sensitive |

| Vancomycin | Sensitive | Sensitive |

*terobacter*, *Klebsiella*, *Streptococcus*, *Bacteroides*, and *Salmonella*[3].

The clinical presentation of IPA is often variable. Symptoms are non-specific and include pain in back, abdomen, flank, hip, or thigh, as well as fever, limp, malaise, nausea, weight loss, and lump in the groin[2]. These unusual clinical features and subacute or chronic nature of symptoms may lead to delay in diagnosis[9]. Laboratory investigations may reveal leukocytosis, anemia, elevations in C-reactive protein, erythrocyte sedimentation rate, and BUN, as well as positive blood cultures[8,10]. While CT is considered the gold standard for definitive diagnosis[11], use of MRI has also been advocated because of better discrimination of soft tissues and the ability to visualize the abscess wall and surrounding structures without an intravenous contrast medium[12,13]. Characteristic radiographic features include focal hypodense lesion(s) within the psoas muscle, presence of gas within the muscle, and CT enhancement of the rim of the abscess with contrast[11]. In addition to confirming diagnosis of an IPA, imaging studies can demonstrate co-existing causative retro- or intra-peritoneal disease in secondary IPA[11].

Once IPA is diagnosed, treatment involves the use of appropriate antibiotics and drainage of the abscess[2]. If primary IPA is suspected, antibiotics with staphylococcal coverage should be selected[14]. In secondary IPA, broad spectrum antibiotics with both aerobic and anaerobic coverage should be considered[15]. Antibiotic therapy can subsequently be tailored to the results of the abscess fluid culture and sensitivity. Drainage of the abscess may be done percutaneously or surgically[2]. CT -guided percutaneous drainage is less invasive and has been proposed as the draining method of choice[16]. Surgical intervention for drainage can be considered in cases of failure of percutaneous drainage, multiloculated abscesses, inability or contraindication to undergo percutaneous drainage, or presence of surgical indication for another intra-abdominal pathology[2,17].

In our patient, radiological investigations led to the diagnosis, which was later confirmed by microbiological reports. While our patient was diagnosed with primary IPA, she did not have evidence of associated risk factors, such as HIV or active malignancy. Both she and her husband denied IVDU in the previous two months. Interestingly, there has been a previous case report of a patient developing IPA two months after cessation of IVDU[6]. However, our patient and her husband also reported sharing the same equipment for home-made tattoos. The identical antibiotic sensitivities of both patients' MRSA strain as well as the reported superficial infection of husband's tattoo site prior to developing IPA suggest that tattooing might have been the etiology of IPA development in these 2 cases. While the temporal relationship as well as biological plausibility makes this a possibility, we cannot confirm a causal relationship since we did not phenotype the MRSA strains or obtain environmental sampling (*e.g.*, culture of the tattooing equipment).

This potential risk factor for IPA is important to recognize as tattooing has become more popular over the recent years. In 2012, 21% of adults in the United States had one or more tattoos, compared to 14% in 2008[18]. There have been reports of outbreaks of tattooing-related infections, including mycobacterial and MRSA infections from contaminated ink[18-20]. Tattooing is also associated with blood-borne infections such as Hepatitis C, independent of IVDU or blood transfusions prior to 1992[20]. It is conceivable that tattooing with potentially contaminated equipment caused transient bacteremia in our patient and her husband, leading to MRSA IPA. To our knowledge, IPA secondary to tattooing has not been reported in the literature. This case report demonstrates importance of recognition of tattooing as a possible risk factor for IPA, which along with maintaining a high clinical suspicion and meticulous clinical examination, can lead to prompt diagnosis, timely initiation of treatment, and reduction of morbidity and mortality.

## COMMENTS

### *Case characteristics*

A 48-year-old female presented with abdominal and back pain, nausea, and vomiting. Physical exam revealed fever, tachycardia, and tachypnea.

### *Differential diagnosis*

An inflammatory or infectious process involving the gastrointestinal (*e.g.*, cholecystitis) or genitourinary system (*e.g.*, pyelonephritis).

### *Laboratory diagnosis*

Labs were only remarkable for leukocytosis, elevated BUN, mild transaminitis, and abnormal urinalysis.

### *Imaging diagnosis*

Computed tomography (CT) of abdomen and pelvis with IV contrast revealed iliopsoas abscess (IPA). CT-guided aspiration of the IPA drained purulent material, which grew methicillin-resistant *Staphylococcus aureus*. Patient was treated successfully with a prolonged course of intravenous vancomycin.

### *Peer review*

Very well documented. Excellent diagnostic approach and treatment. Important

description of potential risks from the tattooing process, expecially when strict antiseptic measures are not followed.

## Abstract

The objective of this study is to increase awareness of the rare presentation, diagnostic difficulties and management of glomus tympanicum of the middle ear. A 49 years old male, with a background of hypertension and epilepsy, presented with a two month history of left sided conductive hearing loss, pulsatile tinnitus and headache. Clinically and radiologically a diagnosis of glomus tympanicum was made. Intraoperatively, extensive osteogenesis of the middle ear resulting in ossicular fixation and erosion was found. This patient required a two stage operation for full clearance of disease. A stapedectomy drill was used to drill off the bony overgrowth surrounding the ossicles resulting in improved hearing thresholds and full clearance of the disease at two year follow up. Glomus tympanicum can result in new bone formation in the middle ear with resultant ossicular fixation and conductive hearing loss. This can be effectively treated surgically with restoration of hearing.

**Key words:** Glomus; Tympanicum; Osteogenesis; conductive hearing loss

**Core tip:** Glomus tympanicum can result in new bone formation in the middle ear with resultant ossicular fixation and conductive hearing loss. This can be effectively treated surgically with restoration of hearing. We describe this previously unreported presentation of glomus tympanicum in the world literature (with reactive osteogenesis and resultant severe conductive hearing loss). We therefore believe our findings would be of interest to the readers of your journal and raise awareness of this as a differential diagnosis which may be under-recognised.

## INTRODUCTION

Glomus tumours or paragangliomas are benign neoplasms that arise from paraganglionic tissue throughout the body with glomus tympanicum being the most common primary soft tissue tumour arising in the middle ear[1,2]. The paraganglionic system is a collection of cells derived from the neural crest and are found in the autonomic nervous system. They act as a source of catecholamines before the development of the adrenal medulla. The term "glomus" is a historical misnomer which was applied to these tumors before a true understanding of the characteristics of these tumors was understood. Extra-adrenal or craniocervical paraganglioma are distributed along the arteries and cranial nerves in head and neck region. Craniocervical paragangliomas can be broadly classified into temporal and vagal.

Temporal paragangliomas commonly arise from "paraganglion cells" along the course of Jacobson's nerve

or Arnold's nerve[2]. They present as a soft tissue mass in the middle ear cavity which is often visible on otoscopy. Patients classically complain of pulsatile tinnitus and conductive hearing loss although depending on the extent of the disease they can experience imbalance, facial nerve palsy, otorrhoea or endocrine symptoms if the tumour is releasing catecholamines[3]. These clinical features lead to a need for further radiological investigations in the form of computed tomography and magnetic resonance imaging of the temporal bones to confirm the likely diagnosis and assess severity. A 24 h urine collection should be performed and analysed for vanillylmandelic acid (VMA) levels to determine whether indeed the lesion is endocrine-active[1-3].

We present a rare variant of a glomus tympanicum tumour that induced extensive osteogenesis in the middle ear causing severe conductive hearing loss secondary to ossicular fixation and erosion.

## CASE REPORT

A 49 years old male presented to otolaryngology outpatient department with a 2 mo history of left-sided "throbbing" earache. He also complained of pulsatile tinnitus and worsening left sided hearing loss. His general practitioner initially diagnosed him with otitis externa and when his symptoms failed to improve he was referred for further specialist management. His past medical history included epilepsy and hypertension.

Examination revealed a red mass arising from behind his tympanic membrane in the attic area and a diagnosis of glomus tympanicum was suspected although the position of the lesion was slightly unusual for a glomus. A pure tone audiogram revealed a mild conductive deafness of 20db especially on high frequencies. A computed tomography (CT) scan of his temporal bone revealed a non-gravity dependent opacification with bony erosion and 24 h urine collection did not show elevated VMA levels indicating a non-secretory glomus tumour.

Multidisciplinary team and patient choice resulted in surgical management of this lesion. Intraoperatively, after exposing the middle ear, apart from inflamed mucosa there was no obvious soft tissue mass found. There was however a bony growth arising from the medial wall of the middle ear and extending between the incus and malleus handle encasing the anterior crura of stapes (Figure 1). After careful dissection the extra bone was peeled of the ossicles and sent for histology leaving the ossicular chain intact. The patient made a very good recovery and his conductive hearing loss improved with closure of the air-bone gap to 5db. Histology revealed thickened and sclerotic bone. The intervening connecting tissue traversing the bone was infiltrated by tumour consisting of hyperchromatic cells with rich vascular stroma and no signs of atypia or mitosis. A diagnosis of benign glomus tumour was made.

During follow up, (ADD COMMA) despite an initial mild improvement in his hearing, the patient developed a worsening conductive hearing loss with thresholds of 60-70db across most frequencies. Computed tomography imaging, 18 mo after his initial operation, (ADD COMMA) suggested recurrent disease and the patient required revision surgery.

Intra-operatively a recurrent bony overgrowth was identified which this time had encased the stapes superstructure and was causing malleo-incudal fixation. The disease could not be removed with a curette and so a stapedectomy drill was used to drill the overgrowth off the stapes superstructure. The malleus and incus were sacrificed and the ossicular chain was reconstructed with conchal cartillage. Histology once again demonstrated bone overgrowth with intervening tumour cells. The patient made a very good recovery and he has a sustained improved hearing of 40db two years postoperatively.

## DISCUSSION

Glomus tumours are fairly rare with an incidence of around 1 per 1 million[4]. They are usually hypervascular tumours that arise within the jugular foramen of the temporal bone[1-4]. They characteristically present with conductive hearing loss and a pulsatile tinnitus as demonstrated in our case. Histologically, chief or granular cells (Type I) and sustentacular cells or satellite cells (Type II) are present in glomus tumours[2]. Management is dependent on the tumour extent and the patient's fitness with the mainstay being surgery and radiotherapy[1-4]. Small tumours can be accessed *via* a transcanal approach with larger ones necessitating a post-auricular approach with mastoid exploration. The tumour is commonly a highly vascular soft tissue lesion which may require pre-operative embolization.

Bony overgrowth over a glomus tumour has not been previously reported in the world literature and as such represents a new clinical entity. The only other incidence of bone in the middle ear associated with a glomus tumour was reported by Yanagisawa *et al*[5], where a glomus tumour coexisted with otosclerosis in a patient. However, our patient did not show any histological features of otosclerosis in that his conductive hearing loss was unilateral, his ossicular chain was mobile after resection of the extra bone in the middle ear and his hearing improved post-operatively without the need for a stapes prosthesis. Furthermore, histology from the bone overgrowth confirmed glomus tumour cells intervening the bony overgrowth. All Fisch class I mesotympanic paragangliomas involve careful resection of tumour around the ossicles. We cleared osteogenesis around the stapes suprastructure using a stapedectomy drill, thus improving upon the incumbent conductive hearing loss. Another management option available in such cases would be removal of the glomus along with stapes suprastucture and reconstructing hearing using a total ossicular replacement prosthesis. Our treatment option, of drilling the bone around the ossicular chain and in particular the stapes, with a stapedectomy drill, proved successful in terms of hearing

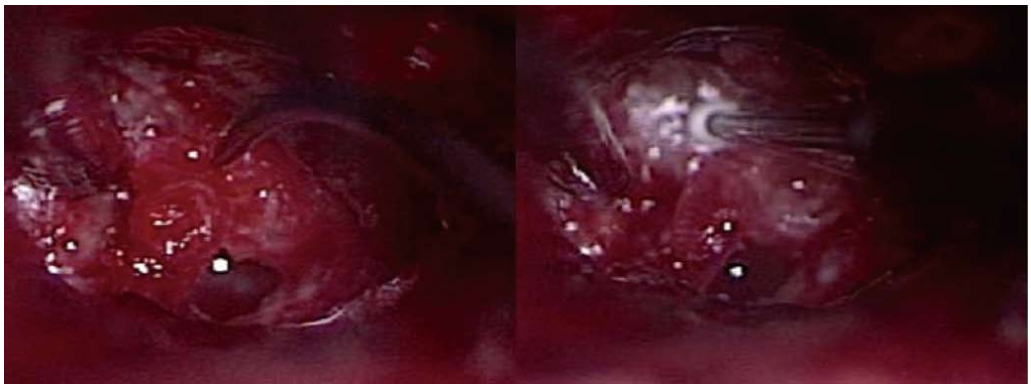

**Figure 1 Microscopic intraoperative view of mesotympanum.**

restoration (whilst ensuring tumour removal) and we propose this as a treatment modality for such rare cases.

In conclusion: (1) Glomus tumours or paragangliomas are rare tumours arising from paraganglionic tissue; (2) Glomus tympanicum tumours are the commonest soft tissue tumour of the middle ear; (3) These lesions typically present with pulsatile tinnitus and hearing loss; (4) A new clinical entity of osteogenesis in the middle ear is described - leading to ossicular fixation and erosion; and (5) Bony overgrowth can be managed by careful dissection off the ossicles or by use of a stapedectomy drill, resulting in improved hearing thresholds.

## COMMENTS

### *Case characteristics*

A 49 years old male with a two month history of left sided conductive hearing loss, pulsatile tinnitus and headache.

### *Clinical diagnosis*

Examination revealed a red mass arising from behind his tympanic membrane in the attic area with an associated mild conductive deafness.

### *Differential diagnosis*

Differentials included glomus tympanicum although the mass was unusually located meaning cholesteatoma, schwannoma and meningioma remained possible.

### *Laboratory diagnosis*

Twenty-four hour urine collection did not show elevated VMA levels indicating a non-secretory glomus tumour.

### *Imaging diagnosis*

Computed tomography scan of his temporal bone revealed a non-gravity dependent opacification with bony erosion.

### *Pathological diagnosis*

Histology revealed thickened and sclerotic bone with intervening connecting tissue traversing the bone infiltrated by tumour consisting of hyperchromatic cells with rich vascular stroma and no signs of atypia or mitosis, leading to a diagnosis of benign glomus tumour.

### *Treatment*

Surgical excision with drilling of newly formed bone and reconstruction of hearing mechanism.

### *Related reports*

Glomus tumours are rare, hypervascular tumour that arises within the jugular foramen of the temporal bone. New bone formation in the middle ear has not previously been reported in the world literature.

### *Term explanation*

VMA is Vanillylmandelic Acid, a metabolic by-product of norepinephrine and epinephrine.

### *Experiences and lessons*

Glomus tympanicum can result in new bone formation in the middle ear with resultant ossicular fixation and conductive hearing loss which can be effectively treated surgically with restoration of hearing.

### *Peer review*

The manuscript reports a clinical case about glomus tympanicum tumour related bone formation in middle ears leading to conductive hearing loss.

## Abstract

A 75-year-old male patient had stable angina pectoris. After coronary angiography we decided to perform a coronary artery bypass graft surgery. Twenty years ago the patient underwent radical cystectomy and bilateral ureterosigmoidostomy because of bladder cancer. After that, his micturition was via the rectum. We did not experience that before. As is known, monitoring of urine output is very important after cardiac surgery. The patient was consulted with an urologist for how to monitor urine output in him. Transrectal catheterization was recommended for our follow-up, but before the catheterization bowel cleansing is necessary. Four-vessel on-pump coronary artery bypass graft surgery was performed without any problem. Peroperative urine volume and arterial blood gas results were normal. Urine output is a sensitive variable reflecting the patient's effective blood volume and tissue perfusion. Urinary catheterization is a standard for all cardiac surgeries, and it allows the patients' urine to drain freely from the bladder for collection. Monitoring of urine output in patients with ureterosigmoidostomy is impossible by standard urinary catheterization method. In this case we performed transrectal catheterization for Urine flow follow-up. Urine flow follow-up is essential after the open-heart surgery and it can be measured in different ways, as in our case.

**Key words:** Open heart surgery; Urine output follow-up; Catheterization; Ureterosigmoidostomy; Coronary artery bypass graft

**Core tip:** With this case, we had experience that we can monitor urine output in different ways rather than urethral catheterization such as catheterization in a transrectal way that we had to do in a patient who had ureterosigmoidostomy.

Haberal I, Ozsoy D, Sipahi E, Mert M. Coronary artery bypass graft surgery in a patient with ureterosigmoidostomy. *World J Clin Cases* 2014; 2(9): 466-468 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i9/466.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i9.466

## INTRODUCTION

Urine output is a sensitive variable reflecting the patient's effective blood volume and tissue perfusion[1]. Urinary catheterization is a standard for all cardiac surgeries, and it allows the patients' urine to drain freely from the bladder for collection. Monitoring of urine output in patients with ureterosigmoidostomy is impossible by standard urinary catheterization method. We could not find any such case report in the literature. Hence we decided to write this case report to explain how we can monitor urine output and which complications may occur after coronary artery bypass graft surgery operation in patients with ureterosigmoidostomy.

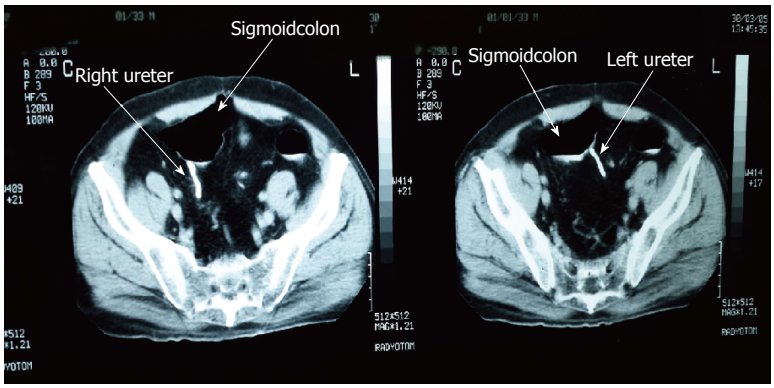

**Figure 1 Bilateral ureterosigmoidostomy revealed by an abdominal computed tomographic scan.**

## CASE REPORT

A 75-year-old male patient had stable angina pectoris. After coronary angiography we decided to perform a coronary artery bypass graft surgery. Preoperative laboratory tests were normal. Twenty years ago the patient underwent radical cystectomy and bilateral ureterosigmoidostomy because of bladder cancer (Figure 1). His urologist confirmed that, he was fully cured after this surgery. After that, his micturition was *via* the rectum. We did not experience that before. As is known, monitoring of urine output is very important after cardiac surgery. The patient was consulted with an urologist for how to monitor urine output in him. Transrectal catheterization was recommended for our follow-up, but before the catheterization bowel cleansing is necessary. After this recommendation we performed a high enema the night before the operation. A 24F urinary catheter was applied in a transrectal way as much as possible to the distal end. A 24F Foley urethral catheter with a 30 cc balloon was inflated to 50 cc in order to minimize the chance that the catheter will be pulled down through the sigmoid colon and then we could monitor urine output by this method perfectly. Four-vessel on-pump coronary artery bypass graft surgery was performed without any problem. Peroperative urine volume and arterial blood gas results were normal. The patient had respiratory problems postoperatively but hemodynamic parameters were normal. Third generation cephalosporins were used to prevent possible urosepsis during the catheterization. During the catheterization the patient was not fed *via* the enteral route. Urine flow was followed for three days until hemodynamic stability was achieved. The catheter was removed three days after the operation and the patient was transferred from intensive care unit to the ward four days after the operation. The patient was discharged from hospital nine days after the surgery without any problem.

## DISCUSSION

Monitoring of urine output could improve the clinical management of cardiac patients and enable clinicians to early recognition of volume status, cardiac output and kidney injury. A urinary catheter is inserted preoperatively in the operation room and kept in place for a minimum of 24-48 h to monitor hourly urine flow. Catheterization is difficult in some patients such as those with prostatic hypertrophy. In some cases, consideration should be given to use of a trocar–introduced suprapubic catheter in adults, rather than a urethral catheter. Our patient was operated 20 years ago because of bladder cancer. Today, orthotopic urinary diversion is an essential component of the surgical procedure after cystectomy. Replacement with an orthotopic ileal neobladder should be the first choice if external urethral sphincter sparing surgery is possible, offering good long-term function, quality of life and patient's acceptance with few complications[2,3]. However in our case, radical cystectomy and bilateral ureterosigmoidostomy were performed because of bladder cancer. Patients undergoing this procedure must be closely monitored for the development of hyperchloremic acidosis. This will occur in the majority of instances, and it is wise to initiate a bicarbonate replacement program at the outset[4]. After the coronary artery bypass graft surgery, apparent acidosis did not occur at the postoperative arterial blood gas follow-up, and this may be because ureterosigmoidostomy was performed 20 years ago. Obviously, all of such patients have exposure of the urinary tract to fecal flora. Most authors would advocate chronic antibacterial agent administration in all patients[5]. Third generation cephalosporins were used in our case to prevent possible urosepsis during the catheterization. Because of the definite concern for the occurrence of rectal cancer some 5 to 50 years (average 21 years) after ureterosigmoidostomy[6], it is suggested that patients with long-term ureterosigmoidostomy be subjected to annual colonic investigation. His urologist confirmed that he was fully cured after radical cystectomy and bilateral ureterosigmoidostomy. At colonoscopic investigations we could not determine any pathological results. In this case, paying particular attention to a few details both preoperatively and postoperatively, coronary artery bypass graft surgery was performed without any problem.

In conclusion, urine flow follow-up is essential after the open-heart surgery and it can be measured in different ways, as in our case.

## COMMENTS

### *Case characteristics*

A 75-year-old male patient with a history of ischemic heart disease presented

with dispnea and angina.

### Clinical diagnosis

Scar to inspection over suprapubic area.

### Differential diagnosis

Aortic dissection, pericarditis, and pneumothorax.

### Laboratory diagnosis

Hematologic and metabolic panels were normal.

### Imaging diagnosis

Coronary angiography revealed multi-vessel coronary artery disease and computed tomography scan showed bilateral ureterosigmoidostomy.

### Pathological diagnosis

Coronary artery disease with radical cystectomy and bilateral ureterosigmoidostomy operation because of bladder cancer.

### Treatment

Four-vessel on-pump coronary artery bypass graft surgery was performed without any problem.

### Related reports

Catheterization is difficult in some patients such as those with prostatic hypertrophy. In some cases, consideration should be given to use of a trocar–introduced suprapubic catheter in adults, rather than a urethral catheter.

### Term explanation

Ureterosigmoidostomy is not widely used in patients with bladder cancer. Nowadays, orthotopic urinary diversion is an essential component of the surgical procedure after cystectomy.

### Experiences and lessons

Urinary output can be monitored transrectally in patients with ureterosigmoidostomy.

### Peer review

Authors describe the case of a patient undergoing CABG who had undergone radical cystectomy with ureterosigmoidostomy. Monitoring urine output is important in these patients, which was performed using a Foley catherther in the colon after bowel cleaning in this case. It is an unusual interesting clinical dilemma with good discussion.

## Abstract

Toxic epidermal necrolysis (TEN) is a severe adverse drug reaction, which is characterized by erythema, blisters, and/or erosions of the mucous membranes and skin, but intestinal involvement is rare. In contrast, pneumatosis cystoides intestinalis (PCI) is a rare condition associated with a wide variety of underlying diseases, but to date no patient has presented with PCI associated with TEN. A 55-year-old man was admitted to intensive care unit for treatment of TEN caused by phenobarbital. On day 8 after admission, he presented with progressive abdominal distention and hypotension. Computed tomography (CT) showed gas in the superior mesenteric vein and air filled cysts in the walls of the small intestine. He was suspected of having septic shock due to PCI. As there were no indications of bowel ischemia or necrosis, the patient was managed conservatively with antibiotics and oxygen therapy. On day 10 after admission, he was weaned off catecholamines, with CT on day 11 showing complete resolution of gas in the superior mesenteric vein and air filled cysts. To our knowledge, this article describes the first patient presenting with PCI associated with TEN.

**Key words:** Toxic epidermal necrolysis; Intestinal involvement; Pneumatosis cystoids intestinalis; Septic shock; Conservative treatment

**Core tip:** Toxic epidermal necrolysis is a severe adverse drug reaction, which affects skin and mucosa of whole body. However, intestinal involvement is rare documented. We report the case of a 55-year-old man with toxic epidermal necrolysis caused by phenobarbital. He was diagnosed with pneumatosis cystoides intestinalis during the clinical course. Although septic shock was accompanied, conservative treatment was effective. To our knowledge, this article describes the first patient presenting with pneumatosis cystoides intestinalis associated with toxic epidermal necrolysis.

Yao SY, Seo R, Nagano T, Yamazaki K. Pneumatosis cystoides intestinalis associated with toxic epidermal necrolysis: A case report. *World J Clin Cases* 2014; 2(9): 469-473 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i9/469.htm
DOI: http://dx.doi.org/10.12998/wjcc.v2.i9.469

## INTRODUCTION

Toxic epidermal necrolysis (TEN) is a rare but potentially fatal condition often caused by adverse drug reactions. TEN is characterized by high fever, widespread blistering of the exanthematous macules and atypical target-like lesions of the skin, as well as mucosal involvement. However, there have been few reports of intestinal involvement of TEN[1].

Pneumatosis cystoides intestinalis (PCI) is a rare condition, in which submucosal or subserosal gas cysts are found in the walls of the small and/or large intestines.

**Figure 1 Skin findings in this patient.** A and B: Wide-spread blistering exanthemas of macules around the face and neck; C: Nikolsky phenomenon (slight rubbing of the skin resulting in exfoliation of the outermost layer) of the lower leg.

The pathogenesis of PCI remains unclear, and the role of emergency surgical intervention in patients with PCI accompanied by portal vein gas or peritoneal irritation remains controversial.

We describe here a patient with PCI encountered during the clinical course of TEN, with the former condition successfully treated by conservative management. To our knowledge, this is the first such patient described to date.

## CASE REPORT

A 55-year-old man with a previous medical history of alcohol-induced epilepsy presented to our dermatology department with complaints of fever and a rapidly evolving rash over his face and trunk. He had been taking two antiepileptic agents, carbamazepine and phenobarbital, for one month. Drug induction was suspected, and oral antihistamine and steroids were started after discontinuation of the antiepileptics.

Despite this treatment, the rash did not improve, spreading to his back, arms, and legs after one week. He was admitted to our hospital with a presumed diagnosis of Stevens-Johnson syndrome (SJS). On the day of admission, he was started on intravenous steroid pulse therapy with prednisolone plus immunoglobulin. However, blister and erosion continued to spread throughout the entire body (Figure 1). The patient was diagnosed with TEN and transferred to intensive care unit (ICU) on day 6 of hospitalization. During his stay in the ICU, his skin condition gradually improved with continuous intravenous steroids. He was also administered a first generation cefem for antibiotic prophylaxis.

Abdominal distension was also observed, beginning on the third day of admission. CT scan performed on day 5 showed no specific findings except for pneumocolon. The patient was put on a bowel regimen, consisting of laxatives and enemas, to regulate his bowel movements.

On day 8, the condition of this patient suddenly deteriorated. His abdominal distension became exacerbated and his blood pressure decreased rapidly. He became less responsive and scored 11 (E2V4M5) on the Glasgow Coma Scale.

Physical examination showed a temperature of 37.2 ℃, blood pressure of 60/28 mmHg, pulse of 110 beats per minute, and oxygen saturation 97% in ambient air. Abdominal examination showed marked fullness and diffuse rebound tenderness throughout the entire abdomen. Laboratory examinations revealed severe acidosis and elevated lactic acid concentration. The results of laboratory examinations are shown in Table 1. A blood culture was positive for a species of Corynebacterium.

Plain abdominal radiography showed small-bowel distension and a low-density linear and bubbly pattern of gas in the small-bowel wall (Figure 2). A non-contrast CT scan revealed gas in the superior mesenteric vein (SMV) and intramural air, but no free air, in the small-bowel wall (Figure 3). The patient was preliminarily diagnosed with septic shock associated with pneumatosis cystoides intes-

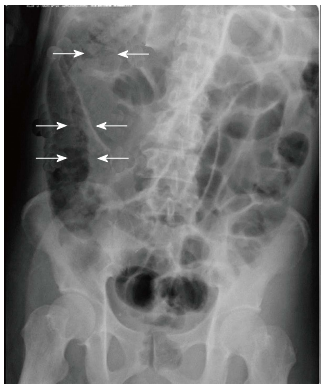

**Figure 2 Plain supine abdominal radiography of patient on day 8 of admission to the intensive care unit, showing small-bowel distension and pneumatosis cystoides intestinalis (arrows).**

tinalis. He was started immediately on oxygen treatment, followed by intravenous broad-spectrum antibiotics and catecholamine. Although an emergency laparotomy was considered, the patient's general condition was too poor to tolerate an operation, and there was no sign of bowel ischemia or necrosis. Therefore, the patient was managed conservatively.

The patient progressed well, recovering from a catecholamine-dependent state two days later. A CT scan, performed three days later, showed that the gas in the small bowel wall had completely disappeared. The abdominal fullness gradually remitted and he was discharged from the ICU after sixteen days. Several days later, a drug lymphocyte stimulating test (DLST) was positive for phenobarbital, indicating that phenobarbital had caused TEN in this patient.

The patient's skin condition completely resolved sixty-two days after admission. No recurrence of PCI and TEN have been observed for three years.

## DISCUSSION

Stevens-Johnson syndrome and TEN are rare diseases, affecting approximately 1 or 2 per million individuals annually. Both of these diseases are considered medical emergencies as they are potentially fatal[2].

Currently, TEN and SJS are considered to be at the two ends of a spectrum of severe epidermolytic adverse cutaneous drug reactions, differing only in their extent of skin detachment. Symptoms of SJS include acute conditions characterized by mucous membrane erosions and skin lesions (described as macules, atypical target-like lesions, bulla, and erosions) involving less than 10% of the total skin surface area, whereas TEN involves more than 10% of the total skin surface area. In addition to skin symptoms, both diseases are often accompanied by complications in numerous organs, including the liver, kidneys, and lungs. The mortality rate for patients with TEN has been reported to range from 25% to 35%[2,3].

Certain drugs, including sulfonamides, non-steroidal anti-inflammatory drugs, cephem antibiotics, barbiturates, and antiepileptics are the most frequent triggers of TEN. A DLST for phenobarbital was positive in this patient, and the TEN was retrospectively determined to be a drug eruption caused by phenobarbital, with the condition progressing to TEN from SJS during its clinical course.

**Table 1 Laboratory data on day 8**

| Laboratory investigation | Results | Reference ranges |
|---|---|---|
| Arterial blood gas | | |
| Blood pH | 7.121 | 7.42 ± 0.04 |

| Prothrombin time-INR | 1.17 | 0.9-1.1 |

Pneumatosis cystoides intestinalis (PCI) is an unusual intestinal condition characterized by the presence of gas within the intestinal wall, usually in the mucosa and submucosa of the small and large intestines. PCI has been classified as primary or secondary, with most patients having secondary PCI due to an underlying condition[4]. These underlying conditions have been classified as (1) traumatic and mechanical (*e.g.*, pyloric stenosis, endoscopy, enteric tube placement volvulus, surgical anastomosis, carcinoma); (2) inflammatory and auto- immune (*e.g.*, Crohn's disease, ulcerative colitis, diverticular disease, necrotizing enterocolitis, polydermatomyositis, scleroderma, mixed connective tissue disease, multiple sclerosis); (3) infectious (*e.g.*, Clostridium difficile, HIV/AIDS, cytomegalovirus, Mycobacterium species); (4) pulmonary (*e.g.*, chronic obstructive pulmonary disease, asthma, cystic fibrosis); (5) drug induced (*e.g.*, cytotoxic agents, immunosuppressants, corticosteroids); or (6) other conditions, such as transplantation, graft versus host disease, leukemia, or intestinal infarction[5].

The pathogenesis of PCI is unclear, although several hypotheses have been suggested. The gas within the intestine wall may be intraluminal, pulmonary or produced by bacteria[5,6]. Mechanical features thought to be responsible for intrusion of intraluminal gas into the bowel wall are mucosal injury and/or increased intraluminal pressure. The possibility of pulmonary gas as a source for PCI is based on the hypothesis that air migrates along vessels within the mediastinum, retroperitoneum and mesentery after alveolar rupture in pulmonary diseases.

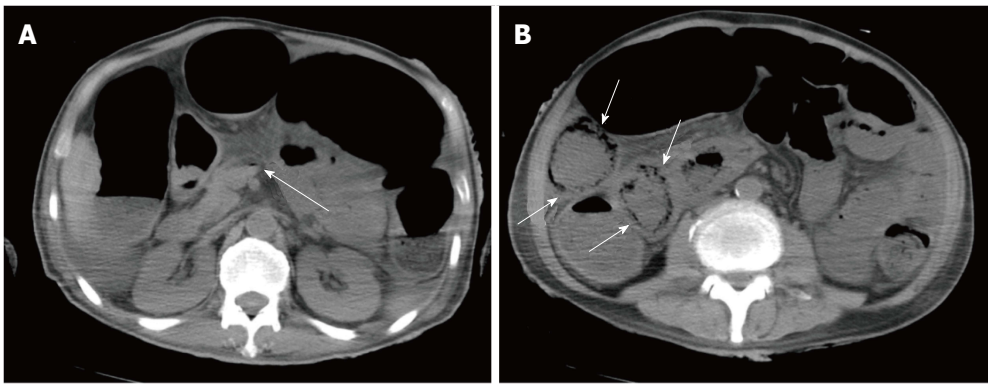

**Figure 3 Abdominal computed tomography of patient on day 8 of admission to the intensive care unit, showing.** A: Gas in the superior mesenteric vein (arrow); B: Extraluminal gas along the small bowel mesentery (arrows).

PCI may be asymptomatic or may manifest symptoms and signs associated with life threatening complications, such as bowel ischemia, perforation and peritonitis. Generally, however, the symptoms of PCI are mild and include abdominal pain, diarrhea or constipation, abdominal distension, bloody stools and/or weight loss. About 3% of patients experience more serious symptoms, including bleeding, ileus, volvulus, intussusception, and/or pneumoperitoneum[7].

Treatment for PCI depends on its symptoms, with no specific treatment standardized. PCI may be detected incidentally by radiographic imaging, screening colonoscopy, or during laparotomy. Intramural gas cysts in asymptomatic patients usually resolve spontaneously over time. Patients with mild to moderate symptoms are usually treated conservatively, with antibiotics, oxygen, and hyperbaric oxygen therapy reported effective[8,9]. Emergency surgical exploration is indicated for patients with suspected intestinal necrosis or abdominal sepsis[10]. Immediate surgery has been indicated for patients with elevated C-reactive protein or WBC, or the signs of sepsis, bowel perforation or portal venous gas. Conservative therapy has been recommended for patients with normal or slightly increased inflammatory parameters in blood samples and no signs of sepsis, bowel perforation or free gas[11].

Since the first report of PCI in France in the 18$^{th}$ century, numerous case reports and reviews have appeared worldwide. However, intestinal lesions in patients with TEN have rarely been reported. To our knowledge, our patient is the first reported to have TEN associated with PCI. Four patients with TEN were reported to present with digestive symptoms, including abdominal pain and bloody diarrhea. Pathological examination of mucosal biopsy specimens revealed that the superficial epithelium was severely damaged by necrosis, while the lamina propia was relatively unaffected[1].

PCI has been reported associated with collagen skin diseases, including scleroderma and dermatomyositis[10,12]. These patients are often treated with corticosteroids, which can induce atrophy of the mucosa and mucosal defects facilitating the intrusion of gas and bacteria[13].

Our patient was treated intravenously with high dose corticosteroids for 15 d, which may have exacerbated the atrophy and necrosis of the intestinal mucosa, which had been damaged by TEN. Persistent constipation may result in chronically elevated intra-luminal pressure, inducing the invasion of intramural compartments by gas and bacteria. The fragility of his intestinal mucosa allowed bacterial translocation and resulted in septic shock of Corynebacterium.

The signs of peritoneal irritation and gas in the SMV suggested the need for an emergency laparotomy, but his poor general condition did not allow surgery. In addition, we were unable to identify any underlying disease that could have induced ischemia or necrosis of the intestine. Conservative treatment with antibiotics, catecholamine, and oxygen therapy was successful. His abdominal symptoms disappeared and he discharged from the ICU after 8 d. In general, patients with signs of peritonitis in addition to metabolic acidosis indicating septic shock are candidates for surgery. However, in the absence of life-threatening situations such as perforation or necrosis, PCI can be managed conservatively. PCI is a clinical sign, and is not itself a diagnosis. Careful evaluation of the underlying disease and accompanying symptoms is essential.

## ACKNOWLEDGEMENTS

## COMMENTS

### *Case characteristics*

A 55-year-old male patient under the treatment of toxic epidermal necrolysis presented abdominal distension and fell into state of shock.

### *Clinical diagnosis*

The patient was diagnosed with pneumatosis cystoides intestinalis.

### *Differential diagnosis*

Perforative peritonitis, acute mesenteric artery occlusion.

### *Laboratory diagnosis*

The patient had severe acidosis (a blood pH of 7.121), acute renal damage (blood urea nitrogen 85 mg/dL, creatine 2.61 mg/dL) and elevated C-reactive protein (10.3 mg/dL).

### *Imaging diagnosis*

A non-contrast computed tomography scan revealed gas in the superior mesenteric vein and intramural air in the small-bowel wall.

### *Pathological diagnosis*

No pathological specimen was obtained but a blood culture was positive for a species of Corynebacterium, showing that the patient had been in the state of sepsis due to pneumatosis cystoides intestinalis.

### *Treatment*

Conservative management including oxygen treatment, intravenous broad-spectrum antibiotics and catecholamine was successful.

### *Related reports*

Toxic epidermal necrolysis is a severe adverse drug reaction, which is characterized by erythema, blisters, and/or erosions of the mucous membranes and skin in whole body, but intestinal involvement is rare reported.

### *Experiences and lessons*

Pneumatosis cystoides intestinalis can be observed during the treatment course of toxic epidermal necrolysis and conservative management is possibly effective when there are no signs of ischemia or necrosis of the intestine.

### *Peer review*

This is an interesting case report of pneumatosis cystoides intestinalis associated with toxic epidermal necrolysis. The manuscript is clearly written, and this unusual presentation has clinical relevance.

## Abstract

The champagne bottle neck (CBN) sign refers to a reduction in the diameter of the proximal portion of the internal carotid artery that resembles a CBN, and is a characteristic feature of Moyamoya disease. A 43-year-old woman with an infarction of the posterior limb of the left internal capsule was diagnosed with Moyamoya syndrome associated with Graves' disease. The CBN sign was observed bilaterally. Cerebral revascularization surgery was performed, including left-sided superficial temporal artery to middle cerebral artery anastomosis. During four years of follow-up, she maintained a euthyroid state and did not have any further cerebral ischemic events. The CBN signs remained unchanged on both sides during this time. This is the first report of the CBN sign in a patient with Moyamoya syndrome associated with Graves' disease.

**Key words:** Champagne bottle neck sign; Moyamoya disease; Moyamoya syndrome; Graves' disease; Revascularization

**Core tip:** The champagne bottle neck (CBN) sign reflects a reduction in the diameter of the proximal portion of the internal carotid artery that resembles a CBN, and is a characteristic feature of Moyamoya disease. This case describes the first report of bilateral CBN signs in a 43-year-old woman diagnosed with Moyamoya syndrome associated with Graves' disease. Cerebral revascularization surgery was performed on the patient, and the CBN signs remained unchanged throughout four years of follow-up.

## INTRODUCTION

Moyamoya disease (MMD) is a cerebrovascular disorder characterized by progressive bilateral stenosis or occlusion of the distal portion of the internal carotid artery (ICA) and proximal portions of the middle cerebral artery (MCA) and anterior cerebral artery (ACA), together with the formation of net-like collateral vessels in the basal ganglia[1,2]. The rarely observed vasculopathy that is characteristic of this disease is seen associated with pathologic conditions such as arteriosclerosis, Down's syndrome, von Recklinghausen's disease, and X-ray irradiation in Moyamoya syndrome (MMS)[3]. Several cases of Moyamoya vasculopathy associated with Graves' disease have been reported[4-7]. Graves' disease is a female-dominant autoimmune thyroid disease characterized by the formation of autoantibodies to thyroid-stimulating hormone (TSH) receptors, resulting in continuous stimulation of the thyroid gland and hyperthyroidism[4].

In 2006, Yasaka *et al*[8] reported that ultrasonography in patients with MMD showed a rapid reduction in the diameter of the proximal ICA to less than half of the

diameter of the common carotid artery, giving the appearance of a champagne bottle neck (CBN). The CBN sign occurred in 74% of patients with MMD, but has not been reported in patients with MMS. We report a case involving a patient with MMS associated with Graves' disease, in whom the CBN sign was observed. The results of long-term follow-up after cerebral revascularization surgery are also presented.

## CASE REPORT

A 43-year-old Japanese woman presented with weakness of the right extremities, which she first noticed when she awoke in the morning. She had a six-month history of fatigue and weight loss. On admission, her blood pressure was 117/72 mmHg and her heart rate was 125 beats/min. Physical examination revealed a right-sided carotid bruit. No goiter or exophthalmos was observed. A neurologic examination showed mild right hemiparesis and dysarthria.

Laboratory data demonstrated hyperthyroidism with a TSH level of 0.015 μU/mL (normal range: 0.35-4.94 μU/mL), free T3 level of 26.42 pg/mL (normal range: 1.71-3.71 pg/mL), and free T4 level of 4.37 ng/dL (normal range: 0.70-1.48 ng/dL). Her TSH receptor antibody level was 36.7% (normal: < 15%). Ultrasonography of the thyroid gland showed a diffuse goiter, and thyroid scintigraphy was positive. She was diagnosed with hyperthyroidism due to Graves' disease, and antithyroid drug treatment with methimazole and potassium iodide was started.

Diffusion-weighted magnetic resonance imaging on admission showed a hyperintense area at the left posterior limb of the internal capsule (Figure 1A). Magnetic resonance angiography (MRA) and three-dimensional computed tomography angiography showed bilateral severe stenosis of the distal ICA and proximal MCA and ACA (Figure 1B). Digital subtraction angiography showed Moyamoya vessels in the left basal ganglia and bilateral stenosis of the distal ICA and proximal MCA and ACA (Figure 1C). No Moyamoya vessels were observed on the right side. Bilateral narrowing of the proximal ICA consistent with the CBN sign was also observed on digital subtraction angiography (Figure 1D), three-dimensional computed tomography angiography (Figure 1E), and ultrasonography (Figure 1F).

The patient was diagnosed with an acute infarction of the posterior limb of the internal capsule due to Moyamoya syndrome (Suzuki stage 3 on the right side and stage 1 on the left side[4]) associated with Graves's disease. She was treated with ozagrel, edaravone and heparin, and subsequently with aspirin and warfarin. Antithyroid drug treatment with methimazole and potassium iodide was continued.

The patient's right hemiparesis and dysarthria were resolved two months later. She had experienced no additional cerebral ischemic events and was euthyroid with a TSH level of < 0.016 μU/mL and a free T3 level of 3.02 pg/mL. MRA showed no change in the bilateral CBN signs (Figure 1G) or the bilateral severe stenosis of the distal ICA and proximal MCA and ACA. Single-photon emission computed tomography with N-isopropyl-p-[$^{123}$I]-iodoamphetamine (IMP-SPECT) showed a markedly compromised vascular reserve in the left MCA territory and slightly decreased cerebral blood flow (41.69 and 43.80 mL/100 g/min in the left and right MCA territories, respectively). The regional cerebrovascular reactivity after acetazolamide loading was 7.10% in the left MCA territory and 11.79% in the right MCA territory.

To treat the perfusion insufficiency in the left MCA territory, left superficial temporal artery to MCA anastomosis, encephalo-duro-arterio-synangiosis and encephalo-myo-synangiosis were performed. The antiplatelet and anticoagulation medications were discontinued postoperatively.

MRA at one month after the cerebral revascularization surgery showed a patent bypass (Figure 1H). There was no change in the bilateral stenosis of the distal ICA and proximal MCA and ACA. IMP-SPECT showed that cerebral blood flow was improved in the left MCA territory (45.75 and 44.41 mL/100 g/min in the left and right MCA territories, respectively) and that regional cerebrovascular reactivity was improved in the left MCA territory (13.07% and 17.45% in the left and right MCA territories, respectively).

During four years of follow-up after surgery, the patient's euthyroid state was maintained with antithyroid therapy and she experienced no additional cerebral ischemic events. An MRA at four years after surgery showed no change in the bilateral CBN signs (Figure 1I).

## DISCUSSION

Although the CBN sign is a characteristic feature of MMD[8], no previous reports have described the clinical significance of this sign or the specific underlying pathophysiologic mechanisms. Histopathologic examination shows eccentrically laminated thickening of the intima of the major intracranial arteries in patients with MMD[9]. Fibrocellular intimal thickening is also observed in other arteries such as the extracranial ICAs, external carotid arteries, pulmonary arteries, renal arteries and coronary arteries[10-12]. At the carotid bifurcation, there is a transitional zone between the elastic portion of the carotid arteries (located > 5 mm proximal to the bifurcation) and the muscular portion of the carotid arteries (located > 15 mm distal to the bifurcation)[13,14]. It is speculated that the muscular portion is more commonly affected than the elastic portion because of its thinner intimal membrane[13], and that the stenosis extends from the distal to the proximal ICA. The narrowing at the transitional zone results in the CBN sign.

This is the first report of the CBN sign in a patient with MMS. Although the association between MMS and Graves' disease is not well understood[3-7], it has been hypothesized that the increased vascular reactivity resulting

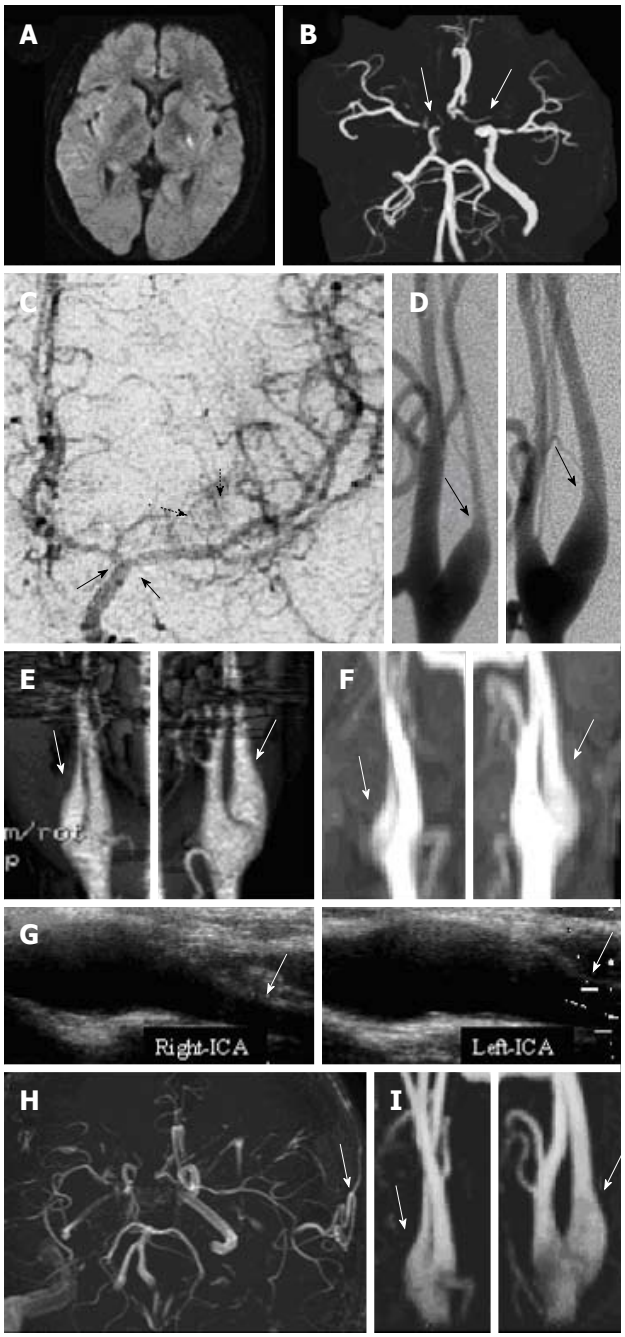

**Figure 1 Imaging results.** A: Diffusion-weighted magnetic resonance imaging three hours after the onset of right hemiparesis revealed a hyperintense area in the posterior limb of the left internal capsule; B: Magnetic resonance angiography (MRA) showing bilateral severe stenosis of the distal portion of the internal carotid artery (ICA) and proximal portions of the middle cerebral artery (MCA) and anterior cerebral artery (ACA); C: Left carotid angiography (anteroposterior view), showing Moyamoya-like vascular changes around the circle of Willis (black dotted arrows) as well as stenosis of the distal left ICA and proximal left MCA and ACA (black arrows); Bilateral champagne bottle neck (CBN) signs at the proximal ICAs (arrows) were observed with D: Digital subtraction angiography; E: Three-dimensional computed tomography angiography; and F: Ultrasonography; G: MRA in the euthyroid state, showing no changes in the bilateral CBN signs (white arrows); H: MRA at four years after superficial temporal artery to MCA anastomosis, showing that the anastomosis remained patent (white arrow); I: No change was observed in the bilateral CBN signs after four years (white arrows)

from hyperthyroidism causes damage to the arterial wall, leading to MMD[15-17]. The CBN sign may reflect intimal thickening of the extracranial ICA.

In the series of patients with MMD reported by Yasaka *et al*[8], the relationships among the stage of MMD, the presence of the CBN sign, and chronologic changes in the CBN sign, were not reported. In our patient, the stage of MMS was more advanced on the left (the symptomatic side) than on the right. Moyamoya vessels were not observed on the right side, and perfusion reserve was impaired in the left MCA territory. However, the CBN sign was observed equally on both sides, and did not change between the hyperthyroid and euthyroid states. During the four years after cerebral revascularization surgery, no changes were observed in the CBN signs. It has previously been reported that Moyamoya-like vascular changes and stenosis of the intracranial arteries and do not occur in patients with MMS associated with Graves' disease after antithyroid treatment and cerebral revascularization[3-5,18]. Likewise, the changes causing the CBN sign are irreversible.

## COMMENTS

### *Case characteristics*

A 43-year-old Japanese woman presented with weakness of the right extremities and had a six-month history of fatigue and weight loss.

### *Clinical diagnosis*

The patient's heart rate was 125 beats/min and a neurologic examination showed mild right hemiparesis and dysarthria.

### *Differential diagnosis*

Brain infarction; Intracerebral hemorrhage; Brain tumor.

### *Laboratory diagnosis*

Laboratory data demonstrated hyperthyroidism with a thyroid-stimulating hormone level of 0.015 μU/mL, free T3 level of 26.42 pg/mL, free T4 level of 4.37 ng/dL, and a thyroid-stimulating hormone receptor antibody level of 36.7%.

### *Imaging diagnosis*

Diffusion-weighted magnetic resonance imaging on admission showed a hyperintense area at the left posterior limb of the internal capsule, and digital subtraction angiography showed Moyamoya vessels in the left basal ganglia and bilateral stenosis of the distal internal carotid artery and proximal middle and anterior cerebral arteries. Bilateral narrowing of the proximal internal carotid artery consistent with the champagne bottle neck (CBN) sign was also observed on three-dimensional computed tomography angiography and ultrasonography.

### *Pathological diagnosis*

The patient was diagnosed with acute infarction of the posterior limb of the internal capsule due to Moyamoya syndrome associated with Graves's disease.

### *Treatment*

Revascularization was performed following antithyroid drug treatment.

### *Related reports*

Ultrasonography in patients with Moyamoya disease showed a rapid reduction in the diameter of the proximal internal carotid artery to less than half of the diameter of the common carotid artery (giving the appearance of a CBN), although the relationships among the disease stage, presence of the CBN sign, and chronologic changes in the CBN sign were not reported.

### *Experiences and lessons*

The CBN signs were not affected by the change between the hyperthyroid and euthyroid states. Furthermore, no changes in the CBN signs were observed after cerebral revascularization surgery, demonstrating their irreversibility.

### *Peer review*

This is the first report of the CBN sign in a patient with Moyamoya syndrome associated with Graves' disease.

## Abstract

As per strict criteria of Das Gupta *et al*, primary splenic lymphoma is very rare. Herein, we are reporting an unusual case of primary large cell splenic lymphoma of B lineage in a middle aged female presenting with massive splenomegaly (3.8 kg) and hypersplenism. After performing therapeutic splenectomy for hypersplenism, a precise diagnosis of diffuse large B cell lymphoma was made on histopathology and confirmed by immunohistochemistry. The patient responded well to standard (Cyclophosphamide, Hydroxydaunorubicin, Oncovin (vincristine), Prednisone or prednisolone) regimen last year and is now in full remission. The splenectomy thereby has prevented the potential grave complications related to hypersplenism and splenic rupture. Our aim behind highlighting the topic is to specify that emergency splenectomy followed by anticoagulation therapy is an effective plan of management to prevent untoward complications related to disease and treatment.

**Key words:** Huge splenic lymphoma; Pancytopenia; Splenectomy; Anticoagulation

**Core tip:** Primary splenic lymphoma is a rare entity, can present with grave complications like hypersplenism and splenic rupture. In such circumstances, emergency splenectomy is an effective therapeutic and diagnostic tool. Now a days laparoscopic splenectomy is emerging because of minimal complications. Postoperative anticoagulation is important to prevent portal splenic vein thrombosis.

## INTRODUCTION

Primary splenic lymphoma is a very unusual entity if strict diagnostic criteria proposed by Das Gupta *et al*[1] are applied. According to their views diagnosis of Primary Splenic Lymphoma should be made when the disease is confined to spleen or at the most involves hilar lymph nodes with no recurrence of disease after splenectomy[1,2]. Herein, we present such an unusual case of Primary Splenic Lymphoma of diffuse large B cell type diagnosed on histopathology and confirmed by immunohistochemistry in a patient presenting with massive splenomegaly and hypersplenism. Splenectomy was followed by anticoagulation therapy and chemotherapy [with standard Cyclophosphamide, Hydroxydaunorubicin, Oncovin (vincristine), Prednisone or prednisolone (CHOP) regimen]. The patient responded well and as on today, is in complete remission preventing grave complications of disease and splenectomy thus justifying both diagnostic and therapeutic utility of splenectomy and effective anticoagulation therapy is must to prevent portal vein splenic

vein thrombosis(PVST).

## CASE REPORT

A 41-year-old female, complained of weight loss and abdominal pain. She was afebrile and physical examination revealed no palpable peripheral lymphadenopathy. Head and neck examination revealed moderate anemia, no jaundice and a clear oropharynx. Heart and lung examination were normal. She had a protuberant abdomen with a firm palpable spleen that extended below the navel. There was no ascites or hepatomegaly. Abdominal ultrasonography and plain computed tomography scanning showed massive splenomegaly without a mass lesion (Figure 1). Blood examination revealed pancytopenia: WBC 1.9 × $10^9$/L (neutrophils 48.0%, eosinophils 0%, basophils 0%, monocytes 4.0%, lymphocytes 48.0%), Hb 10.3 g/dL, platelet count 99 × $10^9$/L, LDH 127 U/L (normal range 100-220 U/L). Air-dried peripheral blood smear showed no abnormal lymphocytes including hairy cells or villous lymphocytes. Liver and renal functions were within normal limits. Bone marrow aspiration and biopsy revealed normocellular bone marrow without abnormal cell involvement, fibrosis, dysplasia or hemophagocytosis. Liver cirrhosis and idiopathic portal hypertension were ruled out. Whole body computed tomography (CT) scanning revealed no abnormal lesions in other organs. Therefore, emergency splenectomy was planned and performed. The operation progressed without complications. The resected spleen weighed 3.8 kg. The cut surface was almost totally effaced by a huge greywhite homogenous tumor soft rubbery in consistency (Figures 2 and 3) Microscopy revealed diffuse proliferation of monotonous population of large neoplastic lymphoid cells [Large B cell lymphoma (DLBCL)] (Figure 4) , The tumor cells were immunopositive for CD 20 and immunonegative for T cell markers (Figure 5). Intraoperative findings did not reveal any lymph node swelling or tumor. Therefore, the patient was diagnosed as stage I splenic lymphoma. Four days after the operation, the patient recovered from the pancytopenia: WBC of 7.6 × $10^9$/L, Hb 13.0 g/dL and platelet count 330 × $10^9$/L although CRP increased to 8.21 mg/dL owing to postoperative infection. 24 h after surgery, received subcutaneous injection of LMWH (Low Molecular Weight Heparin) routinely, 0.3 mL per 12 h for 5 d and then maintained by oral therapy with warfarin for one month to keep the target prothrombin time/international normalized ratio (PT/INR) at a level between 1.25 and 1.5 to prevent PSVT.

Three courses of standard CHOP plus rituximab chemotherapy were given. Complete remission has continued for 12 mo post operatively without any grave complications related to disease and splenectomy. Thus, the case was finally confirmed as primary splenic lymphoma of B

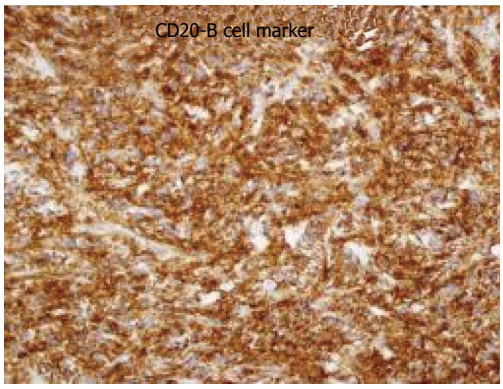

**Figure 5 CD20 positive lymphoid cells.**

cell lineage as per the strict criteria of Das Gupta *et al*[1].

## DISCUSSION

Primary lymphoma of the spleen is very rare if strict criteria for diagnosis suggested by Das Gupta *et al*[1] are applied[2].

Solitary splenic non Hodgkin Lymphoma (NHL) is rare; the incidence is less than 1%[3]. Some solitary lymphomas cannot be discerned by plain CT scanning alone or US alone. Consequently, enhanced CT scanning and Gallium scintigraphy are absolutely required to identify splenic tumor. Splenectomy is often chosen to diagnose solitary splenic lymphoma.

However, several previous reports discussed the risk of splenectomy for massive (greater than 1500 gm) splenomegaly. Splenectomy for massive splenomegaly showed a high rate of perioperative mortality (about 20%[4,5]. In some cases with poor general status, bleeding tendency, complications due to infection or organ failure, one should be hesitant to use an invasive diagnostic method. On the other hand, splenic needle biopsy may provide an adequate diagnosis without severe complications. Tam *et al*[6] reported percutaneous image guided splenic needle biopsy in 156 consecutive cases and concluded that splenic needle biopsy in the evaluation of new or recurrent neoplasm is a minimally invasive procedure with low complication rates and a high diagnostic yield. If it is institutionally and technically possible, splenic needle biopsy should be taken into consideration for high risk patients[6]. Recently, laparoscopic splenectomy has often been used for splenic masses because of fewer complications and since it is rather appropriate for moderate splenomegaly[7,8].

This patient underwent splenectomy because she had no complications. Splenectomy was done to: (1) establish a correct pathological diagnosis; (2) reduce the hypersplenism; (3) reduce the radiation field; (4) relieving symptoms; and (5) prevent splenic rupture and prevented PSVT with effective anticoagulant therapy

Generally speaking,the localized indolent lymphoma is expected to have good prognosis despite the absence of further treatment with chemotherapy. In contrast, most cases of aggressive lymphoma such as DLBCLs show disease expansion and progression, requiring immediate chemotherapy. It is speculated that the high rate of perioperative mortality in massive splenomegaly could be due to rapid progression of disease and such patients should be subjected to less invasive diagnostic methods and treated immediately.

Splenic lymphoma and splenomegaly secondary to lymphoma or other hematological malignancies are often reported as a cause of hypersplenism and the cytopenias resolved after splenectomy in most cases[4,9]. Therefore ,splenectomy is useful not only for diagnosis but also for treatment of the underlying hematologic malignancy.

It is an unusual case of primary splenic lymphoma presenting with massive splenomegaly (3.8 kg) and hypersplenism. In such a critical clinical situation, clinician should keep in mind splenectomy supported by anticoagulation therapy as an effective therapeutic and diagnostic method to prevent grave complications related to disease (hypersplenism, splenic rupture) and splenectomy, *i.e.*, PSVT that could prove fatal. Recently splenic needle biopsy can be used to diagnose the condition earlier.

## COMMENTS

### *Case characteristics*

Massive splenomegaly, hypersplenism.

### *Clinical diagnosis*

Primary splenic lymphoma presenting with huge splenic mass and hypersplenism.

### *Differential diagnosis*

Causes of hypersplenism, lymphoma, leukemia, Malaria, Kala azar.

### *Laboratory diagnosis*

Hypersplenism presenting with thrombocytopenia.

### *Imaging diagnosis*

Computed tomography scan revealing massive splenomegaly without mass lesion.

### *Pathological diagnosis*

Biopsy findings are confirmatory for diffuse large B cell lymphoma.

### *Treatment*

Emergency splenectomy is an effective therapeutic and diagnostic tool in such critical circumstances.

### *Peer review*

This manuscript is very interesting.

## Abstract

Cranial defects often occur due to trauma. The treatment of such defects is a challenge to the skill and knowledge of the practitioner. This article presents one such case, where a 15-year-old boy had suffered extensive loss of the right cranium following a road traffic accident. The patient required rehabilitation of the right fronto-temporal cranial anatomy and was managed using a custom made heat polymerized acrylic alloplastic implant.

**Key words:** Cranioplasty; Cranial implant; Acquired defect; Heat cure poly methyl methacrylate resin

**Core tip:** Prefabricated heat-polymerized acrylic prosthesis, offers the benefits of reducing the tissues to residual monomer or the heat of polymerization. The other advantages are low content of residual monomer in prosthesis because of long curing cycle and prolonged immersion in water. Old orthopantomogram films were used during impression. It is an easy and economical method for recording the defect. In order to reduce the bulk of the prosthesis, the defect area was contoured with plaster. After try in, the wax pattern was covered with an aluminum foil, to check the contour radiographically. Gutta percha points were incorporated as radiopaque marker.

## INTRODUCTION

The loss of a body part reflects significantly on a patient's life. Not only does it have a huge influence on their physical and mental state, it makes social integration difficult; often dampening their expectations to return to normalcy.

Cranial defects may result from trauma, disease or due to congenital malformations. Repair of cranial defects is indicated to protect the underlying brain tissue, provide pain relief at the defect site, improve aesthetics and minimize patient anxiety[1,2]. Humans lack the ability to regenerate a lost body part, but reconstruction can be achieved through prosthetic means and a multidisciplinary approach.

Cranioplasty is one of the oldest known neurosurgical procedures, dating back to 3000 B. C.[3,4]. For centuries, various materials have been tried for covering bony de-

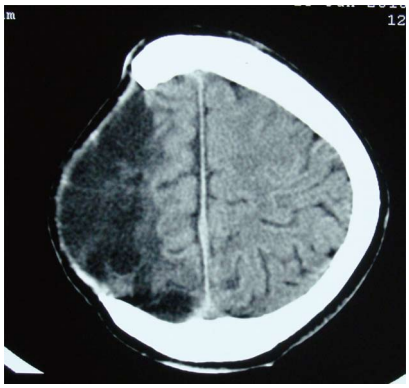

**Figure 1 Computed tomography scan showing right cranial defect.**

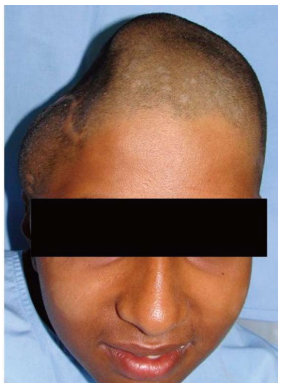

**Figure 2 Frontal view of the cranial defect.**

fects, including coconut shells, bones from both human and non-human donors, metals[5,6] and more recently, biosynthetic materials such as resins and ceramics.

Cranioplasty can be performed using a range of procedures. When plastic materials are used, the main requirement for an effective cranioplasty, is the preoperative shaping of the implant to fit the bony defect precisely[7]. Acrylic cranioplasty is frequently used for patients who have a cranial defect after trauma or an infected craniotomy or meningiomas[8,9]. Two basic methods of cranioplasty are widely accepted - osteoplastic reconstruction and restoration with alloplastic material. This article describes a patient whose cranial defect has been restored with a prefabricated acrylic resin prosthesis.

## CASE REPORT

A 15 years old male patient was referred to the Department of Prosthodontics, from the Department of Neurosurgery for the management of an acquired cranial defect. The patient had a significant medical history of a road traffic accident (RTA), resulting in an open head injury with right temporo-parietal contusion and a fracture of the squamous part of the temporal bone. The patient was treated immediately with a right fronto-temporo parietal craniotomy by the neurosurgeons (Figure 1). Postoperatively it was found that the patient had a lateral hemiplegia on the left side and a large bony defect on the

**Figure 3 Patient preparation before impression making.**

right side of the skull (Figure 2). On examination, the defect was found to be 15 cm × 12 cm in size. The defect that was to be restored was large and a CAD/CAM or a metal prosthesis would have been the most probable option, but considering the economic background of the patient, a custom-made heat-cured acrylic resin cranial prosthesis was planned.

### *Procedure*

The construction of any maxillofacial prosthesis with alloplastic material consists of four stages, each of which is equally important to the success of the rehabilitation effort. These stages include moulage impression and working cast fabrication, Sculpture and formation of the pattern, mould fabrication, and processing of the prosthesis[10]. Patch testing for acrylic was done prior to the prosthesis fabrication to rule out any acrylic allergy[11]. (1) The patient preparation for impression was done by covering the eye and the external auditory meatus with gauze to prevent the ingress of material into the palpebral fissure and the ear canal respectively (Figure 3): (2) Because of the large defect, old orthopantomograms were used as a tray, to confine the impression material during the impression procedure; (3) The defect was outlined and an impression of the defect was made with irreversible hydrocolloid (Dentsply Zelgan Plus irreversible hydrocolloid, India). L-shaped paper clips were inserted for the stabilization of plaster of Paris which was used for reinforcement of the impression material; (4) Once the impression material was set, it was removed carefully and poured with dental stone (Kalstone, laboratory stone, Kalabhai, Mumbai, India) to obtain a cast of the defect (Figure 4); (5) The outline of the defect was marked for the fabrication of onlay type of cranial prosthesis. The marked stone cast was contoured with plaster of Paris so as to obtain the arbitrary shape of the cranium, and a wax pattern (Hindustan dental product, Hyderabad, India) was fabricated over the contoured cast. The wax pattern was then tried on the patient (Figure 5); (6) The contour of the wax pattern was corrected from all sides viz. the frontal, sagittal and occipital, to restore the normal contour and appearance. After the try-in of the wax pattern on the defect, the contours were verified radio-

**Figure 4 Tissue surface of the impression with defect marking.**

**Figure 6 Radiographic verification of the wax pattern.**

**Figure 5 Wax pattern try in.**

**Figure 7 Try in of final heat cure alloplastic cranial implant.**

graphically, by covering the wax pattern with aluminum foil. (Caremate Aluminium foil, Maharashtra India) (Figure 6); (7) The contoured wax pattern was then invested in a maxillofacial flask, using plaster of paris. It was dewaxed using boiling water for 4 min[12]; (8) Following this, clear heat cure acrylic resin (Trevalon, denture base materials, Dentsply India) was packed in the mold space and was then cured using a constant temperature water bath at 74 ℃ for 10 h[13]. A long curing cycle was selected in order to reduce the residual monomer content of the cured prosthesis; (9) The processed prosthesis was removed from the flask carefully. The excess was trimmed and the prosthesis was polished, using pumice and cotton buff. Trial of the contoured and polished prosthesis was done on the patient and checked from all the anatomical aspects (the frontal, sagittal and occipital) (Figure 7); (10) The prosthesis was sterilized with ethylene oxide gas prior to the insertion; (11) The surgical procedure involved the preparation of the scalp with an antiseptic solution and the reflection of the scalp with a U shaped incision to completely expose the bony margins of the defect; (12) Adjustment of the prosthesis was done with an acrylic trimmer so as to fit as closely as possible in the cranial defect. The prosthesis was then secured with titanium plates and screws (Surgiwear, Sharjahanpur, India) to the surrounding bony margins and the defect was then closed (Figure 8); (13) The closed system suction drain (Hemovac, Zimmer United States) was placed immediately after the surgery to reduce the postoperative hematoma; (14) The drain was removed on the 2nd postoperative day and the patient had a good recovery (Figures 9 and 10); (15) The patient and parents were instructed for the care of the reconstructed area; and (16) During the follow-up visits (6 mo, 1 year and 1½ years), the contour of the defect was satisfactory from all the anatomical aspects (Figures 11-13).

## DISCUSSION

Cranioplasties have been performed since the early 1950s[10]. Acrylic resin materials have been used as bone substitutes in dentistry, neurosurgery and orthopedic surgery for decades. Interest in acrylic resins among neurosurgeons increased considerably following Spence's 1954 report of a simple method for fabricating implants at the time of surgery, using auto polymerizing methyl methacrylate[14]. Acrylic implants are dimensionally stable, non-conductive, inexpensive, and can be easily modified and placed[15]. Acrylic resin has some advantages over metal substances; it is easy to shape, lighter in weight, radiates less heat, and radiolucent[16]. In a study, Kumar *et al*[17] in 2011, have proved that large defects, like war defects, can be successfully restored with alloplastic materials. A prefabricated implant can save valuable time in the operating room and better cosmetic results can be achieved, since any adjustments required can be made before the patient

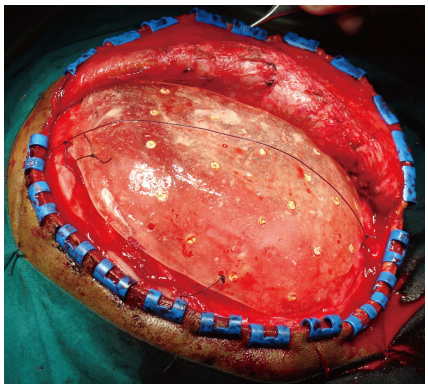

**Figure 8 Placement and suturing of the final prosthesis.**

**Figure 11 Restored cranial defect.**

**Figure 13 Follow up frontal profile.**

undergoes surgery. Fabricating cranial implants before surgery, using moulds and heat-polymerized methyl methacrylate, offers the benefits of using auto polymerizing acrylic resin, without exposing the tissues to residual monomer or the heat of polymerization[18,19]. Heat-polymerized resin is 50% stronger than auto polymerizing resin[20] and contains less than 0.3% residual monomer. Excess free monomer is removed because of the long curing cycle and preparation before implantation. Apart from these advantages, in the present case report, old orthopantomogram films were used during impression. This was an easy and economical method for recording the defect. In order to reduce the bulk of the prosthesis, the defect area of the master cast was contoured with plaster. After try in, the wax pattern was covered with an aluminum foil, which made it possible to check the contour of the prosthesis radiographically. Gutta percha points were incorporated in the final PMMA prosthesis so as to serve as a radiopaque marker. A patch test was performed to rule out any allergic reactions to PMMA. Lee *et al*[21] in 2009 suggested that the infection rate associated with prefabricated PMMA prostheses was lower than that for intra-operatively molded PMMA prostheses and was comparable to that for auto graft bone flaps. Complications such as swelling, infection[18,22] headache, hemianopia were not seen during the follow up period

of one and a half years duration for the same patient Other complications such as implant mobilisation[23] were also not reported by the patient. Recently, CAD CAM generated cranial prostheses or titanium plates have been introduced for a precise fit[24-28] however, the high cost of these prostheses makes their use rare in patients, due to economic reasons.

Prefabricated custom made craniofacial prostheses simplify the restoration of complex cranial defects, reduce the surgical time necessary for implant placement and decrease the risk of contamination that can occur when large implants are shaped intraoperatively. Cranioplasty with prefabricated poly-methyl methacrylate prosthesis is inexpensive and enables shorter operative time with good esthetic results.

## COMMENTS

### *Case characteristic*

Patient had a lateral hemiplegia on the left side and a large bony defect on the right side of the skull.

### *Clinical diagnosis*

Fifteen cm × 12 cm size cranial defect after right fronto-temporo parietal craniotomy.

### *Imaging diagnosis*

Computed tomography, Orthopantomogram showed right fronto-temporo parietal craniotomy defect

### *Treatment*

Prosthetic rehabilitation of the cranial defect with custom made alloplastic heat cure acrylic implant.

### *Related reports*

A 15 years old male patient was referred to the Department of Prosthodontics, from the Department of Neurosurgery for the management of an acquired cranial defect. The patient had a significant medical history of a road traffic accident (RTA), resulting in an open head injury with right temporo-parietal contusion and a fracture of the squamous part of the temporal bone. The patient was treated immediately with a right fronto-temporo parietal craniotomy by the neurosurgeons. Post-operatively it was found that the patient had a lateral hemiplegia on the left side and a large bony defect on the right side of the skull. On examination, the defect was found to be 15 cm × 12 cm in size. The defect was restored with a custom-made heat-cured acrylic resin cranial prosthesis.

### *Term explanation*

Craniotomy-surgical removal of a portion of the skull. Cranioplasty is a surgical repair of a defect or deformity of a skull. Alloplastic: graft of a relatively inert synthetic material. Generally metal, ceramic or polymeric material. Facial Moulage: face impression

### *Innovations and breakthroughs*

A prefabricated implant can save valuable time in the operating room and better cosmetic results can be achieved. Fabricating cranial implants before surgery, using moulds and heat-polymerized methyl methacrylate, offers the benefits of using auto polymerizing acrylic resin, without exposing the tissues to residual monomer or the heat of polymerization. Heat-polymerized resin is 50% stronger than auto polymerizing resin and contains less than 0.3% residual monomer. Excess free monomer is removed because of the long curing cycle and preparation before implantation. In the present case report, old orthopantomogram films were used during impression. This was an easy and economical method for recording the defect. In order to reduce the bulk of the prosthesis, the defect area of the master cast was contoured with plaster. After try in, the wax pattern was covered with an aluminum foil, which made it possible to check the contour of the prosthesis radiographically. Gutta percha points were incorporated in the final PMMA prosthesis so as to serve as a radiopaque marker.

### *Peer review*

This case report provided a good example of the method being used in clinical practice with 18 mo clinical follow-up. The case is particularly well documented with extensive figures and photographs.

## Abstract

Diabetic patients frequently develop a constellation of electrolyte disorders. These disturbances are particularly common in decompensated diabetics, especially in the context of diabetic ketoacidosis or nonketotic hyperglycemic hyperosmolar syndrome. These patients are markedly potassium-, magnesium- and phosphate-depleted. Diabetes mellitus (DM) is linked to both hypo- and hyper-natremia reflecting the coexistence of hyperglycemia-related mechanisms, which tend to change serum sodium to opposite directions. The most important causal factor of chronic hyperkalemia in diabetic individuals is the syndrome of hyporeninemic hypoaldosteronism. Impaired renal function, potassium-sparing drugs, hypertonicity and insulin deficiency are also involved in the development of hyperkalemia. This article provides an overview of the electrolyte disturbances occurring in DM and describes the underlying mechanisms. This insight should pave the way for pathophysiology-directed therapy, thus contributing to the avoidance of the several deleterious effects associated with electrolyte disorders and their treatment.

**Key words:** Glucose; Osmotic diuresis; Hyponatremia; Hyperkalemia; Hypomagnesemia

**Core tip:** Diabetic patients frequently develop a constellation of electrolyte disorders. These patients are often potassium-, magnesium- and phosphate-depleted, especially in the context of diabetic ketoacidosis or nonketotic hyperglycemic hyperosmolar syndrome. Diabetes is linked to both hypo- and hyper-natremia, as well as to chronic hyperkalemia which may be due to hyporeninemic hypoaldosteronism. This article provides an overview of the electrolyte disturbances occurring in diabetes and describes the underlying mechanisms. This insight should pave the way for pathophysiology-directed therapy, thus contributing to the avoidance of the several deleterious effects associated with electrolyte disorders and their treatment.

## INTRODUCTION

Electrolyte disorders are common in clinical practice. They are mainly encountered in hospital populations occurring in a broad spectrum of patients (from asymptomatic to critically ill) and being associated with increased morbidity and mortality[1-3]. The disturbances of electrolyte homeostasis are also frequently observed in community subjects. Community-acquired electrolyte disorders, even chronic and mild, are related to poor prognosis[3]. Electrolyte disorders are usually multifactorial in nature. Various pathophysiological factors, such as nutritional status, gastrointestinal absorption capacity, coexistent acid-base abnormalities, pharmacological agents, other comorbid diseases (mainly renal disease) or acute illness, alone or in combination, play a key role.

Diabetes mellitus (DM) is included among the diseases with increased frequency of electrolyte abnormali-

**Table 1 Principal causes of electrolyte disorders in diabetic patients**

| |
|---|
| Sodium disorders[1] |
| Hyponatremia |
| Pseudohyponatremia (marked hyperlipidemia) |
| Hyperglycemia (hypertonicity)-induced movement of water out of the cells (dilutional hyponatremia) |
| Osmotic diuresis-induced hypovolemic hyponatremia |
| Drug-induced hyponatremia: hypoglycemic agents (chlorpropamide, tolbutamide, insulin) or other medications (*e.g.*, diuretics, amitriptyline) |
| Pseudonormonatremia (marked hyperlipidemia, severe hypoproteinemia) |
| Hypernatremia |
| Pseudohypernatremia (severe hypoproteinemia) |
| Loss of water in excess of sodium and potassium (osmotic dieresis), if this water loss is replaced insufficiently |
| Potassium disorders |
| Hypokalemia |
| Shift hypokalemia: insulin administration |
| Gastrointestinal loss of $K^+$: malabsorption syndromes (diabetic-induced motility disorders, bacterial overgrowth, chronic diarrheal states) |
| Renal loss of $K^+$: osmotic diuresis, hypomagnesemia, diuretics (thiazides, thiazide-like agents, furosemide) |
| Hyperkalemia |
| Shift hyperkalemia: acidosis, insulin deficiency, hypertonicity, rhabdomyolysis, drugs (*e.g.*, beta blockers) |
| Reduced glomerular filtration of $K^+$: acute and chronic kidney disease |
| Reduced tubular secretion of $K^+$: hyporeninemic hypoaldosteronism, drugs (angiotensin-converting enzyme inhibitors, angiotensin Ⅱ receptor blockers, renin inhibitors, beta blockers, potassium-sparing diuretics) |
| Magnesium disorders |
| Hypomagnesemia |
| Pseudohypomagnesemia: hypoalbuminemia |
| Shift hypomagnesemia: insulin administration |
| Poor dietary $Mg^{2+}$ intake |
| Gastrointestinal $Mg^{2+}$ losses: diarrhea as a result of diabetic autonomic neuropathy |
| Increased renal $Mg^{2+}$ losses due to osmotic diuresis, glomerular hyperfiltration, diuretic administration |
| Recurrent metabolic acidosis |
| Calcium disorders |
| Hypocalcemia |
| Pseudohypocalcemia: hypoalbuminemia[2] |
| Acute renal failure due to accompanying hyperphosphatemia |
| Advanced chronic renal insufficiency due to hyperphosphatemia and low levels of vitamin D |
| Nephrotic syndrome: loss of 25-hydroxyvitamin D3 and its binding protein in the urine |
| Hypomagnesemia |
| Vitamin D deficiency |
| Drug-mediated: loop diuretics |
| Hypercalcemia |
| Concurrent hyperparathyroidism |
| Thiazide therapy |
| Phosphorus disorders |
| Hypophosphatemia |
| Osmotic diuresis |
| Drugs: thiazides, loop diuretics, insulin |
| Malabsorption syndromes |
| Primary hyperthyroidism |
| Vitamin D deficiency |

[1]Spurious sodium disorders occur when sodium is measured with indirect ion-selective electrodes; [2]The ionized serum calcium levels are normal.

ties given that the aforementioned factors (especially impaired renal function, malabsorption syndromes, acid-base disorders and multidrug regimens) are often present in diabetics[4].

This article provides an overview of the electrolyte disturbances occurring in DM and describes possible underlying mechanisms (Table 1). This insight should pave the way for pathophysiology-directed therapy, possibly contributing to the avoidance of several deleterious effects associated with electrolyte disorders and their treatment.

## DYSNATREMIAS (HYPONATREMIA AND HYPERNATREMIA)

DM is a well-known cause of dysnatremias *via* several underlying mechanisms[3,5]. Glucose is an osmotically active substance. Hyperglycemia increases serum osmolality, resulting in movement of water out of the cells and subsequently in a reduction of serum sodium levels ($[Na^+]$) by dilution. Therefore, in hyperglycemic patients, the corrected $[Na^+]$ should be taken into account, which is calculated by adding to measured $[Na^+]$ 1.6 mmol/L for every 100 mg/dL (5.55 mmol/L) increment of serum glucose above normal; a correction factor by 2.4 mmol/L is used when serum glucose concentrations are higher than 400 mg/dL (22.2 mmol/L)[6,7]. It is worth mentioning that the corrected $[Na^+]$ after adjustment for the dilutional effect of hyperglycemia should be considered as a useful tool for the monitoring of treatment in hyperglycemic states[8]. Uncontrolled DM can also induce hypovolemic-hypo-

natremia due to osmotic diuresis. Moreover, in diabetic ketoacidosis ketone bodies (b-hydroxybutyrate and acetoacetate) obligate urinary electrolyte losses and aggravate the renal sodium wasting[7,9]. It should be emphasized, however, that hypotonic renal losses (loss of water in excess of sodium and potassium) due to osmotic diuresis can lead to hypernatremia if this water loss is replaced insufficiently. In a study in 113 hypernatremic patients hospitalized in an internal medicine clinic, poorly controlled DM was implicated in the development of hypernatremia in one third of cases (34.5%)[5]. Consequently, in patients with uncontrolled DM serum concentration of [$Na^+$] is variable, reflecting the balance between the hyperglycemia-induced water movement out of the cells that lowers [$Na^+$], and the glucosuria-induced osmotic diuresis, which tends to raise [$Na^+$].

Drug-induced hyponatremia due to hypoglycemic agents (chlorpropamide, tolbutamide, insulin) or other medications (*e.g.*, diuretics, amitriptyline for the treatment of diabetic neuropathy) should be considered in every diabetic patient with low [$Na^+$][10,11]. Chlorpropamide, which is now rarely used in the treatment of patients with DM, can induce hyponatremia in approximately 4% to 6% by potentiating the effect of antidiuretic hormone. Elderly patients concomitantly using diuretics have greater risk of developing hyponatremia[12,13]. Tolbutamide can lead to hyponatremia by decreasing renal free water clearance[13]. Noteworthy, despite fluid retention being a common adverse effect of thiazolidinediones (pioglitazone and rosiglitazone), hyponatremia related to these drugs was reported only once[14]. There is experimental evidence that glucagon-like peptide 1 receptor agonists influence water and electrolyte balance[15]. However, to the best of our knowledge, dysnatremias (or other electrolyte disorders) related to these drugs have not reported in humans. Moreover, the new class of oral antidiabetic agents known as sodium-glucose cotransporter type 2 (SGLT2) inhibitors does not appear to be associated with electrolyte abnormalities in early clinical studies[16,17].

It has been reported that DM *per se* (independently of drugs or hyperglycemia) is associated with hyponatremia[11]. Recently, in a study in 5179 community subjects aged 55 years or more DM was associated with hyponatremia (OR = 1.98; 95%CI: 1.47-2.68), with the serum glucose levels being too low to fully explain the degree of hyponatremia[3]. Altered vasopressin metabolism, interaction between insulin and vasopressin, both of which act in the renal collecting duct, and the reabsorption of more hypotonic fluid due to slower stomach emptying have been proposed as possible underlying mechanisms of this association[18-20]. Although rare, the inverse etiological relation between hyponatremia and DM also exists. In fact, brain edema in the setting of untreated symptomatic hyponatremia may induce cerebral herniation and infarction of pituitary and hypothalamus, leading to central DM and insipidus[21].

DM is also associated with an artificially decreased or elevated serum sodium value, that is different compared with the actual systemic level. In normal subjects, serum is composed of water (approximately 93%), with fats and proteins accounting for the remaining 7%. Sodium is located in the serum water phase only. A reduction in serum water fraction (< 80%) may occur in patients with marked hyperlipidemia as with lactescent serum in uncontrolled DM. In these settings, the serum sodium concentration, measured per liter of serum, not serum water, is artificially reduced (pseudohyponatremia). The presence of normal serum sodium levels in a patient with hyperlipidemia should also raise the suspicion that hypernatremia may be present (pseudonormonatremia). The opposite phenomenon of pseudohypernatremia and pseudonormonatremia may also occur as a result of severe hypoproteinemia, not infrequently observed in diabetics with nephrotic or malabsorption syndromes. In lipemic or hypoproteinemic samples the direct ion-selective electrodes (ISE) method for the measurement of serum sodium should be used, since the indirect ISE is prone to spurious dysnatremias[22].

It is known that rapid correction of serum sodium may be followed by development of central demyelinating lesions, particularly in the pons (a disorder called central pontinemyelinolysis orosmotic demyelination) with major disability or even fatal outcome[2]. Diabetics may have an increased risk for the osmotic demyelination syndrome (ODS) during correction of hyponatremia since risk factors for this disorder (thiazide diuretics, malnutrition, hypokalemia, and hypoxia)[23] are not infrequently present in such patients. Hypokalemia is also associated with a poor outcome in patients who develop the syndrome[24].

It should be emphasized that ODS is mainly observed during overly rapid correction of chronic hyponatremia. However, in diabetic patients hypernatremia and hypokalemia (in the absence of hyponatremia or hyperosmolality) are rarely associated with ODS. The mechanism by which these electrolyte disorders may cause ODS in the diabetic state is not yet known[25,26].

It has been suggested that in cases of nonketotic hyperglycemic hyperosmolar syndrome (HHS) altered mental status is predicted best by [$Na^+$]; serum glucose concentration alone is considered a poor indicator. In fact, there is evidence that hyperglycemic patients with hypertonicity are symptomatic only if hypernatremia is present[5,27]. On the contrary, neurological symptoms may be absent in the context of severe gradually developing hyperglycemia[27,28]. This could be attributed to the capacity of the brain tissue to restore intracellular water by accumulating electrolytes and the so-called idiogenic osmoles. Furthermore, the brain cells are relatively permeable to glucose even in the absence of insulin[28,29]. Therefore, hyperglycemia by itself does not create severe hypertonicity in central nervous system (CNS)[28]. On the other hand, hypernatremia induces severe cellular dehydration in CNS cells. This state is associated with a rather slow compensatory accumulation of brain osmolar content[28].

The development of hypernatremia is associated with endocrine dysfunction. There is some evidence in

animals and man that hypernatremia and hyperosmolarity are associated with impairment of both insulin-mediated glucose metabolism and glucagon-dependent glucose release[30-33]. Thus, hypernatremia and hyperosmolarity should be considered as contributing factors to the occurrence of hyperglycemia in critically ill patients[34]. Moreover, hypernatremia is implicated in the profound inhibition of gonadotrophin release in postmenopausal diabetic women with HHS. Although the underlying mechanisms remain unknown, it appears that hypernatremia induces a decrease in gonadotrophin-releasing hormone expression in GT1-7 neurons[35].

Rhabdomyolysis, though uncommon, has been described in the diabetic state[36]. It appears that high serum sodium and glucose levels represent the most important determinants for the occurrence of this complication[37].

## HYPOKALEMIA

The causes of hypokalemia in diabetics include: (1) redistribution of potassium [$K^+$] from the extracellular to the intracellular fluid compartment (shift hypokalemia due to insulin administration); (2) gastrointestinal loss of $K^+$ due to malabsorption syndromes (diabetic-induced motility disorders, bacterial overgrowth, chronic diarrheal states); and (3) renal loss of $K^+$ (due to osmotic diuresis and/or coexistent hypomagnesemia). Hypomagnesemia can cause hypokalemia possibly because a low intracellular magnesium [$Mg^{2+}$] concentration activates the renal outer medullary $K^+$ channel to secrete more $K^+$[38].

Exogenous insulin can induce mild hypokalemia because it promotes the entry of $K^+$ into skeletal muscles and hepatic cells by increasing the activity of the $Na^+$-$K^+$-ATPase pump[39]. The increased secretion of epinephrine due to insulin-induced hypoglycemia may also play a contributory role[40]. The major setting in which insulin administration leads to hypokalemia is during the treatment of severe hyperglycemia. The majority of patients with diabetic ketoacidosis (DKA) and HHS are markedly $K^+$-depleted. The average $K^+$ deficit is 3-5 mEq/kg, but it can exceed 10 mEq/kg in some cases[41,42]. A number of factors contribute to the DKA- and HHS-associated potassium depletion, including vomiting, increased renal losses due to the osmotic diuresis and ketoacid anion excretion, and the loss of $K^+$ from the cells due to glycogenolysis and proteolysis[41,43]. On admission, however, the serum $K^+$ levels are usually normal, or, in about one-third of patients, increased despite the $K^+$ depletion[41,43]. It is thought that hyperosmolality and insulin deficiency are primarily responsible for the relative rise in the serum potassium concentration in this setting. As mentioned, hyperglycemia increases serum osmolality resulting in movement of water out of cells. The loss of intracellular water leads to an increased intracellular $K^+$ concentration, favoring a gradient for $K^+$ to move out of the cells. Simultaneously, the friction forces between solvent (water) and solute can result in $K^+$ being carried along with water through the water pores in the cell membrane[43]. In contrast, acidemia probably does not play a major role given that organic acids are much less likely to influence the internal $K^+$ distribution[44]. Insulin therapy lowers $K^+$ concentration driving $K^+$ into cells (both directly and indirectly by reversing hyperglycemia). Therefore, insulin therapy may cause severe hypokalemia, particularly in patients with a normal or low serum $K^+$ concentration at presentation. Insulin administration in patients with massive $K^+$ deficits who are hypokalemic prior to therapy should be delayed until the serum $K^+$ is above 3.3 mEq/L to avoid possible arrhythmias, cardiac arrest and respiratory muscle weakness[42,45,46]. It is obvious that the risk of hypokalemia-related complications is particularly higher in diabetic subjects who have hypertension, myocardial infarction/ischemia, or heart failure as comorbidities. In addition, since diabetics are frequently on diuretics, diuretic-associated hypokalemia (as well as hypomagnesemia and hypophosphatemia) should be taken into account in this setting.

Hypokalemia is associated with impaired insulin secretion and decreased peripheral glucose utilization resulting in carbohydrate intolerance and hyperglycemia[47]. This is particularly problematic in diabetic patients causing a vicious circle where low serum $K^+$ levels lead to poorly controlled DM and vice versa.

## HYPERKALEMIA

The incidence of hyperkalemia is higher in diabetic patients than in the general population[48,49]. Redistribution of potassium from the intracellular to the extracellular compartment (shift hyperkalemia) can induce hyperkalemia with no net total body $K^+$ increase. Examples of shift hyperkalemia in DM include acidosis (for each 0.1 fall in pH, potassium increases by approximately 0.4 mmol/L), insulin deficiency, hypertonicity, cell lysis (rhabdomyolysis), and drugs (*e.g.*, beta blockers). Reduced glomerular filtration of $K^+$ (due to acute kidney injury and chronic kidney disease) and many drugs that interfere with $K^+$ excretion are associated with hyperkalemia. These include angiotensin-converting enzyme inhibitors, angiotensin Ⅱ receptor blockers, renin inhibitors, beta blockers and potassium-sparing diuretics. Of note, the typical healthy diabetic diet is often rich in $K^+$ and low in sodium contributing to the occurrence of hyperkalemia in susceptible individuals[48,49]. Nevertheless, the most common causal factor of chronic hyperkalemia in diabetics is the reduced tubular secretion of $K^+$ due to the syndrome of hyporeninemic hypoaldosteronism[50]. This syndrome is characterized by mild to moderate renal insufficiency and patients typically present with asymptomatic hyperkalemia. The development of overt hyperkalemia is most common in patients with other risk factors that further impair the efficiency of potassium excretion, such as renal insufficiency, volume depletion, or the use of medications that interfere with potassium handling (see above).

Of note, dapagliflozin (a SGLT2 inhibitor) may be protective from the development of hyperkalemia in

patients with moderate renal impairment due to osmotic diuresis[17]. However, the administration of SGLT2 inhibitors in hypovolemic patients may cause elevated serum creatinine levels and decreases in glomerular filtration rate due to deterioration of intravascular volume contraction. Indeed, worsening renal function and hyperkalemia may occur in patients on canagliflozin, particularly those predisposed to hyperkalemia due to impaired renal function, medications or other medical conditions[51]. Hyporeninemic hypoaldosteronism is more frequently observed in diabetic and elderly patients as well as in those with chronic renal impairment. Diabetic nephropathy accounts for 43%-63% of cases comprising the most common cause of hyporeninemic hypoaldosteronism[33,50,52]. Normal ageing, especially after the sixth decade, is associated with a decline in renin production. Moreover, elderly patients may have decreased renal function even without significant elevations in serum creatinine levels [< 1.2 mg/dL (106 μmol/L)]. Consequently, diabetics (especially the elderly) on medications known to interfere with $K^+$ homeostasis are at increased risk for hyperkalemia[33,53]. In such cases, close $K^+$ monitoring is fully warranted[54]. Clinicians must also be alert that hyperkalemia in patients with type 1 DM may be due to concurrent adrenal insufficiency in the setting of autoimmune polyglandular syndrome[55].

## HYPOMAGNESEMIA

Hypomagnesemia is a frequent electrolyte disorder in diabetic patients[56]. Recently, DM was identified as an independent risk factor for hypomagnesemia in community subjects aged 55 years or more (OR = 3.32; 95%CI: 2.00-5.50)[3]. In a recent prospective study in hypomagnesemic patients (either on admission or during hospitalization in an internal medicine clinic) DM was evident in a considerable proportion (40%), mainly as a contributing factor. Osmotic diuresis accompanied by inappropriate magnesiuria was the prominent underlying mechanism of hypomagnesemia in these diabetic patients[57]. Except for glucosuria, several other possible explanations for hypomagnesemia in DM have been reported. These include poor dietary intake, glomerular hyperfiltration, altered insulin metabolism, diuretic administration and recurrent metabolic acidosis[56]. Increased gastrointestinal $Mg^{2+}$ losses due to diarrhea as a result of diabetic autonomic neuropathy can also cause low serum $Mg^{2+}$ levels. Of note, a case of symptomatic hypomagnesemia [serum $Mg^{2+}$ concentration 0.66 mEq/L (0.33 mmol/L), reference range 1.42-1.84 mEq/L (0.71-0.94 mmol/L)] was attributed to metformin-induced diarrhea[58]. Furthermore, insulin promotes net shift of $Mg^{2+}$ from extracellular to intracellular space and can contribute to hypomagnesemia[59,60]. The increased secretion of epinephrine due to insulin-induced hypoglycemia may also play a role. The risk of hypomagnesemia related to insulin therapy is increased in poorly controlled diabetic patients given that hyperglycemia induces increased renal $Mg^{2+}$ loss *via* osmotic diuresis. Hypokalemia, hypophosphatemia as well as acidosis-related urinary $Mg^{2+}$ losses contribute to the high incidence of hypomagnesemia in the setting of diabetic ketoacidosis[61,62]. It should be noted that hypoalbuminemia is associated with spurious hypomagnesemia. In hypoalbuminemic states (serum albumin < 4 g/dL) the corrected serum $Mg^{2+}$ should be calculated using the formula: corrected $Mg^{2+}$ (mEq/L) = measured $Mg^{2+}$(mEq/L) + 0.01 × (40 - albumin in g/L)[63].

$Mg^{2+}$ is essential for life being involved in numerous enzymatic reactions, including ATP use, cell membrane, ion channels and mitochondrial function, as well as protein synthesis. The most clinically significant consequences of hypomagnesemia are ascribed to alterations in the function of excitable membranes in nerve, muscle, and the cardiac conducting system. Moreover, low serum $Mg^{2+}$ levels can secondarily induce hypokalemia, hypocalcemia, and hypophosphatemia, potentially causing further derangements in neuromuscular and cardiovascular physiology. Hypomagnesemia has been implicated in various long-term complications of DM, such as hypertension, increased carotid wall thickness, coronary artery disease, dyslipidemia, diabetic retinopathy, neuropathy, ischemic stroke, and foot ulcerations[56]. Hypomagnesemia has also been linked to diabetic nephropathy (from microalbuminuria to advanced renal disease)[64-66]. It has been proposed that hypomagnesemia is a predictor of end-stage renal disease in patients with diabetic nephropathy[66]. In addition, magnesium deficit is associated with carbohydrate intolerance and insulin resistance, thus inducing or worsening existing DM[67,68]. On the contrary, increased dietary $Mg^{2+}$ intake has been associated with a reduced risk of type 2 DM[69].

## HYPOCALCEMIA

Patients with DM have an increased risk for development of acute renal failure due to volume depletion, sepsis, rhabdomyolysis and drugs (*e.g.*, radiographic contrast media). In this setting severe hyperphosphatemia may occur when phosphorus cannot be excreted by the malfunctioning kidney either with or without increased cell catabolism, thus resulting in hypocalcemia. Advanced chronic renal insufficiency may be associated with hypocalcemia due to accompanying hyperphosphatemia and low levels of vitamin D. Patients with nephrotic syndrome may exhibit hypocalcemia, even if the glomerular filtration rate is well preserved. This is attributed to the loss of 25-hydroxyvitamin $D_3$ and its binding protein in the urine. Hypomagnesemia is another potential cause of hypocalcemia in diabetics. $Mg^{2+}$ depletion leads to hypocalcemia mainly because of impaired release of parathyroid hormone (PTH) or skeletal and renal tubule resistance to the action of PTH[1]. Vitamin D deficiency and furosemide administration may also play a role in the occurrence of hypocalcemia[70]. There is evidence that diabetic patients are relatively hypoparathyroid[71]. In fact, a mild shift downwards in the set-point for PTH secretion in patients

with insulin-dependent DM as well as a diminished parathyroid gland responsiveness to hypocalcemia in uremic diabetic patients have been reported[72,73].

Hypoalbuminemia is associated with pseudohypocalcemia defined as a reduction of total serum calcium concentration in the presence of normal ionized serum calcium levels. In hypoalbuminemic states, one of the commonly used formulas to correct total calcium levels is by adding 0.8 mg/dL (0.2 mmol/L) to measured calcium values for every 1 g/dL decrease in serum albumin from normal value (assumed to be 4 g/dL). Given that the accuracy of this method is poor (particularly among critically ill and geriatric patients), the biologically active ionized calcium concentration should be measured when possible[1,74].

## HYPERCALCEMIA

The incidence of DM in primary hyperparathyroidism and that of primary hyperparathyroidism in DM is approximately 8% and 1%, respectively. Both values are about three-fold higher than that anticipated in the general population[75]. Hyperparathyroidism is related to long-term insulin resistance and relative insulin insufficiency, leading to overt DM or deterioration of glycemic control of established DM[75,76]. It is thought that an elevated intracellular free calcium concentration (by decreasing normal insulin-stimulated glucose transport) increases the requirement for insulin, resulting in hyperparathyroidism-mediated insulin resistance[75]. Diabetic patients should be evaluated for hypercalcemia given that untreated hyperparathyroidism is linked to hypertension[75,77]. The detection of high serum calcium levels in a patient with type 1 DM should raise the suspicion that autoimmune hyperparathyroidism associated with anti-calcium-sensing receptor autoantibodies may be present[78]. Recently, a case of severe hypercalcemia [15 mg/dL (3.75 mmol/L)] in DKA was reported[79]. Dehydration might represent the most important causative factor for the occurrence of hypercalcemia in this case. A decreased bone formation due to metabolic acidosis and an increased bone mineral dissolution and resorption due to severe insulin deficiency and metabolic acidosis may also play a role[80]. Hyperglycemia-mediated inhibition of bone mineralization, insulin growth factor-1 deficiency, hypophosphatemia and immobilization are also included among the potential contributory factors of hypercalcemia in DKA[79,81,82]. Also, diabetic patients on thiazide diuretics are more prone to exhibit hypercalcemia.

## HYPOPHOSPHATEMIA

Diabetic patients have underlying conditions that predispose to the development of hypophosphatemia. These include primary hyperthyroidism, vitamin D deficiency, malabsorption, and the use of diuretics (thiazides and furosemide)[83]. It is known that increased insulin levels promote the transport of both glucose and phosphate into the skeletal muscle and liver cells. However, in normal subjects the administration of insulin leads only to a slight decrement of serum phosphate levels. The risk of severe hypophosphatemia is increased in cases of underlying phosphate depletion[62,84]. Decompensated DM with ketoacidosisis associated with excessive phosphate loss due to osmotic diuresis. Despite phosphate depletion, the serum phosphate concentration at presentation is usually normal or even high because both insulin deficiency and metabolic acidosis cause a shift of phosphate out of cells[85]. Administration of insulin and fluids, and correction of ketoacidosis may reveal phosphate deficiency and cause a sharp decrease in plasma phosphate concentration due to intracellular shift[83].

In a study of 69 patient with DKA, the incidence of hyperphosphatemia was 94.7% at presentation. The mean serum phosphate concentration fell from 9.2 mg/dL (3 mmol/L) to 2.8 mg/dL (0.9 mmol/L) 12 h after initiating treatment, while some patients exhibited values as low as 1.0 mg/dL (0.32 mmol/L)[85].

The routine administration of phosphate during treatment of DKA and HHS is not recommended since randomized trials failed to show any clinical benefit from phosphate administration[42,83,86,87]. What is more, correction of hypophosphatemia may have adverse effects, such as hypocalcemia and hypomagnesemia[42,83,88]. Careful phosphate replacement is required in patients with severe hypophosphatemia of less than 1.0 mg/dL (0.32 mmol/L) and in patients who develop cardiac dysfunction, hemolytic anemia, or respiratory depression[42,89,90].

## CONCLUSION

Electrolyte abnormalities are common in diabetic patients and may be associated with increased morbidity and mortality. These disturbances are particularly common in decompensated DM, in the elderly as well as in the presence of renal impairment. Patients with DM may receive complex drug regimens some of which may be associated with electrolyte disorders. Discontinuation of these medications, when possible, as well as strict control of glycemia are of paramount importance to prevent electrolyte abnormalities in diabetic patients. The successful management of these disorders can best be accomplished by elucidating the underlying pathophysiologic mechanisms.

## Abstract

Although high density lipoprotein (HDL)-mediated reverse cholesterol transport is crucial to the prevention and reversal of atheroma, a recent meta-analysis makes evident that current pharmaceutical strategies for modulating HDL cholesterol levels lower cardiovascular risk only to the extent that they concurrently decrease low density lipoprotein (LDL) cholesterol. This corresponds well with findings of a recent Mendelian randomization analysis, in which genetic polymorphisms associated with HDL cholesterol but no other known cardiovascular risk factors failed to predict risk for myocardial infarction. Although it is still seems appropriate to search for therapies that could improve the efficiency with which HDL particles induce reverse cholesterol transport, targeting HDL cholesterol levels *per se* with current measures appears to be futile. It may therefore be more promising to promote reverse cholesterol transport with agents that directly target foam cells. Macrophage expression of the cholesterol transport proteins adenosine triphosphate binding cassette transporter A1, adenosine triphosphate binding cassette transporter G1, and scavenger receptor class B member 1 is transcriptionally up-regulated by activated liver X receptors (LXR), whereas nuclear factor (NF)-kappaB antagonizes their expression. Taurine, which inhibits atherogenesis in rodent studies, has just been discovered to act as a weak agonist for LXRalpha. Conversely, it may be possible to oppose NF-kappaB activation in macrophages with a range of measures. Induction of heme oxygenase-1, which can be attained with phase 2 inducer phytochemicals such as lipoic acid and green tea catechins, promotes reverse cholesterol transport in macrophages and inhibits atherogenesis in rodents, likely due to, in large part, NF-kappaB antagonism. Inhibition of macrophage nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity with the spirulina-derived bilirubin-mimetic phycocyanobilin may also oppose NF-kappaB activation, and salicylic acid similarly should be useful for this purpose. The 5' adenosine monophosphate-activated protein kinase activator berberine promotes macrophage reverse cholesterol transport in cell culture; metformin probably shares this property. Many of these measures could also be expected to promote plaque stability by suppressing foam cell production of inflammatory cytokines and matrix metalloproteinases, and to reduce intimal monocyte infiltration by anti-inflammatory effects on vascular endothelium. Direct targeting of foam cells with agents such as phase 2 inducers, spirulina, salicylate, taurine, and berberine or metformin, may hence have considerable potential for preventing and reversing atheroma, and for preventing the plaque rupture that triggers vascular thrombosis.

**Key words:** Atherosclerosis; Cholesterol; Inflammation;

Phytochemical; Nutraceutical; Atherogenesis; Plaque; Cytokine; Antioxidant

**Core tip:** Reverse cholesterol transport from foam cells is of key importance to prevention and control of atherosclerosis. This essay reviews the molecular biology of foam cell regulation, and proposes that certain agents may be capable of acting directly on foam cells to amplify reverse cholesterol transport while also promoting plaque stability by limiting foam cell production of inflammatory cytokines and matrix metalloproteinases. Phase 2 inducers such as lipoic acid and green tea catechins, spirulina, salicylate, taurine, and 5' adenosine monophosphate-activated protein kinase activators such as metformin or berberine, appear to have potential in this regard-while acting in additional ways to benefit vascular health.

## PHARMACEUTICAL HIGH DENSITY LIPOPROTEIN MODULATION HAS PROVED DISAPPOINTING

Although reverse cholesterol transport from foam cells mediated by high density lipoprotein (HDL) particles clearly plays a key role in the prevention and control of atherosclerosis (Figure 1) and its complications[1-3], a recent meta-analysis strongly suggests that current pharmaceutical measures for increasing HDL cholesterol (*e.g.*, niacin, fibrates, cholesterylester transfer protein inhibitors) do not enhance health outcomes in at-risk subjects-or rather, only do so to the extent that, like niacin, they favorably influence other determinants of atherogenesis such as low density lipoprotein (LDL) and apoB-bearing lipoproteins[4]. The failure of niacin in the AIM-HIGH trial-despite evidence of benefit in other studies[5,6]-might then be explained by the fact that patients in the control group received a higher dose of statin such that reductions of LDL cholesterol were equivalent in each group[7]. Analogously, a Mendelian randomization analysis has determined that genotypes associated with elevated HDL cholesterol (but no other known determinants of cardiovascular risk), are not associated with a decline in risk for myocardial infarction[8]. A similar analysis focusing on genetic determinants of LDL cholesterol provides striking confirmation of LDL's pathogenicity[9]. The well-established epidemiological association of low HDL cholesterol with increased cardiovascular risk might therefore reflect the fact that low HDL cholesterol levels can serve as a marker for metabolic states-such as the metabolic syndrome-that are truly pathogenic; a similar analysis applies to moderately elevated homocysteine. There still may be scope for developing new drugs or procedures that improve the capacity of HDL particles to achieve reverse transport[10-13]-but available pharmaceutical agents capable of elevating HDL cholesterol do not seem to have that property. As the authors of the recent meta-analysis note: "Raising high density lipoprotein cholesterol without considering effects on high density lipoprotein function seem to have little promise for the prevention of cardiovascular events"[4].

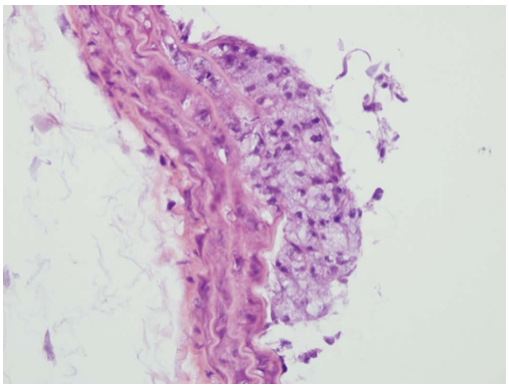

**Figure 1 An atherosclerotic plaque at its early stage of development in the thoracic aorta of an apolipoprotein E-KO mouse is illustrated.** The plaque is primarily composed of apparent foam cells. HE staining × 400.

It bears mentioning that the low HDL cholesterol levels seen in subjects carrying the Milano variant of apoA-1 are not associated with aggravated cardiovascular risk[14]; perhaps this reflects the efficiency with which Milano HDL delivers cholesterol to the liver for catabolism. Conversely, the elevation of HDL cholesterol associated with niacin therapy may reflect the fact that clinical concentrations of niacin impede the liver's ability to catabolize holo-HDL particles[15]; while this increases the circulating apoA-1 pool, the amount of cholesterol per HDL particle also rises. Whether the increase in HDL associated with moderate alcohol consumption-likely attributable to enhanced hepatic synthesis of apoA-1[16]-is partially responsible for the decrease in cardiovascular risk observed in by prudent drinkers, is not yet clear; activation of 5' adenosine monophosphate-activated protein kinase (AMPK) by ethanol-derived acetate may contribute to alcohol's vascular benefits[17].

## TARGETING FOAM CELLS DIRECTLY TO MODULATE FOAM CELL FORMATION AND BEHAVIOUR

Despite the seeming inutility of current efforts to modulate HDL, it may still be feasible to promote reverse cholesterol transport with agents that act directly on foam cells to enhance their capacity to export cholesterol. Moreover, some of these agents could be expected to decrease foam cell uptake of modified LDL particles, and to work in other ways to promote plaque stabilization.

Egress of cholesterol from macrophages and foam

cells is mediated by several membrane transport proteins, namely adenosine triphosphate binding cassette transporter A1 (ABCA1), adenosine triphosphate binding cassette transporter G1 (ABCG1), and scavenger receptor class B member 1 (SRB-1); ABCA1 preferentially interacts with lipid-poor apoA-1, ABCG1 can transfer cholesterol to all HDL particles, and SRB-1 interacts with a wide range of lipoproteins[18]. The transcription of ABCA1 and ABCG1 is promoted by the liver X receptors (LXR) receptor, a transcription factor whose physiological activation is mediated by certain hydroxylated metabolites of cholesterol produced within macrophages which can function as ligands for LXR[19,20]. Increased intracellular cholesterol in macrophages also promotes increased expression of SRB-1, although this effect does not seem to be mediated *via* LXR[21]. In this way, increased cholesterol uptake by macrophages provokes a compensatory increase in cholesterol export induced by cholesterol metabolites. This LXR-mediated promotion of reverse cholesterol transport *via* HDL can be antagonized by a number of pro-inflammatory cytokines and agonists which have the common effect of activating nuclear factor (NF)-kappaB; concurrent suppression of NF-kappaB activity largely eliminates this inhibition of reverse cholesterol transport[22-27]. NF-kappaB activity somehow opposes the transcription of ABCA1, ABCG1, and SRB-1; how this occurs is still unclear. The balance between LXR and NF-kappaB activities is hence a key determinant of foam cell formation. NF-kappaB activation also is a mediator of inflammatory cytokine production by foam cells, and can promote plaque destabilization by inducing production of matrix metalloproteinases (MMP)[25,28]-whereas LXR suppresses production of MMP-9[29].

### *Heme oxygenase-1, phase 2 inducers, bilirubin, and spirulina*

A number of studies reveal that induction of heme oxygenase-1 (HO-1) in foam cells promotes reverse cholesterol transport, induces increased expression of ABCA1, ABCG1, and SRB-1, and acts in other ways to suppress foam cell production of pro-inflammatory cytokines and plaque-destabilizing metalloproteinases[30-37]. Hence, HO-1 induction can aid prevention of plaque formation, promote plaque regression, and render plaque more stable. Suppression of NF-kappaB activation appears likely to underlie many of these protective effects, since HO-1 activity has been shown to impede NF-kappaB activation in a number of circumstances[38-47]. There appears to be no evidence that HO-1 could influence LXR function. Macrophage HO-1 induction can also oppose AP-1 activation, an effect which could be expected to reduce uptake of modified LDL by diminishing expression of the SR-A receptor[32,33]. The respective roles of HO-1 products carbon monoxide and biliverdin/bilirubin in favorable modulation of foam cell function have not yet been clarified. As HO-1 can be induced by phase 2-inductive phytochemicals *via* the Nrf2 transcription factor[48], such agents evidently have potential for promoting reverse cholesterol transport and aiding prevention, regression, and stabilization of plaque. Lipoic acid, a broad range of flavanoids (including notably green tea catechins), isothiocyanates from crucifera, and organosulfur compounds from garlic and onions, can serve as phase 2 inducers[49-57]-albeit what intakes of these might have a functionally significant impact on HO-1 in foam cells is unknown. Lipoic acid is of particular interest in this regard, inasmuch as well-defined dose schedules (600-1800 mg daily) exert protective effects in diabetic neuropathy, which seem likely to reflect phase 2 induction[58]. Not surprisingly, lipoic acid exerts anti-atherosclerotic activity in rodents[59-62].

The antioxidant effects of HO-1 are mediated largely by bilirubin, which functions physiologically to inhibit certain isoforms of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase[63-66]. The inverse correlation of serum bilirubin levels with cardiovascular risk observed in many epidemiological studies[67-69] may well reflect the antioxidant impact of free bilirubin on the vascular wall-endothelium, foam cells, and smooth muscle cells. A number of agonists which stimulate NF-kappaB activity in macrophages concurrently activate NADPH oxidase, which boosts NF-kappaB activation *via* oxidant mechanisms[70-79]. It is therefore reasonable to suspect that HO-1 induction promotes reverse cholesterol transport, in part, by suppressing the up-regulatory impact of NADPH oxidase on NF-kappaB activity. Consistent with this possibility, the ability of advanced glycation end-products to suppress expression of ABCA1 and ABCG1 expression in macrophages is blocked by inhibitors of NADPH oxidase[80,81]. Macrophage NADPH oxidase activity could also be expected to promote foam cell formation by promoting oxidative modification of LDL.

Recent studies indicate that bilirubin's antioxidant effect can be mimicked by phycocyanobilin (PhyCB), a prominent light-absorbing chromophore in cyanobacteria such as spirulina; PhyCB is a metabolite and close structural analog of biliverdin, the precursor of bilirubin[82,83]. Not surprisingly, the only study to date which has evaluated oral administration of spirulina or its PhyCB-bearing protein phycocyanin in a rodent model of atherogenesis (cholesterol-fed hamsters) observed a profound anti-atherosclerotic effect[84]. An anti-inflammatory impact on vascular endothelial cells, coupled with a suppressive impact on intimal foam cell formation, seems likely to account for this observation. The ability of bilirubin and of PhyCB to maintain reverse cholesterol transport in macrophages stimulated with various pro-inflammatory agonists that otherwise would inhibit it, should be assessed.

### *Salicylate suppresses NF-kappaB activity*

Activation of NF-kappaB can often be suppressed more directly with salicylate, a direct inhibitor of inhibit the inhibitor of nuclear factor kappa-B kinase beta (IKK-beta), in clinical doses that do not entail important inhibition of cyclooxygenase, and hence are relatively safe[85-88]. In foam

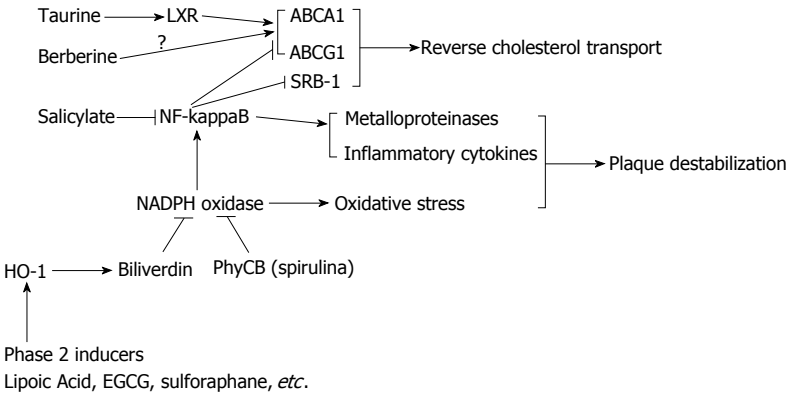

**Figure 2 Nutraceutical/drug regulation of foam cell cholesterol transport and plaque stability.** LXR: Liver X receptors; HO-1: Heme oxygenase-1; NF-kappaB: Nuclear factor-kappaB; ABCA1: Adenosine triphosphate binding cassette transporter A1; ABCG1: Adenosine triphosphate binding cassette transporter G1; SRB-1: Scavenger receptor class B member 1; NADPH oxidase:: Nicotinamide adenine dinucleotide phosphate oxidase:; EGCG: Epigallocatechin gallate; HO-1: Heme oxygenase-1; PhyCB: Phycocyanobilin.

cells *in vitro*, aspirin (which shares salicylate's capacity to inhibit IKK-beta) was found to suppress the transcriptional activity of NF-kappaB and-likely as a result - boost expression of ABCA1 and SRB-1 while suppressing that of matrix metalloproteinase-9 (a mediator of plaque instability)[25]. In doses of 3-4.5 g daily, salicylate (preferably as salsalate) has been shown to modestly aid glycemic control in diabetics, likely *via* its inhibition of IKK-beta[89-91]; it might be feasible to employ salicylate in comparable doses to promote reverse cholesterol transport and stabilize plaque in patients with atheroma.

### *Taurine as an LXR agonist*

Pharmaceutical LXR agonists can promote reverse cholesterol transport in macrophages, and some of these are being evaluated as potential new drugs for control of atherosclerosis[92-94]. Unfortunately, most such agents also boost hepatic lipogenesis *via* LXR activity, an effect viewed as undesirable[94]. A particularly intriguing recent discovery is that the essential cofactor taurine can act as a weak agonist for LXRalpha; moreover, taurine can enhance the expression of ABCA1and ABCG1, and promote reverse cholesterol transport, in cultured macrophages[95]. Curiously, owing to a countervailing effect, taurine fails to promote hepatic lipogenesis, and is very well tolerated[95]. A number of studies have demonstrated that dietary taurine can impede atherogenesis in rodent models of this disorder[96-103]; this effect is stronger than could be predicted from the modest hypolipidemic effects of taurine in rodents, and it would be of interest to know whether a favorable impact on the function of intimal macrophages plays a role in taurine's anti-atherosclerotic activity. If so, taurine-which appears to have minimal impact on serum lipids in humans-might have clinical utility for preventing and controlling atherosclerosis[104,105]. Of related interest is the possibility that taurine's antioxidant activity may be helpful for preventing LDL modification mediated by hypochlorous acid, a myeloperoxidase product[106]. Moreover, rodent and limited clinical studies suggest that taurine supplementation has the potential to favorably influence platelet stability, blood pressure, and the failing heart[107]. The continuing neglect of this inexpensive and well tolerated nutrient by clinical researchers is mystifying.

### *AMPK activators*

The anti-diabetic nutraceutical berberine, whose clinical efficacy resembles that of metformin in being contingent on activation of AMPK, has exerted anti-atherogenic effects in some but not all rodent models of this disorder[108-110]. The AMPK activator AICAR has been shown to promote reverse cholesterol transport in cultured macrophages by boosting expression of ABCG1[111]. Studies examining the impact of berberine on cultured macrophages report that it can exert a range of effects likely to antagonize foam cell formation and stabilize plaque-inhibiting activation of NADPH oxidase and NF-kappaB, inhibiting MMP-9 expression, and antagonizing cholesterol accumulation by inducing expression of ABCA1 or SRB-1, or suppressing expression of the LOX-1 LDL receptor for oxidized LDL[112-114]. On the other hand, one study found that berberine exposure increased macrophage uptake of modified LDL by increasing expression of the SRA-1 receptor[115]. The impact of metformin on foam cell function appears to have received little or no study. *In vivo*, berberine could also be expected to reduce foam cell formation by decreasing circulating LDL; it boosts hepatocyte expression of the LDL receptor by a mechanism that is complementary to that of statins[116].

## CONCLUSION

It should not go unnoted that many of the agents discussed here-notably phase 2 inducers[117-122], PhyCB[123-125], salsalate[126-128], and berberine or metformin[129-134]-have the potential to impede foam cell formation by exerting anti-inflammatory effects on endothelial cells that would be expected to impede monocyte migration across the endothelial barrier into arterial intima. Each of these agents can work in various ways to inhibit endothelial NF-kap-

paB activity, which promotes the adhesion of monocytes to the endothelial surface and their subsequent transmigration (Figure 2)[135-137].

In summation-whereas current pharmaceutical strategies for increasing HDL cholesterol appear to have little clinical utility (aside from those which concurrently lower LDL levels), other clinically feasible measures which directly influence intimal macrophages have the potential to promote reverse cholesterol transport, and hence achieve the primary purpose intended for HDL elevation. These measures include administration of phase 2-inducing nutraceuticals (such as lipoic acid, green tea catechins, and cruciferous isothiocyanates), spirulina or PhyCB, salsalate, taurine, and berberine. These effects are mediated primarily by inhibition of NF-kappaB activation or by LXRalpha agonism. Moreover, most of these agents might be expected to impact foam cell function in other complementary ways that would be clinically useful-suppressing macrophage uptake of modified LDL, and inhibiting macrophage production of inflammatory cytokines and matrix metalloproteinases that could destabilize plaque. And most of them, *via* direct anti-inflammatory effects on vascular endothelium, should also impede foam cell formation by suppressing transendothelial migration of monocytes. These agents evidently merit further evaluation, both in animal models and ultimately clinical trials, as measures for preventing, reversing, and stabilizing arterial plaque. And the fact that most of these agents are nutraceuticals suggests that they might be especially feasible for use in primary prevention.

## Abstract

Marjolin's ulcer (MU) represents malignant degeneration that typically ensues over a period of time in the post-burned lesions and scars or any other chronic wound. This review highlights various facets of the presentation and management of MUs that originate from post-burned lesions. The incidence of MUs in such lesions is reported to be 0.77%-2%. This malignancy characteristically develops in the areas of full thickness skin burns that had been allowed for weeks to months to heal spontaneously by secondary intention, or burn wounds which never healed completely over years and the unstable post-burned scars. In the majority of cases, the MU is a squamous cell carcinoma (SCC). The MUs contribute to an overall 2% of all SCCs and 0.03% of all basal cell carcinomas of the skin. Clinically MUs present in two major morphologic forms. The commoner form is the flat, indurated, ulcerative variety while the less common form is the exophytic papillary variety. Lower limbs represent the most frequently affected body parts. Surgical resection of the primary tumor with 2-4 cm horizontal clearance margin, nodal clearance and radiotherapy constitute the cornerstones of effective oncologic management. Despite best efforts, the overall mortality is reported to be 21%.

**Key words:** Marjolin's ulcer; Malignant degeneration; Post-burned scars and wounds; Sentinel lymph node dissection; Squamous cell carcinoma; Full thickness skin burns; Healing by secondary intention

**Core tip:** This review on Marjolin's ulcer (MU) provides a comprehensive account of the key conceptual issues, historic background as well as recent updates on the management of MU developing in the post-burned lesions and scars. New concepts in the management in general and the evolving concepts in the prophylactic nodal treatment such as the sentinel lymph node mapping are highlighted. The epidemiologic and pathophysiologic factors that surround the development of MU in the post-burned lesions are described in vertical depth with subsequent emphasis on the preventive aspects, which certainly hold the key to eradication of this dreadful menace.

Saaiq M, Ashraf B. Marjolin's ulcers in the post-burned lesions and scars. *World J Clin Cases* 2014; 2(10): 507-514 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/507.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.507

## INTRODUCTION

Malignant degeneration of post-burned lesions and scars is an inevitable eventuality, afflicting at least 0.77%-2% of the deep burns that had been allowed to heal by secondary intention, those which never healed completely and the unstable post-burned scars that frequently ulcerate on trivial traumatic insults of daily life activities[1-3]. Celsus AC deserves acknowledgment for his earliest recognition of this phenomenon in the first century AD[4]. Later on in 1828, the French physician Marjolin JN etiologically classified ulcers as those due to "local" causes

and those secondary to "internal" causes, however he couldn't specifically recognize the malignant potential of these lesions[5,6]. Dupuytren[7] in 1839 provided full description of a case of amputation for a cancer in a patient who had suffered a sulfuric acid burn injury. Da Costa[8] in 1903 was the first to coin the term Marjolin's ulcer (MU) to describe malignant degeneration of skin scars particularly the post-burned scars.

Not surprisingly, MUs can emanate from any chronic wound or unhealed scar, however the neglected burn wounds constitute their commonest seats of origin[9-11]. The following review focuses on the epidemiological and clinical details of MU emanating in the aftermath of burn injuries with a view to provide a comprehensive summary of the key conceptual issues as well as recent updates on management for those who happen to be the frontline care providers for the patients with MU.

## EPIDEMIOLOGIC CONSIDERATIONS

Whereas 0.77%-2% of the post-burned wounds and scars are reported to undergo malignant degeneration[3], overall the post-burned wounds and scars contribute to 2% of all squamous cell carcinomas (SCCs) and 0.03% of all basal cell carcinomas (BCCs) of the skin[4].

MU is relatively commoner among males than females[12-15]. The exact explanation for this is not yet known, however more frequent initial burn trauma among males as well as their more prolonged exposure to sunlight are some of the possible contributors to this higher frequency of MU among males. No age is immune to MU with individuals from almost all age groups including children being afflicted worldwide[1-5]. MU has been reported among individuals of all races[16-20].

There is usually a prolonged latency period between sustaining initial burn insult and developing MU in the post-burned wounds and scars. There is considerable variation in this lag period reported in the published literature[1,2,13,14], ranging from as short as 6 wk[15] to as prolonged as 70 years[18]. The average latency period to malignant transformation is 35 years[1,21,22]. Based on the latency period, the MUs are subdivided into acute and chronic subtypes. The former type refers to the scar carcinoma that evolves within a year of sustaining burn injury, while the later type refers to those that develop from then on[22]. The acute MU usually develops in association with more superficial burn scars and is often a basal cell carcinoma on histology[23]. The latency period of MU inversely relates to the patient's age at the time of sustaining initial burn insult[24]. The younger the patient is at the time of initial burn insult, the longer the time it takes to undergo the malignant transformation. Contrary to this, the older the patient at the time of burn injury the shorter the lag period and more is the chance of acute MU. Understandably, a newly acquired burn injury in an adult of advancing age is more likely to evolve an acute MU, hence a biopsy of all such lesions (of a duration of > 6 wk) is imperative.

Although all underlying mechanisms of burn injury pose an equal risk for subsequent malignant transformation, MU has been reported more frequently among those who had sustained flame burns as compared to the other burn injury mechanisms such as scalds, electric burn injuries, chemical burns, and contact burns. Except for the BCC where contact is the most frequent underlying burn injury mechanism, the other histological types of MU occur with equal frequency amongst flame, scalds and contact burn injuries[2].

Given the global statistics, the burden of burn injuries is disproportionately shared across the globe with most of its brunt being taken by the developing nations such as India, Bangladesh and Pakistan[25]. These countries together with other south Asian countries like Sri Lanka, Bhutan, Nepal, Maldives, and Afghanistan collectively constitute 20% of the world's population, however they contributed only 1.1% of the total PubMed publications during the 25 years period from 1985-2009[26]. One can easily imagine the magnitude of MU that certainly exists in these burn injury endemic countries but is underreported. These developing nations have recognized limitations of their health care systems where the ideal treatment for acute burn injuries is often not instituted[27]. Also many of the patients in these developing countries present late, when the MU is not amenable to curative resection.

## PATHOLOGIC CONSIDERATIONS

### *Etiopathogenesis of MU*

MUs originating from post-burned scars possess certain peculiarities that make them distinct from other cutaneous malignancies. The exact mechanism of how the malignant transformation supervenes the post-burned scars continues to be explored. Many theories have been proposed to provide possible explanations of the mechanisms involved, however no single theory alone can provide a satisfactory answer to all questions that surround this complex process of malignant degeneration.

As per Ewing J's postulates[2,28], MU of post-burned scars would meet the criteria such as evidence of a burn scar, tumour within the boundaries of the scar, no previous tumour in that location, tumour histology being compatible with the cell types found in the skin/scar and presence of a lag period between the burn injury and the tumour development. The post-burned scars is certainly a mutogenic focus with continuous mitotic activity of regeneration and repair being in progress. The same represents the key mechanism that eventually triggers the malignant transformation[10,29,30]. A myriad of factors have been postulated as possible contributors toward the process of malignant transformation. Among these include chronic irritation, repeated trauma, impaired immunologic reactivity of the scar tissue to tumour cells, release of toxins from the unhealthy scar, relative avascularity of the scar tissue, lymphatic obstruction within the scar tissue making it an inaccessible site for the body's natural

**Figure 1 Marjolin's ulcer in the left popliteal fossa region in a 45 years old lady who had sustained flame burn injury at the age of 13.** There is characteristic ulcer with everted edges and poorly granulating floor. The surrounding skin shows post-burned sequel. Histopathology confirmed it to be well differentiated squamous cell carcinom.

**Figure 2 A 46 years male with 3 years history of ulceration and bleeding in right axilla.** He had sustained scald burns at the age of 3. Biopsy confirmed it to be squamous cell carcinoma while computed tomography scan revealed metastasis in the axilla as well as chest.

**Figure 3 A 63 years old male presented with two years history of slowly progressive ulceration in the post burned white skin on his upper back.** He had childhood scald burns at the age of 3 years, and had received burn injury treatment with months of dressings without skin grafting. Multiple biopsies revealed squamous cell carcinoma, while computed tomography scan revealed axillary nodal invasion without chest metastasis. Culture sensitivity revealed Methicillin resistant staphylococcus and pseudomonas aeruginsa.

immunosurveillance[2,10,31,32]. When the full thickness skin loss areas are allowed to heal by secondary intention, there is formation of unstable depigmented substitution tissue which lacks the qualities of normal skin. These unstable depigmented scars have reduced ability to withstand carcinogens[4,32]. Whether genetics or heredity have any contribution to the malignant degeneration of the post-burned scars is not exactly known, however abnormalities in the *p53* gene among these patients have been reported[33,34].

The major risk factors for the development of post-burn MU include healing of full thickness skin burns by secondary intention, non-healing burn wounds, and fragile scars that ulcerate and are easily traumatized[1,2]. The post-burned scars is typically less resistant to injuries, heals poorly especially in body areas such as the joints.

### Histopathology of MU

In most cases, the MU is an SCC (71%), followed by BCC (12%), melanoma (6%), sarcoma (5%), squamobasal cell carcinoma (1%), SCC-melanoma (1%) and other rare neoplasms (4%)[2]. A variety of rare tumours may emerge in the post-burned wounds and scars and include fibrosarcoma, liposarcoma, dermatofibrosarcoma protuberans, and mesenchymal tumors[2,3,35,36]. The grade of the MU can be defined as follows: grade Ⅰ: more than 75% of the cells are differentiated; grade Ⅱ: 25%-75% of the cells are differentiated; grade Ⅲ: less than 25% of the cells are differentiated[10]. Grade of the tumour has bearing on the prognosis of MU. In general, the incidence of metastasis increases with increasing grade and so is the worsening of prognosis.

## CLINICAL COSIDERATIONS

### Clinical presentation

Clinically MU presents in two major morphologic forms[18,37]. The commoner form is the flat, indurated, infiltrative, ulcerative variant while the other less frequent form is the exophytic papillary variety which is generally less severe. The well-differentiated exophytic lesions have a better prognosis than the poorly differentiated, ulcerated and infiltrating forms. Typically the edge of the ulcerated lesion is everted and the floor has poor granulation tissue (Figures 1-9 are representative photographs of some patients with MUs secondary to burn injuries).

A history of a non healing post-burned wound of full thickness skin loss should alert the clinician of the possibility of an MU. It is usually painless. The easy bleeding fragile areas may at times present with unprovoked bleeding, offensive discharge or increasing pain. Superadded infection of the wound may at times be the first clinical presentation[18,38,39].

### Anatomic sites affected by MUs

Lower limbs constitute the most frequent site of MUs. The other sites affected in order of reducing frequency include head and neck region (face, scalp, neck), upper limbs and other body parts[2,3,35]. MU has been reported in post burned scars at rare locations such as the nose[40].

**Figure 4 A lady aged 41, had sustained burn injury secondary to lightning 3 years ago.** She had her burn injuries managed with months of dressing without skin grafting. Subsequently she had recurrent ulceration with bleeding from the unhealed wounds around the knee. Multiple biopsies of the lesions revealed well differentiated squamous cell carcinoma. The groin nodal basin was negative clinically as well as radiologically.

**Figure 5 A 41 years male who had sustained flame burn injury to his left foot in childhood at the age of 4.** The burn injury was managed with months of dressings and the wound never healed completely. There was history of recurrent bleeding and ulceration on the affected site. Multiple biopsies revealed moderately differentiated squamous cell carcinoma. The groin was clinically node positive.

**Figure 6 A 36 years male had sustained chemical burn injury to his left cubital fossa 7 years ago.** The initial burn injury was managed with dressings and had never healed completely. The patient had undergone wide local excision and split thickness skin grafting for Marjolin's ulcer three months ago. Later he presented with a recurrent nodule which was confirmed as squamous cell carcinom on histopathology while the axilla was node negative clinically.

**Figure 7 Right groin metastasis secondary to Marjolin's ulcer on the right side of ankle in 57 years male.** Metastatic work up revealed ascites and lung metastasis. The patient had sustained flame burn injury to the right ankle at the age of 2 years and was managed with wound dressings without skin grafting.

**Figure 8 A 47 years male had sustained flame burn injury to his scalp at the age of 3.** The initial burn injury was managed with months of dressings without skin grafting. Histopathology confirmed it as well differentiated squamous cell carcinoma. Computed tomography scan head and neck did not show deep structures invasion.

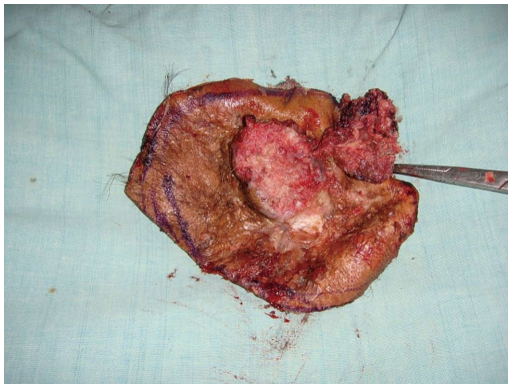

**Figure 9 Same patient (as in Figure 8), the resected Marjolin's ulcer with wide local margins.**

Lower limbs are the commonest sites of MU primarily owing to their more frequent involvement in burn injury insults involving full thickness skin loss. Additionally these patients often present with lesions around the knee

joints as the joints are frequently moved and recurrent ulcerations commonly ensue and persist without healing.

### Diagnosis of MU

The diagnosis of MU is based on the suggestive findings in the patient's history, detailed examination of the ulcer and its draining nodal basin, and the histology of the lesion.

The classic triad of nodule formation, induration, and ulceration at the post-burned scars should prompt a biopsy to confirm the diagnosis[41]. Other clinical signs suggestive of MU include everted or rolled margins, exophytic granulation tissue formation, increasing size, bleeding and regional lymphadenopathy[1-10].

Once the biopsy confirms the diagnosis of MU, determination of the local extent of the lesion and staging comes to the fore. An magnetic resonance imaging (MRI) or computed tomography (CT scan) is performed to determine the local extent of the lesion and invasion of any underlying structures. MRI is certainly the ideal imaging tool for evaluation of the status of the soft-tissues, infiltration of any underlying bone and the involvement of adjacent neurovascular structures[42-44].

The draining lymphatic basin is staged clinically as well as radiologically with either high resolution ultrasonography, MRI or CT scan. Given the aggressive nature of MU, distant metastasis are ruled out with metastatic work up that includes chest CT scan, abdominal ultrasonography and CT scan brain (for lesions on the scalp and face)[1-10].

### Metaststic spread of the MU and the stage of the MU disease

By and large, as long as the MU is confined to the scar it shows typically slow growth and is amenable to curative resection. However when the MU breaks free of the scar it metastasises rapidly *via* lymphatic spread[31]. Once broken free of the confines of the primary lesion, an SCC of the MU variety is known to possess greater metastatic potential than the SCC occurring de novo[18]. At presentation, regional lymph nodes are involved in 20%-36% of the patients[2,18,37,45]. Aydoğdu *et al*[18] have reported even higher percentage of patients (66.66%) with involved regional lymph nodes, dura or bone at initial presentation. Distant metastases are reported among 14% of the patients[2]. Although metastatic spread is primarily to the regional lymph nodes, metastasis to organs such as the liver, lung, brain, kidney may also occur[18].

Stage of the MU has implications for the management as well as the prognosis. As is the case with other malignancies, staging is performed by considering the size of the primary lesion (T), lymph node involvement (N), and distant metastasis (M). As yet there is no MU specific TNM classification of the Union for International cancer control, however the TNM classification for SCC is commonly applied to the MU.

## TREATMENT OF MU

### Role of surgery

Surgery constitutes the mainstay of treatment of the MU. The oncologic clearance entails excision of the primary lesion with a 2-4 cm horizontal clearance margins, and vertical clearance of the un-involved next barrier structure. All the wide local excisions are preferably performed initially with cautery dissection to prevent seeding of the tumor cells and their iatrogenic spread into the blood and lymphatic streams. Additionally a small margin of skin is then excised with a surgical scalpel to ensure good healing[14,20,35]. It is prudent to have the histopathologist onboard when performing such crucial resections to ensure resection of tumour free margins with the help of frozen section studies performed simultaneously with surgery. The defects resulting from MU extirpation are either skin grafted or flap covered. Anecdotally we are now preferring flap coverage of the resultant defects where ever possible and subsequently offer the patients radiotherapy for the tumor bed with the help of radiation oncologist.

As is the established norm of surgical oncology, the clinically or radiologically confirmed involved nodal basins are managed with therapeutic lymph node dissection.

Although there is lack of general consensus regarding management of the clinically negative nodal basins in MU, yet given the aggressive biologic behavior of MU, prophylactic nodal treatment with either elective lymph node dissection or regional nodal irradiation sounds rational[31,37,46-48]. Long term studies are certainly needed to confirm if this aggressive approach offers real benefits in terms of disease free survival or not, as the formal nodal clearance has its own morbidity (particularly lymphedema) attended to the procedure.

The sentinel lymph node dissection (SLND) has been primarily employed for staging the regional nodal basins in malignant melanoma of the limbs, however there is a recent growing recognition of its utility among patients with non-melanoma skin cancers also[49-54]. SLND technique holds the potential to be used more frequently in MU patients as it on one hand will save MU patients from the unnecessary morbidity of formal nodal clearance for negative nodes and on the other hand identify the MU patients who are clinically node negative but have subclinical nodal metastasis.

### Role of radiotherapy

Given the aggressive biological behaviour of the MU and the frequent squamous cell histology, radiotherapy finds an important adjunctive role in managing these malignancies. The indications for radiotherapy include: (1) inoperable regional lymph node metastasis; (2) grade 3 lesions with positive lymph nodes after nodal dissection; (3) tumors with a diameter greater than 10 cm and with positive lymph nodes after regional lymph node dissection; (4) grade 3 lesions with a tumor diameter greater than 10 cm and negative lymph nodes after regional lymph dissection; and (5) lesions of the head and neck with positive lymph nodes after regional lymph node dissection[46].

### Role of chemotherapy

The exact role of chemotherapy or indications thereof in managing MU are not yet established, however che-

motherapy constitutes part of the aggressive multimodal therapy which is often instituted among patients when surgical extirpation of the MU is not possible because of the unfit patient, presence of distant metastasis, recurrent disease, and patients not consenting for surgery.

The chemotherapy is usually based on 5-Fluorouracil with a combination of cisplatin, methotrexate and bleomycin. It may be in the form of adjuvant or neo adjuvant therapy[18].

## PROGNOSIS

Generally speaking, the MU tends to be more aggressive and rapidly spreading as compared to other skin carcinomas of similar histotypes[1,55]. The overall mortality rate of MU is reported to be at least 21%[2]. The survival rates of MU are 52%, 34% and 23% at 5, 10 and 20 years[56].

Poor prognostic clinical features in MU include regional nodal spread, local extension of lesion, lower limb lesions (as these have a greater propensity for nodal involvement), infiltrative variety, primary lesions of $\geqslant$ 2 cm, latency period of $\geqslant$ 5 years, recurrent MU, and the presence of distant metastasis. The poor prognostic indicators on histology include poor differentiation, scarce or absent peritumour T cell infiltration, invasion of reticular dermis or deeper structures, and $\geqslant$ 4 mm vertical thickness of the neoplastic lesion[4,37,46,55-60].

## PREVENTION

Although MU constitutes a formidable foe for reconstructive and burns surgeons around the globe, it is still surmountable to primary as well as secondary prevention. Early excision and grafting of deep burns adequately averts all the wound problems that otherwise predispose the post-burned scars to malignant transformation[61]. Moreover even if an initially neglected or mismanaged burn wound presents later with ulceration or frequent wounding, before any malignancy has set in, the choice of excision and grafting of these unstable scars should still be availed. So primary prevention is ensured by provision of adequate surgical care in the acute phase of burn injury management, while secondary prevention can be instituted where a patient had an initial mismanagement but seeks medical advice before MU has established.

## CONCLUSION

MU is a largely preventable dreadful menace of considerable morbidity and mortality. Although over the years, significant progress has been made in managing MU, the key to successful eradication lies in prevention by ensuring adequate surgical care (with early excision and grafting) of the deep burns in their acute phase.

There is need for randomized controlled trials and high quality evidence on the not yet fully established aspects of the MU management such as the oncologically safe horizontal clearance margins of resection, prophylactic management of the negative nodal basins and MU specific TNM staging system. All these issues need be adequately addressed by future clinical studies.

## Abstract

Gallbladder cancer (GBC) shows a marked geographical variation in its incidence. Middle-aged and elderly women are more commonly affected. Risk factors for its development include the presence of gallstones, chronic infection and pancreaticobiliary maljunction. Controversy remains in regard to the theory of carcinogenesis from adenomyomatosis, porcelain gallbladder and adenoma of the gallbladder. The surgical strategy and prognosis after surgery for GBC differ strikingly according to T-stage. Discrimination of favorable cases, particularly T2 or T3 lesions, is useful for the selection of surgical strategies for individual patients. Although many candidate factors predicting disease progression, such as depth of subserosal invasion, horizontal tumor spread, tumor budding, dedifferentiation, Ki-67 labeling index, p53 nuclear expression, CD8+ tumor-infiltrating lymphocytes, mitotic counts, Laminin-5-gamma-2 chain, hypoxia-inducible factor-1a, cyclooxygenase-2 and the Hedgehog signaling pathway have been investigated, useful prognostic makers or factors have not been established. As GBC is often discovered incidentally after routine cholecystectomy and accurate preoperative diagnosis is difficult, close mutual cooperation between surgeons and pathologists is essential for developing a rational surgical strategy for GBC.

**Key words:** Gallbladder cancer; Surgical strategy; Pathology; Prognostic factors

**Core tip:** This review has documented the basic knowledge and surgical strategies for gallbladder cancer (GBC) based on the clinical and pathological data from previous studies. Discrimination of favorable cases, particularly T2 or T3 lesions, is useful for the selection of surgical strategies for individual patients. As GBC is often discovered incidentally after routine cholecystectomy and accurate preoperative diagnosis is difficult, close mutual cooperation between surgeons and pathologists is essential for developing a rational surgical strategy for GBC.

Kai K, Aishima S, Miyazaki K. Gallbladder cancer: Clinical and pathological approach. *World J Clin Cases* 2014; 2(10): 515-521 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/515.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.515

## EPIDEMIOLOGY

Gallbladder cancer (GBC) has a distinctly higher incidence in certain demographic groups and areas. Women are affected three times more often than men, and the vast majority of patients with GBC are older than 40 years of age. A high incidence has been reported in women in countries such as Chile, Poland, India, Israel, Pakistan, Ecuador, South Korea and Japan, whereas GBC is considered a rare neoplasm in most Western countries and the United States[1-4].

## RISK FACTORS

Gallstones are a well-known risk factor for GBC[5,6]. It has been reported that a large stone size of more than 3

cm, a family history of GBC, and prolonged cholelithiasis are potential risk factors for GBC[7-9]. These factors could be used in the decision making when performing a cholecystectomy for asymptomatic gallstones. However, no definite evidence of a direct causal relationship between gallstones and gallbladder cancer has been presented and biases of other risk factors remain unsolved problems[10]. The composition and mutagenicity of gallstones have previously been studied with inconclusive results[11]. A prospective study of 123 consecutive patients with asymptomatic gallstones who were followed-up for 10 years or longer revealed no cases of GBC[12].

Historically, an association between calcified gallbladder (porcelain gallbladder) and GBC has been reported[13,14], although there has also been a report suggesting that porcelain gallbladder is not associated with GBC[15]. Therefore, the causal association of porcelain gallbladder and GBC remains controversial.

Pancreaticobiliary maljunction (PBM) is considered an established risk factor for biliary tract cancers involving GBC[16,17], especially in relatively young female patients without gallbladder stones[18,19]. It is generally accepted that pancreatic juice reflux into the biliary tract due to PBM plays a pathogenic role in biliary tract cancers. K-ras mutations are more common in biliary tract carcinomas associated with PBM[20].

Adenomyomatosis of the gallbladder has not been considered to have malignant potential; however, several reports have suggested that gallbladder cancer may originate from adenomyomatosis[21-24] or have insisted that segmental-type adenomyomatosis shows an increased risk of progression to gallbladder cancer[25]. Recently, a study showed that gross features of adenomyomatosis were found in approximately a quarter of gallbladders resected under the diagnosis of GBC[26]. Although the magnitude of risk for GBC in patients with adenomyomatosis remains unclear, studies suggesting a correlation between adenomyomatosis and GBC have been gradually accumulating.

In regard to the development of GBC, several theories have been proposed, including the adenoma-carcinoma sequence and dysplasia-carcinoma sequence theories[27-30]. However, recently reported articles have suggested that the vast majority of adenomas and/or polypoid lesions do not become GBC[31,32]. Therefore, the validity of the adenoma-carcinoma sequence theory remains controversial. Other risk factors recently receiving attention include bacterial infections. Although the supporting evidence for an association is weak, Salmonella[33,34] and Helicobacter species[35] would be prime candidates for a bacterial predisposition to GBC.

## SURVIVAL AND GENERAL SURGICAL STRATEGIES ACCORDING TO T-STAGE

The surgical strategy for GBC depends on the extent of the disease, particularly the T-stage from the TNM classification[36]. The prognosis after surgery for GBC differs strikingly according to T-stage. Five-year survival rates after surgery for T1, T2, T3, and T4 stage tumors in 73 cases at our institution were 100%, 78.3%, 16.7%, and 25.0%, respectively[37]. The survival rates of our series were consistent with the results of other previous reports[38-41].

The survival of patients with T1a lesions (invasion restricted to the lamina propria) is particularly good, and lymph node metastasis is extremely rare in such cases. Simple cholecystectomy with or without lymphadenectomy is thus widely accepted as sufficient for T1a lesions[38,42,43]. Intraoperative perforation of the gallbladder and positive surgical margins around the cystic duct are important prognostic factors in surgery for T1a lesions[44].

Survival rates and strategies for T1b (invasion to the muscle layer) remain somewhat controversial. Several studies have reported LN metastasis in up to 20% of cases, with recurrence rates of 30%-60% following simple cholecystectomy[45-51]. In addition, distinguishing T1b lesions from T2 lesions pre- or intraoperatively is usually difficult. Therefore, it seems reasonable to perform cholecystectomy combined with lymphadenectomy with or without liver resection in patients with pre- or intraoperative presumption of T1b GBC. However, T1b GBC is often discovered after laparoscopic cholecystectomy for presumed benign disease. In our T1b series ($n$ = 8), lymph vessel invasion was found only one case and no LN metastases or recurrences were observed, and thus additional operation of lymphadenectomy was not always needed in patients with T1b lesions diagnosed after routine cholecystectomy. However, caution is required in that the pathological work for resected specimens must be performed intensively with sections from the whole specimen, in order to minimize the possibility that a more invasive site or findings of residual lesion remain present in the resected specimen.

The prognosis for T2 (invasion to the subserosal layer) lesions varies widely, with the 5-year survival rates being approximately 20%-70% after simple cholecystectomy, compared to 60%-100% after radical surgery[37,43,52-55]. The surgical strategy for T2 lesions thus remains unclear. The conventional opinion is that patients with T2 lesions should be treated using radical cholecystectomy, including en bloc resection of the adjacent liver as well as regional lymphadenectomy with or without extrahepatic bile duct resection (BDR)[38,56]. Pathologists should pay close attention in order not to misdiagnose a T1a tumor with spreading into the Rokitansky-Aschoff sinuses (RAS) as a T2 tumor with invasion of the subserosal layer.

The prognosis is poor for most patients with T3 tumor, which shows perforation of the serosa and/or direct invasion of the liver and/or one other adjacent organ or structure. Surgery for T3 lesions is only appropriate if there is potential to achieve a curative resection. T3 lesions require hepatic resection with regional lymphadenectomy at a minimum. This can include major hepatectomy if there is extensive spreading into the liver or major vascular structures. In addition, if direct invasion

into an adjacent organ (duodenum, pancreas, stomach or colon) is suspected, *en bloc* resection would be required for curative resection[56]. Because of the high degree of surgical stress involved, the utility of aggressive surgery with extended resection for T3 lesions is often debated in clinical practice, and case-by-case selection is required with due consideration for the patient's performance status, complications, and age.

Chemotherapy or palliation is typically appropriate for T4 disease (tumor invading into the main portal vein or two or more extrahepatic organs or structures), except in rare cases where *en bloc* resection of multiple organs is possible. This is because of the unfortunate prognosis and difficulty of achieving curative resection. Unresectability discovered at the time of laparotomy may be treated with bypass surgery to relieve symptoms related to biliary obstruction. Cases identified preoperatively as unresectable may be considered for percutaneous biliary drainage or endoscopic stenting to address biliary obstruction[38].

## CLINICAL CHALLENGES FOR T2 AND T3 TUMORS

As mentioned above, T2 and T3 tumors are indications for radical surgery. However, which type of radical surgery is most appropriate remains unclear. Although regional lymphadenectomy is widely accepted as necessary at a minimum, the efficacy of extended resection, such as hepatectomy, BDR or pancreatoduodenectomy (PD), remains controversial. BDR is usually necessary in cases with biliary infiltration associated with perineural invasion and complete lymphadenectomy and eradication of the connective tissue around the common bile duct[57-60]. In terms of hepatectomy for GBC, the resection may vary from a small wedge resection near the gallbladder fossa to an extended right hepatectomy. The appropriateness of segment 4a+5 (S4a+5) hepatectomy for advanced GBC is supported by the drainage of the cystic vein into anatomic Couinaud's segments IVa and V and the frequency of liver metastases in this anatomical area[61]. The results of our previous study support the use of S4a+5 hepatectomy combined with BDR and regional lymphadenectomy for the treatment of T2 or T3 GBC[37]. However, additional PD achieved no significant difference in survival in patients with T2 or T3 GBC. Indications for PD in these cases were obvious duodenal or pancreatic invasion, or infiltrating LN metastases at the retro-pancreatic head portion[37].

## ATTEMPTS TO DISCRIMINATE FAVORABLE CASES IN T2 GBC

T2 GBC shows a wide variety of tumor spread. Some T2 tumors show none of the histological invasive factors of LN metastasis, lymphatic or venous invasion, but others show prominent LN metastases, along with venous, lymphatic, or perineural invasion, resulting in poor prognosis. This issue indicates that patients with T2 GBC can be allocated to a favorable prognosis group or a poor prognosis group. If discrimination of favorable cases is appropriately performed, patients with favorable prognosis could be spared excessive extended radical surgery. To identify cases with a favorable prognosis, subset analyses of patients with T2 tumor according to certain pathological criteria have been performed. Several studies, including one from our institution, reported the usefulness of discrimination of T2 GBC according to the depth of subserosal invasion and horizontal tumor spread in the subserosal layer with or without a scoring system[62-65]. Our study focused on the phenomena of dedifferentiation (DD) and tumor budding (BD) demonstrated a significant prognostic impact of both BD and DD in patients with T2 tumor[66].

## INVESTIGATION OF USEFUL PROGNOSTIC MARKERS AND FACTORS

Although prognostic markers of GBC have been widely investigated, promising prognostic makers or factors have not yet been established. Ki-67 labeling index (LI), p53 nuclear expression, CD8+ tumor-infiltrating lymphocytes (TIL) and mitotic count (MC) have classically been considered as candidates for prognostic markers. However, several previous studies have reported no prognostic impact of p53 overexpression in GBC[67-71], although reports of poor prognosis in cases with p53 overexpression are also available in the literature[72,73]. A previous study showed that patients with GBC and high Ki-67 exhibited worse postoperative prognosis than those with low Ki-67[40], although here again, several previous studies also reported that Ki-67 LI of cancer cells was not correlated with patient survival[68,70,71]. Therefore, the prognostic impact of p53 overexpression and Ki-67 LI in GBC remains controversial. In regard to CD8+ TIL, there is little evidence that this is a prognostic indicator. Only one study has reported that CD8+ TIL was correlated with prolonged survival in a univariate analysis[74]. A study from our institution concerning Ki-67 LI, p53 nuclear expression, CD8+ TIL and MC status in a series of 101 GBC patients indicated that only MC reflected the prognosis of GBC. In that study, MC showed a particularly strong prognostic impact in patients with T3 tumor and was identified as an independent prognostic factor in multivariate analyses that included the N and M factors of the TNM system of classification[75]. It is difficult to distinguish the extension of carcinoma in situ (CIS) from invasive carcinoma along the RAS. Laminin-5-gamma-2 chain, which is expressed in various types of invasive carcinoma, can be detected in the invasive fronts of invasive GBC, but is not expressed in CIS with extension along the RAS[76]. The results indicate that laminin-5-gamma-2 chain is a useful marker of determining the T factor. Heparanase and its transcriptional factor, hypoxia-inducible factor-1a, contribute to the invasion and meta-

static potentials, and are correlated with poor survival in GBC[77]. Cyclooxygenase-2, a well-known oxidative stress factor expressed in invasive fronts, is also related with poor prognosis of GBC[78]. The Hedgehog signaling pathway is considered to be a potential therapeutic target for various cancers, and hedgehog signaling factor Gli1 may be involved in the invasive phenotype through the matrix metalloproteinases[79]. Other, more recently reported factors that may have a prognostic impact in GBC based on multivariate analyses include transmembrane protease/serine 4[80], loss of microRNA-335[81], aldehyde dehydrogenase-1A3 overexpression, and decreased glutathione peroxidase-3 expression[82].

## PATHOLOGICAL EXAMINATION FOR OPTIMAL SURGERY

Preoperative diagnosis using an imaging study is very important for selecting the optimal surgery according to T-stage. However, preoperative diagnosis of the T-stage in T1 or T2 GBC is not easy, and it is especially difficult in GBC arising in the gallbladder concomitant with adenomyomatosis, despite advances in medical imaging[83]. As a result, stage T1 or T2 GBC is often discovered incidentally after routine cholecystectomy. In such cases, pathological evaluations of prognostic factors using entire tumor sections can be used to determine the need for additional extended radical surgery. Intraoperative histological examination is usually performed during surgery for lesions preoperatively diagnosed as "suspected GBC" or "possible T1 or T2 GBC". In such cases, the resected specimen from cholecystectomy with or without en bloc liver resection (S4a+5 or liver bed) is submitted for intraoperative histological examination. However, diagnosis of the depth of invasion from frozen sections of GBC is a difficult task, and care must be taken to avoid obstructing the pathological diagnosis of formalin-fixed specimens when the tumor lesion is small.

## CONCLUSION

This review has documented the basic knowledge and surgical strategies for GBC based on clinical and pathological data from previous studies. Discrimination of favorable cases, particularly T2 or T3 lesions, is useful for the selection of surgical strategies for individual patients. To establish useful prognostic markers or factors, further accumulation of studies is needed. As GBC is often discovered incidentally after routine cholecystectomy and definite preoperative diagnosis is often difficult, close cooperation between surgeons and pathologists is essential for developing a rational surgical strategy for GBC.

## Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) is a procedure that can result in serious complications, and thus should be handled by a skilled endoscopist to minimize the risk of complications and to enhance the success rate. The incidence of ERCP-related complications is 5%-10%, most commonly involving post-ERCP pancreatitis and clinically significant post-endoscopic sphincterotomy bleeding. Although ERCP-related perforation has a relatively lower incidence of 0.14%-1.6%, this complication is associated with a high mortality rate of 4.2%-29.6%. A classification of perforation type based on the instrument that caused the perforation was recently described that we postulated could affect the implementation of perforation management. In the present article, an algorithm for management and prevention of ERCP-related perforations is proposed that is based on the perforation type and delay of diagnosis. Available evidence demonstrates that a delayed diagnosis and/or treatment of perforation results in a poorer prognosis, and thus should be at the forefront of procedural consideration. Furthermore, this review provides steps and recommendations from the pre-procedural stage through the post-procedural evaluation with consideration of contributing factors in order to minimize ERCP-related complication risk and improve patient outcome. To avoid perforation, endoscopists must evaluate the risks related to the individual patient and the procedure and perform the procedure gently. Once a perforation occurs, immediate diagnosis and early management are key factors to minimize mortality.

**Key words:** Endoscopic retrograde cholangiopancreatography; Endoscopic retrograde cholangiopancreatography; Perforation; Prevention; Management; Classification

**Core tip:** Endoscopic retrograde cholangiopancreatography (ERCP)-related perforation, is a rare complication with a high morbidity and mortality. An immediate diagnosis and early management of ERCP-related perforation are key factors to minimize mortality. In this review article, the authors shared their experiences and propose an algorithm to avoid perforation and for management once a perforation occurs.

## INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP)

**Table 1 Previous classifications of endoscopic retrograde cholangiopancreatography-related perforations**

| | According to Stapfer *et al*[12] | According to Howard *et al*[13] |
|---|---|---|
| Type Ⅰ | Lateral or medial wall perforation | Duodenal perforation remote from the papilla |
| Type Ⅱ | Perivaterian injury | Periampullary retroperitoneal perforation |
| Type Ⅲ | Distal bile duct injury related to wire/basket instrumentation | Guidewire perforation |
| Type Ⅳ | Retroperitoneal air alone | None |

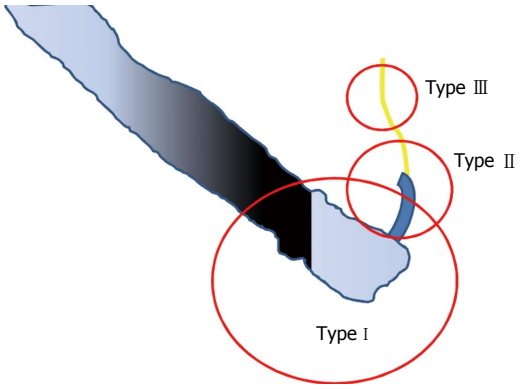

**Figure 1 Classification of endoscopic retrograde cholangiopancreatography-related perforation (based on Kim *et al*[14]).**

is a procedure that should be performed by a skilled endoscopist to maximize the success rate and minimize complications, which occur in 5%-10% of cases[1,2]. The most common complications are post-ERCP pancreatitis (1.0%-3.5% of cases)[3-5] and clinically significant post-endoscopic sphincterotomy bleeding (0.1%-2.0% incidence)[6-9]. ERCP-related perforations are relatively uncommon (incidence of 0.14%-1.6%), though associated with a high mortality rate of 4.2%-29.6%[10,11]. Whereas delayed recognition and treatment of this complication contribute to fatality, early detection and management confer a better prognosis. This review focuses on the classification, early diagnosis, management, and prevention of ERCP-related perforations.

## CLASSIFICATIONS OF ERCP-RELATED PERFORATION

ERCP-related perforations were previously classified into 3-4 types, regardless of the site of perforation[12,13] (Table 1). In 2011, Kim *et al*[14] proposed a new classification based on the instrument that caused the perforation. A type I perforation results from the scope itself, which always causes a large perforation with heavy contamination (Figure 1). A type Ⅱ perforation can be caused by the needle-knife used during the sphincterotomy, from the ERCP cannula or the sphincterotome, which cause a moderate-sized hole with less contamination. Type Ⅲ refers to a perforation caused by the guidewire and is associated with the least risk of contamination. A review of cases presented by Kim *et al*[14] and an additional 62 cases from Kwon *et al*[15] that were reevaluated using the new classification, revealed that 80% of patients with type I perforations (20/25 cases) required surgery, compared to 19% (7/37) of those with type Ⅱ perforations. We therefore postulated that this classification could be used to direct the management of patients with perforations.

## EARLY RECOGNITION OF PERFORATIONS

Most type I perforations are immediately recognized by the endoscopist during the procedure. Large perforations can be definitively indicated by visualization of intra-abdominal organs, whereas smaller perforations may show only yellowish tissue of intra/retroperitoneal fat or by bleeding from other sites such as a lateral wall of the duodenum (Figure 2). If the endoscopist who performed the procedure suspects a perforation, evaluation of the pneumoperitoneum by fluoroscopy can be very helpful (Figure 3A). Some experts also recommend changing the duodenoscope to an end-view type for better mucosal visualization.

Type Ⅱs are typically retroperitoneal perforations that occur during treatment interventions. In some cases, the endoscopist may recognize that an injury is "too deep" with increased bleeding, abnormal positioning of the guidewire, skin emphysema, and a clear kidney shadow. When this type of perforation is suspected, it should be confirmed by fluoroscopy, which can help identify unexplainable air in the retroperitoneum (Figure 3B), or by contrast injection, which will show contrast leakage into the retroperitoneal cavity (Figure 3C).

Type Ⅲ perforationscan be recognized by an unusual guidewire position. If recognized in a timely manner, this type of perforation can be adequately managed by simply pulling the guidewire back into a safe position. However, the perforation can become a type Ⅱ if the endoscopist does not recognize the perforation and continues pushing the instrument further. Up to 20%-30% of type Ⅱ and Ⅲ perforations are not immediately diagnosed, and patients may report abdominal pain and discomfort, which are followed by fever and leukocytosis. These perforations can be confirmed by a computed scan of the abdomen, which reveals retroperitoneal air (Figure 4) or fluid collection[16].

## MANAGEMENT

General principles of management for ERCP-related perforation include a *nil per os* directive, *iv* fluid resuscitation, administration of antibiotics to decrease intra/retroperitoneal contamination or fluid collection, pneumoperitoneal decompression, and, if possible, endoscopic closure. In some cases, surgical consultation may also be needed to control sepsis and repair the perforation, depending on the site and degree of leakage, the patient's condition, and mechanism of injury. Radiologic interventions were

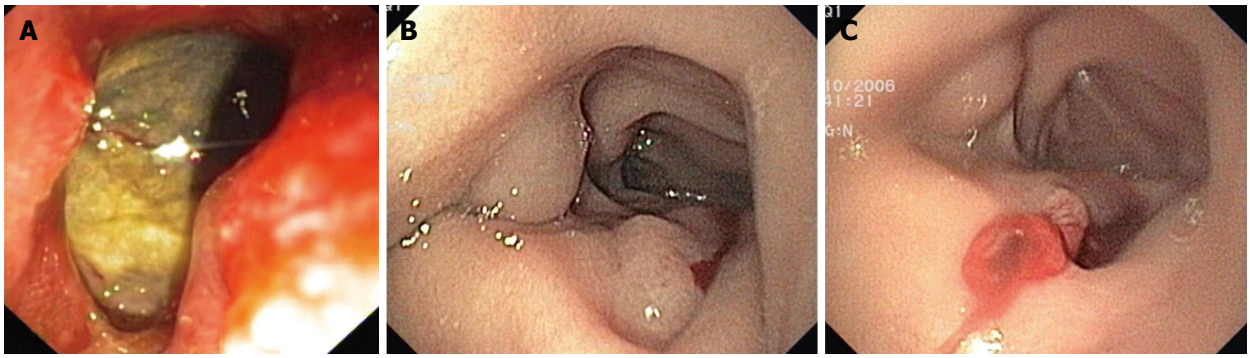

**Figure 2 Endoscopic visualization of perforations.** A: Image of yellowish tissue in the retroperitoneum; B and C: Bleeding from a lateral wall of the duodenum.

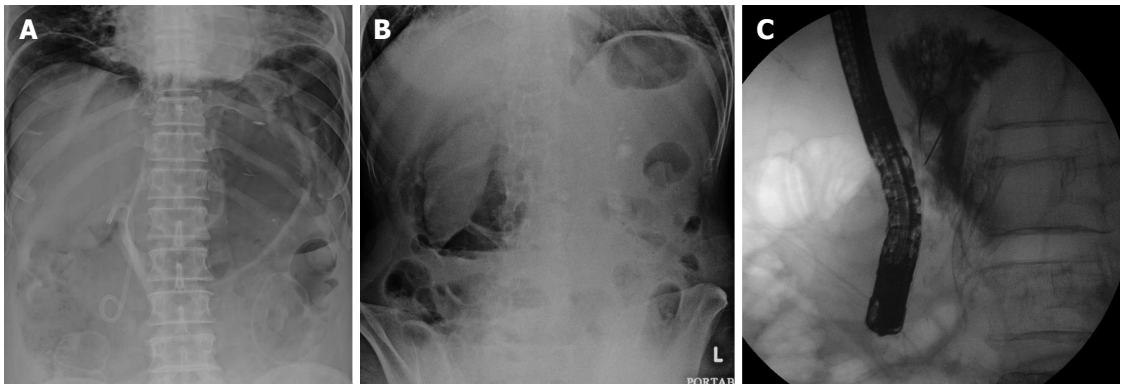

**Figure 3 Fluoroscopy showing pneumoperitoneum (A), retroperitoneal air (B) and leakage of contrast media into the retroperitoneal cavity (C).** The kidney outline (clear region on the right side of the image) showing retroperitoneal air.

**Figure 4 Computed tomography showing retroperitoneal air.**

found to be useful in some particular cases, particularly those with localized retroperitoneal fluid collection and without clinical sign of peritonitis[17]. However, the management of ERCP perforation in that particular study was based upon whether the perforation was diagnosed immediately after it occurred, or delayed by at least 24 h after the procedure (recognized by abnormal vital or abdominal signs).

### *Immediate diagnosis*

Type I perforations, which are typically 1.0-1.3 cm wide, have been successfully treated during ERCP with hemostatic clips either through the gastroscope(with or without cap assistance)[18,19] or with an endoloop[20], or with over-the-scope clips[21]. Contrast injections should be administered to rule out leakage, as 30%-60% of type I perforations fail endoscopic closure and require surgery. Patients who undergo immediate surgical correction typically remain in the hospital for 12-16 d. Prompt diagnosis is crucial, as evidenced by a study of Miller *et al*[11] that reported two deaths out of five cases involving type I perforations, resulting from delayed diagnosis in one case, and delayed operation in the other, and six deaths from delayed surgical repair of type Ⅱ perforations that were initially managed with a conservative treatment strategy[11]. Thus, some surgeons recommend immediate diagnosis and early surgery for ERCP-related perforations[22-24]. In our endoscopic center (within a tertiary care, university-based hospital), 4082 ERCP procedures were performed between January 2009 and June 2013, with a post-ERCP perforation rate of 0.29% ($n$ = 10 type Ⅰ; $n$ =2 type Ⅱ perforation cases). All of the patients (65-91 years old) were diagnosed during or immediately upon finishing the ERCP procedures. Eighty-three percent of these cases underwent surgical correction while only 17% received conservative treatment, with no deaths.

Mao *et al*[25] reported on nine cases of ERCP-related perforation (mostly type Ⅱ), six of which were managed conservatively with hospital stays ranging from 4 to 75 d. Subcutaneous emphysema was a significant clinical sign

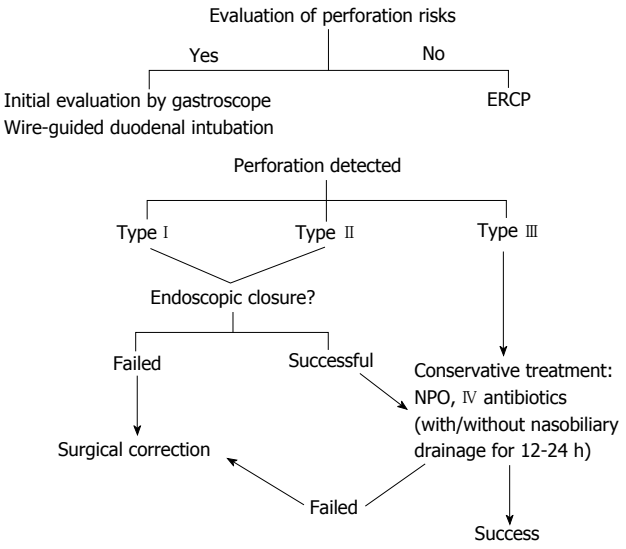

**Figure 5 Algorithm for prevention and management of endoscopic retrograde cholangiopancreatography-related perforations.**

found in seven of the nine patients. To aid in the success of conservative treatments, which included antibiotics, endoscopic treatment (when possible), intensive observation and follow-up imaging, nasobiliary and gastrointestinal drainage was recommended to reduce the leakage of digestive juices. However, very high success rates were also reported with conservative treatment (with or without nasobiliary drainage) by Park *et al*[26] and Vezakis *et al*[27], using fully covered self-expandable metal stents for closure of perforated sites at the ampullary region.

The majority of type Ⅲ perforations involve only mild contrast leakage or pneumoperitoneum without contrast leakage, and can be managed conservatively, requiring hospitalization for only 5-6 d[11,24]. Genzlinger *et al*[28] found that up to 29% of patients who underwent ERCP showed pneumoperitoneum on plain radiography without clinical significance. However, further investigation is recommended in patients who have pneumoperitoneum and clinical signs of infection.

The surgical indications in the studies mentioned here differed from recommendations stated by Stapfer *et al*[12], which include large extravasation of contrast, fluid collection in the peritoneal or retroperitoneal space on follow-up computed tomography scan, massive subcutaneous emphysema, or retained choledocholithiasis. Our recommendation is to perform salvage surgery in patients with: (1) failure of initial endoscopic closure, especially type Ⅰ or type Ⅱ perforations; (2) no improvement in clinical signs of sepsis, or follow-up abdominal signs worsening within 12-24 h after successful endoscopic closure (type Ⅰ) or conservative management (type Ⅱ); and (3) retained instruments or choledocholithiasis requiring surgical removal.

### Delayed diagnosis

The prognosis is generally worse for any type of perforation with a delayed diagnosis, and most patients develop clinical signs of peritonitis and sepsis within 1-5 d after the procedure[26-28]. It is important to note that abdominal signs might be relatively benign within the first few hours, even for type Ⅰ perforations, however the presentation of peritoneal signs as a late finding is related to a poor clinical outcome[11]. Surgical drainage and correction is recommended in cases of delayed type Ⅱ diagnosis with clinical sepsis[11,21,26,27]. However, most patients (50%-90%) having type Ⅱ perforations with minimal leakage or type Ⅲ perforations will respond to conservative treatment.

**Table 2 Factors associated with increased risk of post-endoscopic retrograde cholangiopancreatography perforation (from Enns *et al*[24])**

| Factors | Results of multivariate analysis [OR (95%CI)] |
|---|---|
| Dilated common bile duct | 2.32 (1.02-5.03) |
| Sphincter of oddi dysfunction | 3.20 (1.64-8.94) |
| Longer duration of procedure | 1.02 (1.00-1.04) |
| Biliary stricture dilatation | 7.29 (1.84-28.11) |
| Performance of sphincterotomy | 6.94 (2.43-19.77) |

## PREVENTION OF ERCP-RELATED PERFORATION

There are several factors that have been associated with an increased risk for ERCP-related perforation (Table 2). Nonetheless, there are steps that can be taken to avoid causing ERCP-related perforations, beginning before the procedure, and continuing through the follow-up stage (Figure 5).

### Pre-procedural evaluation

Some patients have a higher risk of perforation because of surgically altered anatomy. Such patients should undergo "endoscopic scanning" using an end-view gastroscope before starting ERCP. In cases of failure to pass the end-view scope owing to anastomotic stricture or too much resistance, continuation with the ERCP procedure should first be discussed with the patients and their families. If the endoscopist decides to follow through with the procedure, a duodenoscope should be inserted in an "over-the-guidewire" fashion to minimize duodenal wall injury. When narrowing of the anastomosis site is encountered, balloon dilatation over the guidewire can be helpful prior to duodenoscope insertion. However, this is not recommended for cases with malignant strictures, but rather duodenal stenting with a self-expandable metal stent followed by ERCP in the subsequent weeks is more appropriate.

### During bile duct cannulation and intervention

There are several comments and recommendations concerning the procedure that should be kept in mind: (1) Patients with periampullary diverticula have a higher risk of perforation, especially from sphincterotomy. Therefore, the endoscopist must be very careful during this

process. A balloon sphincteroplasty is recommended in such cases, rather than endoscopic sphincterotomy; (2) Insertion of any ERCP instruments into the bile duct should be performed in an "over-the-guidewire" fashion to prevent a "false track." Furthermore, the endoscopist should perform ERCP as gently as possible to minimize tissue injury; (3) Endoscopic sphincterotomy should be carried out in the suggested direction of 11 to 12 o' clock for the common bile duct and 12 to 2 o'clock for pancreatic sphincterotomy. Over-bowing of the sphincterotome should be avoided to prevent a "zipper cut," and cutting should not go beyond the second fold above the papilla. Adequate knowledge and intensive observation of ampulla anatomy are essential for all endoscopists who perform ERCP; (4) Needle-knife sphincterotomy should be performed only by experienced endoscopists. Those who are less experienced should recognize their limitations and be responsible enough to request assistance; and (5) Dilatation of the ampulla increases the risk of perforation. Therefore, the endoscopist should consider the length of sphincterotomy or the size of balloon sphincteroplasty suitable for the objective of the maneuver, such as limited or no sphincterotomy for stenting, dilating the ampulla no more than the size of the common bile duct above, and an appropriately sized sphincterotomy depending on the size of the stone.

### *During fluoroscopy*

The endoscopist should observe the patient's abdominal signs and perform fluoroscopy intermittently during the ERCP procedure. A diagnosis can be immediately made upon recognition of an abnormal guidewire position, extravasation of contrast, or pneumoperitoneum, which can allow for prompt treatment. Furthermore, a fluoroscopic abdominal scan should be performed after any difficult procedure to identify possible complications.

### *Post-procedural care*

Patients should be encouraged to promptly report any abdominal symptoms and should be watched for abnormal clinical signs after the ERCP procedure. The ward staff should be notified to maintain special observation of patients with difficult cases for early detection of possible complications.

## CONCLUSION

As ERCP-related perforations are a serious complication with a high mortality rate, endoscopists should perform the procedure with caution. To avoid perforation, endoscopists must evaluate the risks related to the patient and the procedure and perform the procedure with care. Once a perforation occurs, immediate diagnosis and early management are key factors to minimize mortality.

**Key words:** Primary idiopathic intestinal lymphangiectasia; Mucosa-submucosa; Protein loosing enteropathy; Double balloon endoscopy; Biopsy

**Core tip:** Waldmann's disease is an unusual primary idiopathic intestinal lymphangiectasia, which results in protein loosing enteropathy. Recently, double balloon endoscopy and biopsy in combination is an effective diagnostic tool to hit the correct diagnosis to avoid untoward complications related to disease and treatment due to misdiagnosis. Thus, the clinician should keep in mind this rare condition as a differential diagnosis of oedema.

## Abstract

Primary idiopathic intestinal lymphangiectasia is an unusual disease featured by the presence of dilated lymphatic channels which are located in the mucosa, submucosa or subserosa leading to protein loosing enteropathy.Most often affected were children and generally diagnosed before third year of life but may be rarely seen in adults too. Bilateral pitting oedema of lower limb is the main clinical manifestation mimicking the systemic disease and posing a real diagnostic dilemma to the clinicians to differentiate it from other common systemic diseases like Congestive cardiac failure, Nephrotic Syndrome, Protein Energy Malnutrition, *etc.* Diagnosis can be made on capsule endoscopy which can localise the lesion but unable to take biopsy samples. Thus, recently double-balloon enteroscopy and biopsy in combination can be used as an effective diagnostic tool to hit the correct diagnosis. Patients respond dramatically to diet constituting low long chain triglycerides and high protein content with supplements of medium chain triglyceride. So early diagnosis is important to prevent untoward complications related to disease or treatment for the sake of accurate pathological diagnosis.

## INTRODUCTION

Primary Intestinal lymphangiectasia (PIL) was originally described in 1961 by Waldmann *et al*[1]. It is an unusual cause of protein losing enteropathy either due to congenital malformation or obstruction of lymphatics of intestine[2]. Lymphangectasia is characterised by dilated and proliferating lymphatic channels located in mucosa, submucosa or subserosa leading to protein loosing enteropathy and loss of lymph into gut resulting in to hypoproteinemia, hypogammaglobulinemia, hypoalbuminemia and lymphopenia[3-5]. Peripheral oedema usually symmetrical (lower limb oedema) is the main clinical feature posing a real diagnostic dilemma to the clinicians to differentiate it from other common conditions like congestive cardiac failure, nephrotic syndrome, protein energy malnutrition, *etc*[3]. Other symptoms are ascites, pleural effusion, weight loss and abdominal pain, diarrhoea with increased faecal loss of protein and fat with increased serum levels of $\alpha$1-antitrypsin[2,5]. Diagnosis is defined by endoscopic evaluation and confirmed on histopathologi-

cal evaluation of biopsy of small intestine[1].

Now a day double balloon endoscopy and biopsy is the mainstay to arrive at correct diagnosis.

## EPIDEMOLOGY

The worldwide incidence and prevalence of PIL is not known[2,6]. After 1961, as per available literature less than 200 cases were reported[7,8]. Very few familial forms are reported[1,2,9]. There is no specific predilection for sex and race[6]. Most commonly, it has been seen in children and majority of the cases were diagnosed at or before 3 years of age but can be seen in adults also[5,6].

## PATHOPHYSIOLOGY

Waldmann's disease is also called as exudative enteropathy. The pathogenesis is not clear. The proposed hypothetical theories for pathogenesis are.

### *Lymphatic obstruction theory*

The basic cause for protein loss in PIL is poorly understood although lymphatic channel malformation/lymphatic hypoplasia leads to obstruction in lymph flow with resultant increase in intraluminal pressure in lymphatic channels[6,10,11]. This, increased intraluminal pressure will cause dilatation of the submucosal,subserosal lymphatic vessels in the intestine finally leading to the rupture of the cystically dilated channels and leading to discharge of the lymph into the bowel lumen[6,12]. Thus, net result is hypoalbuminemia, hypogammaglobinemia and lymphopenia.

**Genetic theory:** There are mutations in genes that regulate the process of lymphogenesis[5]. Multiple genes, *e.g.*, vascular endothelial growth factor receptor 3, prospero-related homeobox-transcriptional factor, forkhead transcriptional factor and *SOX18* play vital role in lymphogenesis[13]. Mutation of the *CCBE1* gene has been identified as a cause of intestinal lymphangiectasia in Hennekam syndrome.

## CLINICAL PRESENATION

Age-PIL is mainly seen in paediatric age group (usually before 3 years of age) and young adults but may be diagnosed in adults too[2,14-16].

Oedema is the main clinical manifestation. The patient may present with ascites, pleural effusion and pericarditis. Other symptoms are lymphedema, abdominal pain, fatigue, moderate diarrhoea, weight loss and deficiency of fat soluble vitamins may also be present.

Oedema is of pitting type and usually symmetrical in distribution involving lower limb. Sometimes severe oedema involving face, scrotum or vagina[5].

Rarely lymphedema have been described which is elicited by "stemmer's sign" and it is difficult to differentiate from other systemic causes of oedema[2,5]. Sonographic evidence of fetal ascites had also been reported[2,5,17].

Non-specific clinical features such as fatigue, nausea, vomiting, abdominal pain, weight loss, failure to thrive, moderate diarrhoea with faecal loss of fat along with increased faecal loss of protein, leading to rise in alfa-1-antitrypsin levels and there is deficiency of fat soluble vitamins[5,18].

Hypocalcemia-patients can also develop hypocalcemia and tetany due to vitamin D deficiency[2,6,19]. A case of digital clubbing in PIL was reported[20]. Osteomalacia and osteoporosis associated with PIL was reported[21].

Rare Associations-An association of PIL with celiac sprue was described[5,22]. PIL has been reported as a rare cause of lower gastrointestinal bleeding. In addition iron deficiency may occur[5,18]. Recently proved association with angiodysplasia leading to occult blood loss in PIL[5,23,24].

A case of intestinal lymphangiectasia presenting as abdominal mass was reported[2,5,25]. Recurrent haemolytic uraemic syndrome has been described in association with intestinal lymphangiectasia[2,26]. Patients with PIL are prone to develop infections due to lymphopenia and hypogammaglobulinemia[18,27].

Only two cases of disseminated cryptococcal meningitis and osteomyelitis in-patient with lymphangectasia have been reported in the literature so far[28-30]. Recently another case of cryptococcal meningitis as primary manifestation in a patient with intestinal lymphangiectasia has been reported[30]. Lymphoma may complicate the long term outcome of PIL patients[5,31].

PIL may exist as a part of a genetic syndromes, *i.e.*, Noonan, Von Recklinghausen, Hennekam and Yellow nail syndrome[2,5,14]. Finally, an association with autoimmune poly glandular disease type 1 has been described[5,32,33]. Recently a case of intestinal lymphangiectasia in a patient with infantile systemic hyalinosis syndrome has been reported[34].

## DIAGNOSTIC EVALUATION

Now days, diagnosis of Intestinal lymphangiectasia is based on characteristic findings during a double-balloon enteroscopy with further confirmation by histopathological examination of corresponding biopsy specimens[6,35]. To confirm the primary nature of waldmanns disease we must first exclude the secondary causes of intestinal lymphangiectasia[6].

### *Capsule endoscopy*

Capsule endoscopy provides complete examination of small bowel mucosa thus can evaluate the extent of lymphangiectasia[36,37]. However, the drawback of capsular endoscopy is the inability to obtain biopsies. So recently double balloon enteroscopy is evolved.

### *Double balloon enteroscopy*

In view of the drawback of capsular endoscopy, its inability to obtain biopsies, double balloon enteroscopy was

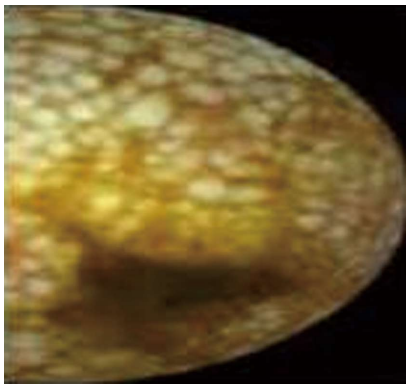

**Figure 1 Snow flake appearance.**

evolved which allowed obtaining biopsies from lesions detected by capsular endoscopy[35,36].

Endoscopy reveals scattered white spots, which have been described as a characteristic snowflake appearance, (Figure 1) overlying the small intestinal mucosa[4,38].

### *On endoscopy*

Histopathological examination of biopsies shows dilated lymphatic vessels in mucosa, submucosa and serosa with polyclonal plasma cells confirming the intestinal lymphangiectasia (Figures 2).

Although various methods are available to investigate PIL, careful histopathological examination of biopsies is must to confirm the diagnosis. Various methods to investigate PIL are $^{99}$Tc-HSA, 24 h stool alfa-1-antitrypsin clearance, lymphoscintigraphy, ultrasonography (USG), computed tomography (CT) scan, magnetic resonance imaging (MRI).

$^{99}$Technetium-labelled scintigraphy is useful to arrive at the diagnosis of PIL. Due to high cost and infectious risk, it has replaced with alfa-1-antitrypsin method[2,39].

Lymphoscintigraphy identifies abnormality in lymphatic tree but at present is not a routine method for PIL diagnosis[2,40,41].

On radiographic barium studies, thickened irregular mucosal fold with tiny nodules representing dilated lymphatic suggest the intestinal lymphangiectasia[42].

### *Non-invasive modalities*

Imaging with USG/CT scan has shown diffuse thickening of small bowel wall because of engorgement of villi that contain the dilated lymphatic channels[5,43]. CT scan may show "halo sign". A halo sign that consist of thickened, low-attenuation inner ring representing dilated lymphatics and higher attenuation outer ring, which consist of muscularis propria and serosa[43-45]. Nonenhanced, fluid-sensitive MRI may show bright signal intensity, which corresponds to lymphangiectasia in the mucosa[42,44].

### *Other laboratory investigations*

PIL is associated with many laboratory findings which include decreased albumin and total protein levels[2,5,45].

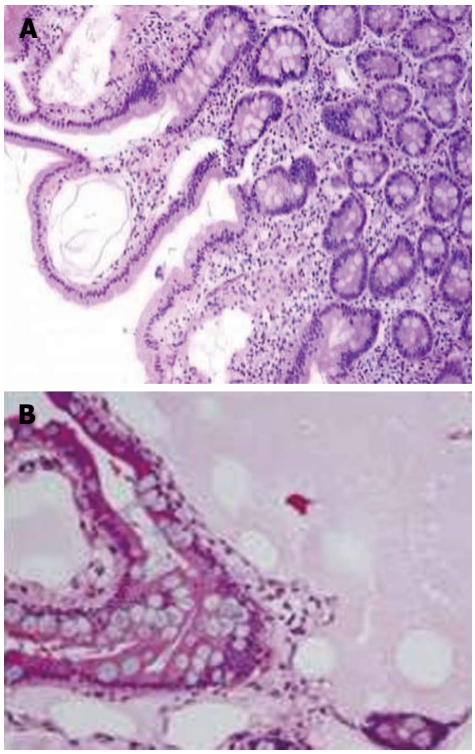

**Figure 2 Histopathological examination of biopsies.** A: Dilated lymphatics in mucosa and submucosa; B: 40 ×; showing dilated lymphatic channels filled with lymph.

In Addition diminished immunoglobulins IgG, IgA and IgM suggesting B cell depletion and reduced numbers of $CD4^+$ cells as naive $CD45RA^+$ lymphocytes and $CD45RO^+CD8^+$T cells reflecting T-cell depletion seen[2,5,46,47].

Finally, a recent report indicates there is failure of compensatory mechanism of production of T lymphocytes by the thymus to overcome the enteric loss of T lymphocytes leading to lymphopenia associated with lymphangiectasia[5,48].

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of PIL is large and involves many conditions producing protein-losinggastroenteropathy. Much closer differential are those, which involve protein loss associated with impaired intestinal lymphatic drainage. Such conditions include cardiac causes like congestive cardiac failure, constrictive pericarditis and cardiomyopathy[49-52]. Surgical repair of complex congenital heart disease (such as the Fontan procedure for a functional single ventricle), other conditions like lymphenteric fistula[10,53], Whipple's disease[54], Crohn's disease[55], sarcoidosis[56], human immunodeficiency virus-related enteropathy[57], intestinal tuberculosis[58], radiation and/or chemotherapy with retroperitoneal fibrosis[59] and portal hypertension or hepatic venous outflow obstruction after liver transplantation and in congenital hepatic fibrosis due to phosphomannose isomerase deficiency[60].

## TREATMENT

The principal treatment for PIL is diet rich in protein, low in fat with supplementation of medium chain triglyceride. Medium chain triglyceride is directly absorbed in portal venous circulation by passing the intestinal lymphatics, thus provides the energy and lessens lacteal engorgement and lymph loss. A low fat diet reduces lymphatic flow and pressure preventing the lacteal dilation and lymph leakage resulting from their rupture. In some, reversal of clinical and biochemical changes has been seen with this dietary modification. In most patients, dietary treatment is permanently needed. This is found to be more effective in children than adults. In some cases, total parenteral nutrition is needed. Supportive therapy includes albumin infusion and paracentesis.

In patients, not responding to such therapy other options may be used after or in combination with dietary modification. These are octreotide, antiplasmin,tranexemic acid, vitamin D supplementation and surgical resection of segmental or localised intestinal lymphangiectasia[8,11,61].

To conclude PIL is an idiopathic protein loosing enteropathy either due to genetic defect or due to lymphatic obstruction. Careful endoscopic examination and meticulous histopathological evaluation is mandatory to arrive at correct pathological diagnosis to decide the proper treatment plan. One should keep in mind this rare condition as a differential diagnosis of oedema.

## Abstract

**AIM:** To study the comparison in terms of root coverage the effect of gingival massaging using an ayurvedic product and semilunar coronally repositioned flap (SCRF) to assess the treatment outcomes in the management of Miller's class I gingival recessions over a-6 mo period.

**METHODS:** The present study comprised of total of 90 sites of Miller's class- I gingival recessions in the maxillary anteriors, the sites were divided into three groups each comprising 30 sites, Group I -were treated by massaging using a Placebo (Ghee) Group II-were treated by massaging using an ayurvedic product (irimedadi taila). Group III-were treated by SCRF. Clinical parameters assessed included recession height, recession width, probing pocket depth, width of attached gingiva, clinical attachment level and thickness of keratinized tissue. Clinical recordings were performed at baseline and 6 mo later. The results were analyzed to determine improvements in the clinical parameters. The comparison was done using Wilcoxon signed rank test. The overall differences in the clinical improvements between the three groups was done using Kruskal-Wallis test. The probability value (*P*-value) of less than 0.01 was considered as statistically significant.

**RESULTS:** Non-surgical periodontal therapy and gingival massaging improves facial gingival recessions and prevents further progression of mucogingival defects. Root coverage was achieved in both the experimental groups. The SCRF group proved to be superior in terms of all the clinical parameters.

**CONCLUSION:** Root coverage is significantly better with semilunar coronally repositioned flap compared with the gingival massaging technique in the treatment of shallow maxillary Miller class I gingival recession defects.

**Key words:** Gingival recession; Semilunar flaps; Gingi-

val massaging; Non-surgical

**Core tip:** Gingival recession is the migration of the gingival margin apical to the cemento-enamel junction. A variety of surgical procedures have been described for the correction and management of mucogngival deformities and defects, with a variable degree of success. However, it should be emphasized that shallow recessions are subject to progression, but there are no case reports or controlled clinical trials to compare the effects of gingival massaging in the treatment of gingival recessions. The aim of our study was to compare in terms of root coverage the effect of gingival massaging using an ayurvedic product and semilunar coronally repositioned flap to assess the treatment outcomes in the management of Miller's class I gingival recessions over a 6 mo period.

Mishra AK, Kumathalli K, Sridhar R, Maru R, Mangal B, Kedia S, Shrihatti R. Comparison of semilunar coronally repositioned flap with gingival massaging using an Ayurvedic product (irimedadi taila) in the treatment of class- I gingival recession: A clinical study. *World J Clin Cases* 2014; 2(10): 534-540 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/534.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.534

## INTRODUCTION

Gingival recession is defined as the migration of the marginal tissue apical to the cemento-enamel junction (CEJ). Its occurrence is common and its prevalence increases with age. The recession of the gingiva resultant of attachment loss and root exposure may be associated with one or more tooth surfaces and lead to clinical problems such as dentinal hypersensitivity, root caries, cervical root abrasions and diminished cosmetic appeal[1,2].

Miller[3] (1985) in his classification of recession has described class I recession as marginal tissue recession that does not extend up to the mucogingival junction and not accompanied by any loss of bone or soft tissue in the interdental area. Very often, it is the most coronal millimeter of recession which is visible when the patient smiles. Thus even a marginal gingival recession, can account for major aesthetic problems and persistent dentinal hypersensitivity[4]. In order to combat these clinical problems, various treatment modalities have been proposed that have in due course evolved based on the knowledge of healing of the gingiva and the attachment system.

Aimetti *et al*[5] (2005) proposed non-surgical therapy *viz* periodic scaling and polishing for the treatment of shallow gingival recession. It was hypothesized that reduction of root convexity and elimination of microbial toxins from the root surface by scaling and root planing promotes creeping attachment of gingival margin. Tarnow[6] (1986) introduced the semilunar coronally repositioned flap (SCRF) procedure as one of the surgical approaches to treat Class I gingival recessions. It entails coronal advancement of a semilunar flap without any tension or disturbance to the subjacent tissues. The flap is stabilized in the desirable position under gravity, hence a sutureless technique.

Gingival massaging an age old practice is said to increase capillary gingival microcirculation, thereby increasing oxygen sufficiency, gingival fibroblastic proliferation, keratinization of oral and sulcuar epithelium, and formation of dense bundles of collagenous connective tissue all of which are attributable to creeping attachment[5,7]. Gingival massaging is carried out using various agents that aid lubrication as well as medication of the tissues. IrimedadiTaila an ayurvedicproductis said to have been used for centuries by many communities in the Middle East and North Africa as a massaging agent[8]. It consists mainly of Acacia arabica a complex mixture of the calcium, magnesium and potassium salts of Arabic acid. Its antiplaque properties are said to create right conditions for gingiva to recapture its biologic dimensions[5,8].

However no much of information is available upon an electronic or manual search concerning the effects of gingival massaging in the treatment of gingival recessions. There is a dearth of information as to by what exact mechanisms the non-surgical approaches help root coverage and to what extent if at all. Given that many patients are skeptical about surgical treatment, scaling/root planing followed by gingival massaging with an agent could be a better option provided their benefits are proved. This study is one such attempt to evaluate the effect of gingival massaging using an ayurvedic product in comparison with SCRF to assess the treatment outcomes in the management of Miller's class I gingival recessions. Hence the aim of the present study was to assess the efficacy of SCRF and gingival massaging (by placebo and IrimedadiTaila) in terms of root coverage in Miller's Class I recession, with respect to clinical parameters [Recession height (RH), recession width (RW), probing depth (PD), clinical attachment level (CAL), thickness of keratinized tissue (TKT) and width of attached gingiva]. Further, intergroup which comparisons of treatment outcomes to assess advantages or disadvantages of one technique over the other was also assessed.

## MATERIALS AND METHODS

A total of 90 sites of Miller's class- I gingival recessions on labial aspects of maxillary anteriors, were selected from the patients reporting to the out-patient department of Periodontics, Modern Dental College and Research Centre, Indore. Teeth associated with inadequate width of attached gingiva, caries/restorations were excluded. Pregnant females and individuals afflicted by systemic disease, tobacco/alcohol abuse, parafunctional habits were excluded from the study. Individuals who were already on the regimen of gingival massage or had undergone mucogingival surgery were dropped out of the study.

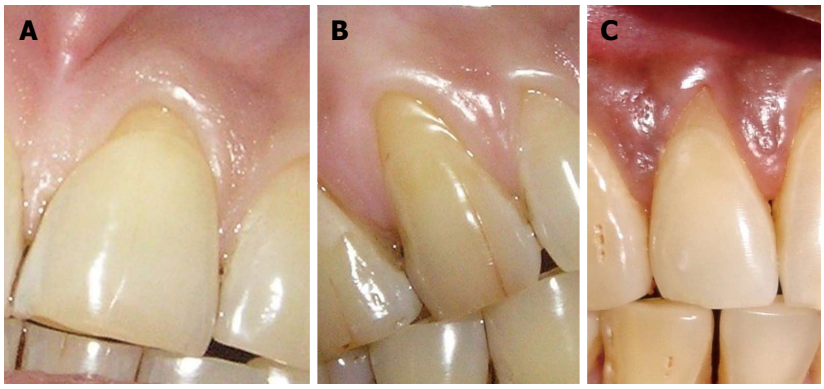

**Figure 1 Miller's class- I gingival recession.** A: Miller's class- I gingival recession with 11; B: Miller's class- I gingival recession with 13; C: Miller's class- I gingival recession with 12.

**Figure 2 Coronally repositioned flap with 12.**

The study protocol was approved by the ethical committee of Modern Dental College and Research Centre, Indore and study sites were randomly allocated to three different study groups after obtaining an informed consent. Group I (control group) comprised of 30 sites that were treated by massaging with placebo (clarified butter). Group Ⅱ (test group) included 30 sites that were treated by massaging with an ayurvdicoil (IrimedadiTaila). Group Ⅲ (test group) included 30 sites to be treated by SCRF[6].

### Clinical evaluation

The sites were subjected to clinical assessments as follows: RH was measured as the distance from the CEJ to the gingival margin (GM), calculated in millimeters. RW was recorded as horizontal width of CEJ. Probing pocket depth was measured as the distance from the GM to the bottom of the gingival sulcus. CAL was calculated as recession height and probing depth (RH + PD). Width of attached gingiva was recorded as the distance between the free gingival groove and the MGJ. All the readings were recorded using a manual pressure-sensitive periodontal probe DB 764 R, (Aesculap, Tuttlingen, Germany) calibrated at a force of 0.2 N. Readings for TKT was obtained by penetrating the tissue with a 15 number endodontic spreader under lidocaine 15 gm spray and subsequently the penetration depth was measured with an electronic caliper of 0.01 mm resolution. The gingival thickness was assessed at midbuccal level in the attached gingiva, half way between the mucogingival junction and free gingival groove[9]. These readings were recorded preoperatively as well as 6 mo post-operatively and then subjected to statistical analysis.

### Clinical procedures

After a detailed examination and diagnosis, scrupulous oral prophylaxis was accomplished to ensure that local etiological factors are eliminated; followed by oral care instructions and patient motivation towards compliance. Patients belonging to group I (Figure 1A) and group Ⅱ (Figure 1B) were trained to master the technique of gingival massaging with either of the agents as the case may be. The technique involved massaging their gums with finger three times daily for two minutes in the concerned area and then rinse away with water. Patients were instructed to comply with gingival massaging for the span of 6 mo, after which to report back for post-operative evaluation. Sites belonging to group Ⅲ (Figure 1C) were treated surgically by semilunar coronally repositioned flap (Figure 2) as recommended by Tarnow[6], followed by suitable postoperative surgical care and oral care instructions. The patients were recalled at 1, 3 and 6 mo post operatively. One and 3 mo postoperative recall visits were utilized for reinforcement of oral care regimen and massaging techniques, wherein, readings at 6 mo postoperative follow up only were utilized for statistical analysis.

### Statistical analysis

Shapiro-Wilk test was applied to test for the Normalcy of the data. The parameters significantly differed from normal distribution, and therefore, all the comparisons were tabulated using Non-Parametric tests, *i.e.*, wilcoxon signed rank test, Kruskal Wallis and Mann Whitney *U* test. All comparisons were done using SPSS Statistical Software Package Version 10.0 and probability value (*P*-value) of less than 0.01 was considered as statistically significant.

## RESULTS

Gingival massaging with placebo (Ghee) (Figure 3A)

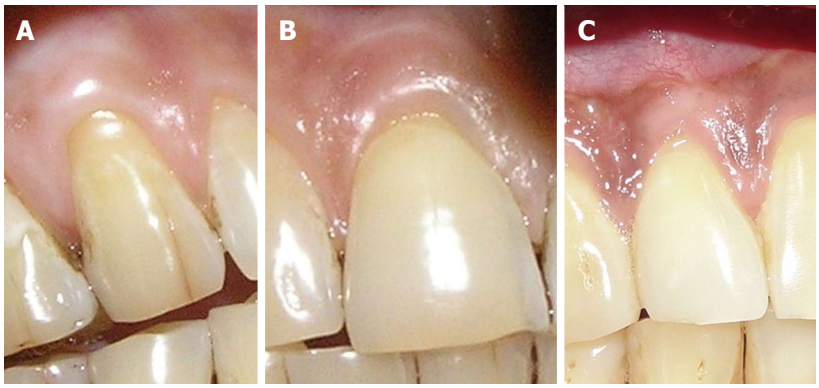

**Figure 3 Six months post-operative view.** A: Six months post-operative view of 12; B: Six months post-operative view of 11; C: Six months post-operative view of 13.

**Table 1 Evaluation of clinical parameters from pre-operative to 6 mo post-operative period for group Ⅰ-gingival massaging using a placebo (Clarified butter) ($n$ = 30)**

| Clinical parameters | Baseline (mean ± SD) | 6 mo (mean ± SD) | *P*-value (significance) |
|---|---|---|---|
| Recession height | 1.7 ± 0.65 | 1.5 ± 0.51 | 0.034 |
| Recession width | 3.8 ± 0.66 | 3.57 ± 0.63 | 0.100 |
| Probing pocket depth | 1.9 ± 0.40 | 1.5 ± 0.51 | 0.001[b] (S) |

**Table 3 Evaluation of clinical parameters from pre-operative to 6 mo post-operative period for Group-Ⅲ semilunar coronally repositioned flap ($n$ = 30)**

| Clinical parameters | Baseline (mean ± SD) | 6 mo (mean ± SD) | *P*-value (significance) |
|---|---|---|---|
| Recession height | 2.33 ± 0.55 | 0.57 ± 0.50 | < 0.001[b] (S) |
| Recession width | 3.33 ± 0.76 | 1.1 ± 0.66 | < 0.001[b] (S) |
| Probing pocket depth | 1.57 ± 0.50 | 1.33 ± 0.48 | 0.071 |
| Clinical attachment level | 3.87 ± 0.73 | 1.9 ± 0.66 | < 0.001[b] (S) |
| Thickness of keratinized tissue | 0.97 ± 0.19 | 1.38 ± 0.23 | < 0.001[b] (S) |
| Width of attached gingiva | 2.63 ± 0.71 | 3.37 ± 0.56 | 0.001 (S) |

[b]$P$ < 0.01, clinical parameters from pre-operative *vs* 6 mo post-operative period. S: Significant.

resulted in a statistically significant reduction in probing pocket depth ($P$ = 0.001), gain in clinical attachment level ($P$ = 0.002) and increase in thickness of keratinized tissue ($P$ < 0.001). The clinical improvements with respect to recession height, recession width and width of attached gingiva were statistically nonsignificant (Table 1). Gingival massaging using an ayurvedic product (IrimedadiTaila) (Figure 3B), on the contrary resulted in to statistically significant reductions in recession height and recession width ($P$ < 0.003 and $P$ < 0.001 respectively); also a significant gain in thickness of keratinized tissue and width of attached gingiva ($P$ < 0.001) and ($P$ = 0.001) respectively. But reductions in probing pocket depth and clinical attachment level were statistically nonsignificant (Table 2). Sites treated by semilunar coronally repositioned flap (Figure 3C) exhibited highly significant improvements with respect to all the clinical parameters except probing pocket depth (Table 3).

Intergroup comparisons (Table 4) *via* Kruskal Wallis test aided in the determination of advantages of one technique over the other. Sites treated by SCRF exhibited highly significant improvements with respect to recession height ($P$ < 0.001), recession width ($P$ < 0.001), CAL ($P$ < 0.001), thickness of keratinized tissue ($P$ < 0.004) as compared to those treated by gingival massaging with the ayurvedic substance. However no significant difference was observed in relation to probing pocket depth between the groups (Table 5). Sites treated by SCRF had similar advantages when compared with sites treated by gingival massaging using a placebo (Table 6).

When compared between gingival massaging with an ayurvedic substance and placebo, former showed remarkable improvements only with respect to recession width ($P$ < 0.001), probing pocket depth ($P$ < 0.001) and thickness of keratinized tissue ($P$ < 0.001). However there was no significant difference with respect to CAL, recession height and width of keratinized gingiva (Table 7).

## DISCUSSION

Gingival recession is a common condition whose extent and prevalence has been noted to increase with age. It

has been estimated that 50% of the population has one or more sites with 1mm or more of such root exposure. This prevalence rate increases to 88% for individuals above 65 years of age[10].

Given the high prevalence rate of gingival recession defects among the general population, it is imperative that dental practitioners have an understanding of the etiology, complications and treatment options of the condition. Even in this era, when sophisticated techniques and materials are available, non-invasive approaches to treatment of recessions remain in practice with paramount importance. This study was carried out to assess the viability of surgical and non-surgical techniques for management of gingival recessions.

Numerous studies reported the efficacy and predictability of proposed surgical techniques. Several factors govern the selection of a surgical technique to treat recessed teeth such as the anatomy of the defect site, such as the size of the recession, width of keratinized tissue adjacent to the defect, dimensions of the interdental soft tissue, and the depth of the vestibule or the presence of frenula and evidence based predictability of various procedures[11-13]. The SCRF surgical procedure is easy to perform and highly reproducible in shallow recession defects (class I) when gingival augmentation is not needed. Case reports[2,14,15] have shown a high success rate for this procedure.

Gingival massaging, an age old traditional oral hygiene practice which has been used for centuries by many communities have two quite separate effects on gingival keratinization. One, the direct effect of frictional stimulation leading to an increased mitotic rate and greater thickness of both the malpighian region and the stratum corneum of the gingival epithelium and the other, an indirect effect of the more efficient removal of dental plaque which leads to a reduction in inflammation, allows the gingival epithelium to express more fully its keratinizing potential[16]. The other effects of gingival massaging is said to increase capillary gingival microcirculation[17,18] thereby increasing oxygen sufficiency[19], gingival fibroblastic proliferation[7], and formation of dense bundles of collagenous connective tissue[20]. However, only one case is available in the literature[21] showing successful root coverage at multiple sites resulting from gingival massage. To our knowledge, there have been no long term controlled studies to provide outcome assessment data with regard to predictability and percentage of recession coverage by gingival massaging using ayurvedicoil. Hence this study was undertaken to compare benefits of gingival massaging using ayurvedic oil with those of SCRF technique in the treatment of class I recession.

This study witnessed that, although SCRF technique proved to be far superior, the clinical outcomes of gingival massaging by an ayurvedic oil (IrimedadiTaila) were

almost close to it (Tables 1, 2 and 3). Both the procedures produced statistically significant improvement with relation to recession height, recession width, thickness of keratinized tissue and width of attached gingiva, implying that both the methods are equivalent in root coverage and increasing width and thickness of attached gingiva. The significant root coverage achieved with of SCRF technique in the present study is almost in accordance with numerous other studies with only slight differences[12,22-26]. Some of those studies with higher success in root coverage have notably used additional methods of flap fixation such as sutures/adhesives or microsurgical techniques that may have enhanced clinical outcomes. Thus the differences in surgical protocols and measurement methods adapted in the study could be held responsible for variations in the results. The significant increase in width of attached gingiva with SCRF technique could be attributed to the granulation tissue that fills the semilunar area. Other studies too have presented similar observation although with slight variations[24,25,27-29]. This variability could be attributed to the bias in the methods used to identify the mucogingival position, surgical approach and improper case selection. The significant increase in the thickness of keratinized tissue in our study goes well in accordance with Bittencourt *et al*[26]. Increase in the thickness of gingival tissue is desirable since it can resist gingival recession resulting from faulty tooth brushing and inflammatory reactions[29,30]. But some authors have questioned the ability of thick gingival tissue in the prevention of recession. Based on a 2 year prospective clinical study authors recommend the practice of correct brushing technique to prevent recession instead of relying on the ability of thickness of gingiva[31]. Only long term follow up studies can determine the sound basis for this association. SCRF technique also leads to significant gain in CAL in the study sample. Similar observations have been reported by other studies too[24,26,32]. The probing depth reductions were non-significant.

In this study, an attempt was made to elucidate the role of creeping attachment in root coverage following gingival massaging with ayurvedic oil. Gain in CAL was assumed to be reflecting creeping attachment but the gain in CAL following gingival massaging were negligible (0.4-0.89 mm) and statistically non-significant (Table 2). These results are weak to support the hypothesis that, gingival massaging brings root coverage *via* creeping attachment. The available literature also lacks exact details as to when and how the creeping attachment starts and progresses. Certain studies have observed that creeping attachment occurs between 1 mo to 1 year.

In contrast, there was increase in the probing depths although negligible. This leads us to speculate that, massaging action may have lead to flattening and adaptation of gingival margin, or even marginal hypertrophy that majorly attributes to reduction in width and height of visible recession. Though this speculation may not hold strong consideration, it cannot be denied.

Intergroup comparisons (Table 4) demonstrated clear advantages of SCRF over gingival massaging with ayurvedic oil, which inturn is advantageous over gingival massaging with placebo (clarified butter). This clearly states the superior nature of SCRF in the treatment of class I recessions, while, gingival massaging with ayurvedic oil maintains close proximity to SCRF in terms of its clinical outcomes. Unfortunately no such data is available in the literature against which our observations could be compared.

Nevertheless SCRF procedure is a gold standard approach in terms of all the clinical parameters except for probing pocket depth and width of attached gingiva compared to the gingival massaging group. Under the circumstances where SCRF procedure remains contraindicated, or in patients who are skeptical on having to undergo surgical therapy for recession coverage, gingival massaging with an ayurvedic substance (IrimedadiTaila) offers a best alternative with almost equivalent benefits. Even the simple gingival massaging using an inert lubricant (such as Ghee) can be opted for as an adjunct to Scaling and root planing in areas of recession during maintenance phase.

## COMMENTS

### Background

The Semilunar coronally repositioned flap (SCRF) is one of the procedure described in the *Journal of Clinical Periodontology* in 1986 for the treatment of shallow recession. So far, however, no controlled clinical study has evaluated the SCRF performed as originally described and compared it with gingival massaging using an Ayurvedic product.

### Research frontiers

Root coverage was achieved in both the groups and was stable during the evaluation period of 6 mo.

### Innovations and breakthroughs

This is the pioneer study, where authors have used Ayurvedic product for massaging and results were significant when compared with SCRF technique.

### Applications

Daily home care by the patient and gingival massaging might play an important role in improving gingival recessions and prevents further progression of mucogingival defects.

### Terminology

IrimedadiTaila: Name of Ayurvedic massaging oil, with ingrediants like Acacia Arabica, *etc.*, which is used for maintaining plaque free environment in the oral cavity.

### Peer review

The authors have chosen a very interesting and inexhaustible theme for the article.

## Abstract

**AIM:** To describe human leukocyte antigen (HLA) alleles in individuals with Down syndrome and alopecia areata.

**METHODS:** A cross-sectional study was conducted, which evaluated 109 individuals. Ten with down syndrome (DS) and alopecia areata (AA), ten with DS without AA and ten with AA without DS, and their families. The individuals were matched by gender and age. The following data were computed: gender, age, ethnic group, karyotype, clinical presentation and family history of alopecia areata. Descriptive analysis: measures of central tendency and frequency distribution. Inferential analysis: Fisher's exact test to compare categorical data between the three groups and Kruskal-Wallis *ANOVA* test for numerical data.

**RESULTS:** Seventy per cent of evaluated individuals in the DS and AA group were male; presented mean age of 18.6 (SD ± 7.2) years and 70% were Caucasian. We observed involvement of the scalp, with a single lesion in 10% and multiple in 90% of subjects. It was observed that there is no significant difference in the frequency distributions of the alleles HLA loci A, B, C, DRB1 and DQB1 of subjects studied. However, according to Fisher's exact test, there is a trend ($P$ = 0.089) of DS group to present higher proportions of HLA-A 36 and HLA-B 15 than the AA group and AA and DS group.

**CONCLUSION:** There was a tendency for the DS group, to present proportion of HLA-A 36 and HLA-B 15 higher than the AA group and group of individuals with AA and DS. However, there was no significant difference in the frequency distribution of the alleles.

**Key words:** Down syndrome; Alopecia areata; Human leukocyte antigen antigens; Immunology; Genetic

**Core tip:** The prevalence of alopecia areata (AA) in down syndrome (DS) individuals ranges from 1% to 11%, higher than in general population. The frequency distribution of human leukocyte antigen alleles in the groups was heterogeneous; there was a tendency of alleles A-36 and B-15 in DS group. The cause of AA in DS remains unknown.

HLA antigens in individuals with down syndrome and alopecia areata. *World J Clin Cases* 2014; 2(10): 541-545 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/541.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.541

## INTRODUCTION

Down syndrome (DS) is the most frequent chromosomal anomaly and common cause of mental retardation[1,2]. The prevalence of DS is approximately 1:770 births, with a slight preponderance in the male gender[3].

This syndrome presents an increased prevalence of autoimmune disorders[4]. The prevalence of alopecia areata (AA) in DS ranges from 1% to 11%, more frequent in this group than the general population[5-11]. Some studies conducted with DS patients with and without AA showed changes related to the immune system. There are few studies involving the histocompatibility antigens (HLA), DS and AA[12-14].

The purpose of this study was to describe HLA alleles (loci A, B, C, DRB1 and DQB1) in individuals with DS and AA.

## MATERIALS AND METHODS

A cross-sectional study was conducted, in which 109 individuals were evaluated; 10 individuals with DS without AA (Group A) and 10 individuals with AA without DS (Group B), 10 individuals with DS and AA (Group C) and their families (Figure 1). The individuals were matched by gender and age. The clinical research protocol was approved by the Ethical Research Committee of the Martagão Gesteira Pediatric Institute (IPPMG) and all participants or their caregivers signed the informed consent.

All DS individuals were diagnosed clinically, most by cytogenetic analysis, and presented a documented medical history of AA or presented alopecia at the time of a consultation at the Medical Genetics Service. AA was considered to be hair loss leading to a "flaw" on any hairy body surface.

All the participants of the study were submitted to anamnesis and clinical exam to confirm DS and/or AA diagnosis by a clinical geneticist and by a dermatologist respectively. Exclusion criteria included: trichotillomania and presence of polycystic ovaries (evaluated by pelvic ultrasound in post-menarche female DS and/or AA patients).

The following data were computed: (1) gender and age; (2) cytogenetic exam; (3) ethnic group; (4) clinical picture of AA; (5) family history of AA; (6) HLA alleles; and (7) evaluation of family.

The HLA typing was performed using commercial kits: LABType® Typing sequence specific oligonucleotide probes (SSO) Tests (One Lambda, Inc. CA, United States), which are based on the use of SSO which are connected on the microbeads encoded by fluorescence identifying alleles encoded by the DNA sample.

A descriptive analysis with measures of central tendency and frequency distribution was made and an inferential analysis on exploratory level was made by Fisher's exact test to compare categorical data between the three groups by ANOVA and Kruskal-Wallis test for numerical data. Nonparametric test was used because the variables were not normally distributed (Gaussian), due to the dispersion of the data and rejection of the hypothesis of normality according to the Kolmogorov-Smirnov test. The criterion for determination of significance level was 5%.

## RESULTS

Table 1 provides the frequency (*n*) and percentage (%) of categorical variables and disease according to demographic groups (A, B and C) and the corresponding descriptive level (*P* value) of Fisher's exact test. The age in months and the number of family members were expressed as mean, median and standard deviation and compared by Kruskal-Wallis ANOVA.

Table 2 provides the frequency (*n*) and the percentage (%) of the loci of HLA-A, B, C, DQB1 and DRB1 alleles, in the groups (DS, AA and DS + AA) and corresponding descriptive level (*P* value) of Fisher's exact test.

Regarding the relatives evaluation of first and second degrees, it was observed that the majority of alleles showed a low frequency. We emphasize some alleles such as HLA-C 07 (21/55), HLA-DQB1 03 (28/55) and HLA-DQB1 06 (22/55) which had a high frequency (> 50%) in the first-degree relatives of all groups.

## DISCUSSION

This study reflects an unpublished investigation in patients with DS. However, there was no statistical significance in the distribution of HLA in DS with or without AA. Although the sample size reflected a small number of patients, in general, the groups did not differ (Table 1), reflecting the selection criteria used. Several studies have focused on the association of HLA and AA; some of them correlating prognosis, extent, chance of recurrence and family history with HLA[15-17]. These studies report that HLADQB1*03 allele was presented in 80% of all patients with AA, independently of the phenotype, and in 92% of individuals with total or universal AA. It was also demonstrated that the frequency of HLA-DRB1*1104 was increased in all sorts of AA[15,16]. These data were not reported in this study.

Although the literature reports that the AA in individuals with DS is more common in females[5,18], the sample was predominantly male (70.0%). Schepis *et al*[19] (2005) studied individuals with DS and AA, and also identified more men with AA (92.3%). Concerning the 352 DS cases recorded in IPPMG, 15 of them presented AA; the most frequently occurrence of AA in males was not significant ($P > 0.05$). AA can occur as a single and self-limited episode, but also can recur in DS patients[20,21]. In this study, 90% (9/10) individuals with DS and AA had

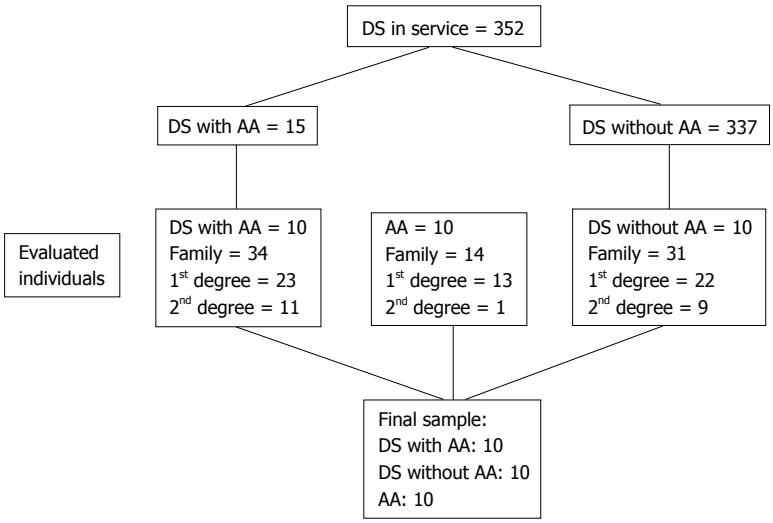

**Figure 1 Structure of selected sample.** DS: Down syndrome; AA: Alopecia areata.

more than one lesion on the scalp, and 10% (1/10) presented single lesion on the scalp. This finding was similar which is reported in the literature[19]. AA can affect any hairy area and the most affected is scalp (90%)[22-25]. All evaluated individuals presented scalp lesion.

Regarding family history, it is present in 10%-25% of cases of AA[10,26]. In this study we observed two cases (20%) of family history (first degree relative) in AA without DS group.

Genetic studies of AA have focused on HLA antigens due to immunological aspects of the disease[15,17,27,28]. Some have demonstrated that major complex of histocompatibility genes are the major determinants for diseases mediated by T cells, including AA[29,30]. In this study, no significant difference was observed at the level of 5% on the proportion of HLA-A between groups. According to Fisher's exact test, there is a trend ($P = 0.089$) of the DS group, present proportion of HLA-A 36 (30%) higher than the AA (0%) and DS with AA (0%) group. Xiao *et al*[17] (2006) evaluated Chinese individuals, 192 with AA and 252 controls and found higher frequency of HLA-A*02 and A*03 in patients than in controls. Despite not being the same allele, we can see that the distribution is in fact heterogeneous.

In the same study[17], comparing patients and controls, a higher frequency of HLA-B*18 and HLA-B*27

**Table 2 Distribution of the most frequent human leukocyte antigen A, B, C, DQB1 and DRB1 alleles**

| Alleles | DS group (A) | | AA group (B) | | DS + AA group (C) | | *P* value[1] |
|---|---|---|---|---|---|---|---|
| HLA-A 02 | 4 | (40.0) | 3 | (30.0) | 5 | (50.0) | 0.890 |
| HLA-A 24 | 1 | (10.0) | 0 | 0.0 | 3 | (30.0) | 0.290 |

[1]Fisher Exact test. HLA-A 01, -03, -11, -23, -25, -30, -31, -32, -33, -66, -68, -80. HLA-B 07, -08, -13, -14, -27, -37, -40, -42, -48, -49, - 50, -51, -52,- 57, -58, -81. HLA-C 01, -03,- 04,- 05, -06,- 08, -14,-16,-17. HLA-DQB1 04, -05, -06. HLA-DRB1 01, -07, -08, -10, -12, -15, -16 alleles had a frequency less than 1 and were not included in the Table 2. HLA: Human leukocyte antigen; DS: Down syndrome; AA: Alopecia areata.

was found in patients. In this study there was no significant difference at 5% in the proportion of HLA-B and between groups. According to Fisher's exact test, there is a trend ($P$ = 0.094) in DS group presenting a higher proportion of HLA-B 15 (40%) than the others groups. There is few published data on HLA-C and AA. It was described in literature the highest frequency of HLA-Cw*0704 in patients with AA. In this study, it was observed that there is no significant difference at 5%, proportion of HLA-C, HLA-DQB1 and HLA-DRB1 alleles between groups.

This finding was different from some studies reported in the literature, conducted in patients with AA without DS, which showed a predisposition to develop AA in cases with HLA-DRB1*03, HLA-DRB1*04, HLA-DQB1*06, HLADRB1*13, HLADRw52a, DQ7, HLADQB1*03, HLA-DRB1*11[15-17,27,31,32].

Different HLA types are found in the population and it is rare to find two individuals having the same HLA[33]. The frequencies of alleles tend to be different among populations racially and ethnically distinct. The Brazilian population is genetically very different and it is justified by the contribution of three groups: Caucasians, Africans and Native Americans[34]. This fact may explain the heterogeneous distribution in this study and the differences found in earlier studies.

This study was conducted with a small sample. Moreover, it was difficult to collect some relatives of the subjects, especially the second degree, who refused to participate. These two factors were found limitations in this research.

In a conclusion, The frequency distribution of HLA alleles (loci A, B, C, DRB1 and DQB1) was heterogeneous in the three groups, with no significant difference in the proportion. There was a trend ($P$ = 0.089) of the DS group to present higher proportion of HLA-A 36 than the others groups and a trend ($P$ = 0.094) of the DS group to present higher proportion of HLA-B 15 than the others groups. HLA-C 07, HLA-DQB1 03 and HLA-DQB1 06 alleles showed high frequency (> 50%) in first-degree relatives of the total sample.

This study was conducted with a small sample. We suggest further studies with larger sample.

## COMMENTS

### Background

The prevalence of alopecia areata (AA) in down syndrome (DS) individuals ranges from 1% to 11%, higher than in general population.

### Research frontiers

This study was undertaken to describe human leukocyte antigen (HLA) alleles in individuals with DS and AA, and try to explain the higher prevalence of AA in these individuals.

### Innovations and breakthroughs

The frequency distribution of HLA alleles in the groups was heterogeneous; there was a tendency of alleles A-36 and B-15 in DS group. The cause of AA in DS remains unknown. The authors suggest further studies with a larger sample.

### Peer review

The work presented in the paper provides an indication that individuals with Down syndrome exhibit a higher prevalence of AA than the general population. In spite a small sample size, the manuscript provides some interesting insights into the immune system disturbances in DS individuals.

## Abstract

**AIM:** To understand and analyze what young Italian males attending high school would like to ask andrologists but do not know how to or do not have the courage to do so.

**METHODS:** As part of our "Androlife" campaign, we invited 1565 students attending the last year of high school to participate in our research. Firstly, they attended a lesson on general and andrological health and then, on a voluntary basis, they responded to a survey and were subjected to a preventive andrological visit.

**RESULTS:** The data analysis showed that the main topics in which young people are interested are: sexual activity and sexuality, sexually transmitted diseases, andrological health and fertility, and lifestyle.

**CONCLUSION:** This study highlights that young people are very interested in sexual health issues and that they have specific needs and interests with regard to sexual health information. Public education campaigns such as Androlife should be supported and further improved on the basis of the advice received by young participants. Sexual and reproductive health education targeting adolescents and young adults represent the basis both for wellness and for fertility preservation, and thus benefits of increased support to educational campaigns would be apparent not only in terms of individual health but also in terms of cost reduction in public spending.

**Key words:** Men's health; Adolescence; Prevention; Education; Sexual health; Andrologist

**Core tip:** This article considers the questions young people are most frequently asking. It can be considered an innovative paper because in Italy and other countries many of these topics are considered taboo. Moreover, in this article we underline that the benefits of increased support for educational campaigns would be apparent not only in terms of individual health but also in terms of cost reduction in public spending.

Foresta C, Pizzol D. He had always wanted to ask an andrologist but had never done so. *World J Clin Cases* 2014; 2(10): 546-551 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/546.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.546

## INTRODUCTION

Sexual health, sexual disorders and everything related to sex have often been considered a taboo topic in Italy for many reasons, including cultural, social and religious factors. Furthermore, while the specialist in gynecology is now both well known and readily accepted, the specialist in andrology is not yet fully established among the public. However, both in Italy and all over the world, societies are becoming increasingly aware that men as well as women need sexual health care services, while at the same time services that are available are underutilized[1].

The absence of a referring specialist for men adds to the lack of heath education and prevention programs with the result that young people, particularly males, often are not knowledgeable of diseases and risk factors related to sexual health. This situation inevitably leads to difficulties in implementing preventive measures. Moreover, the difficulty that young people encounter in talking to parents and seeking medical attention for sex-related problems motivates adolescents to attempt to solve problems by using the web or by relying on word of mouth and often on urban myths. Consequently, if the user is unable to select and identify the correct information there exists a major risk that not only problems are seldom solved, but also that they are often aggravated[2]. However, the tendency to high-risk behavior and to low utilization of sexual health services is not only characteristic of young males but also extends to adult men, and it may contribute to lower male life expectancy[3]. Some authors have already taken into account social, behavioral and psychosocial factors associated with sexual activity among young adolescents in order to create effective and enforceable prevention programs[4-6], and in many countries these programs have already been activated[7-9]. In Italy, male sexual health has received growing attention in recent years and a previous study on young men has identified a number of risk factors for adolescents, highlighting a strong influence of body mass index (BMI) on skeletal proportions and penis length and identifying a large proportion of subjects with testicular hypotrophy at risk of future fertility problems[10]. A strong impetus to andrological health prevention was given by the campaign "Androlife". This was a project aimed mainly at young people with the aim of providing information, promoting prevention and collecting data. In this project, an anonymous questionnaire was administered to young participants selected among high school students. This paper focuses on just one section of this survey. In particular, we wanted to understand and analyze what young Italian males attending high school would like to ask andrologists but do not know how to or do not have the courage to do so.

## MATERIALS AND METHODS

### Androlife campaign

Androlife is a project that has the following objectives: (1) to sensitize and to inform young people on general and andrological health; (2) to promote primary prevention of diseases, especially concerning the male reproductive system; (3) to collect information on the habits, lifestyles, general and sexual health status of young people through an anonymous questionnaire; and (4) to highlight pathological conditions detectable by a free medical examination performed only in volunteers.

To achieve these objectives the "Androlife team" organized social and cultural events, free clinics dedicated to andrological prevention, and interventions by specialists in high schools for students in their final year in order to inform, educate and provide a free medical preventive evaluation for those who wished it.

### Patients and setting

A total of 1565 students attending the final year of high school in 2012-2013 in the Veneto Region of North-East Italy were enrolled in the study. All students, aged 18-19 years, attended an informative session held by a physician of the University of Padua. Of all participants, 1492 agreed to complete an anonymous survey. On a voluntary basis, 1083 participants then elected to undergo an on-site clinical examination. The study was approved by the local Ethics Committee with the protocol number 2208P.

### Information session

The sessions focused on 5 main topics: sexually transmitted diseases, andrological diseases, lifestyle, drugs and alcohol and cybersex. For each topic, the specialist explained the risk factors, how to prevent them, how to take care of one's own health, the forms of self examination such as testicular self-examination, and possible solutions to existing problems. Students could also ask questions in public and/or ask further information in private on the topics covered.

### Survey

The anonymous survey included a general family history and a number of questions on lifestyle, with particular attention to smoking, diet, physical activity and the use and, or, abuse of drugs. Moreover, a large section focused on sexual activity, such as number of partners, sexual orientation, use of condoms, and use and/or abuse of pornography on the web. Finally, the last section of the survey contained an empty space where each participant was invited to write questions they might have wanted to ask an andrologist but had never done so. This section represented the topic of this paper.

### Visit

On-site clinical examination was aimed at collecting anthropometric and penile measurements that included: height, weight, BMI, waist circumference, arm span, pubis-to-floor and crown-to-pubis length, penis length, penis circumference and testicular examination.

## RESULTS

Among 1492 subjects who completed the survey, 1184 provided a question that they had always wanted to ask a specialist but had never done so. Of these, 793 (67%) claimed to already know the word andrologist, but only 274 (23.1%) had already undergone an andrological check. After collecting all the questions, we clustered them into four main groups, taking into account the frequency with which questions were asked (Table 1): 475 (40.2%) adolescents had asked questions about sexuality and sexual activity, 242 (20.4%) about sexually transmitted diseases, 216 (18.2%) about andrological health and fertility, and 142 (12%) about lifestyle. A further 109 (9.2%) questions did not fit into one of these groups and were combined into a generic group. The first 3 clusters were further divided into subgroups. The first cluster on

**Table 1 The main and most frequent questions of 1184 young Italian men *n* (%)**

| | | |
|---|---|---|
| Sexuality and sexual activity | Masturbation | Is masturbation normal? |
| 475 (40.2) | 223 (46.9) | Can a frequent masturbation cause damage to the penis and/or to the body? |
| | | Can masturbation be useful before a sexual intercourse? |
| | | Can masturbation have negative effects on sports performance? |
| | | Can masturbation reduce the risk of prostate cancer? |
| | Sexual intercourses | Which are the safest contraceptive methods? |
| | 199 (41.9) | The oral sex cause oral cancer? |
| | | Can anal sex be risky? |
| | | What is the right age for the first sexual intercourse? |
| | Drugs for sex | Are there effective drugs to treat premature ejaculation? |
| | 53 (11.2) | At what age can you use phosphodiesterase inhibitors?[1] |
| | | Are there drugs to help penis growth? |
| | | Are web products, to improve sexual performance, effective and safe? |
| Sexually transmitted diseases | HIV | Is HIV treatable? |
| 242 (20.4) | 95 (39.3) | Is a single sexual intercourse, with an HIV positive subject, enough to acquire the infection? |
| | | Is HIV transmissible through masturbation? |
| | | Why there is no cure for HIV? |
| | HPV | Is HPV a virus that can also affect men? |
| | 79 (32.6) | How is HPV transmitted? |
| | | Is it possible, and how, heal from HPV infection? |
| | Generic questions | Is the birth control pill effective against STD? |
| | 68 (28.1) | Is sexual intercourse the only way of transmission of STD? |
| | | What should you do in case of STD? |
| | | Can those who have never had sexual intercourse have a STD? |
| Andrological health and fertility | Varicocele | How can I know if I have a varicocele? |
| 216 (18.2) | 91 (42.1) | Which are the effects of varicocele? |
| | | Is always necessary to operate in case of varicocele? |
| | | After the operation, may varicocele recur? |
| | Testicular tumours | Which are the symptoms of testicular cancer? |
| | 80 (37.1) | Is it possible to prevent testicular cancer? |
| | | Is it possible to heal from testicular cancer? |
| | | Does testicular cancer always cause infertility? |
| | Generic questions | Does andropause exist? What age? |
| | 45 (20.8) | Which are the consequences of testicular trauma? |
| | | Is short frenulum dangerous? |
| | | Can you return fertile after vasectomy? |
| Lifestyle | Can illicit drugs and alcohol interfere with sexual health? | |
| 142 (12) | Does physical activity improve andrological health? | |
| | Is the use of androgens helpful or harmful to the andrological health? | |
| Generic questions | Can virginity be established for a man? | |
| 109 (9.2) | Can web pornography cause addiction? | |
| | Has the partner a role in sexual desire? | |
| | To keep your cell phone in your pocket can damage fertility and or sexuality? | |
| | How can an issue of sexual orientation be addressed? | |

[1]Students did not know the active ingredient of these drugs and, in the questions, they used the most famous trade names. HIV: Human immunodeficiency virus; STD: Sexually transmitted disease; HPV: Human papillomavirus virus.

sexuality and sexual activity was divided into masturbation, sexual intercourse and drug use for sex; the sexually transmitted diseases group into human immunodeficiency virus, human papillomavirus virus and into a third generic group; andrological health and fertility was divided into varicocele, testicular tumors, and a final generic one. Table 1 shows the main and most frequent questions that young men provided in the survey, while in Table 2 we have given short answers to the received questions.

## DISCUSSION

### *Sexuality and sexual activity*

The issue of sexuality is still a difficult topic to discuss with young people, and too little is being done to provide correct information to adolescents who are just starting to explore their sexuality. In this context, the Androlife campaign intended to be helpful to the largest number of young men not only in giving information but also in facilitating the promotion of health, and in particular andrological health. This campaign, aimed at high school students, highlighted, on the one hand, much interest and active participation by adolescents in the topic, and, on the other hand, a fundamental difficulty in dealing with these issues and a fundamental lack of knowledge of many basic facts on the part of the participants. The worst consequences are a lack of preventative measures, and a reliance on the web for addressing problems, with the result that such problems are not always approached properly, nor are they effectively solved. In this paper we have considered the main topics on which young men would like to receive information or clarification but do not know how to or where to find it. In particular, the largest number of questions was related to masturba-

**Table 2 Answers to the most frequent questions of young Italian men**

| | |
|---|---|
| Sexuality and sexual activity | Yes, masturbation is normal |
| | Masturbation doesn't cause damage to the penis and/or to the body |
| | There is no evidence that masturbation is useful before sexual intercourse |
| | There is no evidence that masturbation has negative effects on sports performance |
| | It has not been demonstrated that masturbation reduces the risk of prostate cancer |
| | The safest considered contraceptives are condoms, the contraceptive pill and intrauterine devices |
| | The risk of cancer caused by oral sex is related to the transmission of HPV |
| | Anal sex can be risky due to the transmission of STD |
| | There isn't a "right age" for the first sexual intercourse because everyone reaches maturity at different ages |
| | There are effective drugs to treat premature ejaculation, but not all cases require drug treatment |
| | The clinic, not the age determine the use of phosphodiesterase inhibitors |
| | Drugs are useful for the growth of the genitals only in the case of some diseases (*e.g.*, certain hormone deficiencies) |
| | Is not safe, and often even effective, to rely on the web to improve sexual performance |
| Sexually transmitted diseases | HIV is treatable but not curable |
| | Even a single sexual intercourse, with an HIV positive subject, is enough to acquire the infection |
| | HIV is transmissible through masturbation only if the biological produced fluids come into contact with wounds |
| | The complexity of the virus causes the current treatment options to treat but not to heal from infection by HIV |
| | Yes, HPV can also affect men |
| | HPV is transmitted through all forms of sexual activity |
| | It is possible heal from HPV infection reducing risk factors (smoking, unprotected sex, low hygiene...) |
| | The birth control pill is absolutely not effective against STDs |
| | Sexual intercourse is not the only way of transmission of STD |
| | In case of STDs the first thing to do is consult a doctor as soon as possible |
| | STDs can also be present in people who have not had sex but have been in contact in other ways (*e.g.*, transfusions with infected blood) |
| Andrological health and fertility | A varicocele can be diagnosed by clinical examination or ultrasound |
| | A varicocele may be asymptomatic, present with scrotal symptoms or pains, and in some cases worse spermatogenesis and testicular function |
| | It is not always necessary to operate in the presence of a varicocele |
| | In some cases, after operation, varicocele may recur |
| | Symptoms of testicular cancer: presence of a mass, change in size, change in texture, scrotal and/or inguinal pain, scrotal weight feeling |
| | It is necessary to prevent testicular cancer |
| | Yes, it is possible to heal from testicular cancer |
| | If early treated, testicular cancer not always cause infertility |
| | There is no well-defined andropause but fertility and sexual potency decrease with age |
| | Severe testicular trauma may have consequences on testicular function and fertility |
| | A short frenulum is not dangerous and it is easily solved |
| | Regaining fertility after vasectomy is sometimes possible but difficult |
| Lifestyle | It is well established that drugs and alcohol negatively interfere with sexual health |
| | Physical activity is necessary to maintain and improve andrological health |
| | If not necessary, the use of androgens is harmful to the andrological health |
| Generic questions | Male virginity can not be established |
| | Yes, web pornography can cause addiction |
| | Yes, also the partner plays a very important role in sexual desire |
| | To date there are conflicting data on the role of cell phone on fertility and or sexuality |
| | It is good to deal with issues relating to sexual orientation with trained and professional doctors and psychologists |

HIV: Human immunodeficiency virus; STD: Sexually transmitted disease; HPV: Human papillomavirus virus.

tion, denoting ignorance in this respect and highlighting widespread beliefs in popular myths. In fact, many young males are not aware of the fact that masturbation is integral to normal sexual development and that it represents a dynamic process during adolescence, and only compulsive masturbation should be considered a problem[11,12]. The other issue of great interest was, unsurprisingly, sexual intercourse. Interestingly, the main concern in this regard, was in contraceptives and methods for optimal performance, as well as about oral and anal sex while the risk of sexually transmitted disease (STD) did not seem to be prominent. Although previous studies have highlighted that there are a number of different pathways that may lead to either voluntary or involuntary adult sexual inexperience[13], it is more likely that many of the concerns voiced by the participants arise from actual voluntary practice, considering the growing proportion of adolescents engaged in oral and anal sex practices[14].

### Sexually transmitted diseases

In our opinion, what should be worrisome is the lack of interest and concern displayed by the participants in STDs. In fact, the questions show that adolescents are poorly informed about the transmission pathways, consequences, and possible treatments for infections, and at the same time, they do not seem to give considerable thought to these issues. This observation is in agreement with the data collected by other authors who have highlighted the need for effective interventions to reduce adolescent STD infection[15]. Moreover, STDs also represent

the most significant modifiable risk factors for this age group with regard to fertility[16]. This topic does not seem to be a priority for adolescents, but this may only be the consequence of a lack of sexual health education and not of indifference toward these issues.

### Andrological health and fertility

STDs do not seem to be of great interest, but when made aware of these issues, students expressed the will to learn more both in terms of the most common diseases and of those they are more afraid of, such as varicoceles and testicular tumors. A varicocele is one of the most common pathologies but despite numerous studies concerning its evaluation and treatment, uncertainties remain. Both overtreatment and undertreatment are particularly costly. Expensive ultrasound, office visits and surgery must be avoided in those who do not need these treatments, while a careful follow-up and eventual intervention must be guaranteed to subjects who may be in need of them[17]. Another disease of great interest to students is testicular cancer, which represents the most common malignancy in young men, with the highest incidence among men in Nordic countries. Known risk factors are cryptorchidism, a previous history of testicular cancer and a family history of testicular cancer, and early detection and appropriate treatment are the only methods to decrease mortality[18,19]. In fact, if adequately treated and followed up it represents the most curable solid tumour and survival rate exceeds 90% in young males[20]. Unfortunately, the majority of young males is not aware of this information, which is critical for successful health prevention. Therefore, this survey, in accordance with data collected by other authors, underscores the continued need for comprehensive sexual and reproductive health education for adolescents and young adults[21].

### Lifestyle

A widespread social problem all over the world is the use and abuse of alcohol and illicit drugs[22]. This represents the main topic of lifestyle in which young people are involved and on which they focus their interest, and prevention and treatment efforts would benefit from more careful attention in preventive health programs. Another matter to consider is physical activity during adolescence. The long-term benefits of habitual physical activity are recognized[23], but it is necessary to inform adolescents about the risks of using doping substances, particularly considering the increased consumption of such substances by young people who practice sport[24,25].

### Generic questions

In the last cluster, we collected less frequent but perhaps more topical and current questions asked by the participants. In addition to the issue about the possible negative effects of the use of mobile phones on fertility, questions asked by participants were commonly questions to which there are conflicting answers[26], and questions on topics of interest concerning web pornography and sexual orientation. Web pornography is a phenomenon of such increasing interest as to be defined by some authors as the new sexual revolution[27]. To date, a number of studies have highlighted the reasons why web pornography has such widespread use, and considered the characteristics of this new form of sexuality[28,29]. However, no one has yet taken into account the possible negative effects of the use or abuse of web pornography in terms of an increase or decrease in interest in real sexuality and in real sexual intercourse. Sexual orientation represents a difficult topic for adolescents to bring up, particularly because of the family and social context in Italy. It is demonstrated that homosexual young people face different developmental challenges during adolescence than those faced by heterosexual youths or individuals who recognize their homosexual orientation later in life[30]. Though sexuality has acquired new dimensions in many countries including Italy, religions and cultures consider sexuality almost exclusively as focused on reproduction[31]. Hence, there exists a difficulty for young people to deal with the issue of sexual orientation and therefore, the necessity to provide an adequate and qualified service for information and assistance. In conclusion, this study highlights not only that young people are very interested in general health issues, but also that they have very specific needs and interests on sexual health and sexual health information. In our opinion, public education campaigns such as Androlife should be increased in number and frequency and improved on the basis of the view of young participants. Sexual and reproductive health education and promotion for adolescents and young adults represents the basis both for wellness and for fertility preservation. Finally, the benefits of increased support for educational campaigns would be apparent not only in terms of individual health but also in terms of a reduction in public spending costs.

## ACKNOWLEDGMENTS

The authors thank Dr. Pelizzon Alessandro, School of Law and Justice, Southern Cross University-East Lismore NSW 2480-Australia, for his kindly and careful editing.

## COMMENTS

### Background

Sexual activity, sexual health and sexual disorders are open issues and current problems especially among adolescents.

### Innovations and breakthroughs

This study highlights not only that young people are very interested in general health issues, but also that they have very specific needs and interests on sexual health and sexual health information.

### Applications

This is an interesting and meaningful topic which brings attention to the health care providers and raises public awareness for the importance of education in reproductive health.

### Peer review

This is an interesting and meaningful topic.

SYSTEMATIC REVIEWS

# Reporting of dental status from full-arch radiographs: Descriptive analysis and methodological aspects

Fabian Huettig, Detlef Axmann

Fabian Huettig, Detlef Axmann, Department of Prosthodontics with Section "Medical Materials and Technology" at the Centre of Dentistry, Oral Medicine, Maxillofacial Surgery of Eberhard-Karls-University Hospital, D-72076 Tuebingen, Germany
Author contributions: Huettig F and Axmann D established the search strategy, selection criteria and methodology of report; Huettig F performed the literature research, selected the articles and performed the full text review; Axmann D reviewed the data aquisiton by spot tests; Huettig F wrote and Axmann D reviewed the paper.

Supported by The "Walter and Anna Koerner-Scholarship" as part of the Land of Baden-Wurttemberg's Dentists Chamber (Stuttgart, Germany) within the cooperation of Tuebingen University and Peking University Dental Schools; by Mrs. Barbara Welder of Dental Clinics Library at Eberhard-Karls-University (Tuebingen, Germany); by Lucas M Leister for English proofreading

## Abstract

**AIM:** To identify standards, how entities of dental status are assessed and reported from full-arch radiographs of adults.

**METHODS:** A PubMed (Medline) search was performed in November 2011. Literature had to report at least one out of four defined entities using radiographs: number of teeth or implants; caries, fillings or restorations; root-canal fillings and apical health; alveolar bone level. Cohorts included to the study had to be of adult age. Methods of radiographic assessment were noted and checked for the later mode of report in text, tables or diagrams. For comparability, the encountered mode of report was operationalized to a logical expression.

**RESULTS:** Thirty-seven out of 199 articles were evaluated *via* full-text review. Only one article reported all four entities. Eight articles reported at the maximum 3 comparable entities. However, comparability is impeded because of the usage of absolute or relative frequency, mean or median values as well as grouping. Furthermore the methods of assessment were different or not described sufficiently. Consequently, established sum scores turned out to be highly questionable, too. The amount of missing data within all studies remained unclear. It is even so remissed to mention supernumerary and aplased teeth as well as the count of third molars.

**CONCLUSION:** Data about dental findings from radiographs is, if at all possible, only comparable with serious limitations. A standardization of both, assessing and reporting entities of dental status from radiographs is missing and has to be established within a report guideline.

**Key words:** Research design; Guideline; Dental radiography; Epidemiology; Public health; EQUATOR

**Core tip:** Full mouth dental radiographs are in worldwide daily use and contain various informations about dental and oral health of adult patients. This is why it is often used for epidemiologic research or to augment clinical data. But, when reported, data is presented in multifarious ways. Thus no or only little comparison of research outcome is possible. Existing standards of evaluation and reporting should be fixed in a reporting guideline regarding: number of teeth and implants; caries, fillings and restorations; root-canal fillings and apical health; alveolar bone level. Application of sum scores turned out to be very questionable.

Huettig F, Axmann D. Reporting of dental status from full-arch

radiographs: Descriptive analysis and methodological aspects. *World J Clin Cases* 2014; 2(10): 552-564 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/552.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.552

## INTRODUCTION

Beside diagnosis support, X-rays are an established method to follow up treatments with surrogate characteristics, such as: bone loss in implantology, periodontology and maxillo-facial surgery, or apical flare up and loss of teeth in endodontology, or caries prevalence in operative dentistry.

Moreover, it is used for assessment of skeletal changes focussing orthodontic or temporo-mandibular-disorders. It is even possible to find approaches of forensic medicine, *i.e.*, for non-invasive age determination *via* orthopantomograms.

The quality of panoramic radiographs has enhanced during the last years. Namely their sensitivity and specifity to diagnose findings, as mentioned before, is considered to be satisfying. Problems of underestimation are discussed commonly. Nevertheless, determining oral health by radiographic presentable dimensions of the dental status is possible. That is why panoramic radiographs are often used for epidemiologic and retrospective analysis of dental status and oral health respectively. Recently, a review subsumed the competence and application of panoramic radiographs for epidemiologic studies of oral health[1]. However, it remains uncertain, whether standards are established to report radiographic findings which describe dental status or oral health data in general. No results, neither in Pubmed/Medline, EQUATOR-Network (www.equator-network.com) or Cochrane Library could be identified searching a relevant guideline. Therefore, this systematic review was launched, to find out, which approaches are commonly used, to assess and report the entities: decay, missing, restorative, endodontic and periodontal status as surrogate dimensions of oral health (Table 1).

## MATERIALS AND METHODS

### Search and identification/inclusion and exclusion

A Medline/PubMed search was performed for articles reporting findings from full arch radiographs, focused on oral health and dental status of adults. This search was conducted in November 2011. No time limit was set. Panoramic X-ray or a full-mouth radiographic survey with periapical radiographs of all remaining teeth were definied as "Full arch radiograph". In the following, the term "radiograph" will be only used in this sense.

To find and include such papers the following search-string was constructed stepwise and applied finally as: ("radiographic study" or "panoramic") and ("oral health" or "dental status" or "dental health" or "dentition") not (children OR review OR edentulous)

The following inclusion and exclusion criteria were set for a full text review of findings: All peer-reviewed reports with dental findings obtained from full arch radiographs are included, even if there had been additional clinical examination or patient chart reviews. These reports had to focus on at least one surrogate of "dental status" or "oral health" (Table 1), whereas reports handling edentulous or partially edentulous patients were disregarded.

Only articles written in English were included. Studied cohorts had to be of adult age, respectively the mean age had to be at least 18 years.

If it was not determinable in the abstract, which kind of radiography was applied or which variables of dental status were reported, the article was included to full-text review.

Excluded was all literature handling radiometric issues only [*i.e.*, bone density, cephalometric angles of jaw and joint, subjected to soft-tissues (carotis, lymphal-nodes)] or focusing on specific teeth/tooth types only (such as caries in third molars) as well as anthropologic analysis. Articles were also excluded, if they turned out to report on the basis of bitewing radiographs or specific single radiographs to fulfill their objective.

### Definition of variables of interest

Every previously included paper was reviewed towards the report of at least one out of the following eight variables ( I a-Ⅳ), which reflect the surrogates listed in Table 1. If inclusion was validated, information about: (1) Bibliography and focus of study; (2) Number of patients studied and country of origin; (3) Number and kind of radiographs studied was noted first. Then the materials and method section (MMS) and results were checked for the following 8 variables of interest: I a: remaining/missing teeth (also included in DMFT/S); I b: implants or implant-loss; Ⅱ a: fillings (also included in DMFT/S); Ⅱ b: decay/caries (also included in DMFT/S); Ⅱ c: restorations (*i.e.*, crowns); Ⅲ a: root canal treatment; Ⅲ b: apical status; Ⅳ: alveolar bone level on teeth or implants.

These variables were recorded by their mode of report. Further statistical analyses applied to these variables within the articles were disregarded, due to the different focus of the studies. Regarding the application of these variables, it was noted if additional arrangements, exclusion or inclusion criteria towards the report were mentioned by the authors. For example: how to handle the "third molars", supernumerary teeth or teeth not depicted clearly on radiographs.

If a variable was mentioned in the section "methods" but not reported, it was mentioned not reported "(NR)". If a variable was not mentioned within the method section, it was noted as not defined "(ND)". Furthermore it was recorded, if the authors applied a special method of evaluation and how it was described or whom they cited. A "?" was assigned to indicate an assumption by the reviewers throughout the data, whenever there was no clear statement within the context of the article. For lon-

**Table 1 Entities of dental status and their surrogates in oral health: Left column notes the entities of dental status, which can be assessed from a full-arch radiograph**

| Focused entities | Subject of clinical dentistry | Surrogate of oral health |
|---|---|---|
| Alveolar bone loss, furcation and vertical bony defects | Periodontology, implantology | Periodontitis/inflammation, risk of tooth loss |
| Fillings/inlays | Operative dentistry | Oral hygiene, caries, decay, risk for massive fillings/partial crowns |
| Massive filling/partial crown | Operative dentistry, prosthodontics | Risk of root canal treatment, risk for crown-treatment |
| Crowns and fixed dental prosthesis/ pontics | Prosthodontics, periodontology | Massive decay (even of healthy teeth), risen risk for caries and endodontic problems, risk for bone loss and fracture (missing teeth), missing teeth |
| Root canal filling and root posts | Operative dentistry, endodontology, prosthodontics | High number of life events of intervention, risk of tooth loss by fracture/ inflammation, need for crown |
| Apical lesion | Endodontology, oral surgery | High risk of tooth loss, poor root canal treatment, inflammation |
| Missing teeth | Prosthodontics, implantology | High number of life events of interventions, former inflammations, trauma, hypodontia, malocclussion |
| Implants | Periodontology, prosthodontics | Missing teeth, higher risk for inflammation (periimplantitis), occlusal rehabilitation |
| Edentoulism | Prosthodontics, oral surgery | High number of life events, no further risk of odontogenic inflammation (caries, periodontitis, apical lesions) |

Their possible relation as a surrogate of oral health is shown in the right column. The involved subjects of Dental Medicine are noted in the middle column. Reading the table from top to down, it has to be considered, that surrogates include content of cells above.

gitudinal studies, the different comparisons between the dates of results were not considered, as far as no other way of report was applied. Information about removable dentures had been neglected, because these are generally not allowed to be seen on radiographs at all. If results of a study or cohort were published twice, first, the longer observation period and, secondly, the higher impact factor in year of publication gave favor for inclusion.

### *Operationalization of findings*

The report of variables I to Ⅳ was reduced to a simple logic expression. Every expression, shown in Table 2, can be translated with the following "keys-words" and abbreviations: "ND" or "NR" indicates "not defined" or "not reported".

"N" = "number"; "[]" = "of/in"; "()" = "expressed as"; "/" = "by presenting values"; "," = "and"; "+" = "with"; "G" = "in group (s)"; "F" = frequency, "%" = percentage, "SD" = standard deviation, "Q" = quartiles, "rg" = range, "al" = "all patients/teeth/surfaces", "tot" = "total", "pat" = "patient(s)", "grades" = "declared graduation or scaling of measurements", "FDP" = "fixed dental prosthesis".

Variable I refers to "r" = remaining, "m" = missing or "f" = lost/failed teeth. Variables Ⅱ-Ⅳ always refer to affected patients, teeth, lesions, surfaces or sites. Following groups were standardized: age, gender, jaw, tooth-type, age-group, grades (of a previously defined classification).

If authors introduce special groupings (*i.e.*, diseased/ healthy, baseline/follow-up and so on), it was abbreviated "spec" for "special". This was mandatory due to the different outcome-variables of the studies.

For dental terms following abbreviations were used: "ABL" = "alveolar bone level/loss", "apH" = "apical health", "RCF" = "root canal filled", "FDI" = "FDI-tooth code", "FDP" = "fixed dental prosthesis".

**Two examples of this operationalization:** The following expression in the column "Ⅱb Caries/Decay": "N[surface](mean, SD)[pat]/G[age, gender]" is translated to "The number of carious surfaces is expressed as mean and standard deviation in a patient, by presenting values in groups of age and gender".

Another exemplary expression in the column "Ⅲa RCT" is "N[pat + teeth](F)" translated to "Number of patients with affected teeth is expressed as frequency".

### *Subsumption*

All included papers were ordered according to their objective. Bibliography as well as number and origin of patients were described by frequency distributions. To discuss the consistency, the findings were subsumed for all papers towards each entity of interest. Therefore cited methods of radiographic evaluation were full-text reviewed, as far as these were written in English or German and obtainable *via* library services.

## RESULTS

Following Figure 1, thirty-seven studies were evaluated and can be found in Table 2.

The years of publication of all results are shown in Figure 2. In whole 27447 (median = 191) X-rays have been evaluated and reported within 37 studies including 27772 (median = 215) patients. Figure 3 shows the shares of patients towards their origin. Ninety-four percent of the patients studied were from United States and Europe.

For nine journals no Impact Factor (IF) was noted at *Journal Citation Report* (JCR) of "Web of Knowledge" (www.webofknowledge.com). The 5-year IF in 2010 of all JCR-listed and evaluated journals was median = 2.23, range: 0.89-6.39, SD = 1.16. So the included articles represent an extract of high ranked journals, regarding an average IF of about 1.3 (median = 1.2, mean = 1.5) for

**Table 2 Evaluated articles and encountered mode of report: All full-text reviewed articles are sorted by the year of publication**

The date is followed by a discretionary index for the 5 year Impact Factor of the journal in 2010 (a < 1.5; b < 3; c > 3; d: None). Please see caption: Operationalization of findings in "Materials and Methods" section to decipher content in columns Ⅰa-Ⅳ. Column Ⅱb "Implants" is not shown for a comprehensive view and due to the lack of noteworthy reports. RCF: Root-canal-fillings; apF: Apical findings; ABL: Alveolar bone loss; ND: Not defined; NR: Not reported.

Dental Journals listed in the JCR in 2011.

All modes of report are shown-according to the scheme of operationalization-in Table 2. The following subheadings subsume these findings and focus on the methodic of radiographic assessment.

### *Missing/remaining teeth and implants*

Thirty/37 (81%) of all studies reported remaining and/or missing teeth. Four articles intended a report of these values within their material and method section, but did not so. Beside mean-and median values, two artificial approaches were found: Ma *et al*[2] reported the prevalence of missing tooth types (first molars). Other authors gave the number of absolute frequency of missing teeth within their studied cohort[3]. In addition to this the following groupings were found: "< 10 missing teeth"[4], "0, 1-5, 6-14, 15-20, > 20 missing teeth"[5], "1-7, 8-20, 21-32 teeth"[6], "1-2, 3-5, 6-9, 10-14, 15-20, 21-27 missing teeth"[7], "0, 1-11, 21-12, 22-27, 28-31, 32"[8].

This approach of grouping allowed the authors mentioned above to report only the "number of patients" within their established groups. Before 1990 absolute frequencies were reported more frequently. Due to the variety of dentition, especially existence of 3rd molars, the problem of report is thoroughly discussed below.

Only 3 articles considered and reported dental implants. That is why this column is not shown in Table 2. The modes of report were: "N[pat + implants](%)/G[age]"[9], "N[implants](F)[all pat]/G[spec]"[3] and worded "some"[10].

### *Caries, fillings and restorations*

Due to the clinical DMFT-index decayed (carious) and filled (restored) teeth are often pooled and mixed up. Six authors did so-three out of these using the DMFT/DMFS-Index[11-13]. Overall 19 out of 37 papers mentioned to evaluate "carious problem", "-lesions", "-teeth" or "defective teeth". One did not report their announced findings[14] and two remained unclear[15,16]. Four authors got more specific towards their assessment by mentioning the following criteria: "deep caries cavities"[17], "carious pulpal exposure lesions"[18], "lesions clearly perforating the enamel and clear radiolucencies under old fillings were recorded. Enamel caries was excluded"[19], "gross carious lesions … in posterior teeth"[7].

Pelton *et al*[20] classified caries lesions within a reliability study of panoramic and periapical radiographs as "C1: radiographically viewed that involved the enamel, but did not penetrate the dentin; C2: … involved the enamel and the dentin, but not the pulp; C3: … said to involve the pulp".

Two other authors explained more concrete: "Caries was judged to be present in the radiograph when a clearly defined reduction in mineral content of the proximal, occlusal, and/or restored surfaces was evident"[6], and "(Caries was) present when the lesion reached the dentin proximally or occlusally or was found at restored surfaces"[21].

Kirkevang *et al*[22] used a method published by Wenzel[23] described as follows: "A surface was assessed as having a caries lesion if a radiolucency, exhibiting the shape of a caries lesion and observed at a caries-susceptible site", and augmented with "extended into dentine; radiolucencies confined to the enamel were ignored".

In the same article Kirkevang *et al*[22] gave concrete information about fillings: "Registrations were performed on mesial, distal and occlusal or incisal surfaces. Fillings in pits and fissures in oral and buccal surfaces were not registered".

Tabrizi *et al*[11] stated "Restorations and dental caries were also calculated for each participant", but owes the data by presenting only DMFT-values.

Reporting is also structured by using absolute frequencies of patients with "lesions"[18,19], or "affected teeth" in all patients[3]. In addition to this, following groupings were found: "0,

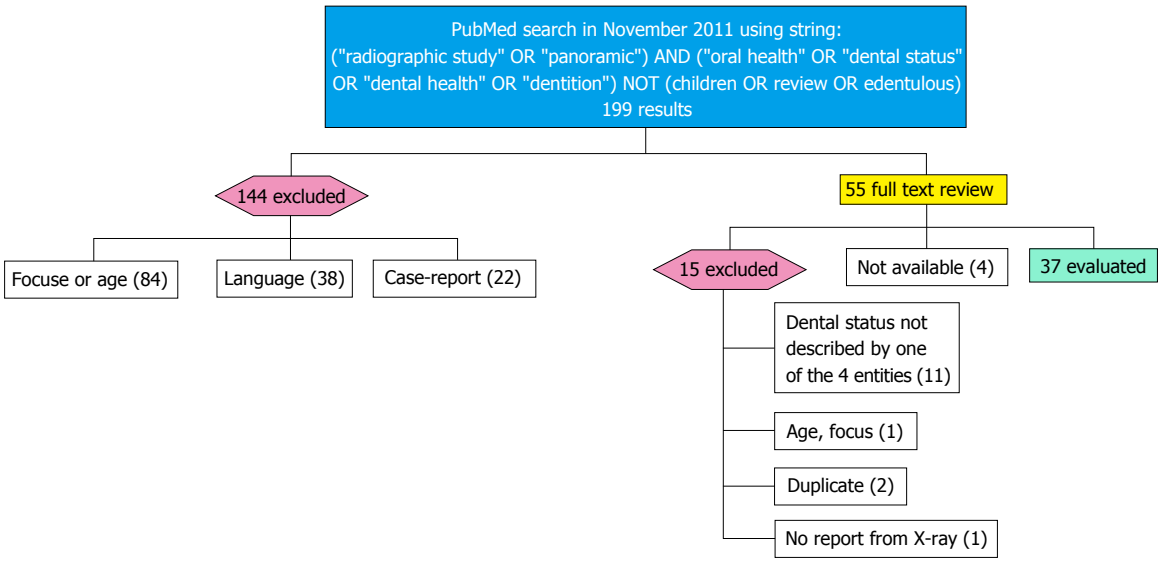

**Figure 1 Flow chart of review strategy and finally evaluated articles: The flow chart shows the systematic exclusion of search results towards the finally evaluated studies.** The primary reasons for exclusion are mentioned including the number of concerned articles.

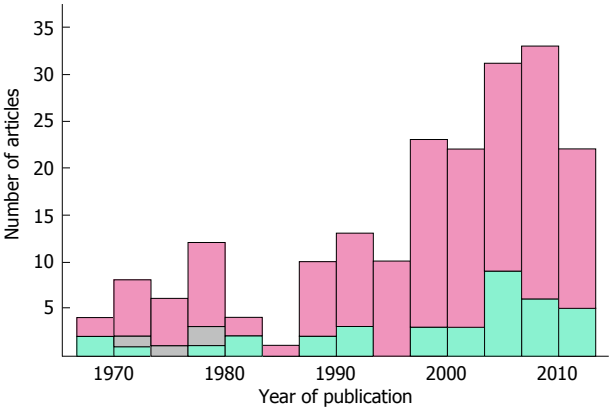

**Figure 2 Distribution of included and excluded articles: Distribution of the 37 evaluated (green) and 159 excluded (red) studies of the search results ordered by their date of publication.** Shaded fractions represent the 4 articles which were not available as full text version.

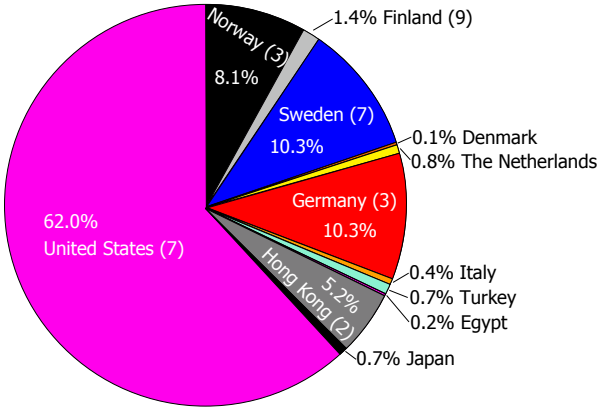

**Figure 3 Shares of patients in the 37 evaluated studies with respect to the country of origin: The number of contributing studies is noted in brackets behind the country.** Preponderance of United States is due to two reports of "mass X-ray evaluation" in the years 1977 and 1982. If these two are left out of consideration the median value of studied subjects in a paper is 212 (mean = 485).

< 5, > 5 defective teeth"[5], "0, 1-2, ⩾ 3 carious lesions"[19]. Restorations were reported six times[9,10,16,24-26], but 2 articles did insufficiently[10,27]. Within three out of seven articles restorations, fillings and decay were merged[5,11,15].

### *Root canal fillings and apical health*

Identification of root canal filled teeth was taken for granted in 15 out of the 18 papers. Within 3 papers it was clarified in more detail within the MMS as "ongoing or completed root canal treatment, …, pulp amputation", "teeth with pulp amputation, endodontic fillings, or both"[3,6,21]. One article merged root canal fillings and apical health[28].

Seventeen further articles focused on apical health. The periapical index (PAI) by Orstavik *et al*[29] was used for diagnosis of periapical health by only three authors, who regarded the PAI-scores 3-5 as positive finding[3,28,30].

For Peltola *et al*[31] "A radiolucency measuring > 2 mm in the apical bone was considered to be an apical rarefaction". Nalçaci *et al*[26] cited Soikkonen *et al*[32] method: "A periapical lesion, interpreted as apical periodontitis, was recorded if there was a clearly discernible local widening of the apical periodontal membrane space". But, this approach is not described within this referred citation (handling edentulous patients at all). Hakeberg *et al*[33] divided "Periradicular destructions … into three different classes according to size; 1 = pathologically altered lamina dura and radiolucency less than 2 mm, 2 = radiolucency of 2-10 mm, 3 = radiolucency > 10 mm"[33], and set grade 2 as cut-off for affection. The earliest grading found was in Lilly *et al*[8] 1967: "less than 5 mm and 5-10 mm apical translucency"[8].

The remaining five articles only mentioned to evaluate "apical radiolucencies"[17], "periapical lesions"[5], without further criteria or mentioning additions like: "radicular cysts as well as sclerotic periapical lesions indicating con-

densing osteitis"[6,21], or "sign of osteolysis"[12].

### Alveolar bone level

The most various methods in assessment and reporting were found for alveolar bone level.

Metric measurements were used by five authors[6,7,17,21,33]. In addition to this following groupings were found: "≥ 6 mm, ≥ 4 mm"[17], "> 1-3 mm, > 3-6 mm, > 6 mm"[6], "< 2 mm, 2-4 mm, > 4 mm"[33]. "< 4 mm = moderate periodontitis, > 4 mm = severe periodontits"[7].

To relativize metric measures the following formula for alveolar bone loss is used: "total bone height divided by total root length [the distance from the radiographic apex to the cemento-enamel junction (CEJ)] multiplied by 100.", and applied *i.e.*, by Tabrizi *et al*[11].

Rosenquist[5,12] decided to use a modified criterion of Lindhe[34]: "< 1/3 of the root length, > 1/3 of the root length, and horizontal loss supporting tissues, > 1/3 of the root length, angular bony defects and/or furcation involvement" which is similar to Nyman *et al*[35] cited by Tabrizi *et al*[11]. Two authors used a relative root length, but went for an overall approach and added a criterion for "diseased" *via* their amount of findings: "≥ 30% of the sites with ≥ 1/3 bone loss"[36] and "including one or more teeth"[37].

Semiquantitative approaches were found specified: "classified as extension to: (1) to the coronal third of the root; (2) the middle third of the root; and (3) the apical third of the root"[18,21]. Graduations apart from thirds exist also: *i.e.*, as an ordinal scale with five grades: "0%, 1%-24%, 25%-49%, 50%-74%, or ≥ 75%"[38] or with only one cut-off point as: "one-fourth or more of the normal bone height"[37].

A direct measurement of ABL-percentages was developed by Schei *et al*[39] and used by only one author[38].

For two authors "A healthy horizontal bone level was considered to be 2 mm"[21,31]. Huumonen *et al*[3] graded into "(1) No bone loss, bone level within 2-3 mm of the cemento-enamel junction area; (2) Slight bone loss, bone level at the cervical third of theroots; and (3) Moderate to advanced bone loss, bone level between the middle third of the roots at or beyond the apex"[3]. Slightly different graduation-starting out the same with level 0-Nalçaci *et al*[26] continues: "(1) Moderate bone loss, bone level at the middle third of the roots; (2) Advanced bone loss, bone level at the apical third of the roots; and (3) Severe bone loss, bone level at or beyond the apex", but did not mentioned a cut-off. So it remains unclear (ND) what the reported "horizontal bone loss" is intended to be.

In three cases the results were presented with previously not defined expressions like "periodontal problem"[18] or undefined graduations like "Slight marginal bone loss … and vertical bone loss"[19]. The definition lacks what exactly is supposed to mean "affected" in this context. Likewise less helpful is a more historical graduation we came over: "If considerable bone loss was seen, this was called 'gross periodontal disease'. If there was pronounced 'arclike' bone loss limited to the molar and incisor regions, this was designated as periodontosis"[25].

One methodical article on forensics was coping with the calculation of DMFT and DFT-Index. They stated within their material and method section to grade ABL of 2nd premolars towards the criteria "0, less than half of first third, up to third of root, more than a third". But the findings were not reported at all[14].

## DISCUSSION

The diversity of assessments and report modes is found to be alarming. The applied search strategy covers only a small, but high-ranked, sample of articles handling radiographic findings. It has to be assumed, that diagnosis and report of the entities studied here are not standardized at all, as it is for clinical dental status, namely the DMFT-, CPITN-, PI-, or BOP-Index for example.

In the following, each above mentioned and studied entity is discussed critically towards assessment and report. Further consequences are subsumed.

### Number of teeth and implants

The method to identify teeth from a radiograph is quite simple. Not so the communication of amounts and values.

Commonly, every time when the descriptive level of absolute frequencies (*i.e.*, number of affected patients) is not used, the calculation has to be relative to a standardized data-set (*i.e.*, all patients studied, all patients with root canal treatment). It gets even more complicated, if the complete dentition is handled as an entity: When median-or mean values are used, the calculation base has to be clear. For the first: including the third molars to the calculation, or not? For the second: how to handle missing or supernumerary teeth? For the third: are edentulous patients excluded[17,40], or included to the calculation-or have there been other selection criteria like "at least 15 remaining own teeth"[9]?

Unfortunately this was not clear for 9 out of the 37 studied papers. Twenty-three included, 4 excluded, the third molars for evaluation. Two articles presented both approaches. Due to the variety of third molars dental history (retention, extraction) it make sense-similar to DMFT Index-to exclude these, if these are not primary focus of a study. Please follow the subheading "report of values" below, where more inherent details are addressed.

Against the backdrop of costly dental implants as a routine therapy after about 40 years now, their presence in oral status should be reported. Their number can give not only important dental input, but also ideas towards the financial background of an individual patient, a group, a whole cohort or even the social system.

### Carious lesions, fillings and restorations

The detection of carious lesions within radiographs is discussed and researched by operative dentistry, foremost. Searching "detecting caries and X-ray" *via* Pubmed/Medline results around 100 findings. The definitions used by the authors studied herein are inconsistent. This is why

a clear statement which definition can be used as a gold standard to assess a tooth as affected by caries, would be favorable. We found the approach of Pelton and Bethart the most reproducible[20].

As fillings are made from radiopaque resin, cement, compomer, or metal, these can be easily seen on radiographs. If a restoration material is only slightly radiopaque, like silicate ceramic, the used adhesive composite or luting cements is clearly visible. However, the size of restorations can only be guessed, due to the 2-dimensional projection. But, the amount of decay could be derived from the ratio of filling and remaining coronal tooth substance.

These remarks are valid for fixed restorations (crowns, pontics) too. For all of these 3 findings, the mode of report as a comparable number and the report of missing values has to be standardized.

### Root canal fillings

Root canal fillings can be recognized just as easily as a tooth or restoration itself can be, because radiopaque materials are used around the world very commonly. Two authors judged the quality of root canal fillings[3,30]. If the quality or length of root canal fillings should be regarded or not, remains to be discussed by endodontologist. Works about the potential already exist[41]. Furthermore the existence of root canal posts has to be taken into account. Some of these are either not radiolucent (Fiberposts) or radiopaque and due to their form not possible to distinct from a perfect root canal filling.

Regarding the reporting mode as frequency or percentage is same as discussed for missing/remaining teeth. Furthermore reporting authors should care about the problem that the number of teeth is easier to compare than the number of roots or even root canals. Moreover the values of root canal treatments should be reported separately from apical affection(s) of a tooth or root.

### Apical health

Beside the controversy of detection capability with periapical and panoramic radiographs (augmented with the problem: digital *vs* analog), the key point is to diagnose the affection in awareness of healthy variations-without a clinical examination. This is analog to the detection of caries. The method of the PAI by Orstavik *et al*[29] is a good example for standardization and should be used more often. This 5-grade assessment tool is based on standardized pictures. It might be most reliable if used with a cut-off at Grade 3.

Confusing is the usage of "lesion" or "finding" in contrast to "affected tooth", because *i.e.*, a lower first molar may have 2 apical or carious lesions (mesial and distal), but is only 1 affected tooth. As for the above-mentioned root-canal fillings, at this point of time no consensus could be found. But, we found one possibility for clarification: "For multi-rooted teeth, the root presenting the highest PAI-score and the quality of the corresponding root filling was used"[30].

### Alveolar bone loss

The "radiographic alveolar bone loss" is one classical research dimension of periodontology and implantology. Thereby it has been of interest for ages-expressed in hundreds of publications. Thus radiographic assessment of this entity is just as many-faceted. Two general approaches could be identified: metric measuring and proportions of bone height towards root length. The latter might be the better choice due to the variety of root length by anatomy and radiographic projection. Moreover, approaches including the age dependence of bone loss are described[42].

Beside bone level, furcation and vertical defects might be taken into account, too. The authors do not want to judge, which way is the best. But, even if a standard can be found in the future, also the cut off values for healthy and affected shall be defined by the authorities (see caption "grading and cut-offs"). Until then, the authors find the relative approach coping with the "first third of the root", described by Nyman *et al*[35], the most reliable.

### Missing values/misinterpretation

Depiction problems of X-rays may lead to missing values, because it is not always possible to state a finding (*i.e.*, the vertical alveolar bone height by overlapped projection of two teeth, carious lesion at a filling by a "burn out" artifact). Only 5 papers mentioned depiction problems right in their material and methods section as follows: "If the image of the permanent teeth was blurred, supplementary digital intraoral radiographs were taken of these teeth"[28], "For areas poorly visible in the panoramic radiograph, intraoral radiographs were made"[6,26,37], "A tooth was judged as non-measurable if the CEJ or bone crest could not be identified properly because of overlapping caries or restorations. In cases where any one of the dental or bony landmarks could not be identified on one aspect (mesial or distal), the tooth was excluded"[11]. Projection artifacts may also lead to misinterpretation, which is mostly ruled out by the use of 2 examiners and/or reliability assurance. Such problems were solved differently: "In case of disagreement between the observers, their mean is used in the calculation"[43].

"Only panoramic radiographs that displayed the whole dentition without asymmetry, distortion or error in patient positioning were included"[2], "The radiographs were assessed twice, the first time by each dentist separately and next time by all in cooperation"[10].

One article announced within materials and method section: "Missing values were registered with suitable so-called 'missing values"[9], but-it was true for all articles above mentioned, these values were not reported.

One of the articles revealed depiction problems while studying the X-rays and stated: "A total of 54 teeth, most often maxillary pre-molars, were excluded"[11].

Discussions about sensitivity and specifity of panoramic radiographs were only anecdotal, not concrete. Montebugnoli *et al*[44] dropped an important sentence, which was unfortunately not discussed further or towards their findings: "Other factors that could affect the outcomes include differences in the way of measuring … dental status (the measures used to assess the oral status seem to be related to the strength and significance of the

associations reported)"[44].

Beside this, Langland *et al*[16] mentioned within their comparative study in 1980: "Discrepancies in the percentages of periodontal disease may be attributed to variance in the classification of each disease entity each year …."[16] and also Grover *et al*[7] did so in 1982: "Several discrepancies in findings … explained by variance … in diagnostic methods". One author explicitly complained about the absence of guidelines and stated: "We found it difficult to clearly define what a short root was and how to define early obliteration of the pulp. There are no guidelines in the literature, which defined what is a short root, and what is obliteration. For that reason it was difficult to compare our data with earlier studies"[10].

In summary, it has to be pointed out again, that panoramic radiographs can be regarded as sufficient diagnosis instrument. During the past 5 years digital imaging made great strides. But, sufficient comprehensive data about quality progress is not published yet. Nonetheless, the assessment of dental findings within a radiograph is restricted by anatomical deviations of oral structures, such as dislocation or rotation of teeth. That implies missing data are common in radiographic based studies-especially for alveolar bone loss, apical health and caries. The option of an "indiscernible/unclear" criteria will reduce bias since firstly, no accidental attribution as "affected" or "healthy" have to take place, secondly an idea about overall image quality is given.

Such missing values may be handled statistically, but have to be reported and how these were regarded in calculation.

### Report of values: Mean and median, absolute frequencies and percentages

The number of remaining and missing teeth is reported most frequently (see caption "missing/remaining teeth and implants"). But even in this case, comparability is difficult due to the different modes of reporting. 4 authors decided for the report of median-number, 16 for mean, 6 for absolute frequencies. The same utilization can be found across the other studied entities: caries, root-canal-filled teeth, apical lesions and even alveolar bone level.

For the report of frequencies the use of median values can be assigned as the better choice due to its lower susceptibility towards extreme single values and the non-normal distribution of remaining and missing teeth in patients. To clarify the distribution of data we recommend the report of both: mean and medium value, augmented with SD, range and quartiles.

### Dichotomization, groups, grades and cut-offs

A grouping of age, findings, measures are often necessary for further analyses, especially to calculate odd-ratios or only to compare such "self-made" groups. Grouping with a cut-off allows additionally to report absolute and relative frequencies of teeth or patients, instead of mean or median values. Examples for the last mentioned would be "1-10 missing teeth" or "< 20 remaining teeth". Especially the rationales behind the cut-offs points are questionable. Sometimes these are set following previous analysis of the same sample, such as: "Each group comprised one-third of the dentate subjects in the baseline study"[6], or "Each dental index was dichotomized at the mean value"[44]. It can also be empirical reasons as: "The cut-off point (< 45 and > 45 years) was selected in accordance with the introduction of a new social-security law"[21]. However, cut-off points for "healthy" and "diseased" varied, especially if diagnosis of alveolar bone height and apical lesions are dichotomized for analyses, graphic art and report.

With such intervention to data, these are not universally valid anymore. Further comparability is hindered, if the crude data are not available from the paper.

### The DMFT and other sum scores

Three authors reported DMFT-values[11-13]. One team reported only the number of patients (one time as percentage, one time as an absolute frequency) with a DMFT value of zero[19,31]. The DMFT would be helpful for a comparison with existing epidemiological data, but it hinders to extract missing/remaining teeth if only given as a sum score. If not separated by the author, no more information can be extracted from the DMFT; the DMFS is even worse. Furthermore alveolar bone level and apical health are not covered within this (exclusively) clinical index.

Within our review other indices could be found: six authors cited Mattila *et al*[45]: "Association between dental health and acute myocardial infarction" and their sum score of a "Total Dental Index" or "Pantomographic Index"[6,12,18,46]. This is also cited as panoramic tomography score, which is "the sum of radiolucent periapical lesions, third-degree caries lesions, vertical bone pockets, radiolucent lesions in furcation areas[47]" and was applied by Montebugnoli *et al*[44]. Even if published and cited in high-ranked journals, we found this system neither comprehensible in development nor validated for multipurpose application. Its focus is both: infective oral lesions in a combination of oral and radiographic evaluation as well as from radiographic assessment itself. Furthermore the description of index does not contain either methods of oral nor radiographic assessment for its entities. Despite of this fact, the sum of total dental index (TDI) can reach values "between zero and 10"[45]. Nevertheless, the scale of this cited index varies between publication due to modification by the authors: "0-14"[48], "0-8"[49], "0-10"[18,50], 0-15[6]. Seppänen *et al*[18] used a classification of the sum scores "good, moderate and poor" which was not established by Mattila *et al*[45] 1989 as cited in this very article. Montebugnoli *et al*[44] decided to dicromize "each dental index … at the mean value". Buhlin *et al*[49] separated the index according to the statement "TDI of 0 or 1 are considered to have good oral health and those with TDI 4-8 have poor". Especially these inconstancies left this tool highly questionable. However, further investigation is needed for a concluding evaluation of this approach. Beside, and discussed for the DMFT, a sum score-with such complexity of terms-might not be

useful for report. Foremost because, the values of each contained entity are not given to the reader and for future comparison.

### Limitations of this report

This report is only based on articles indexed at PubMed/Medline. The variety of applied approaches was expected to grow if further databases (*i.e.*, EMBASE or MEDPILOT) are searched. Although this might harden the presented conclusion, it would not rise the informative content of this report.

Detailed information about type of X-ray and films used as well as acts of calibration of examiners was not included to this review. We took into account, that journal reviewers have already checked the applied intervention and found these appropriate. Furthermore, the widespread use of dental radiographs implies standardization on a reasonable level and quality. Findings in adults were favored, due to the variety of radiographic studies and dentition in children and adolescents. The variety of the mixed dentition is in fact a problem of standardization. The authors are aware that for every entity studied within this review, hundreds of other articles exist and there might be even standards scientists agree on. But, this can only be figured out by further systematic reviews-one for each entity and a final harmonization in a reporting guideline. Such a general guideline would support the authors preparing their studies and manuscripts as well as the scientists to compare data.

Only one article covered all entities studied in this review[26]. Nevertheless, all researches would have been enabled to report all these entities. Evidently it is often not of interest to report about *i.e.*, alveolar bone loss while presenting results about the prevalence of apical lesions. Nonetheless, such data would contrast and illustrate findings by thorough information about the studied cohort. More accompanied information could be conveyed about dental status of studied subjects. Thus, comparability and multi-variate analyses would be simplified generally. The authors think it would be worthwhile to have an easy reporting system of all entities. Today's possibilities to provide such data digital *via* online publication would enable authors and publishers to share data without expensive printed pages.

There are established but not generally accepted and enforced standards to assess and report findings from radiographic surveys. Thereby comparability of published findings is only possible with chief limitations. There is need to agree on standardized assessment and diagnosis first, and about the mode of report secondly. An easy and validated multi-term report-system of dental status would allow a widespread application, especially for dental public health and epidemiology. In consequence: there is need for a reporting guideline.

## COMMENTS

### Background

Reporting standards are necessary to compare research outcomes especially in medical science. Full-mouth radiographic surveys allow information about the dental status. These are: number of teeth, caries, fillings/restorations, root canal treatments/filling, apical health and alveolar bone loss. But findings have to be evaluated and reported in such a way, that a comparison between published results is possible. There is no reporting guideline, yet. Which mode of report could be proper is neither finally discussed nor published. The paper shows shortcommings in current acquisition and presentation of data, hereinafter it recommends suitable methodical approaches.

### Research frontiers

Dental radiology, epidemiology, research methodology in dentistry and medical statistics for oral health variables.

### Innovations and breakthroughs

Only 8 out of 37 scientifically papers are at the maximum comparable towards 3 out of 7 entities of dental status. Evaluation of radiographs differ is widely. Reporting with statistical tools like mean and median or grouping and dichotomization did not allow further comparison, due to a lack of raw data. Also sum scores or indices like Decayed, Missing and Filled Teeth (DMFT) impede comparability of data. Thus no standard could be identified. Besides, missing values are underreported.

### Applications

A guideline of standards for evaluation, report and cut-off points is needed. So far it can be advised, that: (1) depicting problems and resulting missing values are reported; (2) it must be stated, if third molars are included or not when reporting the number of missing or remaining teeth; (3) implants should be taken into account; (4) sum scores are only present with crude data of the study. In case of DMFT the decayed teeth, missing teeth, filled teeth and decayed and filled teeth should be given separately, too; (5) apical health should be evaluated with a validated tool preferably the Peri-Apical-Index; (6) alveolar bone loss should be evaluated and reported in exact percentage or "in thirds" (Lindhe) not in absolute millimeters; (7) all distributions of data are presented with mean and medium value, augmented with SD, range and quartiles; and (8) the reader is given the rational for grouping or a cut-off point if data is dichotomized.

### Terminology

"Full-arch radiographs" are radiographs taken mostly in dental office and depicting all teeth (including the complete root) of a human dentition. Mostly a so called "panoramic radiograph" is taken; but also a survey with intraoral radiographs can be applied. "Apical health" describes the situation around the tip of the tooth root inside the bone of the jaw. This area might be retreat for bacteria causing a painless infection, which is relevant for systemic health and inflammation parameters. Such infections can be detected by radiographs. "Alveolar bone loss" describes the loss of jaw bone around teeth. The amout of lost bone correlates with the infection of tissues around teeth, which is a multifactorial disease promoted by bacteria. As seen in the radiograph the occurrence of a a so called "periodontitis" (inflammation of the gums) can be anticipated by the loss of bone. "DMFT" is the World Health Organization-standard to report a clinically assessed dental status. It is namely the sum of Decayed, Missing and Filled Teeth in a dentition. "Reporting guideline" is a standardization for scientific reporting of findings. Today many such guideline exists in Medicine (www.equator-network.com).

### Peer review

It is a well organized and written paper.

## Abstract

Chemotherapy has been linked with Takotsubo cardiomyopathy. Most of the literature on chemotherapy associated Takotsubo cardiomyopathy is on the drug 5-fluorouracil. In this report, we describe the case of a 55-year-old Asian male who developed Takotsubo cardiomyopathy while receiving dual chemotherapy with cytarabine and daunorubicin for acute myeloid leukemia. To our knowledge, it is the first case of Takotsubo cardiomyopathy associated with daunorubicin and/or cytarabine.

**Key words:** Takotsubo cardiomyopathy; Chemotherapy; Cytarabine; Daunorubicin

**Core tip:** In this case report, we describe first case of Takotsubo cardiomyopathy associated with daunorubicin and/or cytarabine.

## INTRODUCTION

Chemotherapeutic drugs have a wide range of cardiotoxic effects. Recently, there have been case reports of chemotherapy [namely 5-fluorouracil (5-FU)] induced Takotsubo cardiomyopathy (TC)[1-5]. However, to the best of our knowledge, there has been no published literature on cytarabine and/or daunorubicin causing TC. In this report, we describe the case of a 55-year-old Chinese male who developed TC while receiving dual chemotherapy with cytarabine and daunorubicin for non M3 acute myeloid leukemia.

## CASE REPORT

A 55-year-old male with past medical history of diabetes mellitus (type Ⅱ) presented to our hospital with complaints of pleuritic chest pain with non-productive cough and fever (Tmax 101.2 °F) for 3 d. Chest X-ray showed right-sided lung infiltrates. Patient was admitted to the medical floor with the diagnosis of community-acquired pneumonia and was started on moxifloxacin. The patient's blood work showed an incidental finding of 12% blast cells with a total white cell count of 9.9. Electrocardiogram performed on the day of admission revealed sinus tachycardia with abnormal R wave progression. Echocardiogram showed ejection fraction (EF) of 60%-65%, with normal chamber size and mild diastolic dysfunction. Three sets of cardiac enzymes including cardiac Troponin I and creatine kinase-MB were negative. Patient was evaluated by the hematology and oncology team for the incidental finding of blast cells on peripheral blood smear. The next day, as per the hematologist's recommendation, the patient underwent a bone marrow biopsy which showed the presence of pro-myelocytes, suggestive of M3 acute myeloid leukemia. The patient was started on All Trans-Retinoic Acid induction chemotherapy regimen. Prophylactic valacyclovir, omeprazole and intrave-

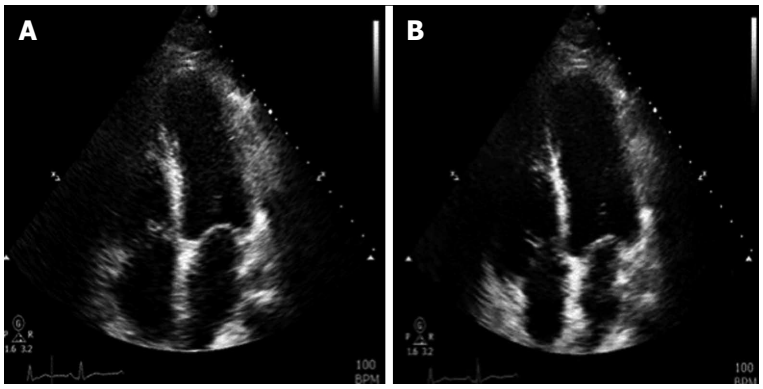

**Figure 1 Echocardiogram showing ballooning of the apex with hyper contracted basal segment at end systole (A) end diastolic phase (B).**

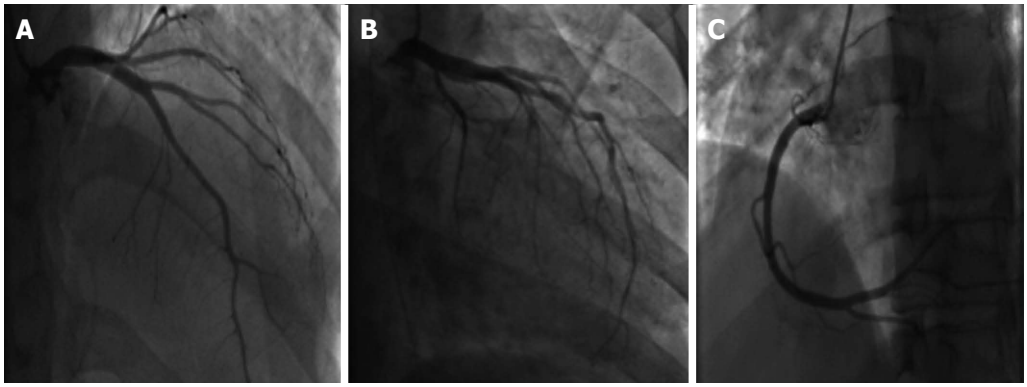

**Figure 2 Coronary angiogram showing clean coronaries with thrombolysis in myocardial infarction 3 blood flow left main and left anterior descending (A), left circumflex (B) and right coronary artery(C).**

nous (*iv*) fluids were also started.

Two days after the initiation of chemotherapy, fluorescent *in situ* hybridization results demonstrated a negative translocation of chromosomes 15, 17, thus confirming the diagnosis of non-M3. As a result, the chemotherapy regimen was changed to cytarabine 100 mg/m$^2$ and daunorubicin 60 mg/m$^2$. On day 6 of chemotherapy with cytarabine and daunorubicin, the patient began to experience non-radiating sub sternal chest pain associated with palpitations. Electrocardiogram obtained at that time showed sinus tachycardia of 170 bpm with ST segment elevation in leads I, aVL, V5, V6; consistent with anterolateral wall ST elevation myocardial infarction (STEMI). The patient was transferred to the cardiac intensive care unit (CCU) with a diagnosis of STEMI. Cardiac enzymes were obtained which showed Cardiac Troponin I of 8.54 upon initial transfer to the CCU, reaching a maximum of 38.64 after 18 h (normal values 0-0.1 ng/mL). Given the patient's immunocompromised state, cardiac catheterization was deferred and he was managed medically with aspirin, clopidogrel, rosuvastatin, and aggressive *iv* hydration. Echocardiogram done on day 6 of chemotherapy showed an EF of 30%-35% with segmental wall motion abnormalities: mild anterior, septal, apical, inferior and lateral wall hypokinesia, with normal diastolic function consistent with mid-left anterior descending artery occlusion (Figure 1). On day 20 of admission, patient underwent an elective cardiac angiogram, which showed non-obstructive coronary vasculature, mildly decreased left ventricular systolic function, EF of 50% with mild anterolateral and anterobasal hypokinesia (Figure 2).

## DISCUSSION

This case report demonstrates a strong causal relationship between chemotherapy and the development of TC as evidenced in the patient's presentation on day 6 of chemotherapy induction. Symptomatic recovery of the patient after supportive medical management, with the concomitant discontinuation of the chemotherapeutic agent, also strengthens this causal relationship. The patient's repeat echocardiogram (performed 2 wk after discontinuation of the chemotherapeutic agents) showed a complete recovery of the EF with no wall motion abnormalities. In addition, a coronary angiogram demonstrated non-obstructed coronary vasculature. Given the patient's clinical presentation and the diagnostic evidence obtained, there is no alternative justification for the clinical course observed other than Takotsubo cardiomyopathy. This is the first case report of daunorubicin and/or cytarabine induced TC.

Most of the literature on chemotherapy associated TC is published on the drug 5-FU, a widely used chemotherapeutic agent for solid tumors. One case report from

Japan described daunorubicin-induced TC in a patient with refractory multiple myeloma[6]. However, to our knowledge, this is the first case report of daunorubicin and/or cytarabine induced TC in the United States.

Chemotherapy induces increased sympathetic tone with resulting elevation of cytokine, free radical, prostaglandin, catecholamine and growth factor levels. The excess of these modulators can potentiate worsening adrenoreceptor sensitivity, and can contribute to the clinical presentation of TC[1-5]. Daunorubicin belongs to the anthracycline class of chemotherapeutic agents, which remains among the most active anti-cancer drugs for solid tumor and hematologic malignancies. The exact pathogenic mechanisms responsible for the underlying cardiotoxic effects of anthracycline agents has yet to be elucidated. The current postulated mechanism supports the role of free radical induced cardiac damage (known to be caused by the excessive production of hydrogen peroxide, hydroxyl radicals and reactive oxygen species)[6-10]. These free radicals promote lipid peroxidation which contributes to cell membrane damage, and thus results in the activation of pro-apoptotic enzymes, such as Bax, Cytochrome-c and caspase-3, in myocyte mitochondria, triggering apoptosis and resulting in cardiac myocyte cell death[6-10]. Cardiac myocytes are more susceptible to lipid peroxidation due the presence of a high mitochondrial density with resultant high-energy requirements and the lack of anti-oxidant enzymes, which are required for the detoxification of superoxide anions and hydrogen peroxide. As a result of this cardiac myocyte susceptibility, a dose-related and irreversible loss of cardiac myocytes occurs, resulting in cardiomyopathy[11]. Though the exact mechanism of cardiotoxicity caused by cytarabine has yet to be elucidated, it is postulated that this drug can result in a hypersensitivity reaction or possible immune-mediated damage of cardiac myocyte[12].

In conclusion, we suggest that physicians be vigilant when treating patients with daunorubicin and/or cytarabine and should be aware of a possible association of these chemotherapeutic agents with TC.

## COMMENTS

### Case characteristics

A 55-year-old male receiving treatment with Daunorubicin and Cytarabine for non M3 acute myeloid leukemia (AML) experience non-radiating sub sternal chest pain associated with palpitations on 6th day after chemotherapy.

### Clinical diagnosis

Acute coronary syndrome.

### Differential diagnosis

ST segment elevation myocardial infarction (STEMI), non-STEMI, Unstable Angina, Aortic Dissection, Pulmonary embolism, cardiomyopathy, Ventricular wall rupture.

### Laboratory diagnosis

Cardiac troponin I and creatine kinase-MB elevation with continued uptrend, consistent with myocardial ischemia.

### Imaging diagnosis

Electrocardiogram-anterolateral STEMI; Echocardiogram (ECHO) at day 6 of therapy-ejection fraction (EF) of 30%-35% with segmental wall motion abnormalities; repeat ECHO (two weeks later)-Normalization of EF and no wall motion abnormalities; cardiac catheterization (two weeks later)-clean coronaries. Pt diagnosed with Takotsubo cardiomyopathy.

### Treatment

Due to patient's immunocompromised state, he was medically managed with aspirin, clopidogrel, rosuvastatin, and aggressive intravenous hydration in cardiac intensive care unit.

### Related reports

Patient initially thought to have acute coronary syndrome but was eventually found to have Takotsubo cardiomyopathy. Patient had clean coronaries on Cardiac catheterization and on repeat ECHO, his EF normalized and wall motion abnormalities resolved.

### Term explanation

Non M3 AML-According to French-American-British classification acute myeloid leukemia are sub grouped in to 8 categories M0-M7. This classification guides the therapy and prognosis in patients diagnosed with AML.

### Experiences and lessons

Vigilance should be observed while treating patients with daunorubicin and/or cytarabine.

### Peer review

This is first case report of takotsubo cardiomyopathy associated with daunorubicin and/or cytarabine.

## Abstract

Recent randomized clinical trials have established the efficacy of Comprehensive Behavioral Intervention for Tics (CBIT) in treating children and adults with Tourette syndrome and persistent tic disorders. However, the standard CBIT protocol uses a weekly outpatient treatment format (*i.e.*, 8 sessions over 10 wk), which may be inconvenient or impractical for some patients, particularly patients, who are required to travel long distances in order to receive care. In contrast, an intensive outpatient program may increase accessibility to evidence-based behavioral treatments for Tourette syndrome and other persistent tic disorders by eliminating the necessity of repeated travel. This case series evaluated the use of an intensive outpatient program CBIT (IOP CBIT) for the treatment of 2 preadolescent males (ages 10 and 14 years) with Tourette syndrome. The IOP CBIT treatment protocol included several hours of daily treatment over a 4-d period. Both children evidenced notable reductions in their tics and maintained treatment gains at follow-up. Moreover, both patients and their parents expressed treatment satisfaction with the IOP CBIT format. This case series addresses an important research gap in the behavioral treatment of tic disorders literature. The patients' treatment outcomes indicate that IOP CBIT is a promising treatment that warrants more systematic investigation.

**Key words:** Tourette syndrome; Tics; Habit reversal; Intensive outpatient; Behavior therapy

**Core tip:** Comprehensive Behavioral Intervention for Tics (CBIT) is an empirically supported treatment for individuals with Tourette syndrome. However, the standard, weekly outpatient format of CBIT may preclude some from receiving care. This is the first case series to examine the treatment outcomes of intensive outpatient CBIT (Intensive Outpatient Program CBIT) in children. Despite marked differences between the two boy's presentations, outcomes for both cases were positive.

Intensive outpatient comprehensive behavioral intervention for tics: A case series. *World J Clin Cases* 2014; 2(10): 569-577 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/569.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.569

## INTRODUCTION

Tourette syndrome (TS) is a disorder characterized by multiple motor tics and at least one vocal tic that occur regularly and are present for at least 12 mo[1]. On average, tics emerge between the ages of 3 and 8 years, peak between 10 and 12 years, and decrease in adulthood[2,3]. An estimated 60% of children with Tourette syndrome also

meet diagnostic criteria for at least one psychological disorder, with attention deficit hyperactive disorder (ADHD) being the most common comorbid condition[4], followed by obsessive compulsive disorder (OCD), social anxiety, depression, and externalizing behaviors[4-6].

### Standard treatments for tourette syndrome and persistent tics

Historically, pharmacologic interventions have been used as the first-line treatment for symptom management in Tourette syndrome patients[7]. However, medications require long-term continuous use and are associated with negative side effects that frequently lead to discontinuation of treatment (for review, see[7-9]). Alternatively, behavioral interventions reduce concerns regarding negative side effects and potential long-term consequences of prolonged medication use. A number of behavioral interventions have been examined (for review, see[10]) with habit reversal therapy[11] garnering the most support (for review, see[12]). Habit reversal consists of awareness training, contingency management, relaxation training, competing response training, social support, and generalization training.

Comprehensive Behavioral Intervention for Tics (CBIT)[13] is a multiple-component behavioral treatment for Tourette syndrome and persistent tic disorders that expands on the original habit reversal therapy protocol and includes additional emphasis on psychoeducation, functional interventions, and relapse prevention. Recently, two large randomized controlled trials examined the efficacy of CBIT compared to supportive therapy in adults and children diagnosed with Tourette syndrome and persistent tic disorders. The child study ($n$ = 126; mean age 11.7 years) found that CBIT was superior to a psychoeducation and supportive therapy comparison condition in reducing tics (52.5% *vs* 18.5%, respectively)[14]. The adult study ($n$ = 122; 16-69 years) also found superior results for CBIT, with 38.1% of the participants who received CBIT *vs* 6.4% in the psychoeducation and supportive therapy condition experiencing a significant improvement in their tics symptoms at post-treatment[15]. Importantly, both adults and children in the CBIT condition maintained treatment gains and reported decreased psychological symptoms at the six-month follow-up.

Taken together, these findings indicate that CBIT produces similar outcomes as medication without the side effects and that patients continue to experience benefits after treatment is completed[14]. In response to mounting evidence, CBIT is now considered a first-line treatment for persistent tic disorders in Europe[12] and Canada[16].

### Rationale for intensive outpatient CBIT

The standard outpatient CBIT protocol is comprised of eight sessions that are completed over 10 wk, followed by three monthly booster sessions. However, weekly sessions may be inconvenient or impractical for some patients depending on the complexity of their symptoms or their accessibility to care. Instead, these patients may benefit from an intensive outpatient program (IOP) that compresses CBIT into a week-long protocol. An IOP can help extend treatment catchment areas and compensate for the current lack of CBIT providers. Importantly, IOP also allows for patients to practice CBIT without the distraction of school or work. This is particularly relevant to the use of the competing response procedure, which is to be implemented upon the detection of a premonitory urge to tic or the actual occurrence of a tic. The IOP CBIT allows patients to dedicate time specifically to detecting urges and tics and implementing the competing responses without the distractions of day-to-day life. To date, no studies have been published evaluating the effectiveness of an IOP CBIT. However, Flancbuam *et al*[17] presented a case study detailing the outcome of a 25-year-old male diagnosed with TS who traveled to the United States in order to receive seven sessions of adapted CBIT over two weeks[13]. The patient reported notable decreases in tic frequency and subjective distress and high treatment satisfaction at posttreatment, although he also reported a lapse in his tic symptoms when he returned home.

Little is known about the benefits of IOP CBIT, but there is precedence for treating children with an IOP behavioral program. For example, Whiteside and colleagues[18] present a case series of three adolescents who received 10 sessions of exposure and response prevention for OCD over five days. Each of the three adolescents experienced a decrease in OCD symptoms at posttreatment, and two maintained gains after three months. Moreover, an IOP (one session) protocol has been used to treat specific phobia in children and has demonstrated efficacy in three randomized controlled trials (for review, see[19]).

### Goals of the case series

The current case series addresses an important limitation in the literature by examining whether IOP CBIT can help quickly reduce tic severity in two youth diagnosed with TS. Although the boys in the case series differed markedly by age, ethnicity, psychological symptoms, behavioral distress, and tic severity, and although they were treated by different treatment teams (see Table 1), both evidenced a notable reduction in tics and maintained their treatment gains. The patients and their parents provided written informed consent for this case series.

## CASE REPORT

### Patient A

Patient A (see Table 1) was a 10-year-old Asian-American male in the fourth grade. He was placed in the gifted-and-talented program and advanced mathematics. He maintained good grades but had occasional behavioral problems at school. He had several friends and was involved in piano, karate, and chess.

Patient A's tics were first noticed by his second grade teacher when he was 7 years old. He was evaluated by a neurologist and a psychologist a year prior to receiving IOP CBIT. Both diagnosed him with Tourette syndrome.

The neurologist recommended medication, which his parents decided against, and the psychologist recommended yoga and family therapy. They attended two sessions of family therapy but discontinued treatment after deciding that it was not helpful. After researching behavioral treatments on the Internet, Patient A's mother contacted one of the authors (ALP) to inquire about receiving CBIT for her son. Since the family would be required to travel to another city to receive CBIT, the staff and his mother agreed to use an IOP CBIT protocol. The patient presented for care in March 2013. At baseline, he and his mother reported that he experienced frequent facial tics that interfered with piano practice and chess competitions, but the tics did not interfere with his academic or social functioning. However, his mother was concerned that he would have tic-related social difficulties when he started middle school the following year.

### Baseline assessment

A baseline assessment was conducted by a master's level independent evaluator (IE), who was not involved in the patient's treatment. The Yale Global Tic Severity Scale (YGTSS)[20] and the Clinical Global Impression Scale (CGI)[21] were administered at baseline, posttreatment, and follow-up and were the main outcome measures for treatment (see Table 2). The YGTSS, a semi-structured clinical interview, is routinely used in the TS literature and has well established psychometric properties (*e.g.*,[14, 20, 22,23]). It provides a Total Motor Tic Score (range: 0-25), Total Phonic Tic Score (range: 0-25), Total Tic Score (range: 0-50); past studies have used YGTSS Total Scores greater than 13 as a cut-off for clinically significant tics (> 9 if patient has only motor or vocal tics; *e.g.*,[14]). A decrease of 4 points on the YGTSS is considered clinically meaningful in children[14]. The YGTSS was conducted by the IE and was completed by the patient with the help of his mother. The CGI-S and CGI-I scales are well-established rating tools applicable to all psychiatric disorders[21]. The CGI-S scale is used to assess treatment response in patients. The CGI-S requires the clinician to rate the severity of the patient's illness at the time of the assessment, relative to the clinician's past experience with patients who have the same diagnosis. The CGI-I requires the clinician to rate how much the patient's illness has improved or worsened relative to a baseline state.

The IE also administered the Kiddie Schedule for Affective Disorders and Schizophrenia-Present and Lifetime Version[24], a semi-structured clinical interview designed to determine present episode and lifetime history of psychiatric illness based on the diagnostic criteria of the

Session 2 (S2) scores were not recorded; Subjective Unit of Distress Scale range from 0 to 10, with 0: No Distress; 10: Extreme distress.

Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision[25]. In addition, the patient completed the Premonitory Urge Scale[26], the Child Yale-Brown Obsessive Compulsive Scale[27,28], and the ADHD Interview[29] at baseline. These commonly used measures were selected to provide a comprehensive evaluation of the patient's tic-related symptoms and psychiatric functioning.

The assessment confirmed a diagnosis of Tourette syndrome with evidence of clinically meaningful motor tics. He had a history of vocal tics but was not experiencing them at the time of the assessment. He did not endorse OCD symptoms and reported only minimal ADHD symptoms. Patient did not meet diagnostic criteria for other Axis I diagnoses.

### Formulation, rationale, and treatment plan

Environmental and social factors are believed to play a significant role in tic manifestation[22]. CBIT is an evidence-based behavioral treatment that recognizes and targets these factors. The patient completed eight sessions (60 to 90 min each) of CBIT over four consecutive days (see Table 3). The protocol was administered by a treatment team, including two licensed psychologists and a pre-doctoral psychology intern.

### Course of treatment

Psychosocial and tic history were gathered and treatment rationale was provided in Session 1. Consistent with the CBIT manual, Session 1 focused on information gathering and providing a treatment overview and rationale. Patient A's mother was already well versed on TS. Patient A and his mother identified five current motor tics (neck jerk, eye blink, upper lip tic, facial grimace, and nose flair) that occurred in isolation and as a single complex tic (see Table 4). Tic monitoring and the role of social support to encourage skill use were introduced and a reward program was established to reinforce treatment compliance.

The Tic Hassle worksheet[30], the functional assessment procedure, and the competing response procedure were introduced in Session 2 and were conducted each session for the remainder of treatment. The Tic Hassle worksheet uses a Subjective Units of Distress Scale (SUDS), in which patients verbally rate their level of distress on an 11-point scale, with 0 representing minimal distress and 10 representing extreme distress. In Session 2, Patient A identified neck pain (SUDS = 9), people noticing (SUDS = 3), his grandfather staring at him (SUDS = 4), interruption of piano practice (SUDS = 6), and increasing the time it takes to complete school work (SUDS = 5) as tic hassles. By the end of the eighth session, he no longer experienced distress from these hassles. Patient A and his mother had difficulty completing the functional

assessment for the individual tics throughout treatment. They reported that the tics occurred with equal frequency across all settings and denied consequences following tic occurrence. Moreover, due to the format of treatment, they had little to no opportunity to implement relevant function-based interventions at home.

Competing response training focused on one tic at a time, starting with his most distressing tic (*i.e.*, neck jerk tic). This component of treatment requires that patients become more aware of their tics and premonitory urges. Consequently, Patient A was asked to describe his tic and its corresponding premonitory urge, identify each time he engaged in the tic during the training, and then identify each time he experienced the premonitory urge. Next, the patient and the provider collaboratively selected an appropriate competing response. Effective competing responses are physically incompatible with and less conspicuous than the tic, can be performed for at least 60 s, and do not disrupt normal activity[13]. For example, the competing response for the patient's neck jerk tic involved having him gently move his chin forward and focusing on one spot each time he experience the tic or the premonitory urge. Self-monitoring indicated that his neck jerk tic occurred frequently (30 times in 5 min). By Session 4, he described decreased neck pain, and his mother reported a notable decrease in the neck jerk tic. The competing response training was implemented for his eye-blink and lip tics in Sessions 3 and 4, respectively. His competing responses included slow, rhythmic blinking for the eye tic and pursing his lips gently together for the lip tic. He demonstrated quick mastery over the lip tic but continued to have difficulty with his eye-blink tic. Consequently, the eye-blink tic remained the focus of CBIT for Sessions 5 to 8. By Session 8, both he and his mother reported improvement in his eye-blink tic, although his mother still occasionally had to prompt him to engage in his competing response.

Relaxation training was initiated in Session 4, and relapse prevention was discussed in Sessions 7 and 8. Since they had previously disagreed about what constituted a tic, both the patient and his mother were asked to discuss how they would handle new tics should they emerge. Ways to communicate about potential tics were explored, and a plan for this type of conversation was developed. At the end of treatment, both Patient A and his mother expressed high treatment satisfaction.

### Patient B

Patient B (see Table 1) was a 14-year-old African-American male. He participated in a home school program in which he attended classes several times per week outside his home and was also involved in track and field. At the time of the intervention, Patient B had not shared information about his diagnosis with peers. As a result, he often suppressed his vocal and motor tics when around peers and then released his urges to tic at home. At intake, Patient B's vocal and motor tics had occurred for approximately six months. He had already been evaluated by pediatric neurology and developmental pediatrics and was prescribed methylphenidate for ADHD, clonidine for tics, and melatonin for sleep. Patient B completed an magnetic resonance imaging and electroencephalography with pediatric neurology, and it was determined that he did not present with epilepsy or other neurological concerns. When the tics were unresponsive to medication intervention, Patient B and his family were referred for behavioral treatment. Patient B's psychological history was positive for developmental delays, ADHD, and learning difficulties, with no prior history of tics. He had previously undergone treatment for specific phobia and stuttering.

Patient B presented for behavioral treatment in Spring 2012. Given the severity of his behaviors at his initial appointment (*i.e.*, grabbing his mother's arm, punching the floor, and difficulty starting and stopping movements), consultation with ALP was sought regarding the appropriateness of outpatient services. It was determined that he might benefit from an intensive outpatient treatment protocol, which started in Summer 2012.

### Baseline assessment

A baseline assessment of Patient B's current functioning was conducted by a master's level IE, who was not involved in the treatment delivery, and included the YGTSS[20] and the clinician-rated CGI[21] and the Hopkins Motor/Vocal Tic Scale (HMVTS)[31]. Only the YGTSS and CGI were used as outcome assessments, and additional information about their psychometric properties can be found under Patient A's baseline assessment section. The assessment confirmed the diagnosis of TS and indicated that Patient B was experiencing clinically significant vocal and motor tics (as defined[14]). Specifically, Patient B and his parents reported six motor and four vocal tics, which significantly interfered with family interactions and had begun to interfere with his peer relationships.

### Formulation, rationale, and treatment plan

The treatment team met with Patient B and his family to discuss treatment options including IOP CBIT. The family had already exhausted many other options in the community with little to no success, and his parents were hopeful that this alternative approach would alleviate his symptoms. Given the severity of his symptoms, Patient B continued to take clonidine during his participation in IOP CBIT.

Patient B and his parents attended one baseline assessment session and three IOP CBIT sessions over the course of four consecutive days. Although only three IOP CBIT sessions were conducted, the total amount of time spent for the intervention was comparable to that of the standard eight session CBIT protocol. During the course of treatment, Patient B's parents observed through a one-way mirror. Treatment was administered by a team consisting of a board certified child and adolescent psychologist and two child and adolescent postdoctoral fellows (see Table 5 for a summary of the specific treatment schedule).

PMR: Progressive muscle relaxation; Sx: Symptoms; CR: Competing response; OOSA: Out of session assignment; F(x) = Function.

### *Course of treatment*

During the baseline assessment, Patient B and his parents identified six current motor tics (grabbing/touching, putting napkins in mouth, full-body twitches, open mouth with head nodding, "closing" self into small spaces, tapping surfaces) and four vocal tics (screaming, humming, repeating self, and "Aahh" sounds). The treatment agenda, rationale, tic monitoring, and family support were discussed with Patient B and his parents.

CBIT was initiated in Session 2. The treatment team provided psychoeducation about tic disorders, the rationale for competing response training, awareness training, and the stress and relaxation responses. The team also engaged the patient in several relaxation strategies and progressive muscle relaxation, which yielded a notable decrease in his tics. A hierarchy of the patient's current tics was developed. Patient B was assigned relaxation and tic monitoring homework, which was reviewed at the start of the next session (see Table 5).

The following day, Patient B reported some benefit with homework while his mother reported a reduction in the severity and intensity of the grabbing tic in public places. Session 3 focused on completing the tic hassles worksheet[30], in which Patient B described the grabbing tic and vocal tic as most bothersome. He identified arm pain (SUDS = 9), parental dependence (SUDS = 11), and annoying others (SUDS = 7) as tic hassles. Patient B reported that his vocal tic was embarrassing (SUDS = 10). Competing response training was implemented with one tic at a time, starting with the most distressing tic (grabbing), followed by the vocal tic. For the grabbing tic, Patient B was asked to practice squeezing his hands together and pushing them down as a competing response. For the vocal tic, Patient B was instructed to clench his teeth and push his tongue against the roof of his mouth as his competing response.

On Day 4, the treatment team reviewed the homework, in which the patient's mother observed only one vocal tic during several discrete tic observation periods. Patient B reported not having any tics or urges while at a friend's house, and he stated that he did not feel as though he was suppressing his tics. Because Patient B was still reporting some difficulty identifying premonitory urges, a token economy was also implemented during the session whereby Patient B earned points towards a desirable reward for detecting a premonitory urge by notifying the provider (*i.e.*, raising his finger) and engaging in the appropriate competing response. Patient B responded positively to the token economy and was motivated to identify premonitory urges. He was also able to resist the urge to tic or engaged in the tic for markedly less time compared to pretreatment. At the end of the session, Patient B and his mother reported improvement in the awareness of his tics and premonitory urges. The treatment team also practiced relaxation strategies, summarized treatment progress, and discussed relapse prevention during the last part of the session. Providers emphasized the importance of ongoing social and family support.

Over four days of assessment and treatment, behavioral improvement was observed and noted by all three providers, Patient B, and his parents. Patient B reported feeling skeptical at the beginning of the week about whether this treatment would be effective, but at the last session he stated, "I stand corrected." Patient B was able to control his tics by either stopping them from occurring, notifying providers when he was about to have one, and/or decreasing the length of time spent engaging in specific tic behaviors. Overall, Patient B and his parents verbally reported high treatment satisfaction.

### *Results*

**Patient A:** By the end of treatment, Patient A and his mother reported a clinically meaningful decrease in his tic severity as assessed by the YGTSS and the CGI. Importantly, his tic severity scores had decreased further by the

one-month follow-up (see Table 2). Following their one-month follow-up assessment, Patient A and his mother attended a 60-min booster session, in which his mother reported that she only occasionally noticed a slight eye-blink tic. Patient A disagreed with his mother that this was a tic. He also reported that although he still experienced an urge to tic, the urge was less severe and occurred less frequently. Both Patient A and his mother reported continued treatment satisfaction with IOP CBIT at follow-up. Patient A and his mother reported continued treatment gains at the seven-month follow-up and high treatment satisfaction. More specifically, he reported that he continued to occasionally experience a slight eye tic. However, both he and his mother agreed that the tic was not noticeable to others and did not cause him interference. No new tics emerged from the time of treatment completion through the seven-month follow-up period.

**Patient B:** The YGTSS (see Table 5) and HMVTS were administered by the same IE and completed by Patient B with the help of his parents at one week, one month, and six months. Overall, the assessments revealed clinically meaningful improvement in Patient B's functioning (see Table 2). At the one-week follow up, there was an overall reduction in number of tics (10 *vs* 2). The parents reported that Patient B had not engaged in the grabbing tic in the previous week, that he was more aware of the urge to grab, and that he was able to apply a more appropriate competing response (*i.e.*, walking away, distraction, breathing). During follow-up interviews, Patient B was observed using several appropriate competing responses (*i.e.*, crossing his arms, sitting on his hands) in reaction to the urge to grab others. Patient B also reported feeling "a lot better," stating, "I don't really tic as much." He also reported that the duration of his tics had decreased, that he was less bothered by his tics, and that the tics were less noticeable to others in public. The parents confirmed his impressions. Patient B was also provided with additional suggestions on competing responses to use for the remaining tics. The treatment team reviewed the follow-up plan with parents, which included booster sessions.

At the one-month follow-up, the YGTSS revealed that treatment gains had been maintained, and Patient B demonstrated a reduction in tic number, frequency, and interference of both motor and vocal tics. By the six-month follow-up, Patient B was exhibiting a slight increase in the frequency of vocal tics and an increase in the complexity and interference of motor tics (see Table 2); however, Patient B admitted to not practicing the breathing and relaxation strategies. Therefore, booster sessions were scheduled to review IOP CBIT components.

Although Patient B's presentation at six months post-treatment revealed some regression (as seen in Table 2), the family expressed their appreciation for Patient B's progress and his ability to function better at home and at school. The family also stated that the tics had become "so subtle" that he was no longer concerned or upset by them.

## DISCUSSION

The current case series describes the implementation of an intensive outpatient behavioral treatment with two preadolescents who presented with Tourette syndrome. Despite their different presentations, both patients demonstrated treatment gains following the IOP CBIT intervention. The generalizability of the current case series is unknown at this time. However, IOP CBIT may be appropriate for individuals who present with moderate to severe tics, those who are experiencing clinically significant impairment in daily academic and social functioning, and for individuals and their families who desire to experience a quick reduction in motor and/or vocal tics. On the other hand, individuals who might not be good candidates for CBIT include those with oppositional and/or defiant behaviors, since adherence to the treatment protocol would likely prove to be a challenge. In addition, because it is important for individuals with Tourette's to receive adequate psychosocial support in monitoring and reducing their tics, those with chaotic or limited family and social support systems may find this protocol challenging.

It should be noted that many individuals with Tourette syndrome experience a waxing and waning of symptoms over time and that many tics resolve on their own[2,3]. Although CBIT is not a cure for Tourette syndrome, based on the current case series, individuals who follow the treatment protocol can expect to learn tools and skills to better manage their tics, understand their premonitory urges, reduce the negative impact of the tics on their lives, and experience improvement in their overall academic and social functioning[14].

### *Limitations and future directions*

Despite addressing an important gap in the literature pertaining to the use of an intensive outpatient CBIT approach with children and adolescents, there are several limitations to the current case series that should be noted. First, an intensive treatment approach requires a time commitment from parents and patients that would likely require a parent to request time away from work and/or a child to be absent from school. This might present a financial challenge for some parents and possibly create academic stressors for some children. It also raises the question about the most convenient time to deliver an intensive outpatient intervention for children and adolescents. That is, Patient A received his treatment during a planned school break, while Patient B was seen during the summer. Clinicians should consider and discuss the time commitment it takes for families to participate in this type of intensive treatment approach.

Second, both patients received treatment at academic medical centers without individual fee-for-service costs as a part of psychology internship and postdoctoral training programs. It is possible that many families might find paying out-of-pocket for an intensive outpatient treatment to be a financial burden. Moreover, with the increased limitations placed on behavioral health services by managed

care organizations, insurance companies might be unable or unwilling to pay for an intensive outpatient program. Future research should examine the generalizability of a comprehensive behavioral intervention for TS in the community at large. Third, receiving treatment as part of a research study or through a military treatment facility would also facilitate access to services for this population. While members of the current treatment teams received training, consultation, and/or supervision from one of the leading researchers (ALP) in the field of TS, accessibility of behavioral health providers who are trained in CBIT might be more limited in other geographical areas. Both families reported feeling grateful that they had access to the current treatment teams. Agencies and educational institutions would greatly benefit the community by offering more training opportunities for behavioral health providers in the treatment of TS. The Tourette Syndrome Association has sponsored many CBIT training programs.

Finally, the intensive outpatient program implemented in the current treatment protocol might compromise the external validity of the intervention. Both patients received the intensive treatment at a much faster pace compared to traditional therapy, creating an artificial environment in which to practice the skills learned. This limited both patients' ability to practice the functional based interventions in their everyday environments at a more natural pace. Future research should continue to examine the generalizability and long-term benefits of IOP CBIT. Future research should also consider a single subject research design or an experimental research design to include a control group receiving traditional weekly CBIT with the experimental group receiving IOP CBIT over 3-4 d.

The current case series adds an important piece to the scientific literature on the behavioral treatment of Tourette syndrome and persistent tic disorders by demonstrating that Cognitive Behavioral Intervention for Tics employed as part of an intensive outpatient program can reduce tic severity. The use of an intensive outpatient program incorporating Comprehensive Behavioral Intervention for Tics appears to offer several benefits. First, the patients in this case study were able to make notable progress over the span of 1 wk *vs* 10 wk. Additionally, IOP CBIT allows patients to focus almost exclusively on developing and practicing their competing responses without the interference of work or school. IOP CBIT also expands the potential treatment catchment areas, which would make CBIT more accessible to a wider range of patients who would otherwise be limited by geography or expense. Importantly, an IOP CBIT has the potential to help compensate for the current lack of CBIT providers.

## COMMENTS

### *Case characteristics*

Both Patients A (10-year-old male) and B (14-year-old male) experienced multiple tics that were consistent with Tourette syndrome.

### *Clinical diagnosis*

Patients A and B both met diagnostic criteria for Tourette syndrome.

### *Differential diagnosis*

Patients A and B were both assessed for attention deficit hyperactive disorder and obsessive compulsive disorder.

### *Treatment*

Patients completed intensive outpatient Comprehensive Behavioral Interventions for Tics (CBIT).

### *Related reports*

Although previous studies support the use of CBIT, when delivered in eight weekly sessions, more research is needed to determine whether an intensive outpatient format can improve tic management in children with a persistent tic disorders; however, the treatment outcome of these two cases are promising.

### *Experiences and lessons*

This case series represents the first report of treatment outcomes following an intensive outpatient CBIT protocol for children. Although future research is required before more definitive conclusions can be reached, the findings of this case series suggest that Intensive Outpatient Program CBIT may reduce tic symptoms in children with Tourette syndrome.

### *Peer review*

This is a template for a valuable modification of CBIT for those who desire thorough management in a short period of time. This represents a promising approach that merits confirmation by other investigators in other settings.

## Abstract

Introduction: World Health Organization announced on April 2009 a public health emergency of international concern caused by swine-origin influenza A (H1N1) virus. Acute respiratory distress syndrome (ARDS) has been reported to be the most devastating complications of this pathogen. Extracorporeal membrane oxygenator (ECMO) therapy for patients with H1N1 related ARDS has been described once all other therapeutic options have been exhausted. Here, we report the case of a child (German, male) with H1N1-associated fulminate respiratory and secondary hemodynamic deterioration who was rescued by initial emergent ECMO established through a dialysis catheter and subsequent switch to central cannulation following median sternotomy. This report highlights several important issues. First, it describes a successful use of a dialysis catheter for the establishment of a veno-venous ECMO in an emergency case by child. Second, it highlights the importance of a closely monitoring of clotting parameters during ECMO therapy and third, if severe respiratory failure is complicated by cardiogenic shock, veno-atrial ECMO support *via* median sternotomy should be considered as a viable treatment option without further delay.

**Key words:** Airway; Circulatory temporary support; Coagulants; Extracorporeal membrane oxygenation; Infection

**Core tip:** Here, we report the case of a child with swine-origin influenza A-associated fulminate respiratory and secondary hemodynamic deterioration, who was rescued by initial emergent extracorporeal membrane oxygenator (ECMO) established through a dialysis catheter and subsequent switch to veno-atrial ECMO (VA-ECMO) *via* central cannulation. This report highlights several important issues. First, it describes a successful use of a dialysis catheter for the veno-venous ECMO-establishment in an emergency case by child. Second, it highlights the importance of a closely monitoring of clotting parameters and third, if severe respiratory failure is complicated by cardiogenic shock, VA-ECMO support *via* median sternotomy should be considered as a viable treatment option without further delay.

## INTRODUCTION

Establishment of extracorporal membrane oxygenation (ECMO) through percutaneous placement of cannulas in

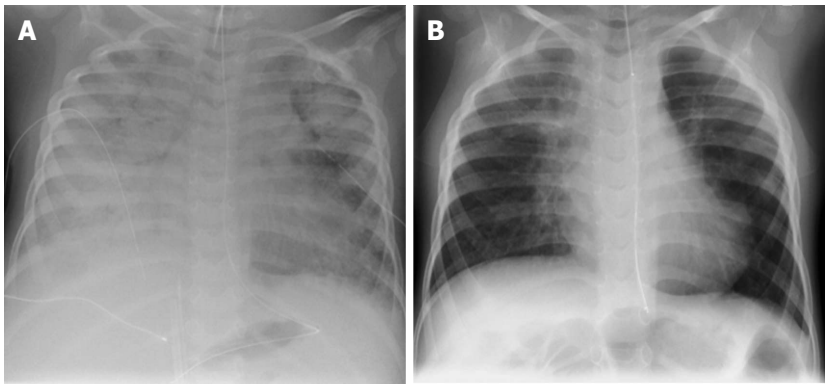

**Figure 1 Anterior-posterior chest radiograph.** A: Postintubation anterior-posterior chest radiograph of a 4 years old boy before Extracorporeal membrane oxygenator (ECMO) support with acute respiratory distress syndrome caused by proven novel 2009 H1N1 influenza virus; B: Anterior-posterior chest radiograph of the same patients after successful veno-atrial ECMO weaning and successful decanulation.

children can be difficult because of the small vessel size[1]. Median sternotomy may be necessary in selected cases to cannulate the ascending aorta and right atrium for sufficient ECMO flow[1,2].

## CASE REPORT

A 4 years old German boy presented in our emergency room with a 24 h history of shortness of breathe following several days of an influenza-like illness. At presentation, he suffered from respiratory failure requiring urgent intubation and mechanical ventilation. After his admission to our intensive care unit the initial chest radiograph revealed bilateral patchy infiltrates (Figure 1A). H1N1 influenza virus was confirmed by the reverse transcriptase-polymerase chain reaction assay of respiratory secretions. Bacterial cultures were negative. He was treated empirically with Oseltamivir. Within 24 h after hospital admission the patient had severely impaired gas exchange despite maximum respiratory support on the ventilator. For this reason high frequency oscillation ventilation (HFOV) was initiated. Since there was no improvement of the respiratory situation within 4 d of HFOV-treatment, veno-venous ECMO (VV-ECMO) had to be established.

Because of the small vessel size of the child, save cannulation sites for percutaneous placement of the ECMO cannulas were limited and included the internal jugular veins and the femoral veins. Placement of a cannula through the jugular vein was not successful. The child was in critical clinical condition and we decided to start VV-ECMO support *via* an 11 Fr dialysis catheter (Dolphin Protect, Gambo, Hechingen, Germany) placed into the left femoral vein. We established ECMO outflow of oxygenated blood *via* the arterial lumen and inflow of deoxygenated blood *via* the venous lumen of the dialysis catheter. We connected ECMO-tubes with the dialysis catheter *via* a connector (1/4 × LLm, Maquet GETINGE GROUP, Hirrlingen, Germany). ECMO circuit consisted of a Quadrox id pediatric (Maquet Cardiovascular, Wayne, NJ, United States) polymethylpentene oxygenator and a Rotaflow (Maquet Cardiovascular) centrifugal pump. This setting allowed for a flow of 400-milliliter per min. Despite the rather low circuit flow, the combination of VV-ECMO and HFOV allowed for an immediate improvement of oxygenation and weaning of vasopressor support.

Three days later, following an initial course of stabilization a sudden exchange of the VV-ECMO-system had to be performed due to massive clot-formations in the oxygenator. Notably there was an exponential elevation of fibrinogen and D-Dimer, as a result of disseminated intravascular coagulation (DIC), which could be detected from the establishment of the VV-ECMO support on until the system change. In order to avoid further clotting formations continuous application of heparin directly in the venous cannula of the new ECMO circuit has been established.

One day after the system change a sudden hemodynamic instability required high inotropic and vasopressor support. Therefore we decided to switch the VV-ECMO to veno-atrial ECMO (VA-ECMO). In order to reliably maintain adequate flow in this critical situation we performed a median sternotomy and established VA-ECMO support *via* the right atrial appendage and the ascending aorta. A Bio-Medicus (Medtronic, Inc., Minneapolis, MI, United States) arteria cannula was used as the return cannula for oxygenated blood. For venous drainage a multiport Bio-Medicus (Medtronic, Inc.) cannula was used. Circuit flow of 1.2 liters $min^{-1}$ led to a stabilization of the hemodynamic situation with immediate weaning from the vasopressor and intotropic support.

VA-ECMO was provided for a total of 10 d and could afterwards be successfully explanted. The patient could be successfully decannulated and control chest radiograph showed normal lung morphology (Figure 1B). The 4-year-old boy could be discharged from the hospital after a total of 38 d with full resolution of symptoms.

## DISCUSSION

This report highlights several important issues. First, it describes a successful use of a dialysis catheter for the establishment of a VV-ECMO in an emergency case, in which, due to the small vessel size of the child, the

percutaneous placement of routine ECMO cannulas was not possible. Second, as clotting formations in the ECMO-oxygenator is a possible and devastating complication especially in critically ill patients with H1N1 infection suffering a DIC, it is vital that clotting parameters, especially fibrinogen and D-Dimer, of such patients are closely monitored. Third, if severe respiratory failure is complicated by cardiogenic shock, VA-ECMO support *via* median sternotomy should be considered as a viable treatment option without further delay[3-9].

## COMMENTS

### Case characteristics

The 4 years old patient presented in the emergency room with the main symptom of dyspnoea.

### Clinical diagnosis

Clinical diagnosis of acute respiratory failure leads to an urgent intubation and mechanical ventilation of the young boy.

### Differential diagnosis

Bacterial infection could be excluded once the bacterial cultures were negative.

### Laboratory diagnosis

Swine-origin influenza A (H1N1) influenza virus was confirmed by the reverse transcriptase-polymerase chain reaction assay of respiratory secretions.

### Imaging diagnosis

After his admission to the authors intensive care unit the initial chest radiograph revealed bilateral patchy infiltrates.

### Pathological diagnosis

Within 24 h after hospital admission the patient had severely impaired gas exchange despite maximum respiratory support on the ventilator.

### Treatment

For this reason high frequency oscillation ventilation (HFOV) was initiated. Due to the fulminate respiratory and secondary hemodynamic deterioration, initial emergent veno-venous extracorporeal membrane oxygenator (VV-ECMO) (extracorporeal membrane oxygenator) established through a dialysis catheter and subsequent switches to veno-atrial ECMO (VA-ECMO) through central cannulation following median sternotomy, has to be performed.

### Term explanation

ECMO therapy for patients with H1N1 related acute respiratory distress syndrome (ARDS) has been described once all other therapeutic options have been exhausted. This report highlights several important issues. First, it describes a successful use of a dialysis catheter for the establishment of a VV-ECMO in an emergency case by child. Second, it highlights the importance of a closely monitoring of clotting parameters during ECMO therapy and third, if severe respiratory failure is complicated by cardiogenic shock, VA-ECMO support *via* median sternotomy should be considered as a viable treatment option without further delay.

### Peer review

This manuscript lights on the problem of the ECMO cannulation in emergency and in the pediatric patient, and indicate as a solution the use of the dialysis catheter instead of the double lumen pediatric ECMO's cannula.

## Abstract

Left ventricular wall rupture (LVWR) comprises a complication of acute myocardial infarction (AMI). Acute LVWR is a fatal condition, unless the formation of a pseudoaneurysm occurs. Several risk factors have been described, predisposing to LVWR. High index of suspicion and imaging techniques, namely echocardiography and computed tomography, are the cornerstones of timely diagnosis of the condition. As LVWR usually leads to death, emergency surgery is the treatment of choice, resulting in significant reduction in mortality and providing favorable short-term outcomes and adequate prognosis during late follow-up. Herein, we present two patients who were diagnosed with LVWR following AMI, and subsequent pseudoaneurysm formation. In parallel, we review the aforementioned condition.

**Key words:** Pseudoaneurysm; Left ventricle rupture; Myocardial infarction

**Core tip:** Ventricular wall rupture (LVWR) comprises a complication of acute myocardial infarction. Acute LVWR is a fatal condition, unless the formation of a pseudoaneurysm occurs.

## INTRODUCTION

Cardiac rupture as a pathophysiological entity was first described by Harvey[1] in 1647. It is a complication of acute acute myocardial infarction (AMI) with an overall incidence of 6.2%[2,3]. It represents the second cause of death after cardiogenic shock, and accounts for as much as 15% of in-hospital mortality[4-6]. Rupture may involve any cardiac structure, *i.e.*, atria, ventricles, interatrial or interventricular septum, papillary muscles or chordae tendineae, or one of the heart valves. Left ventricular wall rupture (LVWR) occurs up to 10 times more frequently than septal rupture, affecting up to 11% of patients after AMI and is almost invariably fatal, with death occurring within minutes after the development of chest pain[6]. In contrast, subacute LVWR and containment by false aneu-

rysm formation of the pericardial layers may lead to patient's survival for hours or even days, but rarely weeks[7-9].

## CASE REPORT

### *Case 1*

A 62-year-old man was referred for echocardiographic evaluation. Two weeks ago, he had been admitted to another hospital for a non-ST segment elevation myocardial infarction for which he had undergone coronary arteriography. Coronary angiography revealed a 60% occlusion of the left anterior descending artery (LAD), a totally occluded right coronary artery (RCA), and a totally occluded left internal mammary artery (LIMA) graft to the LAD. The patient's history included coronary artery bypass grafting operation, with a LIMA graft to the LAD, and an ascending aorta replacement with an aortic graft (Hemashield straight tube, Boston Scientific) due to aneurysm, twelve years earlier. Moreover, nine years ago, he had undergone percutaneous coronary angioplasty and had received a drug-eluting stent to the RCA. Echocardiography revealed rupture of the left ventricular posterior wall which was contained by pericardium, thus forming a sizeable pseudoaneurysm (Figure 1). There was no significant pericardial effusion and the overall systolic function of both ventricles was found within normal limits. Based on the echocardiographic diagnosis the patient was admitted to our hospital for further investigation and treatment. The patient's admission 12-lead surface electrocardiogram (ECG) showed ischemic changes in the inferior leads (Ⅱ, Ⅲ, aVF). Cardiac computed tomographic angiography (Figure 2A) and volume rendering technique (Figure 2B) confirmed the presence of a pseudoaneurysm, with 50 mm × 50 mm dimensions, at the posterior wall of the left ventricle. The patient was referred to Surgery and a surgical repair of the defect with application of a Dacron patch with continuous suture was performed. Repeat echocardiography demonstrated a well-placed patch at the site of the rupture, enforcing the walls of the pseudoaneurysm. The patient had an uneventful postoperative recovery and was discharged on day 6 with explicit instructions and medication.

### *Case 2*

An 86-year-old man presented with exertional dyspnea of five months duration. He had a history consistent with chronic atrial fibrillation under acenocoumarol and atenolol, and dyslipidemia under simvastatin. He had no history of documented coronary artery disease the 12-lead ECG showed Q waves in leads Ⅲ and aVF. He was hemodynamically stable with normal vital signs. The echocardiographic study demonstrated a pseudoaneu-

rysm at the akinetic basal inferior lateral wall of the left ventricle, close to the base of the anterolateral papillary muscle (Figure 3). The overall function of the left ventricle was preserved. Cardiac computed tomographic angiography and volume rendering technique revealed significant atherosclerosis and coronary arteries narrowing. The echocardiographic findings were confirmed; a circular opacified 19 mm × 16 mm protrusion originating from the lateral wall of the left ventricle was observed (Figure 4). The patient's clinical condition and echocardiographic findings remained stable over his 3 years follow-up.

## DISCUSSION

### *Time of occurrence and factors related to LVWR in AMI*

The traditional risk factors for LVWR include older age (> 60 years), female sex, first lateral or anterior wall AMI, severe one-vessel coronary artery disease with lack of collateral circulation, and absence of previous angina[4,10,11]. On the contrary, the presence of multivessel disease may exert a protective effect, probably linked to development of greater collateral circulation[12]. Furthermore, it has been reported that the majority of patients with LVWR had suffered ST segment elevation AMI, with positive cardiac biomarkers, and a higher heart rate, lower blood pressure, and higher GRACE risk score at admission than patients without LVWR[13-15]. Chronic hypertension and diabetes mellitus do not seem to modify the incidence of LVWR[16], and contrary to a previous report[17], steroid use and late thrombolysis do not appear to increase the risk of LVWR[18,19]. Concerning thrombolysis, three mechanisms have been proposed as been responsible for occurrence of LVWR: hemorrhage to the ischemic zone resulting in loss of muscular tissue strength[20,21], increased collagen degradation and synthesis restrain by thrombolytic agents[22], lymphocytic migration to the infarct zone initiating absorption of collagen and proteolysis[21]. Depending on the time of its occurrence, LVWR may be classified as early, when it develops within the first 48 h post-AMI, or late, when it occurs beyond 48 h post-AMI. The early form represents 40%-50% of cases[23], however it is generally accepted that the true proportion is likely to be higher when including patients who die suddenly from LVWR before reaching hospital[24].

### *Differentiating true aneurysm from pseudoaneurysm*

Rarely, LVWR is contained by an adherent pericardium, creating a pseudoaneurysm. Differentiation between left ventricular aneurysm and pseudoaneurysm is difficult, yet it is the most important task to carry out in order to facilitate therapeutic decision making. Pericardial friction rub, decreased heart sounds, sinus bradycardia or junctional rhythm, are all signs of pseudoaneurysm[25]. However, chest pain, dyspnea and hypotension, as well as persistent

ST segment elevation in the area of AMI on the surface ECG, are common for both true aneurysm and pseudoaneurysm[26]. Thus, distinguishing between these two entities is very difficult merely on a clinical basis, because many characteristics are common. Especially concerning electrocardiographic predictors of LVWR and aneurysm or pseudoaneurysm formation, a deviation of the ST segment or T wave, or both, from the usual evolutionary pattern after AMI has been observed[27]. Furthermore, differing opinions exist concerning the most common site of LVWR. Some reports indicate the anterior wall as the most frequent site of aneurysm and pseudoaneurysm formation, where areas more recent series have observed a predominance of lateral and posterior wall ruptures[27].

### *Imaging modalities in the diagnosis of LVWR in AMI*

The most available and sensitive diagnostic tool to establish the different types of cardiac rupture is echocardiography[28]. In patients with LVWR the most frequent echocardiographic finding is pericardial effusion; in fact, the absence of pericardial effusion has a high negative predictive value and excludes cardiac rupture in patients with AMI[29]. However, in our cases no pericardial effusion was found. The presence of pericardial effusion has a low positive predictive value for LVWR as it may be present in 28% of patients with AMI without cardiac rupture[30]. The absence of pericardial effusion in our patients could be due to the lack of rupture of the left ventricular wall. The presence of echogenic masses in the effusion fluid is a relevant sign, particularly in patients with subacute LVWR, since these signs may be found in fibrinous pericarditis associated with AMI[31]. Direct visualization of the myocardial tear, true aneurysm or pseudoaneurysm is diagnostic, however, it is possible in only one third of LVWR cases[32]. Recently, cardiac magnetic resonance (CMR) imaging, especially with contrast enhancement, has emerged as a valuable diagnostic tool providing visualization of the entire heart, and clear differentiation of structures such as the pericardium, myocardium, thrombus and epicardial fat[33], as well as the pathological scar tissue substrates for life-threatening ventricular arrhythmias in AMI patients[34]. CMR can provide morphological definition of LVWR and pseudoaneurysm location, extension and relation to adjacent structures. Furthermore, CMR has an enormous value in differentiating between left ventricular aneurysms and pseudoaneurysms, in stable patients, with the ability to obtain cross sectional views in any plane[35].

We presented two patients who survived LVWR following an AMI. The patients' survival was clearly due to the containment of the rupture by the pericardial sac and the formation of the pseudoaneurysm. As LVWR usually leads to death, emergency surgery is the treatment of choice regardless the patient's condition. Surgical repair, enforcing the pericardial layers at the ventricular locus resistentiae minoris, results in significant reduction in mortality and provides favorable short-term outcomes and adequate prognosis during late follow-up[36]. Interestingly, our second patient survives for 3 years after diagnosis without surgery. Early diagnosis of LVWR is based on clinical suspicion. Echocardiography is of paramount importance, while computed tomography and CMR can be used to confirm diagnosis in stable patients.

## COMMENTS

### *Case characteristics*

Two patients who were diagnosed with left ventricular wall rupture (LVMR) following acute myocardial infarction (AMI), and subsequent pseudoaneurysm formation.

### *Clinical diagnosis*

Variable clinical presentation, ranging from asymptomatic forms of the condition to more typical angina pectoris or dyspnea.

### *Differential diagnosis*

Cardiac ischemia, pulmonary disease and heart failure are the main differential diagnoses.

### *Laboratory diagnosis*

There are no specific laboratory findings in the condition described. However, negative cardiac enzymes could exclude novel myocardial infarction.

### *Imaging diagnosis*

Echocardiography is the most useful and available imaging method in the diagnosis of left ventricular aneurysm and pseudoaneurysm formation. Computed tomography and cardiac magnetic resonance are complementary modalities, however of paramount importance in differentiating between the two aforementioned entities.

### *Treatment*

Surgery is the treatment of choice for post-myocardial infarction left ventricular pseudoaneurysms.

### *Related reports*

Left ventricular rupture and pseudoaneurysm formation have been described in the literature. However, long-term follow-up in an untreated patient (the authors' second case) is quite rare.

### *Term explanation*

LVWR following an AMI and containment by false aneurysm formation of the pericardial layers may lead to patient's survival for hours or even days, but rarely weeks.

### *Experience and lessons*

LVWR may be a rare condition in the era of primary percutaneous interventions, however it should always be a consideration in post-myocardial infarction patients.

### *Peer review*

This is an interesting manuscript.

CASE REPORT

# Importance of defining the best treatment of a genital gunshot wound: A case report

## Abstract

Twenty percent of genital traumas are caused by penetrating injuries; accordingly gunshot and stab wounds have increased in the last couple of years around the globe, even in Colombia. A 67-year-old male patient was admitted to the emergency room because he received multiple gunshot wounds. On physical examination, multiple wounds on his penis with loss of tissue in the foreskin, glans, anterior urethra (distal third) and cavernous corpora were found. The urologist performed a partial penectomy with a penis reconstruction, he debrided the cutaneous flap of the dorsal foreskin and its glans, sutured the distal cavernous corpora and dissected the urethra. Penetrating genital injuries are extremely important due to their impact on the functional, psychological and the aesthetic consequences. It is necessary to define the best possible treatment to minimize the damage.

**Key words:** Genital; Penile; Injuries; Trauma; Amputation

**Core tip:** Genital injuries are a common problem in civil war. For example, in developing countries its incidence is increasing, so it is of vital importance to notice how to focus the clinical case and how to treat patients with this condition. The impact on functional and aesthetic aspects calls our attention to treat these patients correctly.

García-Perdomo HA. Importance of defining the best treatment of a genital gunshot wound: A case report. *World J Clin Cases* 2014; 2(10): 587-590 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/587.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.587

## INTRODUCTION

Twenty percent of genital traumas are caused by penetrating injuries[1-3]; with traumatic amputations-as part of genital traumas-usually happening in acute psychotic events[4-6]. In only a small percentage they are caused by agricultural and industrial accidents or even by gunshot or stab wounds[4-6]. Due to a raise of civil war conflicts, gunshot and stab wounds have increased in the last couple of years, especially in Columbia[7], making this type of injuries prevalently seen at Hospital Universitario del Valle (Cali, Colombia). In both males and females, the penetrating genital injuries occur with other associated injuries in 70% of cases[8,9].

It is therefore important to know that the injured persons will have a different degree of damage and that the urologists will have to determine the probability of reattaching the part of the amputated or reconstructing the injured penis[4].

The purpose of this report is to describe an interesting case of a genital gunshot wound associated with a literature review to support the case and treatment, according to CARE guidelines for Case Reports.

## CASE REPORT

A 67-year-old male patient was admitted to the emergen-

**Figure 1 Glans and cavernous corpora injured.**

**Figure 2 Injured urethra.**

**Figure 3 Left sided retraction.**

**Figure 4 Mild meatus stenosis.**

cy room because he received multiple gunshot wounds. On physical examination, a suprapubic and multiple wounds on his penis were found, with loss of tissue in the foreskin, glans, anterior urethra (distal third) and cavernous corpora on the left side (Figures 1 and 2). Because of the extent of injuries and the inability to have a permeable urinary tract, a suprapubic tube (cystostomy) was placed and a surgical cleansing and debridement were performed.

On the next hospitalization day, he was taken to the operating room, where following conditions were found: devitalized glans with some necrosis areas, loss of the pendulous urethra up to its middle third, and a partial loss of its foreskin, but with some good cutaneous flap remaining. The urologist decided to perform a partial penectomy with a penis reconstruction, he debrided the cutaneous flap of the dorsal foreskin and its glans, sutured the distal cavernous corpora and dissected the urethra. Following the reconstruction a urethral Foley catheter was placed.

Three days after his admission, on his second postop day, he was managed as an outpatient due to good clinical status.

As an outpatient, two months later, he showed up with good clinical status, the surgical wound was healed but some left-sided retraction of the neomeatus was found (Figures 3 and 4).

## DISCUSSION

In an emergency room, a patient with multiple injuries or even with isolated genital damage requires prompt assessment and course of action[3]. Sometimes it is important to assess the range, caliber and type of weapon to evaluate the amount of the damage, before the treatment can be initiated[1]. Primarily physicians should focus on life threatening conditions and their treatment; and only then focus on genital and associated trauma. The surgical approach will depend on the site of the damage but a lateral or a sub-coronal degloving should supply a good exposure[3].

The first principles of caring of genitalia are debridement of devitalized tissue, preservation of as much viable tissue as possible, diversion of urine, hemostasis and removal of foreign bodies if necessary[3]; the conservative management is election for most cases[10]. If some tissue is not completely viable, the conservative management is encouraged for a delayed penile repair, perhaps 4 wk after trauma[3]. A tunica albuginea defect could be repaired easily but if bigger damage is found, the surgeon should use an autologous or xenograft[3].

When loss of genital skin is mild to moderate, reconstruction with the same skin is preferable but when an extensive injury is encountered, a full-thickness skin graft should be established for reconstruction[10,11]. This could

be taken from the abdomen, buttock, thigh or axilla, depends of the preference of the surgeon[11].

According to the grade of damage, there are a variety of treatments, for example: closure of residual stump, surgical reanastomosis or total phallic substitution with reconstruction[4,12].

The penis and the amputated part should be washed out and debrided with saline or ringer solution[3,13] in every case. If replantation is attempted, it should be done within 24 h with proper maneuvers and conservation of the amputated part (usually the glans) because success has been reported within this time[14] and this could be performed in a micro or non-microvascular approach with better results in the first one[3].

Particularly in this case, the patient had a genital gunshot wound with loss and devitalized tissue: the glans, the urethra and the cavernous corpora, so the replantation was not indicated, then the second choice of treatment was used as literature says: a closure of the penile stump was performed (cavernous corpora) and the urethra was spatulated as in a standard partial penectomy[4]. The phallic substitution with reconstruction is usually recommended for patients with a good mental status and after the episode has passed and the patient is stable[4], but this is not going to be discussed in this article.

The postoperative management should include: antibiotics for the risk of infection, a Foley catheter for the urethral reconstruction, and some dressings over the penis[4]. These recommendations are based on descriptive studies due to the lack of clinical trials to assess the best treatment possible.

Based on the aesthetic and functional results the patient could need a second or third surgery accompanied by the plastic surgeon[4,15], for example, this patient will need a reconstructive surgery to place the parts where they go and also perhaps an urethral reconstruction to assure the functional status.

It is important to recognize the need to interact with different specialists for example the plastic surgeon, the psychologist/psychiatrist, and the urologist for sure[4]. This is not something easy to treat, so the general physician, the urologist and every doctor involved in the treatment should recognize, diagnose and treat according to the damage to minimize the sequels.

This case allows us to recognize and to keep in mind how important and relevant these injuries are due to their impact on the functional, psychological and the aesthetic consequences. It is necessary to wash out and debride the injured tissue and consequently, defining the best possible treatment to minimize the damage.

## COMMENTS

### Case characteristics

A male patient received multiple gunshot wounds.

### Clinical diagnosis

Multiple wounds caused tissue lost in the foreskin, glans, anterior urethra and cavernous corpora.

### Differential diagnosis

There are not differential diagnosis, but according to the findings urologists need to check for damage to the urethra, glans and cavernous corpora.

### Treatment

The treatment offered to this patient was a partial penectomy along with penis and urethral reconstruction.

### Term explanation

Partial penectomy: to take a part of the penis off. Cystostomy: to put a suprapubic tube to permit drainage of urine from the badder.

### Experiences and lessons

The author confirmed how important and relevant these injuries are due to their impact on the functional, psychological and the aesthetic consequences.

### Peer review

This paper is well-written, and this case report is informative for readers.

## Abstract

Extra-adrenal chromaffin cell-related tumours or paragangliomas are rare, especially in the bladder. In this article, we reported three different clinical cases of bladder paraganglioma, followed by a review of current literature on the pathophysiology and management of bladder paraganglioma. Case 1 involved a 23 years old female patient who complained of a 10-year history of micturition-related headaches, palpitations and diaphoresis; while in case 2, a 58 years old female patient presented with history of painless haematuria and an incidentally diagnosis of a functioning paraganglioma during endoscopic transurethral resection of bladder tumour; and lastly in case 3, a 54 years old male renal transplant recipient was referred to the urology outpatient with a suspicious bladder mass found incidentally on routine transplant workshop.

**Key words:** Bladder paraganglioma; Bladder mass; Catecholamine and its metabolites; Nuclear imaging

**Core tip:** Bladder paraganglioma is a rare condition and patients can present with various clinical presentations. Biochemical profiling and nuclear imaging study can assist in the identification of this lesion. Preoperative care with volume hydration and adrenergic blockade are often necessary and surgery remains the only cure for these patients.

Ranaweera M, Chung E. Bladder paraganglioma: A report of case series and critical review of current literature. *World J Clin Cases* 2014; 2(10): 591-595 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/591.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.591

## INTRODUCTION

Paragangliomas are rare tumours that arises from extra-adrenal paraganglia and consists of specialized neural crest-derived cells (catecholamine-secreting chromaffin cells)[1]. Of all chromaffin cell-related tumours, paraganglioma accounts for less than a quarter of cases[1,2]. The sympathetic paraganglia are symmetrically distributed along the paravertebral axis and small sympathetic paraganglia can also be found in other organs such as the bladder. Primary paraganglioma of the urinary bladder is very rare making up less than 0.05% of all bladder malignancy. Paragangliomas can present with clinical symptoms secondary to catecholamine hypersecretion or mass effect, incidental finding on radiographic imaging, and/or on routine family screening for hereditary paraganglioma. We explore three different clinical cases of bladder paraganglioma that were treated at our institution.

## CASE REPORT

### *Case report 1*

A 23 years old female was referred by her general practitioner with history of urinary urgency and an incidental finding of bladder mass on urinary tract ultrasound.

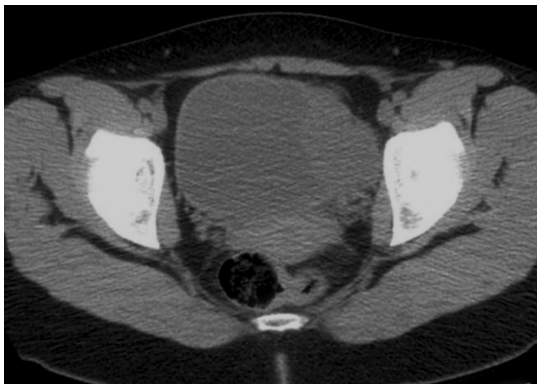

**Figure 1 Computer tomography showing an avidly enhancing mass in the left urinary bladder wall.**

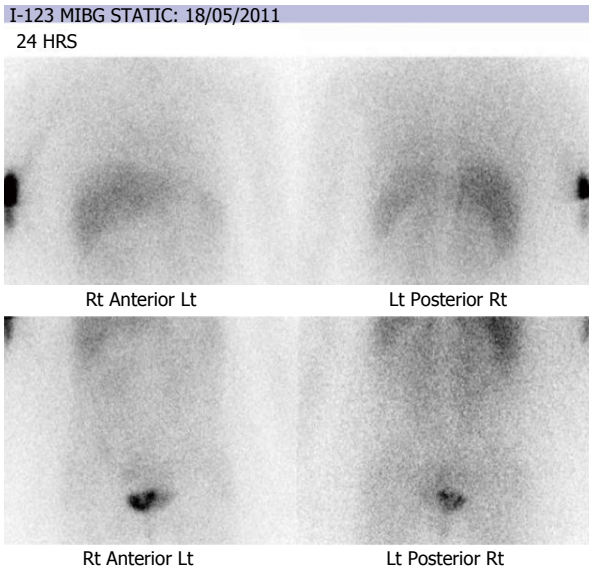

**Figure 2 Iodine-123-meta-iodobenzylguanidine scintiscan showing intense tracer uptake in the left side of the bladder consistent with bladder paraganglioma as well as injection artefact in the right cubital fossa.** I-123 MIBG: Iodine-123-meta-iodobenzylguanidine.

**Figure 3 Macroscopic view of bladder paraganglioma.** The tumour is red-brown in colour and well-circumscribed.

When enquired further, she described a long-standing history of episodic severe throbbing headaches lasting few minutes, dating back to as early as the age of 12 years. These paroxysmal attacks of headache coincided with her bladder emptying and over the last few years, she also experienced palpitations, nausea, sweat and facial pallor post-micturition. In addition, she recalled the presence of microscopic hematuria in her urine dipstick since the age of 12 years. She has been diagnosed with borderline hypertension in her late teens but is not on antihypertensive medication. There was no family history to suggest a hereditary endocrine disorder.

Urinary tract ultrasonography revealed a large vascular soft tissue mass on the left bladder wall and her urine cytology revealed mildly atypical urothelial cells in two out of three samples. There was a marked elevation of urinary noradrenaline (4748 nmol/dL, Reference: [50-600]) and its metabolites on 24 h urine collection. Plasma metanephrine was also significantly elevated (8500 pmol/L, reference < 900 pmol/L). Staging computed topography of the abdomen and pelvis showed a 6.2 cm × 4 cm × 4.9 cm solid and enhancing, loculated mass near to the left vesicoureteric junction (Figure 1). Following consultation with the endocrinologist, alpha (α)-adrenergic and beta (β)-adrenergic blockade was achieved with a combination of phenoxybenzamine and metoprolol for a minimum of 2 wk prior to surgery. During this time, further imaging with Iodine-123-meta-iodobenzylguanidine (I-123 MIBG) scintiscan confirmed the presence of bladder phaeochromocytoma without metastatic disease (Figure 2).

A formal rigid cystoscopy, left retrograde pyelogram and examination under anesthesia were performed and showed a firm, irregular, well circumscribed lesion in the left bladder that was not fixed to the pelvis and a normal distal left ureter configuration. She was hypertensive intraoperative and required α-adrenergic blockade with phentolamine. Discussion ensued about her condition and she underwent partial cystectomy 2 wk later with volume hydration and antihypertensive medication. A combination of adrenergic blockade with phentolamine, esmolol and metaraminol were utilised intraoperatively during her partial cystectomy.

The histopathology of the bladder wall specimen sections showed a 35 mm × 32 mm well-circumscribed, lobulated, red-brown tumour (Figure 3). Microscopically, the tumour was composed of nests of cells with eosinophilic cytoplasm and round nuclei with vesicular chromatin. It was encapsulated with no evidence of extracapsular invasion and surgical margins were clear (Figure 4). The tumour cells stained positive for chromogranin, patchy for S-100 and negative for cytokeratin consistent with urinary bladder paraganglioma.

Further immunohistochemistry on the tumour specimen revealed the tumour was negative for succinate dehydrogenase subunit B (SDHB). She was subsequently discharged and remained asymptomatic at 36 mo of follow up.

### *Case report 2*

A 58 years old female underwent a routine uneventful resection of bladder mass found during investigation for

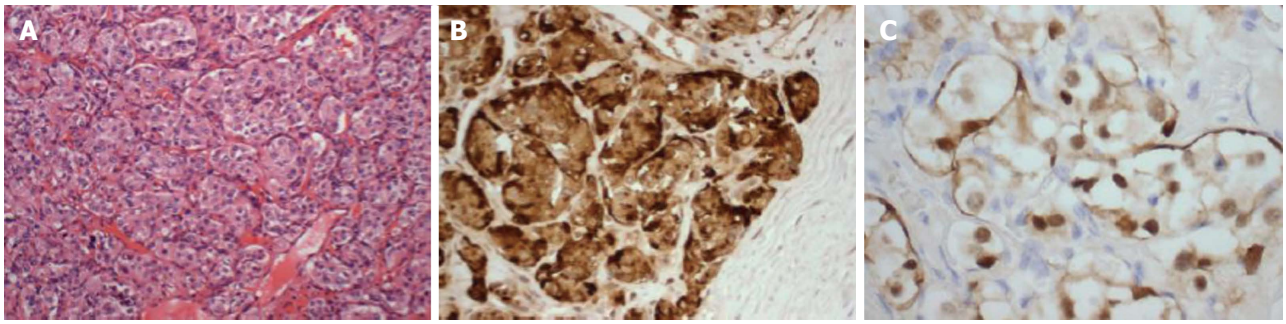

**Figure 4 Haematoxylin and eosin staining of bladder paraganglioma tumour (A) showing characteristic nests of cells with eosinophilic cytoplasm and round nuclei.** Chromogranin staining (B) was strongly positive, whilst S100 staining (C) was positive in patches.

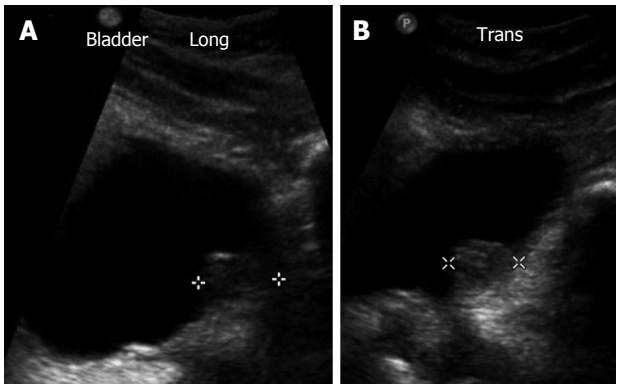

**Figure 5 Longitudinal and transverse views of a paraganglioma protruding into the bladder.**

painless macroscopic haematuria. The histopathology of this mass showed solid nests of plump epithelial cells with granular to foamy cytoplasm and enlarged, moderate pleomorphic nuclei. Immunohistochemical staining was strongly positive for chromogranin, neuron-specific enolase (NSE), synaptophysin and protein gene product 9.5, consistent with a neuroendocrine tumour. On retrospect history, she had been taking atenolol and oxazepam for her moderate hypertension and anxiety disorder. Given that the patient's younger sister had a history of poorly controlled hypertension, both sisters underwent genetic testing and von Hippel Lindau (VHL), SDHB and succinate dehydrogenase screening, but were negative.

Further investigations showed an elevated creatinine ratio of urinary normetanephrine (0.40 mmol/mmol creatinine) and metanephrine (0.13 mmol/mmol creatinine), and an increased 24-h excretion of normetanephrine (3.2 μmol/24 h). Nuclear imaging study with I-123 MIBG scan showed a discrete round focus on the left side of the bladder with no further evidence of metastases.

The patient was commenced on phenoxybenzamine and propranolol preoperatively for 2 wk and underwent open partial cystectomy and re-implantation of her left ureter. Intra-operatively the patient remained haemodynamically stable. Histopathology confirmed bladder paraganglioma with multiple nodules found predominately within the muscularis propria but not extending into the peri-vesicle soft tissue and a clear of the surgical margins. The tumour showed focal moderate nuclear pleomorphism with no lymphovascular invasion. She remained asymptomatic with normal imaging test at 60 m of follow up.

### *Case report 3*

A 54 years old male renal transplant recipient for end-stage renal failure (secondary to Alport's syndrome) was referred for investigation of an asymptomatic bladder mass. After having undergone a left sided radical nephrectomy for papillary renal cell carcinoma 12 mo earlier, this bladder mass was discovered on surveillance urinary tract ultrasonography (Figure 5). He underwent routine cystoscopy which revealed a submucosal polyp at the anterior bladder suspicious for urothelial tumour and this bladder "tumour" was completely resected.

Histological examination revealed tumour cells arranged in nested architecture with circumscribed margin and focal areas of smooth muscle invasion. Interestingly the immunohistochemistry staining of the tumour cells were positive for synaptophysin and chromogranin but negative for cytokeratin.

The patient subsequently underwent an I-123 MIBG scan and metastatic disease was excluded. Serum and urinary catecholamines were negative too. Follow-up flexible cystoscopy at 1 year post-resection showed no evidence of disease recurrence.

## DISCUSSION

Bladder paraganglioma is rare and accounts for less than 1% of all catecholamine secreting neoplasms and only 0.5% of all bladder tumours[3]. They are thought to arise from embryonic rests of chromaffin cells within the bladder wall and often occur in young women in their second to fourth decade of life[4]. Paragangliomas that secrete catecholamine may give rise to clinical presentation similar to a hyperfunctioning adrenal phaeochromocytoma. Episodic symptoms may occur in spells or paroxysms, and can be highly variable. The position of these tumours within the bladder results in characteristic symptom complex related to micturition or over-distension of the bladder with catecholamine release. The majority of patients will experience micturition related hypertension, cold

sweats, palpitations, headaches, dizziness and sweating much like the Case 1 in our series[5]. Systemic catecholamine secretion occurs with increased bladder pressure after bladder contraction, triggering these sympathomimetic attacks[6]. These symptoms may also be precipitated by defaecation, sexual activity, ejaculation or bladder instrumentation. Approximately 55%-60% of patients will also experience painless haematuria, although it is mostly microscopic in nature[7]. While hematuria is commonly reported in patient with bladder mass, this is not specific for paraganglioma. Only a minority of patients will experience weight loss, nausea, tremor, postural hypotension, syncope, chest pain, blurred vision, laryngismus, high blood sugar levels or symptoms associated with catecholamine cardiomyopathy[5].

Suspected cases of paragangliomas should first be investigated by measuring the level of catecholamine and its metabolites such as metanephrine and vanillylmandelic acid secretion in either the blood or urine. The measurement of serum adrenaline and noradrenaline can be costly and is usually unnecessary[8]. The majority of paragangliomas are not hormonally active, thus preoperative catecholamine levels maybe normal[1,8]. Bladder paraganglioma can often be difficult to distinguish radiologically from other bladder lesions[8]. The use of intravenous contrast may precipitates a hypertensive crisis although non-ionic contrast is reported to be safe[9]. In contrast to the hyperintense T2 signalling on magnetic resonance imaging with adrenal phaeochromocytoma, paraganglioma is likely to be homogenous on T2 signal[10]. Both I-131 MIBG and $^{18}$F-fluorodeoxyglucose, positron emission tomography are useful for localization of potential metastatic disease. I-123 MIBG can be used as an alternative to I-131 MIBG for accurate preoperative localization of small lymph node[11].

As many as half of the cases of paraganglioma share a genetic basisa and can be related to a number of hereditary conditions including VHL, neurofibromatosis type 1, Carney triad, Multiple Endocrine Neoplasia types 2a and 2b and familial paraganglioma[1]. Therefore, genetic testing should be offered in cases of young patient (under 50 years old) with a positive family history or with history of bilateral, extra-adrenal or multifocal phaeochromocytoma, a positive genetic mutation as well as those tumours with negative SDHB staining[12].

Since paraganglia are distributed throughout the bladder wall, paraganglioma can be found in any part of the bladder. These tumours are mostly well circumscribed and usually form nodules or small mass. Placing the tumour in a Zenker's fixative will turn the tumour black; a positive chromaffin reaction. Histologically, paraganglioma is often misdiagnosed as urothelial carcinoma[13] and paraganglioma may mimic high grade urothelial carcinoma with a nest pattern. Features of paraganglioma include zellballen architecture where tumour cells are arranged into nests and lobules, a delicate fibrovascular stroma and eosinophilic cytoplasm. Immunohistochemistry is usually positive for NSE, chromogranin and synaptophysin and negative for cytokeratin. There are no definitive characteristics which reliably distinguish benign from malignant tumour, and desmoplastic reaction is often absent[12]. The distinction between benign and malignant paraganglioma has long been contentious, with the only widely accepted and definitive proof of malignancy being metastasis to other organs. Some histological features such as tumour necrosis, a mitotic rate greater than 3/30 high power field, capsular invasion, large nests with central degeneration, a lack of hyaline globules, a high nuclear/cytoplasmic ration, monotony of a cytological pattern and spindle cells patters are suggestive of increased malignant predilection[14]. Immunohistochemistry stains are often useful in helping to establish the diagnosis and those with SDHB negative-stain may indicate a succinate dehydrogenase subunit-mutated tumour. Urothelial carcinoma and carcinoid tumours are positive for cytokeratin, while melanoma cells show positivity for S100, HMB45 and Melan A stains.

Complete surgical removal of the tumour is the treatment of choice[1,4,6]. If the paraganglioma is a catecholamine secreting tumour, the effects of excess circulating catecholamines should be reversed prior to surgical extirpation. Combined preoperative α- and β-adrenergic blockade are required to control the blood pressure in order to prevent intra-operative hypertensive crisis. An α-adrenergic blockade should be commenced prior to β-adrenergic blockade, to allow for volume expansion of the contracted blood volume and a liberal salt diet and adequate hydration are also advised. Once adequate α-adrenergic blockade is achieved, β-adrenergic blockade can be initiated. Localised tumours can be removed in partial cystectomy while transurethral resection is adequate in superficial and small bladder lesion[8]. Postoperative 24 h urinary catecholamine and its metabolites should be conducted at week 2 and if the levels are normal, the resection of paraganglioma is considered complete.

As discussed earlier, malignant phaeochromocytoma remains a challenging entity to diagnose and treat. Up to 15% of bladder paraganglioma can become metastasis, and metastasis is the only reliable indicator of malignancy. Young age, extensive local disease and micturition attacks are risk factors for malignancy while features such as vascular invasion, a deeply invasive growth patterns and recurrence are often poor prognostic signs. Metastatic potential is often unclear and thus long-term annual follow up is suggested[15]. In patients with metastatic disease, complete cystectomy and pelvic lymph node dissection is the preferred option[16]. Nuclear imaging such as I-131 MIBG radiotherapy has also been shown to be useful for palliative control of tumour function in metastatic disease, but the current chemotherapy and radiotherapy treatment options are limited[17].

Bladder paraganglioma is a rare condition and patients can present with various clinical presentations. Biochemical profiling and nuclear imaging study can assist in the identification of this lesion. Preoperative care with volume hydration and adrenergic blockade are often nec-

essary to control the blood pressure and to prevent intra-operative hypertensive crisis. Surgical extirpation remains the only cure for these patients and further research into this rare condition is warranted.

## COMMENTS

### Case characteristic

All patients presented with bladder mass with various clinical symptoms.

### Clinical diagnosis

Bladder paraganglioma is diagnosed through biochemical hormonal profiling and nuclear imaging study.

### Differential diagnosis

Urothelial cancer, benign bladder lesion.

### Laboratory diagnosis

Measurement of catecholamine and its metabolites levels such as metanephrine and vanillylmandelic acid secretion in either the blood or urine.

### Imaging diagnosis

Nuclear imaging study using iodine-131-meta-iodobenzylguanidine and $^{18}$F-fluorodeoxyglucose, positron emission tomography.

### Pathological diagnosis

Features of paraganglioma include zellballen architecture where tumour cells are arranged into nests and lobules, a delicate fibrovascular stroma and eosinophilic cytoplasm. Immunohistochemistry is usually positive for neuron-specific enolase, chromogranin and synaptophysin and negative for cytokeratin.

### Treatment

Preoperative care with volume hydration and adrenergic blockade are often necessary to control the blood pressure and to prevent intra-operative hypertensive crisis. Surgical extirpation remains the only cure.

### Related reports

Bladder paraganglioma is a rare condition and patients can present with various clinical presentations. Malignant phaeochromocytoma remains a challenging entity to diagnose and treat, and further research into this rare condition is warranted.

### Experiences and lessons

This case series highlights the various clinical presentation of bladder paraganglioma and provides a clinical review of the current literature on management of this rare condition.

### Peer review

This is a well-written report of three cases of bladder paraganglioma. Bladder paraganglioma is very rare. Their pathological diagnosis is quite proper and clinical practice is also well-summarized.

## Abstract

Redo-sternotomy and aortic valve replacement in patients with advanced liver disease is rare and associated with a prohibitive morbidity and mortality. Refractory coagulopathy is common and a consequence of intense activation of the coagulation system that can be triggered by contact of blood with the cardiopulmonary bypass circuitry, bypass-induced fibrinolysis, platelet activation and dysfunction, haemodilution, surgical trauma, hepatic decompensation and hypothermia. Management can be further complicated by right heart dysfunction, porto-pulmonary hypertension, poor myocardial protection, and hepato-renal syndrome. Complex interactions between coagulation/fibrinolysis and systemic inflammatory response syndrome reactions like "post-perfusion-syndrome" also compound haemostatic failure. Given the limited information available for the specific management and prevention of cardiopulmonary bypass-induced haemostatic failure, this report serves to guide the anaesthesia and medical management of future cases of a similar kind. We discuss our multimodal management of haemostatic failure using pharmacological strategies, thromboelastography, continuous cerebral and liver oximetry, and continuous cardiac output monitoring.

**Key words:** Cardiac surgery; Liver failure; Coagulopathy; Cardiopulmonary bypass

**Core tip:** Cardiac surgery in patients with advanced liver disease is associated with significant morbidity and mortality. Refractory coagulopathy is common and requires a proactive multidisciplinary haemostatic management strategy. Given the limited information available for the specific management and prevention of cardiopulmonary bypass induced haemostatic failure, this report serves to guide the anaesthesia and medical management of future cases of a similar kind. We discuss our multimodal management of haemostatic failure using pharmacological strategies, thromboelastography, continuous cerebral and liver oximetry, and continuous cardiac output monitoring.

agement for aortic valve replacement in a patient with advanced liver disease. *World J Clin Cases* 2014; 2(10): 596-603 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/596.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.596

## INTRODUCTION

Redo-sternotomy and aortic valve replacement (AVR) in patients with advanced liver disease is rare and associated with a prohibitive morbidity and mortality. Refractory coagulopathy is common and a consequence of intense activation of the coagulation system that can be triggered by contact of blood with the cardiopulmonary bypass (CPB) circuitry, CPB-induced fibrinolysis, platelet activation and dysfunction, haemodilution, surgical trauma, hepatic decompensation and hypothermia. Management can be further complicated by right heart dysfunction, porto-pulmonary hypertension, poor myocardial protection, and hepato-renal syndrome. Complex interactions between coagulation/fibrinolysis and systemic inflammatory response syndrome (SIRS) reactions like "post-perfusion-syndrome" also compound haemostatic failure.

We present a patient with critical aortic stenosis who underwent redo-sternotomy and AVR prior to being listed for orthotopic liver transplantation. In this context, there is little information on the specific management of CPB-induced haemostatic failure. Therefore, we discuss our multimodal management of haemostatic failure using pharmacological strategies, thromboelastography (TEG), continuous cerebral and liver oximetry, and continuous cardiac output monitoring.

## CASE REPORT

A 46-year-old male (weight 68 kg, height 183 cm) presented to our institution with acute pulmonary oedema secondary to severe aortic stenosis. The patient consented for a redo-sternotomy and AVR, with an estimated perioperative mortality of 50%. Previous cardiac history included open valvotomy *via* median sternotomy for a congenital calcified bicuspid aortic valve at age 6. The patient had a 10-year history of chronic liver disease secondary to alcohol abuse, with a Child Pugh Score of 8 (Child Class B), and a Model for End-Stage Liver Disease (MELD) Score of 12. The liver disease was further complicated by severe portal hypertension with ascites, thrombocytopaenia, oesophageal varices and portal hypertensive gastropathy. Two years prior, he underwent an emergency laparotomy for bleeding umbilical varices, which required intensive care unit (ICU) admission and an 8-unit red blood cell transfusion for hemorrhagic shock.

On this admission a transthoracic echocardiogram revealed preserved systolic left and right ventricular function, a severely calcified bicuspid valve (aortic valve area: 0.7 $cm^2$; mean aortic valve pressure gradient of 60 mmHg), moderate aortic regurgitation, mild mitral regurgitation, moderate pulmonary hypertension and a dilated ascending aorta (5.4 cm). Other cardiovascular risk factors included IgA nephropathy (creatinine 110 μmol/L, estimated glomerular filtration rate 73 mL/min per 1.73 $m^2$). There was no history of smoking or diabetes. The pulmonary oedema settled with conservative medical therapy. A coronary angiogram and right heart catheter study revealed no occlusive coronary artery disease, with a cardiac index of 3.4 L/min per square meter and a pulmonary artery pressure of 71/30 mmHg (mean 33 mmHg). Preoperative investigations including TEG are summarised in Tables 1-3. A detailed perioperative haemostatic coagulation strategy was formulated by a team composed of anaesthetist, haematologist, cardiac surgeon and intensivist.

The day before surgery, terlipressin [1 mg intravenous (*iv*) every 6 h] was commenced. Prior to induction of anaesthesia, an 8-French Rapid Infuser Catheter (Arrow) was inserted into each arm. Invasive monitoring included a 20 Gauge arterial line, 4-lumen central venous catheter, continuous cardiac output and continuous mixed venous oximetry measured with a fiberoptic pulmonary artery catheter (Edwards Lifesciences, Irvine CA) (Figure 1). External defibrillator pads were applied as a safety precaution. Bispectral index monitoring and cerebral and hepatic tissue oxygenation (Invos, Somanetics®) were measured with a cerebral/somatic oximeter, by placing disposable transducers over the right and left forehead (Figure 1), and on the skin overlying the lower right costal margin (Figure 2). The oximeters provided real-time monitoring of brain and liver oxygen saturations, measuring oxygen consumption and delivery. This allowed for detection and correction of cerebral and hepatic oxygen desaturation to optimise haemodynamic intervention. Tranexamic acid (1 g *iv* load then 500 g/h infusion) was commenced to minimize fibrinolysis during and after CPB. Octreotide (100 mcg bolus, then 25 mcg/h) was commenced to control portal hypertension and minimise hepatic ischaemia reperfusion injury from CPB. Vancomycin (1 g *iv*) and ceftriaxone (1 g *iv*) were administered for antimicrobial prophylaxis.

Redo-sternotomy was performed using an oscillating saw while lifting up the sternal wires. Dense adhesions of the right ventricle and posterior table of the sternum precluded access to the heart for central venous cannulation. Consequently, the femoral artery and vein were cannulated and the venous cannula carefully positioned using transoesophageal echocardiography guidance in the right atrium. After careful dissection around the heart and full heparinisation, the standard on-pump AVR technique was applied. A second venous cannula was added *via* the superior vena cava to the venous circuit to allow venous drainage, further minimizing hepatic congestion. After aortic cross clamp, pulsatile CPB was established, complete with haemofiltration to prevent fluid overload and maintain electrolyte neutrality. During CPB the patient was severely vasoplegic requiring escalating doses of noradrenaline (20 μg/min *iv*) and vasopressin (0.4 IU/min *iv*) to maintain a mean arterial pressure of 50 mmHg. Optimal pump flow rates and vasopressor use were

guided by cerebral and liver oximetry. There was excellent correlation between cardiac output, mixed venous saturations and cerebral and liver oximetry throughout the case (Figures 3 and 4). In response to progressive refractory vasoplegia, methylene blue (1 mg/kg *iv*) was administered, which rapidly re-established an acceptable mean arterial pressure. The noradrenaline and vasopressin requirements were weaned to 3 μg/min and 0.05 IU/min

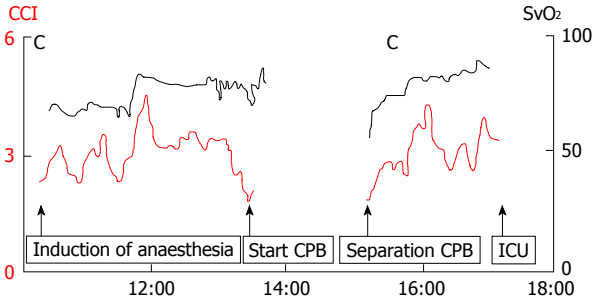

**Figure 3 Intraoperative continuous cardiac index and mixed venous oxygenations tracings measured from the pulmonary artery catheter displayed on a Vigilance™ Monitor (Edwards Lifesciences, Irvine CA).** ICU: Intensive care unit; CPB: Cardiopulmonary bypass; CCI: Continuous cardiac index.

respectively. A 25 mm Mitroflow® aortic pericardial valve (Sorin, Milan, Italy) was inserted without complication.

Prior to separation from CPB, a rewarming heparinase TEG was performed (Table 1, Figure 5). Desmopressin acetate (0.3 mcg/kg *iv* over 20 min) was administered to increase the plasma levels of factor Ⅷ and von Willebrand factor to minimize post-operative blood loss. Based on the rewarming TEG (Table 2 and Figure 5), fresh frozen plasma (15 mg/kg) was added to the CPB circuit to avoid volume overload and right ventricular distension during bypass separation. Glyceryl trinitrate (5 μg/min *iv*), and frusemide (20 mg *iv*) were administered to further reduce right ventricular preload and hepatic congestion.

After successful separation from CPB, haemostatic management focused on minimizing intraoperative bleeding and maintaining normothermia. Protamine (500 mg *iv*) was given to reverse the effects of heparin and correct activated clotting time to baseline values, followed by two bags of pooled platelets and *iv* administration of concentrated fibrinogen (4 g *iv*) (Riastap®, *iv* Behring, Australia). The dose of fibrinogen was calculated according to the patient's body weight (68 kg) and his estimated blood volume (4.8 L). Based on a preoperative haemoglobin of 9.8 g/L, a haematocrit of 30% of plasma volume (3.4 L), and a preoperative fibrinogen level of 2.5 g/L, we calculated that a dose of 4 g of fibrinogen would be needed to increase plasma fibrinogen levels by an estimated 1.2 g/L. With haemodilution on bypass, we expected the fibrinogen to fall by approximately 1-1.5 g/L. Following administration of concentrated fibrinogen, a heparinase TEG revealed significant prolongation of the R-time, confirming an underlying coagulopathy (Figure 5). Human prothrombin complex® (500 IU *iv* bolus, then 100 IU/h *iv* infusion) (CSL Behring, Australia) was administered, which corrected the R-time and improved haemostasis (Figure 5). Calcium chloride (1-2 g *iv*) was also administered. The total CPB time was 141 min and aortic cross-clamp time 61 min. Temporary epicardial pacing wires were not used to avoid the small risk of cardiac bleeding on wire removal additional. A topical haemostatic matrix (FLOSEAL™, Baxter, Pty) was used to control bleeding

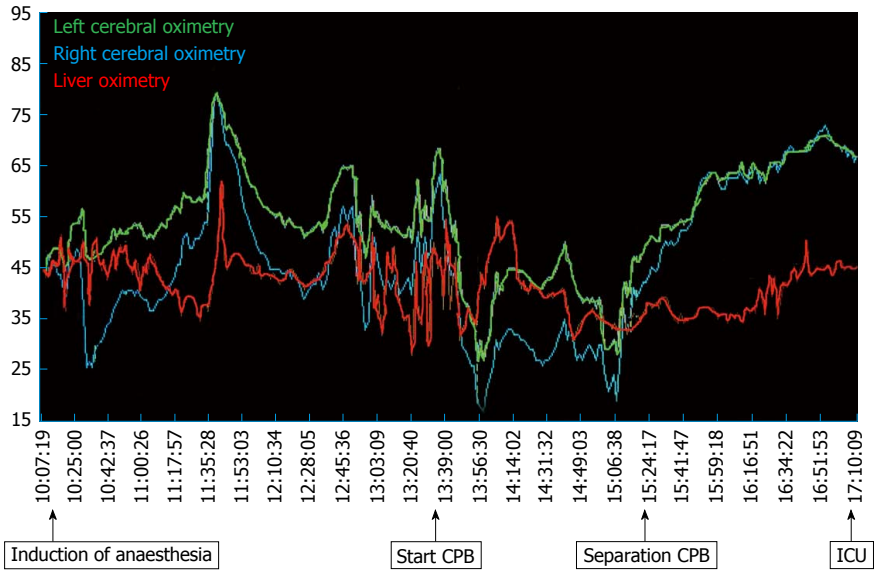

**Figure 4 Cerebral and hepatic tissue oxygenation tracings measured with a cerebral/somatic oximeter (Invos Somanetics®) throughout the surgery and during cardiopulmonary bypass.** ICU: Intensive care unit; CPB: Cardiopulmonary bypass.

from the suture lines, and thrombin dried powder (GELFOAM®, Baxter, Pty) was applied to the bone marrow of the sternum, which allowed sternal closure with minimal bleeding. Mediastinal and bilateral pleural drains were placed so that volume losses could be measured in ICU, and collection of blood around the heart avoided during the postoperative period.

In ICU, the octreotide (25 mcg/h *iv*) and prothrombinex (100 IU/h *iv*) infusions were continued for 8 h. Haemodynamic stability was maintained and the noradrenaline and vasopressin infusions weaned after 6 h, and the patient was extubated. Terlipressin (1 mg *iv*) was continued every 6 h for a further 24 h. The patient was transferred to the ward the following day, and discharged home ten days later without complications. There were no further requirements for coagulation or blood product intervention. Postoperatively, renal, haematological and liver function tests remained stable, and are summarised in Tables 1-3.

Three months post discharge, and at the time of writing, the patient continues to make satisfactory cardiac progress and is currently awaiting liver transplantation.

## DISCUSSION

This case illustrates that redo-sternotomy and aortic valve AVR in the setting of advanced liver disease is feasible but requires careful planning. The central management decisions for such cases include to either (1) replace the valve first and then proceed with liver transplantation at a later date; (2) offer a combined procedure, *i.e.*, AVR and liver transplantation simultaneously; and (3) proceed with liver transplantation first, and then replace the valve at a later stage. In the case described here, after extensive multidisciplinary discussion a consensus was reached that the risks of liver transplantation in the setting of uncorrected symptomatic severe aortic stenosis were prohibitive. In view of the bicuspid valve and dilated ascending aorta, a transcatheter AVR was not a consideration. A combined AVR and liver transplant was considered but there were concerns that there may be further cardiac decompensation during the waiting period. Given that the patient was progressively symptomatic, a redo-sternotomy and AVR was considered to afford the best chance of survival, with activation for liver transplantation initiated at a later stage if the outcome was successful.

As shown in this case, redo cardiac surgery provides several technical challenges that distinguish it from primary cardiac surgery. These obstacles include repeat sternotomy, injury to the heart during dissection, quality and availability of conduits if required, a calcified ascending aorta, and more-advanced coronary disease involving the native vessels. As a result, operative mortality in most reoperations is 3 to 5 times that for a primary AVR. Adding in the ensuing complications of advanced liver disease, perioperative mortality increases with an estimated perioperative risk of mortality of 50%[1]. Each patient's condition and presentation is unique, and thus requires individualized management delivered by a multidisciplinary team. Consideration must be given to the sequence of procedures, cardiac surgical technique, and management of anticoagulation.

Combined cardiac and liver transplantation was first reported by Starzl *et al*[2] in 1984, but has remained uncommon because of the unique medical and surgical challenges it poses . In two descriptive reports of outcomes in patients with advanced liver cirrhosis undergoing cardiac surgery[3,4], hepatic decompensation, respiratory and renal failure, gastrointestinal haemorrhagic events, sepsis and mediastinitis were among the most common postoperative complications. The association of MELD scores and Child-Turcotte-Pugh classification, and adverse outcomes is less clear. In the study by Filsoufi *et al*[4], mortality rate increased significantly according to the

Child-Turcotte-Pugh classification (class A, 10%; B, 18%; and C, 67%). The reported mortality of redo cardiac surgery was approximately 50%[3]. Similarly, the rate of complications was higher in class B (50%) and C (100%) compared to class A (20%). Suman *et al*[5] reported that a cutoff Child-Pugh score > 7 had a sensitivity and specificity of 86% and 92% for mortality, although there was no association between mortality and MELD scores. In contrast, Morimoto *et al*[3] reported that Child-Pugh class score did not correlate with hospital mortality, although MELD score was significantly higher in patients who died immediately post cardiac surgery. To date, there have been several reports of combined AVR and liver transplantation[6]. Postoperative outcomes are variable; the majority of cases have been successful however, mortality due to clotting disturbances has also been reported. As a result, careful preoperative preparation must be conducted in such highly complex cases to prevent catastrophic

outcomes.

As seen in this case, a common yet serious complication of CPB is vasoplegic syndrome, a post-perfusion syndrome characterised by low systemic vascular resistance, significant hypotension, and a high cardiac output. It has an incidence of 5%-25% and a mortality rate as high as 25%[7]. In this case, we used the standard first line vasoactive treatment (noradrenaline and vasopressin) to maintain a mean arterial pressure of 50 mmHg[8]. However methylene blue was required during CPB to reduce the severity of vasoplegia. Use of methylene blue had been used effectively for the treatment of refractory vasoplegia in two randomised control trials[9,10], acting through its inhibitory effect on cyclic guanosine 3',5'-monophosphate-mediated vasodilatation. Despite restoring vascular tone intraoperatively, discontinuation of vasopressin has been associated with postoperative refractory vasoplegia, therefore in the case described here, vasopressin was for continued for 6 h postoperatively.

AVR performed in the context of advanced liver disease added an additional layer of complexity in preventing further decline of hepatic and renal function. The patient's history of significant portal hypertension justified the use of both terlipressin and octreotide to prevent variceal beeding[11-13]. Terlipressin has also been shown to improve hepatorenal syndrome, thought to be due to arteriolar vasoconstriction in the splanchnic area, which was an important consideration for the patient's underlying IgA nephropathy. Its effects are mediated *via* V1 receptors on vascular smooth muscle[13]. In animal models, octreotide has been shown to improve hepatic ischaemia-reperfusion injury by down-regulating inflammatory cytokines (tumor necrosis factor alpha and interleukin-1 beta) and inhibition of hepatocellular apoptosis[14], and in this case, served an added benefit when separating from bypass.

Coagulopathy is a frequent occurrence during CPB and is due to a number of factors including excessive fibrinolysis, platelet dysfunction, coagulation factor consumption, and coagulation factor dilution from intravascular volume replacement. We used a variety of multimodal pharmacological agents to prevent intraoperative and postoperative bleeding. Hypofibrinogenemia is common in cardiac surgery, which was minimized preoperatively with tranexamic acid, and intraoperatively with concentrated fibrinogen[15,16]. Desmopressin acetate[17,18], Human Prothrombin-X complex[19] and protamine were also implemented as described previously.

In this case, we employed several haemostatic and haemodynamic monitoring methods to guide our management. TEG, commonly used in cardiac surgery, is a useful tool in denoting a patient's clotting profile at landmark time points to influence specific pharmacologic decisions[20,21]. Figure 5 summarizes consecutive TEG readings and the subsequent interventions undertaken. It should also be noted that TEG requires trained personnel to operate and therefore poses as a limiting factor for its use[20]. Additional haemodynamic monitoring included pulmonary artery catheter sampling of mixed venous blood ($SvO_2$) and tissue oximetry. Intraoperatively, we were primarily concerned about the key factors that influence oxygen delivery, namely haemoglobin, oxygenation, and cardiac output. Continuous liver, cerebral and mixed venous oximetry enabled immediate detection of adverse changes, prompting correction and subsequent visualization of improvements of haemodynamic trends. Continuous recordings of cardiac output and global oxygenation status are presented in Figure 3. The brain and liver tissue oxygenation tracings are shown in Figure 4. In the context of low liver oximetry, in addition to the aforementioned factors that influence tissue oxygenation, hepatic congestion secondary to the outflow obstruction was also carefully monitored. Then, depending on the determined underlying cause, suitable corrections were made in the form of red cell transfusion, adjustment pump flow rates, and ensuring adequate venous drainage at all times. Although hepatic oximetry is predominantly used in the paediatric setting[22,23], we justified its use to intensively monitor the already compromised liver, and guide therapy as above. Interestingly, the liver oximeter tracing tracked the cerebral oximeter tracing very accurately (Figure 4), providing reassurance of continual intact hepatic perfusion.

In conclusion, we report a case of AVR in a patient with advanced liver disease. Given the limited information available for specific management and prevention of haemostatic failure, this report serves to guide future cases of a similar kind.

## COMMENTS

### Case characteristics

A 46-year-old male with a history of chronic liver disease secondary to alcohol abuse, presents with acute pulmonary oedema secondary to left ventricular failure.

### Clinical diagnosis

Severe aortic stenosis.

### Differential diagnosis

Non cardiogenic causes of pulmonary oedema include pulmonary contusion, acute respiratory distress syndrome, transfusion-related acute lung injury, aspiration, hypertensive crisis, upper airway obstruction, and neurogenic causes (seizures, intracranial haemorrhage).

### Laboratory diagnosis

Plasma creatinine 110 μmol/L; albumin 31 g/L; bilirubin 40 μmol/L; haemoglobin 90 g/L; prothrombin time 1.3 s; platelets 76 ($\times 10^9$).

### Imaging diagnosis

Transthoracic echocardiogram a severely calcified bicuspid valve, with an aortic valve area of 0.7 $cm^2$; mean aortic valve pressure gradient of 60 mmHg with moderate pulmonary hypertension.

### Treatment

The patients underwent redo-aortic valve replacement requiring aggressive haemostatic therapy for coagulopathy and refractory vasoplegia.

### Related reports

Combined cardiac surgery in patients with advanced liver disease.

### Experiences and lessons

Cardiac surgery in patients with advanced liver disease is associated with significant morbidity and mortality. Refractory coagulopathy is common and requires a proactive multidisciplinary haemostatic management strategy.

### Peer review

Weinberg *et al* present an interesting and complex case report of a patient with critical aortic stenosis and advanced liver disease who underwent redo-

sternotomy and aortic valve replacement prior to being listed for orthotopic liver transplantation.

## Abstract

Pyogenic liver abscess is a common entity in Indian subcontinent and is mostly caused by gram negative bacteria. Melioidosis is not commonly seen in India and only a few cases are reported. It can give rise to multiple abscesses at different sites including liver. We report a case of isolated liver abscess caused by *Burkholderia pseudomallei* (*B. pseudomallei*) in a 29-year-old recently diagnosed diabetic, immunocompetent male. Diagnosis was made by imaging and culture of pus aspirated from the abscess and he was treated with percutaneous pigtail catheter drainage followed by antibiotics (meropenem and trimethoprim-sulphmethoxazole). Melioidosis is an emerging infection in India and has high mortality rate, so early diagnosis and prompt management is warranted which requires clinical vigilance and an intensive microbiological workup. Clinicians should be aware of isolated liver abscess caused by *B. pseudomallei* in appropriate clinical settings.

**Key words:** Liver abscess; Diabetes; *Burkholderia pseudomallei*; Emerging infection; India

**Core tip:** Liver abscess due to *Burkholderia pseudomallei* (*B. pseudomallei*) is extremely rare and is mostly reported from Taiwan. In India, most of the reports of are from southern coastal India and this entity is exceedingly rare in eastern India. The actual magnitude of this emerging infection may be under reported due to non-availability of confirmatory tests. Accurate diagnosis is necessary as outcome is fatal with ineffective treatment. We report a case of multiple liver abscesses caused by *B. pseudomallei* in a 29-year-old diabetic male, who was referred as a case of recurrence of pyogenic liver abscess which was previously caused by pseudomonas not responding to antibiotic therapy and aspiration. Diagnosis was made by imaging and culture of aspirated pus revealed *B. pseudomallei* and he was treated successfully with surgical drainage and prolonged course of intravenous and oral antibiotics. So, in a case of pyogenic liver abscess not responding to conventional antibiotics, *B. pseudomallei* should always be thought as a possibility which can be identified by its characteristic appearance on culture and microscopy or direct immunofluorescence testing as well as unique imaging features.

Liver abscess caused by *Burkholderia pseudomallei* in a young man: A case report and review of literature. *World J Clin Cases* 2014; 2(10): 604-607 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i10/604.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i10.604

## INTRODUCTION

Liver abscess is the commonest intra-abdominal abscess, which may be of biliary tract origin (commonest) or hematogenous spread from a distant site, and rarely traumatic. Pyogenic liver abscess is a rare but potentially lethal condition, with a reported incidence of 20 per 100000 hospital admissions in a western population[1]. Both gram positive and gram negative aerobes and anaerobes have been found on culture of aspirated pus, among them *Escherichia coli* (*E. coli*) is cultured most frequently in Western countries[2] and Klebsiella in Asian countries[3].

*Burkholderia pseudomallei* (*B. pseudomallei*), a category Ⅱ bioterrorism agent, is the causative organism melioidosis and is endemic in Southeast Asia and northern Australia[4]. *B. pseudomallei* is found in soil and water and infection occurs by inoculation, inhalation, or ingestion[4]. Melioidosis is most commonly known to present as pneumonia followed by abscesses in the skin. Abscesses in internal organs like spleen, kidney, prostate and liver have also been reported as part of disseminated disease. Isolated liver abscess in melioidosis is a rare clinical condition.

Cases of melioidosis have been reported from southern coastal part of India, but melioidosis causing liver abscess is rare. In cases of liver abscess not responding to conventional anti-microbial the possibility of melioidosis should always be kept in mind. Because of high relapse and mortality rate, early diagnosis and prolonged treatment is a must in this case.

## CASE REPORT

A 29-year-old male was referred to us with high grade fever for 20 d and cough for 2 wk. He had no history of tuberculosis, foreign travel or animal exposure and is farmer by occupation. He had a pyogenic liver abscess by *Pseudomonas aeruginosa* along with pancytopenia about one year back. On admission patient was toxic with high grade fever (37.7 ℃-39.4 ℃) with a pulse rate of 126/min and blood pressure of 100/76 mmHg. Liver was enlarged, tender with a liver span of 15 cm and spleen was just palpable. There was no free fluid in abdomen clinically.

Investigations revealed hemoglobin 10.3 gm/dL, total leucocyte count of 9400/μL, neutrophil 88%, lymphocyte 10%, eosinophil 2% and platelet count of 175 × $10^9$/μL. Fasting plasma glucose was 164 mg/dL and HbA1c was 8.1%. So he was newly diagnosed of having diabetes mellitus and started on treatment with insulin. Renal function and liver function tests were within normal limits. Human immunodeficiency virus serology was negative. Acid fast bacilli were not found in sputum and sputum culture showed no growth of any pathogenic organism. Chest radiograph showed elevation of right dome of diaphragm (Figure 1A). Abdominal ultrasound revealed hepatomegaly with a large hypoechoic space occupying lesion (88 mm × 91 mm) in right lobe of liver with splenomegaly. Contrast enhanced computed tomography of abdomen showed hepatomegaly with loculated hypodense lesion (8.5 cm × 7.4 cm) in the anterior part of right lobe (Figure 1B), and multiple small hypodense lesions with confluence in the posterior part of right lobe (Figure 1C). Pus was aspirated from the abscess which on culture showed dry, wrinkled colonies (Figure 2A) on 5% sheep blood agar and McConkey's agar after 48 h of incubation at 37 ℃. Gram-negative, oxidase-positive, motile, aerobic bacilli with typical bipolar "Safety pin" appearance (Figure 2B) was seen on gram stain suggestive of *B. pseudomallei*, which was identified by Vitek 2 compact system. Culture sensitivity was done, which was sensitive to ceftazidime, piperacillin-tazobactum, meropenem, trimethoprim-sulphmethoxazole and minocycline.

Patient was treated with percutaneous catheter drainage, antibiotics and strict glycemic control. Intravenous meropenem was continued for two weeks followed by trimethoprim-sulphmethoxazole for 20 wk after which follow up computed tomography (CT) scan showed complete resolution of the liver abscess.

## DISCUSSION

Liver abscess is a common entity in India; among which pyogenic liver abscess is a rare variety. Ascending infection from biliary tract is the most common cause, followed by hematogenous spread[4]. *E. coli*, is the most often cultured bacteria, accounting for about 33% of the cases followed by streptococcal group[5].

Melioidosis varies from asymptomatic infections and localized skin abscess without systemic illness to fulminant diseases with abscesses involving lungs and other internal organs especially when the host immunity is compromised. Cases of isolated liver abscess are not very common and rarely reported. It is an environmental saprophyte and is endemic in Southeast Asia and northern Australia. In India it is found in southern parts in the states of Karnataka, Tamil Nadu, Kerala and Maharastra[6]. Twenty eight cases of septicemic melioidosis were reported from a tertiary care hospital in south India between 1993 and 2002[7] and it is an emerging infection in India. Liver abscess caused by *B. pseudomallei* is rare and only 9 cases have been reported in India[6,8-10] till now, and few cases have been reported in Taiwan[11-13]. Gopalakrishnan *et al*[14], in a series of 32 cases of culture proven Melioidosis found localized infections in 14 patients but did not encounter even a single case of liver abscess.

The most important risk factors are diabetes, renal disease, liver cirrhosis, thalassemia, alcoholism, use of immunosuppressive agents, cystic fibrosis and kava (a Hawaiian drink) consumption[15]. The presenting symptoms may vary from fever, dry cough due to irritation of diaphragm by abscess, abdominal pain, localized swelling to septicemia shock. Lung is most commonly involved in melioidosis. Abscess in other internal organs such as liver and spleen may be a presenting feature in an immunocompromised host. The risk factor for our patient was diabetes but isolated liver abscess without any other organ involvement has seldom been reported previously.

A positive culture of *B. pseudomallei* from the aspirated pus from liver abscess is the definitive diagnosis. It is

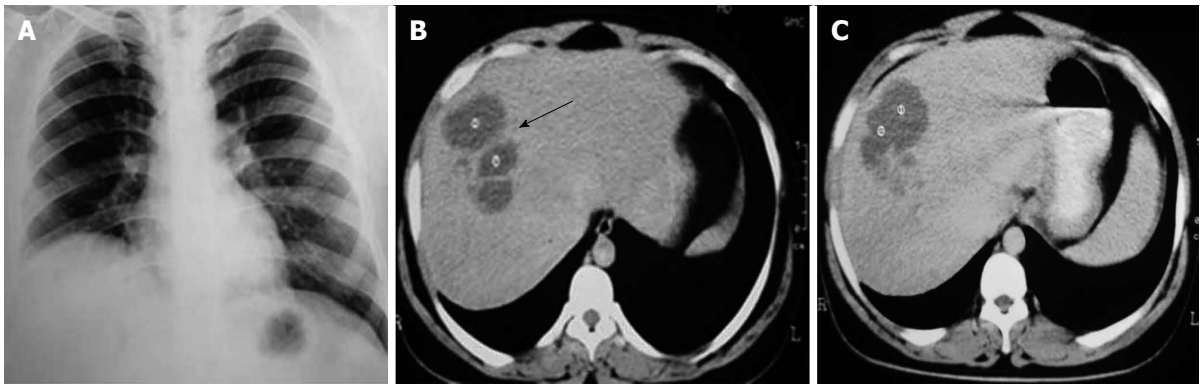

**Figure 1 Computed tomography.** A: Chest radiograph shows elevation of right hemi-diaphragm; B: Contrast enhanced computed tomography of upper abdomen shows one loculated hypodense lesion (8.5 cm × 7.4 cm) with irregular inner margin noted in the right lobe of liver (black arrow); C: Multiple small hypodense lesions with confluences also seen in posterior part of right lobe.

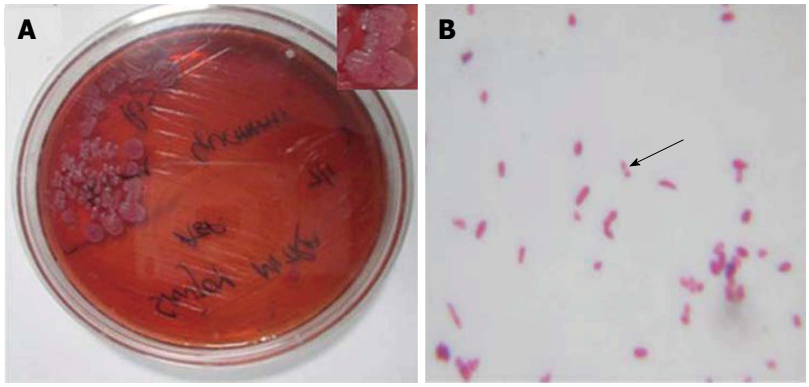

**Figure 2 Identification of bacteria.** A: Showing dry wrinkled colonies on 5% sheep blood agar (48 h of incubation at 37%). Inset: colonies in enlarged view; B: Gram negative oxidase positive bacillus with typical bipolar "safety-pin" appearance on gram stain (black arrow).

difficult to differentiate *B. pseudomallei* from other gram negative bacilli. Direct immunofluorescence microscopy is 98% specific and 70% sensitive compared to culture[7]. Chest radiograph may show elevation of right dome of diaphragm as in our case. CT scan findings will include liver abscesses with a "honeycomb" pattern of multiseptate, multiloculated lesions and a "necklace sign" with multiple peripheral radial loculations contained within the larger hypodense honeycomb lesions[16]. These findings were shown in a retrospective study in a small number of cases of liver abscess with melioidosis.

*B. pseudomallei* is characteristically resistant to penicillin other than ureidopenicillins, ampicillin, first- and second-generation cephalosporins, gentamicin, tobramycin, streptomycin and macrolides. It is only susceptible to chloramphenicol, tetracyclines, trimethoprim-sulfamethoxazole, ureidopenicillins, third-generation cephalosporins, carbapenems and amoxicillin-clavulanate[14]. The antibiotic of choice for melioidosis is ceftazidime (40 mg/kg every 8 h)[17]. Imipenem or intravenous amoxicillin-clavulanate is the alternative choices[18]. Parenteral antibiotics should be continued for at least 10-14 d, or until patient is able to take oral medications. Oral maintenance therapy for at least 20 wk with amoxicillin-clavulanate (amoxicillin 27 mg/kg per day divided into three doses) or trimethoprim-sulfamethoxazole (trimethoprim 8 mg/kg per day and sulfamethoxazole 40 mg/kg per day) should be given in patients with abscess for complete resolution[14]. Patients need to be followed up for at least 6 mo after complete resolution of abscess.

In conclusion, *E. coli* is the commonest cause of pyogenic liver abscess in India, but *B. pseudomallei* should also be kept in mind because of its rising incidence and misdiagnosis can lead to treatment failure and high mortality rate. Diabetes and immunosuppressed state are the important risk factors. Prolonged treatment with antibiotic is necessary for complete resolution in *B. pseudomallei* liver abscess. Liver abscess in a diabetic not responding to aminoglycosides and penicillins should be dealt with rigorous attention or otherwise the outcome will be fatal.

## COMMENTS

### *Case characteristics*

A 29-year-old farmer presented with high grade fever and cough for 3 wk.

### *Clinical diagnosis*

High grade pyrexia, tachycardia, just palpable splenomegaly and tender hepatomegaly.

### *Differential diagnosis*

An infectious etiology common in tropical countries such as pyogenic liver abscess, malaria, tuberculosis and an immunocompromised state [*e.g.*, human

immunodeficiency virus (HIV)] have been considered.

### Laboratory diagnosis

Mild anemia, neutrophilia, fasting hyperglycemia, raised glycosylated hemoglobin was present whereas sputum for Acid-fast bacilli, HIV serology, blood for malaria parasite were negative.

### Imaging diagnosis

Chest X-ray, abdominal ultrasound and abdominal contrast enhanced computed tomography were done which showed elevated hemidiaphragm on X-ray and hypodense loculated lesion in right lobe of liver on ultrasound and tomography.

### Pathological diagnosis

Aspirated pus from the abscess inoculated on 5% sheep blood agar and McConkey's agar showed gram-negative, oxidase-positive, motile, aerobic bacilli with typical bipolar "Safety pin" appearance on gram stain suggestive of *Burkholderia pseudomallei* (*B. Pseudomallei*), later confirmed *via* automated Vitek-2 compact system and was sensitive to ceftazidime, piperacillin-tazobactum, meropenem, trimethoprim-sulphmethoxazole and minocycline.

### Treatment

Patient was treated with percutaneous catheter drainage, strict glycemic control with insulin, intravenous meropenem for 2 wk followed by trimethoprim-sulphmethoxazole for 20 wk which led to resolution of abscess.

### Term explanation

"Safety Pin" appearance: bipolar staining of *B. Pseudomallei* on gram stain as if the organism resembles a "Safety Pin", "Necklace sign" on computed tomography scan: multiple peripheral radial loculations contained within the larger hypodense honeycomb lesions of liver abscess.

### Experiences and lessons

Isolated liver abscess due to *B. Pseudomallei* can occur specially in immunosuppressed and diabetic patients who need prolonged treatment with antibiotics for resolution and misdiagnosis may lead to treatment failure and high mortality rates.

### Peer review

This paper is interesting and it could be accepted pending review.

**AIM AND SCOPE**

*World Journal of Clinical Cases* (*World J Clin Cases*, *WJCC*, online ISSN 2307-8960, DOI: 10.12998) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

The primary task of *WJCC* is to rapidly publish high-quality Autobiography, Case Report, Clinical Case Conference (Clinicopathological Conference), Clinical Management, Diagnostic Advances, Editorial, Field of Vision, Frontier, Medical Ethics, Original Articles, Clinical Practice, Meta-Analysis, Minireviews, Review, Therapeutics Advances, and Topic Highlight, in the fields of allergy, anesthesiology, cardiac medicine, clinical genetics, clinical neurology, critical care, dentistry, dermatology, emergency medicine, endocrinology, family medicine, gastroenterology and hepatology, geriatrics and gerontology, hematology, immunology, infectious diseases, internal medicine, obstetrics and gynecology, oncology, ophthalmology, orthopedics, otolaryngology, pathology, pediatrics, peripheral vascular disease, psychiatry, radiology, rehabilitation, respiratory medicine, rheumatology, surgery, toxicology, transplantation, and urology and nephrology.

**Key words:** Case report; Case series; Neuroendocrine tumors; Carcinoids; Pancreatic neuroendocrine tumor

**Core tip:** A review of neuroendocrine tumors, which are rare diseases, strongly supports the prominent role and value of reporting of rare cases or small case series in uncommon disorders.

Nakamura T, Igarashi H, Ito T, Jensen RT. Important of case-reports/series, in rare diseases: Using neuroendocrine tumors as an example. *World J Clin Cases* 2014; 2(11): 608-613 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/608.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.608

## Abstract

At present the publishing of case reports or case series involving small numbers of cases is controversial. While in the past they were commonly published by most journals, recently a number of prominent journals have either stopped publishing them or markedly reduced the numbers published. However, recently an increasing case is being made for their value and a number of new journals have been started devoted specifically to their publication. One of the arguments used for their value is their prominent role in rare diseases either in their recognition, full description or development of treatments. However this aspect has not been specifically studied. In this editorial this aspect is specifically examined using their role in neuroendocrine tumors as an example. Furthermore, the background of the controversy is briefly reviewed to better understand the context of this editorial.

Case reports (1 patient) or case series (> 1 patient) reporting are not without controversy: held in high regard by some[1-4] and looked down on by others as occupying the lowest rung in the evidence pyramid hierarchy[5-10]. It is necessary to understand a little more of this controversy to understand why this editorial is being written, which will be covered briefly in the next paragraph. The purpose of this editorial is to demonstrate, how in the case of an uncommon disease, such as clinically important gastrointestinal (GI) neuroendocrine tumors [carcinoids (incidence-7-13 cases/million per year) and pancreatic neuroendocrine tumors (pNETs) (incidence-1-5 cases/million per year)][11,12], case reports and case series reports have played, and are still playing, a vital and essential role in their recognition and also management/treatment.

Case or case series reports are controversial because an increasing number of prominent journals, starting in the 1980's no longer regularly published them[9,13,14]. In a survey in 1979[15] of three prominent medical journals (NEJM, JAMA, Lancet) of articles published between 1946-1974, the frequency of case reports/series (< 10 patients) remained unchanged, at 38% of all articles.

However, analyzing the same journals from 1971-1991[14], found that case reports/series frequency, as a percentage of all articles, decreased 86% from 30% to 4% of all articles, replaced by an increase in primarily clinical trials and other evidence based medicine (EBM) reports [randomized clinical trials (RCT), *etc.*]. In another study in 2006[16] of 25 journals covering various aspect of medicine, only 32% regularly published case reports/series and 33% never published them. Furthermore, other publications including areas as diverse as psychiatry and anesthesia, found that journals prominent in their field, either stopping reporting case reports/series or only infrequently published them[5,9,10,13]. This change in policy is generally attributed primarily to two factors: a general conclusion that case reports/series represent a lower level of evidence [compared to randomized clinical trials (RCT), systematic reviews, meta-analyses, cohort studies, case control studies][6,10] and the rise of the importance of impact factors (IF)[6,10].

In general case reports/series are ranked as providing one of the lowest levels (Level 3) in the evidence based hierarchy[2,6,9,10]. They have a denominator of only one (or a small number); the results can not be used for predictive value, and they can be notoriously affected by publication bias[6,10,17,18]. For example, one study[17] demonstrated in a review of case reports/series, successes were reported in 90% and failures in only 10%. It has been stated that nearly all discarded once-popular therapies were likely supported by a series of favorable cases[18]. Over the last few years, the impact factor of journals (which is determined by the citation rate) is assuming increasing importance. This is occurring because, not only is it widely used as a measure of a journal's quality, which can not only have an economic influence on the journal and the quality of the papers submitted, but also have an affect on authors, because it is increasingly used in assessing an individual's academic credentials in terms of assessing quality of publications for possible placement, promotion or other advancement[6,9,10]. The problem here is that case reports/series are generally cited less than evidence-based medicine (EBM) articles with the result they can decrease the IF of the journal[2,6,8-10,19]. This is well shown in a 2005 study[8] comparing the impact factor of various types of articles (2646 articles published in 1991, 2001). This study[8] showed case reports were the most poorly cited compared to EBM studies (meta-analysis, RCTs, epidemiological studies, case control studies). Similar results were found in a study assessing the citation rate in 2008 of papers published in *Am J Medical Genetics*, Part A in 2006, which found that the non-citation rate was 2.3 fold higher in the case reports/series than in EBM articles, and the citation rate in the case reports/series was not > 6 citations for any article, whereas in the EBM articles, many had rates higher than this.

While the presence of these negative factors discussed above, might be assumed to be leaving the case report/series in its terminal throes, in the last few years an increasing argument in their defense has been made by many[1-3,6,7,17,19-21] and for its restoration, as a prominent and useful medical reporting method. This is evidenced by both the recent appearance of numerous publications devoted to case reports/series such as the *World J of Clinical Cases*, as well as the re-institution of the case report/series format in some prominent journals[19,20,22]. One study[17] assessed one aspect of the re-inclusion of case reports into the journal Lancet[20] by studying the impact of case reports/series of innovative treatments reported in 1995/1996. This approach was taken because it is recognized that for a clinical study to be funded, evidence must be provide that proposed treatments may have merit, and case reports/series are often the first line of such evidence[17]. Of the 64 cases reports and 39 case series identified, it was found the cases were clearly read because they had an average citation rate of 17 times (range 0-336), and they also affect subsequent approaches because 22% of the cases lead to followup trials (9%-controlled trials)[17]. Other important points raised in their defense include that case reports/series: have a long tradition in teaching in medicine; they often report and establish the cause of various disorders with few observations; they provide the clinical foundation for postulating the possible pathogenesis of disorders; for therapies they are often the first evidence of the effectiveness of a new therapy, as well as often the major source of initially reporting adverse effects of different therapies; are an important teaching, education and career vehicle for young physicians (students, residents, fellows, starting faculty) to publish and contribute to the medical literature; and are important in recognizing new diseases, particularly in the case of rare diseases or rare variations of more common diseases[2,6,10,17,19,21-23]. While numerous articles have mentioned the importance of case reports/series reporting in rare diseases, this point has not been specifically examined and emphasized. It occurred to us that the study of GI-NETs (carcinoids, pNETs) offers a very good example of this assertion and thus will be briefly reviewed here and in Table 1.

Both GI- carcinoids and pNETs are classified as neuroendocrine tumors (NETs)[24-26] and although they have a different pathogenesis, they share similar histological features, aspects of their biological behavior, and many features of their management including localization methods, treatment approaches, and their abilities to be associated with hormonal-excess states due to ectopic production of biologically active substances[24,25,27-29]. There are 10 well-established pNET syndromes of which 9 are associated with specific hormone excess syndromes [Gastrinomas; insulinomas; VIPomas; glucagonomas; somatostatinomas; GRFomas; pancreatic ACTHomas; pNETs causing carcinoid syndrome, or hypercalcemia and nonfunctional pNETs (NF-pNETs)][11,26]. In addition to these 10 established pNET syndromes there are 5 other very rare (< 5 cases reported) syndromes associated with pNETs[26], which also likely represent a functional pNET syndrome. These include: pNETs secreting erythropoietin causing erythroblastosis[30]; pNETs secreting

**Table 1 Sentinel case reports/series defining syndromes of disease aspects in patients with gastrointestinal neuroendocrine tumors**

| Year | Author | Pt# | Type of report | Syndrome | Importance | Ref. |

| 1982 | Guillemin *et al* | 1 | Biochemistry | GRFoma | Isolation of growth-hormone releasing factor (GRF) from patient with acromegaly with pNET | [45] |
| 1982 | Rivier *et al* | 1 | Case report | GRFoma | | [64] |
| 1982 | Ruddy *et al* | 1 | Case report | Reninoma | First description of renin secreting pancreatic tumor causing symptoms | [31] |
| 2004 | Samyn *et al* | 1 | Case report | EPOma | Description of pNET secreting erythropoietin with syndrome | [30] |
| 2004 | Brignardello *et al* | 1 | Case report | LHoma | Description of pNET secreting luteinizing hormone with syndrome | [35] |
| 2008 | Chung *et al* | 1 | Case report | IGF-2oma | First report of pNET secreting IGF-2 with symptoms | [33] |
| 2012 | Roberts *et al* | 1 | Case report | GLP-1oma | First description of pNET secreting GLP-1 causing symptoms | [32] |
| 2013 | Rehfeld *et al* | 1 | Case report | CCKoma | First description of CCK secreting pNET with syndrome | [47] |

CCKoma: pNET secreting cholecystokinin; EPoma: pNET secreting erythropoietin; GRFoma: pNET secreting Growth Hormone Releasing Factor; IGF-1oma/IGF-2oma: pNET secreting insulin-like growth factor 1 or 2; LHoma: pNET secreting luteinizing hormone; NET: Neuroendocrine tumor: NME: Necrolytic migratory erythema (skin rash) seen in glucagonoma cases; pNET: Pancreatic neuroendocrine tumor; Reninoma: pNET secreting renin; Somatostatinoma: pNET secreting somatostatin; VIPoma: pNET secreting vasoactive intestinal peptide; WDHA: Watery diarrhea, hypokalemia and achlorhydria which are features seen in VIPoma patients; ZES: Zollinger-Ellison syndrome due to ectopic secretion of gastrin by a gastrinoma causing acid hypersecretion.

renin causing hypertension[31]; pNETs secreting GLP-1 or GLP-2 causing hypoglycemia[32,33] and pNETs secreting luteinizing hormone causing masculinization[34,35]. Although the incidence of both carcinoid tumors and pNETs is increasing, they are still classified as rare conditions[36]. Whereas gastrinoma, insulinoma and NF-pNETs are the most frequent pNETs, they still have an incidence < 2/million per year and are thus rare diseases (less 1 in 1500), whereas the other pNET syndromes are 1/10-1/100 less frequent[11,12,26,29]. The functional syndrome seen most frequently with GI-carcinoid tumors is the carcinoid syndrome, characterized by flushing, diarrhea, asthma and heart disease primarily due to ectopic release of serotonin, neurokinins and perhaps other biologically active peptides[29]. The carcinoid syndrome occurs in 5%-10% of patients with carcinoid tumors and thus is also present at < 3-5/million per year and hence is also a rare disease.

As can be seen in Table 1, case reports or case series, often involving < 5 cases, played a sentinel role in most GI-NET/pNET syndromes, usually providing the initial description of the functional syndrome or in

elucidation its full clinical manifestations. Specifically, case reports/series provided the initial description of insulinoma[37], glucagonoma[38], pNETs causing ectopic Cushing's syndrome[39], gastrinoma causing the Zollinger-Ellison syndrome[40], the VIPoma (WDHA) syndrome[41], somatostatinoma and somatostatinoma syndrome[42-44], GRFoma[45,46], pNETs secreting renin[31], pNETs secreting erythropoietin[30], pNETs secreting luteinizing hormone[35], pNET secreting IGF-2 (IGF-2oma)[33], pNETs seeing IGF-1(IGF-1oma)[32], and CCKoma[47]. The initial description of the carcinoid syndrome, seen in patients with metastatic carcinoid tumors to the liver (usually ileal-jejunal-midgut tumors) was described also in a case series[48]. The sentinel role of some case reports was recognized by naming the syndrome after the initial case description such as the Verner Morrison syndrome (VIPoma-WDHA) and the Zollinger-Ellison syndrome (gastrinoma). Some of the case reports/series played other sentinel roles. These include the first description of a pNET in a report of one patient[49]; the first description of an ileal carcinoid in one case[50]; the initial use of insulin for diabetes in a case series by Banting[51] and the initial description of the clinical triad that is commonly used, even today, to suspect the diagnosis of insulinoma[26,28,52] was in a case series review, and is now referred to as Whipple's triad after this sentinel paper[53]. Some case reports/series were not the first to report a new syndrome, but played an important role in defining the spectrum of the syndrome by describing additional features of the rare pNET syndrome. This is illustrated by case reports describing the full features of the VIPoma syndrome (diarrhea, hypokalemia, achlorhydria, hypercalcemia, not associated with peptic ulcer disease or gastric hypersecretion)[11,26], after the initial report of a nonbeta cell islet tumor (pNET) associated with large volume diarrhea causing hypokalemia[41]. Similarly additional case reports/case series after the initial description of the glucagonoma syndrome (pNET with skin rash)[38], described the association of a pNET with hyperglycemia and hyperglucagonemia[54], and emphasized its association with a characteristic skin rash, which was named necrolytic migratory erythema (NME)[55-57], and which was sufficiently distinctive to become one of the main features leading to the diagnosis of glucagonomas, even at present[11,26,28,58]. Lastly, this is also the case with the somatostatinoma syndrome which was first proposed in 1977 with the description of a somatostatin secreting pNET[42], whereas the full clinical features we generally recognize today [diabetes mellitus, cholelithiasis, steatorrhea, weight loss hypo/achlorhydria, anemia][11,26,58], were later described in another case report[44]. This latter finding, illustrates another important role of case reports/case series not only in rare disorders, but also in common disorders[2,3,10,19,21,59], by reporting an uncommon feature of a common disorder or, in our case, an additional feature of a previously described, uncommon disorder.

Another conclusion that can be drawn from the findings in pNETs illustrated in Table 1 is that case reports/series have had a prominent role in GI-NETs for longer than one century, and are still playing a prominent role. This is illustrated by the descriptions of numerous new pNET functional syndromes since 2000 (Table 1) with the most recent being a case report of a patient with a cholecystokinin secreting tumor syndrome (CCKoma)[47]. The CCKoma syndrome clinically included diarrhea, severe weight loss, advanced peptic ulcer disease, cholelithiasis, all of which can be explained by the known actions of CCK expected from the profound hyperCCKemia this patient had (1000-fold increased)[47]. At present it remains unknown whether this is a very rare syndrome, which has long evaded description, or whether it is more frequent and might be responsible for patients presenting with ZES-like feature, but with normal serum gastrin levels[47,60,61].

In conclusion, a review of the role of case reports/case series in the description and establishment of the GI-NET syndromes strongly support their importance in this rare group of diseases and supports the proposal that they can play a particularly important role in any rare disease[2,6,10,17,19,21-23]. The use of case reports/case series has not only provided many of the original descriptions of these rare GI-NET syndromes, they have provided other features leading to treatments as well as full characterization of aspects of the syndromes. Case reports/small series have been important throughout the last century in the elucidation of these rare syndromes and are as important today, as they were in the past.

## Abstract

Acute ischemic stroke (AIS) is a common medical problem associated with significant morbidity and mortality worldwide. A small proportion of AIS patients meet eligibility criteria for intravenous thrombolysis (IVT) with recombinant tissue plasminogen activator, and its efficacy for large vessel occlusion is poor. Therefore, an increasing number of patients with AIS are being treated with endovascular mechanical thrombectomy when IVT is ineffective or contraindicated. Rapid advancement in catheter-based and endovascular device technology has led to significant improvements in rates of cerebral reperfusion with these devices. Stentrievers and modern aspiration catheters have now surpassed earlier generation devices in the degree and rapidity of revascularization. This progress has been achieved with no concurrent increase in risk of major complications or mortality, both when used alone or in combination with IVT. The initial randomized controlled trials comparing endovascular therapy to IVT for AIS failed to show superior outcomes with endovascular treatment, but key limitations of each trial may limit the significance of these results to current practice. While endovascular devices and operator experience continue to evolve, we are optimistic that this will be accompanied by improvements in patient outcomes. This review highlights the major endovascular devices used in current practice and the trials which have investigated their efficacy.

**Key words:** Cerebral infarction; Endovascular procedures; Intracranial hemorrhages; Stents; Stroke

**Core tip:** This review discusses the critical advancements in endovascular device technology for the treatment of acute ischemic stroke. Endovascular mechanical thrombectomy is becoming an increasingly utilized treatment approach for patients in whom intravenous thrombolysis with recombinant tissue plasminogen activator is ineffective or contraindicated. While three recent randomized controlled trials found no benefit of endovascular thrombectomy over intravenous therapy, it is important for clinicians to understand the limitations of these trials and recognize the expected key role of endovascular therapy in the future management of stroke patients.

## INTRODUCTION

The annual incidence of stroke in the United States is approximately 795000[1]. Stroke is the second leading cause of lost disability-adjusted life-years in high-income

**Table 1 Summary of endovascular mechanical thrombectomy devices**

| Device | Manufacturer | Mechanism |
|---|---|---|
| Merci retriever | Concentric Medical | Thrombus retrieved with helical snare |
| Penumbra system | Penumbra Inc. | Thromboaspiration |
| Solitaire FR | eV3 Endovascular | Thrombus incorporated into struts of deployed stent |
| Trevo Pro | Stryker neurovascular | Thrombus incorporated into struts of deployed stent |

countries and the second most common cause of mortality worldwide[2,3]. Approximately 80% of strokes are ischemic and 20% are hemorrhagic[4]. Acute ischemic stroke (AIS) is caused by a focal interruption of cerebral blood flow, most commonly due to occlusion of a major cerebral artery by local thrombosis or embolus. The resulting ischemia leads to tissue damage through a complex pathophysiological response of excitotoxicity, peri-infarction depolarization, inflammation and apoptosis[5].

The goal of therapy for AIS is to achieve cerebral reperfusion before neurological damage becomes irreversible. The correlation between vessel recanalization and favorable neurological outcome is well-studied[6,7], although additional factors such as stroke severity and age are also likely to have a significant impact on clinical outcome[8,9]. Currently, the only FDA-approved treatment with level 1 evidence for AIS is intravenous thrombolysis (IVT) with recombinant tissue plasminogen activator (alteplase) within three hours of symptom onset[10]. Additional trials have demonstrated that extending this time window to 4.5 h is beneficial in appropriately selected patients[11,12]. However, few patients (< 10%) meet eligibility criteria for this therapy[13-15]. Additionally, larger and more proximally-located thrombi may be relatively resistant to IVT[16-21]. Successful recanalization of large vessel occlusion (LVO) with IVT alone is infrequent, ranging from 10% in internal carotid artery (ICA) occlusions to 30% in middle cerebral artery occlusions, and IVT is associated with a risk of systemic and intracerebral hemorrhage (ICH)[22].

These limitations have led to the exploration of alternative or complementary treatment approaches for AIS. Endovascular mechanical thrombectomy has developed over the past decade as a safe and effective intervention. Rapid advancement in catheter-based and endovascular device technology has led to an increasing number of patients with AIS being treated when IVT is ineffective or contraindicated[14]. Here, we review the evolution of endovascular mechanical thrombectomy devices for the treatment of AIS.

## ENDOVASCULAR MECHANICAL THROMBECTOMY

Endovascular treatment of AIS began with intra-arterial (IA) infusion of thrombolytic agents. Several studies investigating these therapies reported favorable rates of vessel recanalization and neurological outcomes[23-25]. Given the relatively favorable risk to benefit profiles of current mechanical thrombectomy devices, IA thrombolysis is infrequently used in modern endovascular AIS therapy. This was followed by the implementation of balloon angioplasty and microwire techniques to mechanically disrupt thromboemboli[26,27]. Additionally, intracranial stents were shown to be effective at restoring blood flow when deployed within an occluded vessel[28,29].

Endovascular retrieval devices were first developed to recover errant coils and other foreign bodies that had embolized within the cerebral circulation during endovascular procedures[30-32]. The development of devices to remove occlusive thromboemboli was thus a natural extension of pre-existing technology. Endovascular mechanical thrombectomy involves physical extraction of the thrombus through a catheter. Due to the anatomical limitations imposed by vascular anatomy on currently available thrombectomy catheters, thrombi in large ICA, the Circle of Willis and the first two branches of the anterior (A1 and A2), middle (M1 and M2) and posterior (P1 and P2) cerebral arteries) are the most readily accessible. Smaller branches of the cerebral circulation are often too narrow and tortuous to undergo successful mechanical thrombectomy.

Alternative treatment methods for strokes from LVO are an important development, as medical management is often unsuccessful, and these strokes are associated with high rates of morbidity and mortality[25]. The two main methods of endovascular mechanical thrombectomy for LVO include: (1) physical grasping and removal of thrombi with retrieval devices and (2) aspiration of occlusive thrombi with suction devices (Table 1).

## MERCI RETRIEVER

The Merci Retriever (Concentric Medical, Mountainview, CA) was FDA-approved in August 2004 as the first clot retriever device in the United States. This device utilizes memory shaped nitinol (nickel titanium) material to convert from a straight to helical configuration to grasp the thrombus. In this procedure[33]: (1) the retriever is advanced through the thrombus in its straight configuration; (2) two to three helical loops are deployed beyond the thrombus; (3) the device is retracted to contact the thrombus, and proximal loops are deployed within the thrombus; (4) a balloon guide catheter located in the common or internal carotid artery is inflated to control intracranial blood flow; and (5) three to five clockwise rotations are performed to fully ensnare the thrombus, and the Merci Retriever-thrombus complex and microcatheter are removed together.

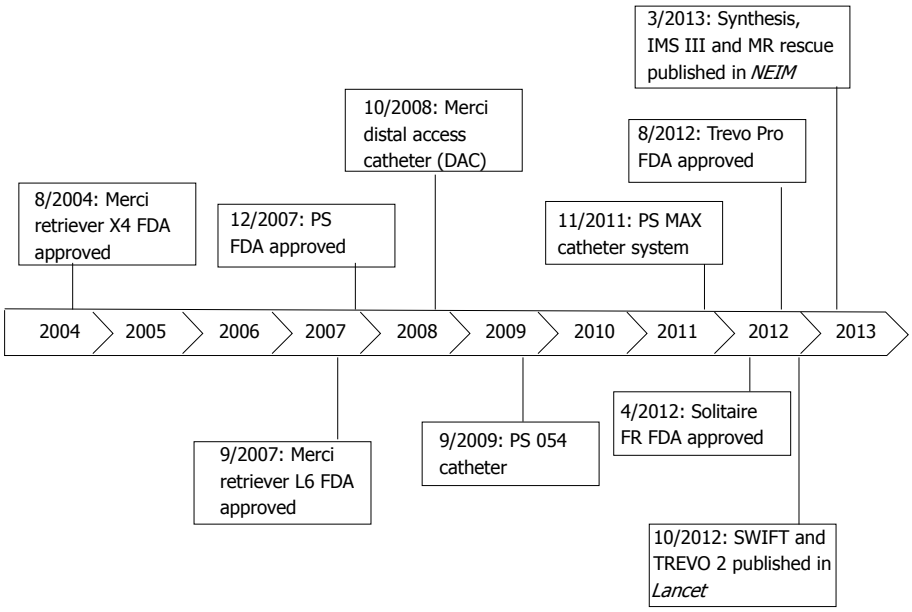

**Figure 1 Timeline of FDA approval, release dates and randomized controlled trials of endovascular mechanical thrombectomy devices.**

The Mechanical Embolus Removal in Cerebral Ischemia (MERCI) trial was a prospective, non-randomized, multicenter trial that first evaluated this device[34]. Recanalization, defined as Thrombolysis in Myocardial Infarction (TIMI) grade 2 or 3 flow in all treatable vessels, was achieved in 48% (68/141) of patients. Patients with recanalization had better neurological outcomes ($P < 0.0001$), as determined by modified Rankin Score (mRS) of 2 or less at 90 d, and lower mortality rates ($P = 0.01$) than those without recanalization, and procedure-related complication and symptomatic ICH rates were comparable to trials of IV t-PA, combined IV/intra-arterial t-PA, and intra-arterial prourokinase[10,25,35].

Newer device generations (Figure 1) have moderately improved rates of recanalization[36]. One such advancement was the Distal Access Catheter (DAC; Concentric Medical) in 2008. The DAC has a flexible distal shaft that facilitates its navigation around the anterior genu of the ICA, beyond the origin of the ophthalmic artery[37]. This improved the navigation of the Merci Retriever through the carotid siphon with each pass, improving procedural efficiency.

## PENUMBRA SYSTEM

The Penumbra System (PS) (Penumbra Inc., Alameda, CA) was FDA-approved in December 2007 and utilizes aspiration for thrombus extraction. In this procedure[38]: (1) the PS catheter is advanced through a guide catheter to a point just proximal to the occlusion; (2) a microwire called a separator is repeatedly passed through the thrombus in order to fragment the clot; and (3) constant suction is applied to the PS catheter to aspirate the thrombus fragments.

The PS was evaluated in a prospective, multicenter study of 125 patients with National Institute of Health Stroke Scale (NIHSS) score $\geqslant 8$ who were ineligible for or refractory to IVT[38]. Recanalization (TIMI $\geqslant 2$) was achieved in a high proportion (81.6%) of patients without significantly different complication rates than those seen in the MERCI trials. Good clinical outcome (mRS $\leqslant 2$) was observed in 25% of patients at 30-d follow-up. More recent generations of the PS include the 054 Reperfusion catheter (2009) and the MAX Reperfusion catheter line (2011). These devices achieve greater aspiration force due to larger proximal lumens[39]. The 054 Reperfusion device was found to accomplish recanalization at a median time of 20 min[40], significantly less than the median time of 45 min reported in the penumbra pivotal trial using previous generation technology.

## STENTRIEVER DEVICES

Stentrievers utilize a retrievable stent to engage and remove the thrombus. In this procedure[41]: (1) the stentriever is advanced within a microcatheter through the thrombus until it is a few millimeters distal to the clot; (2) the stent is deployed, incorporating the thrombus into the stent struts and displacing it radially to the vascular wall; and (3) after three to five minutes, the microcatheter and stentriever are removed together under continuous proximal aspiration with a syringe. This must be performed cautiously, as at least one case of intracranial extravasation during device withdrawal has been reported[42]. It is also possible to perform a control angiogram while the stentriever is deployed, which can confirm flow restoration. However, since this may promote distal migration of thrombus fragments, the utility of performing an angiogram during stentriever deployment is controversial.

### *Solitaire FR*

The Solitaire FR (eV3 Endovascular, Irvine, CA) was

**Table 2 Comparison of randomized trials of endovascular thrombectomy for AIS**

| Trial | Treatment arms | *n* | Revascularization[a] (%) | Good outcome[bc] (%) | Symptomati[c] ICH (%) | Mortality[b] (%) |

[a]Defined as TIMI or TICI grade ⩾ 2a, final revascularization rate including rescue therapies; [b]Assessed at 90 d unless otherwise specified; [c]Defined as mRS ⩽ 2 unless otherwise specified; [d]This study used mRS ⩽ 1 as the primary clinical efficacy endpoint and assessed mortality at day 7 ± 2; [e]Reported as 65%, 81%, 70% and 77% for ICA, M1, single M2 and multiple M2 occlusions, respectively; statistically significant ($P < 0.05$); SWIFT: SOLITAIRE™ with the intention for thrombectomy; TREVO 2: Thrombectomy REvascularization of Large Vessel Occlusions in Acute Ischemic Stroke; AIS: Acute ischemic stroke; IMS: Interventional Management of Stroke; IVT: Intravenous thrombolysis; ICH: Intracerebral hemorrhage; TIMI: Thrombolysis in Myocardial Infarction; TICI: Thrombolysis in Cerebral Ischemia; mRS: Modified Rankin Score.

approved by the FDA in March 2012. Initial non-randomized case series with the Solitaire FR demonstrated high rates of recanalization (89%-96%) and improved rates of favorable clinical outcome (mRS ⩽ 2; 42%-69%) compared to earlier devices[29,41,43-45]. The Solitaire FR was then directly compared to the Merci Retriever in the SOLITAIRE™ with the intention for thrombectomy (SWIFT) trial (Table 2)[46]. This was a parallel-group, non-inferiority trial of 113 patients randomized to either the Solitaire ($n$ = 58) or Merci ($n$ = 55) device. The primary outcome (TIMI ⩾ 2) was more likely to be achieved in the Solitaire group than the Merci group (64% *vs* 24%; $P < 0.0001$ non-inferiority; $P = 0.0001$ superiority). Additionally, patients in the Solitaire group were more likely to achieve a good neurological outcome (mRS ⩽ 2) at 90 d (58% *vs* 33%; $P < 0.0001$ non-inferiority; $P = 0.02$ superiority) and had a lower 90-d mortality rate (17% *vs* 38%; $P = 0.0001$ non-inferiority; $P = 0.02$ superiority) than those in the Merci group. Subsequent prospective and retrospective studies have continued to demonstrate high rates of vessel recanalization and good clinical outcomes with the Solitaire FR[47,48].

### *Trevo Pro*

The Trevo Pro (Stryker Neurovascular, Kalamazoo, MI) is another retrievable stent system which was approved by the FDA in August 2012. Similar to the Solitaire FR, the Trevo Pro was found to be superior to the Merci Retriever in a head-to-head randomized study[49]. The Thrombectomy REvascularization of Large Vessel Occlusions in Acute Ischemic Stroke trial assigned patients with AIS from LVO to either the Trevo Pro ($n$ = 88) or Merci Retriever ($n$ = 90) device. Patients in the Trevo Pro group were significantly more likely to reach the primary outcome, defined as Thrombolysis in Cerebral Ischemia (TICI) grade ⩾ 2, (86% *vs* 60%; $P < 0.0001$ superiority) and achieve a good 90-d neurological outcome (mRS ⩽ 2; $P = 0.013$) than those in the Merci Retriever group. No significant difference was observed in the safety profile (a composite of symptomatic ICH and procedure-related complications; $P = 0.1826$) or 90-d mortality rates ($P = 0.1845$) of these two devices.

A review of 13 prospective trials endorsed improved rates of vessel recanalization with the newer generation stentriever devices[50]. While early trials (mainly utilizing IA thrombolysis and the Merci Retriever) reported recanalization rates of approximately 50%, recent trials with stentrievers consistently reported rates of approximately 85%. A significantly greater time from symptom onset to endovascular treatment in more recent trials was also observed. This may explain their finding that although vessel recanalization rates have significantly improved over time, functional outcomes remain relatively stagnant. Nevertheless, stentrievers and large bore aspiration catheters have become the dominant endovascular devices used to treat AIS in modern practice. A recent prospective trial found no major differences in the efficacy or safety of the Solitaire FR and Trevo Pro[51].

## COMBINED SUCTION EMBOLECTOMY AND MECHANICAL RETRIEVAL

The MAX reperfusion catheters allowed for the development of direct aspiration as an additional thrombectomy technique. Direct suction can be applied from the PS device or a syringe plunger connected to the proximal hub of the catheter. Previously, this technique was limited by the challenges of tracking an aspiration catheter through the intracranial circulation, but the improved trackability of the MAX reperfusion catheters has facilitated its development[37]. Furthermore, these catheters can still be used in combination with other endovascular devices. The ADAPT technique[52] is an increasingly utilized ap-

proach which combines modern aspiration and retrieval technology. Direct aspiration with a large bore aspiration catheter (commonly MAX reperfusion system) is first performed. If direct aspiration fails, stentrievers, balloons and stents can be still be passed through the catheter. A recent retrospective series of 98 patients by Turk *et al*[53] reported revascularization (TICI ⩾ 2b) in 78% of cases following direct aspiration. When stentrievers were used following failed direct aspiration, this rate rose to 95%, a previously unparalleled result.

### *Penumbra 3D separator*

The Penumbra 3D Separator is the newest generation PS device currently being investigated in randomized controlled trials. It is designed to combine stentriever and direct aspiration technology into a single device. The new separator device is configured similarly to a stentriever, with an additional radial dimension to fragment the clot under continuous direct aspiration. The stent struts are designed to minimize vessel contact and thus theoretically reduce iatrogenic injury to the endothelium. An initial prospective study of 20 patients treated with the Penumbra 3D Separator demonstrated vessel recanalization (TICI ⩾ 2b) and favorable neurological outcome (mRS ⩽ 2) in 85% and 50% of patients, respectively[54].

## ENDOVASCULAR THERAPY *VS* IVT FOR AIS

Due to the promising results from early pilot trials of endovascular mechanical thrombectomy for AIS[55,56], randomized controlled trials were undertaken to evaluate the benefit of endovascular therapy compared to IVT in a more rigorous fashion.

### *IMS III*

The Interventional Management of Stroke (IMS) Ⅲ trial[57] randomly assigned 656 patients who had received IVT within three hours of AIS symptom onset to receive additional endovascular therapy ($n$ = 434) or IVT alone ($n$ = 222) in a 2:1 ratio. In the endovascular group, 330 patients received treatment: IA thrombolysis alone ($n$ = 160), mechanical thrombectomy alone ($n$ = 57), IA thrombolysis plus mechanical thrombectomy ($n$ = 97) and combinations of multiple mechanical thrombectomy devices with or without IA thrombolysis ($n$ = 16). There was no significant difference between the endovascular and IVT groups for achieving a 90-d mRS ⩽ 2 (40.8% and 38.7%, respectively; 95%CI: -6.1 to 9.1). Additional subgroup analyses showed no difference between the two groups in patients with NIHSS ⩾ 20 (95%CI: -4.4 to 18.1) or NIHSS < 20 (95%CI, -10.8 to 8.8). Similar rates of symptomatic ICH (6.2% in the endovascular group and 5.9% in the IVT group; $P$ = 0.83) and 90-d mortality (19.1% in the endovascular group and 21.6% in the IVT group; $P$ = 0.52) were observed.

Enrollment and treatment of patients in the endovascular arm of this trial was not optimal. Over 20% of patients in the endovascular arm were included for analysis despite not receiving any endovascular therapy (due to lack of LVO on angiography). Notably, subgroup analysis of patients with LVO confirmed by CTA showed that endovascular therapy was associated with better functional outcomes than IVT alone ($P$ = 0.01)[58]. The time to endovascular treatment was also significantly longer in the IMS Ⅲ trial compared to the previous IMS I and II trials. These earlier trials demonstrated that there is a close association between time to reperfusion and neurological outcome, with a linear decrease in probability of good neurological outcome with time[59]. Thus, this treatment delay may have reduced the clinical benefit of endovascular therapy in this trial. Lastly, of those treated, less than 5% were treated with stentrievers, either alone or in combination with other devices. This likely contributed to only 40% of patients achieving TICI grade 2b or 3 vessel recanalization[60].

### *SYNTHESIS Expansion*

The SYNTHESIS Expansion trial[61] randomly assigned 362 patients with AIS within 4.5 h of symptom onset to either endovascular therapy ($n$ = 181) or IVT ($n$ = 181). Patients in the endovascular group who underwent treatment ($n$ = 165) received either IA thrombolysis ($n$ = 109) alone or in combination with mechanical thrombectomy ($n$ = 56) without any prior IVT. Survival-free disability (mRS ⩽ 1) at 90 d, adjusted for key variables (age, sex, initial NIHSS grade and history of atrial fibrillation) did not significantly differ between the endovascular and IVT groups (30.4% and 34.8%, respectively; $P$ = 0.16). Secondary outcomes including NIHSS score ⩽ 6, neurological deterioration, mortality, symptomatic ICH, and recurrent AIS also did not significantly differ between groups.

Again, the protocol of this trial likely resulted in enrollment of patients who were not suitable candidates for endovascular therapy under current recommendations. No preoperative imaging was required to confirm LVO prior to randomization, and a significant portion of patients (> 33%) had a NIHSS ⩽ 10. Additionally, the majority of patients in the endovascular arm received interventions that would no longer be considered standard of care. Only 13% of patients in the endovascular arm were treated with stentrievers[62], while 60% were treated with IA thrombolysis alone without mechanical retrieval. Because vessel recanalization rates were not reported, it is unclear if these patients received optimal therapeutic effect.

### *MR Rescue*

The MR Rescue trial[63] randomized 118 patients with large vessel anterior circulation strokes to either mechanical thrombectomy ($n$ = 64) or IVT ($n$ = 54) within eight hours of symptom onset. Patient groups were also stratified based on pre-treatment imaging into favorable or non- penumbral patterns. Some studies have suggested that measuring the extent of salvageable brain tissue or ischemic penumbra on preoperative imaging may identify

patients who could preferentially benefit from endovascular therapy[64-67]. Favorable penumbral pattern was defined as a predicted infarct core of 90 mL or less and a proportion of infarct tissue within the at-risk region of 70 mL or less after pre-treatment magnetic resonance imaging or computed tomography. Results showed no significant difference in mean 90-d mRS observed among groups, both in the overall cohort ($P$ = 0.99) or when stratified based on penumbral pattern (favorable, $P$ = 0.23; non-penumbral, $P$ = 0.32). No differences in the rates of symptomatic ICH ($P$ = 0.24) or mortality ($P$ = 0.75) were observed between groups. These results correlate with findings from a recent study which showed that a non-perfect preoperative ASPECT score did not significantly affect functional outcome[68].

No patients in the endovascular arm of the MR Rescue trial were treated with stentrievers. Similar to IMS Ⅲ, this likely contributed to the low overall rate of recanalization. Only 27% of patients in the endovascular arm achieved recanalization of TICI grade 2b or 3[60]. Additionally, this trial may have been underpowered due to the relatively low number of patients in each group.

### *Conclusions from Randomized Trials*

While these trials provided valuable preliminary data for the assessment of endovascular intervention for AIS, each had significant limitations[60,62]. In SYNTHESIS and IMS Ⅲ, patients with LVO were not appropriately selected based on preoperative imaging. In all three trials, due to the pace of advancement in endovascular technologies, a minority of patients were treated with the most modern endovascular devices. Stentrievers were used infrequently in all three studies, which resulted in vessel recanalization rates below current standards. There is evidence that recanalization is associated with improved functional outcomes and reduced mortality[7]. Thus, the generalizability of the results from these trials to modern endovascular stroke practice is limited, and future randomized controlled trials are still needed.

As supported by the subgroup analysis of patients with CTA-positive LVO from the IMS Ⅲ trial, evidence still supports the use of endovascular mechanical thrombectomy for LVO within eight hours of symptom onset. Importantly, none of these trials raised questions about the safety of endovascular therapy. Recanalization is now possible in over 80% of cases, and for many patients, endovascular therapy is the only available treatment option. As endovascular devices and operator experience continue to evolve, improvements in patient outcomes are expected. Future trials will need to focus on proper patient selection and achieving optimal therapeutic effect (vessel recanalization) with modern endovascular devices[69]. Three ongoing clinical trials (THERAPY, SWIFT-PRIME, and POSITIVE) appear to have incorporated these key principles into their study design.

## CONCLUSION

Endovascular mechanical thrombectomy involves the physical extraction of an occluding thromboembolus *via* grasping devices and/or direct/indirect aspiration. Over the past decade, advancements in catheter-based and endovascular device technology have led to strong improvements in rates of vessel recanalization. Initial randomized trials failed to show benefit of endovascular therapy over IVT, but limitations in study design have abated widespread acceptance of their conclusions. Future randomized trials evaluating endovascular mechanical thrombectomy for AIS will need to enroll and treat patients based off of the currently accepted standards of care.

## Abstract

Long-term epilepsy associated tumors (LEAT) represent a well known cause of focal epilepsies. Glioneuronal tumors are the most frequent histological type consisting of a mixture of glial and neuronal elements and most commonly arising in the temporal lobe. Cortical dysplasia or other neuronal migration abnormalities often coexist. Epilepsy associated with LEAT is generally poorly controlled by antiepileptic drugs while, on the other hand, it is high responsive to surgical treatment. However the best management strategy of tumor-related focal epilepsies remains controversial representing a contemporary issues in epilepsy surgery. Temporo-mesial LEAT have a widespread epileptic network with complex epileptogenic mechanisms. By using an epilepsy surgery oriented strategy LEAT may have an excellent seizure outcome therefore surgical treatment should be offered early, irrespective of pharmacoresistance, avoiding both the consequences of uncontrolled seizures as well as the side effects of prolonged pharmacological therapy and the rare risk of malignant transformation.

**Key words:** Epilepsy; Low grade tumors; Long-term epilepsy associated tumors; Glioneuronal tumors; Ganglioglioma; Dysembryoplastic neuroepithelial tumor; Lesionectomy; Epilepsy surgery

**Core tip:** Long-term epilepsy associated tumors (LEAT) represent a frequent cause of focal epilepsies, particularly in children and young adults. Epilepsy associated with LEAT is generally poorly controlled by antiepileptic drugs while it is extremely responsive to surgical treatment. Temporo-mesial LEAT have a widespread epileptic network and complex epileptogenic mechanisms. The best management strategy of tumor-related focal epilepsies remains controversial representing a contemporary issues in epilepsy surgery.

Baruzzi A, Tinuper P, Rubboli G. Epilepsy associated tumors: Review article. *World J Clin Cases* 2014; 2(11): 623-641 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/623.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.623

## INTRODUCTION

Brain tumors, mostly low grade tumors, are associated with epilepsy in more than a half of cases and approximately 30% of tumor-associated epilepsy are pharmacoresistant.

Recent advances in neuroimaging and neurophysiology have allowed the recognition of subtle epilepsy-associated focal structural lesions, and have improved our understanding of the complex functional relevance of these lesions for seizure generation. Among this group of lesions the concept of long-term epilepsy associated tumors (LEAT) describes the wide group of low grade tumors in patients associated with chronic focal epilepsy[1-5]. Indeed, developmental brain lesions, in particular glioneuronal tumors (GNT), often associated with malformations of cortical development, in particular focal cortical dysplasia (FCD)[1,3,4], are among the most common causes of pharmacologically intractable epilepsy. In the setting of epilepsy surgery a brain tumor is the second most common cause of focal epilepsy[6] and it could be encountered in approximately 30% of patients operated on for refractory focal epilepsy[5,7,8].

Epilepsy associated-tumor is a debilitating condition, causing distress and adversely affecting the quality of life[3,5,9-17].

Epileptic seizure incidence varies according to tumour location and hystotype. Furthermore low-grade tumors often are more epileptogenic than high-grade tumours[8,10,12,13,16,18].

Epilepsy associated with brain tumours can be divided into two groups: tumors without other symptoms (usually low-grade tumors affecting children or young patients) or tumors together with neurological deficits (more frequently high-grade tumours in middle-aged and older patients)[10].

In the group of epilepsy associated with low grade tumors it is useful to further distinguish between the preeminence of oncological and epileptic logical aspects. In the group of the "diffuse low grade glioma" (LGG) the oncological aspects should prevail according to the progressive course of the neoplastic brain disease[10-12,15,16,19-22]. On the contrary in the group of LEAT, mainly represented by glioneuronal tumors (GNTs), epilepsy control should be the main goal[1,3-5,8,23-28].

The group of LEAT, is currently enlarging not only for the recognition of new, often rare, histotypes but also for the identification of tumors having hybrid and/or mixed features[3,29-32]. The biologic behaviour of LEAT is generally benign even if some tumors could present recurrence or malignant transformation[5,33]. New tumoral entities have been recently introduced and there is ongoing debate on improving consensus for diagnosis of LEAT between specialized centers[3,30]. While LEAT rarely coexist with hippocampal sclerosis (2%-25% of cases ) they may often be associated with FCD (40%-80% of cases)[2,23,24,29,34-36].

## LONG TERM EPILEPSY ASSOCIATED TUMORS

The histological characteristics of these tumors influence their propensity to generate seizures.

### *Gangliogliomas*

Gangliogliomas (GG) are the most common neoplasm causing chronic focal epileptic disorders (about 40%)[5,37-39]. GG can occur in any part of the central nervous system, although the temporal lobe is the most common location[5,33,40] followed by the frontal lobe, the optic pathway, the spinal cord, the brainstem, the cerebellum and the pineal gland.

### *Dysembryoplastic neuroepithelial tumors*

Dysembryoplastic neuroepithelial tumors (DNT) are grade I WHO tumors with cystic components, described by Daumas-Duport *et al*[41] in 1988 as a typically cortical tumor affecting children and young adults with long-standing, drug-resistant epilepsy. Most frequently DNT are sited in the cortex of temporal lobe above all at the temporo-mesial site[42-46]. Rarely DNTs have been described in ectopic locations (septum pellucidum and the caudate nucleus)[47] in the pons, thalamus, basal ganglia, cerebellum, third ventricle, and brainstem. Familial occurrence of these neoplasms have been described.

### *Pleomorphic Xanthoastrocytoma*

Recently also pleomorphic Xanthoastrocytoma (PXA) has been considered part of this group of tumors. In fact, in addition to the astrocytic nature, there is growing evidence that PXA exhibits some histological, immunophenotypic and ultrastructural neuronal features[48,49]. Furthermore occasionally, FCD can be associated with PXA.

### *Papillary glioneuronal tumor*

Firstly described by Kim *et al*[50] 1997, Papillary glioneuronal tumor (PGNT) most frequently arises in a supratentorial locationwith rare case showing multilobar involvement[3]. At MRI they appear as a cystic enhancing lesion with solid areas and often a mural nodule. PGNTs affect young adults.

### *Pilocytic astrocytoma*

Supratentorial pilocytic astrocytoma (PA) is frequently presents with chronic epilepsy. PA are included within the common histological entities encountered in series of tumor-associated epilepsy cases[3,5,30,51].

### *Diffuse astrocytoma*

Diffuse astrocytomas mostly arise in the cerebral hemi-

spheres of young adults (frontal and temporal cerebral lobes) and seizures represent one of the most common symptoms. It has been described in the group of LEAT[52]. Some author stated that initial presentation with seizures could influence long-term survival[30,53].

### Oligodendroglioma

Oligodendrogliomas usually arise in the cerebral hemispheres of young adults. They belong to LEAT group. Seizures represent a common presenting symptom[5,5,30].

### Angiocentric gliomas

low grade cerebral tumor mostly affecting children and young adults and it is more and more frequently identified in the setting of chronic epilepsy[3]. Angiocentric gliomas (AG) have a cerebro-cortical location, often with involvement of the fronto-parietal and temporal lobe.

### Extraventricular neurocytoma

This rare entity, may be considered in the spectrum of GNT associated with focal epilepsy[29].

### LEAT with mixed tumor features

"Hybrid" tumors constituted by mixed forms of gangliglioma and DNT but also PXA and gangliglioma, PXA with DNT and, PXA with an oligodendroglioma have long been recognised, representing an increasing group of tumors in epilepsy surgical series. Cases where a PA developed within a DNT, as well as PA grew in combination with a low-grade oligodendroglioma, have been noted[54,55].

## TUMOR SITE

In the setting of low grade tumors associated with epilepsy, diffuse LGG (WHO grade Ⅱ gliomas) are mainly found in the insular, fronto-insular, temporo-insular regions (namely paralimbic structures) representing the iso-mesocortical transition zone[56].

Instead, LEAT mainly arise in the temporo-mesial structures (namely limbic lobe) in the site of allo-isocortical transition, harboring more frequently a neuronal differentiation maybe due to their proximity to the hippocampal granular layer where neurogenesis during adult life takes place[56-62].

In our findings[8,26,28,36] according with others[62-65] in the mesial temporal lobe both the lesion and hippocampus seem to be epileptogenic even if there are no other MRI abnormality (hippocampal sclerosis) and pathological examination shows normal findings.

## PATHOGENESIS OF TUMOR-ASSOCIATED SEIZURES

Epileptogenesis of brain tumors depends on the histotype and location, even if the complexity of structural and molecular changes implies a multifactoriality of the pathogenesis[10,28,66,67] and may differ according to histologies (GNT *vs* diffuse low grade gliomas)[4,10,15,16,68,69]. The comprehension of the epileptogenesis in GNT is crucial to treat effectively pharmacologically intractable epilepsy (as discussed above) represents the initial, and often the only, clinical manifestation of the tumor and critically affects the patient's daily life.

LEAT are often large tumors, with a high propensity to develop seizures when located in temporal or frontal lobes[10,70]. GNT are composed of peculiar cellular components with hyperexcitable neurons, functionally integrated into excitatory circuitries, and neurochemical characteristics that can be relevant for epileptogenesis[34]. Data provided by intralesional EEG recording have demonstrated intrinsic epileptogenicity of GG and DNT[71,72]. In addition, immunocytochemical studies showing high expression of specific glutamate receptors (GluR) subtypes suggest a hyperexcitability in the neuronal constituent of GNT[73,74]. An additional mechanism that can sustain epileptogenesis is related to an unbalance between excitation and inhibition due to to a prominent expression of mGluR5 and downregulation of several gammaaminobutyric acid (GABA-A) a receptor (GABA-AR) subunits that suggest an impairment of GABAergic inhibition[75,76]. Furthermore, a disturbed ion homeostasis and transport could represent an additional potential mechanism leading to increased excitability in GNT[9,77].

Another potential epileptogenic mechanism is related to a possible role of inflammation in the pathophysiology of human epilepsy[78]. Proinflammatory molecules have been shown in experimental models to decrease the seizure threshold[78,79] and may be involved in the generation of seizures in brain tumors, particularly in GNT[80]. Different mechanisms can cause an increment of neuronal excitability, for instance by enhancing the extracellular glutamate concentrations, as well as modifying the function of both glutamate and GABA receptors. Furthermore in GNT, particularly in GG, inflammatory changes have been showed to be associated with evidence of alterations in blood-brain barrier (BBB), with albumin extravasation and uptake in tumor astrocytes[66,81]. Interestingly, some data have shown also a prominent upregulation of the mTOR pathway, known to be a key regulator of cellular changes involved in epileptogenesis in GNT, particularly in GG[82,83].

Several other additional mechanisms have been hypothesized to account for enhanced excitability in GG, such as for example, hypoxia and acidosis, ionic changes, and deposition of hemosiderin in the peritumoral region[10]. Enzymatic changes may also occur in peritumoral tissue, impairing neurotransmitter synthesis and storage, and contributing to tumor-associated epilepsy. Finally, association with cortical dysplasia (as discussed below) also has to be considered in the evaluation of the epileptogenicity of GG. Indeed the identification of a coexistent pathology may be clinically relevant since it has been extensively reported that the tumor itself may be electrically silent and the origin of seizures is from a pathological tissue adjacent to the tumor[42,77,84]. The implication is that excising the tumor and leaving in place the nearby abnor-

mal epileptogenic tissue, may give unsatisfactory results on the seizure outcome. Young age and long duration of illness are associated with an increased risk of secondary epileptogenesis. GNT can be intrinsically epileptogenic, even when associated with FCD[71].

## CLINICAL AND EEG FEATURES OF FOCAL EPILEPSY ASSOCIATED WITH LEATs

### *Clinical features*

Focal epilepsy is the most common and often the only symptom of LEAT. Neurological deficits are relatively uncommon, varying from 0% to 15% according to different series: the neurological sparing might depend on the indolent and slow course of LEAT that might allow compensation of possible brain impairment by slowly developing plastic processes, particularly in the young age. Epilepsy can appear at any age: however, the majority of cases present with an epilepsy onset in adolescence and young adulthood. In DNET, seizures appear almost always and more than half of the patients have focal seizures with alterated consciousness, with or without secondary generalization[85]. Regarding GGs, 80%-90% of patients seizures represent the only clinical symptom (mainly secondarily generalized tonic-clonic seizures)[86,87]. As already reported, the most common location of GG is the temporal lobe where they are frequently positive to CD34 glycoprotein staining. On the contrary it is not reported the association with CD34 for GG located in other sites of the brain[37,86-88]. It could be argued that this protein might represent a marker of dysplastic differentiation and that it could contribute to epileptogenesis. Seizure semiology is related to the site of tumor. In general, complex partial seizures with aura are more common in LEAT located in the temporal lobe, whereas secondary generalization is more common in epilepsies associated with extratemporal LEAT[39]. However, the extension of the tumor-related epileptogenic area may vary according to the anatomical location of the neoplasm: in fact, several data suggest that epileptogenic zone may be more widespread and complex in focal epilepsies associated to LEAT in the mesial temporal lobe in comparison to neocortical temporal lateral locations[36,40,61,65]. Occurrence of status epilepticus has been reported to be rare. Clinical parameters that differentiated patients operated on in childhood from patients operated on in adulthood were: (1) aura that was reported more often in the adult group, but it should be noted that this finding might at least partially depend on the fact that, in general, children are less able to refer their auras; and (2) mean age at seizure: probably due to the fact that developing brain has a low seizure threshold which leads to early and frequent seizures. Moreover, in pediatric age, malformations of cortical development are most often the basis of lesional epilepsy that is characterized by a high seizure frequency that can facilitate an early diagnosis and that can lead to early evaluation for a surgical approach. No differences between the clinical features of epilepsy associated with DNET and with GG have been reported[42,89]. A favorable seizure outcome has been observed in cases with a short duration of epilepsy, only partial seizure and the lack of secondary generalization . Response of GNT-associated epilepsy to antiepileptic treatment is variable, but drug-resistance is quite common[5,39,42,90].

Task Force of the ILAE Commission on Therapeutic Strategies defined drug resistant epilepsy as the failure of adequate trials of two tolerated, appropriately chosen and used antiepileptic drug (AEDs) schedules (whether as monotherapies or in combination) to achieve sustained seizure freedom[91].

Several explanations could be at the basis for drug resistance. AEDs could be affected by the biochemical milieu of the peri-tumoral space.

Furthermore significant interactions between AEDs and other drugs (*i.e.*, chemoterapeutics) may decrease antiepileptic effectiveness, while increasing side effects interfering with the hepatic cytochrome P450 system. Furthermore AEDs resistance might result from over expression of multi-drug resistance-related proteins (MRPs) in tumors (particularly in capillary endothelial cells and astrocytes), which restrict the penetration of lipophilic substances into the pathologic tissue[10].

### *EEG features*

Usually interictal EEG shows spikes and/or, sharp waves, sometimes intermixed with slow activities; in some instances normal EEG have been reported. These abnormalities, in preoperative EEG are commonly lateralized to the tumor side, less often to the correct lobe. However, Morris *et al*[39] (1998) reported that the occurrence of interictal EEG abnormalities and ictal EEG onset in correspondence of the site of the tumor may not be predictive of seizure outcome; indeed, in some cases a post-operative poor seizure outcome has been reported in patients with EEG interictal and ictal findings perfectly concordant with tumor location. On the other hand, also patients with EEG slow or epileptiform abnormalities distant from the tumor site or with ictal EEG onset non-localized or widespread to a whole hemisphere improved regarding seizure outcome after tumor resection[39]. In temporal lobe GNT, long-term video-EEG monitoring may allow recording of seizures and identification of the epileptogenic zone; indeed, several data suggest that in mesial temporal lobe GNT a tailored resection that include, besides the tumor, the epileptogenic area as defined by the anatomic and electroclinical correlations performed on the ictal video-EEG data, provides better post-operative seizure outcome as compared to simple lesionectomy[36,45,61,92,93]. In cases of undetermined lateralization of seizure focus, invasive EEG investigations may provide useful information, although in GNT-associated focal epilepsy the main goal of intracerebral recordings is usually to map eloquent cortex in proximity of the neoplasm. Several reports focused on prediction

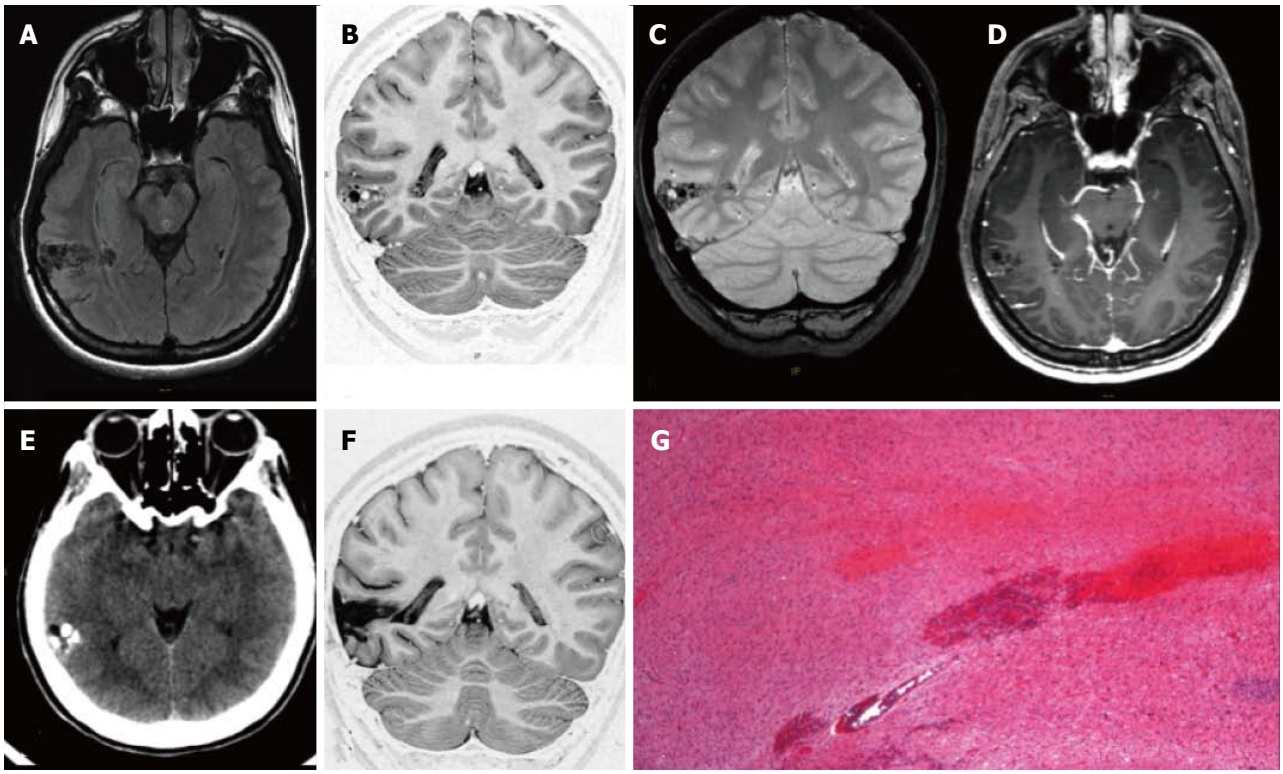

**Figure 1 Ganglioglioma World Health Organization grade I of the right posterior middle temporal gyrus.** Axial FLAIR T2-w (A) and coronal IR T1-w (B) images show inhomogeneous cortical-subcortical mass extending within the deep white matter and reaching the ependymal layer. The tumor presents a combination of solid, cystic and calcified components. The latter is better identified on coronal T2*-w sequence (C). Post-contrast axial T1-w image (D) shows no pathological enhancement and axial CT scan (E) confirms the calcified component. Coronal IR T1-w image (F) demonstrates lesion resec-tion; G: Histological examination evidences a biphasic neoplastic population, with neu-ronal and glial elements.

of poor postoperative outcome by identifying ECoG spike discharge patterns in FCD and the persistence of seizure patterns or continuous epileptiform discharges in post-resection ECoG recordings . There are little evidences about the ECoG discharge patterns in patients with GNTs because of the small numbers of patients investigated[89,93,94]. Different disorders (LEAT and FCD) may have similar electrocorticographic abnormalities probably due to the common developmental origin. In these cases have been observed continuous spiking (more often in FCD), bursts, and recruiting discharges. When continuous spiking is found in GNT, it is likely to be due to associated dysplastic regions with a high neuronal density[45,93]. A recent study employed MEG to investigate possible differences in whole brain topology of epileptic glioma patients, comparing them to patients with non-glial lesions and healthy controls. LGG patients showed decreased network synchronizability compared to healthy controls in the theta frequency range (4-8 Hz), similar to patients with non glial lesions. Network characteristics are associated with clinical presentation (seizure frequency in LGG), and with poorer cognitive performance (both low grade and high grade glioma) suggesting that histology could partly determine differences in epileptogenesis and epileptic probably due to differences in cortical plasticity. Interestingly, it would seem that low grade glioma and non tumoral lesions have a decreased synchronizability that could predispose to a high occurrence of seizures and cognitive decline.

## IMAGING

### *Gangliogliomas and gangliocytoma*

The differentation between GG and gangliocytoma (GC) is mainly based on histology. They may have variable tumour size (2-3 cm) and a typical location at the periphery of cerebral hemispheres. There is usually little associated mass effect and peripheral vasogenic edema and superficial lesions may expand cortex and remodel bone.

The MR signal of GG is variable and inhomogeneous due to the presence of a combination of solid, cystic and calcified components[46,95] (Figures 1-4).

Calcifcations can be more conspicuous as areas of hypointensity on T2* gradient echo weighted images, or even more evident at unenhanced CT (Figure 1E).

Medium contrast enhancement could be variable: nodular, intense and homogenous (Figure 3E); "ringlike" appearance (Figure 4C) but also nonenhancing (Figure 1D). Although extremely rare GG may show focal leptomeningeal involvement (Figure 4C).

### *Dysembryoplastic neuroepithelial tumor*

DNET are well-demarcated, wedge shaped, multinodular, "bubbly" intracortical tumors often similar to other LGG.

DNET may show a multicystic morphology more

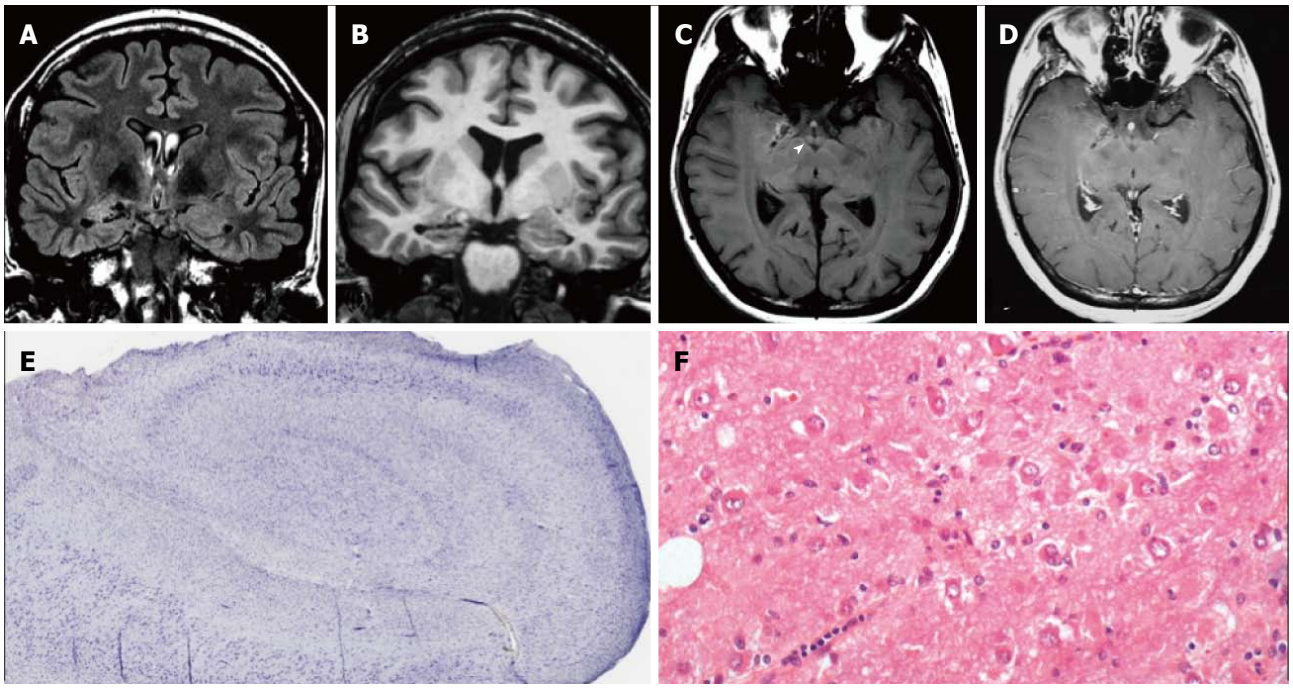

**Figure 2 Gangliocytoma and Mesial Temporal Sclerosis MTS (dual pathology).** Coronal Flair T2 (A) and T1-w images (B) demonstrate a right hippocampal atrophy with signal hyperintensity on FLAIR. The ipsilateral temporal horn is dilated. Axial T1-w pre- (C) and post-contrast injection (D) show a non-enhancing multicystic lesion with calcification near the optic tract. The right mammillary body is atrophic (arrowhead); E: Neoplastic ganglion cells exhibit disorganized clusters and show abnormal cytologic features; F: Hippocampal specimen displays ILAE hippocampal sclerosis type 1, with severe pyramidal cell loss in both CA1, CA3 and CA4 sectors.

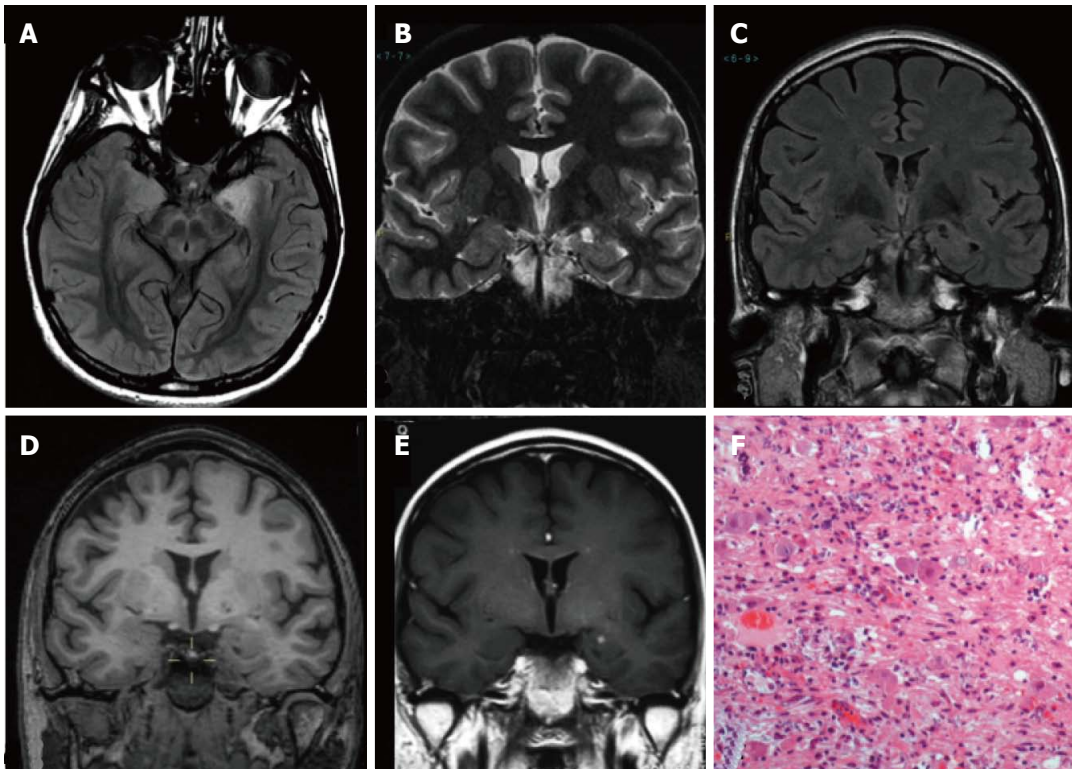

**Figure 3 Ganglioglioma World Health Organization grade I of the left temporo-mesial cortex.** The tumor shows heterogeneous cortical-subcortical high signal on axial proton density weighted image (A). It appears partially cystic on coronal IR T1 (B) FLAIR T2 (C), T1 (D) weighted sequences. Post-contast T1-w image displays nodular, intense and homogenous enhancement (E). Low-magnification view shows a vaguely lobulated, hypocellular vascularized neoplasia, with scattered lymphocytic infiltrates (F).

frequently than GG. Absent or very slow increase in size over time is typical of DNET, and recurrence is also extremely rare. Contrast enhancement could be found in about 30% of cases.

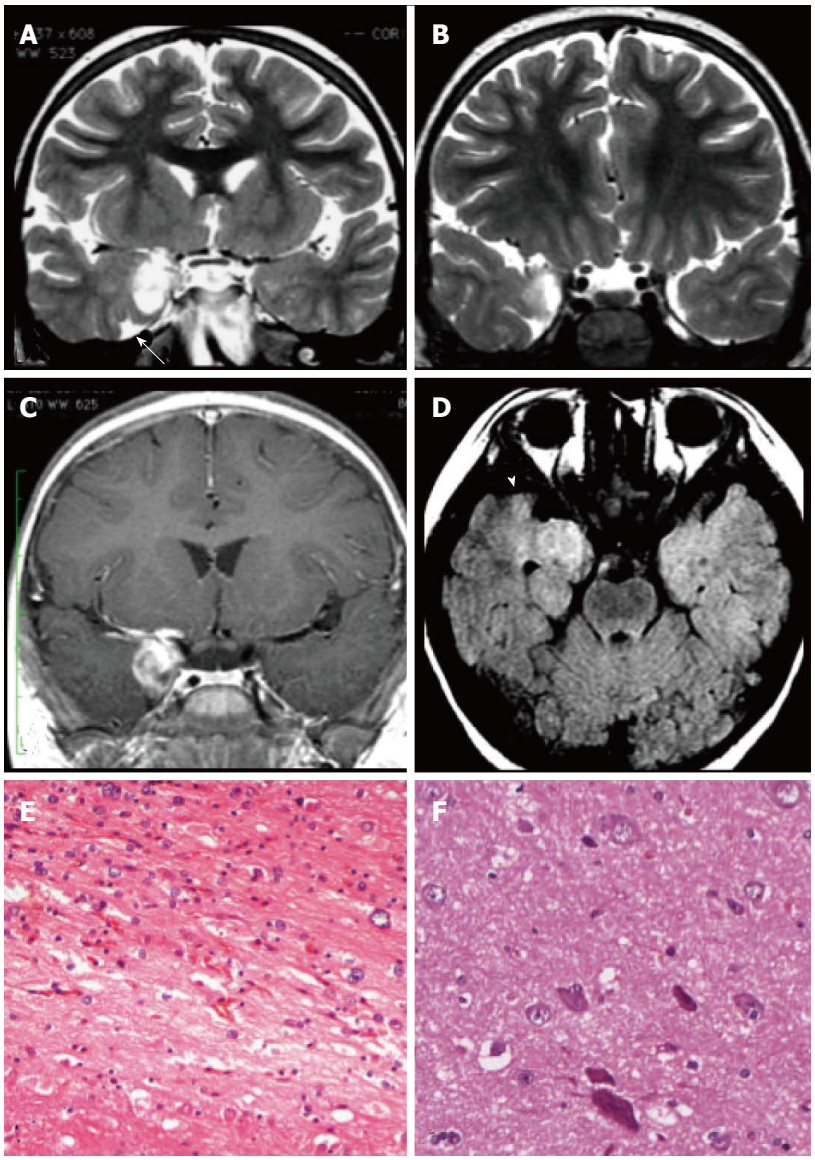

**Figure 4 Ganglioglioma and associated focal cortical dysplasia IIa.** Coronal FSE T2-w (A, B) demonstrate a temporo-mesial heterogeneously hyperintense lesion. Post-contrast coronal T1-w (C) shows enhancement of the tumor and adjacent leptomeninges. A signal abnormality extending from the surface of the ventricle to the pole (arrowheads in D) and adjacent anomalous sulci (arrow in A) were suspicious for FCD, subsequently histologically confirmed. Microscopy evidenced a tumor composed of ganglion cells intimately intermixed with astrocytic elements (E) and focal cortical dysplasia with dysmorphic neurons (FCD Type IIa) (F).

On CT scan the tumor appears as a cortical-subcortical hypoattenuating mass with sporadic calcifications. Scalloping of the adjacent inner table of the skull may also be present. At MR imaging, DNET most commonly manifest as pseudocystic, multinodular cortical masses that are hypointense on T1-weighted images and hyperintense on T2-weighted images with minimal or without mass effect and surrounding vasogenic edema (Figures 5 and 6).

Some lesions may expand involving cortical gyri and, producing a soap bubble appearance at the cortical margin. (Figures 5 and 6).

### *Pleomorphic Xanthoastrocytoma*

PXA classically, although not specifically, appear as cystic supratentorial mass containing a mural nodule and involvong cortex and adjacent leptomeninges[96]. PXA is usually a circumscribed and slow growing lesion, that rarely recurs; size and morphology are variable.

At unenhanced CT the tumor appears as a hypo or isoattenuating mass. Calcifications are rare. On MRI T1-WI PXA are usually hypo to isointense displaying inhomogenous, mainly iso-hyperintense, signal intensity on T2-weighted sequences. Peritumoral edema is relatively uncommon. They usually enhance after gadolinium injection (Figure 7). Leptomeninges contrast enhcement is highly characteristic[97].

### *Extraventricular neurocytoma*

Extraventricular neurocytoma may be difficult to differentiate from other types of low-grade tumor, such as GGs or DNET. It could be a well circumscribed, heterogeneous and variably enhancing mass. CT and MRI aspects depend on the cellularity and degree of calcification. They may have peritumoral oedema and intralesional cyst but rarely intralesional bleeding[29,98,99].

### *Pilocytic astrocytoma*

Pilocytic astrocytomas are the most common form of glioma in childhood and most frequently manifest in the first two decades of life[100]. They may arise anywhere within the neuraxis, but among the pediatric population

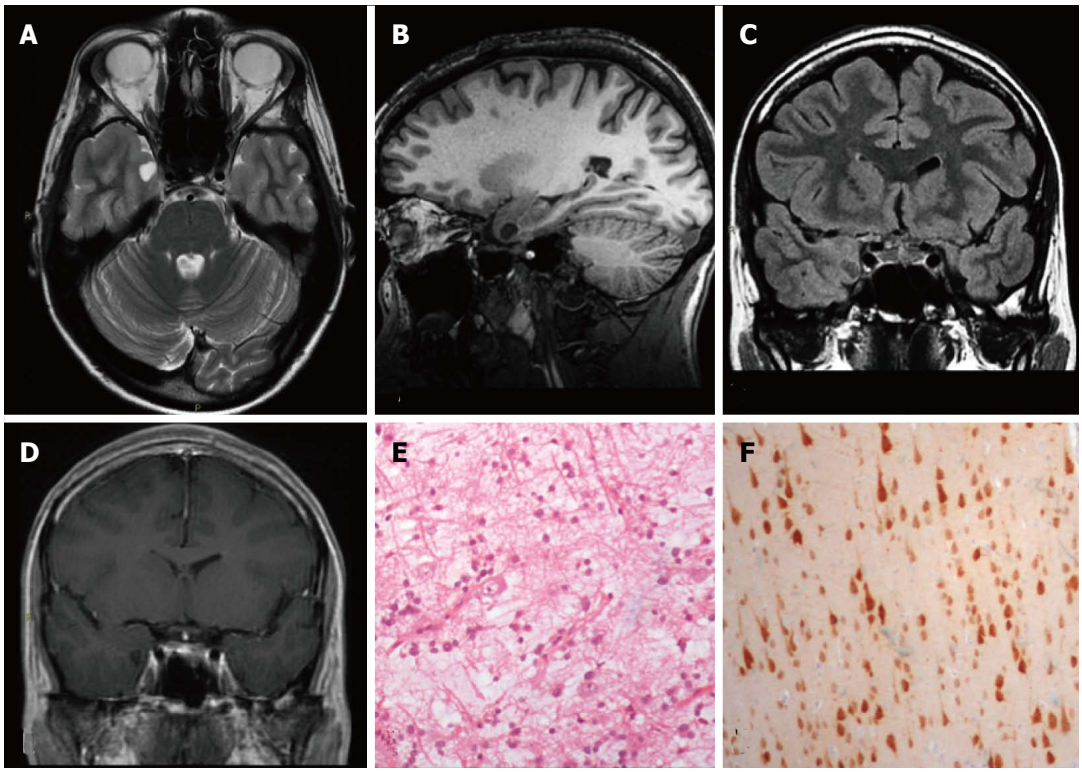

**Figure 5 DNET of the right uncus.** Axial T2-w (A) and sagittal 3D T1-w (B) reveal a cystic cortical mass well-demarcated, without perilesional oedema or mass effect. On coronal FLAIR T2-w image (C) the tumor is variably hypo- and isointense. Post-contrast axial T1-w sequence (D) shows no enhancement. Histological examination shows a tu-mor characterized by the "specific glioneuronal element", typical of DNET, (E), while the cortex adjacent to the tumor displays cortical lamination abnormalities compatible with FCD type IIIb (F); the latter was not depicted at MR study.

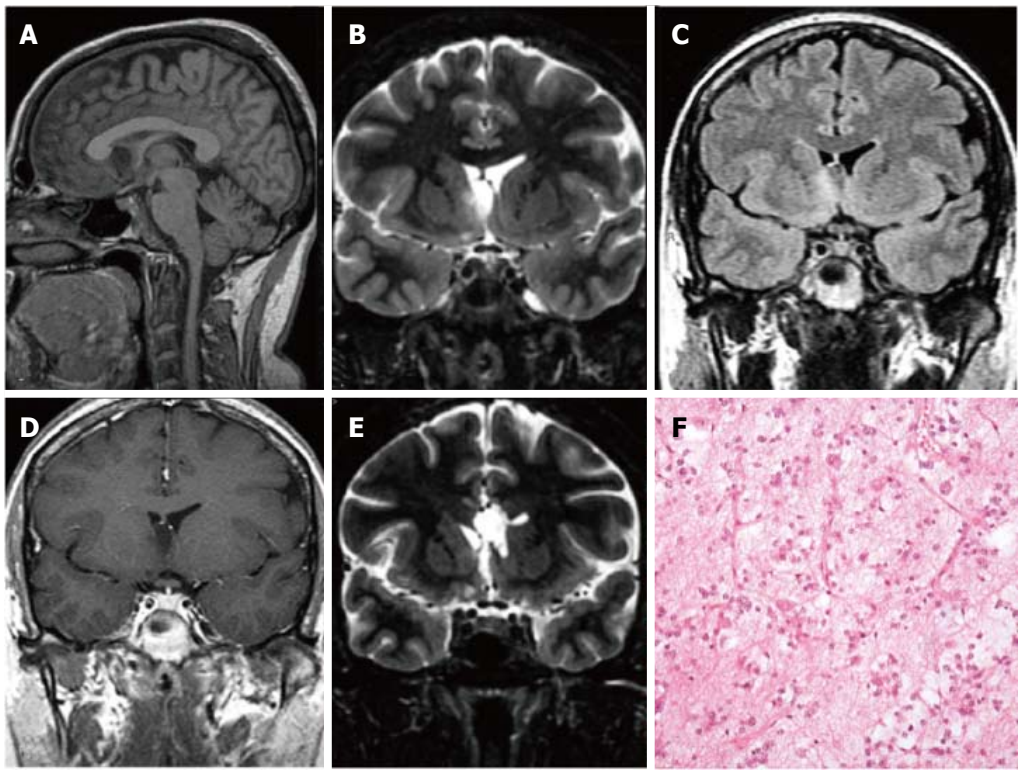

**Figure 6 Extra temporal DNET.** Sagittal 3D T1 (A) coronal IR T1 (B) and FLAIR T2-w (C) demonstrate a cystic wedge-shaped lesion in the right fronto-orbital gyrus. On FLAIR T2-w the tumor is slightly hypointense with a faint hyperintense rim. On post contrast coronal T1-w images there is no enhancement uptake (D); E: Post-surgical scan on cor-onal IR T1-w; F: Microscopic study evidences the presence of floating neurons, a feature of DNET, in microcystic areas lined with oligo-like cells.

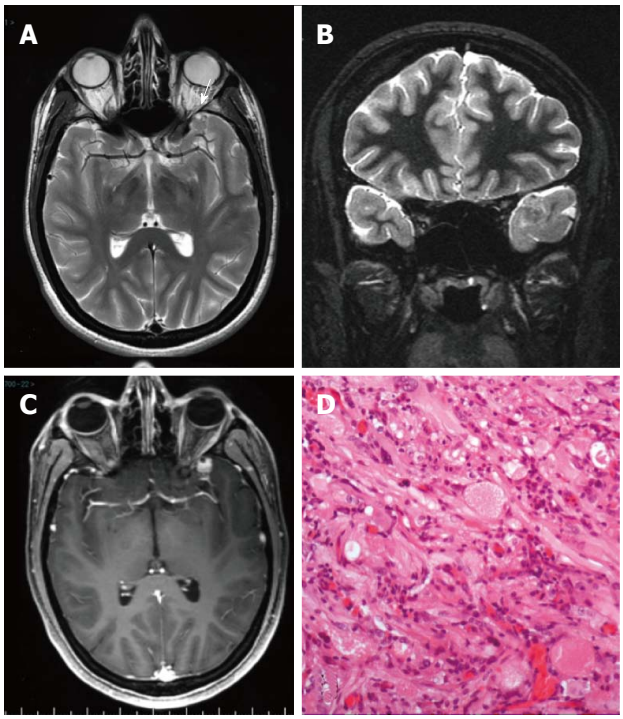

**Figure 7 Pleomorphic xanthoastrocytoma World Health Organization grade II.** Axial T2 w (A) and coronal IR T1-w (B) images show temporo-polar mixed signal intensity cortical mass with a small cystic component anteriorly (arrow in A). Post-contrast coronal SE T1w (C) shows a well-delineated, peripherally located enhancing nodule. (D) Microscopically the tumor is characterized by huge cytologic atypia, a vaguely fascicular arrangement and scattered eosinophilic granular bodies.

they are more frequently found infratentorially. Optic nerves, optic chiasm and hypothalamus, basal ganglia, and thalamus represent other common localtions. Cerebral hemispheres involvement has been less frequently described[100].

Pilocytic Astrocytomas are commonly characterized by fluid accumulation, with subsequent cyst formation and by mural nodule or a rim of tissue surrounding the cyst that enhances on post-contrast imaging. Predominantly solid mass lesions with minimal or no cyst have been described[101] (Figure 8).

Calcification may be seen in up to 25% of cases and haemorrhage has been reported. On MRI the solid portion of the neoplasm is typically isointense to hypointense on T1 weighted images and hyperintense on T2 weighted sequences to grey matter and it enhances after gadolinium chelates injection (Figure 8D). The signal intensity of the cystic portion is often not suppressed on FLAIR T2 weighted images due to its protein content.

MR spectroscopy reveals elevation in choline and reduction in NAA, with minimal elevation in lipid peak (Figure 8F). Lactate peak could be elevated, representing alteration in mitochondrial metabolism or variability in glucose uptake[102].

### *Diffuse astrocytoma*

Diffuse astrocytomas are diffusely infiltrating primary brain neoplasms of astrocytic origin that are classified as WHO grade Ⅱ.

Diffuse astrocytomas are usually at unenhanced CT iso to hypoattenuating lesions. They do not enhance on post-contrast imaging. Calcifications may be present in approximately 20%; cyst formation is rare.

MRI demonstrates astrocytomas as relatively homogenous mass involving and expanding more typically cerebral hemispheres cortex and adjacent white matter. The lesions are high in water content, thus appearing as hyperintense on T2 weighted images and hypo isointense on T1 weighted sequences. They usually lack peritumoral oedema (Figure 9).

Well differentiated Astrocytomas has a variable appearance after contrast agent administration, but usually shows no significant contrast enhancement (Figure 9C). In general, contrast enhancement is not recognized as a reliable indicator of the grade of infiltrative astrocytomas. MR perfusion imaging however seems to be more informative for distinguish low- and high-grade astrocytoma and for identifying low-grade lesions that could more likely behave aggressively[103].

On dynamic contrast enhanced T2* weighted MR perfusion imaging study rCBV is typically less than 1.75 (Figure 9D)[104].

MR Spectroscopy should display Cho elevation and NAA reduction. A High myo-inositol to Creatine ratio (Myo/Cre) in also present (Figure 9E)[105].

## FOCAL CORTICAL DYSPLASIA AND LEAT

LEAT and focal cortical dysplasia FCD are common findings in drug-resistant focal epilepsies, and frequently coexist[1,6,8,24,34,36,104,106-109].

Rarely MRI features of LEAT could be misinterpreted as FCD. Generally most important neuroradiological findings in FCD are increased cortical thickness, blurring of the cortical-white matter junction, increased signal on T2-W, a radially oriented linear or conical transmantle stripe of T2 hyperintensity, cortical thinning, and localized brain atrophy[34,110-112] (Figure 10).

Some limitations are encountered in the correct identification of different FCD types or subtypes[111-114]. A high number of false negatives is detected with FCD type I and slightly fewer with FCD type Ⅱa (about 50% sensitivity). FCD Ⅱb is much more easily identified (about 90% sensitivity)[112,113] (Figure 10).

Association between LEAT and FCD poses further issues into its correct identification. In a limited serie of patients with LEAT, who underwent surgery at our Institution associated FCD has been correctly identified in the majority of cases[113] (Figure 4). In a few cases peritumoral edema and neoplastic infiltration both caused subcortical white matter signal alterations, determining false positives (FP) and false negatives (FN) FCD results. Indeed, the signal abnormality is able to mimic a blurring, but it could hide a FCD contiguous to the tumour (Figure 11).

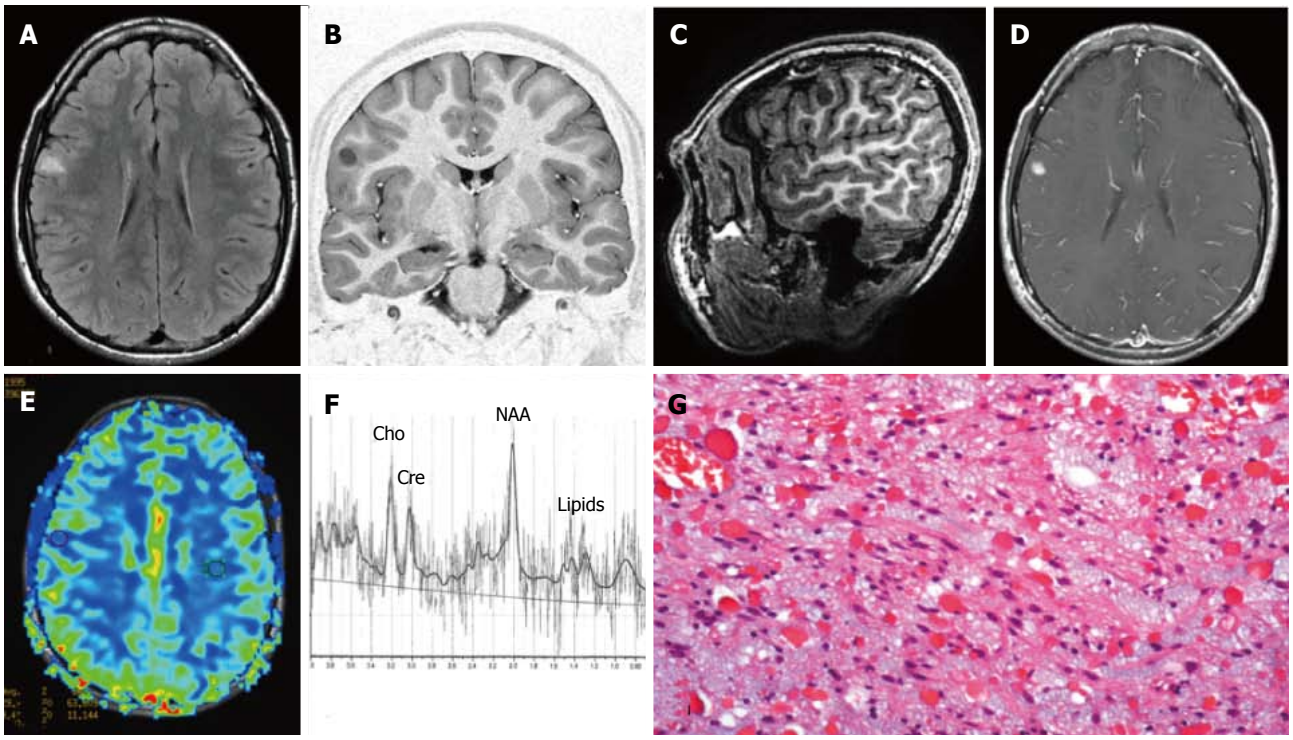

**Figure 8 Pilocytic astrocytoma World Health Organization grade I of the right frontal lobe.** Axial FLAIR T2-w (A) and coronal IR T1-w (B) images show a cortical-subcortical lesion, with cystic component, with minimal mass effect. The tumor appears well de-marcated (C) on 3D sagittal sequence and displays nodular and homogeneous en-hancement on post-contrast axial T1-w images (D). Perfusion study doesn't show any rCBV increase within the lesion (E). MR Spectroscopy (MRS) study (F) reveals elevation in choline and reduction in NAA. (G) Histological examination shows a tumor com-posed of areas rich in myxoid material, elongated glial elements with uniform nuclei and numerous eosinophilic granular bodies.

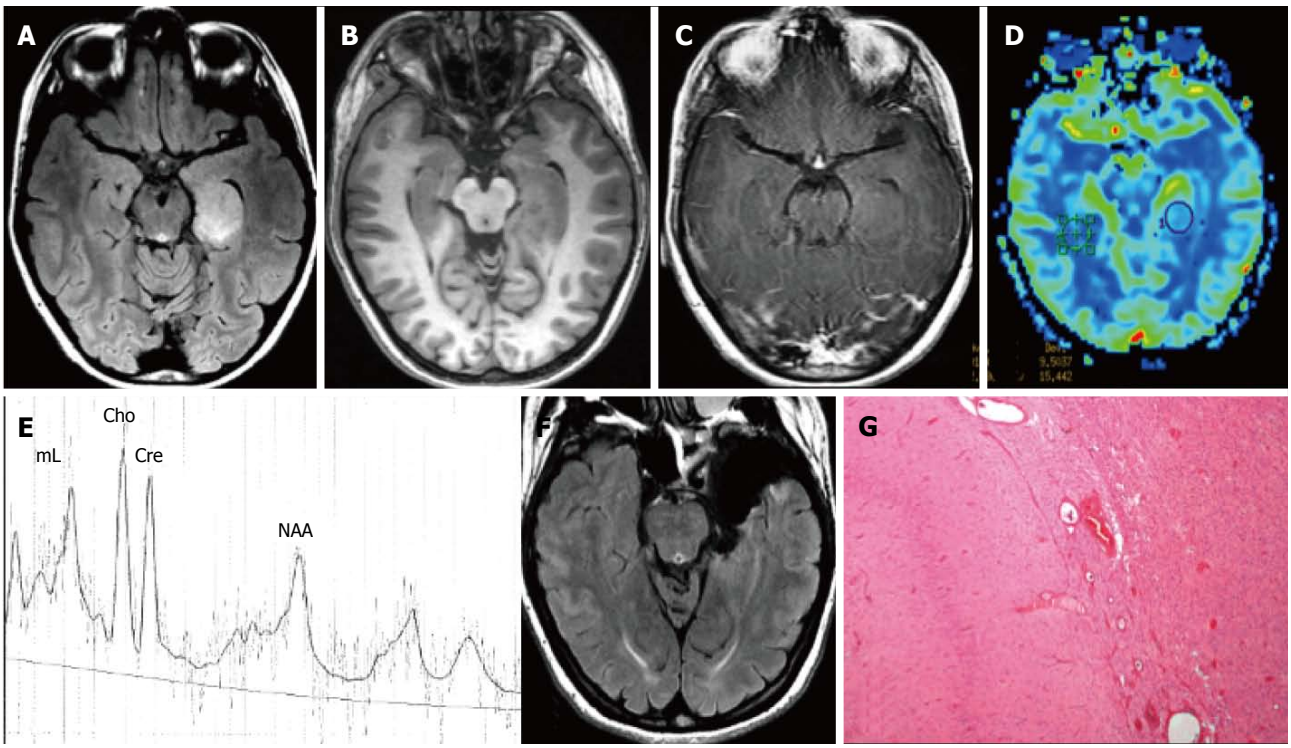

**Figure 9 Temporo-mesial astrocytoma World Health Organization grade II.** Axial FLAIR T2-w (A) shows a left temporal hyperintense mass, involving mainly the hippocampus. The lesion is slightly hypointense on T1-w image (B) and does not demonstrate enhancement after gadolinium injection (C). Perfusion study reveals no significant rCBV increase (D). MRS study shows a faint NAA reduction, a slight Cho elevation and high mI, expression of low grade glioma (E). Postsurgical axial FLAIR T2-w (F). (G) This histological picture exhibits in the left side a portion of hippocampus and in the right side an infiltrating astrocytoma, composed of fibrillary elements with varying degree of hypercellularity.

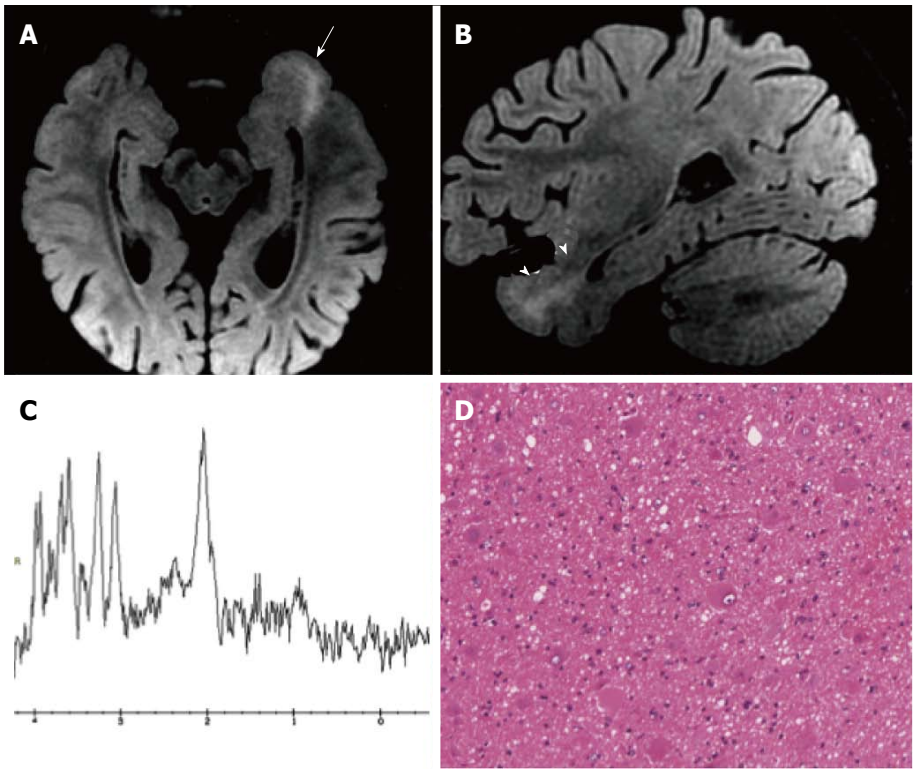

**Figure 10 Focal cortical dysplasia with balloon cells (Taylor).** Axial (A) and sagittal (B) reformatted fat-saturated 3D FLAIR images show a left temporo-mesial cortical thicken-ing (arrow) and white matter tapering to the temporal horn of the lateral ventricle (arrowheads). MR spectroscopy shows normal metabolite concentrations (C). (D) Histol-ogy demonstrates the presence of typical balloon cells, showing large and opalescent glassy eosinophilic cytoplasm.

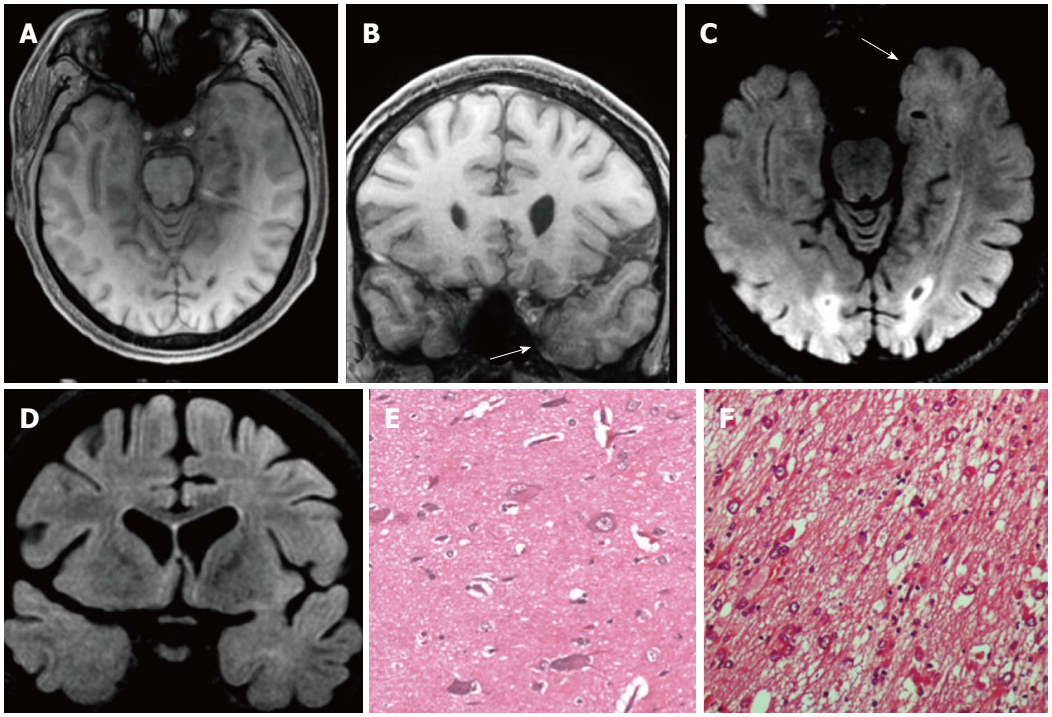

**Figure 11 Gangliogliomas World Health Organization grade I of the left temporo-mesial region and focal cortical dysplasia IIa subtype associated.** Axial and coronal T1-w images (A-B) show thickening of amygdala and uncus (arrow in B). Axial and coronal FLAIR T2-w images (C-D) present blurring and adjacent subcortical high signal abnormality compatible with a focal cortical dysplasia (FCD). Microscopy evidenced a glioneuronal tumor, with scattered binucleated ganglion cells, compatible with a gan-glioglioma (E) and dysmorphic neurons in the adjacent cortex (FCD Type IIa) (F).

These limitations were more evident when tumour size is larger (Figure 12). MRI sensibility can be reduced

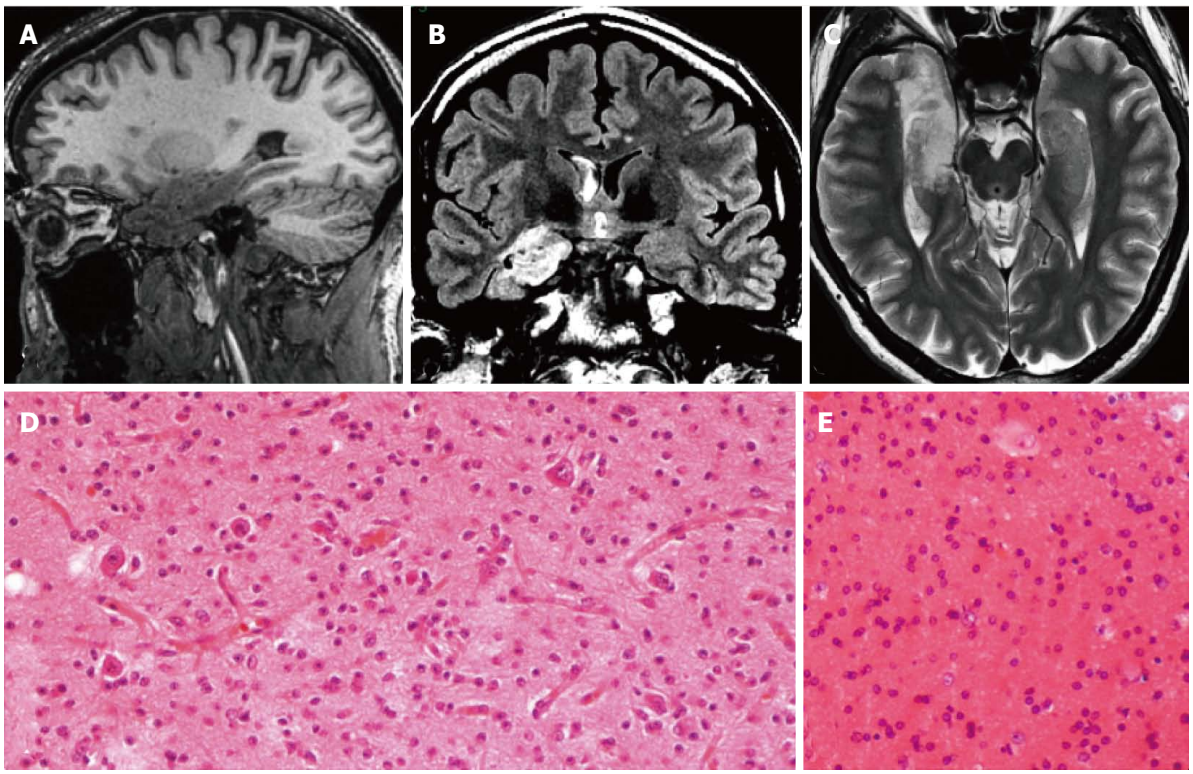

**Figure 12 Gangliogliomas and focal cortical dysplasia IIa.** Sagittal 3D T1-w (A), coronal FLAIR T2-w (B) and axial T2-w (C) reveal an inhomogeneous mass, involving the right hippocampus and the temporal pole. Due to the size of the tumor, the associated dysplasia is not clearly visible. Histological examination demonstrates the presence of a glioneuronal tumor with small ganglion cells in a desmoplastic stroma (D) and of dysmorphic neurons in the adjacent cortex (focal cortical dysplasia Type IIa) (E).

by an incomplete protocol too.

## MOLECULAR ASPECT OF LEAT

The following molecular markers may facilitate differential diagnosis of LEAT: (1) IDH1 and IDH2 mutations: common in low grade diffuse gliomas (70%-80%), while they are generally not present in PA and GNT[115]; (2) LOH 1p/19q: constitutes the keystone in diagnosis of oligodendrogliomas (> 70% of tumors), while it has not been detected in DNT, a useful difference in those cases in which histological aspects do not permit a conclusive diagnosis[116]; and (3) BRAF V600E mutations: frequently found in PXA, GG and PA, whereas diffuse grade Ⅱ gliomas harbor only rarely these mutations[117].

As recently observed these BRAF-mutant grade Ⅱ diffuse gliomas seem to present with refractory seizures and frequently are located within the temporal lobe.It as been proposed that BRAF mutations could be strictly linked to epileptogenesis[118].

Interestingly we found that BRAF mutations could be present in the FCD associated with LEAT, suggesting a pathogenetic role of BRAF mutations in cyto-architectural dysplasia and in the tumorigenesis of LEAT[109].

## SURGICAL STRATEGIES FOR LEAT

Epilepsies associated to LEAT are usually unsatisfactorily controlled by antiepileptic drugs, whereas excellent results can be achieved by surgery[4,5,26,28,42,65,92,119]. Various surgical approaches have been adopted for the radical resection of these tumors. The choice of surgical approach is also related to the goal of surgical strategy.

The surgical strategy may be directed only to oncological issues and/or to resolve epilepsy. In this last condition we must have an epilepsy surgery oriented approach.

A non-invasive presurgical study and neuropsycological assessment**,** may define the extension of the epileptogenic zone and may address the choice of the better surgical strategy to optimise seizure control (lesionectomy or tailored resection)[24,26,28,36,120].

Rarely in the setting of epilepsy associated tumor may be necessary an invasive presurgical study (using subdural grid, depth electrodes, or stereo-EEG)[24,64,121-123]. LEAT are certainly the prototype of cases where epilepsy is the main problem. However, in recent years, even in cases where the main problem is oncological, it is becoming equally important trying to preserve brain functions and to best cure even epilepsy (especially when tumors involve mesiotemporal structures, the insular lobe, or the central area) in order to improve the quality of life[15,63,64,124].

Several authors analyzed epileptological outcome according to surgical treatment in tumor-related chronic epilepsy. While some argue that lesionectomy alone is enough for good seizure control others say that the best manage-

ment should include additional resection of epileptogenic zones adjacent to the tumor[26,28,36,39,40,44,62,119,120,125,126].

In Epilepsy-associated tumors it reaches a special meaning for the epileptogenicity and surgical strategies, the site of the lesion, *i.e.*, temporal, mesio-temporal (or limbic), temporo-lateral, paralimbic, extratemporal, eloquent areas[8,26,28,36,40,44,45,56,63,119,125,126].

Regarding limbic and paralimbic system, the role of hippocampus in the epilepsy network is pivotal since that could play a pivotal role in epileptogenesis even without obvious neuroradiological and pathological changes (*i.e.*, hippocampal sclerosis)[26,28,36,61,64,127].

The limbic system consists of the following elements, which are all directly or indirectly interconnected: the temporo-mesial structures (hippocampus, the parahippocampus,giryus) and the cingulate gyrus[58,60,61,128]. The paralimbic system is composed of 3 independent anatomical parts: the orbitofrontal cortex, the temporopolar cortex, and the insula[58,60,128]. The limbic system is connected *via* the entorhinal cortex and the uncinate fasciculus to the paralimbic system. In the setting of low-grade tumors associated with epilepsy WHO Grade Ⅱ gliomas are mainly found in the paralimbic system while glioneuronal tumors are found in the limbic system (temporomesial structures)[8,57].

LEAT are frequently associated with type Ⅰ or type Ⅱ a cortical dysplasia which, in contrast to focal cortical dysplasia type Ⅱb, are more difficult to identify with MRI[1,8,24,36,109,111,113]. It means that the anatomical structural lesion can be larger than what have been detected by MRI[110,113].

For this reason the target of the surgical resection should be the epileptogenic zone defined according to neuroradiological, clinical, neurophysiological and neuropsycological findings[40,129].

In case of LEAT located near or in eloquent area, the surgical approach is usually directed only to the anatomical structural lesion. Regarding the more frequent site of these tumors, *i.e.*, the temporal lobe, several approach have been used. The surgical strategy used in temporal lobe tumors includes lesionectomy, extended lesionectomy, tailored resection, anterior temporal lobectomy.

The majority of authors agree that lesionectomy alone provides the best seizure outcome results in LEAT located in the extratemporal and temporo-lateral site[40,42,44] while its results for temporomesial lesions are questionable[5,8,26,28,40]. Some authors suggested that the involvement of temporo-mesial regions may extend and make more complex the epileptogenic zone.

For this reason the amount of tissue removed in temporomesial surgeries is considered crucial to gain good postoperative results[5,8,60,62,63,65,125,130,131].

One important and persistent problem are the conflicting needs of the necessary extent of resection and the avoidance of neuropsychological deficits[126,131,132].

## SEIZURE OUTCOME

Focal epilepsy associated with LEAT and particularly GG and DNT shows the best seizure outcome after surgery[5,18,28,36,92,95,119,132-134]. Some authors observed improvement of seizure outcome in young patients whereas others found no correlation with age at the time of surgery[4,28,38,132].

A recent literature meta-analysis about epileptogenic gangliogliomas in adult showed that an early surgical intervention of less than 3 years from the onset of seizure is significantly associated with improved seizure control[90].

Several studies reported that lesionectomy plus temporal tailored resection seems to offer the best results for seizure outcome[8,24,26,28,36,40]. Several authors insist that the the temporal pole has a pivotal role in epileptogenesis in temporomesial epilepsy[130,135,136].

The higher effectiveness of an extended resection beyond the LEAT might depend on the frequent association of this tumor type with other epileptogenic pathologies, such as the spectrum of cortical dysplasias that might represent the origin of a widespread epileptic network[8,24,34,36,68].

The new class FCD Type Ⅲb, which includes cases with abnormal cortical layering associated with a glial or glioneuronal tumor, has been introduced by the ILAE classification[34].

However in light of the frequent association of FCD Type Ⅱ with LEAT and the immunohistochemical evidence of a common pathogenesis linking LEAT and FCD Type Ⅱ[8,24,36,105], the possibility of creating a unifying class also for this kind of FCD should be considered.

With respect to oncological behavior, LEAT are usually indolent WHO Grade I lesions, although several reports have demonstrated that gangliogliomas may potentially have an evolving course and may demonstrate malignant transformation[33,40,70]. Pleomorphic xanthoastrocytoma can carry a higher risk of early recurrence when it is characterized by numerous mitoses and/or necrosis[137-139].

## CONCLUSION

We believe that the adjective "long-term" included in the acronym LEAT could be prospectively confusing or misleading. Nowadays patients with LEAT are operated 5 years earlier compared to mid 1990s (mean of 7.4 years *vs* 12.9 years, respectively)[1,2].

The further increase in knowledge and a better recognition of these lesions among the scientific community (neurologists, epileptologists, neuropediatrics, neuroradiologists, epilepsy surgeons, neuropathologists) will lead to modify the present concept of "pharmacoresistance" *vs* a "tailored concept" of pharmacoresistance related to the underliyng pathology submitting many more patients to an early surgical treatment[107,132,140].

As a pathology-based approach to epilepsy surgery will be increasingly adopted[2,28,36,107,132,140,141] an early surgical treatment will become unavoidable.

In the near future this prototype of "surgically reme-

diable cause of epilepsy" will be properly operated early, irrespective of the concept of pharmacoresistance, making the adjective "long-term" obsolete and not appropriated.

An early surgical strategy can achieve various aims, namely to obtain a definite diagnosis, to contrast epilepsy progression (including psychosocial consequences and/or adverse effects of pharmacological treatment) and even to prevent the risk, present although uncommon, of tumor growth and malignant transformation. In addition, early surgery may reduce the risk of sudden unexplained death (SUDEP) or seizure-related injuries.

Such predictable future approach will modify the clinical history of these patients, and features of epilepsy as "chronic" or "long term", nowadays adopted in the definition of epilepsy-associated tumors, will loose sense. Neurophysiological aspects together with a proper histological and molecular characterization will become increasingly necessary for an accurate diagnosis of these epileptomas[25,34,85,142].

Therefore, what characterizes and makes up special for this group of tumors it is not the "chronic" or "long term" epilepsy history, but their pathological-biological features (*i.e.*, sharing of immunopositivity for CD34 and of BRAF (V600E) mutation[109,143].

## Abstract

The aim of this article was to analyze the theories underpinning dental fear, anxiety and phobias. To be included, articles must have been published between the years of 1949 and 2013 concerning fears and phobias within dentistry and/or psychiatry. Of 200 articles originally under review, 140 were included and reviewed by the authors.Five specific pathways relating to dental fear and anxiety were identified; Cognitive Conditioning, Informative, Visual Vicarious, Verbal Threat, and Parental. Eight currently accepted management techniques across all dental disciplines for dental fear and anxiety were identified. Further research is required to identify clinical diagnosis and treatment for fears originating from different pathways.

**Key words:** Dentistry; Fear and anxiety; Phobia; Origin; Therapies and management

**Core tip:** (1) 5 pathways to the origin of dental fear and anxiety have been identified in this review: Cognitive Conditioning, Informative, Visual Vicarious, Verbal Threat, and Parental; (2) Development of fear and anxiety may be unique for each individual, with patients often associating fear to a combination of factors (Pathways); and (3) Management of fear and anxiety should include an understanding of the origins of dental fear.

## INTRODUCTION

Odontophobia (dental fear) is a "unique phobia with special psychosomatic components that impact on the dental health of the odontophobic persons"[1]. For some individuals, dental fear may be so great that normal life is impaired. In these instances, the individual experiences fear or anxiety that is out of proportion to the actual danger present in the situation. This often leads to avoidance behavior, and clinically significant levels of distress or impaired functioning[2]. Such avoidance behavior is well known by any dentist who has treated patients with high levels of dental fear before. In Australia, people with higher levels of dental fear tend to avoid the dentist and have irregular attendance records, usually only seeking treatment when symptomatic[3,4]. This data is consistent with other studies that noted that, although patients booked appointments, they did not keep their appointment or prematurely cancelled their appointments out of

fear[5-12].

The incidence of dental fear and anxiety appears to be relatively consistent throughout the world, with some sub-groups reporting higher levels than others. An Australian study reported that 16.1% of individuals experienced high levels of dental fear, where adults between the ages of 40 and 64 years reported a higher incidence of dental fear, and females of any age were reportedly more afraid of the dentist than males were[4]. Of note, people from low socioeconomic status (SES) groups reported a generally higher level of dental fear than those individuals from high SES groups[4]. The reported incidence of high dental fear and anxiety was a little lower in an Icelandic study, at only 10%[11], but slightly higher in a Singaporean population, at 17.1%[12]. A cross-cultural study of Chinese and Danish patients reported moderate to high dental fear in 30% of Chinese and 15% of Danish participants[10]. In 2009, a study of dental fear prevalence in 1959 Netherlands reported 24.3% of the participants had moderate to high dental fear[13]. Dental fear studies on German populations have reported a mean Dental Anxiety Score (DAS) of 8.6[14] and a dental phobia incidence of 11%[15]. The highest prevalence of dental fear appears to be in Japan, where a study of 3041 students and adults reported that 42.1% had high dental fear[16].

The overall effect of dental fear and anxiety appears to be multifaceted, such that the individual not only avoids their dental appointments but also tends to have worse oral health[17]. The extent to which this is a causal relationship is unknown. An understanding of the factors underlying the etiology and maintenance of dental anxiety may assist dentists and researchers in developing interventions designed to reduce dental avoidance behaviors. In turn, this will contribute to improvements in oral health. Mehrstedt *et al*[18] (2004) noted that dental fears were negatively linked to quality of life with respect to psychological well-being, social functioning, and vitality. This finding indicates that the link between dental fear and perceived negative quality of life is multifaceted. Some early Scandinavian studies reported on the malicious circle of dental anxiety and fear, whereby fear and avoidance lead to premature cancellation of dental appointments and further worsening of oral health conditions[2,6,19,20]. A qualitative study by Moore *et al*[21] (2004) reported on the contributing role that embarrassment plays in dental phobia. Among other things, these researchers analyzed the social powerlessness associated with the embarrassment that arises from poor oral health. In this study, the authors concluded that patients may be so embarrassed by their poor oral health/hygiene that they avoid seeing the dentist out of fear of being reproached[1,21]. Understanding the extremely complex psychology of dental fear is essential in the prevention and treatment of dental anxiety, fear and phobias[21].

In order to understanding the extremely complex psychology of dental fear it is essential to understanding possible pathways of dental fear and anxiety. This study identified relevant studies using Medline Database (Medline/PubMed). The search covered the period 1900 to 2014, including only articles written in English. Search terms included "dental fear and anxiety," "cognitive," "informative," "verbal threat," "vicarious," "parental," and "origin of fear." A total of 300 references were retrieved from the database search. Only articles directly relating to the management, origin of fear, and dental fear theories were evaluated to understand the pathways of fear and anxiety in dentistry. Of the three hundred retrieved references, only 137 related to fear and anxiety in dentistry, however only 10 related specifically to origins of fear and anxiety in dentistry. The aim of this review is to highlight the possible pathways of fear and anxiety in dentistry and not to analysis the actual experience of fear and anxiety.

## ETIOLOGY OF GENERAL FEAR AND ANXIETY

Processes known to contribute to the etiology of dental fear and phobia include a variety of genetic, behavioral, and cognitive factors. An individual's dental fear/phobia is likely to have been created by involving a multitude of factors.

### *Genetic vulnerability*

Individuals with specific phobias, including odontophobia, may have inherited genetic vulnerability factors that predispose them to anxiety in general or certain phobias specifically. While individuals with dental phobia do not directly inherit the phobia itself, genetic vulnerability factors may interact with other etiological elements that cause the phobia[22,23]. Controversy over the reliability of phylogenetic origin of fear arises in relation to a study of 173 Swedish twins, which reported that whilst "phenotypic correlations were moderate," they were found to be counterintuitive to the electrophysical skin conductance response (SCR)[23]. In summary, it has been suggested that although genetics can predict some factors related to dental fear, it appears to be distally and not strongly related to the actual development of phobic symptom[24-26].

### *Negative affectivity/anxiety vulnerability*

Negative affectivity refers to a vulnerability to experiencing negative emotional states. Negative affectivity appears to be a stable personality trait that predisposes individuals to a range of psychological disorders, including phobias[27]. The relationship between negative affectivity and dental phobia has not yet been established.

### *Preparedness*

Through the process of natural selection, individuals who readily acquired fear and avoidance responses to genuinely dangerous situations (*e.g.*, dangerous animals, storms, heights, small spaces, *etc.*) have passed on this tendency to their progeny[28]. As such, the human species is "prepared" to more readily acquire fear reactions to stimuli that may have posed a genuine danger to our ancestors[28,29]. Dental

phobia may be part of an evolutionarily beneficial tendency to protect the body envelope from intrusion by foreign (non-nutritional) objects.

### Cognitive conditioning (pavlovian)

Classical (or pavlovian) conditioning refers to the process by which a previously neutral stimulus acquires the ability to directly elicit a response through pairing this stimulus with another unconditioned stimulus (US) that elicits the same response[30-33]. For example, an individual who experiences a painful procedure (and the unconditioned response of anxiety/fear) during a dental visit may acquire a conditioned association between the dentist (the conditioned stimulus) and anxiety/fear (the conditioned response)[34-37]. Re-presentation of the conditioned stimulus (the dentist or related stimuli) is then able to elicit the conditioned response of anxiety during the patient's next dental consultation.

### Operant conditioning

Operant conditioning refers to a process whereby the frequency of a particular behavior ("operant") is modified through the consequences that follow the behavior. Certain behaviors may be "reinforced" (*i.e.*, increased in frequency) through their association with positive consequences ("positive reinforcement") or through the removal of negative consequences ("negative reinforcement")[30,34,35,38,39]. Alternatively, behaviors may be "punished" (*i.e.*, reduced in frequency) if they lead to negative consequences ("positive punishment") or the removal of positive consequences ("negative punishment")[38]. For phobias, the process of positive punishment (*e.g.*, pain and anxiety that occurs during a visit to the dentist) and negative reinforcement (*e.g.*, the reduction in anxiety that results when the individual avoids the dentist) are thought to be most important, and these comprise Mowrer's two-factor model of phobia acquisition and maintenance[40].

### Vicarious

In addition to direct contributors to phobia acquisition, Rachman[41] (1978) proposes that individuals may also acquire phobic responses indirectly. One such pathway has been called vicarious experience or vicarious conditioning. In vicarious conditioning, the individual acquires a fear response through seeing the fearful experience of others. In dental phobia, for example, a child who observes a fear response of a parent attending the dentist may learn indirectly that the situation poses a significant threat.

### Verbal threat

Rachman[36] (1977) proposed a second indirect pathway to phobia acquisition referred to as "verbal transmission". In this process, the individual acquires a fear or phobia through learning about the dangerousness of a situation from others without observing it directly[36]. In dental phobia, for example, an individual may hear stories from others about traumatic or painful experiences that they have had during dental treatment, which may lead to a learned fear of dental procedures[42].

### Cognitive content

There are a range of cognitions that have been identified as important in the acquisition and maintenance of anxiety disorders, including specific phobias. These include a set of ideas about the probability (*e.g.*, "If I go to the dentist it will definitely be painful") and severity (*e.g.*, "If I go to the dentist the pain will be excruciating") of negative outcomes[43]. Additionally, individuals may hold beliefs about their inability to cope in the face of an aversive outcome (*e.g.*, "If I am in pain at the dentist, it will be unbearable")[44].

### Cognitive biases

In addition to the content of cognition, phobias are associated with biases in the process of cognition[43]. For example, individuals with anxiety disorders such as phobias are known to have memory biases in which memories of threat-consistent experiences and information are more readily retrieved[45]. Although the link between cognitive bias and dental fear and anxiety is plausible, no research has yet been done to confirm this.

## CURRENT KNOWLEDGE OF DENTAL FEAR: WHAT WE KNOW RIGHT NOW

Current literature on dental fear is limited relative to other fields. Specifically, most of our understanding surrounding dental fear is based on results from two meta-analyses; one of which focuses on adults, while the other on children and adolescents.

In a meta-analysis of 32 articles on dental behavior management problems, Klingberg *et al*[46] (2007) reported that children and adolescents were expected to experience mild fear and anxiety. This fear and anxiety only becomes a concern if it is "disproportionate to the actual threat and daily functioning becomes impaired", a definition very similar to the DSM-IV. However, this research also noted that the third criterion for dental phobia (recognition that the fear is unreasonable or excessive) does not always apply to children. This is a reasonable argument, as coping with pain and anxiety requires a high level of cognitive function and self-control that a young child might not have yet developed. However, one must attempt to separate general fearfulness (an anxiety-related personality trait) from a specific fear because both are capable of presenting as an acute fear reaction (*e.g.*, screaming at the sight of a drill). This distinction can be difficult to make if the parent-child relationship is synergistically inflating the dental fear. Research demonstrates that the dental fear of a child who is 8 years or younger is significantly related to the dental fear of the parent[47]. However, in children older than 8, the relationship is less clear. In addition, it was noted that girls presented as more anxious and harder to manage than boys, sup-

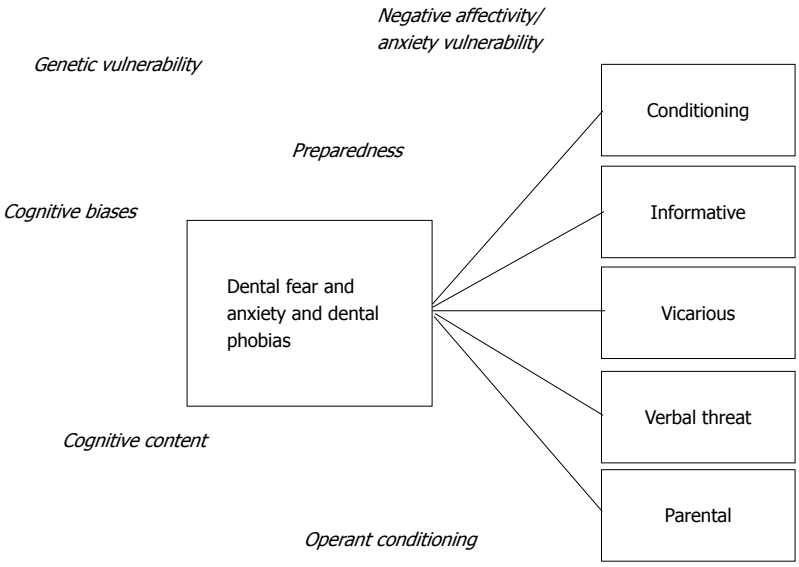

**Figure 1 Pathways of fear in dentistry with background influences.**

porting the current accepted relationship between anxiety disorders and gender in children and adolescents[48]. However, particular fears changed as the child grew older, such that one-year-old had separation anxiety but primary school children had more social anxieties, demonstrating a positive development of metacognition. Also, younger children were more likely to have more fears of higher intensity. However, there is inconclusive evidence regarding the origin of fear among children and adolescents due to the gap in the literature examining this cohort. In their review, Klingberg *et al* (2007) did, however, agree on 3 distinct, yet commonly occurring causes for dental fear in children (not including neuropsychiatric disorders): (1) Some children's past "negative experiences with dental care" was the origin of their dental behavior management problems; (2) Other children were "genetically prone to react with fear…to threatening situations"; and (3) Other children still reacted to frustrating demands (*e.g.*, sitting still) with anger[46].

The first represents direct trauma from treatment[36], while the second and third are officially undefined at present and require further investigation. It must be noted that parental dental fear has an effect on the child' s dental fear[47,49]. Making it an important part of the conceptualization of an individual's dental phobia.

With regard to adults, it is generally accepted that the patient developed fear either due to personal trauma from a dental treatment or because of some form of psychological disorder or constitutional vulnerability. Yet, few studies analyze the actual pathway or origin of fear adults experience with regard to dental fear. However, it is possible that some of these origins may apply directly to dental fear[50] (Figure 1). Originally Watson *et al*[33] (1920) and Rachman[41] (1978) purported that specific fears were condition-based, vicarious, or based on information learning. Between the 1920s and 1970s, these theories dominated the discipline of fear and anxiety management and diagnosis. In 1970, Seligman proposed that mankind is prepared by evolution to associate certain situations (previously encountered by ancestors) with particular outcomes, and thus the mind reacts to these situations by instigating fear (See Figure 1: Preparedness framework)[51]. In 2001, Mineka *et al*[28,52] suggested that the amygdala and hippocampus were responsible creating generalized fear responses. Analogous to this and supporting Seligman's theory, Poulton *et al*[53,54] (2002) posited that evolutionarily associated fears can manifest without a stimulus. Among these theories, the associative and non-associative theories are the most distinctive. Menzies *et al*[55,56] (1993a) first described the associative theory in relation to water phobia, where fears occur in response to a bad experience (CS), while non-associative fears are innate (US). In addition, Muris *et al*[57] posited that parental modeling contributes to the fearfulness found in children. Here, the trait anxiety was related to that of both parents (Mother: $r = 0.34$, $P < 0.05$, Father: $r = 0.31$, $P < 0.05$), but the act of being fearful was only related to mother's fearfulness ($r = 0.56$, $P < 0.001$)[57]. Klingberg *et al*[58] also supported the notion of maternal dental fear impacting the development of dental fear in children.

Of these theories, there are 5 pathways that are thought to specifically relate to dental fear and anxiety: Cognitive Conditioning, Vicarious, Verbal Threat, Informative, and Parental (Figure 1). These five pathways are discussed further in this article but it is important to note that a single or a combination of background factors disused in the etiology of general fear and anxiety may affect these pathways.

### *Conditioning pathway*

Conditioning is a process where the participant learns through personal experience that the event or stimulus heralds a detrimental outcome[50,59]. Pioneers in early conditioning research Watson *et al*[60] (1917) who theorized that in infancy there are limited emotional reaction patterns (*e.g.*, fear, rage, love) and that there must be some stimuli which are associated with these. Watson *et al*[33] (1920) then performed experimental work on an infant,

analyzing directly conditioned emotional responses. Their results showed that the non-fear-inducing stimuli elicited a fearful emotional response when the fear-inducing and non-fear-inducing stimuli were shown together, and when the non-fear-inducing stimuli was shown on its own later[33]. In 1927, Pavlov[32] published his seminal paper on "Conditioned Reflexes," which perhaps represents the first in-depth and detailed experiment on the development of conditioning. Pavlov[32] identified that animals can learn to associate a conditioned stimuli with a new non-conditioned stimuli so that the non-conditioned stimuli causes a conditioned response. Here, the animals (dogs) began to associate food and salivating with the sound of a bell. Thus, anytime the bell sounded, the dogs salivated[32]. In a similar attempt to replicate physiological responses during fear, Rachman[41] (1978) then successfully demonstrated that physiological responses, such as sweating and increased heart rate, occur when individuals experience fear. Such responses are evident in odontophobic patients, where heart rate, breathing, and sweating all increase due to fear associated with dental environments and dental stimuli[19,61-63]. In addition, many individuals report painful past experiences being the cause for their subsequent dental fear[44,64-66]. Researchers[67] have indeed found a "strong direct relationship between severity of trauma-related symptomatology and severity of dental anxiety where the shared variance was 38%"[67]. Thus, it can be proposed that the majority of dental fears are reactions to stressful experiences that provoke anxiety in the individual[36,68-70]. In summary, the conditioning pathway appears to be the most commonly utilized pathway by patients.

### Informative pathway

The informative pathway is another indirect pathway for fear acquisition, which does not require the presence of an unconditioned stimulus. As far back as 1977, Rachman discussed the relevance of the informative pathway in so much as child-rearing involved information giving[36]. Rachman[36] noted that the instructional process of child rearing may lead to biases for commonly encountered fears. Such a dynamic could help explain childhood dental anxiety, where children learn to fear the dental environment from dental phobic elders, negative connotations advertised by media (*e.g.,* television, movies), and friends with personal negative experiences.

### Vicarious pathway

The vicarious pathway is an indirect pathway for fear acquisition that does not require the presence of an unconditioned stimulus. It has been acknowledged in the literature that people with extreme dental fear avoid the dentist[3,4,17,33,71-78]. In a recent Australian study using Armfield's Index of Dental Anxiety and Fear (IDAF), it was found that participants who indicated extreme dental fear were marginally more likely not to undertake an oral examination, here females exhibited significantly higher dental fear than males[4,71]. Whether this fear is purely conditioned or vicarious is not yet fully understood[76]. Conceivably, one of the most renowned contributions to the theory of "vicarious conditioning in phobia acquisition"[50] was by a pair of researchers[38,52,79] whose experiments provided convincing evidence that fear can be learned vicariously[36,69,80]. By utilizing this vicarious pathway, it is plausible to suggest that vicarious learning could be contributing to pediatric fears, whereby expressions of fear by elders at the dentist in front of children leads to fear acquisition in the children[81,82].

### Verbal threat pathway

The verbal threat pathway presents another indirect pathway for fear acquisition that does not require the presence of an unconditioned stimulus. To explain the origin of a fear that is not seen or experienced, it is essential to understand the "*emotion*" of fear. Research[83] has suggested that emotions arise because of three factors: verbal cognition, behavior changes, and physiological states. This "*emotion*" is known as the "tripartite," and appears to govern onset and origin of fears generated by the verbal threat pathway[83-87]. Many articles examining the effects that "word of mouth" information has upon children and acquisition of fear[81,82,84-86,88-97] note that children become fearful of a stimulus or situation when they hear or read that it may be dangerous. To control for bias, all studies were done on medically healthy children, aged 6-13 years. The majority of participants (88.9%) demonstrated that self-reported fears increase as children were given violent/dangerous/threatening information about a particular stimulus, irrespective of its actual threat[85,86,92-94]. Simultaneously, it has been found that giving positive information results in a decrease in children's self-reported fear[89,91]. Similar research on children ages 7-9 years found that when given verbal information about a "monster, "children's fear-beliefs changed. However, these fear-beliefs only changed when information came from an adult[96]. In short, one interpretation of the verbal threat pathway is that fear is induced when an authority figure threatens an individual with a painful experience. In the case of dental fear, painful and/or negative experiences are linked to dental visits. Although perhaps within strict psychological terminology the informative and verbal threat pathways are similar. Within odontophobia the two pathways differ in that the verbal threat pathway occurs when a "visit to the dentist" is literally used as a form of punishment for bad behavior. This does not occur in the informative pathway.

### Parental pathway

The parental modeling pathway presents another indirect pathway for fear acquisition that does not require an US. The concept of parental modeling is supported by research[69] demonstrating that in a sample of 40 children between the ages of 9 and 12 years, children's fear was positively related to their mother's dental fear. Specifically, mothers who expressed heightened levels of fear in front of their children were more likely to have fearful children.

Conversely, mothers who did not frequently express fear had less fearful children[69]. These findings are consistent with another study showing that most adults attributed the origin of their fears to informative and vicarious factors occurring in childhood (56% and 39%, respectively) more so than to cognitive model events (37%)[84]. Given that the majority of heightened levels of fear in some children was a consequence of an amalgamation of different learning dynamics[69], it has been suggested that "fear is more likely to develop as a result of synergistic effects of various sources or origins"[56]. However, one must note that any relationship between parent and child fears may also be due to the informative or vicarious pathways because they are all linked in some way. Again, strict psychological terminology may not necessarily differentiate between the parental and vicarious pathways. However within odontophobia individuals utilizing the parental pathway had their sole influence of odontophobia from their parents' expression of fear, whereas the vicarious pathway is multifaceted. Further investigation is needed to identify criteria for each pathway's application.

## MEASUREMENT INSTRUMENTS AND DIAGNOSTIC CATEGORIES OF DENTAL FEAR AND ANXIETY

### *Measures of dental anxiety (Pre-1990)*

The first widely accepted questionnaire for assessing dental fear was the Phobic Origins Questionnaire (POQ). Out of the 10 items, the first 9 required the participant to make a binary Yes/No response[98,99]. Following the POQ, a 16-item self-report questionnaire referred to as the Origins Questionnaire (OQ)[56,100] became popular. This measure also examined individuals' history in relation to their phobia[55,56]. However, as several studies have indicated[56,101-103], the POQ is inherently biased towards conditioning models. It was found that the POQ indicated conditioning was the primary origin for fear 56%-78% of the time, while the vicarious pathway accounted for 17%-42%[104]. Additionally, given that the control group for this research[99] consisted of only analogue cases of mild and low level fear by different researchers[77,105-107], it cannot be confirmed that this research represents the general populations' origins of fear. Numerous other researchers have criticized the POQ, noting that the authors wrongly systematized frightening stimuli to relate to the cognitive model origin, even though no unconditioned stimulus was described by participants[55,56,108,109]. Consequently, the construct validity and convergent validity of the POQ was found to be very poor[55,56,100,101,103,110,111].

### *Measures of dental anxiety (Post 1990)*

As dental fear can be difficult to define and measure effectively[103,109], research began to create a more practical, reliable, and theoretically efficacious dental fear measurement. Research found that the Index of Dental Anxiety and Fear (IDAF-4C+), developed by Jason Armfield presented strong statistically significant correlations with previous measures of dental fear (Corah's DAS, 1969). Armfield's reasoning for creating a new dental fear scale was due to problems with existing scales such as Kleinknecht's Dental Fear Survey (DFS, 1973), Stouthard's Dental Anxiety Inventory Short-Form (DAI-S, 1993), the Modified Dental Anxiety Scale (MDAS, 1995), and the Hierarchical Anxiety Questionnaire (HAQ, 1999). Problems associated with these measures were that they were too long, measured fear-related stimuli rather than fear itself, and had poor construct validity[71,77,112,113].

Consisting of 3 modules, each with 8 items, the IDAF-4C+ analyzes emotional, behavioral, physiological, and cognitive responses related to dental fear[66,113]. Each module uses a Likert scale ranging from 1-5, where 1 represents "strongly disagree" and 5 represents "strongly agree." Utilizing an exploratory analysis, "all items showed good internal consistency (Cronbach's alpha = 0.94) and test-retest reliability at 4 mo review ($r$ = 0.82)"[71,114]. With regard to phobia diagnoses, positive results were found with regard to the convergent and predictive validity of the IDAF-4C+ when compared to Corah's DAS, $Eta^2$ = 0.154 and 0.060, respectively[71].

### *Diagnostic categories of dental fear*

Individuals who are classified as "dentally anxious," tend not to have qualities that can be catalogued. As such, they differ in their origin of fear, specific fear stimulus, age of onset, as well as the bodily reactions and psychological reactions that manifest in response to fear-related stimuli. The etiology of dental fear is wide-ranging and can be attributed to personal traumatic experiences (conditioning)[38], threats of dental visits as punishment (verbal threat pathway)[86,93], and fear through observing pain in loved ones and others (vicarious pathway) to name a few[50,99,115,116]. Moreover, at times, dental fear has been shown to be part of a larger "set" of fears such as arachnophobia and claustrophobia, and fears of mutilation and suffocation. Consequently, there has been debate on whether dental anxiety is a "simple" CS, or a component of a "set" of fears and mood or anxiety disorders[117]. Previous and well documented research has described these two variations of dental fear as exogenous and endogenous[118].

A group of researchers, well known for their clinical experience, developed a richer, more detailed classification system for dental fear. Their system, known as the Seattle System, mirrored the origin and the main stimuli of fear surrounding dental anxiety and phobias[116]. Essentially, the Seattle System can be used to classify individuals with respect to the severity of the psychological phobia relative to dentistry and the dentist as a person, based on a range of mean scores that represent different levels of dental fear. These mean scores have been applied to a number of questionnaires [*i.e.*, DAS, Fear Survey Schedule II (FSSII), Spielberger Trait Anxiety Index (STA), Anxiety Sensitivity Index (ASI), Emotional Control Questionnaire (ECQ), General Health Question-

naire (GHQ), Fear of Pain Scale (FPS), and Mutilation Questionnaire (MQ)]. The Seattle System consists of four diagnostic elements: (1) simple CS of specific dental stimuli; (2) anxiety about somatic reactions during dental treatment; (3) patients with a generalized anxiety state and multi-phobic symptoms; and (4) distrust of dental personnel[116,119]. Despite the fact that the classification was originally designed for pragmatic academic purposes, it has shown to hold some evidence of psychologically valid identifications of dental anxiety subtypes[19]. Of note is the qualitative evaluation component of the Seattle System, which consists of in-depth interviews that give a more thorough understanding of the true multiphobic nature that dental fear can present with[19]. Indeed, subjects with type 4 Seattle fear were further split into 3 subgroups, which met the criteria for distinct uniqueness, internal consistency, and distinct response to treatment type as proposed by earlier researchers[120].

Roughly comparable results were reported three years later utilizing the DSM-III-TR criteria for simple dental phobia (code 300.29-Specific phobia)[121]. However, although the results did not support the theory that the Seattle System corresponds to the DSM-III-TR, as proposed three years earlier[19], the researchers proposed that dentally anxious subjects should be calibrated for fear using a distinct method that differs from that for psychiatric mood and personality disorders[121]. Then, just before the turn of the century, newly published research brought to light some intriguing facts regarding the Seattle System[119]. Here, it was proposed that the Seattle System was valid from a psychological perspective in addition to being a well-rounded tool for clinical diagnosis (Table 1). Accordingly, they discovered that some participants in the older age brackets were of type 3 fear (Seattle System), indicating that those with simple phobias are able to recover in time, while those individuals with more complex multiphasic conditions may require psychological treatment[119].

## CURRENT MANAGEMENT TECHNIQUES FOR DENTAL FEAR AND ANXIETY (CBT)

With regard to treatment of dental fear and anxiety, there a number of possible avenues to explore with patients, including pre-treatment anxiety questionnaires, cognitive behavioral therapy (CBT), relaxation therapy, computer-assisted relaxation learning (CARL), hypnotherapy (HT), group therapy (GT), individual systematic desensitization (ISD), pharmacological, flooding (implosion), and swallowing relaxation. These forms of treatment are essentially a form of counter conditioning to reverse the fear into a state of acceptance and calm.

### *Pre-treatment anxiety questionnaires*

To date, only one study exists as to general dentists' use of pre-treatment anxiety questionnaires to assess patient anxiety before treatment. A study of United Kingdom dentists reported that only 20% of the dentists surveyed used adult anxiety questionnaires, and only 17% formally assessed children's levels of fear and anxiety[122]. Interestingly the study reported that when treating adults, male dentist used pre-treatment fear surveys more often than female dentist ($P < 0.05$)[122]. The authors believe that these pre-treatment surveys can help enhance patient care; however it would be interesting to evaluate the current utilization rate of these anxiety surveys and methods to encourage this practice.

### *Individual systematic desensitization and group therapy*

Individual systematic desensitization (ISD) is a behavioral therapy whereby individuals are gradually exposed or incrementally exposed to fearful stimuli. In this process, the individual must first identify and accept the fear-related stimulus; second, the individual must learn to employ a relaxation or coping technique; and finally, the individual must utilize the learned relaxation or coping strategy to react and overcome the fearful stimulus. In 2002, Moore *et al*[123] compared GT and ISD (as well as HT) and found that after 3 years, 65.5% of patients' with ISD and 69.6% with GT maintained dental appointments (although these results were not significant). In this work, the ISD was a combination of muscle relaxation therapy and video reel exposures (looped) of threatening dental situations and instruments with intermittent tension awareness training and breath control lessons. GT involved groups of patients meeting for seven 2-h sessions led by a dentist, dental assistant, and successful former patient. Video desensitization reels were also played and a final demonstration of injection and drilling was performed at the last session. Unfortunately, Moore *et al*[123] (2002) did not identify the origin of fear for the participants. Thus, the current results cannot be extrapolated to the pathways and further research is needed.

### *Flooding/implosion*

Flooding is a form of desensitization for treating phobias when the patient has a directly conditioned origin of fear (Origin 2). In flooding therapy, the patient is subjected to repeated exposure of fear-inducing stimuli until they no longer show a fear response, causing termination of the CR[124]. Implosion is used for either indirect conditioned or non-conditioned origins of fear (Origins 1 and 3) that may be imagined. However, the technique of flooding has not been examined in the literature since Mathews *et al*[125] in 1977. In this work, Mathews *et al*[126] report that among subjects who attended 2 or more flooding sessions, 48% successfully completed dental treatment 2 mo later. No further investigations appear to have been performed on this technique; this might be due to the highly anxiety-inducing nature of the treatment.

### *Cognitive behavioral therapy*

Cognitive behavioral therapy (CBT) is a psychotherapeutic approach to address dysfunctional emotions and negative behaviors and cognitions using a series of goal-oriented sessions. Davies *et al*[126] (2011) found that of 21

**Table 1 Seattle system diagnostic criteria for dental phobia**

| Fear type | Diagnostic Item | Classification of fear |
|---|---|---|
| Type 1 | Fear of dental procedures | Simple conditioned phobia |
| Type 2 | Fear of fainting, panic attack, heart attack | Fear of catastrophe |
| Type 3 | Nervous person in general | Generalized anxiety |
| Type 4 | Distrust of dentists | Fear of dentists |
| Subclass a | | →High fear of dental procedures |
| Subclass b | | →Generally anxious |
| Subclass c | | →Fearful of dental catastrophes |

patients offered CBT to overcome their dental fear as opposed to using sedation, 90% continued to be able to attend dental appointments without sedation ten years later. Current research appears to support CBT and relaxation therapy for treatment of directly conditioned fears (Origin 2)[127,128].

### Relaxation therapy

Relaxation therapy is a diverse set of practices aimed at eliciting a relaxation response, including a reduction in overall physical arousal symptoms. The phobic individual implements a particular mental relaxation technique (*e.g.*, slow breathing, counting, relaxation swallowing) to reduce stress. ten Berge *et al*[129] (2001) reported that parents play a more secondary role in treatment of child dental fear and anxiety. Results seem to suggest that CBT is more effective but should be combined with parental guidance in treatment of pediatric dental fear. Extrapolating this data, a combination of CBT and relaxation guidance may provide effective treatment of parental modeling dental fears (Origin 1).

### Computer-assisted relaxation learning

A recent development in the treatment of dental fear, computer-assisted relaxation learning (CARL) is a self-paced treatment for dental phobic individuals for treating needle phobia. The program begins by introducing its purpose, followed by activities and videos on how to cope with their fear. The program is based on the theory of systematic desensitization and in a recent study in 2013, researchers compared CARL to information pamphlets (control) in a block randomized study[130]. The authors reported that CARL significantly reduced self-reported general and injection-specific dental anxiety ($P < 0.001$)[131]. After the intervention, twice as many CARL participants (35.3%) *vs* controls (17.6%) were comfortable enough to receive an injection though not significant (12 of 34)[131]. Participants' origins of fear were not assessed, thus it cannot currently be determined which pathways were involved, and further research is required. However, as CARL is self-paced, it may perhaps aid in treating patients who wish to learn to cope without therapists, thereby improving access to oral health care.

### Hypnotherapy

Perhaps one of the least understood treatments for dental fear is hypnotherapy (HT). HT attempts to create a state of unconscious change, whereby the individual forms new responses, attitudes, and behaviors to previously feared stimuli. Few studies have analyzed the clinical effectiveness of hypnotherapy. In 1995, research reported that when compared to psychophysiological therapies such as CBT, HT did not significantly reduce dental fear[132]. Researchers purported that this was because some people were put off by the concept of hypnotherapy and were not fully receptive to the therapy[132]. Some years later, Moore *et al*[123] (2002) found that although 54.5% of HT patients were able to maintain regular dental appointments, at 3 years post treatment, there was no difference between the HT, GT, or ISD groups.

### Pharmacological

The use of nitrous oxide (NO) and benzodiazepines in dentistry has long been employed to reduce anxiety. NO has often been compared to the effectiveness of CBT and relaxation therapies. For example, Willumsen *et al*[133] (2001) reported no significant differences between NO and CBT or applied relaxation therapy. They suggested that in the short term, either treatment was effective. Interestingly the study reported a 95% of participants attended rate a year later, with the greatest reduction in dental fear observed in the relaxation therapy group[130]. While all groups reported normal levels of dental fear (as per Corah's DAS) one year later[130], analysis of benzodiazepines when combined with ISD did not reduce overall therapy time and was not advantageous for treating injection phobia[134]. The studies did note that the results might have been skewed by the fact that each participant's dental fear might have different origins. Thus, research is required to determine whether certain origins of fear and pathways are more receptive to pharmacological agents than others are.

## CONCLUSION

The present article has highlighted the possible types of dental fear, their origins in dentistry and current knowledge on management of patient with fear and anxiety. There is, however, a lack of knowledge of the effects of demographics, causal factors, ethnicity, and treatment modalities relative to the origin and pathways of fear in dentistry. Understanding, the origin of a patient's fears and anxiety could help enhance patient management and care.

## Abstract

Despite the low incidence, squamous cell carcinoma (SCC) remains the most common scrotal malignancy with a propensity for recurrence and metastasis. In recent years there has been a significant change in the epidemiology of scrotal SCC. Surgery is the mainstay of treatment for resectable disease. Sentinel lymph node dissection adapted from experience with penile SCC can reduce the morbidity of routine lymph node dissection. Emerging treatments for advanced and metastatic SCC are at the cusp of significantly changing management of this disease. We have performed a comprehensive review of scrotal SCC with a focus on these topics.

**Key words:** Squamous cell carcinoma; Genital cancer; Scrotal cancer

**Core tip:** Scrotal squamous cell carcinoma (SCC) although rare, represents one of the most common forms of scrotal malignancy. The epidemiology of SCC has changed over time and iatrogenic conditions (psoralens and ultraviolet A radiation, immunosuppression, *etc.*) and human papilloma virus infection play a significant role as associated conditions. Surgery is the cornerstone of treatment and primary excision with a risk stratified approach for staging and treatment of regional lymph node is advisable. Sentinel lymph node biopsy can mitigate the morbidities of unwarranted inguinal lymph node dissection in selected cases. For locally advanced and metastatic disease palliative chemotherapy is advocated. Targeted therapies might hold promise for management of advanced SCC.

## INTRODUCTION

Squamous cell carcinoma (SCC) is the most common scrotal malignancy[1,2]. Despite awareness and removal of occupational carcinogens over the last century, after initial reduction in incidence, scrotal SCC has maintained a steady incidence rate. Due to significant associated morbidity and mortality it remains an important urogenital malignancy for the urologist. Our aim was to review recent published literature on scrotal SCC and highlight changing epidemiology as well as emerging therapies.

## HISTORICAL BACKGROUND

The earliest accounts of scrotal SCC date back to the Persian nomads who used to transport pots of burning coal between their legs to keep warm as they travelled[3]. The first clinical descriptions of cases occurring were by Bassius and Treyling in the mid 1700s, with Treyling describing a case in a Cavalryman[4]. Sir Percival Potts in 1775 was the first to link the chronic lodgment of soot in the rugal folds of the scrotum occurring in chimney sweeps to development of scrotal SCC[5-7]. It hence became known as the first described occupational disease. The active carcinogen discovered later was 3,4-benzpyrene. Occupational scrotal SCC was also later described in association with other occupations with chronic carcinogen exposure including cotton mule spinners, paraffin and tar workers, creosote workers, shale oil workers, lathe workers, pitch workers and machine tool setters and operators[4,8-12]. More recently it has been described in car mechanics, car and airplane manufacture, gas workers, engineers, steel manufacture and aluminum workers[11,13-15]. The majority of occupationally related scrotal SCC can be attributed to exposure to carcinogenic polycyclic aromatic hydrocarbons[10].

## EPIDEMIOLOGY

In order to assess recent trends in the epidemiology of scrotal SCC, we examined all clinical studies published on scrotal SCC since the year 2000.

There were six case series published including two Surveillance Epidemiology, and End Results (SEER) based analyses, one Netherlands Cancer Registry (NCR) based analysis, one prospective multi-institutional study and two retrospective studies[1,2,16-19].

Studies in the mid-to-late 1900s reported that scrotal SCC accounting for the majority (80%-100%) of all scrotal malignancies but in more recent reports it only accounts for one-third of all scrotal malignancies[1,2,16,20,21]. However scrotal SCC still remains the most common scrotal malignancy[1,2,16]. Other scrotal malignancies include extramammary Paget's disease (EMPD), sarcoma, basal cell carcinoma, melanoma, Bowen's disease (SCCIS) and adnexal skin tumors. Median age at diagnosis ranges from 52-57 years[1,18,19]. Most cases occur in Caucasian men followed by Black and Asian men and other ethnicities.

Verhoeven *et al*[1] reported the age-standardized 5-year incidence rate of all histologic types of scrotal cancer in the Netherlands and this varied between 0.9 and 1.8 per 1000000 male person-years from 1986 to 2006 with no statistically significant change over time[1]. Age-standardized incidence rate of scrotal SCC varied between 0.34 and 0.44 per 1000000 male person-years from 1986 to 2006. Over a similar time period Wright *et al*[2] reported on the age-adjusted incidence rate of scrotal cancer in the United states which increased from 0.49 per 1000000 persons in 1973 to 0.95 per 1000000 persons in 2002. While specific incidence rate of scrotal SCC was not provided they did report no change in incidence rates by histologic type[2]. The incidence reported from the Connecticut Tumor registry data from 1935 to 1979 showed stable incidence rates of all scrotal malignancies and epithelial scrotal malignancies[22]. It has been speculated that the reason for this sustained incidence despite occupation carcinogen avoidance has been the emergence of new risk factors such as phototherapy for the treatment of skin diseases and human papilloma virus (HPV).

Johnson *et al*[16] reported on the largest SEER series of scrotal squamous cell carcinoma with 269 patients focusing on histologic subtypes. They categorized scrotal SCC, melanoma and adnexal skin tumors as high-risk scrotal cancer and scrotal basal cell carcinoma, EMPD and sarcoma as low-risk based on median overall survival of 118 mo for the high-risk group and 166 mo for the low-risk group[16]. Survival for scrotal SCC was 115 mo (range 97-133), which was the second lowest with lowest being adnexal skin tumors with median overall survival of 114 mo[16]. Wright *et al*[2] reported statistically significant worse survival for those with SCC than for those with other histologic types. SCC comprised 35% of all scrotal tumors in whites compared to 69% in blacks[2]. Dutch researchers reported 77% 5-year survival for scrotal SCC[1].

In early 1990s, Goldolf *et al*[23] reported that the incidence of scrotal SCC despite increase in the rates of UV exposure through sunbeds and sunlamps has not changed. However psoralens and ultraviolet A radiation (PUVA) used for the treatment of psoriasis and other inflammatory skin diseases has been implicated with the development of scrotal SCC[24,25]. In 1990 Stern reported on a prospective 12.3 year study in 892 men who had undergone ultraviolet radiation as part of their psoriasis treatment, out of which 14 developed genital tumors including 5 patients who developed 9 invasive scrotal SCC and one scrotal SCC in situ (SCCIS)[26]. They found that patients with high dose PUVA had 286 times the risk of the general population to develop invasive genital SCC, low dose PUVA had 16.3 times the risk and high dose UVB was associated with 4.6 times elevation of the risk[26]. Authors recommended genital protection for men undergoing UV radiation for treatment of skin diseases.

Increasing incidence of oropharyngeal SCC has been attributed to increasing prevalence of oral mucosal HPV[27,28]. HPV viral oncoproteins E5, E6 and E7 have an important role in carcinogenesis with p53 tumor suppressor gene and Rb oncogene being the major targets[29]. HPV infection in scrotal SCC has only been reported in a few case reports or small series[18,30-33]. Andrews *et al*[32] reported a total of 6 (42.9%) out of 14 cases were associated with HPV.

Matoso *et al*[18] reported on 29 patients with scrotal SCC and found high-risk HPV in 7 cases (24.1%) assessed by *in-situ* hybridization. These authors also reported p16 positivity and elevated Ki67 in HPV positive scrotal SCC. These cases were also more likely to display a basaloid or

warty morphology. They suggested p16 stain to be used for screening for HPV infection with addition of Ki67 in cases with equivocal p16. If indeed the true proportion of HPV associated scrotal SCC lies between 24%-42% as in these small series, it has important implications for preventive therapy with the availability of HPV vaccines.

Chronic mechanical irritation has been associated with scrotal SCC. Long-term rubber urinal use[34], topical nitrogen mustard[35] and coal tar[36] have been reported to be associated with scrotal SCC. Initially scrotal SCC was thought to be uncommon among non-Caucasian ethnicities however subsequent reports in Africans, African Americans and other ethnicities including Chinese refuted this hypothesis[37,38].

Both preceding and subsequent increased malignancy risk has been described in patients with scrotal SCC[39]. Verhoeven reported 18% of patients with scrotal malignancy developed one or more tumors after the scrotal tumor with lung cancer, skin SCC and second scrotal tumor being the most common second malignancy[1].

## DIAGNOSIS

The most common presentation of scrotal SCC is of an erythematous scrotal nodule or plaque[40]. Ulceration and pruritus often accompany the lesion. It occurs most commonly in the left scrotum, lower and anterior areas[40,41]. It can uncommonly present as abscess or ulcer[42]. The main differential diagnoses are extramammary Paget's disease, verrucous carcinoma and bowenoid papulosis[43-46]. Pigmented scrotal SCC and scrotal SCCIS have been rarely reported[38,47]. Multiple scrotal SCCs in the same patient have often been described[26,48]. Table 1 lists the risk factors that have been associated with scrotal SCC.

**Table 2 Lowe's staging of scrotal squamous cell carcinoma**

| | |
|---|---|
| A1 | Disease localized to scrotum |
| A2 | Locally extensive disease involving adjacent structures (penis, perineum, testis or cord, and pubic bone) by continuity but without evident metastasis |
| B | Superficial lymph node metastasis, resectable |
| C | Pelvic lymph node metastasis or any unresectable metastasis |
| D | Distant metastasis beyond regional nodes |

## STAGING

In 1983, Lowe modified the initial staging system proposed by Ray and Whitmore and this staging system is still in use as outlined in Table 2[49].

The American Joint committee on Cancer (AJCC), TNM classification for scrotal SCC is similar to TNM classification for SCC in other locations (with the exception of Eyelid, Vulva and Penis) and is shown in Table 3.

For staging, clinical examination including the assessment of extension and depth of the scrotal lesion and examination of inguinal lymph nodes is mandatory. Plain chest X-ray for evaluation of the lungs is recommended. MRI scan and ultrasonography can be used for assessing the depth of the lesion and evidence of involvement of underlying structures where this is suspected. For inguinal lymph node imaging CT scan can detect enlarged inguinal and pelvic lymph nodes but is unable to identify small metastatic deposits in normal sized nodes. For nodal disease ultrasound and fine needle biopsy of suspicious lymph nodes similar to penile cancer might be of diagnostic value[50]. Similarly with improvement in sensitivity and specificity profile, 18F-FDG PET/CT might have a role in further staging of inguinal lymph nodes in patients with scrotal SCC[51]. For high-risk cases sentinel lymph node biopsy at the time of excision of primary lesion similar to penile cancer has been advocated[52].

## MANAGEMENT

Few case series have been reported since 2000 (Table 4).

### *Primary tumour*

Wide local excision of the lesion with a negative margin is the goal for the treatment of primary tumor. A surgical margin of 2-3 cm has been advocated by some authors[53], however the available guidelines for the management of cutaneous SCC recommend a 4mm radial margin for small (< 2 cm) lesions with well define edges and a radial margin of 6mm for larger lesions with poor defined edges and risk of subcutaneous extension[54]. Based on evidence from penile SCC, for < T2 disease a margin of $\geqslant$ 3 mm is considered safe where for $\geqslant$ T2 disease a surgical margin of 5-10 mm is considered appropriate[55]. Given the redundancy and laxity of scrotal skin primary scrotal closure is usually possible, but after large tumor resection primary closure might not be achievable. The defect can be reconstructed with simple closure, flap,

**Table 3 TNM staging system for squamous cell carcinoma**

| Stage | Primary tumour | Regional lymph nodes | Distant metastasis |
|---|---|---|---|
| Stage 0 | Tis = carcinoma in situ | N0 = no regional lymph node involvement | M0 |
| Stage Ⅰ | T1 = tumour 2 cm or less | N0 | M0 |
| Stage Ⅱ | T2 = tumour > 2 cm but < 5 cm | N0 | M0 |
| | T3 = tumour > 5 cm | N0 | M0 |
| Stage Ⅲ | T4 = Invasion of deeper extradermal structures | N0 | M0 |
| | Any T | N1 = regional lymph node spread. | M0 |
| Stage Ⅳ | Any T | Any N | M1 = distant metastasis. |

split thickness skin graft, mesh grafts or mycocutaneous grafts. Hemiscrotectomy is required for more advanced disease. Contralateral testicular transposition is an option if preservation of testis is preferable[56].

For patients with significant co-morbidities in whom surgical management is not suitable less invasive treatments such as CO2 laser for invasive SCC and 5-fluorouracil, photodynamic therapy or imiquimod for SCCIS may be considered[57,58]. Imiquimod has also been used as adjuvant to surgery post-excision[18]. Superficial small SCC and SCCIS are also amenable to mohs micrographic surgery which offers full evaluation of the surgical margins at the time of surgery and skin-sparing surgery with good functional and aesthetic outcomes[59,60].

### *Inguinal lymph node*

Morley observed early on in the 20th century that the raphe of the scrotum does not provide a physical barrier to scrotal lymphatic drainage and the scrotum has bilateral inguinal drainage[61]. This observation forms the basis for bilateral inguinal assessment when treating patients with scrotal SCC. Data from early series suggest that similar to penile cancer only half of the patients with inguinal lymphadenopathy at the time of diagnosis, harbor metastatic disease at inguinal lymph node dissection (ILND) questioning the need for routine ILND in patients with inguinal adenopathy[62]. The authors advocated a period of follow-up (2-3 mo) after excision of primary lesion and ipsilateral ilioinguinal dissection if patient developed biopsy proven evidence of metastasis, and to defer contralateral node dissection until clinical verification of metastasis is evident.

The more contemporary algorithm for treatment of inguinal lymph node in patients with scrotal SCC has many similarities to patients with penile cancer[63]. A risk based approach to minimize morbidity associated with

ILND advocates the use of inguinal sentinel lymph node biopsy[49], with subsequent complete ILND in cases where sentinel lymph node biopsy is positive[64]. Due to rarity of this condition data from large case series are lacking and the current recommendations are largely based on experts' opinions and extrapolation of data from series with penile SCCs.

### *Locally advanced and metastatic disease*

Adjuvant chemotherapy has been utilized in advanced stage and metastatic disease. Systemic chemotherapy is also indicated for inoperable scrotal SCC. Combination chemotherapy with methotrexate, bleomycin and cisplatin has been reported in inoperable or metastatic SCC of male genital tract with response rate of 72%, however median response duration was only 6 mo and only 14% achieved complete response[65]. Bleomycin has been utilized in the neoadjuvant setting. Adjuvant radiation has been shown to not change outcomes[32].

## EMERGING THERAPIES

The era of targeted molecular and immunotherapies holds promise for management of advanced squamous cell carcinoma. Cetuximab an anti-epidermal growth factor receptor (EGFR) monoclonal antibody is an approved agent for treatment of head and neck SCC[66]. Emerging therapies for head and neck SCC include EGFR tyrosine kinase inhibitors, vascular endothelial growth factor receptor (VEGFR) inhibitors, insulin-like growth factor receptor (IGF-1R) inhibitors and inhibitors of the PI3K/AKT/mTOR pathway may have a role in the treatment of patients with scrotal SCC in future[67]. Unfortunately currently data on the efficacy of such therapies for patients with scrotal SCC is lacking.

Recently Lavens *et al*[68] showed increased EGFR expression in penile SCC. Carthon *et al*[69] evaluated EGFR targeted therapy in patients with advanced penile or scrotal cancer in a retrospective case series of twenty-four patients. Only one of twenty-four patients had scrotal SCC. This patient developed metastases to right groin with disease progression despite paclitaxel, ifosfamide, and cisplatin (TIP) chemotherapy. The addition of EGFR targeted therapy lead to reduction in tumor burden and allowed resection of residual disease. He was reported to be disease free 38 mo post EGFR therapy.

Further studies need to focus on establishing EGFR status in scrotal SCC tissue before prospective evaluation of benefits of EGFR targeted therapies. Due to low incidence of scrotal SCC, multi-institutional collaboration would be a more feasible approach. Further genomic and molecular characterization of scrotal SCC would be important in identifying key pathways and developing therapeutic targets.

## CONCLUSION

Scrotal SCC is a rare clinical entity that represents one of the most common forms of scrotal malignancy. Although historically considered as an occupational disease, its epidemiology has changed in recent years and iatrogenic conditions (PUVA, Immunosuppression, *etc*.) and HPV infection play a significant role as associating conditions. Surgery is the cornerstone of the treatment algorithm for scrotal SCC. Excision of the primary lesion and a risk stratified approach for staging and treatment of regional lymph nodes is advisable. For patients with high-risk disease and negative clinical lymph nodes, sentinel lymph node biopsy can mitigate the morbidities of unwarranted ILND. For locally advanced and metastatic disease palliative chemotherapy is advocated. Future endeavors with focus on targeted therapies might hold promise for management of advanced squamous cell carcinoma. Given the rarity of this condition, multi-institutional trials in conjunction with trials for the treatment of penile SCC are likely to provide us with further knowledge in this field.

**Key words:** Dementia; Aging; Olfaction; Olfactory dysfunction

**Core tip:** Olfactory dysfunction is often present as a symptom of a neurodegenerative disease. The potential clinical value (prodromal/pre-diagnostic, diagnostic, intervention target) of olfactory dysfunction still remains to be fully established. Standardized and easy to use tools are available and can be implemented to improve the definite differential profiles, through its widespread integration in clinical practice and research.

## Abstract

The natural aging process brings about some inevitable consequences, such as olfactory dysfunction, which is also frequently linked to numerous neurodegenerative disorders. Many age-related dementia, such as Alzheimer's disease, Vascular dementia, Parkinson's disease, and Frontotemporal Dementia often display olfactory dysfunction. Despite the overwhelming evidence of above mentioned facts, the symptomatic relevance and potential clinical and pre-clinical value of olfactory dysfunction remains overlooked by many clinicians and public alike. Olfactory dysfunction has strong practical implications on daily activities and, although not as prominent as in other mammals, olfaction is still an evolutionarily relevant sense involved in human survival (*e.g.*, smelling gas; bad food). In this work, we provide a brief review of current research related to the olfactory dysfunction profiles in different types of dementia. Additionally, we present a compilation of accessible, easy to use olfaction assessment tools; and highlight future directions in terms of improving clinical diagnosis in patient care and research.

## INTRODUCTION

Although olfaction is a topic of scientific interest for both public and many professionals[1], awareness concerning olfactory dysfunction, both in healthy aging and dementia, remains limited even when considering the widespread prevalence of age-related olfactory decline. For example, half of the elderly population between 65 and 80 years of age have evident olfactory dysfunction[2-4].

Moreover, olfactory dysfunction has been acknowledged as a symptom present in dementias, such as Alzheimer's disease, vascular dementia, Parkinson and Frontotemporal Dementia (FTD)[5].

Indeed, olfactory dysfunction has a considerable prevalence in dementia, with estimated numbers as high as 100% in Alzheimer's disease (AD)[6], 90% in Parkinson's disease (PD)[7]; 96% in the frontal variant of FTD[8] and 15% in Vascular dementia (VD)[6].

In the next sections we will briefly review the main types of dementia in which olfactory dysfunction is present.

## RESEARCH

The present study is a selective narrative review. The selected articles consisted of literature/articles previously known by the authors, complemented with a search on PubMed/MEDLINE focusing on olfactory dysfunction with the following search terms: olfaction (and related expressions - olfactory), Alzheimer's disease, vascular dementia, Parkinson's disease, frontotemporal dementia, Lewy body dementia, and dysfunction/impairment/deficit. Relevant articles were selected through abstract inspection. Both, reviews and clinical studies were included.

## OLFACTION IN HEALTHY AGING

### *Olfactory loss associated with normal aging*

Olfactory dysfunction has a considerable prevalence with recent estimates pointing to 3.8% in adults between 21 and 84 years of age, increasing prevalence with age (from 0.6% in those < 35 years to 13.9% among those ⩾ 65 years), with higher prevalence in men[9]. Factors involved in age-related olfactory dysfunction include changes in non-olfactory elements of the nose (*e.g.*, airflow patterns and mucous composition), olfactory neuroepithelium, olfactory bulb, central brain regions involved in olfactory processing, and neurochemical changes in the brain (for a detailed review see Doty and Kamath[10]).

Measured with University of Pennsylvania Smell Identification Test UPSIT, Djordjevic[11] and Morgan[12] refer values of approximately 33-35 as a normal olfactory performance. Doty *et al*[2] also provide a prototypical progression of olfactory decline during normal aging. They report median UPSIT values of normal olfactory performance around 37, with olfactory decline starting in the 60 s, reaching around 34 in the 70 s, and 26 in the 80 s. Lower values than those of the observed normative scores would imply a loss of olfactory abilities (for further details please see Doty *et al*[2] or Doty and Kamath[10]) For a systematic review on normative and pathological values of olfactory performance in dementia please refer to Sun *et al*[13].

Besides the normal age-related olfactory decrements, sensory and central processing impairments in the components of olfaction, are observed in number of neurodegenerative conditions[14]. These impairments might influence appetite in people with dementia and lead to dietary restrictions with negative implications on nutrition and overall health[15].

It is important to note, however, that the performance in olfactory assessment tasks might also be influenced by the assessment method as well as other brain functions such as memory. For example, Larson *et al*[16] suggest that age-related difficulties in the activation of odor knowledge (*i.e.*, odor names) might contribute to the observed age differences.

## OLFACTION IN DEMENTIA

### *Alzheimer's disease*

Alzheimer's disease is characterized by neuropathological changes, such as neurofibrillary tangles, neuritic plaques and atrophy, leading to progressively marked deficits in memory (amnestic presentation) and/or other domains such as language and visuospatial capacities (non-amnestic presentations)[17]. Olfactory bulbs are considered to be involved from the early stages of the disease and related to the neuropathological changes[18-20]. Indeed, there is evidence for considerable olfactory tau pathology in post-mortem confirmed AD, with tau pathology correlating with dementia severity[21]. Moreover, similar pathologic changes have been reported in the brain and olfactory mucosa of AD patients[14].

As expected due to the aforementioned lesional pattern, olfactory dysfunction, namely odor identification, is also a widely acknowledged, feature of Alzheimer's[22] with patients showing overt deficits in odor identification[22,23].

Olfactory dysfunction may even be present during the amnestic mild cognitive impairment (MCI) stage of Alzheimer's disease, mainly as an odor discrimination and identification difficulty and less of an odor detection deficit[24]. While cognitive and sensory characteristics associated with visuospatial, language and immediate memory skills are interconnected with olfactory discrimination, olfactory identification in itself is more related to delayed memory processing[24].

Although evidence is still limited, differential profiles between AD and other dementias have been observed which are evidently due to the underlying neurological decline characteristic of each dementia type. For example, smell identification seems to be more impaired in AD than in VD[23], however Gray *et al*[25] found impairment similarities. In the same way, AD and PD patients show equivalent levels of hyposmia (assessed through odor identification)[26]. On the other hand, there is evidence of more olfactory impairment in mild Dementia with Lewy Bodies (DLB) than in MCI or AD[27].

However, whether the available olfactory screening tests are well adjusted and specifically tailored for each of these dementias is still unclear.

### *Vascular dementia*

Vascular dementia (VD) is characterized by cognitive decline, typically in a stepwise manner, compatible with dementia related to cerebrovascular disease[28].

VD is considered the second main cause of dementia[29] and is the topic of a considerable amount of research concerning its characterization and etiopathology. Research on olfactory dysfunction in VD is comparatively scarce. However, it has been found that VD patients score below normative performance in olfactory tests[25]. Nonetheless, when comparing VD and AD, there are mixed findings with Gray *et al*[25] reporting a similar degree of olfactory impairment between AD and VD while Duff *et al*[6] state lower performance in AD patients.

Interestingly, preliminary data, on people with history of stroke, identified them having within normal or slightly below normal olfactory performance[30].

From the aforementioned data it seems plausible to

hypothesize that the presence or absence, the range/extent and type of olfactory deficit might depend on the location and extension of vascular pathology.

### Parkinson disease and other synucleinopathies

Parkinson's disease belongs to a group of neurological conditions named movement disorders, which occur due to a loss of nigrostriatal dopaminergic neurons in certain circuits of the brain[31].

Diagnosis usually occurs after the fifth decade of life typically with a slow progression of disease which is based on neurological examination and the patient's clinical history[31]. Feature symptoms include tremor, trembling of hands, legs, jaw, and face; stiffness of the limbs and trunk; bradykinesia of movements; and postural instability, resulting in impaired balance and coordination. As expected, these symptoms interfere with several daily living activities[31].

Researchers have recently directed their attention towards olfactory dysfunction in PD, as it is a prominent symptom, occurring in about 80%-90% of PD patients[32]. Moreover, olfactory dysfunction is usually prodromal to motor symptoms by several years[33,34]. Olfactory dysfunction also occurs alongside non-motor symptoms, such as in autonomic[35] (cardiovascular changes) and REM-sleep Behavior Disorders[36] (RBD), both during and at the premotor phases of PD.

Therefore, authors argue that deficits in the sense of smell may be used to assess the risk of developing PD in apparent asymptomatic patients[37].

In a population-based prospective study (longitudinal Honolulu-Asia Aging Study; HAAS), authors have demonstrated that odor identification deficits may precede the development of clinical PD in men by at least 4 years[34].

The fact that olfactory deficits appear even before confirmed PD diagnosis[38], while motor signs appear afterwards and gradually worsen, might explain the lack of relationship found between olfactory deficits and PD severity or disease duration[39].

Unsurprisingly, olfactory testing is quite sensitive and specific in distinguishing PD from other movement disorders[33,37,40]. In particular, considering that hyposmia is relatively rare in atypical Parkinson syndromes or in essential tremor, olfactory dysfunction presents added value due to its discriminatory power to differentiate neurodegenerative diseases[33]. Several tests are currently being used[10,41], some of them purposely adapted and implemented for assisting in Parkinson's Disease diagnosis, presenting appropriate sensitivity and specificity indices[42].

Decreased odor identification in PD patients has been associated with older age, greater smoking habits, more coffee intake and lower performance in cognition tests[34]. Additionally, hyposmia was also found to be predictive of dementia installation in PD patients within 3 years of assessment[43]. Furthermore, patients with severe hyposmia at baseline, display more prominent cognitive decline in the follow-up assessment.

More recently, Lee *et al*[44] divided non-demented PD participants into three groups according to their performance in an olfactory test (Cross-Cultural Smell Identification; CCSI[45]): PD-H (high score), PD-M (middle score) and PD-L (low score group). They further noted that the clinical dementia rating score was lower in the PD-H patients than in the PD-M or PD-L patients[44]. Moreover, the PD-L patients performance in the verbal memory tests was noted to be worse than that of the PD-H patients[44], which is in consonance with previous findings[34,43].

In terms of the neuropathological findings in olfactory bulb, depositions of α-Syn have been found in Lewy Body Diseases[33], with additional lesions extending to the olfactory epithelium as well as to the olfactory cortex and other olfactory-related structures[33,46]. Indeed, MRI studies confirmed that PD patients present greater Gray Matter (GM) loss in brain regions subserving primary and secondary olfactory processing, namely, bilateral piriform cortex (PC) and bilateral orbitofrontal cortex (OFC), when compared to controls (*e.g.,* Lee *et al*[47]). Additionally, right PC and left OFC volumes were correlated with the performance in olfactory tests (reduced performance correlated with lower GM volumes)[47].

These results foster the hypothesis that olfactory dysfunction is related with extranigral cortical involvement, which is consistent with the fact that the olfactory function does not improve with dopaminergic treatments[41]. Hence, other neurotransmitter systems are being considered to be involved in olfactory dysfunction (*e.g.,* cholinergic[48,49]).

Importantly, differences between studies may also be explained by the tested components such as odor threshold, discrimination and identification. Each of these olfactory components can be related to atrophy in different brain structures[47] therefore possibly contributing to the diverse smell deficits.

Finally, Takeda *et al*[41] highlight some considerations: there is actually no established standard odorants for the olfactory testing; environmental conditions such as humidity may interfere in olfactory stimulation; and sniffing (the act by one inhales air to be able to smell) may be impaired in PD patients due to motor deficits[41].

Since olfactory dysfunction is an evident feature of PD, which can be detected in early stages of the disease, to improve diagnostic precision, stronger efforts should be made to include olfactory assessment in the routine neurological examinations[41].

### Frontotemporal dementia

Frontotemporal dementia is a clinical syndrome associated with shrinking/degeneration of the frontal and anterior temporal lobes of the brain[50], sometimes called frontotemporal lobar degeneration[51]. FTD was formerly known as Pick's disease[50], however, currently, FTD groups several neurological designations such as Pick's disease, primary progressive aphasia and semantic dementia[50,52].

FTD accounts for up to 10% to 20% of presenile

dementia cases and its onset tends to occur between the ages of 45 and 65 years[52,53]. The main feature in FTD is a marked change in the behavior, usually characterized by either impulsive, disinhibited or apathetic behaviors; accompanied by inappropriate social interaction, lack of social skills, lack of empathy, distractibility and compulsive behavior. Regarding language disturbances, patients may present difficulties in producing or understanding speech[50,52].

Concerning other cognitive abilities, such as spatial skills and memory, they tend to remain intact. For a careful characterization of this clinical syndrome, core features and cognitive changes in FTD, refer to the works of Snowden *et al*[52] and Neary *et al*[51].

Regarding its neuropathology, FTD is mostly characterized by cortical loss of pyramidal cells, and spongiform degeneration. In fewer cases, neuron swellings or inclusions are observed, that is, accumulation of tau proteins in neurons, visible as silver-staining aggregations (Pick bodies)[50,52].

Despite being less frequent than in Parkinson's Disease, olfactory dysfunction has been reported in FTD as well[54]. Considering the neuroanatomy of the olfactory system (involving parahippocampal gyrus and entorhinal area) and the existing compromise of the temporal cortex in FTD, olfactory dysfunction should be expected as well. One of the first studies comparing several dementia types, concluded that, when compared with AD and Semantic Dementia (SD) FTD patients do present olfactory impairment but at a lesser degree[54]. Namely, FTD patients demonstrate preserved odor discrimination abilities, whereas impairment surfaced in tasks of odor naming and odor-picture matching[54]. Additionally, the authors found a correlation between odor identification performance and measures of executive functioning[54].

In the same line of findings, McLaughlin and Westervelt[55] compared groups of FTD, AD patients and controls in an odor identification test (BSIT). The authors found that the FTD performed significantly worse than the controls, but very similar to the AD group[55]. Additionally, a tendency towards correlation between FTD severity and olfactory identification ability was observed.

In another study[8] patients with the frontal variant of FTD presented olfactory recognition deficits. The authors highlight the need to assess olfactory function in FTD patients more often, since initially these patients are commonly misdiagnosed as having depressive disorder. Considering the fact that depressive patients are expected to have better olfactory function, olfactory testing could be used to distinguish depression in elderly from a FTD diagnosis[8].

When comparing variants of FTD in an odor identification test, Omar *et al*[56] did not find differences between the subgroups, even when compared in a flavor identification task. Interestingly, these authors also found that the odor identification performance paralleled the flavor identification and both performances were correlated in clinical groups[56].

## CONCLUSION

### *General conclusions and future directions*

In the present review, in hopes of providing a primer of the topic, we summarized the main findings regarding olfactory dysfunction in aging and the main types of dementia (please refer to Table 1 for a summary of main findings in different dementias).

While there is still no solid olfactory profile for each type of dementia, olfactory assessment might prove to be a valuable tool in assisting diagnosis, as a biomarker for disease progression and a surrogate marker for disease-modifying drug efficacy[33,57]. Easy to use tests/assessments (Table 2 for an exemplifying list of standardized tests) are available and can be easily implemented from a practice-research integrative perspective, leading into an improved evidence-based profiling. However, a clear definition of the evaluated component (identification, recognition, retrieval, choice) must be regarded carefully since the discrepancies in the results reported throughout this work might have the contribution of confounding variables such as memory and naming difficulties.

Regarding these procedural issues, computerized odor systems might provide a more accurate disposal of odorants and determination of potential differential olfactory thresholds in early stages of different types of dementia. Although, functional neuroimaging studies, concerning the present topic, are scarce, if implemented more often they may assist in the clarification of the existence of different *in vivo* neural signatures related to differential olfactory impairments (*e.g.,* naming identification, confrontation identification, retrieval).

In the context of neuroimaging, despite the costs associated with sophisticated olfactometer apparatus, simpler alternatives, such as odorant saturated cotton can be implemented as well (although with less reliability). Also, semi-automatic olfactometers/odor dispensers for imaging setting can be built on a rather reasonable budget[58].

Although olfactory symptoms are a feature of dementia, which is regarded as such with a relative consensus, diagnostic guidelines seldom highlight its role or presence as a supportive feature. In this regard, screening pocket olfactory tests could be recommended in healthcare and diagnostic guidelines as a supportive test for improving differential diagnosis through fast data collection and prior screening for the purposes of a more extensive olfactory assessment. Although one may argue that these tests are not exempt of costs, there are alternatives, such as the Smell Diskettes, which can be reused for several months.

The use of olfactory baseline measurements, similar to the neuropsychological baseline assessments used in some countries, should be implemented worldwide. However, as in neuropsychological assessments, baseline olfactory results are seldom available.

As noted recently, olfactory assessments could also be included in other routine sensory assessments, such as in

**Table 1 Table of main findings (comparing findings in different dementias)**

| Type of dementia | Profile/main findings | Differences between dementias (extent/degree/severity of impairment) |
|---|---|---|
| Alzheimer | Odor identification deficit, is a widely acknowledged feature of Alzheimer's | Mixed findings:<br>AD > VD[6,23]; AD = VD[25] |
| VD | Olfactory performance below normative scores; Unclear differential profile with other dementias | AD = PD[26]; mild DLB > MCI/AD[27]<br>FTD < AD[54] |
| PD | Decreased odor identification, which may precede the development of clinical PD | FTD = AD[55]<br>Legend: > more impaired; < less impaired; = similar |
| FTD | FTD patients demonstrate preserved odor discrimination abilities, Impairments in odor naming and odor-picture | |

AD: Alzheimer's disease; VD: Vascular dementia; PD: Parkinson's disease; FTD: Frontotemporal dementia; DLB: Dementia with Lewy bodies; MCI: Mild cognitive impairment.

eye or hearing tests[59]. Routine olfactory tests, assessing several olfaction components[54], could assist not only in the detection and the discovery of causes for olfactory dysfunctions, but also aid longitudinal studies aiming to understand olfaction, and more immediately in the detection of common causes of olfactory dysfunctions, such as airway disorders and viral or bacterial infections.

In order to improve and generalize these baseline assessment practices, it is important to increase awareness of its clinical and research relevance not only among the researchers, but also among the physicians and the psychologists. Concerted informative action for generating awareness among governmental and legislative health bodies should be implemented by researchers and clinicians in all the fields of olfactory dysfunction. The absence of baseline assessments will continue to minimize accuracy in studies and clinical practices, since comparisons of patient values exclusively to group results, and not to individual levels of olfactory functioning, will only yield approximate results.

In sum, we hope that the potential of utilizing the olfactory dysfunction for diagnosis and perhaps even as intervention outcome, together with an awareness of available inexpensive and easy to implement assessment tools, can lead to its wider clinical use (integrated with research efforts). The latter mentioned proposal may very well improve dementia diagnosis and allow an establishment of differential profiles. Implementation of olfactory tests in standard neuropsychological screening and diagnostic batteries, from preclinical and early stages of dementia, will clarify if olfactory dysfunction holds any potential for aiding research progress in the field of dementia[13,24].

## Abstract

The processes of lung fibrogenesis and fibrotic healing are common to a number of conditions with different etiologies. The lungs are the only affected organ in some cases, whereas in others, several organ systems are involved. Therapeutic options can be discussed from various perspectives. In this review, we address the localization of therapeutic targets with regard to cell compartments, including secreted ligands, cell surface, plasma membrane-cytosol interplay, cytosol and nucleus. Complex approach using stem cell therapy is also discussed. As the prognosis of patients with these disorders remains grim, treatment combinations targeting different molecules within the cell should sometimes be considered. It is reasonable to assume that blocking specific pathways will more likely lead to disease stabilization, while stem cell-based treatments could potentially restore lung architecture. Gene therapy could be a candidate for preventive care in families with proven specific gene polymorphisms and documented familial lung fibrosis. Chronobiology, that takes into account effect of circadian rhythm on cell biology, has demonstrated that timed drug administration can improve treatment outcomes. However, the specific recommendations for optimal approaches are still under debate. A multifaceted approach to interstitial lung disorders, including cooperation between those doing basic research and clinical doctors as well as tailoring research and treatment strategies toward (until now) unmet medical needs, could improve our understanding of the diseases and, above all, provide benefits for our patients.

**Key words:** Interstitial lung disease; Treatment; Idiopathic pulmonary fibrosis; Connective tissue disease; Cell compartments; Signaling molecules; Signal transducers; Transcription factors

**Core tip:** Novel treatment targets in patients with fibrosing interstitial lung diseases are summarized. Targets are listed according to defined cell compartments. Ongoing clinical studies focusing on some of the promising targets provide insight into current progress in lung fibrosis research.

Sterclova M, Vasakova M. Promising new treatment targets in patients with fibrosing lung disorders. *World J Clin Cases* 2014; 2(11): 668-675 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/668.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.668

## INTRODUCTION

The processes of lung fibrogenesis and fibrotic healing are common to a number of conditions with different etiologies. The lungs are the only affected organ in some cases, whereas in others, several organ systems are involved. There are several similar features that can be observed in adult patients with fibrosing lung disorders: *e.g.*, a history of exposure to inhaled antigens (organic or

**Table 1 Interstitial lung diseases with a fibro-proliferative pattern, radiologic/histologic phenotypes and new treatment modalities**

| Etiology | Radiologic/histopathologic phenotype | New treatment modalities studied |
|---|---|---|
| Lung-specific involvement | | |
| Inhalation of organic antigens (*e.g.*, EAA) | NSIP, UIP, OP, DIP, AIP | No |
| Inhalation of inorganic materials (*e.g.*, asbestosis) | NSIP, UIP, OP, DIP, AIP | No |
| Drug and radiation toxicity | NSIP, UIP, OP, DIP, AIP | No |
| Idiopathic pulmonary fibrosis | UIP ± NSIP | Yes |
| Idiopathic nonspecific interstitial pneumonia | NSIP ± UIP | No |
| Systemic involvement | | |
| ILDs associated with connective tissue diseases | NSIP, UIP, OP, DIP, AIP | Yes |
| Sarcoidosis and other granulomatoses | NSIP, UIP, OP, DIP, AIP | Yes |

EAA: Extrinsic allergic alveolitis; IPF: Idiopathic pulmonary fibrosis; NSIP: Nonspecific interstitial pneumonia; ILD: Interstitial lung disease; UIP: Usual interstitial pneumonia; OP: Organizing pneumonia; DIP: Desquamative interstitial pneumonia; AIP: Acute interstitial pneumonia.

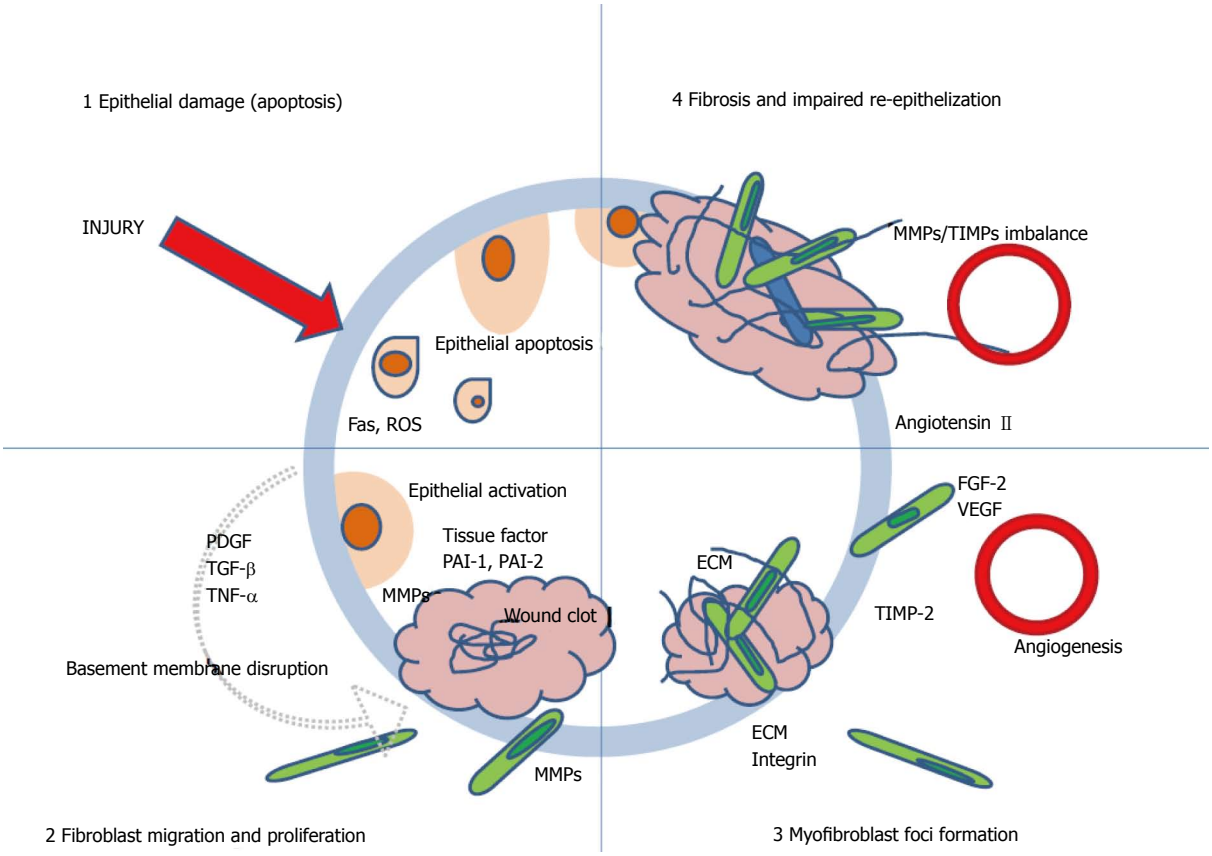

**Figure 1 Suggested pathogenesis of idiopathic pulmonary fibrosis.** ROS: Reactive oxygen species; PDGF: Platelet-derived growth factor; TGF-β: Transforming growth factor beta; TNF-α: Tumor necrosis factor alpha; MMPs: Matrix metalloproteases; PAI: Platelet activator inhibitor; ECM: Extracellular matrix; TIMP: Tissue inhibitor of metalloproteases; FGF: Fibroblast growth factor; VEGF: Vascular endothelial growth factor.

inorganic compounds, smoking), respiratory infections (viral), extra-esophageal reflux, impaired coagulation cascade, signs of immune system disorders with detectable autoantibodies, and genetic susceptibility[1-5]. In some patients, both fibrosis and inflammation may be observed; in contrast, in the pathogenesis of idiopathic pulmonary fibrosis (IPF), inflammation plays a relatively minor role[6].

The spectrum of interstitial lung diseases with a fibro-proliferative pattern of healing is summarized in Table 1.

Until recently, most treatment options in patients with interstitial lung disorders have focused on inflammation and lung fibrosis, relying on anti-inflammatory and immunosuppressive agents[7]. However, these strategies have been found to be effective only in specific groups of patients (patients with connective tissue-associated ILD, history of inhalation of organic antigens, drug- and radiation-induced ILD, sarcoidosis or other granulomatoses). In IPF patients, as documented in the Panther study, these treatments not only failed, but they seemed to negatively impact the mortality and morbidity outcomes of patients[8].

Figure 1 depicts the hypothesized mechanism underlying the pathogenesis of IPF. Repeated micro-injuries to

**Table 2 Potential treatment targets in patients with fibrosing lung disease, according to target location**

| Target | Potential molecular target |
|---|---|
| Signals from other cells | Cytokines, survival factors, chemokines, hormones, transmitters, growth factors, extracellular |
| Autocrine signals | matrix compounds, Wnt, Hedgehog, death factor |
| Cell surface | Cytokine receptors, receptor tyrosine kinase, G protein-coupled receptors, integrins, Frizzled, Patched, Fas receptor, ion channels |
| Plasma membrane-cytosol interface | Kinases |
| | miRNAs |
| Cytosol signal transducers | Apoptosis-related proteins |
| Nucleus | Transcription factors |
| | Epigenetic modifiers |

miRNA: Micro-ribonucleic acid.

**Table 3 Ongoing clinical studies in idiopathic pulmonary fibrosis patients**

| Target | Potential molecular target | Ongoing clinical study |
|---|---|---|
| Signals from other cells | Interleukin 13 | Lebrikizumab NCT01872689 |
| Autocrine signals | Connective tissue growth factor | Tralokinumab NCT02036580 |
| | | FG-3019 NCT01890265 |
| Cell surface | Lysophosphatidic acid receptor | Lysophosphatic acid receptor antagonist-NCT01766817 |
| | Lysyl oxidase LOXL2 | Simtuzumab NCT01769196 |
| | CD20 | Rituximab NCT01969409 |
| | Androgen receptor | Nandrolone decanoate NCT02055456 |
| Plasma membrane-cytosol interface | Phosphoinositol kinase PI3K | Phosphoinositol kinase PI3K inhibitor NCT01725139 |
| Cytosol signal transducers | Avβ6 integrin | STX-100 NCT01371305 |
| Nucleus | | None |
| Stem cells | | Autologous adipose-derived adult stem cells NCT02135380 |
| | | Autologous mesenchymal bone marrow-derived stem cells NCT01919827 |
| | | Allogenic human mesenchymal stem cells NCT02013700 |

the alveolar epithelium seem to play a key role in the initiation of the disease. Fibroblasts are attracted to the site of injury, proliferate and eventually form fibroblast foci with exaggerated extracellular matrix production[9]. Some of the epithelial type II alveolar cells may undergo transdifferentiation into fibroblasts and become activated[10]. Developmentally active programs, including Sonic hedgehog (Shh), Notch and Wingless-related MMTV integration site (Wnt), were found to be repeated in IPF[11,12]. However, unlike in "normal" development, these pathways seem to be dysregulated, resulting in an overactive development phenotype[13].

These clinical observations as well as new insights into the pathogenesis of fibrosing lung diseases have led to a vigorous search for alternative treatments. Potential targets for the treatment of fibrosing ILD are listed in Table 2. Table 3 presents ongoing clinical studies in IPF patients.

## SECRETED LIGANDS (SIGNALS FROM OTHER CELLS, AUTOCRINE SIGNALS)

Cytokines, chemokines, growth factors and their receptors have been widely investigated in patients with various fibrosing lung diseases. These molecules play a role in inflammation, fibrogenesis and angiogenesis, and most of them have been found to be somehow involved in the pathogenesis of fibrosing lung disorders[14]. Although *in vitro* studies and experiments using mouse models have provided promising results suggesting that blocking certain chemokines or cytokines could prevent the progression of lung fibrosis, results from clinical studies have not been convincing. For instance, although tumor necrosis factor alpha (TNF-alpha) inhibitors were found to be useful in the management of connective tissue diseases (CTDs) and sarcoidosis, they were demonstrated to have no benefit in patients with marked lung fibroproliferation, such as in IPF patients[15,16]. Moreover, in patients with pulmonary involvement due to CTDs, the role of TNF-alpha inhibitors has yet to be established[17]. Other agents, such as interleukin-13 (IL-13) inhibitors, chemokine (C-C motif) ligand 2 inhibitors, connective tissue growth factor (CTGF) inhibitors, transforming growth factor (TGF) inhibitors and (beta 1 isoform) lysyl oxidase-like (LOXL) 2 inhibitors, are currently the subject of clinical studies[18]. TGF beta is considered an important mediator of fibrotic processes. It plays a role in in wound healing, extracellular matrix production and angiogenesis. However, it is also involved in inflammatory responses and can exhibit both pro-inflammatory and anti-inflammatory properties. TGF beta also plays an ambiguous role in oncogenesis: it can inhibit the growth of some tumor cells while enhancing migration and growth in others[19]. As the fibrogenic properties of TGF beta

have been known and extensively studied, an anti-TGF beta antibody (fresolimumab) has already been tested in IPF patients. Current strategies are directed mostly at downstream mediators, which are thought to have fewer harmful effects on tissue homeostasis[20].

Oxidative stress is considered to be a key mediator in IPF pathogenesis. It is not known whether this is due to the overproduction of reactive oxygen species (ROS) or to the diminished scavenger capacity of various cells[21]. NADPH oxidase (NOX) is one of the ROS-generating enzyme systems expressed by alveolar epithelial cells, endothelial cells, macrophages, neutrophils, mesenchymal cells and smooth muscle cells. Several isoforms of NOX have been characterized, with NOX-1, NOX-2 and NOX-4 appearing to be the most relevant in IPF pathogenesis. Specific NOX inhibitors may prove to be effective drug targets in IPF[22].

## CELL SURFACE

Pirfenidone was found to inhibit the synthesis of TGF beta and TNF alpha, even though the underlying mechanism has yet to be elucidated. Compared to placebo, pirfenidone delays the progression of IPF and mortality, and it is currently the only registered molecule for IPF treatment in some countries[23].

Lung fibrosis with distortion of vessel architecture is accompanied by enhanced coagulation. The primary function of the coagulation cascade is to promote hemostasis and limit blood loss in response to tissue injury. However, coagulation also plays a pivotal role in inflammatory and tissue repair responses, including lung fibrosis[24]. Hyperplastic alveolar epithelium in patients with fibro-proliferative lung disorders might be an important source of several coagulation-promoting factors. There have been several studies on the potential therapeutic role of warfarin, but these resulted in a strong recommendation against the use of warfarin in IPF treatment. Further studies have shown that other components of the coagulation cascade can be targeted. Proteinase-activated receptor 1 (PAR-1) is a major high-affinity receptor for thrombin and its activation leads to a number of pro-fibrotic events, including the proliferation of fibroblasts and their differentiation into myofibroblasts[25]. PAR-1 has been suggested as a major player in endothelial-epithelial barrier disruption. Atopaxar and vorapaxar inhibit PAR-1 and may represent possible options in IPF treatment[26].

Given that fibroblast proliferation and extracellular matrix production are the hallmark of fibrotic lung diseases, huge efforts have been made to investigate fibroblast biology and signaling[27]. Lung fibroblasts derived from IPF patients have enhanced motility compared to their normal counterparts. This hypermotile phenotype of fibroblasts is thought to be driven by ligation of urokinase with its receptor (uPAR), which leads to the formation of unique lipid raft platforms. Blocking fibroblast migration *via* uPAR represents one possible future treatment option for IPF patients[28].

Another therapeutic approach may involve blocking signaling mechanisms in cells that are common to multiple pathways. The pro-fibrotic effect of TGF beta 1 and basic fibroblast growth factor (FGF) was found to be dependent on a $Ca^{2+}$-activated $K^+$ channel ($K_{Ca}3.1$). Inhibiting this channel can block the function of pro-fibrotic human lung myofibroblasts. This makes the $K_{Ca}3.1$ channel an attractive pharmacological target, particularly as it appears to play only a minor role in normal physiology[29]. So far, inhibitors of this channel have been used in humans with sickle cell disease with few side effects.

## PLASMA MEMBRANE-CYTOSOL INTERPLAY

Tyrosine kinase (TK) inhibition also attenuates downstream signaling in cells and might be useful if a mutation in the gene coding for tyrosine kinase leads to uncontrolled activation of the cell, manifested as unregulated cell cycle or protein production. Several authors have suggested that similar features and pathogenic pathways might play a key role in idiopathic pulmonary fibrosis and lung cancer[30]. In both diseases, epigenetic and genetic changes result in altered responses to regulatory signals, abnormal expression of microRNAs and activation of specific signaling pathways, which raises suspicion that a similar treatment approach could be useful. Inhibitors of TKs or TK-dependent signal transduction pathways might be very helpful in controlling the growth of cancer cells[31]. Although studies with imatinib mesylate in IPF patients showed a lack of efficacy, this compound is not the only inhibitor of TK signal transduction that has been tested. Nintedanib is a triple inhibitor of TK receptors (platelet-derived growth factor, vascular endothelial growth factor, and fibroblast growth factor receptors) and is just one of the new drugs that may improve the prognosis of IPF patients[32]. Recently published data show that nintedanib reduces lung function decline and slows the progression of IPF[33].

Another member of the protein kinase family is a group of serine-threonine kinases. Rho-kinase (ROCK) is a member of this group and is involved in the regulation of cell movement and shape and plays a role in the function of the tumor suppressor gene PTEN and the mechanism of apoptosis[34]. The rho-kinase inhibitor fasudil has potential as a new treatment in systemic scleroderma patients. Additionally, this molecule was found to inhibit lung fibrosis in the bleomycin mouse model and has been suggested as a possible treatment for IPF patients[35].

As mentioned above, pathological remodeling of the extracellular matrix by fibroblasts plays a role in IPF pathogenesis. Parker *et al*[36] noted that expansion of fibrotic lesions after the initial insult leading to fibrogenesis is likely driven by a positive feedback loop between fibroblasts and the extracellular matrix. An interesting option for blocking this loop could be miR-29, which is a potent negative regulator of extracellular matrix genes. Gener-

ally, miRNAs are a type of non-coding, small-sized, evolutionarily preserved RNA and they act as repressors of gene expression at the post-transcriptional level. Other miRNAs that may play a role in IPF and may represent treatment opportunities include miR-21, miR-155 and miR-200[37].

## NUCLEUS

Novel treatment targets are not just limited to the cell surface or cytoplasm; some potential treatments also target the nucleus. Transcription factors are proteins necessary for the transcription of DNA into mRNA. There are specific transcription factors involved in development, response to environmental stimuli, cell cycle control and response to intercellular signals. Immediate-early response transcription factor (Egr-1) takes part in mitogenesis and differentiation. It is thought to be a tumor suppressor gene. Egr-1 has been found to play a role in the fibrotic process, in addition to oncogenesis. It can regulate the expression of extracellular matrix components, matrix remodeling enzymes and fibrogenic cytokines, and drive myofibroblast differentiation[38,39]. Although several drugs have been found to have potent inhibitory activity against Egr-1 induction or activity (*e.g.*, mycophenolate mofetil, cyclosporine, imatinib mesylate), clinical studies have only supported their potential use in a subset of patients (ILD associated with CTD)[40]. Although mycophenolate mofetil, cyclosporine or imatinib mesylate may be useful in patients with autoimmune disorders that also affect the lung, they are not routinely recommended for IPF patients. The role of simvastatin and rosiglitazone still needs to be established[41,42].

Gene therapy has been suggested as a potential treatment option in numerous respiratory diseases. Gene preparations can be administered to target organs by intravenous, intramuscular or intra-tumor injections. One possible noninvasive delivery strategy includes intranasal administration[43]. Effective introduction to the lungs is thought to be possible because of the large absorption area of the mucous membrane and high perfusion. Most research in this area is concentrated on monogenic diseases and lung cancer, with few data on IPF thus far. Gene therapy has been combined with conventional treatment in cancer models and seems to offer interesting treatment possibilities in cases with a known genetic cause - especially for familial lung fibrosis due to short telomere syndrome or MUC5B (gene for mucin) gene polymorphisms[44-46].

## TISSUE REPAIR- POTENTIAL FOR STEM CELLS

Stem cells represent a more complex treatment approach than specific molecular targeted therapy. Stem cells were expected to be the ultimate strategy for restoring diseased lungs, including structural repair (engraftment of cells) and immunomodulation. Endogenous lung progenitors, endothelial stem cells, induced pluripotent cells, mesenchymal stem cells and epithelial stem cells have all been proposed as prospective treatments, especially for IPF patients[47,48]. Intravenous and intratracheal administration of epithelial type Ⅱ alveolar cells is now being tested in humans. Mesenchymal stem cells (MSCs) were found to be immunosuppressive, they have low immunogenicity and they home to sites of injury after systemic administration. However, MSCs appear to be more efficient in resolving diseases with high inflammatory activity and are less able to preserve organ function or restore cell derangements in patients with chronic disease. It has been suggested that systematically administered bone marrow MSCs can differentiate into type Ⅱ epithelial cells and suppress the expression of proinflammatory and profibrotic genes[49,50]. However, ongoing studies in IPF patients were designed as safety studies and their results are still somewhat controversial. The therapeutic potential of bone marrow MSCs may be further enhanced by using a cell-based gene delivery approach.

## CHRONOBIOLOGY

Although circadian rhythms have proved to be strong regulators of many tissue-specific genes, the data concerning lung fibrosis patients are limited. A study by Pekovic-Vaughan suggests that susceptibility to oxidative stress lung injury may vary during the day, because the activity of redox-sensitive transcription factor Nrf2 correlates with the circadian rhythm[51]. Not only does Nrf2 enhance oxidative stress, it also points toward a new site for lung fibrosis research[52]. Chronobiology has demonstrated that timed drug administration can improve treatment outcomes.

## NON-IPF DISORDERS

In patients with non-IPF fibrosing interstitial lung disorders that continue to progress despite conventional immunosuppression, the anti-CD20 monoclonal antibody rituximab has been tested and appears to be an effective therapeutic intervention, regardless of the final diagnosis[53]. However, the data on the optimal treatment strategy in CTD-related fibrosing lung disease are still limited. In patients with systemic lupus erythematosus (SLE), belimumab (IgG1 lambda monoclonal antibody binding circulating B-lymphocyte stimulator) may be an attractive alternative to rituximab. The anti-interferon antibody sifalimumab is being studied in SLE patients and may represent a new treatment option for other autoimmune disorders[54]. Whether it could also be beneficial in patients with associated interstitial lung disease is still unknown.

Pulmonary involvement in systemic sclerosis (SSc) patients is common and it is considered to a major cause of death in SSc patients. The pathogenesis of SSc is characterized by significant accumulation of inflammatory cells in the lung parenchyma, even in patients with an otherwise usual interstitial pneumonia (UIP) pattern

of interstitial lung fibrosis. There is an ongoing debate regarding the optimal immunosuppressive agents for SSc ILD patients, especially concerning newer agents such as mycophenolate or rituximab. According to some authors, cyclophosphamide should not be routinely replaced by mycophenolate in SSc ILD subjects[55]. Several studies have indicated that rituximab can be useful, but it should be further investigated[56]. Pirfenidone, STX-100 and fasudil represent interesting possible treatment options in SSc ILD patients.

## CONCLUSION

Despite recent advances and deeper insight into the pathogenesis of fibrosing lung disorders, we are still unable to successfully treat our patients. Several points need to be addressed, and several intriguing questions need to be answered: (1) How do we define effective treatment? Should effective treatment be defined in terms of disease stabilization and prevention of further decline in lung function? Should we define effective treatment as an improvement in patient quality of life, without necessarily extending it? Should the optimal definition of "effective treatment" include restoration of the lung parenchyma and resolution of both fibrosis and inflammation (if any is present)? It is reasonable to assume that blocking specific pathways will more likely lead to disease stabilization, while stem cell-based treatments could potentially restore lung architecture. Gene therapy could be a candidate for preventive care in families with proven specific gene polymorphisms and documented familial lung fibrosis; (2) Radiological and histopathological patterns of usual interstitial pneumonia (UIP) may be observed in patients with fibrosing lung disease of known cause, such as CTDs, drug-induced lung fibrosis or in patients with a history of exposure to inorganic/organic inhalation antigens. Can any of the above-mentioned therapeutic approaches also be used in non-IPF patients with a radiographic/histopathologic UIP pattern? (3) Should a combination of drugs and therapeutic approaches be used instead of monotherapy? and (4) Similarities between IPF and lung cancer were listed above. What should we learn from the oncological approach? Should we use different treatment strategies according to the stage of the disease and the individual genetic background of patients? If so, what should the staging of lung fibrosis be based on?

We believe that a multifaceted approach to IPF, including cooperation between those doing basic research and clinical doctors as well as tailoring research and treatment strategies toward (until now) unmet medical needs, could improve our understanding of the disease and, above all, provide benefits for our patients.

## Abstract

The purpose of this review article is to discuss the clinical spectrum of recurrent traumatic anterior shoulder instability with the current concepts and controversies at the scientific level. Because of increasing participation of people from any age group of the population in sports activities, health care professionals dealing with the care of trauma patients must have a thorough understanding of the anatomy, patho-physiology, risk factors, and management of anterior shoulder instability. The risk factors for recurrent shoulder dislocation are young age, participation in high demand contact sports activities, presence of Hill-Sachs or osseous Bankart lesion, previous history of ipsilateral traumatic dislocation, ipsilateral rotator cuff or deltoid muscle insufficiency, and underlying ligamentous laxity. Achieving the best result for any particular patient depends on the procedure that allows observation of the joint surfaces, provides the anatomical repair, maintains range of motion, and also can be applied with low rates of complications and recurrence. Although various surgical techniques have been described, a consensus does not exist and thus, orthopedic surgeons should follow and try to improve the current evidence-based treatment modalities for the patients.

**Key words:** Recurrent instability; Glenohumeral joint; Dislocation; Shoulder; Review

**Core tip:** Recurrent anterior instability of the shoulder is a complex disorder which mainly affects younger population, and generally requires surgical intervention to restore joint stability. Although many authors published good to excellent clinical results regarding various techniques described in the literature, a consensus on the ideal treatment modality has not been established yet. In this review article, we present an overview of recurrent anterior instability of the glenohumeral joint and discuss the treatment options with current concepts.

Recurrent anterior shoulder instability: Review of the literature and current concepts. *World J Clin Cases* 2014; 2(11): 676-682 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/676.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.676

## INTRODUCTION

Anterior glenohumeral dislocation during sports activities or social life is one of the most commonly seen pathologies in the clinical practice of orthopedic traumatology. The prevalence of anterior glenohumeral instability has been reported as 2%[1]. The glenohumeral joint has been

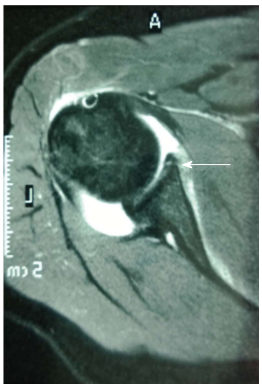

**Figure 1 The Bankart lesion on magnetic resonance imaging.**

reported as the most commonly dislocated synovial joint of the human body[2]. Forced abduction and external rotation of the shoulder can cause anterior dislocation resulting in instability[3]. Participation in athletics can place exceptional demands on the musculoskeletal system, especially the shoulders of the ones who perform overhead activities[4]. Shoulder instability most commonly affects people who are in their late teens to mid-thirties[5]. A major problem following a primary traumatic anterior shoulder dislocation is the high risk of recurrence among young patients[6]. Rhee *et al*[7] mentioned that these injuries occur at a younger age, with higher rates of recurrence, and with shorter intervals between initial injury and recurrent instability events among athletes. Because of increasing participation of people from any age group of the population in sports activities, health care professionals dealing with the care of trauma patients must have a thorough understanding of the anatomy, patho-physiology, risk factors, and management of anterior shoulder instability. Degenerative arthropathy in the shoulder joint is generally the final result of chronic instability[8]. The purpose of this review article is to discuss the clinical spectrum of recurrent traumatic anterior shoulder instability with the current concepts and controversies at the scientific level.

## FUNCTIONAL ANATOMY

Shoulder joint is a complex anatomical and biomechanical structure which functions in a manner that several stabilizers play role in a special harmony in different stages of motion. Stability of the shoulder is established by the glenohumeral articulation, labrum, glenohumeral ligaments, rotator cuff, and deltoid muscle. The contact surface of the humeral head with the glenoid is about 30%, which means that the joint has a limited osseous constraint so that the primary stability is due to other soft tissue components rather than the osseous contact[9]. This allows a very large range of motion but in turn, a predisposition to subluxation or dislocation as well. The anterior labrum plays a key role in anteroposterior stability as it deepens the glenoid cavity up to 50%[10]. Therefore, injuries causing detachment of the labrum from its original anatomic location can cause recurrent anterior instability. A Bankart lesion, which is defined as the anteroinferior detachment of the glenoid labrum, was demonstrated in 87% to 100% of first-time dislocations[11-13] (Figure 1).

The superior, middle and inferior glenohumeral ligaments unite to form a soft tissue complex which functions as a static stabilizer for the joint. Each component of this ligamentous structure has its unique contribution to joint stability during different stages of motion. The coracohumeral ligament also functions synergistically with the superior glenohumeral ligament in resisting inferior translation of an adducted shoulder joint[14]. The middle and inferior glenohumeral ligaments provide anterior stability in different degrees of shoulder abduction and external rotation. The anteroinferior portion is the weakest part of the glenohumeral ligament complex in an abducted and externally rotated shoulder.

The deltoid muscle and the rotator cuff are named as the primary dynamic stabilizers which are active during shoulder motion in all axes[9]. The pathologies affecting the deltoid muscle and the rotator cuff not only cause decrease in range of motion of the shoulder joint but also disturbance of the biomechanical stability. Muscle weakness and/or imbalance of the dynamic stabilizers have been reported as leading to recurrent anterior shoulder instability[15-20].

## CLINICAL EVALUATION

A detailed history and a careful physical examination of the patient are the primary steps of the clinical assessment. Mechanism of the first incident, time period from the first dislocation to recurrent instability, activities leading to recurrence or apprehension, number of dislocations, and history of reducibility without emergency visit should be noted for each patient. Schrumpf *et al*[14] mentioned the importance of distinguishing traumatic subluxation or dislocation and multidirectional instability, as the pathophysiologies and the treatment approaches of them were far different.

Physical examination is crucial in understanding the mechanism of recurrent dislocations. Comparative evaluation of both shoulders should be performed. Any visible deformity and/or muscle atrophy with respect to contralateral shoulder, or any scar tissue related to past trauma or surgery are important and simply recognizable just by a careful inspection. Active and passive range of motion in all planes should be measured and noted for both shoulders in every patient. Generalized ligamentous laxity should be kept in mind and checked in every patient. Axillary nerve examination should always be considered as critically important during clinical assessment. Apprehension and relocation tests as provocative examination are the fundamentals of clinical evaluation of any patient with a medical history of recurrent instability (Figure 2). Anterior apprehension test is performed with the shoulder in 90 degrees of abduction and the elbow in 90 degrees of flexion, with forced external rota-

**Figure 2 Apprehension and relocation tests.**

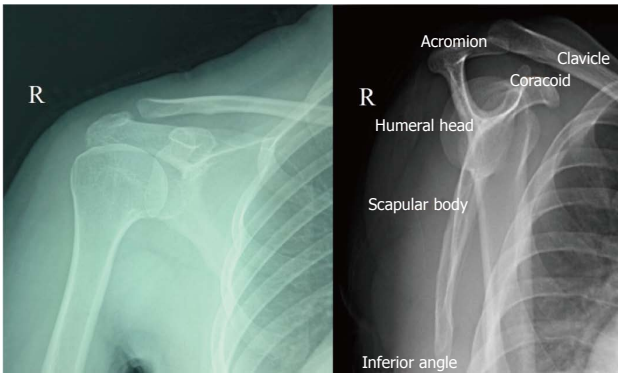

**Figure 3 Anteroposterior shoulder view and scapular Y view radiographs.**

tion applied to the extremity as anterior stress is applied to the humerus. Relocation test is performed while the patient is supine and the shoulder in 90 degrees of abduction and external rotation. Anterior stress is applied to the humerus in various degrees of abduction. When the pain or apprehension occurs, posterior-directed force is applied to relocate the humeral head. If the release of posteriorly directed stress used to relocate the humeral head produces a feeling of apprehension or subluxation, it indicates anterior instability. Laxity specific to lesions of inferior glenohumeral ligament can be distinguished by performing the hyperabduction test (Gagey's sign)[21].

Anteroposterior, axillary lateral and scapular Y-view images are the primary routine radiographic evaluation tools in patients with recurrent instability (Figure 3). Different specific radiographic imaging techniques including apical oblique view, West point axillary view or Stryker notch view can also be valuable to detect particular pathologies related to patient's complaint. West point axillary view is used to evaluate for a glenoid rim fracture, whereas Stryker notch view is for Hill-Sachs lesion. However, a three-dimensional computed tomography is gold-standard technique to detect osseous pathologies as well as quantifying the degree of bone loss[22]. Magnetic resonance imaging (MRI) is a very useful tool in detecting soft tissue pathologies. Gadolinium-enhanced MRI is a minimally invasive and effective radiographic method to diagnose any capsular or labral damage pre-operatively.

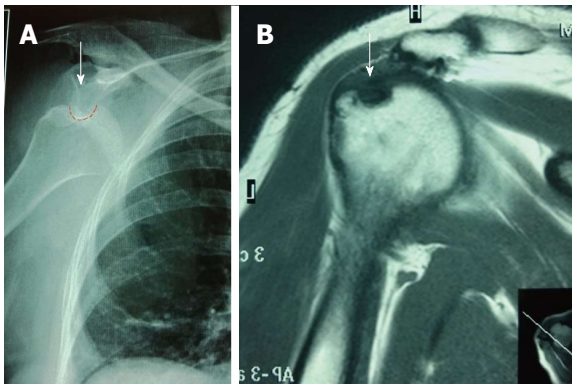

**Figure 4 Engaging Hill-Sachs lesion leading to recurrent anterior instability (A) and Hill-Sachs lesion on magnetic resonance imaging (B).**

## RISK FACTORS FOR RECURRENT INSTABILITY

Many different risk factors for recurrent anterior shoulder dislocation such as young age, participation in high demand contact sports activities, previous history of ipsilateral traumatic dislocation, presence of Hill-Sachs or osseous Bankart lesion, ipsilateral rotator cuff or deltoid muscle insufficiency, and underlying ligamentous laxity have been described[1,23-30]. Ramsey *et al*[31] reported that traumatic anterior instability of the shoulder is associated with a high rate of recurrence in young patients. Marans *et al*[32] reported 100% redislocation rate in twenty-one skeletally immature patients who were treated with a sling.

According to Porcellini *et al*[33], age at the time of the first dislocation, male sex, and the time from the first dislocation until surgery were significant risk factors for recurrence. However, in a prospective multicenter clinical study with twenty-five years of follow-up no significant differences with respect to gender could be demonstrated[34]. According to the results of a Level-I prospective cohort study subjects with a prior history of glenohumeral joint instability were approximately five times more likely to experience a subsequent instability event, regardless of direction[35]. Although glenoid bone loss is more common, engaging Hill-Sachs lesions can also be a cause of recurrent instability[36] (Figure 4). A Hill-Sachs lesion, which is defined as an osseous defect resulting from forceful impaction on the posterolateral side of the humeral head during anterior dislocation, was demonstrated as high as 90% to 100% of the patients with shoulder instability[11-13]. Hovelius *et al*[34] reported that immobilization was not found to be associated with the risk of redislocation.

## TREATMENT

Recurrent anterior shoulder instability resulted from an initial traumatic dislocation can be as serious as preventing an athlete from returning to sports. Without proper treatment, chronic instability generally results in a degen-

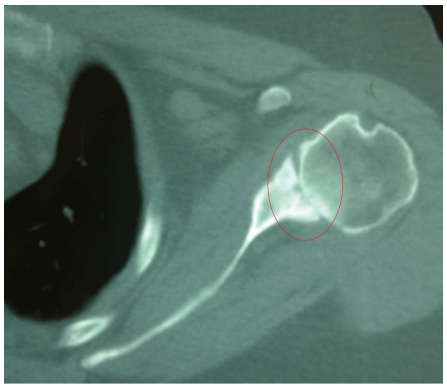

**Figure 5 Degenerative arthritis secondary to chronic instability.**

**Figure 6 Rotator-cuff tear in a patient with recurrent anterior instability.**

erative arthropathy in the shoulder joint (Figure 5). The common surgical interventions address the labral tears as well as the capsular laxity which are generally the basic underlying pathologies. Surgical repair of any accompanying rotator cuff tear should also be included in the treatment process (Figure 6). Although many different surgical techniques have been described to treat traumatic recurrent anterior instability of the shoulder, the best method still remains controversial. A successful clinical outcome basically requires an accurate surgical technique applied *via* adequate exposure. The main objective of the treatment should be considered as the most anatomical repair of the well defined pathological condition leading to recurrent instability. Achieving the best result for any particular patient depends on the procedure which allows observation of the joint surfaces, provides the anatomical repair, maintains range of motion, and also can be applied with low rates of complications and recurrence.

Open and arthroscopic procedures are treatment options in patients with traumatic recurrent anterior instability of the shoulder which is unresponsive to conservative measures. The arthroscopic treatment of glenohumeral instability requires that a level of expertise be achieved and retained[31]. Although open stabilization was reported as more effective than arthroscopic stabilization in the aspect of post-operative recurrence rates in 1990s, clinical outcomes have become similar in time. Technological improvements in arthroscopic instrumentation as well as the development of the innovative surgical techniques as a result of the cumulative experience with improved understanding of the factors leading failure in such patients have played the key role[24,33,37-43]. In their prospective randomized study, Fabbriciani *et al*[41] reported equal results between arthroscopic and open surgical repair of Bankart lesion in the aspect of recurrence. According to the results of another recent prospective randomized clinical trial comparing open and arthroscopic techniques, the difference in quality of life between the patients in the two groups was neither significant nor clinically important at two years follow-up; however significantly lower risk of recurrence was obtained in patients for whom open repair was preferred[5]. Surgical treatment of athletes participating in contact sports is still controversial. Rhee *et al*[44] compared the results of arthroscopic and open stabilization in young contact athletes and reported recurrent instability as 25% in the arthroscopic group and 13% in the open stabilization group. Some authors mentioned that athletic activity plays a greater role in post-operative recurrence than the surgical method used for stabilization[39,45].

Bone loss either on the glenoid or the humeral head may cause or complicate recurrent shoulder dislocations. Recurrent episodes of anterior instability of the shoulder joint may cause Hill-Sachs or osseous Bankart lesion get larger which leads further instability[46,47]. Therefore, isolated Bankart repair is generally not sufficient as the surgical management of the patients with osseous lesions. In their study which evaluates the morphology of the glenoid cavity in patients with recurrent anterior instability of the shoulder, Sugaya *et al*[48] concluded that 10% of subjects did not have osseous pathology, 40% had bony erosion, and 50% had an osseous Bankart lesion. If bone loss is greater than 25% of the glenoid surface, surgical treatment should include a bony reconstruction procedure[49]. Ideal technique for the surgical management of bony defects on the glenoid rim is controversial. Reduction and fixation of the displaced glenoid rim fracture, transfer of the coracoid process to the anterior glenoid, and reconstruction by using autograft or allograft bone block are the methods to restore the normal width and depth of the glenoid cavity. Basically, all of the various surgical interventions aim to restore more anatomic glenoid morphology to prevent recurrent instability. Park *et al*[50] reported that following successful fixation of the glenoid fracture in its anatomic position, fragments unite and survive without resorption at one year. When the bone loss is greater than 25% of the glenoid surface with a missing fragment, transfer of the coracoid process to the anterior glenoid rim as a structural block is the best approach. Bristow, Latarjet, or Trillat procedures are effective, most widely known and used techniques of coracoid transfer into the glenoid lesion. Latarjet procedure, which was first described in 1954, is the transfer of the coracoid process through the subscapularis tendon to provide an osseous block during joint motion. Bristow procedure is the technique in which the terminal 1 cm

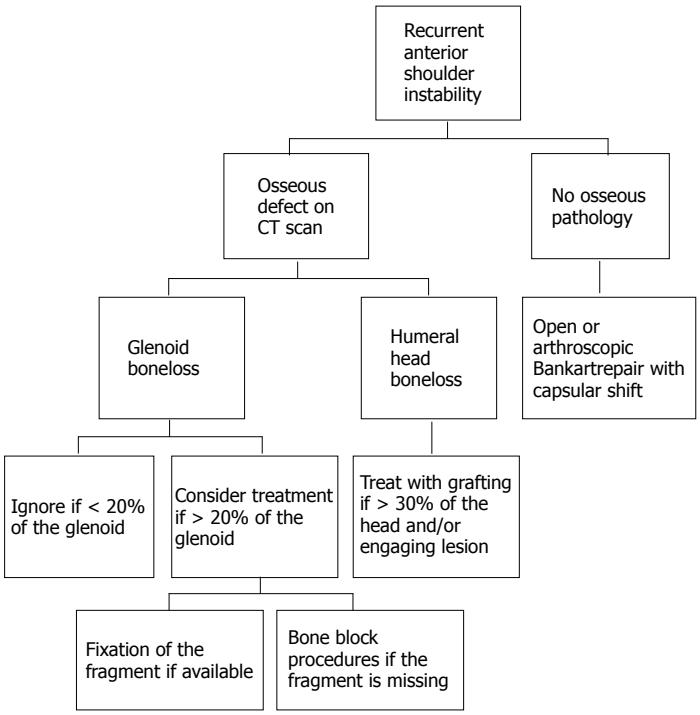

**Figure 7 Treatment algorithm that we follow in our clinical practice.**

of the coracoid is transferred together with the conjoint tendon onto the neck of the scapula through a horizontal slit in the subscapularis muscle. In Trillat procedure, the coracoid is osteotomized following an arthrotomy, then it is displaced and fixed with a coracoscapular screw. Burkhart *et al*[51] reported that no recurrent instability was detected at a mean follow-up of 4.9 years following coracoid transfer performed in forty-seven patients. The Latarjet procedure, also as a revision to manage recurrence of anterior shoulder instability after previous operative repair associated with defects of the anterior glenoid rim and an intact subscapularis muscle, was reported as satisfactorily restoring glenohumeral stability[52]. Warner *et al*[53] and Scheibel *et al*[54] evaluated recurrence of the anterior instability following anterior glenoid augmentation by using iliac crest bone autograft and they reported no evidence of recurrent instability in their series.

Burkhart *et al*[24] used the term "engaging Hill-Sachs lesion" to describe a compression fracture on the posterosuperior aspect of the humeral head which drops over the glenoid rim in external rotation of an abducted shoulder and is associated with recurrent instability. Tenodesis of the infraspinatus into the lesion which is also called "remplissage" and bone grafting of the defect are the surgical interventions described to address the osseous defect on the humeral head. Boileau *et al*[55] reported that arthroscopic Hill-Sachs remplissage procedure in combination with Bankart repair in the treatment of patients with a large bony defect on the humeral head was an effective method. The authors also concluded that 98% of the patients had a stable shoulder joint at the latest follow-up with approximately 10 degrees of restriction in external rotation which did not significantly affect return to sports activity. An *in-vitro* study evaluating biomechanical effects of remplissage showed that in specimens with a 30% Hill-Sachs lesion it prevented engagement of the lesion[56]. Bone grafting can also be applied as another treatment option for defects of the humeral head. Osteoarticular plugs and osteoarticular humeral head allograft are the options for large diameter lesions[36,57]. Collapse or resorption of the graft should be kept in mind as an important risk factor which may lead to failure in such cases.

There are various techniques addressing different pathologies of both the soft tissues and bones which generally unite to form a complex disease process. Therefore, when dealing with the clinical management of recurrent anterior instability of the shoulder joint, one should always carefully analyze the patient-specific pathologies and consider treatment options according to the needs of every particular case. In this regard, a guideline is generally needed. Figure 7 demonstrates the algorithm that we use in the management of patients with recurrent anterior instability of the shoulder joint.

## CONCLUSION

Anterior shoulder instability is among the most commonly seen disorders in traumatology, which typically affects the younger age population with high rates of recurrence. Recurrent anterior instability of the shoulder is a complex disease which may include both soft tissue and osseous pathologies. Primary clinical approach should be the combination of a careful medical history, a detailed physical examination, and appropriate imaging studies to recognize changes leading to recurrence. Although various surgical techniques have been described, a consensus does not exist and thus, surgeons should select the most effective procedure to restore joint stability in a patient-specific manner.

## Abstract

The edentulous posterior maxilla is considered a clinical challenge during dental implant treatment for many dental practitioners. This is because its insufficient bone quality, deficient alveolar ridge, spiny ridges, undercuts, and sinus pneumatization are often encountered after tooth loss. To overcome these problems, several approaches have been developed and are currently used, including sinus augmentation and bone augmentation. Today, two main procedures of sinus floor elevation for dental implant placement are in use: a two-stage technique using the lateral window approach, and a one-stage technique using a lateral or a crestal approach. In this study, we deal with the anatomic relations of the structures of the maxillary sinus during sinus augmentation. These anatomical findings can help in complications and potential injuries of the maxillary sinus procedures. It can be suggested that pre-operative evaluation is helpful for diagnosis and treatment planning and minimizing complication during the surgery.

**Key words:** Anatomy; Intraoperative complications; Sinus floor augmentation

**Core tip:** The edentulous posterior maxilla is considered a clinical challenge during dental implant treatment. Sinus augmentation and bone augmentation are used to overcome these problems. Maxillary sinus septa have been related to increased risk of perforation of the membrane during sinus augmentation. The lateral window design may be modified by the making of two windows or one w-shape window if the septum is lower. The branches of the maxillary artery should be taken into consideration to avoid bleeding complications. It can be suggested that pre-operative evaluation is helpful for diagnosis and treatment planning and minimizing complication during the surgery.

## INTRODUCTION

For many dental practitioners, the edentulous posterior maxilla is considered a clinical challenge during dental implant treatment[1]. This is because its insufficient bone quality, deficient alveolar ridge, spiny ridges, undercuts,

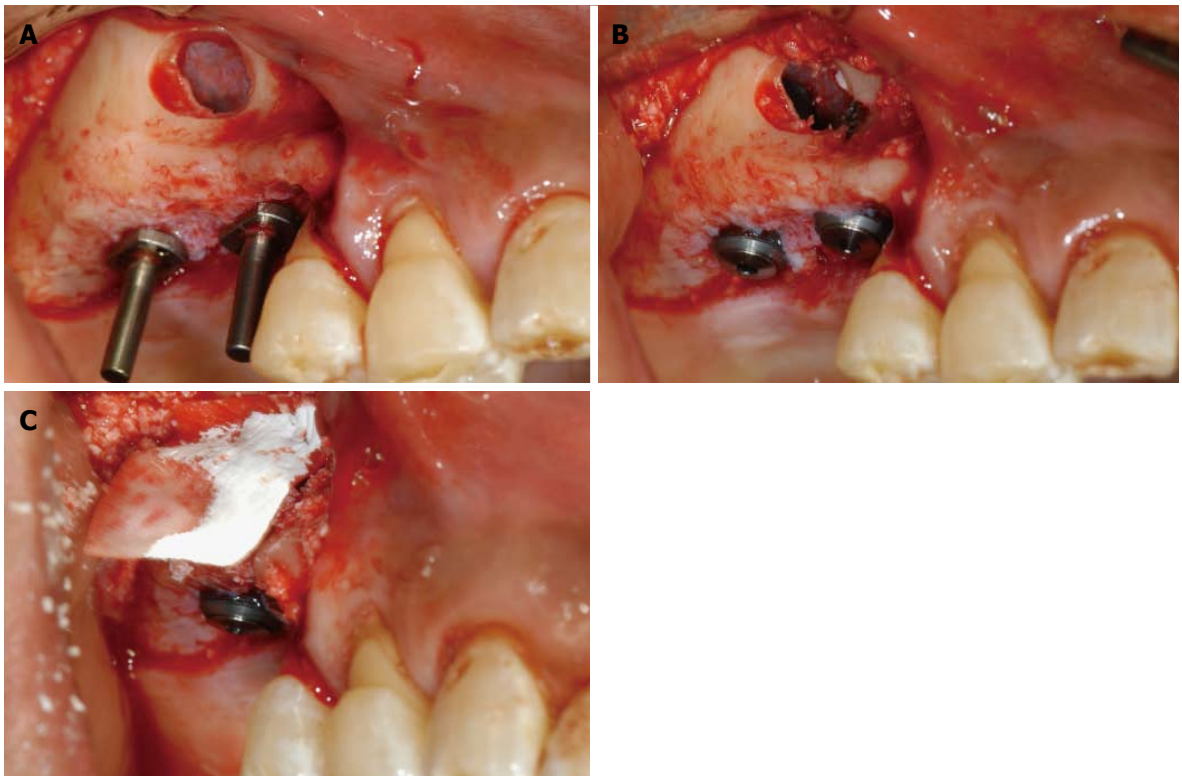

**Figure 1 Buccal and clinical view.** A: Buccal view after elevation of sinus membrane; B: Buccal view after installation of dental implants; C: Clinical view after application of graft material.

and sinus pneumatization are often encountered after tooth loss. Several approaches have been developed and are currently used to overcome these problems, two of them being sinus augmentation and bone augmentation[2,3]. Elevation of the maxillary sinus floor was first published by Boyne *et al*[4] in 1980. After these reports, several techniques were reported for successful sinus floor elevation, including crestal and transalveolar approaches[5,6]. A crestal approach uses the osteotome technique introduced by Summers in 1994[5]. Today, dental practitioners use two main procedures of sinus floor elevation for dental implant placement: a two-stage technique using the lateral window approach, and a one-stage technique using a lateral or a crestal approach (Figure 1)[7].

In this report, we have reviewed anatomical consideration in the posterior maxillae for sinus augmentation, to ensure predictable sinus graft surgery and help decide surgical technique with minimum complication. Preoperative evaluation seems necessary for implant surgery to succeed without complication.

## ANATOMY OF MAXILLARY SINUS

Before performing sinus augmentation surgery, it is crucial to understand the anatomy of maxillary sinus. The function of the maxillary sinus is not yet well known. Theories on its physiologic function include: (1) weight reduction to maintain equipoise of the head; (2) protection of intracranial structures; (3) thermal insulation of vital parts; (4) humidification and warming of inhaled air; (5) secretion of mucus to moisten the nasal cavity; (6) secretion of mucus to moisten the nasal cavity; (7) increasing the area for olfaction; and (8) imparting resonance to the voice[8].

The maxillary sinus is the largest and most constant of the paranasal sinuses. After birth, it undergoes two periods of rapid growth, first between birth and 3 years since, and then between ages 7 and 18 years[9]. The maxillary sinus has a pyramidal shape, with an anterior wall corresponding to the facial surface of the maxilla. Its posterior bony wall separates it from the pterygomaxillary fossa medially and from the infratemporal fossa laterally. Its medial wall is the lateral nasal wall and separates the sinus from the nasal cavity and communicates with the nasal cavity *via* the ostium semilunaris to the hiatus semilunaris (middle meatus)[10]. The ostium of the maxillary sinus is high up on the medial wall and on average is 2.4 mm in diameter[10].

The Maxillary sinus floor consists of the alveolar process of the maxilla. The sinus floor is usually convex, with its lowest point around the first and second upper molars[11]. As aging occurs, the sinus floor tends to resorb and form dehiscences around the roots[12]. The root ends may jut into the cavity, covered only by the Schneiderian membrane and a small bone cortex flap[13].

## SINUS PNEUMATIZATION AND RESIDUAL BONE RESORPTION

Maxillary sinus pnematization is a physiologic process

**Figure 2 Panoramic view from cone beam computed tomography showing septum.**

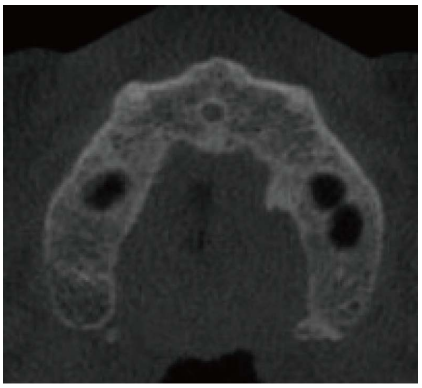

**Figure 3 Axial view from cone beam computed tomography with septum on left maxillary sinus.**

that occurs in all paranasal sinuses during the growth period, causing them to increase in volume[14]. The reasons for sinus pneumatization are poorly understood, but factors that cause this process include heredity, the pneumatization drive of the nose's mucous membrane, craniofacial configuration, density of the bone, growth hormones, sinus air pressure, sinus surgery, and posterior tooth extraction[15]. According to a radiographic study, pneumatization was more significant after extraction of teeth enveloped by a superiorly curving sinus floor, extraction of several adjacent posterior teeth, and extraction of second molars as opposed to first molars[15].

Residual ridge resorption following tooth extraction is unavoidable process in posterior maxillary area. Extensive ridge resorption is one of the many problems for implant-prosthetic treatment in the posterior maxillae. Although resorption rate is subject to individual variability and almost resorption occurs in 6 mo after extraction, the alveolar ridge resorption persists for subsequent years to decades[16,17].

Available alveolar bone may be compromised in the in the posterior maxillae may be compromised because of sinus pneumatization and/or residual ridge resorption after tooth loss. The average height of the available bone in the edentulous maxilla was classified into three classes[14]. Class 1 had a residual bone height of 10 mm, usually found in edentulism of no more than 5 years' standing. Class 2 had a residual bone height of 5-10 mm, usually found in edentulism of 5-10 years. Class 3 indicated a bone height of 0-5 mm, usually found in edentulism of more than 10 years. A previous report has recommended that sinus augmentation be performed in classes 2 and 3. If the implant with 10 mm length is planned, sinus augmentation should be considered in Classes 2 and 3.

## SEPTA OF THE MAXILLARY SINUS

Maxillary sinus septa are barriers of cortical bone that divide the maxillary sinus into multiple compartments, known as recesses. Diagnosis of septa presence by computed tomography is important for planning maxillary sinus elevation surgery and later separating the sinus membrane from the septa (Figures 2 and 3)[18]. Septa have become increasingly important in maxillary sinus anatomy as surgical technique has developed. The cause of antral septa has been described previously[19]. Congenital septa are thought to have evolved during the growth of the middle part of the face, and the other, secondary septa are reported to be arisen from irregular pneumatization of the sinus floor after tooth extraction. Other reports classify septa as primary septa if they are located above the maxillary tooth and as other septa if they are located above an edentulous ridge, since septa may be either primary or secondary, or a combination of both types[20,21].

A previous report has showed that septa are significantly higher in the atrophic sinus than in the dentate maxillae, and septa are more commonly located in the molar regions than in the premolar and retromolar areas[22]. Prevalence of sinus septa is between 20% and 35%[19,23], and the mean height of septa is 7.5 mm[22]. Diagnosis using two-dimensional panoramic radiographs yields incorrect results in 29% of cases, and it has been suggested that three-dimensional computed tomography may be used to avoid complications during sinus augmentation[22].

The septum has been related to increased risk of perforation of the membrane during sinus augmentation[24,25]. The lateral window design may be modified by the making of two windows or one w-shape window if the septum is lower (Figure 4). Septa may be cut with a chisel and be removed so that the graft can be placed without interruption[20].

## VASCULAR SYSTEM OF THE MAXILLARY SINUS

The blood supply of the maxillary sinus is derived from three arteries: the infra-orbital artery, the posterior lateral nasal artery, and the posterior superior alveolar artery[26,27]. Among these arteries, the posterior superior alveolar artery and the infra-orbital artery supply the buccal part of the maxillary sinus, and they also supply local oral mucosa as well as the mucous membrane in a double

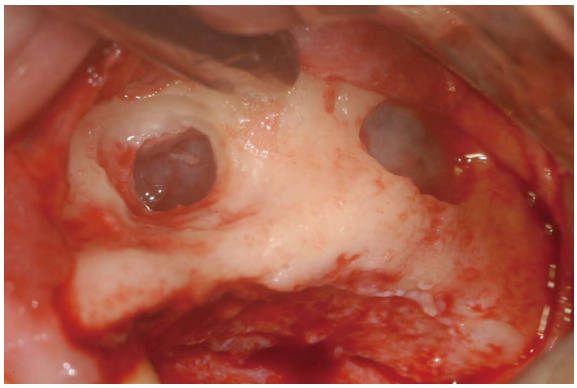

**Figure 4 Buccal view showing lateral window design having two windows.**

arterial circle[28]. The posterior superior alveolar artery enters the pterygopalatine fossa, and divides into one extraosseous and one intraosseous branch, which enter the maxillary tuberosity[29]. To prevent damage to the extraosseous anastomosis, it is crucial to analyze its height from the cortical bone, its diameter, and the course of the artery. The anastamosis forms a concave arch at the first molar, and that is the lowest point of the bony canal's arch course, and the mean distance between the bone crest and the canal is 19 mm[26,30]. An intraosseous vascular canal at the lateral antral wall has been found in over 50% of cases[28]. To avoid bleeding complications, the branches of the maxillary artery should be taken into consideration.

## SCHNEIDERIAN MEMBRANE

The Schneiderian membrane lines the inner walls of the sinus, which is represented by ciliated columnar cells, goblet cells, and basal cells resting on the basement membrane[10]. The membrane's thickness varies but is generally 0.3-0.8 mm in unfixed, fresh cadavers without sinusitis[31]. A study with cone beam computed tomography has showed that individuals vary greatly in the thickness of their Schneiderian membranes, from 0.16 to 34.61 mm, and the highest mean values have been found in the midsagittal aspect[32]. Other local or systemic factors that influence the thickness of the Schneiderian membrane are described in previous reports. Gingival thickness and sex are reported to be related to the Schneiderian membrane's thickness: the membrane is thicker in patients with thick gingival biotype and thinner in female subjects[32-34]. Higher Schneiderian membrane thickness has been noted next to restored teeth and periodontal and endodontic lesions. Especially in molar regions with periodontal destruction, the Schneiderian membrane has thickened, particularly when there are small bone layers above the root tips or periapical lesions. In addition, inflammation or allergic phenomena, as well as smoking, are correlated with increased mucosal thickness[35].

It has been shown that the Schneiderian membrane swells significantly, by 6.7 mm, after sinus augmentation, and that this swelling disappears three weeks later[36]. In one report, patients' computed tomographic scans have been compared before bone grafting and 4 to 6 mo after bone grafting[37]. Sinus membrane thickness differs significantly before (0.8-1.2 mm) and after (1.5-1.3 mm) augmentation surgery, with a mean increase of 0.8-1.6 mm (maximum: 4.4 mm), and only 28% of augmented sinuses do not show membrane thickening. Other reports, however, show no significant change in the membrane thickness between computed tomographic scans taken before operation and an average of 8.9 mo after operation[38]. This discrepancy may be explained by the study design: the latter study excluded bilateral sinus augmentations and had higher membrane thickness before operation, with a higher history of periodontitis (75.7 %).

Which types of mucosal thickening require therapy is still unknown, but historically 2 mm is considered a reliable threshold for pathological mucosal swelling[39]. Since the most frequent surgical complication occurring during sinus augmentation is perforation of the Schneiderian membrane (10%-56%)[40], it is crucial to check the Scheniderian membrane status by cone beam computed tomography or with an endoscope, and to eliminate sinusitis and other potential pathological conditions before any surgery. A previous study shows that 38.2% of presumably reversible ear, nose, and throat contraindications have been detected and resolved before sinus augmentation, and the same study suggests that a careful multitasking preoperative management, including an ear, nose, and throat assessment with fiberoptic endoscopy and a radiological evaluation extended to the ostiomeatal complex, may be very useful in candidates for sinus augmentation[41].

## CONCLUSION

In this report, we have dealt with the anatomic relations of the structures of the maxillary sinus during sinus augmentation. These anatomical findings can help with complications and potential injuries in procedures involving the maxillary sinus. It can be suggested that preoperative evaluation is helpful for diagnosis and treatment planning, as well as for minimizing complications during surgery.

## Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) has become the mainstay of treatment in hepato-pancreato-biliary disease. However, ERCP requires a high level of technical skills and experience in therapeutic endoscopy, there is always a risk of complications. Especially, the perforation per se affects the patient adversely, and the clinical course may lead to a poor prognosis, even with appropriate management. The treatments for ERCP-related perforation are diverse, depending on the location and mechanism of the bowel perforation and the time of diagnosis. Thus, we reviewed the appropriate surgical and non-surgical management options for therapeutic ERCP-related perforations, especially, evaluating metallic stenting as a treatment modality in perivaterian perforation.

**Key words:** Endoscopic retrograde cholangiopancreatography; Perforation; Self-expandable metallic stent; Duodenum; Perivaterian

**Core tip:** Although the evidence supporting the use of fully covered self-expandable metallic stent in perivaterian perforations is still insufficient, the clinical outcomes were encouraging.

Value of temporary stents for the management of perivaterian perforation during endoscopic retrograde cholangiopancreatography. *World J Clin Cases* 2014; 2(11): 689-697 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/689.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.689

## INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) has become the mainstay of treatment in hepato-pancreato-biliary disease since its introduction in 1968[1]. In the past, ERCP had been used as a *diagnostic* tool in choledocholithiasis presenting with jaundice, dilated common bile duct, acute pancreatitis, and cholangitis, but recently ERCP combined with sphincterotomy and stone removal has become a valuable *therapeutic* procedure[2].

Because ERCP requires a high level of technical skills and experience in therapeutic endoscopy, there is always a risk of complications, such as bleeding, perforation, pancreatitis, and cholangitis. Indeed, complication rates range from 5.4% to 11.2%[3-11], among which the rate of perforation, a potentially fatal complication, is 0.3%-1.0%[3,12,13], and the rate of mortality in perforated patients is high (8%-23%)[3,12-14]. Moreover, perforation *per se* affects the patient adversely, and the clinical course may lead to a poor prognosis, even with appropriate management. Delayed diagnosis and management can further affect clinical outcomes adversely[15,16].

The treatments for ERCP-related perforation are diverse, depending on the location and mechanism of the

bowel perforation and the time of diagnosis[17,18]. Previously, most ERCP-related perforations, regardless of the above factors, were managed using surgery, and the mortality rate with such surgery was generally high. However, after the introduction of treatment strategies according to the type of perforation, nonsurgical management, such as radiologic interventions using percutaneous transhepatic biliary drainage (PTBD) and endoscopic management using endoscopic nasobiliary drainage (ENBD), endoscopic retrograde biliary drainage (ERBD), endoclips, and fibrin glue, have been developed. Consequently, treatment outcomes have improved greatly over time[12,15-24].

Now, nonsurgical techniques are being used in suitable select patients more than often than surgery. Among the various nonsurgical options, several recent studies have reported that fully covered self-expandable metallic stents (SEMSs) could be used in ERCP-related perforation, especially in periampullary perforations[25-28]. Thus, we reviewed the appropriate surgical and non-surgical management options for therapeutic ERCP-related perforations, especially, evaluating metallic stenting as a treatment modality in perivaterian perforation.

## CLASSIFICATION OF ERCP-RELATED PERFORATION

The treatment modality in ERCP-related perforations is associated with the type of the perforation (Table 1). Stapfer *et al*[18] classified perforations into four types according to anatomical location and severity. Type Ⅰ duodenal injuries are perforations of the lateral or medial wall, caused by the endoscope itself. Type Ⅱ duodenal injuries are perforations of the medial wall. These are perivaterian or periampullary perforations, and most occur during endoscopic sphincterotomies. Type Ⅲ duodenal injuries are perforations of the distal bile duct, typically due to wire or basket instrumentation. Type Ⅳ duodenal injuries are diminutive retroperitoneal perforations due to excessive use of compressed air to retain a patent bowel lumen.

Similar to Stapfer's classification, Howard *et al*[17] reported three types of ERCP-related perforations in accordance with the mechanism of injury. Group Ⅰ perforations are guidewire perforations of the duct, group Ⅱ perforations are periampullary perforations, and group Ⅲ perforations are duodenal perforations remote from the ampulla.

Regarding incidence by type of perforation, generally, periampullary perforations caused by endoscopic sphincterotomies are most common, 15%-55%[12,17-19]. Polydorou *et al*[23] reported incidences using a modified classification of ERCP-related perforation. Type Ⅰ, and type Ⅱ injuries are identical with Stapfer's type Ⅰ and Ⅱ injuries, but type Ⅲ injuries are ductal or duodenal perforations caused by endoscopic instruments, but not guidewires, and type Ⅳ injuries are guidewire perforations with the presence of retroperitoneal air on X-ray examination. They showed incidences of 68% for type Ⅱ, 16% for type Ⅰ, 11% for type Ⅲ, and 4% for type Ⅳ perforations. Another study showed that guidewire-related perforations were most common (32%)[19]. Moreover, 15% were sphincterotomy-related perforations, 11% occurred during passage of the endoscope, and 9% occurred due to stent migration. Morgan *et al*[22] reported that 12 of 24 cases of ERCP-related perforations were related to sphincterotomy, and the other 12 cases were perforations remote from the papilla. Although the incidence of ERCP-related perforations varied slightly among the previous studies, sphincterotomy-related perforations tend to be most common, followed by guidewire-related perforations and free wall perforations.

## RISK FACTORS FOR ERCP-RELATED PERFORATIONS

Several studies have reported risk factors for ERCP-related perforations. Overall risk factors, regardless of the type of ERCP-related perforation, include old age and a longer ERCP procedure time. Enns *et al*[12] demonstrated that patients older than 65 years had a greater risk of ERCP-related perforation. Longer procedure times are often accompanied by repeated cannulation or more invasive methods to achieve "good" results. Thus, there tends to also be a greater risk of perforation. Additionally, ERCP-related perforation may be increased when performed by a trainee endoscopist. However, experts in the therapeutic ERCP field operate frequently and especially with severe and difficult cases; thus, there is always a risk of perforation during the procedure regardless of the surgeon's experience.

Risk factors for Stapfer's type Ⅰ perforation are abnormal anatomical structures, such as gastrojejunostomy, pancreaticoduodenectomy, duodenal diverticulum or stricture, and situs inversus[22,29-31]. With anatomical features that differ from those of normal situations, it may be difficult to penetrate the bowel lumen using a side-viewing endoscope, increasing the risk of perforation by the endoscope itself.

Risk factors for Stapfer's type Ⅱ, Ⅲ, and Ⅳ perforations are similar and overlapping. They include sphincter of Oddi dysfunction, precut sphincterotomy, and a dilated common bile duct on abdominal imaging[12]. Precut sphincterotomy has been reported as a known risk factor

for pancreatitis[6,7,32]. However, several studies have demonstrated that precut sphincterotomy also increases the risk of perforation compared with a conventional sphincterotomy. In fact, the risk of perforation increases if the incision for the sphincterotomy is outside of the usually recommended sector (11 to 1 o'clock position)[6,33-35]. A previous report demonstrated that 7 of 13 sphincterotomy-related perforations were associated with precutting[12]. Since a dilated common bile duct is associated with distal common bile duct stricture, the risk of perforation may be related to the deep manipulation needed to achieve a deep cannulation. Additionally, an ampullectomy can increase the risk of perforations. Alfieri *et al*[15] reported that ampullectomy had been performed in 7 of 30 (23%) cases of ERCP-related perforations.

## CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with ERCP-related perforations may complain mainly of epigastric pain and tenderness, but obviously these complaints are very nonspecific. Other symptoms and signs include fever, tachycardia, leukocytosis, and mildly elevated serum amylase levels. Several studies have reported rare complications after ERCP, such as pneumomediastinum, pneumothorax, and gas in the portal system[36-42], whereas patients with retroperitoneal air present on abdominal imaging, after an endoscopic sphincterotomy, can be asymptomatic clinically. Generally, the patients did not require intervention but only conservative management. Genzlinger *et al*[43] showed that asymptomatic patients with retroperitoneal air evident on a computed tomography (CT) scan did not require surgical intervention. As the range is diverse, from asymptomatic to severe signs of peritonitis, to suspect and recognize the possibility of perforation early, during and after ERCP is most important. For early detection of perforation, it is necessary to check the patient's condition immediately after ERCP. If the patient complains severe abdominal pain, abdominal X-ray and CT are good methods to identify ERCP-related perforation. If retroperitoneal air is visible during the procedure, abdominal X-ray and CT are also useful.

ERCP-related perforation can sometimes be diagnosed readily by imaging if suspected. Typically, an abdominal X-ray may show retroperitoneal air around the right kidney. Suspected perforation may not be confirmed by an abdominal X-ray, but a contrast CT scan or upper gastrointestinal oral contrast evaluation should be helpful. However, this could be delayed unless the physician suspects a perforation. Furthermore, if the patient has elevated serum amylase levels and complaints of epigastric pain, it is difficult to distinguish between perforation and pancreatitis. Gottlieb *et al*[44] reported that post-ERCP pancreatitis can be excluded if their values of amylase and lipase 2 h after ERCP are below 276 U/L and 1000 U/L, respectively. Another study demonstrated that post-ERCP pancreatitis cases showed serum amylase levels greater than five-fold the normal level[45]. Thus, laboratory findings, especially serum amylase and lipase levels, may be important clues for differentiating perforation from pancreatitis.

Although a physical examination is frequently useful in suspected patients, not all perforated patients show signs of acute peritonitis[43]. Bell *et al*[46] demonstrated positive physical findings in 75% of the included patients, but no specific finding of perforations. Thus, it is important to consider not only a physical examination and laboratory findings but also abdominal imaging, such as abdominal X-ray and abdominal CT scans, for an accurate diagnosis.

## TREATMENT OF ERCP-RELATED PERFORATION

Traditionally, ERCP-related perforation has been managed surgically. The objectives of such surgical management include control of infection and inflammation (drainage of the retroperitoneal/intraperitoneal fluid and air and drainage of the biliary system) and closure of the perforation, with or without bypass[2]. However, the recent trend has been towards a selective approach according to the type of perforation and, more recently, according to the overall status of the patient, considering issues such as age, vital signs, peritoneal signs, comorbidities, and CT images.

Duodenal free wall perforations (Stapfer type I or Howard Group Ⅲ) tend to be larger and located remotely from the ampulla and to cause substantial collections in the peritoneal or retroperitoneal space. Thus, these perforations should be subjected to prompt surgical intervention. One study reported three of four cases of type I perforation that underwent surgery immediately[12]. One case had abnormal anatomy, a gastrojejunostomy, and the others cases had duodenal diverticulum and stricture. All three patients were suspected and diagnosed immediately; there was no mortality. The one patient without surgical management had severe comorbidities, thus receiving only conservative management but died 2 d later. Polydorou *et al*[23] reported that 83% (6/7) of Stapfer's type I perforation cases underwent surgery. Three patients with type I perforation showed abnormal anatomy due to Billroth Ⅱ gastrectomies. Among the patients who underwent surgery, two died as a result of respiratory insufficiency and aspiration pneumonia. One patient with a type I perforation, caused by rupture of the diverticulum, was managed conservatively. The patient had no fever or signs of peritonitis but only complained of mild abdominal pain.

In the studies mentioned above, in general most of the type I perforations were treated using surgery due to the large size of the perforation. Recently, some studies have introduced endoscopic management using simple metallic endoclips or an endoloop with multiple endoclips and fibrin glue for free wall duodenal perforations[28,34,47-50]. In addition, an over-the-scope-clip, used

Conservative management: intravenous antibiotics, fluids, pain control, nil-by-mouth, close monitoring, and nasogastric drainage. ENBD: Endoscopic nasobiliary drainage; PTBD: Percutaneous transhepatic biliary drainage; ERBD: Endoscopic retrograde biliary drainage.

primarily in gastrointestinal bleeding or perforation, could be considered for use in post-ERCP perforations[51,52].

Distal bile duct injuries (Stapfer type Ⅲ or Howard Group Ⅰ), caused by penetration of the guidewire through the bile duct during cannulation in a narrow or obstructed duct, tend to be smaller than duodenal free wall perforations. Commonly, these perforations tend to become obstructed spontaneously, and these patients can be 'cured' by conservative management with intravenous antibiotics, hydration, pain control, or nil-by-mouth[12,17,18,53]. However, since some patients have ongoing bile leakage, endoscopic management to prevent bile leakage to the retroperitoneum may be necessary. To prevent such leakage, ENBD or ERBD together with insertion of a plastic or metallic stent can be used. If endoscopic management is not possible, PTBD can be performed.

Diminutive duodenal perforation (Stapfer type Ⅳ) is not a true perforation; generally, it can be treated sufficiently with conservative management alone. In fact, Genzlinger *et al*[43] reported that retroperitoneal air alone, with no abnormal clinical signs or symptoms, does not require surgical intervention. However, regardless of the type of perforation, patients with retained stones or unalleviated biliary obstruction should undergo surgery[18].

Perivaterian perforations (Stapfer type Ⅱ or Howard group Ⅱ) occurring after endoscopic sphincterotomy are controversial issues in the treatment field presently because of variation in clinical outcomes[14,18,34,41,53-57]. Surgical intervention is not an issue but is an abstruse problem, because it seems that conservative management alone, including biliary drainage, may aggravate or fail to cure the perforation. Several studies have demonstrated that conservative management with or without biliary drainage was successful in peri-ampullary perforation patients[18,53-55].

Wu *et al*[16] reported that 55% (6/11) of patients with type II perforations were treated with conservative management with or without biliary drainage. In all patients, clinical signs and symptoms improved rapidly. However, 80% (4/5) of the patients who underwent surgery died, due to delayed diagnosis and operation as well as sepsis. The surgical indications for those patients were large retroperitoneal fluid collections, liver abscess on abdominal CT scan, and severe abdominal pain. Enns *et al*[12] demonstrated that 46% (6/13) of patients with type II perforations were treated using conservative management with or without nasogastric suction. In 38% (5/13) of the patients, biliary drainage (stent insertion with three, PTBD with two) was performed. The mortality rate was zero in patients managed conservatively and with biliary drainage. Alfieri *et al*[15] showed that 40% (6/15) of patients with type Ⅱ perforations were treated successfully by conservative management with biliary drainage (PTBD or nasobiliary drainage).

The rates of nonsurgical management *vs* surgical intervention in peri-ampullary perforation vary widely (Table 2)[12,15-18,22,23,58,59]. Thus, the appropriate choice of treatment modality for peri-ampullary perforation remains an important issue. Most surgical indications in peri-ampullary perforations include hemodynamic instability, signs of peritonitis, continuing leakage, septic conditions, and a perforation of large size. One author also suggested that patients with a large amount of fluid collection in the peritoneum or retroperitoneum on abdominal CT should be treated aggressively[12], because the possibility of continuing leakage is high. If there is no surgical indication, the essential aspects of nonsurgical management consist of diversion of duodenal, biliary, and pancreatic drainage[21]. A nasogastric or nasoduodenal tube for duodenal

decompression can be used. ENBD or ERBD can be used in internal biliary drainage to prevent leakage of bile juice into the perforation site. For external biliary drainage, PTBD is used as well.

However, some conditions, such as severe common bile duct dilatation or a large perforation hole, may reduce the diversion of biliary drainage using ENBD or ERBD[27]. Thus, several studies have reported that fully covered self-expandable metallic stents (SEMS) can be useful in biliary stenting for perivaterian perforations[25-28].

Initially, most periampullary perforation patients receive conservative management with or without biliary drainage, according to most previous studies. If conservative management failed and a delayed operation was then performed, the subsequent clinical course was found to be poor in some studies[15,16]. Thus, there is a need to treat using active conservative management. Taking advantage of biliary drainage by ENBD, ERBD, use of plastic or metallic stents, PTBD, duodenal drainage *via* a nasogastric or nasoduodenal tube, pancreatic drainage, and inflammation control are essential. "Conservative management" indicating only intravenous antibiotics, hydration, pain control, and nil-by-mouth is inadequate. Indeed, it is important to combine methods to prevent bile leakage into the perforation site.

## ARE FULLY COVERED SEMS IN ERCP-RELATED PERFORATIONS VALUABLE?

As mentioned above, it is important to divert biliary drainage to prevent leakage of bile juice into the peritoneum in a peri-ampullary perforation. For such diversion, fully covered SEMS occlude the perforation site by radial force, and the perforation site can heal quickly. That is, recovery of the epithelium in the injury site, stent-associated reepithelialization, is achieved. A similar procedure has been performed previously in esophageal perforations. Siersema *et al*[60,61] reported that a fully covered SEMS was useful in nonmalignant and traumatic esophageal perforations; however, in general fully covered SEMS have been used for malignant perforations or fistulas for palliative management. A fully covered SEMS enabled the sealing of an esophageal perforation and prevented mediastinal infection.

Some case series have reported the use of SEMS in ERCP-related perforations (Table 3)[25-28]. Vezakis *et al*[28] reported a case of a persistent high-volume duodenal fistula, caused during an endoscopic sphincterotomy, that was treated successfully using a partially covered SEMS. Jeon *et al*[26] also reported the use of a fully covered SEMS in a sphincterotomy-related duodenal perforation. Although this patient had retroperitoneal fluid collections and peritonitis, she was not considered a candidate for surgery. She was treated with multiple plastic stents for internal biliary drainage and with PTBD for external biliary drainage due to her poor medical condition and old age (82 years). However, because of persistent percutaneous catheter drainage (> 150 mL/d) and contrast leakage from a distal common bile duct on tubogram, a fully covered SEMS was inserted after removing the previous plastic stents. She then recovered completely, and the fully covered SEMS was removed 1 mo later.

Park *et al*[27] also considered duodenal perforation after endoscopic sphincterotomy, similar to the above two studies. Their case was a 61-year-old female complaining of right upper quadrant pain. Biliary duct dilatation had been detected on an abdominal CT scan, and therefore ERCP with sphincterotomy was performed. The day after ERCP, she developed severe abdominal pain, fever, and leukocytosis according to laboratory findings. An abdominal CT showed retroperitoneal air and fluid collection, and the diagnosis was peri-ampullary perforation. A fully covered SEMS (5-cm-long, 10 mm in diameter) was inserted immediately after identifying the perforation, and the patient recovered completely. The retroperitoneal fluid collection seen on the abdominal CT scan resolved. The stent was then removed 10 d after insertion.

In another previously unpublished case, a 46-year-old male was referred to the hospital for right quadrant abdominal pain. He had previously undergone a Billroth I operation for gastric ulcer perforation. Because the patient developed abnormal liver functioning and gallbladder stones on abdominal CT scan, ERCP was performed to identify the biliary duct stone. However, after endoscopic sphincterotomy, a peri-ampullary perforation was detected, and a fully covered SEMS was placed immediately during the ERCP (Figures 1 and 2). After stent-

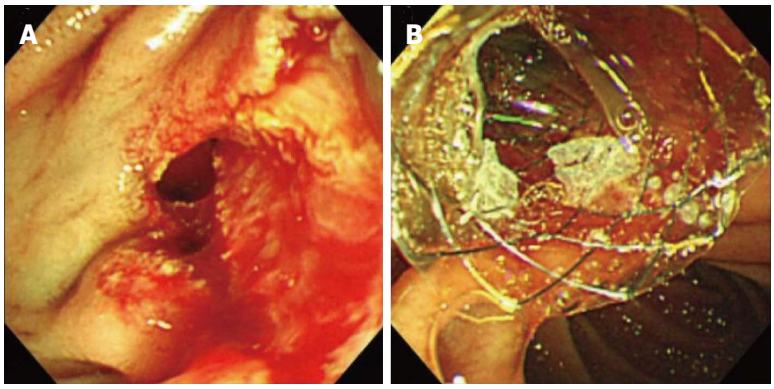

**Figure 1 Insertion of fully covered self-expandable metallic stent for the management of periampullary perforation immediately after endoscopic sphincterotomy.** A: A peri-ampullary perforation was seen after endoscopic sphincterotomy; B: A fully covered self-expandable metallic stent (5-cm-long, 10 mm in diameter) inserted into the common bile duct to prevent bile entering the perforation site can be seen at the ampulla of vater.

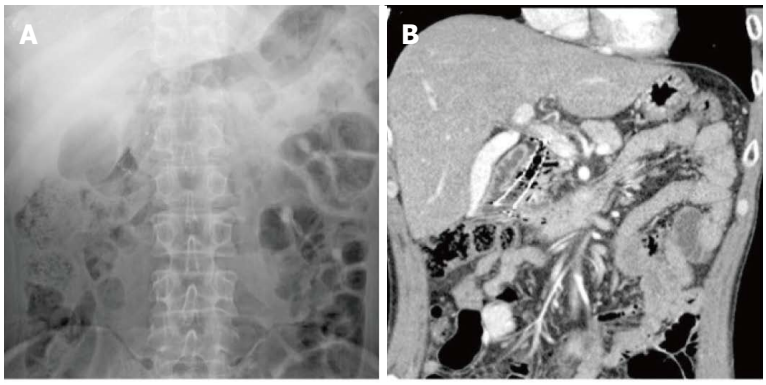

**Figure 2 Deployed fully covered self-expandable metallic stent on (A) abdominal X-ray and (B) abdominal computed tomography scan.**

ing, the patient was stable and was discharged without complications. Although he underwent endoscopy for removal of the stent on day 28 after insertion, the stent had already fallen out spontaneously.

Because fully covered SEMS are available in large diameters, they can be used in a dilated common bile duct without stent migration. They are capable of maintaining long-term patency of the lumen, in contrast to plastic stents. Also, in comparison with uncovered SEMS, fully covered SEMS have several benefits. Uncovered SEMS tend to embed readily in the duct, making it difficult to remove the stent[62-64]. Thus, it is inappropriate to use them for benign conditions, such as strictures, obstructions, and traumatic perforations. The fully covered SEMS overcomes these disadvantage, and can be removed readily[64-66].

However, the optimal duration of stenting has not been established. Bakken *et al*[67] reported that the mean duration of stent placement was 67 (range, 0-279) d for benign strictures and 59 (range, 1-601) d for leaks, fistulas, and perforations. Another study showed that the mean duration was 37 (range, 4-84) d for benign conditions[68]. While discrepancies exist among studies, the time until stent removal is approximately 2 mo for benign esophageal conditions. Several studies have reported stenting durations in peri-ampullary perforations ranging from 10 to 30 d[25-28]. Moreover, because the treatment outcome did not seem to depend on the duration of stenting, and the stent was removed according to the status of the patient, a stent should be removed when the patient shows improved perforation-related symptoms, signs, and imaging results, such as simple abdominal X-rays and abdominal CT scans, even after 1 wk of stenting.

Although several studies have demonstrated good outcomes using temporary fully covered SEMS in ERCP-related perforations, clinically, the situation has not been clarified entirely. Because treatment failure after non-surgical treatment, including the insertion of plastic stents and fully covered SEMS, can cause high mortality and morbidity, close attention must be paid to the decision on treatment modality. A decision taking into consideration the surgery time, while performed non-surgical treatment, is also important. Unrelieved abdominal pain, continued leakage on abdominal CT scans, or hemodynamic instability despite non-surgical management are considerations relevant to surgical intervention. Thus, frequent physical examinations and serial follow-up using abdominal CT scans are helpful in checking for adverse events or treatment failure. However, a patient's condition, such as cardiopulmonary comorbidity, hemodynamic instability, and old age, is also highly relevant to postoperative mortality. If a patient with peri-ampullary perforation has an inoperable condition due to high postoperative risks, a fully covered SEMS can be attempted for palliative treatment[26]. First, it is better to use a fully covered SEMS, especially for a major leakage and large perforation, because ENBD and ERBD may not prevent bile flow into the perforation site completely. Although it is essential to select cases according to their condition, optimal conservative management using a fully covered SEMS may be a good treatment option.

In conclusion, early diagnosis of ERCP-related duodenal perforation is important, and according to the type of perforation, its treatment varies from conservative

management to surgical intervention. Although conservative management is the mainstay for all types of perforations, except type I perforations, the most appropriate treatment modality should be established by performing a comprehensive evaluation of the patient. In particular, a fully covered SEMS for perivaterian perforations was used in selected cases, and the clinical outcomes were encouraging. However, the evidence supporting the use of fully covered SEMS in perivaterian perforations is still insufficient, and further studies are required.

## Abstract

**AIM:** To assess the outcomes of men treated for urolithiasis at the time of radical prostatectomy.

**METHODS:** From 1991 to 2010, 22 patients were retrospectively identified who were treated simultaneously ($n$ = 10) at radical prostatectomy, or ($n$ = 12) within 120 d prior to prostatectomy, for urolithiasis. Clinical characteristics were reviewed including: type of prostatectomy and stone surgery, location and amount of stone burden, perioperative change in hemoglobin and creatinine, stent frequency, total hospital d, stone-free rates, additional stone procedures and complications. Long-term functional outcomes including stress urinary incontinence and bladder neck contracture were reported. Differences between cohorts (simultaneous *vs* staged treatment) were assessed.

**RESULTS:** Among men undergoing radical prostatectomy, primary stone procedures included 12 ureteroscopy, 6 shock wave lithotripsy, 2 open nephrolithotomy and 2 percutaneous nephrolithotomy. In staged shock wave lithotripsy there were 4 complications and 3 additional procedures *vs* 1 ($P$ = 0.5) and 0 ($P$ = 0.2) in the simultaneous cohort. Meanwhile in staged ureteroscopy there were 5 complications and 1 additional procedure *vs* 1 ($P$ = 0.2) and 1 ($P$ = 0.9) in the simultaneous cohort. Additional procedures for residual stones was greater among patients with asymptomatic upper tract calculi 3 (60%) relative to patients with symptomatic stones 2 (13%; $P$ = 0.02). Likewise, patients with proximal or multiple calculi had a greater total hospital days 5.5 *vs* 4.1 ($P$ = 0.04), additional procedures 6 *vs* 0 ($P$ = 0.04) and lower stone-free rates 39% *vs* 89% ($P$ = 0.02) relative to men with distal stones. Finally, there was no difference in the incidence of bladder neck contracture ($P$ = 0.4) or stress urinary incontinence ($P$ = 0.7) between cohorts.

**CONCLUSION:** Ureteroscopic treatment of symptomatic distal urolithiasis at radical prostatectomy appears to be safe and efficacious with a low rate of adverse postoperative outcomes.

**Key words:** Urolithiasis; Kidney stone; Prostate cancer; Radical prostatectomy

**Core tip:** Prostate cancer and urolithiasis can present simultaneously. An acute stone event in the immediate perioperative radical prostatectomy period poses unique management issues. Herein, we describe our experience with the simultaneous treatment of urolithiasis at the time of prostatectomy. We concluded that simultaneous ureteroscopy among symptomatic men with distal ureteral calculi appears to be safe and efficacious. Whereas, in asymptomatic men, or those with proximal/multiple calculi, one should consider treatment in a staged fashion secondary to an increased risk of additional procedures and lower stone-free rates.

## INTRODUCTION

The incidence of urolithiasis and associated healthcare costs continues to rise[1-5]. Specifically, the prevalence of stone disease in the male population ages 50 to 74 years old has increased from 13% from 1988-1994 to 19% in 2007-2010[2], representing a roughly equivalent to 40% relative increase in stone disease[6]. A similar increase in the incidence of prostate cancer has also been observed due to prostate-specific antigen (PSA) screening[7-11]. Currently, it is estimated that greater than 240000 patients are diagnosed with prostate cancer annually in the United States[8,9]. As such, a significant number of male patients diagnosed with prostate cancer may harbor urolithiasis.

As part of prostate cancer evaluation a subset of high-risk men undergo cross-sectional imaging to evaluate for metastatic disease[12-15]. If urinary stone disease is discovered, these patients pose a complex management dilemma given that 44% of asymptomatic patients with urolithiasis will develop symptoms within 1.3 years[16-19]. An acute stone event within the immediate post radical prostatectomy period poses a unique concern; specifically, instrumentation of the fresh vesicourethral anastomosis has the potential for anastomotic injury with resultant long-term urinary incontinence[20,21] and/or bladder neck contracture[22,23]. Historically, at our institution, such cases have been temporized with a nephrostomy tube and delayed definitive stone management until after the vesicourethral anastomosis matures (approximately 120 d).

To date, the safety and feasibility of synchronous treatment of urinary stone disease at radical prostatectomy is unknown. The goal of this study is to assess outcomes of patients with upper tract stone disease treated at the time of prostatectomy compared to those treated in the preoperative period.

## MATERIALS AND METHODS

We retrospectively reviewed all male patients who underwent radical prostatectomy from 1991 to 2010. A total of 22 patients were identified who underwent radical retropubic prostatectomy (RRP) or robotic-assisted radical prostatectomy (RARP) treated simultaneously, or within 120 d preoperatively, for urolithiasis. We evaluated clinical characteristics including type of prostatectomy and stone surgery, location and amount of stone burden, perioperative change in hemoglobin and creatinine, stent frequency, total hospital days, stone-free rates, additional stone procedures and postoperative complications including: steinstrasse, intraoperative bleeding requiring transfusion, acute kidney injury[24], and urosepsis. The total length of hospital stay included both stone and radical prostatectomy procedure. Urinary incontinence was defined as bothersome leakage with straining or need for pad. Bladder neck contracture was identified during post-prostatectomy cystoscopy for obstructive voiding symptoms.

The urinary stone procedure was determined by the operating surgeon based on stone location, timing and type of radical prostatectomy. Simultaneous primary stone intervention was defined as occurring under the same anesthetic as the radical prostatectomy. Staged stone treatments were those within the 120 d before prostatectomy. Maximum stone diameter, location and total burden were determined by preoperative abdominal radiography or computerized tomography. Urolithiasis follow-up included metabolic evaluation, urinalysis with culture and kidney, ureter, and bladder (KUB) X-ray with renal ultrasound between 6-12 wk following stone treatment. Additional cross-sectional imaging, or KUB X-ray with tomograms, was obtained based upon patient symptomology and at the discretion of the treating provider. Stone-free status, after the primary stone procedure was defined as no residual fragments. Postoperative prostate cancer surveillance included physical examinations and serum PSA measurement quarterly for 2 years, semiannually for an additional 2 years and annually thereafter.

Statistical analysis was performed with Student's *t*-test or Wilcoxon Rank Sum for continuous data and Chi-Square or Fisher's Exact test for categorical outcome analysis using JMP software (SAS Institute Inc., Cary, North Carolina), with a P value $< 0.05$ considered statistically significant.

## RESULTS

A total of 29 stone procedures were performed in 19 (86%) men undergoing RRP and 3 (14%) RARP at a median age of 65 years [Interquartile range (IQR) 62-69] (Table 1). Mean follow-up in the simultaneous cohort was 48.5 mo *vs* 45.7 mo in staged patients. In the staged cohort stones were treated prior to radical prostatectomy at a median 31 d (IQR 21-55). A prior history of urolithiasis was present in 16 (73%) men overall. At the time of stone surgery 17 (77%) men presented with one or more symptoms of flank pain, hematuria, urinary tract infection, pyelonephritis or acute renal failure. Ureteral stent was placed in 20 of 21 patients (95%) and nephrostomy tube only in 1 patient. In the simultaneous cohort, ureteral stent was removed at the time of urethral catheter removal 14 d post-prostatectomy with stent string secured to urinary catheter in 4 (40%), *via* clinic cystoscopy 21 d after procedure in 3 (30%), at the time of subsequent stone procedure in 1 (10%) or other method in 2 (20%). In staged patients, ureteral stents were all removed prior to radical prostatectomy or at the time of RRP. Follow-up imaging to determine stone-free status was obtained

[1]Student's *t*-test; [2]Fisher's Exact; [3]$\chi^2$. IQR: Interquartile range; SD: Standard deviation; SWL: Shock wave lithotripsy; URS: Ureteroscopy; PCNL: Percutaneous nephrolithotomy; RARP: Robot assisted radical prostatectomy; RRP: Radical retropubic prostatectomy.

in all patients. Mean stone diameter was 9.1 mm (range 4-20 mm) with no difference in stone size or location between groups. After the initial stone procedure, 6 (60%) simultaneous and 7 (58%) staged were stone-free ($P$ = 0.9) with no difference in stone size between stone-free patients and those with residual calculi (mean 8.3 mm *vs* 10.2 mm; $P$ = 0.3).

Postoperative complications were noted in 5 (42%) staged and 3 (30%) simultaneous patients ($P$ = 0.6), for a total of 7 and 3 complications ($P$ = 0.3) (Table 2). In the simultaneous cohort, bleeding requiring transfusion occurred during radical prostatectomy in 2 (20%) and postoperative urosepsis in 1 (10%). In the staged cohort, there were 7 complications in 5 (42%) patients including 2 (17%) steinstrasse, 4 (33%) bleeding events during and 1 (8%) acute kidney injury after radical prostatectomy. Overall, bladder neck contracture occurred in 3 (14%) patients of whom all required bladder neck dilation. Stress urinary incontinence persisted in 7 (39%), with 1 (4.5%) requiring artificial urinary sphincter and 6 (27%) utilizing ≤ 1 pad with activity.

We then performed a subgroup analysis of simultaneous *vs* staged ureteroscopy (URS) and shock wave lithotripsy (SWL) and found no significant difference in outcomes between groups including: perioperative complications, bladder neck contracture, urinary incontinence, stone-free rates or number of additional procedures(Tables 3 and 4). Among patients undergoing simultaneous URS there were no stone related complications or bladder neck contractures; furthermore only 1 (17%) patient required an additional procedure. In those undergoing SWL, 4 (67%) patients experienced significant complications and 3 (50%) required additional procedures.

[1]Fisher's Exact; [2]Occurred at the time of prostatectomy; [3]Student's *t*-test; [4]$\chi^2$. BNC: Bladder neck contracture; AKI: Acute kidney injury; Cr: Creatinine; Hb: Hemoglobin; SD: Standard deviation.

When stratified by symptomology, 5 (23%) were asymptomatic and 17 (77%) had stone related symptoms; of which, multiple procedures were required in 3 (60%) *vs* 2 (12%; $P$ = 0.02) respectively with no difference in adverse events or length of hospitalization. When stone location was analyzed, 9 (41%) patients had distal ureteral calculi and 13 (59%) had proximal or multiple stones. Relative to patients with multiple or proximal stones, patients with distal calculi had a significantly shorter hospital stay (mean 4.1 *vs* 5.5 d; $P$ = 0.040) and need for subsequent procedures (mean 1.0 procedures/patient; $P$ = 0.03). Moreover, in proximal or multiple stones, 5 (36%) patients required 6 additional procedures (mean 1.46 procedures/patient; $P$ = 0.050) with a stone-free rate following the initial procedure of 5 (39%) *vs* 8 (89%) for distal ureteral calculi ($P$ = 0.02). Finally, there was no difference in complications among those with distal stones compared to proximal or multiple stones [3 (33%) *vs* 5 (38%); $P$ = 0.8].

## DISCUSSION

We evaluate the feasibility, safety and efficacy of simultaneous prostate cancer and urinary stone disease treatment. The potential advantages of this approach include the minimization of perioperative complications associated with urolithiasis and the need for additional procedures. We found no significant difference in treatment outcomes among simultaneous or staged patients; including those men undergoing URS. Meanwhile, men with multiple or proximal stones were at increased risk for additional procedures, longer hospitalization and lower stone-free rates relative to those with distal stones. Similarly, asymptomatic patients were more likely to require additional procedures. Finally, men undergoing SWL had a high rate of stone related complications and retreatment making this a poor option for a simultaneous

treatment approach. As such, given its low rate of complications, and need for secondary procedures, we conclude that there is a potential role for the simultaneous use of URS to treat symptomatic distal ureteral stones at the time of RP.

With a high incidence of prostate cancer[7-9] and urolithiasis in the aging male population[2], a significant proportion of these men may present with urinary stone disease discovered during cancer staging and treatment. In general, asymptomatic urolithiasis has an 8% prevalence with approximately 20% developing a symptomatic stone event within 1.3 years[16]; and, up to 26% may require surgical intervention[18]. However, the appropriate management of the asymptomatic patient that is incidentally found to have stone disease prior to radical prostatectomy remains unknown. Furthermore, for the symptomatic patient that presents a trial of passage may be a reasonable option. However, in those patients who fail medical expulsion therapy[25,26], elect for surgical management[27], or have high-risk prostate cancer the timing of urinary stone treatment becomes paramount.

Meanwhile, the risk of injury to the vesicourethral anastomosis with instrumentation is likely greatest in the immediate postoperative period. Unfortunately, little work has been done to assess the true risk to radical prostatectomy patients undergoing instrumentation for urinary stone treatment in the perioperative period. Gibbons *et al*[28] evaluated the feasibility of retrograde endoscopy in the post-prostatectomy patient. They observed no complications or adverse effect on urinary continence in 21 patients with a mean interval between radical prostatectomy and retrograde endoscopy of 24 mo[28]. Although reassuring, their series may not reflect the true long-term risk due to a short follow-up and significant time between prostatectomy and endoscopy. Herein, we found no significant difference between groups with 14% developing bladder neck contracture and 39% having mild to moderate urinary incontinence at last follow-up. Currently, depending on method of evaluation, 60%-93% of patients will regain urinary continence by 12 mo[20] and 2%-18% develop bladder neck contracture[22], which is not considerably different from our cohort.

In our series complications occurred in 42% *vs* 30% and additional stone procedures in 33% *vs* 10% of staged and simultaneous patients, respectively. We included complications secondary to the stone procedure (urosepsis and steinstrasse) and radical prostatectomy (bleeding). Thus, our increased rate of overall complications is not typically observed with traditional stone procedures. Furthermore, after subgroup analysis of patients undergoing URS and SWL, there remained no significant difference in outcomes. However, in SWL, 50% of staged patients developed steinstrasse and 75% required subsequent procedures which may place a patient at undue risk following prostatectomy. Salem *et al*[29] prospectively evaluated over 3000 patients undergoing SWL and noted a retreatment rate of 37% and steinstrasse in 24% of patients. Our increased retreatment rate reflects an attempt to render all patients stone-free following SWL and limit acute stone events following radical prostatectomy. As such, given the high rate of secondary procedures we feel that SWL should only be performed in a staged setting.

Multiple studies have established the importance of stone size, location and number in predicting stone-free rates[30-35]. Rippel *et al*[30] evaluated patients with CT imaging 30 to 90 d post-operatively. On univariate analysis 49% patients with multiple and 50% with intrarenal calculi had residual stone fragments greater than 2 mm. In our study, only stone location was significantly associated with a risk of retreatment as 38% of patients with proxi-

mal or multiple stones required additional procedures. Meanwhile our stone-free rate, although not significantly different between simultaneous and staged patients, was lower in patients with multiple or upper tract stones ($P$ = 0.02) with no difference based on stone burden ($P$ = 0.3).

Interestingly, patient symptomology was significantly associated with an increased risk of subsequent procedures as 60% of asymptomatic patients required additional stone treatment. We hypothesize that urinary obstruction over time allows for passive dilation of the collecting system thus increasing compliance and allowing ease of stone passage and instrumentation. Frequently, in our experience, the treatment of asymptomatic patients in a single-stage setting can be difficult often requiring multiple procedures and leading to increased complications. Keeley *et al*[36] prospectively evaluated patients undergoing SWL treatment of small (< 15 mm) asymptomatic renal calculi and found a stone-free rate of only 28% at 2.2 years. Despite evidence suggesting that a patient's symptomatology may be a predictor of treatment outcomes; this question has yet to be previously addressed among patients undergoing URS.

Certain limitations of our study exist. We acknowledge that the small patient population, and its retrospective nature, may limit any definitive clinical recommendations for a change of practice. Furthermore, we do not know the incidence of symptomatic progression of urinary stone disease following RP in those men who undergo expectant management preoperatively. Despite these limitations, this study attempts to address the safety, feasibility and utility of performing simultaneous stone treatment at the time of radical prostatectomy. We demonstrate no difference in outcomes which may suggest a role for simultaneous stone removal, specifically URS, in appropriately selected patients. Further prospective trials are needed to identify eligible patients, risk factors for significant short and long-term complications and cost-analysis of a single-stage procedure.

The current study demonstrates that simultaneous treatment of symptomatic distal urolithiasis with URS at the time of radical prostatectomy is safe and efficacious. Meanwhile, given the high rate of residual stone fragments and re-instrumentation following SWL, we recommend it be performed in a staged fashion. Finally, in asymptomatic patients, or those with multiple or upper tract stones, one should consider a staged approach due to the increased risk of additional procedures and reduced stone-free rates.

## COMMENTS

### Background

The prevalence of urinary stone disease in the male population ages 50 to 74 years old has increased from 13% from 1988-1994 to 19% in 2007-2010, representing a roughly equivalent to 40% relative increase in stone disease. A similar increase in the incidence of prostate cancer has also been observed due to PSA screening. As such, a significant number of male patients diagnosed with prostate cancer may harbor urolithiasis. If urinary stone disease is discovered, these patients pose a complex management dilemma given that 44% of asymptomatic patients with urolithiasis will develop symptoms within 1.3 years. An acute stone event within the immediate post radical prostatectomy period poses a unique concern; specifically, instrumentation of the fresh vesicourethral anastomosis has the potential for anastomotic injury with resultant long-term urinary incontinence and/or bladder neck contracture.

### Research frontiers

Ongoing research in the field of urinary stone disease is attempting to identify modifiable patient risk factors to prevent future stone events. Moreover, among men undergoing radical prostatectomy for prostate cancer, significant research efforts are ongoing, including investigation of minimally invasive techniques and minimizing post prostatectomy complications such as urinary incontinence and bladder neck contracture; which can be disabling.

### Innovations and breakthroughs

To the best of our knowledge, this is the first study to investigate the safety and efficacy of synchronous upper tract urinary stone treatment at the time of radical prostatectomy. One previous study has evaluated the association between upper tract endoscopy following radical prostatectomy and stress urinary incontinence. They found no difference in outcomes among men underwent ureteroscopy at a mean 24 mo following prostatectomy.

### Applications

With a high incidence of prostate cancer and urolithiasis in the aging male population, a significant proportion of these men may present with urinary stone disease discovered during cancer staging and treatment. In general, asymptomatic urolithiasis has an 8% prevalence with approximately 20% developing a symptomatic stone event within 1.3 years; and, up to 26% requiring surgical intervention. Meanwhile, the risk of injury to the vesicourethral anastomosis with instrumentation in the setting of an acute stone event is likely greatest in the immediate postoperative period. As such, the appropriate management and timing of treatment in these men is of paramount significance. The potential advantages of a synchronous approach include the minimization of perioperative complications associated with urolithiasis and the need for additional procedures. The current study demonstrates that simultaneous treatment of symptomatic distal urolithiasis with ureteroscopy at the time of radical prostatectomy is safe and efficacious. Meanwhile, we noted a high rate of residual stone fragments and re-instrumentation following shock wave lithotripsy and as such recommend it be performed in a staged fashion. Finally, in asymptomatic patients, or those with multiple or upper tract stones, one should consider a staged approach due to the increased risk of additional procedures and reduced stone-free rates.

### Terminology

Radical prostatectomy is the surgical removal of the prostate gland for the treatment of prostate cancer. Ureteroscopy is a minimally invasive endoscopic procedure to diagnose and treat upper urinary tract disorders. Shock Wave Lithotripsy is a technique for fragmenting a kidney stone with a shock wave that is produced outside the body. Steinstrasse is a complication of shock wave lithotripsy for urinary tract calculi in which stone fragments obstruct the renal unit. Percutaneous Nephrolithotomy is a technique for treating upper tract urinary stone disease by which percutaneous access into the renal unit is obtain. Stone Free refers to no residual stone fragments following stone treatment.

### Peer review

The present study by Amy E Krambeck is investigated the differences in perioperative and long-term outcomes of patients, which treated for urolithiasis at the time of radical prostatectomy (simultaneous) in the preoperative period (staged). The results showed that the simultaneous ureteroscopic treatment of symptomatic urolithiasis appeared to be safe and efficacious with radical prostatectomy. In general, the work was interesting, except several issues to be addressed to increase the quality of the present work.

## Abstract

**AIM:** To evaluate the effect of chemotherapy to the acute toxicity of a hypofractionated radiotherapy (HFRT) schedule for breast cancer.

**METHODS:** We retrospectively analyzed 116 breast cancer patients with T1, 2N0Mx. The patients received 3-D conformal radiotherapy with a total physical dose of 50.54 Gy or 53.2 Gy in 19 or 20 fractions according to stage, over 23-24 d. The last three to four fractions were delivered as a sequential tumor boost. All patients were monitored for acute skin toxicity according to the European Organization for Research and Treatment of Cancer/Radiation Therapy Oncology Group criteria. The maximum monitored value was taken as the final grading score. Multivariate analysis was performed for the contribution of age, chemotherapy and 19 *vs* 20 fractions to the radiation acute skin toxicity.

**RESULTS:** The acute radiation induced skin toxicity was as following: grade Ⅰ 27.6%, grade Ⅱ 7.8% and grade Ⅲ 2.6%. No significant correlation was noted between toxicity grading and chemotherapy ($P$ = 0.154, $\chi^2$ test). The mean values of acute toxicity score in terms of chemotherapy or not, were 0.64 and 0.46 respectively ($P$ = 0.109, Mann Whitney test). No significant correlation was also noted between acute skin toxicity and radiotherapy fractions ($P$ = 0.47, $\chi^2$ test). According to univariate analysis, only chemotherapy contributed significantly to the development of acute skin toxicity but with a critical value of $P$ = 0.05. However, in multivariate analysis, chemotherapy lost its statistical significance. None of the patients during the 2-years of follow-up presented any locoregional relapse.

**CONCLUSION:** There is no clear evidence that chemotherapy has an impact to acute skin toxicity after an HFRT schedule. A randomized trial is needed for definite conclusions.

**Key words:** Hypofractionated radiotherapy; Breast can-

cer; Acute toxicity; Chemotherapy; Retrospective analysis

**Core tip:** The adjuvant radiotherapy for early breast cancer after lumpectomy is an established treatment. Hypofractionation is an attractive approach and the trend nowadays towards new techniques involving hypofractionation is huge, mainly due to the long waiting lists, patients' desire for fast treatment, better planning of radiotherapy with computed tomography-based target definition and better dose homogeneity assured by 3D conformal planning. The aim of the current study is to evaluate the potential effect of previous chemotherapy to the acute skin toxicity and the local control followed for 2 years in patients with breast cancer, treated with hypofractionated radiotherapy regimen.

Adjuvant chemotherapy and acute toxicity in hypofractionated radiotherapy for early breast cancer. *World J Clin Cases* 2014; 2(11): 705-710 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/705.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.705

## INTRODUCTION

The adjuvant radiotherapy (RT) for early breast cancer after lumpectomy is an established treatment. The most widely used schedule for whole breast irradiation is 50 Gy in 25 fractions (conventional), while randomized trials comparing conventional radiotherapy schedules to different hypofractionation, have shown equivalent results[1]. A lot of shorter (accelerated hypofractionated) RT schedules have been already used in clinical practice[2-6]. Hypofractionation is an attractive approach and the trend nowadays towards new techniques involving hypofractionation is huge, mainly due to the long waiting lists, patients' desire for fast treatment, better planning of radiotherapy with computed tomography (CT)-based target definition and better dose homogeneity assured by 3D conformal planning.

However it is quite difficult to compare the treatment outcome due to the variation of clinical parameters, such as patient selection, chemo/hormonotherapy, differences in breast size, radiation dosimetry and RT techniques[2-6].

The aim of the current paper is to evaluate the potential effect of previous chemotherapy to the acute skin toxicity and to the local control followed for 2 years in breast cancer patients irradiated with this hypofractionated regimen.

## MATERIALS AND METHODS

One hundred sixteen patients were retrospectively selected, between May 2004 and December 2010. Patients characteristics are shown in details in Table 1. All patients received radiotherapy with a total prescription dose of 50.54 Gy or 53.2 Gy by 2.66 Gy per fraction, in 19 or 20 fractions, over 23-24 d. The decision of giving either 19 or 20 fractions was made in terms of stage (T1, 2) or in case maxima in dose distributions more than 108%. The last three to four fractions were delivered as a sequential tumor boost. The patients were irradiated either at the Radiotherapy unit of the 1st Department of Radiology in ATTIKON University Hospital or at the Radiotherapy Unit of the 2nd Department of Radiology in Aretaieion University Hospital[7,8]. However, the follow-up was realized in several departments either in Athens or Larisa.

**Table 1 Patients' characteristics**

| | |
|---|---|
| Age median (range) | 58.5 (35-86) |
| T1 | 81 |
| T2 | 35 |
| Chemotherapy | |
| Yes | 83 |
| No | 33 |

Inclusion criteria in this study were breast cancer patients with stage Ⅰ-Ⅱ invasive carcinoma after conservative surgery and axillary lymph node dissection. Any adjuvant chemotherapy had to be completed before the start of RT.

The exclusion criteria were: mastectomy, presence of Paget's disease, presence of autoimmune conditions, previous thoracic neoplasia (cancer, sarcoma, lymphoma), previous breast cancer operated with bad cosmesis, diagnosis of previous or concomitant malignancies or skin disease, breast size in craniocaudal dimension more than 20 cm (or alternatively less than 2500 mL) and presence of psychiatric or addictive disorders[7].

All patients were monitored for acute skin toxicity according to the European Organization for Research and Treatment of Cancer/Radiation Therapy Oncology Group (EORTC/RTOG) criteria, during radiotherapy schedule once per week and one month thereafter[9]. The maximum monitored value was taken as the final grading score. The primary outcome measure was radiation induced acute skin toxicity. The secondary end point was the local recurrence free survival. Clinical and laboratory tests suggested recurrent disease were investigated, while the criterion for local disease recurrence was recurrent tumor within the treated irradiated field. Hormonal therapy, if prescribed according to indications, was administered after the completion of radiotherapy.

### *Simulation and treatment planning*

Patients underwent standard CT simulation in the supine position. The ipsilateral breast and tumor bed with surgical clips were contoured for the delineation of Clinical Target Volumes (CTV), while contralateral breast, left and right lung and heart were contoured as organs at risk (OARs)[10]. When surgical clips were not present, preoperative mammography and ultrasound data were used for

**Table 2 Incidence of acute skin toxicity in terms of previous chemotherapy or not**

| | | EORTC/RTOG radiation induced acute skin toxicity grade | | | | Total |
|---|---|---|---|---|---|---|
| | | 0 | 1 | 2 | 3 | |
| Chemotherapy | No | 56/83 (67.5%) | 18/83 (21.7%) | 7/83 (8.4%) | 2/83 (2.4%) | 83 |
| | Yes | 16/33 (48.5%) | 14/33 (42.4%) | 2/33 (6.0%) | 1/33 (3.0%) | 33 |
| Total | | 72/116 (62.1%) | 32/116 (27.6%) | 9/116 (7.8%) | 3/116 (2.6%) | 116 |

No significant correlation was noted (Pearson $\chi^2$ $P$ = 0.15). EORTC/RTOG: Organization for Research and Treatment of Cancer/Radiation Therapy.

tumor bed definition. The planning target volume of the tumor bed ($PTV_t$) was a 1-2 cm expansion around the clinical target volume (CTV). The ipsilateral breast volume was the planning target volume ($PTV_B$), excluding the chest wall and 0.5 cm from the skin[10].

### Radiobiological issue

We used linear-quadratic (LQ) model in order to assess the equivalent of hypofractionation schedules to the Normalised Total Dose (NTD) if delivered in conventional scheme of 2 Gy per fraction[11-16]:

$NTD = D_{new}[(d_{new} + \alpha/\beta)/(2 + \alpha/\beta)]$

where Dnew and dnew are the total dose and dose per fraction for the hypofractionated schedule, respectively. Normalized Total Dose - NTD has been calculated and tabulated for both breast ($\alpha/\beta$ = 4 Gy) and acute reacting tissues ($\alpha/\beta$ = 10 Gy)[11-16]. When considering that $\alpha/\beta$ = 4, the NTD was 56.10 Gy and 59.05 Gy for 19 and 20 fractions, respectively. When considering that $\alpha/\beta$ = 10, the NTD was 53.3 Gy and 56.13 Gy for 19 and 20 fractions, respectively.

We used the QUANTEC trial for the dose constrains, as described below, concerning NTD values for an $\alpha/\beta$ = 3 (late reacting tissues)[17,18]: (1) Ipsilateral lung: < 15% of lung should receive less than 30% of prescribed dose; (2) Heart (left sided breast): Volume of heart getting 5% of dose (V5) should be less than 40%; (3) Heart (right sided breast): < 5% of heart should receive less than 5% of the prescribed dose; (4) Contralateral breast: should receive less than < 3% of prescribed dose to any point; and (5) Contralateral lung: < 15% of lung should receive less than 5% of prescribed dose.

### Systemic therapy

Patients with axillary nodal metastases received adjuvant systemic treatment. Concerning the premenopausal women, two schedules were used: 62 patients received 4 cycles of epirubicin and endoxan every 2 wk, 3 wk brake and then 4 cycles taxotere every 3 wk; 54 patients received 6 cycles of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) chemotherapy *iv* every 21 d. Postmenopausal patients received also tamoxifen 20 mg daily for 5 years, after the completion of radiotherapy. All patients received irradiation in a time post chemotherapy ranged 25-45 d.

### Statistical analysis

The comparison of mean value of toxicity score between patients undergone adjuvant chemotherapy *vs* no chemotherapy was done with the Mann Whitney non-parametric test. The correlation of the incidence of toxicity grading with either the administration of chemotherapy or the prescribed schedule of 19 *vs* 20 radiotherapy fractions was performed with the $\chi^2$ test. The impact of age, chemotherapy and total dose to the radiation induced acute skin toxicity was performed with the logistic linear regression analysis in two steps: first all variables were entered in the equation as a univariate analysis; second only variables with a statistical significance were entered in a multivariate model. The significance level was set at 0.05. All the analysis was performed using the SPSS ver. 10 software (IL, United States).

## RESULTS

Thirty three patients underwent a radiotherapy schedule of 19 fractions while 83 underwent schedule of 20 fractions. Overall, acute radiation induced skin toxicity, according to European Organization for Research and Treatment of Cancer/Radiation Therapy Oncology Group criteria, was as following: grade Ⅰ 27.6%, grade Ⅱ 7.8% and grade Ⅲ 2.6%. The acute radiation induced toxicity score in details is shown in Table 2. No treatment interruption was occurred since no skin toxicity more than grade 3 was noted. No significant correlation was noted between toxicity grading and chemotherapy ($P$ = 0.154, $\chi^2$ test). The mean values of acute toxicity score in terms of chemotherapy or not, were 0.64 and 0.46 respectively (Figure 1). No significant difference was noted ($P$ = 109, Mann Whitney test). No significant correlation was also noted between acute skin toxicity and radiotherapy fractions ($P$ = 0.47, $\chi^2$ test). The logistic regression analysis performed in two steps is shown in Table 3. According to univariate analysis, only chemotherapy contributed significantly to the development of acute skin toxicity but with a critical value of 0.05. However, in multivariate analysis chemotherapy lost its statistical significance.

None of the patients during the 2-years of follow-up presented with any locoregional relapse. The acute radiation skin toxicity decreased rapidly after the completion of radiotherapy. Three months post irradiation, 107 out of 116 (92.2%) patients presented grade 0 of skin toxicity, while 9 out of 116 (7.7%) presented only grade I acute skin toxicity.

## DISCUSSION

The linear quadratic (LQ) is a well established model that

**Table 3 Logistic regression analysis performed for analyzing the contribution of age, chemotherapy and radiotherapy fractions (19 *vs* 20) to the development of acute radiation induced skin toxicity**

| | Univariate analysis | | | Multivariate analysis | | |
|---|---|---|---|---|---|---|
| | *P* | RR | 95%CI | *P* | RR | 95%CI |
| Age | 0.31 | - | - | 0.41 | - | - |
| Chemotherapy | 0.05 | 2.35 | 1.01-5.52 | 0.057 | - | - |
| 19 *vs* 20 fractions | 0.55 | - | - | 0.66 | - | - |

The univariate model chi-square with 3 degrees of freedom was 4.97 ($P = 0.17$). None of the variables entered to the multivariate model. RR: Risk ratio.

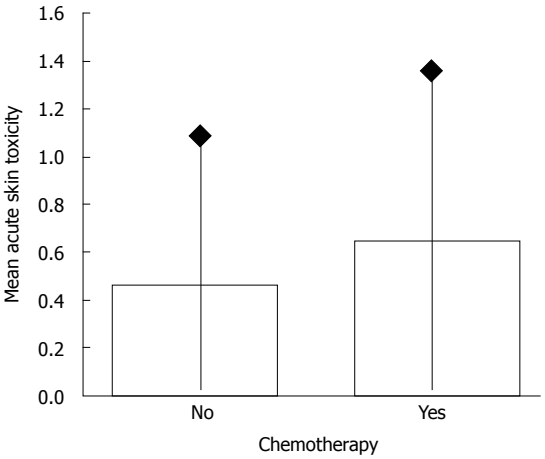

**Figure 1 Mean acute skin toxicity score for patients undergone chemotherapy or not (*P* = 0.109, Mann Whitney test).**

provides assessments of equivalent doses to both tumor and normal tissues[11-17].

Biological factors related to proliferation (overall time and delayed after irradiation), and the effect of dose per fraction, are basic knowledge necessary for the planning of new irradiation schedules which are effective in practice[11-16].

In our institution we have already reported on the efficacy of the certain hypofractionated schedule for breast cancer[7,8]. Moreover we have made a thorough dosimetric analysis for the dose deposited at the contralateral breast[19]. However, this is the first study according to our knowledge, evaluating the impact of adjuvant chemotherapy to the skin toxicity for a hypofractionated irradiation schedule for breast cancer. In univariate analysis the parameter of chemotherapy seems to have a significant impact to the radiation induced skin toxicity with a critical value of 0.05. However, in multivariate analysis chemotherapy lost its statistical significance. Thus eventually neither chemotherapy, nor the age and the total dose seemed to have any impact to acute skin toxicity.

Sanguineti *et al*[20] investigated whether chemotherapy administered at earlier or concomitant with radiotherapy, has an impact either to the RT duration or to the hematological profile. The RT schedule was consisted of 50 Gy in five weeks. The investigators concluded that there is no correlation in terms of toxicity between chemotherapy dose-density and dose-intensity of RT. However, the concomitant administration of chemotherapy and RT decreases the ability of prescribing a full irradiation scheme. The only toxicity observed was in white blood cells (WBC). The toxicity on late responding tissues with the combination of hypofractionation and chemotherapy was not investigated. In terms of multivariate analysis, no significant correlation was assessed between skin toxicity and weekly dose rate, while the analysis of potential factors associated with skin toxicity was not a subject of this study[20].

According to current literature concerning clinical guidelines and randomized trails, Hypofractionated RT in breast cancer patients offers equivalent outcome to the standard conventional schedule, in terms of tumor control and normal tissue damage[21-24]. In clinical practice the most commonly used schedule of 2.66 Gy in 16 fractions is equivalent to 50 in 2.0 Gy fractions, when the $a/\beta$ value is equal to 3Gy. Any potential loss of therapeutic ratio (2.9 Gy loss of anti-tumor dose) would be compensating with the shorted treatment time due to reduced tumor repopulation and either adjuvant or neo-adjuvant chemotherapy[21].

One of the trials, published in 2002 by Whelan *et al*[23], compared a schedule of of 42.5 Gy in 16 fractions over 22 d (accelerated arm 266 Gy/fraction) with conventional breast irradiation consisted of 50 Gy in 25 fractions over 35 d (2 Gy/fraction). No boost was added. The randomized women had invasive breast cancer, free resection margins, uninvolved axillary lymph nodes. After 69 mo (more than 5 years) follow up the randomized trial determined that the accelerated arm was as effective as the conventional arm concerning the two outcomes- local control and cosmetic results. As it was obvious in the long term results, published in 2010, the local recurrence rate at 10 years was 7.5% in the conventional group as compared with 7.4% in the accelerated group[24]. The survival rate at 10 years was equivalent in both arms by means of 84.4% in the conventional group *vs* 84.6% in the accelerated group, while cosmetic outcomes were also similar concerning a rate of 4% or less grade 3 radiation induced toxicity[24].

The 5 year results of two big randomized trials - the United Kingdom Standardisation of Breast Radiotherapy (START) Trial A and START Trial B have been also reported[25,26]. START Trial A[25] compared each of two schedules of hypofractionation 41.6 Gy or 39 Gy in 13 fractions of 3.2 Gy or 3.0 Gy over 5 wk with conven-

tional whole-breast irradiation and START Trial B[26] compared 40 Gy in 15 fractions of 2.67 Gy over 3 wk with conventional irradiation 50 Gy in 25 fractions of 2 Gy. The interpretations of the results from the two trials were that the hypofractionation schedules offered similar rates of tumour control and normal tissue damage as the international standard fractionation schedule of 50 Gy in 25 fractions. The endpoints of both studies at term of tumor relapse, late normal tissue effects, and quality of life were at least as favorable as the standard schedule. Boost irradiation was according to protocol guidelines in both START trials, while adjuvant chemotherapy was used more widely than in Whelan et all trial[23], while up to nowadays follow-up, no significant increase in toxicity has been reported. Zygogianni *et al*[8] in a previous study, at the end of RT reported 24.1% of grade I and 9.3% of grade II acute skin toxicity, while 66.7% of the patients showed no radiation induced skin morbidity. In this study the results are equivalent with 27.6% and 7.8% of grade I and II skin toxicity, respectively.

Dorn *et al*[27] studied the skin toxicity in large breasts by an hypofractionated schedule of 42.56 Gy in 2.66 Gy per fraction. Of the 80 treated patients with large breasts, the maximum acute skin toxicity was mild erythema or hyperpigmentation in 70.0%, dry desquamation in 21.25% and focal moist desquamation in 8.75%. Maximum acute toxicity occurred after the completion of radiation in 31.9% of patients. Breast volume was the only patient-related factor significantly associated with moist desquamation on multivariable analysis ($P = 0.01$). Patients with breast volume > 2500 mL showed focal moist desquamation in 27.2% of cases *vs* 6.34% in patients with breast volume < 2500 mL ($P = 0.03$). In our case, according to eligibility criteria, all patients had a breast volume less than 2500 mL.

In another study referring to 44 patients with primary stage breast cancer after adjuvant chemotherapy and hypofractionated RT, Zygogianni *et al*[28] reported a significantly acute skin toxicity when the intermediate time between chemotherapy and RT was less than 20 d ($P < 0.05$). All patients in this study received irradiation 25 d at the minimum after chemotherapy.

Although, all the above mentioned trials studied skin toxicity according to the hypofractionated schedule, none of them explored the impact of chemotherapy on acute skin morbidity. According to our results, the hypofractioned radiotherapy for breast cancer is safe in terms of mild toxicity, independently with the sequential chemotherapy, if administered. Our acute toxicity is in accordance with the reported values in all previous published studies. Obviously, the maximum grade of skin toxicity was noted during the whole breast irradiation and not during the boost radiotherapy. On the other hand, it seems that chemotherapy might not be a major factor affecting the radiation induced morbidity. However, due to the retrospective nature of our study, it is difficult to extract safe conclusions, while a randomized prospective study is needed to answer the question: has chemotherapy a definite impact to radiation induced morbidity if a hypofractionated schedule is used? Consequently, the question is still open.

## COMMENTS

### Background

The Hypofractionated irradiation for breast cancer patients has been involved in the routine clinical practice for several years. However, the impact of previous chemotherapy to radiation induced toxicity has not been studied thoroughly.

### Research frontiers

No clear evidence that chemotherapy has an impact to radiation induced skin toxicity has been noted.

### Innovations and breakthroughs

This is a retrospective study documenting the absence of clear impact of previous chemotherapy to Hypofractionated radiotherapy for breast cancer.

### Applications

Clinicians that decide to use hypofractionated irradiation for breast cancer may prescribe this schedule independently to previous chemotherapy.

### Terminology

Hypofractionated: irradiation schedule with more than 200 cGy per fraction.

### Peer review

In this study, the authors evaluated the impact of chemotherapy to the acute toxicity of a hypofractionated irradiation schedule for breast cancer. Delivering postoperative radiotherapy in a shorter time could effectively be much more convenient for patients and several clinical randomized trials have shown that hypofractionated adjuvant radiotherapy in breast cancer offers similar rates of tumour control and normal tissue damage as the standard schedule.

## Abstract

We report the first case of a neonate with concurrent Chiari Ⅱ malformation and achondroplasia. Although rare, both these conditions contribute to several deleterious anatomical changes at the cervicomedullary junction and thus predispose to acute hydrocephalus. Although our patient was initially asymptomatic, hydrocephalus ensued several weeks after birth and required cerebral spinal fluid diversion. We discuss the potential links between the two conditions, the pathophysiology, and the important clinical implications for the management of the increased risk of hydrocephalus.

**Key words:** Achondroplasia; Chiari Ⅱ malformation; Hydrocephalus; Shunt failure; Cervicomedullary junction; Cerebral spinal fluid diversion

**Core tip:** Achondroplasia and Chiari Ⅱ malformations can induce similar anatomical changes at the cervicomedullary junction which increase the risk of acute hydrocephalus. Chiari decompression may not always be necessary, however, diligent and acute follow-up is important to monitor for signs of impeding hydrocephalus. If cerebral spinal fluid diversion is required, remember that shunt failure is common in the pediatric age group and also requires close follow-up.

Awad AW, Aleck KA, Bhardwaj RD. Concomitant achondroplasia and Chiari Ⅱ malformation: A double-hit at the cervicomedullary junction. *World J Clin Cases* 2014; 2(11): 711-716 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/711.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.711

## INTRODUCTION

Achondroplasia is the most common cause of dwarfism, occurring at a frequency of 1 and 26000 live births[1]. Mutations of the *FGFR3* gene, which encodes a tyrosine kinase receptor that is deferentially expressed during various stages of development, are responsible for the characteristic short-stature and macrocephaly[2,3]. The condition follows an autosomal dominant inheritance pattern with complete penetrance, however 80%-90% of cases are due to sporadic mutation[1,4]. The FGFR3 gene has been mapped to chromosome 4p16.3, and is part of a larger family of fibroblast growth factor receptor genes which play important roles in skeletal development[2,3].

The Chiari Ⅱ malformation (CM Ⅱ) is a well characterized congenital malformation of the central nervous system. Although the exact mechanism is still disputed, the condition is defined by a small posterior fossa and caudal displacement of the brainstem and cerebellum through the foramen magnum[5]. In addition, all cases of CM Ⅱ are associated with a myelomeningocele[5] which can be further complicated by hydrocephalus, syringomyelia, heterotopias, and agenesis of the corpus callosum are only some of the commonly reported sequelae[5-7].

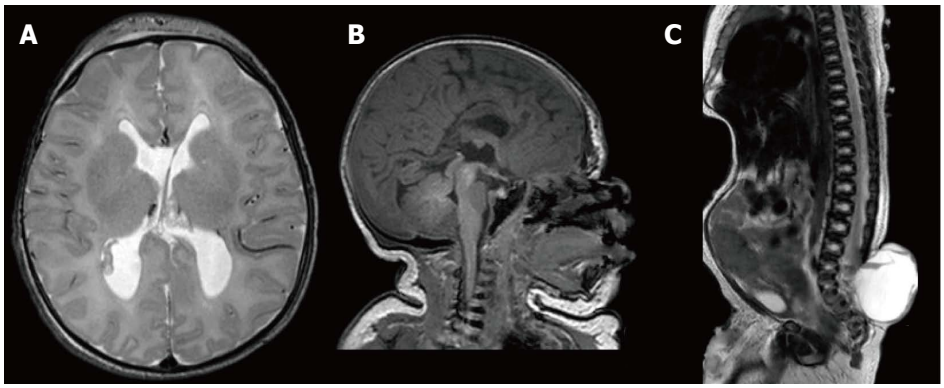

**Figure 1 Pre-operative magnetic resonance imaging imaging of the patient to evaluate and screen for anatomical abnormalities.** A: Axial T2 MRI of the head at birth demonstrating no signs of hydrocephalus; B: Sagittal T1 MRI of the head and neck at birth with evidence of a tight cervicomedullary junction, a small posterior fossa, and hypoplastic corpus callosum and cerebellar vermis; C: Sagittal T2 MRI of the spine at birth demonstrating a large 7 cm × 7 cm sacral myelomeningocele with evidence of tethering. MRI: Magnetic resonance imaging.

In our literature review we found two case reports of patients with both achondroplasia and Chiari I malformations[8,9], however to our knowledge there are no published case reports of concomitant achondroplasia and CM Ⅱ. Here we report the first such case in a neonate, and discuss the potential links between the two conditions, the pathophysiology, and the management of the increased risk of hydrocephalous.

## CASE REPORT

### History of present illness

A 1 d old male born after 39-3/7 wk of gestation to a 39-year-old gravid 1, para 0 women presented after delivery for surgical correction of a sacral mass. During pregnancy, an elevated AFP was noted and ultrasound findings demonstrated enlarged ventricles, large for gestational age status, and a sacral myelomeningocele. The infant was delivered *via* cesarean section with no complications; at birth, 1 and 5 min APGARs were 8 and 9 respectively. The child's cranium appeared relatively macrocephalic and measured in the 75$^{th}$ percentile with a short cranial base and mild frontal bossing. A 7 cm × 7 cm sacral myelomeningocele was noted and no cerebral spinal fluid (CSF) leak was evident. The extremities showed shortening of the femurs and humeri with relatively long fibulae and a trident confirmation of the hands. The patient had a short stature with an upper-lower segment ratio of 1.9 (normal 1.6 to 1.7), these exam findings initiated a genetic and skeletal survey for achondroplasia. The remainder of the physical and neurological exam were normal.

### Imaging studies

An axial T-2 magnetic resonance image (MRI) of the head showed no signs of hydrocephalus (Figure 1A). There was no evidence of a tonsillar herniation, however, a tight cervicomedullary junction was noted on the sagittal T-1 MRI of the head (Figure 1B), and the lateral and third ventricles were slightly enlarged. The corpus callosum and cerebral vermis were noted to be hypoplastic and a small posterior fossa with frontal bossing were evident. A sagittal T-2 MRI of the spine (Figure 1C) demonstrated a well circumscribed hyperintense sacral mass protruding dorsally, with a loss of posterior spinal elements distal to L3. There was some evidence of cauda equina involvement and tethering of the cord.

### Operative course

The patient's radiographic and physical exam findings were consistent with a CM Ⅱ. The patient was taken to the operating room on the same day of presentation to undergo repair of the myelomeningocele. A typical elliptical incision was made adjacent to the defect with midline extension caudal and rostral to the dome. The myelomeningocele was delicately dissected away from the dome skin and the surrounding fascial and dural layers. The termination of the placode was detethered from the dome skin, and the dorsal and ventral nerve roots were mobilized laterally. The lateral edges of the placode were approximated and sutured to form a closed cavity. The dura was then closed and no signs of CSF leak were evident after valsalva. Finally, the fascial layers and skin were re-approximated; some trimming of the excess skin was necessary. The operation was completed without complications and the patient's recovery was monitored in the neonatal intensive care unit.

### Post-operative course

A genetic evaluation for achondroplasia was positive for a mutation of the *FGFR3* gene on chromosome 4 showed a glycine to arginine substation mutation at the 380$^{th}$ amino acid residue confirming a diagnosis of achondroplasia. It was not immediately clear if the CM Ⅱ was related to the patients' concomitant achondroplasia. The patient was monitored post-operatively for 6 d. During that period the fontanelles remained soft and there were no signs of increased intracranial pressure (ICP). The patients' family was counseled on the symptoms of hydrocephalous and the patient was discharged home with

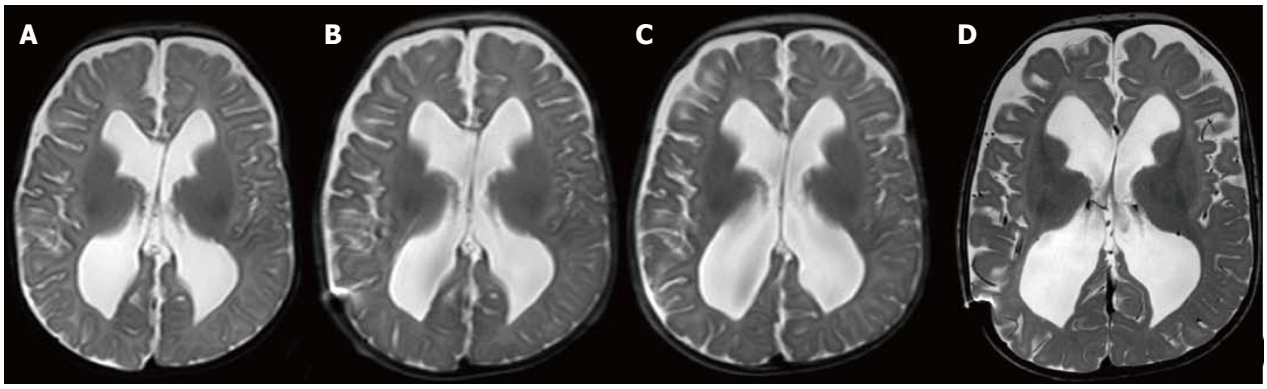

**Figure 2 T-2 weighted magnetic resonance imaging demonstrating shunt failure and progression of hydrocephalous over the course of 4 mo of treatment.** A: Pre-shunting axial T-2 weighted MRI ordered after patient had increased head circumference and suture splaying demonstrating ventriculomegaly; B, C: Subtle increase in ventricular size at 2 wk (B) and 6 wk post-shunting (C); D: At 4 mo post-operative shunting with significant increase in ventriculomegaly and extra axial fluid spacing. MRI: Magnetic resonance imaging.

instructions to follow up in 2 wk.

### *Progressive hydrocephalus*

In the subsequent weeks, the patient had bi-weekly clinical and ultrasound exams which were normal. At 8 wk however, the patients head circumference was in the 97$^{th}$ percentile, the anterior fontanelle was full and pulsatile with signs of sagittal suture splaying, but the patient had no signs of respiratory distress. A T2 MRI (Figure 2A) showed evidence of ventriculomegaly with increased extra-axial spacing. Given the physical exam and radiographic findings we placed a ventriculoperitoneal (VP) shunt in the right lateral ventricle without incident.

After discharge the patient was monitored with serial MRIs (Figure 2B, C) which demonstrated subtle but continued ventriculomegaly. During this time the patient was asymptomatic and had normal exam findings.

### *Shunt failure*

Four months following shunt placement, the patient was found to have an enlarged head circumference that measured above the 95$^{th}$ percentile. The patient was reported to be less active than usual and the anterior fontanelle was full but soft. A T-2 MRI demonstrated the VP shunt catheter was no longer in the lateral ventricle; subsequently, the lateral and third ventricle had enlarged (Figure 2D) and there was evidence of encroachment of the cerebellar tonsils into the spinal canal. The patient required shut revision, which was completed without complications. At the time of the shunt revision, somatosensory evoked potentials were within normal limits and Chiari decompression was not carried out.

The patient is now 10 mo old and we continue to monitor his head circumference which has stabilized since shunt revision.

## DISCUSSION

### *Genetic associations*

Embryogenesis is a complex physiologic phenomenon that is subject to a wide range of exogenous and endogenous forces that can have significant impact on developmental outcomes. At times, these changes are so gross they can be detected in-utero as in the case of a CM Ⅱ, in which a myelomeningocele is evident in pre-partum ultrasound. Conversely, in conditions like achondroplasia, developmental changes become apparent shortly after birth. Although the exact mechanism by which these effects take place are not entirely delineated, understanding them is crucial to the development of preventive and therapeutic strategies.

As in our case, almost all cases of achondroplasia are due to a substitution mutation of the 380$^{th}$ amino acid Gly for an Arg residue, which resides in the transmembrane domain of the receptor protein[2,3]. Gene expression studies in mice have shown elevated levels of mRNA encoding the FGFR3 protein in the rudimentary cartilage of all premature bone during organogenesis[10]. The effects of achondroplasia on the developing calvarium can produce signs and symptoms similar to those seen in CM Ⅱ. In addition to the characteristic macrocephalic changes commonly seen, changes in the shape and size of the foramen magnum, cervical stenosis, cervicomedullary compression and upward herniation of the brainstem are common[8,11].

Although there are several proposed hypotheses describing the pathogenesis of CM Ⅱ, the exact mechanism remains elusive. Animal models have demonstrated that open neural tube defects (NTD) are causative in the case of CM Ⅱ. NTD that were surgically created in mouse, rat, and sheep models replicate the hindbrain herniation through the foramen magnum that is stereotypical of CM Ⅱ[12-14]. This finding has two important implications; firstly it lends considerable evidence to the widely accepted "unified theory" of CM Ⅱ[6]. This theory alleges the loss of CSF through the open caudal NTD causes a subsequent drop in ICP. This loss of pressure at a critical point during fetal development results in poor cranial vault expansion culminating into a small posterior fossa. The unexpectedly narrowed posterior fossa leads

to the caudal displacement of the brainstem and cerebellum through the foramen magnum[6]. Secondly, the causal relationship of NTD and CM Ⅱ has valuable corollaries for prevention. Folic acid supplementation has been found to reduce the incidence of NTD by 70%[15]. The incidence of CM Ⅱ has not been well studied to determine whether the expected decrease exists following the increased use of folic acid supplementation.

Due to the association of folic acid and NTD, there has been considerable research evaluating the role of enzymes and transport proteins involved in its metabolism, namely MTRR, MTHFD1 and FOLR1-2[16]. However, these genes appear to have little relation to those of achondroplasia and make up only a small portion of candidate genes. The genetic causes of NTD appear to be far more complex and varied than originally anticipated; over 200 gene mutations in mice are known to cause NTD[17]. Similarly in humans, NTD defects arise in the setting of multiple syndromes (Pallister-Hall, Walker-Warburg and Fanconi anemia among others) and chromosomal abnormalities including Trisomies 13 and 18[18-20]. Of the wide range of potential gene candidates we focused on reports of mutations involving chromosome 4, where the *FGFR3* gene is located. In a small series of 5 autopsy reports of fetuses with Wolf-Hirschhorn syndrome due to partial mutations (deletion/substitution) of the short arm of chromosome 4, three patients had sacral dimples, while 2 had partial or complete agenesis of the corpus callosum, all patients exhibited growth retardation, and had consistent craniofacial abnormalities including frontal bossing[21]. Furthermore, reports of achondroplasia and other spinal dysraphisms exist including tethered cords and lipomas indicating the range of phenotypes that ensue from genetic mutations in this region[22,23].

Familial studies of Chiari malformations are limited mainly to Chiari I malformations, as such, the genetics of CM Ⅱ are not as well characterized. Animal models have suggested possible gene candidates. The Splotch mouse model for example can produce NTD and the hindbrain herniation characteristic of the CM Ⅱ[6]. The genetic mutation responsible for this phenotype in mouse models was mapped to the human *Pax*-3 gene on chromosome 1, encodes transcription factors which play various roles in embryogenesis[24,25]. Further studies in humans however, demonstrated that mutations in Pax-3 generate distinct features not commonly seen in CM Ⅱ, namely deafness and abnormal pigmentation which were later characterized into a distinct Waardenburg Syndrome[25,26].

### *Clinical management*

Given our patients' concurrent conditions, the concern for hydrocephalus was high. Brainstem herniation as a result of hydrocephalus in both CM Ⅱ and achondroplasia can be acutely progressive, and greatly increases the risk of apneic spells and acute respiratory failure[1,11,27]. At the time of presentation we believed the degree of cervicomedullary constriction present did not warrant surgical Chiari decompression, as a result the patient underwent myelomeningocele repair with acute follow-up. Although our patient ultimately required CSF diversion, there were no overt signs of respiratory distress, spasticity, or dysphagia which would warrant a surgical Chiari decompression. In a large series of 148 patients with CM Ⅱ, only 14% of patients required surgical decompression[7]. Treating the obstructive hydrocephalus by shutting is a more common method that is associated with fewer risks. In a series of 71 cases of CM Ⅱ, 64 (90%) patients had hydrocephalus, 89% of which required VP shunting[28]. As in our case, shunt placement necessitates close follow-up and thorough patient education. Unfortunately, our patient experienced shunt failure due to tip migration, a risk associated with this treatment. A large series of 1015 patients who underwent VP shunting reported a failure rate of 46.3%, in the pediatric group however, failure rates were reported to be 79.2%, the majority of which occurred in the first 6 mo[29]. Importantly, in patients with spinal dysraphisms, as in our case, failure rates were 84.8%[29]. At last follow up (10 mo) the patient was symptom free with signs of improved CSF outflow. Due to the compounding effects of both underlying conditions on the potential hydrocephalus we continue to monitor the patient with routine monthly follow-up.

In conclusion, both achondroplasia and the CM Ⅱ are relatively common as independent conditions; however, they very rarely occur concomitantly. Importantly, the CM Ⅱ is a consequence of NTDs which appear to have multifocal genetic and environmental etiologies. Although the genes involved in achondroplasia appear to be distinct from those of the CM Ⅱ, due to the complexity of embryologic development, there may be key interactions between the downstream pathways which may account for some of the similar anatomic changes seen at the cervicomedullary junction. As such the management of the potential hydrocephalus that may arise within patients with this unique predisposition requires acute and diligent follow up and patient education.

## COMMENTS

### *Case characteristics*

A newborn boy presented with macrocephaly, short limbs, and a sacral mass.

### *Clinical diagnosis*

Concurrent achondroplasia and Chiari Ⅱ malformation.

### *Differential diagnosis*

Myelomeningocele has a unique gross presentation however a sacrococcygeal teratoma should be considered and the two conditions can be easily differentiated using magnetic resonance imaging. The differential of a newborn with macrocephaly is quite large and includes congenital infections, obstructive hydrocephalus, metabolic conditions (Canavan's disease, Alexander's disease, *etc.*), and osteogenesis imperfecta are only a few to consider.

### *Laboratory diagnosis*

A genetic test indicated a missense mutation of the *FGFR3* gene on chromosome 4 confirming a diagnosis of Achondroplasia.

### *Imaging diagnosis*

MRI of the head and spinal column confirmed a diagnosis of Chiari Ⅱ malformation.

### *Treatment*

Surgical myelomeningocele repair and ventriculoperitoneal shunting due to

hydrocephalous is a standard treatment.

### Related reports

This is the first reported case of both a Chiari Ⅱ malformation and achondroplasia in the same patient. Cases of concurrent Chiari I malformation and achondroplasia have been reported in references 7 and 8.

### Term explanation

Spina bifida is an incomplete closure of the spine during embryogenesis. A myelomeningocele is a form of spina bidifia that includes a herniation of the spinal meninges through the spinal defect.

### Experiences and lessons

Shunt failure is more common in pediatric patients with spinal dysraphisms, generally occurring within the first 6 mo.

### Peer review

The manuscript of Awad *et al* describes a neonate case with concomitant achondroplasia and Chiari Ⅱ malformation. According to a literature review performed by the authors this is the first case report of a patient with this combination. This is definitely an interesting case that is thoroughly documented. Everything seems to be very well described.

## Abstract

The management of patients with non-progressive metastatic colorectal cancer after six months of treatment has not yet been codified. The most relevant concerns are the effectiveness of maintenance *vs* discontinuation, and the tolerability of prolonged treatment. Here we report the case of a 72-year-old man affected by colorectal cancer with lung metastases who achieved a complete response after receiving capecitabine, oxaliplatin and bevacizumab for six months, and bevacizumab alone for six months. Bevacizumab was continued as maintenance regimen for more than three years. It was discontinued because of an arthroplasty. Fifty-eight months after beginning first-line treatment, the patient remains free from relapse. Adverse effects were minimal and easily controlled.

**Key words:** Metastatic colorectal cancer; Bevacizumab; Maintenance

**Core tip:** A colorectal cancer patient with lung metastases received bevacizumab combined with chemotherapy for six months, and then bevacizumab monotherapy as maintenance treatment for more than three years. The patient achieved a complete response without evidence of side effects. He remains relapse free 58 mo after diagnosis.

Bevacizumab maintenance in metastatic colorectal cancer: How long? *World J Clin Cases* 2014; 2(11): 717-723 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/717.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.717

## INTRODUCTION

The management of metastatic colorectal cancer (mCRC) has evolved over the past decade[1]. Patients receiving irinotecan[2], oxaliplatin[3] and fluorouracil achieve the best outcome (median survival, approximately 21 mo), regardless of treatment sequence[4]. Adding biological drugs such as anti-vascular endothelial growth factor (VEGF) or anti-epidermal growth factor receptor (EGFR) monoclonal antibodies to chemotherapy improved survival further[5]. The anti-VEGF monoclonal antibody bevacizumab significantly prolonged survival when added to first-line[6] or second-line chemotherapy[7]. Recent clinical

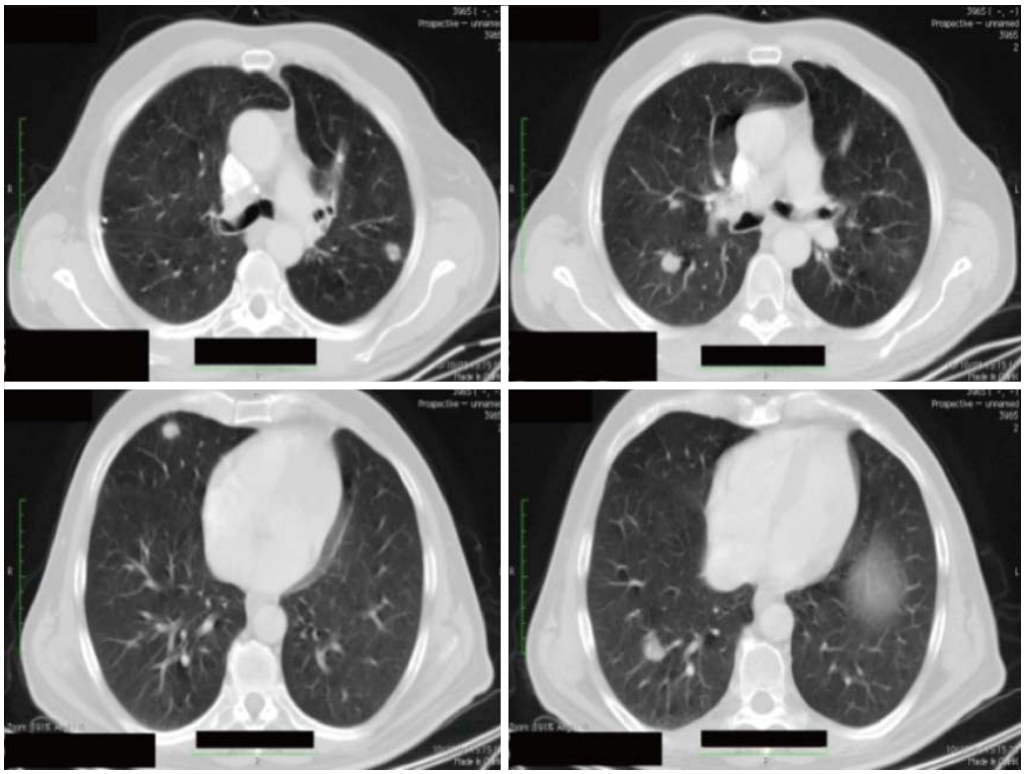

**Figure 1 Thorax computed tomography-scan before starting chemotherapy (October 2008).**

trials showed a clinical benefit in patients receiving bevacizumab even beyond progression[8,9].

Although often used in clinical practice, maintenance therapy in non-progressive patients after four-six months of chemotherapy ± biological drugs is not yet codified in terms of duration (indefinitely until disease progression?) and type of drugs (same chemotherapy regimen, simplified chemotherapy, targeted drug alone?). The most relevant concerns are the effectiveness of maintenance *vs* discontinuation, and the tolerability of such prolonged treatment.

Here, we report the case of a 72-year-old man affected by mCRC who obtained a complete response after treatment with capecitabine, oxaliplatin and bevacizumab for six months, followed by bevacizumab alone for a further six months. He then continued with bevacizumab as maintenance treatment for the following three years with no evidence of disease relapse or toxicity.

## CASE REPORT

In October 2008, a 72-year-old man underwent left hemicolectomy for an obstructing mass located at the sigmoid-rectal junction. The pathological diagnosis was an undifferentiated (G3) adenocarcinoma, invading through the muscularis mucosae up to the peri-colic fat tissue (pT3); 12 nodes were isolated, all of which were metastatic (pN2). Radiological staging by contrast enhanced CT-scan showed several lung lesions (4 measurable) up to 20 mm in diameter (Figure 1). No liver metastases were detected. KRAS mutational status showed a mutation in codon 12 of exon 2.

The patient was referred to the Division of Medical Oncology of the University of Naples "Federico II" in November 2008 to begin first-line chemotherapy. He was in good condition (ECOG performance status = 1), and was only taking an ACE-inhibitor for arterial hypertension. Serum tumor markers exceeded the upper normal level: CA19.9 was 54 U/L (normal values < 37 U/L), and CEA 23.3 ng/mL (normal values < 5 ng/mL).

He began chemotherapy with the XELOX + bevacizumab schedule (capecitabine 1000 mg/m$^2$ twice daily, days 1-14; oxaliplatin 130 mg/m$^2$, and bevacizumab 7.5 mg/kg day 1, every 21 d). The work-up consisted of blood cell count and hematology before each cycle, and CT-scan every three months (or four cycles). Arterial blood pressure was measured before and after bevacizumab administration on day 1 and, thereafter, once daily with an electronic sphygmomanometer. The worse adverse events were: grade 1 peripheral neuropathy, grade 2 arterial hypertension, grade 1 hand-foot syndrome and grade 2 thrombocytopenia. Due to the worsening of arterial hypertension after the first treatment cycle, a diuretic and a calcium channel blocker were added to the antihypertensive treatment, which resulted in good blood pressure control. Bevacizumab administration remained unchanged, and blood pressure was well controlled.

Re-staging performed by whole-body CT scan after the fourth and the eighth (Figure 2) cycle of treatment showed a stable disease according to RECIST criteria. Thus, after completing eight courses (six months), capecitabine and oxaliplatin were discontinued and main-

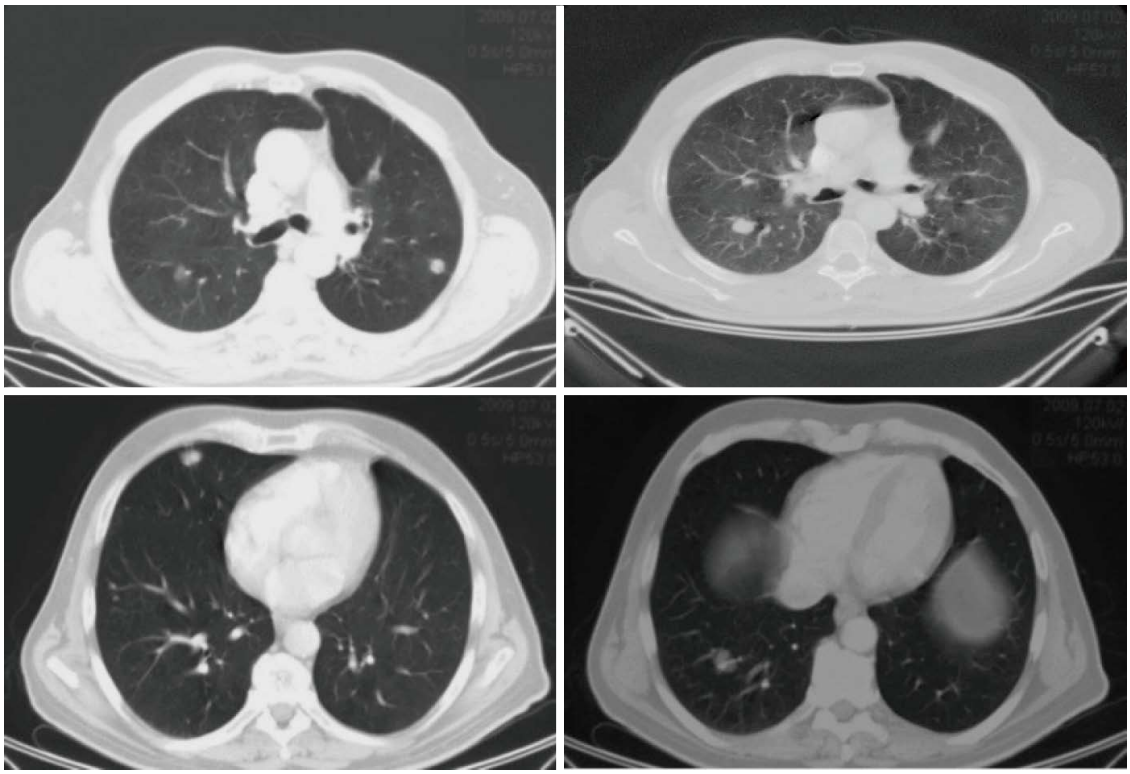

**Figure 2 Thorax computed tomography-scan after 8 cycles of treatment.** Note stabilization of the disease according to RECIST criteria (June 2009).

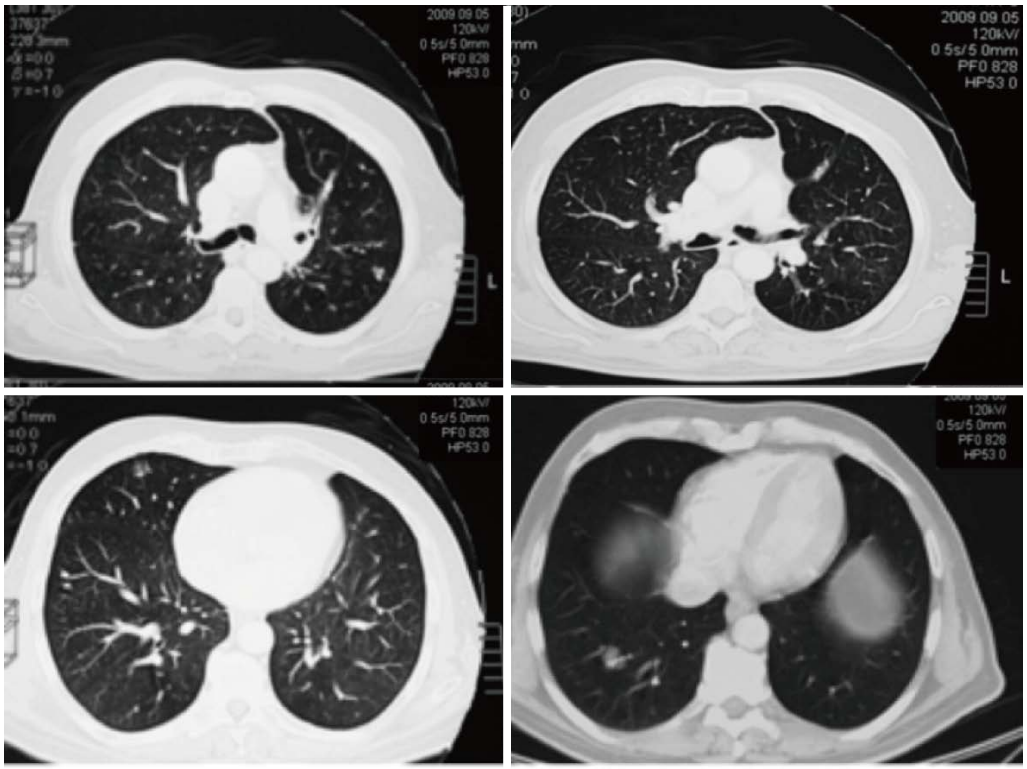

**Figure 3 Thorax computed tomography-scan after two months of maintenance treatment.** Note a partial regression of disease according to RECIST criteria (September 2009).

tenance with bevacizumab alone (7.5 mg/kg every 21 d) was started. During the maintenance period, re-staging by whole-body CT scan was scheduled every three months. In September 2009, the CT scan showed a significant reduction of the maximum diameter of the four measurable lung metastases (Figure 3), which were no longer

**Figure 4 Thorax computed tomography-scan after 4 mo of maintenance treatment.** The disease has completely regressed according to RECIST criteria (November 2009).

detected after a further 3 mo of treatment (November 2009) (Figure 4).

The patient continued with bevacizumab for the following 44 mo, remaining free from metastases (Figure 5), and without reporting any adverse event. Serum marker levels mirrored the outcome of the lung metastases throughout treatment and follow-up (Figure 6). In January 2013, bevacizumab was discontinued to enable the patient to undergo hip arthoplasty because of right coxarthrosis. Currently (June 2014), 68 mo after diagnosis, the patient has a good ECOG performance status with no evidence of metastatic disease (Figure 7). He attends follow-up controls every three months.

## DISCUSSION

Here we report the case of a 72-year-old man with multiple lung metastases from a colon adenocarcinoma who achieved a complete radiological response after 12 mo of treatment: six with chemotherapy plus bevacizumab and six with bevacizumab alone. Bevacizumab alone was continued as maintenance therapy with bevacizumab alone for 44 mo, and patient experienced only a few side effects that were easily managed, and he enjoyed a good quality of life throughout the entire course of treatment.

Bevacizumab in combination with fluoropyrimidine-based chemotherapy is indicated for the treatment of patients with metastatic carcinoma of the colon or rectum, and it is recommended that treatment be continued until disease progression or unacceptable toxicity. However, when used as monotherapy, bevacizumab is not known to induce tumor regression or disappearance[7].

Saltz *et al*[10] reported that the addition of bevacizumab to an oxaliplatin-based regimen in the first-line setting significantly prolonged median progression-free survival (9.4 mo *vs* 8.0 mo; $P = 0.0023$), but did not significantly improve overall survival or the response rate[10]. However, many patients discontinued bevacizumab combined with chemotherapy for reasons other than progression or toxicity. A pre-defined analysis of on-treatment patients showed a much higher magnitude of benefit in progression-free survival for treatment until progression (HR = 0.63) than pre-progression discontinuation (HR = 0.83), which suggests that it is important to continue bevacizumab to maximize the benefit of its addition to chemotherapy[10].

The role of maintenance therapy in mCRC is still controversial. The most recent ESMO consensus guidelines suggest that treatment discontinuation or maintenance are feasible options after 4-6 mo of full-dose first-line therapy[11]. Two randomized trials-MACRO[12], and DREAM[13]-support the role of maintenance with bevacizumab alone[12] or with erlotinib[13].

However, the magnitude of the benefit of maintenance therapy over the discontinuation approach has been addressed in 3 clinical trials, comparing maintenance with complete treatment discontinuation. The CAIRO 3 trial after a 4 mo' period of treatment (CAP-OX plus bevacizumab regimen) randomized not progressive patients to maintenance with capecitabine plus bevacizumab or

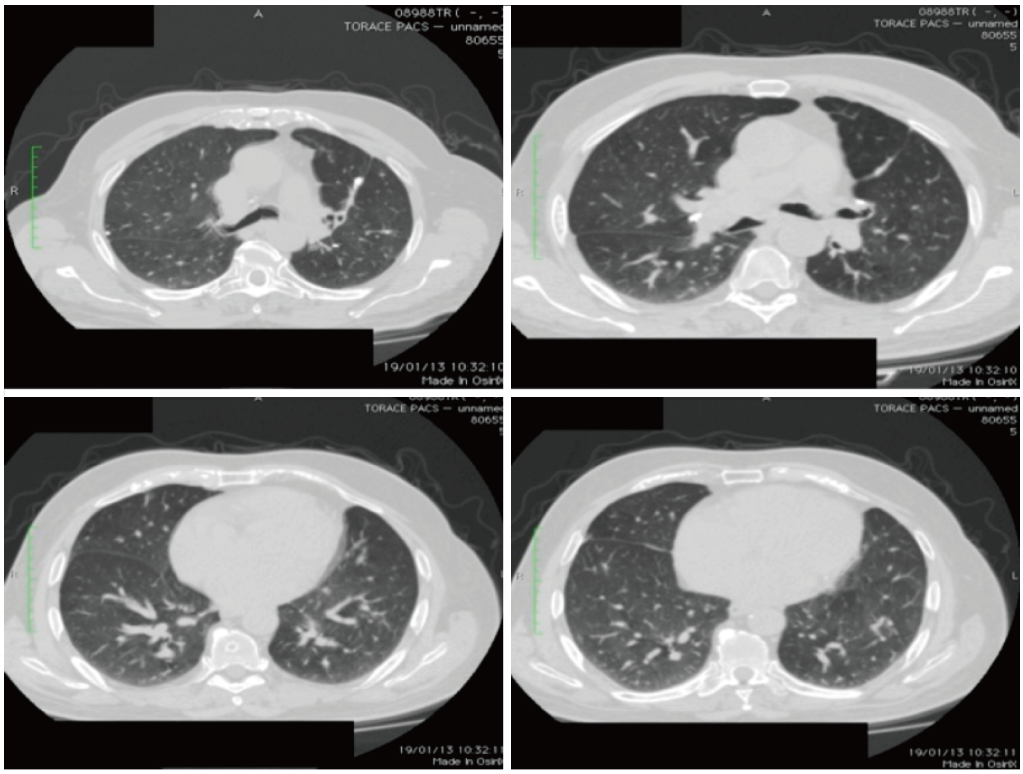

**Figure 5 Thorax computed tomography-scan showing the complete response after discontinuing bevacizumab (January 2013).**

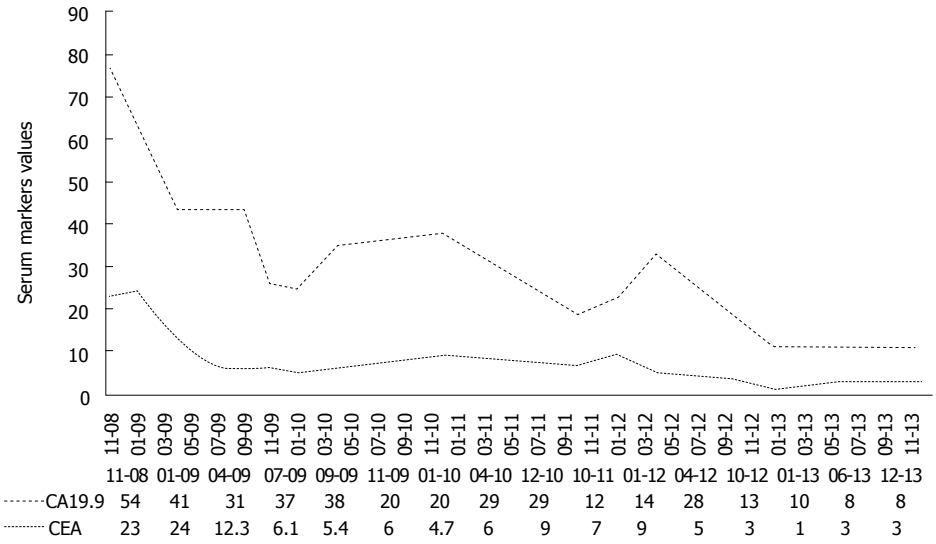

**Figure 6 CEA (ng/mL) and CA19.9 (U/mL) serum levels throughout the treatment and follow-up period.**

no further therapy. First and second progression-free survival times and time to second progression were improved in the maintenance arm.

The SAKK (41/06) trial was designed to demonstrate the non-inferiority of complete discontinuation of treatment as compared to maintenance with bevacizumab a after 4-6 mo of chemotherapy plus bevacizumab. The non-inferiority was not statistically demonstrated, suggesting that maintenance with bevacizumab might be considered an appropriate option.

At ASCO 2014 the results of AIO0207 were presented. After 24 wk of induction therapy with fluoropyrimidines, oxaliplatin and bevacizumab, maintenance with fluoropyrimidines plus bevacizumab was compared with bevacizumab alone or with complete discontinuation. Maintenance treatment with fluoropyrimidines and bevacizumab prolongs progression free survival and time to failure of strategy with respect to complete discontinuation.

When we decided the maintenance strategy for our patient, there was no information available about the role of fluoropyrimidines in this condition, therefore only be-

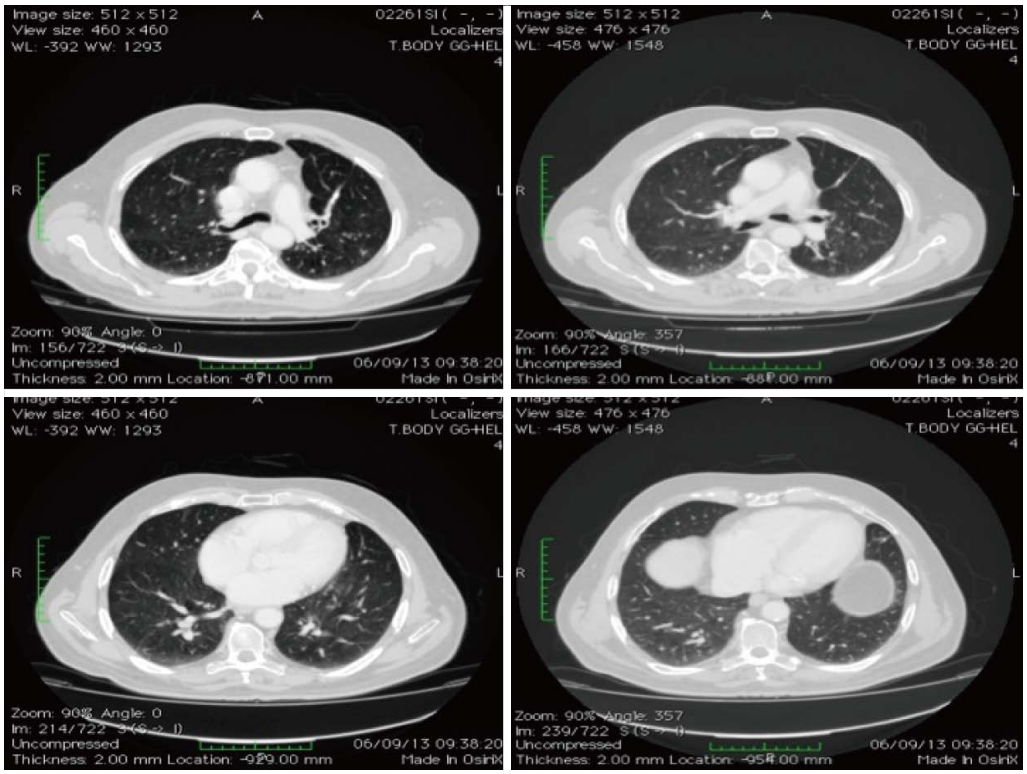

**Figure 7 Thorax computed tomography-scan, showing the response at 60 mo since diagnosis (September 2013).**

vacizumab was continued. Of note, our patient achieved a complete response after 12 mo of treatment and a very long progression-free survival, which supports continuing bevacizumab after stopping chemotherapy.

Another issue we were able to address is the tolerability of very long treatment with bevacizumab. Our patient was 72-year-old when metastatic disease was diagnosed, and was affected by arterial hypertension. Bleeding, hypertension and venous thromboembolic events are the most frequent side effects of bevacizumab recorded, also in a randomized clinical study[14]. Although hypertension was much more frequent in patients treated with bevacizumab than in controls, only arterial thromboembolic events were significantly higher in the bevacizumab-treated patients aged ≥ 70 years (6.7% *vs* 3.2% in the control group)[14]. It is noteworthy that patients enrolled in clinical trials are selected for their very good conditions, and with very limited comorbidities. However, similar results were in that BRITE observational study, where only a modest increase of arterial thromboembolic events was observed in elderly patients: unadjusted rate per 100 patients-years was 1.4 for patients < 75 years old, 4.0 for patients aged 75-80, and 4.8 for older patients)[15]. Moreover, in the BRITE study, the median time to occurrence of bleeding and arterial thromboembolic events was about 5 mo and the risk of cardiovascular side effects did not increase with the duration of bevacizumab treatment[15].

The AVEX trial[16] was the first phase Ⅲ trial to prospectively evaluate the use of bevacizumab in elderly patients (≥ 70-year-old) affected by mCRC. Bleeding (25.4%), arterial hypertension (19.4%), venous thromboembolic (11.9%) and arterial thromboembolic events (4.5%) were the most common all-grade adverse events in the cohort of 140 patients receiving bevacizumab[16].

In our patient, arterial hypertension worsened after the first administration of bevacizumab, and was successfully managed with anti-hypertensive therapy, without discontinuing bevacizumab.

In conclusion, our report, although based on a single patient, supports the feasibility and, possibly, the benefit of continuing bevacizumab as maintenance treatment for a very long period. Moreover, the case reported here suggests that this regimen can be administered even in elderly patients provided they are fit. Indeed, they can have the same benefits as adult subjects, possibly without a significant increase in toxicity.

## COMMENTS

### *Case characteristics*

The case reports the clinical case of a colorectal cancer patient presenting with lung metastases.

### *Clinical diagnosis*

He underwent first line chemotherapy with capecitabine, oxaliplatin and bevacizumab as induction treatment for six months, after which he continued receiving bevacizumab monotherapy for more than three years.

### *Treatment*

He achieved a complete response and is currently free from relapse.

### *Experiences and lessons*

The long progression-free survival time and the absence of side effects indicates that bevacizumab-based maintenance treatment is beneficial in mCRC patients. However, although some studies reported a benefit of maintenance therapy in PFS or TTF, the definite role of maintenance on survival and the best maintenance regimen might be further investigated in properly designed clinical trials.

### *Peer review*

It is a very interested topic for physicians of multiple specialties such as Internal Medicine, Oncology, Surgery, Family Medicine. The manuscript is very well written.

## Abstract

In the last years, operative laparoscopy became a standard approach in gynaecology and general surgery. Even in pregnancy its use is becoming more widely accepted. In fact, it offers advantages similar to those in no pregnant women, associated with good maternal and fetal outcomes. Around 0.2% of pregnant women require abdominal surgery. The most common indications of laparoscopy in pregnancy are cholelithiasis complications, appendicitis, persistent ovarian cyst and adnexal torsion. Authors describe a very rare case of acute abdomen due to isolated Fallopian tube torsion in a 24th weeks pregnant woman, managed by laparoscopic salpingectomy.

**Key words:** Fallopian tube torsion; Acute abdomen; Pregnancy; Laparoscopy

**Core tip:** Authors describe a very rare case of acute abdomen due to isolated Fallopian tube torsion in a 24th weeks pregnant woman, managed by laparoscopic salpingectomy. In all literature the most recent estimation for its incidence dates from 1970, when Hansen estimated 1 per 1.5 million women to have isolated Fallopian tube torsion in Denmark. And since 1933 only 25 cases of Fallopian tube torsion in pregnant women were described.

Sidiropoulou Z, Setúbal A. Acute abdomen in pregnancy due to isolated Fallopian tube torsion: The laparoscopic treatment of a rare case. *World J Clin Cases* 2014; 2(11): 724-727 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/724.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.724

## INTRODUCTION

The Fallopian tube torsion is a rare cause of acute abdomen and even more rare during pregnancy. In 1933, Regad )[1] reported 201 cases of tubal torsion, 12% of these occurred in pregnant women ($n$ = 24). Since 1933 until 2013 only 25 cases were described.

The etiology is uncertain, but some authors described factors that could be implicated in the occurrence of Fallopian tube torsion. Some of them are intrinsic of the tube like congenital anomalies or acquired pathology (hidrosalpinx, hematosalpinx, neoplasm, surgery) or autonomic dysfunction and abnormal peristalsis; and other are extrinsic like adhesions, pregnancy, mechanical factors, movement or trauma to the pelvic organs or pelvic congestion[2,3].

Since the Fallopian tube torsion is a rare condition and sporadic cases are reported, its real incidence is unknown, and it seems that it is more frequent in the reproductive age, which is understandable because almost all risk factors are not frequent before menarche or during menopause[3].

The clinical characteristics, the laboratory or the imaging studies are not specific, so the diagnosis is difficult. The acute abdominal pain at the lower quadrants is the most common symptom, with sensitive painful palpa-

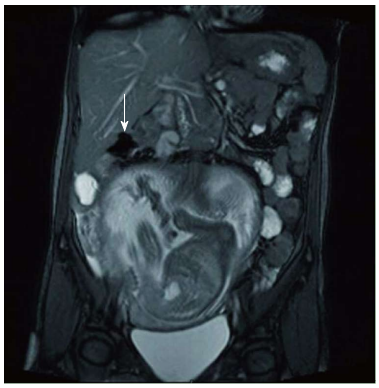

**Figure 1 Cystic structure on the right adnexa (magnetic resonance imaging image).**

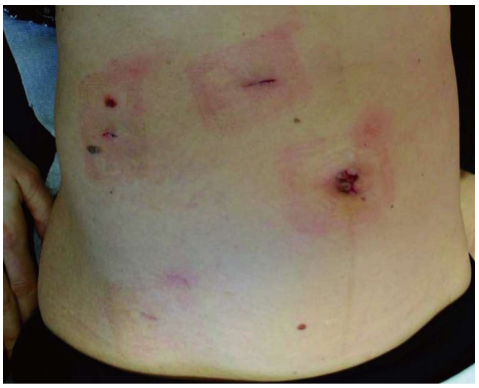

**Figure 2 The abdominal sites of the auxiliary trocares.**

tion of the same abdominal area. As the clinical and the complementary study are not specific, the definitive diagnosis can be made by laparoscopy. The authors think that, at the present time, laparoscopy in the setting of experienced and dedicated teams should be the standard approach for this situation, even in pregnant women.

We described a case of a 24 wk pregnancy with a right Fallopian tube torsion which was managed by laparoscopic salpingectomy.

## CASE REPORT

A 36-year-old healthy primigravida, with an uneventful pregnancy until the 24$^{th}$ week of pregnancy. At this time she complained of a persistent right flank abdominal pain with a sudden increase. Physical examination revealed abdominal enlargement compatible with pregnancy age and a painful right mid abdominal quadrant palpation, with tenderness and without palpable masses.

The ultrasound study revealed a single, life fetus, with a biometry compatible to a 24 wk pregnancy, with normal amniotic fluid volume and with a normal placenta with no signs of abruption; and in the right lower area it showed a cystic structure measuring 4 cm × 3 cm in diameter, probably with an adnexial origin. The MRI confirmed the cystic image, without anyother pathology (Figure 1). Because pain persists, laboratory findings were unspecific and physical examination then was a persisting pain with poor tenderness and peritoneal reaction (acute abdominal pain), two diagnoses were made - acute appendicitis and adnexal torsion.

A diagnostic laparoscopy was then performed. Because the uterus extends 5 cm above the umbilicus, this fact limits the abdomen first entrance, so a direct entrance in the umbilicus could accidental damage the uterus. Alternative Palmer point or the 9$^{th}$ intercostal space is also dangerous because the big pregnant uterus push all the abdominal viscera up. The surgery that we described was an emergent situation, the bowel was not prepared, the viscera distortion was bigger. So the decision was to perform the open technique with the Hasson trocar. The problem was identified by the diagnostic laparoscopy and then the auxiliary trocars were placed underdirect vision and according to the best ergonomic approach for the salpingectomy (Figure 2). We decided to perform a salpingectomy because of the gangrenous aspect of the tube as consequence of its pedicle torsion (Figure 3), without any macroscopic changes of the appendix. The specimen was extracted with a laparoscopic bag. The patient was discharged on the second day after surgery without any complains or surgical and obstetric complication. The reason for two days of hospital stay was based on the diagnosis in a 24$^{th}$ week pregnant woman and immediate control of fetal well-being.

The histopathologic examination of the specimen showed a necrotic tube, secondary of a paraovarian cyst torsion. She delivery a healthy, 3350 g, baby at the 40$^{th}$ week of pregnancy by an instrumental vaccum vaginal delivery because of a progressive distocia at the 2$^{nd}$ stage. No maternal or fetal complications occurred at the peripartum period.

## DISCUSSION

Isolated torsion of Fallopian tube is a very uncommon condition, even more rare in pregnant women. In all literature the most recent estimation for its incidence dates from 1970, when Hansen[4] estimated 1 per 1.5 million women to have isolated Fallopian tube torsion in Denmark. And since 1933 only 25 cases of Fallopian tube torsion in pregnant women were Described[2,5,6]. Since this is a very rare situation, probably the series published underestimate the real incidence of this pathology.

Other aspect hard to describe is its etiology. Its real cause is uncertain and it can happen in healthy tubes, but some risk factors were described as possible causes. This factors were divided in two types: internal or intrinsic like congenital anomalies (excessive length of tube or spiral course), acquired pathology (hidrosalpinx, hematosalpinx, neoplasm, surgery) or autonomic dysfunction and abnormal peristalsis; and external or extrinsic factors such as changes in neighboring organs (neoplasm, adhesions, pregnancy), mechanical factors, movement or trauma to the pelvic organs or pelvic congestion[2,3,7].

Although the clinical characteristics are not exclusive

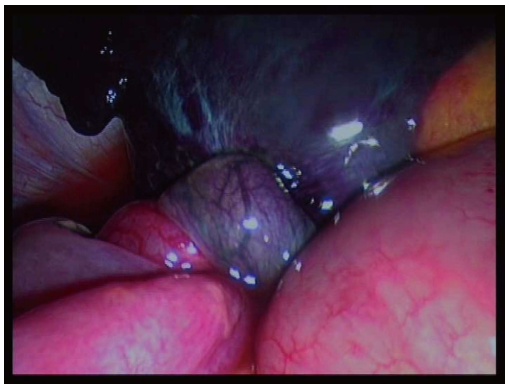

**Figure 3 The pedicle torsion of the right Fallopian tube.**

of the Fallopian tube torsion, the most common symptom is the lower abdominal pain, generally with a sudden onset and accompanied by nausea, vomiting or urinary urgency[2,3]. Physical findings include abdominal tenderness, with or without peritoneal signs and an inconstant palpable mass[2,3].

All this clinical signs and symptoms are common with other medical conditions and give the physician a differential diagnosis problem, which includes ovarian torsion, acute appendicitis, ectopic pregnancy, acute salpingitis, tuboovarian abscess, ruptured ovarian cyst, degenerated leiomyoma, urolithiasis, intestinal obstruction or perforation[7-9]. Laboratory values are nonspecific and do not help in the differential diagnosis[7,9]. The sonographic findings of isolated Fallopian tube torsion are not pathognomonic and are quite variable[9], especially in second and third trimesters of pregnancy, where the adnexas are more difficult to visualize. But the finding of a high impedance or absence of flow in a tubular structure, especially in a patient with a history of tubal ligation, can be indicative of the diagnosis[10,11].

Pre-operative diagnosis of tubal torsion is very difficult and as its management is surgical the diagnostic laparoscopy is the tool for the definitive diagnosis and treatment[3], even in advanced pregnancies, like the case described.

Until now, there are no prospective and randomized studies that compared laparoscopic procedures with laparotomy during pregnancy. Retrospective studies published, show that laparoscopy in pregnancy appears safe and can be performed without a considerable increment in maternal and fetal complications. Mathevet *et al*[12] published the results of 48 laparoscopic procedures for management of adnexal masses in pregnancy (17 cases were performed during the first trimester, 27 cases in the second trimester and 4 in the third trimester). Except one fetal loss 4 d after surgery, no complications were observed during the intra and post-operative periods and obstetrical outcomes were. So the authors concluded that laparoscopic management of adnexal masses in pregnancy is a safe and effective procedure, performed by an experienced team. Similar conclusions were made by Lenglet *et al*[13] in a series of 26 pregnant patients who underwent the laparoscopic surgery of ovarian cysts.

Despite the limited data, it seems that laparoscopic surgery in pregnancy, in experienced hands, is a technique acceptable with some advantages, including early return of bowel function, early ambulation, short hospital stay, rapid return to normal activity, low rate of wound infection and hernia and less pain after the procedure[14,15]. Another advantage of laparoscopy is the lesser manipulation of the uterus which leads to less uterine contractions, so less spontaneous abortion, preterm labor and premature delivery[14]. However laparoscopy during pregnancy should be performed with caution and some precautions should be taken like: routinely intraoperative fetal monitoring, attention with patient position (for example, the lateral decubitus position should be preferred to prevent inferior vena cava compression), the Hasson trocar open technique seems to be safer to prevent inadvertent puncture of the uterus (but no studies showed a real advantage under the Veress technique), intra-abdominal pressure should be kept less than 15 mmHg, maternal end- tidal volume $CO_2$ should be monitored and kept within the normal range, depending on the height of the uterus the secondary trocars should be inserted under direct vision and their position decided according to the uterus size and the position of the abnormal findings. The administration of prophylactic tocolytics is not necessary; it can be given if there is evidence of uterine contractions[14,16].

In conclusion, isolated Fallopian tube torsion should be considered as a possible diagnosis of acute abdominal pain in pregnancy. The diagnostic laparoscopy is the gold standard for its definitive diagnosis and allows the tube torsion resolution with a minimal invasive technique, even in pregnant women.

## COMMENTS

### *Case characteristics*

Acute abdómen in pregnancy, diagnostic challenges.

### *Clinical diagnosis*

Abdominal enlargement compatible with pregnancy age and a painful right mid abdominal quadrant palpation, with tenderness and without palpable masses.

### *Differential diagnosis*

Laboratory and image exams, high clinical suspicion.

### *Imaging diagnosis*

Ultrasonnography in first approach, magnetic resonance imaging confirmation.

### *Pathological diagnosis*

Histology validates the findings.

### *Treatment*

Laparoscopy, diagnostic and treatment.

### *Experiences and lessons*

Laparoscopy in experienced hands might be the gold standard approach in acute abdómen in pregnant woman.

### *Peer review*

In this case report, the authors highlighted the useful of laparoscopic approach for emergent abdominal surgery in pregnant women. Their assertion is acceptable and the manuscript is well written.

## Abstract

Abdominal cocoon syndrome is a rare cause of intestinal obstruction with unknown etiology. Diagnosis of this syndrome, which can be summarized as the small intestine being surrounded by a fibrous capsule not containing the mesothelium, is difficult in the preoperative period. A 47-year-old male patient was referred to the emergency department with complaints of abdominal pain, nausea, and vomiting for two days. The abdominal computed tomography examination detected dilated small intestinal loops containing air-fluid levels clustered in the left upper quadrant of the abdomen and surrounded by a thick, saclike, contrast-enhanced membrane. During exploratory surgery, a capsular structure was identified in the upper left quadrant with a regular surface that was solid-fibrous in nature. Abdominal cocoon syndrome is a rarely seen condition, for which the preoperative diagnosis is difficult. The combination of physical examination and radiological signs, and the knowledge of "recurrent characteristics of the complaints" that can be learned by a careful history, may be helpful in diagnosis.

**Key words:** Intestinal obstruction; Abdominal cocoon syndrome; Preoperatively diagnosis; Adult patient

**Core tip:** Abdominal "cocoon" is an extremely rare cause of small bowel obstruction. It should be thought of as a rare cause of small bowel obstruction. Its diagnosis is rarely made preoperatively. It has been reported mainly in young adolescent women. But in this adult patient, the small bowel is encased in a fibrous sac called an abdominal cocoon. The clinical manifestations of abdominal "cocoon" are non-specific. The combination of physical examination and radiological signs, and the knowledge of "recurrent characteristics of the complaints" which can be learned by a careful history, may be helpful in diagnosis. Surgery remains the main stay of treatment with satisfactory outcome.

Rare etiology of mechanical intestinal obstruction: Abdominal cocoon syndrome. *World J Clin Cases* 2014; 2(11): 728-731 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i11/728.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i11.728

## INTRODUCTION

Abdominal cocoon syndrome, which was first defined in 1978[1], is relatively rare, with descriptions in the literature

**Figure 1 Abdominal radiography, multiple air-fluid levels are seen, which was more prominent in the left upper quadrant.**

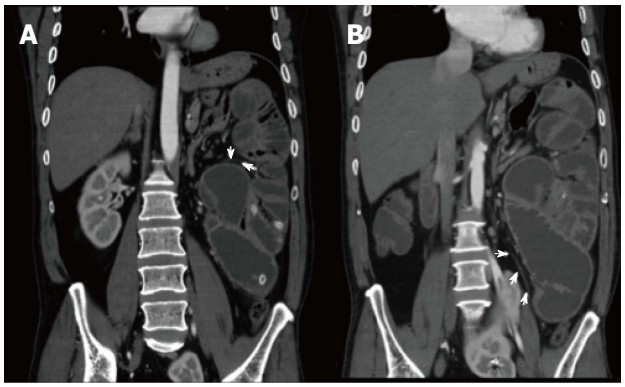

**Figure 2 Abdominal computerized tomography - coronal section; dilated small intestinal loops containing air-fluid levels clustered in the left upper quadrant of the abdomen and surrounded by a thick, saclike, contrast-enhanced membrane in the sections close to the root of mesentery (white arrows).** A: Superior; B: Inferior.

limited to case reports. In this syndrome, a portion or all of the small intestine is surrounded with a fibrocollagenous membrane not containing the mesothelium. As it is rarely seen, and its clinical findings nonspecific, it is generally diagnosed during surgery[2]. However, it can be characterized by the membrane surrounding the small intestine with contrast-enhanced abdominal computerized tomography (CT) during the preoperative period. Surgical treatment that releases the small intestine by cutting away the adhesions after excision of the membrane is the basic intervention in these cases. This article presents a case with abdominal cocoon syndrome diagnosed, following recurrent complaints, with abdominal CT during the preoperative period and surgically treated.

## CASE REPORT

A 47-year-old male patient was referred to the emergency department with complaints of abdominal pain, nausea, and vomiting for two days. The detailed medical history of the patient, who did not have a known chronic systemic disease or a previous history of any abdominal procedures, revealed similar complaints dating back several years that recurred at certain time intervals and had been

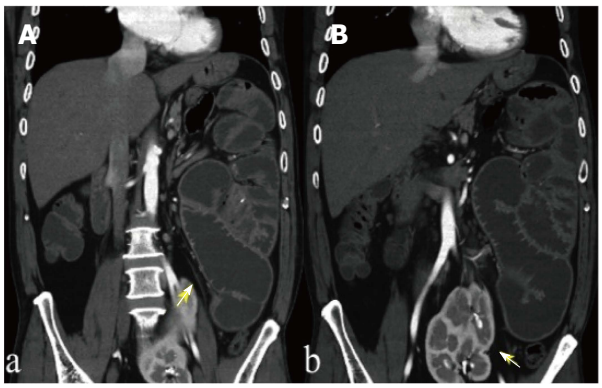

**Figure 3 Abdominal computerized tomography - coronal section; dilated small intestinal loops containing air-fluid levels clustered in the left upper quadrant of the abdomen and surrounded by a thick, saclike, contrast-enhanced membrane (A) (arrow).** The left kidney was also located ectopically at the midline in the abdomen at the level of the pelvis (B) (arrow).

treated. Upon physical examination, there was asymmetrical distension and general tenderness, especially prominent in upper regions of the abdomen, with heightened intestinal sounds. The laboratory examinations were normal, except for leukocytosis (14.300 $mm^3$). Multiple air-fluid levels were detected on abdominal radiography, which was more prominent in the left upper quadrant (Figure 1). The abdominal CT examination detected dilated small intestinal loops containing air-fluid levels clustered in the left upper quadrant of the abdomen and surrounded by a thick, saclike, contrast-enhanced membrane. The left kidney was also located ectopically at the midline in the abdomen at the level of the pelvis (Figures 2 and 3). During exploratory surgery, widespread adhesions with the peritoneum and small intestine could not be seen. Upon further exploration, a capsular structure was identified in the upper left quadrant with a regular surface that was solid-fibrous in nature. Only 20 cm of the jejunal and ileal segments in the proximal and distal portions of the small intestine were intra-abdominally localized. The remaining small intestinal segments were inside this structure and the greater omentum was hypoplastic (Figure 4). When the capsule was opened, the small intestinal segments inside the capsule were dilated due to obstruction but otherwise normal in structure. The obstruction was caused by fibrous bands of irregular thickness inside the capsule. The operation was completed after total excision of the capsule and removal of the adhesions. The patient manifested clinical signs of ileus on postoperative day 3 due to the adhesions. He was medically treated with nasogastric decompression and parenteral nutrition and discharged on postoperative day 12 without any problems. Upon histopathological examination, a nonspecific inflammatory reaction in conjunction with fibrous connective tissue proliferation was found. On the third month of his follow-up, the patient did not report any problems.

## DISCUSSION

Abdominal cocoon syndrome is a rare cause of acute or

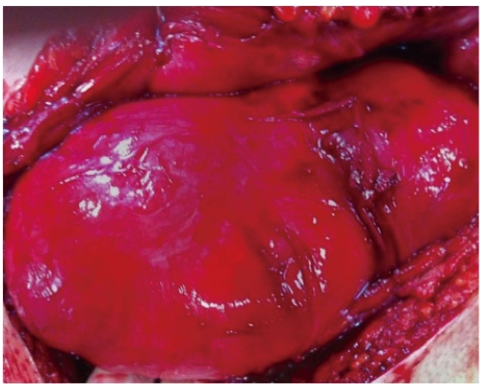

**Figure 4 Intraoperative findings; small intestine could not be seen, a capsular structure was identified in the upper left quadrant with a regular surface that was solid-fibrous in nature.**

subacute intestinal obstruction, and its' classified as primary (idiopathic) and secondary. Although the etiology is not precisely known, conditions that result in chronic asymptomatic peritonitis (such as: the use of practalol, peritoneal dialysis, endometriosis, and abdominal tuberculosis) are risk factors. Moreover, accompanied by some diseases (systemic lupus erythematosus, familial Mediterranean fever, infections of the Fallopian tubes, retrograde menstruation) have also been reported[3-6] . In a two-case series reported by Yeniay *et al*[7], the greater omentum was absent, suggesting that genetic factors may also play a role in the etiology. Our case reports the role of genetic factors since our patient developed chronic peritonitis without having any of the known risk factors, the greater omentum was hypoplastic, and there was a locational abnormality in the left kidney.

The clinical presentation of abdominal cocoon syndrome is generally acute or subacute intestinal obstruction. There is an increase in intestinal sounds and abdominal distension on physical examination. However, abdominal distension may be asymmetrical, as the small intestine is surrounded by a membrane and not mobile[8]. Common complaints during patient history include the recurrence of nonspecific symptoms such as nausea and vomiting that spontaneously recover or respond to medical therapy. Chronic constipation, anorexia, weight loss, and intra-abdominal masses rarely present in these patients[9]. In the current case, there were signs of intestinal obstruction associated with asymmetrical distension during the physical examination of the abdomen.

As it is rarely seen and the clinical symptoms are nonspecific, diagnosis in the preoperative period is difficult. Clusters of intestinal loops and a surrounding membrane in contrast-enhanced abdominal CT, especially multislice CT, are diagnostic[10]. An abdominal CT that is performed during the preoperative period provides both diagnosis and differential diagnosis, and determines the associated congenital changes, such as the midline location of the left kidney in our case. This prevents undesirable complications during surgery. However, in spite of all opportunities, preoperative diagnosis is difficult and requires advanced radiological experience. In a retrospective study of twenty-four cases, it was reported that only 16% of the cases could be preoperatively diagnosed[11].

There is a consensus that surgical treatment is ideal in these patients. The recommended procedure excises the membrane and unbinds the adhesions between intestinal segments[7,10]. However, this process requires great care, due to the general possibility of secondary damage, as there are extensive adhesions between the membrane and between the intestinal segments. Bowel perforation, enterocutaneous fistula or sepsis occurring as a result of secondary damage, are among the complications that can be encountered during the postoperative period[3]. The recurrence of the cocoon in the postoperative period is rare but the most probable complication is the obstruction of small intestine due to adhesions. The current case revealed clinical signs of ileus during postoperative day 3 that responded to medical therapy.

In conclusion, abdominal cocoon syndrome is a rarely seen condition, for which the preoperative diagnosis is difficult. The combination of physical examination and radiological signs, and the knowledge of "recurrent characteristics of the complaints" which can be learned by a careful history, may be helpful in diagnosis. It should be remembered that medical treatment will not be beneficial and definitive treatment requires careful surgical excision during the early stages of the disease.

## COMMENTS

### *Case characteristics*

Patient was referred to the emergency department with complaints of abdominal pain, nausea, and vomiting for two days.

### *Clinical diagnosis*

Upon physical examination, there was asymmetrical distension and general tenderness, especially prominent in upper regions of the abdomen, with heightened intestinal sounds.

### *Differential diagnosis*

The abdominal computerized tomography examination detected dilated small intestinal loops containing air-fluid levels clustered in the left upper quadrant of the abdomen and surrounded by a thick, saclike, contrast-enhanced membrane.

### *Laboratory diagnosis*

During exploratory surgery, widespread adhesions with the peritoneum and small intestine could not be seen.

### *Imaging diagnosis*

Please summarize imaging methods and major findings in one sentence.

### *Pathological diagnosis*

When the capsule was opened, the small intestinal segments inside the capsule were dilated due to obstruction but otherwise normal in structure.

### *Treatment*

The operation was completed after total excision of the capsule and removal of the adhesions.

### *Term explanation*

Early diagnosis is important.

### *Experiences and lessons*

It should be remembered that medical treatment will not be beneficial and definitive treatment requires careful surgical excision during the early stages of the disease.

### *Peer review*

The case report and the discussion are well-written.

## Abstract

Adenoid cystic carcinoma (ACC) of the breast is a rare special subtype of breast cancer characterized by the presence of a dual cell population of luminal and basaloid cells arranged in specific growth patterns. Most breast cancers with triple-negative, basal-like breast features (*i.e.*, tumors that are devoid of estrogen receptor, progesterone receptor, and human epidermal growth factor receptor 2 expression, and express basal cell markers) are generally high-grade tumors with an aggressive clinical course. Conversely, while ACCs also display a triple-negative, basal-like phenotype, they are usually low-grade and exhibit an indolent clinical behavior. Many discoveries regarding the molecular and genetic features of the ACC, including a specific chromosomal translocation t(6;9) that results in a *MYB-NFIB* fusion gene, have been made in recent years. This comprehensive review provides our experience with ACC of the breast, as well as an overview of clinical, histopathological, and molecular genetic features.

## INTRODUCTION

Invasive breast carcinoma comprises a heterogeneous group of tumors with various clinical, morphologic, and molecular genetic features[1,2]. According to the 2012 World Health Organization classification, invasive ductal carcinoma of no special type (NST) is the most common histologic type, accounting for up to 75% of all invasive breast carcinomas[3]. The remainder of the invasive cancers represent at least 18 different special and rare histomorphologic subtypes, including adenoid cystic carcinoma (ACC), a salivary gland-type of breast carcinoma[3].

A characteristic histologic pattern of ACC of the breast includes both epithelial and myoepithelial compo-

nents and resembles a well-known tumor of the salivary gland origin known by the same name. However, patients diagnosed with ACC of the breast have a better prognosis than those who are diagnosed with ACC of the salivary gland[4-6]. ACC of the breast belongs to the basal-like subgroup of breast cancers[7-9]. Based on extensive molecular and genetic profiling studies, basal-like tumors are most often hormone receptor [estrogen receptor (ER) and progesterone receptor (PR)] negative, do not express human epidermal growth factor receptor 2 (Her2), but express one or more basal/myoepithelial cell markers [*e.g.*, cytokeratins (CKs) 5, 5/6, 14 and 17][10]. Unlike other triple-negative breast cancers that are associated with poor prognosis, ACC has an overall excellent prognosis[11]. Because of these distinct clinicopathologic features that set it apart from the other triple-negative breast cancers, an understanding of ACC of the breast is essential for surgical pathologists, breast surgeons, and oncologists. This review will focus on ACC of the breast and will outline important updates in its epidemiology, clinical features, histomorphologic/immunohistochemical characteristics, molecular genetic features, and prognosis/treatment. In addition, we will address our team's experience with this clinical entity.

## EPIDEMIOLOGY

ACC is an uncommon subtype of invasive breast carcinoma and accounts for less than 0.1% of all primary carcinomas of the breast[3,12,13]. Recently, several independent studies based on large patient cohorts have provided more insight into its epidemiology and clinical characteristics[11,14-20]. This information, in the recent studies published in 2010 and after, is summarized in Table 1. The reported age distribution for patients diagnosed with ACC of the breast ranges from 38 to 81 years (with a median age of 60 years; Table 1) and is similar to that seen in other invasive breast cancer cases[3]. Moreover, a previous case series of 338 patients with ACC of the breast conducted over a 30-year period identified its age-adjusted incidence ratio (AAIR) to be 0.92 per 1 million person-years. The AAIR remained constant during the 30-year period and was 39%, lower in African-Americans than in Caucasian-Americans[11]. Most cases are in females, but occasional cases have been reported in male patients[21,22].

## CLINICAL FEATURES

ACC of the breast affects the left and right breasts equally and tumors arise irrespective of the breast quadrants. However, in about 50 percent of patients, lesions are found in subareolar region[23]. Pain or tenderness described in the minority of cases has not been correlated with histologically-confirmed perineural invasion[24]. Mammographically, these tumors may appear as asymmetric densities or irregular masses. Sonographically, they appear as well-defined, irregular, heterogeneous, or hypoechoic masses. Nonetheless, the radiographic findings are non-specific and can be misdiagnosed as benign lesions[13,25]. Subsequently, it could be challenging for a radiologist to make the correct diagnosis of carcinoma without histologic confirmation[25]. Lastly, although most patients present with a solitary tumor, a few cases of multifocal ACC of the breast have also been reported[26,27].

## HISTOMORPHOLOGIC/ IMMUNOHISTOCHEMICAL CHARACTERISTICS

The mean size of ACC is 3.0 cm (range, 0.7 to 12.0 cm)[28]. Most cases are macroscopically well-circumscribed. Occasionally, pink, tan, or gray microcysts are evident[28]. ACC usually presents as a localized disease of pathologic T1 or T2 (Table 1).

The histology of ACC of the breast is similar to that of their salivary gland counterparts. A variety of microscopic patterns detected in the ACC of the salivary glands may also be present in the ACC of the breast. A tumor typically consists of a dual-cell population of luminal and myoepithelial-basal cells which may be arranged in one or more of three architectural patterns: tubular-trabecular, cribriform, and solid-basaloid (Figure 1)[3]. There are two types of structures lined by these two different types of cells: true glandular spaces and pseudolumina. Luminal cells, characterized by round nuclei and eosinophilic cytoplasm, surround true gland lumina containing periodic acid-Schiff-positive neutral mucin. Immunohistochemically, the luminal cells are positive for CK7, CK8/18, epithelial membrane antigen, and CD117 (c-Kit)[2,29-31]. On the other hand, the myoepithelial-basal cells exhibit central oval nuclei and scant cytoplasm, and form pseudolumina, which result from intraluminal invaginations of

the stroma. The myoepithelial-basal cells are immunoreactive for basal cytokeratins (CK5, CK5/6, CK14, CK17) (Figure 2), myoepithelial markers (p63, actin, calponin, S-100 protein), vimentin, and epidermal growth factor receptor (EGFR)[2,29-32]. Kasami *et al*[33] reported that the polarity of the different types of cells could be demonstrated by immunohistochemistry: myoepithelial-basal cells usually express laminin, fibronectin, basal lamina related proteins, and type Ⅳ collagen, whereas the luminal cells express proteins related to cell polarization and epithelial differentiation, including fodrin, E-cadherin, and β-catenin. The authors suggest that this preserved cell polarity and segregated cell differentiation could explain the lack of metastatic capacity observed in this tumor type. Other reports describe areas of squamous differentiation and even rare sebaceous differentiation in ACC of the breast[34,35].

In a way akin to the ACC of the salivary gland, ACCs of the breast are graded according to the proportion of solid growth: tumors with either cribriform or tubular-trabecular pattern and without solid elements are considered grade Ⅰ, tumors with ≤ 30% of solid growth are classified as grade Ⅱ, and tumors having more than 30% solid growth are designated grade Ⅲ[4,36]. Ro *et al*[4] reported that tumors with a solid pattern (grade Ⅱ and Ⅲ) had a tendency to be larger than those without a solid pattern (grade Ⅰ), and that grade Ⅱ and Ⅲ tumors were more likely to develop recurrences. In their series, three patients who developed metastatic ACC had grade Ⅱ or Ⅲ lesions. Furthermore, Shin *et al*[37] reported 9 cases of the solid (basaloid) variant of breast ACC in which the tumor cells tended to be larger, with hyperchromatic nuclei showing moderate to marked atypia, pleomorphism, and increased mitotic activity. This solid variant of ACC was associated with an aggressive clinical course. However, it is important to note that the histological grade defined by this system did not correlate with disease outcomes observed in two other studies[34,38]. The most recent American Joint Committee on Cancer staging manual (7th edition) recommends that Nottingham histologic grading be provided uniformly for all breast carcinomas[39]. Based on this grading scheme, most ACCs would belong to the histologic grade 1 (3 - 1 + 1) or histologic grade 2 (3 + 2 + 1).

Phenotypically, both luminal and myoepithelial-basaloid cells in ACC of the breast are generally negative for ER, PR, and Her2 proteins (Table 2 and Figure 3)[11,14,40-43]. The immunohistochemical profile of ACC of the breast fits well within that of triple-negative breast cancers with basal-like features. In one study, ER and PR expression was detected in 46% and 36% of ACC cases, respectively[5]. Although this cohort was one of the larger series of ACCs reported to date ($n$ = 28), the cases were collected from different institutions and did not undergo a central review of the diagnosis. Consequently, it cannot be ruled out that a substantial number of these cases were actually invasive cribriform carcinomas with ER and PR immunoreactivity. In addition, it should be noted that

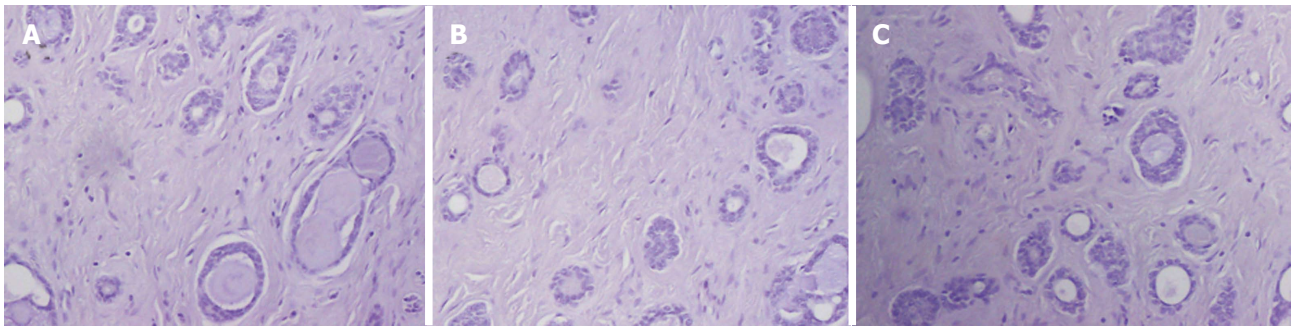

**Figure 3 Immunohistochemical findings in adenoid cystic carcinoma of the breast.** A: Estrogen receptor; B: Progesterone receptor; C: Human epidermal growth factor receptor 2. All these markers are negative in a case of adenoid cystic carcinoma of the breast. Original magnification × 100.

AJCC: American Joint Committee on Cancer.

in the latter study, dextran-coated charcoal assay was used to assess expression for ER and PR instead of the now more widely used immunohistochemistry. Since normal breast lobules and ducts are often entrapped within the tumor tissues, it may lead to false positive results of the dextran-coated charcoal assay.

There have been several case reports suggesting an association between ACC of the breast and various benign lesions including microglandular adenosis, tubular adenosis, adenomyoepithelioma, and fibroadenoma[44-48]. Acs *et al*[44] suggested that ACC of the breast may develop in a background of and in continuity with microglandular adenosis. Following this hypothesis, their group described a morphological spectrum of lesions with a trend of progression, encompassing microglandular adenosis, "atypical microglandular adenosis" (also described as "ACC in situ"), and invasive ACC[44]. Da Silva *et al*[45] reported a morphological characterization of tubular adenosis arising concurrently with ACC in the breast, although the comparative genomic hybridization (CGH) analysis performed on these two lesions failed to provide evidence of molecular evolution from tubular adenosis to ACC. Importantly, breast that harbors an ACC can rarely also contain other types of carcinoma, as was shown in a case where the ACC of the breast coexisted with an invasive ductal carcinoma of NST[49,50].

ACC of the breast that exhibits a cribriform/tubular pattern should be distinguished from invasive cribriform/tubular carcinoma or a benign condition termed collagenous spherulosis[51,52]. This is especially important when a pathologist is provided with tiny tissue specimens obtained by core needle biopsies[36]. Invasive cribriform/tubular carcinomas are characterized by the hyper-proliferation of a single type of neoplastic cells (*i.e.*, luminal cell) only, in contrast to the dual cell types observed in ACC. Moreover, cribriform/tubular carcinomas are generally immunoreactive for ER and PR, whereas ACCs are negative for both[53]. In addition, limited evidence exists of c-Kit and/or p63 immunoreactivity in ACCs of the breast (positive for both), compared to the invasive cribriform/tubular carcinomas which are negative for both markers[40]. In collagenous spherulosis, collagenous spherules are irregular, mostly observed at the periphery of the lesions, and no mucosubstance is detected within lumina. Immunohistochemically, ACCs are c-Kit (+), calponin (-), and smooth muscle myosin (-), whereas collagenous spherulosis lesions are c-Kit (-), calponin (+), and smooth muscle myosin (+), which may help to differentiate between these two types of lesions[54]. The differential diagnosis of the solid (basaloid) variant of ACC includes small cell carcinoma (neuroendocrine carcinoma), solid papillary carcinoma, metaplastic carcinoma, and malignant lymphoma[37]. Although an extensive and careful search for a more typical cribriform pattern of ACC should be performed, immunohistochemistry can also be helpful to distinguish these tumors from ACC.

## MOLECULAR GENETIC FEATURES

Microarray-based gene expression profiling studies have been performed in common types of breast cancer, such as the invasive ductal and lobular carcinomas[7-9]. However, most of these studies did not focus on special types of breast cancer, and consequently, there is only limited transcriptomic data on the ACC features. A recent molecular subtype analysis using a single sample predictor (*i.e.*, centroid) performed on 4 ACCs revealed that two of the samples were classified as basal-like, while the other two

were shown to exhibit the normal breast-like phenotype. Based on this divergence in the results, they could be an artifact of sample representation, perhaps caused by the contamination with normal tissues[55]. In fact, molecular subtype assignment following hierarchical clustering showed that all four ACCs consistently displayed a basal-like phenotype, and all of them clustered with one of the five subgroups of the triple-negative breast cancers. In another study that utilized the immunohistochemical staining analysis and microarray-based gene expression profiling for a series of 113 tumors that belonged to 11 special histologic types of breast cancer (including 4 ACCs), Weigelt *et al*[43] reported that the ACC, medullary carcinoma, and metaplastic carcinoma were highly similar in their immunohistochemical and gene expression profile. However, ACCs did not intermingle with medullary and metaplastic carcinomas in the hierarchical clustering, but formed a separate group. Another study, an array-based CGH analysis of 59 breast cancers that belonged to 10 special histologic special types established that while medullary and metaplastic carcinomas displayed complex genomes, ACCs consistently exhibited simpler patterns of gene copy number aberrations[56]. In line with these results, a recent CGH analysis study revealed that ACC of the breast manifested significantly lower frequencies of genetic instability and lower copy number alterations than the histologic grade-matched basal-like and invasive ductal carcinomas of NST[29]. At the genomic level, ACC is substantially different from the other basal-like breast cancers. Studies show that it rarely harbors genomic aberrations associated with basal-like invasive ductal carcinomas of NST, such as gains of 1q, 6p, 8q, and 10p, and losses of 4p, 5q, and 10q[29,57,58]. Furthermore, aneuploidy is reported in fewer than 10% of cases with ACC of the breast[5]. Together, these findings illustrate the heterogeneity of triple-negative, basal-like breast cancers. Although the majority of these tumors are high grade cancers with high levels of genetic instability and an aggressive clinical course (*e.g.*, grade 3 invasive ductal carcinoma of NST, medullary carcinoma, and metaplastic carcinoma), there is also a subgroup of low grade tumors with low frequencies of genetic instability and an indolent clinical behavior (*e.g.*, ACC and secretory carcinoma)[10,41,43,59-61]. Thus, we emphasize that based solely on molecular subtyping and without proper histologic classification, ACCs, which have an indolent clinical behavior, would be classified as triple-negative, clinically aggressive tumors. Therefore, information regarding the histologic type of triple-negative breast cancers should be included in histopathology reports and taken into account for clinical decision-making.

Although studies using next-generation sequencing (NGS) for whole exome or microRNA expression profiling for ACC of the salivary gland have been recently reported[62-65], there have been few studies using NGS for ACC of the breast. In one study utilizing microRNA expression profiling for two cases each of ACC of the salivary gland and breast, Kiss *et al*[65] reported that the let-7b was overexpressed in ACC of the salivary gland, while decreased in ACC of the breast. In addition, the miR-24 was decreased in salivary gland-derived but overexpressed in breast-derived adenoid cystic carcinomas.

Similar to ACCs of the salivary gland, ACCs of the breast are characterized by the t(6;9) (q22-23; p23-24) chromosomal translocation, which generates fusion transcripts involving the oncogene *MYB* and the transcription factor gene *NFIB*. Several previous studies reported that this chromosomal translocation is present in over 90% of ACC cases and is a key ACC oncogenic mechanism[29,66,67]. The myeloblastoma (MYB)- nuclear factor I/B (NFIB) fusion protein retains the DNA-binding and transactivation domains of a wild-type MYB, and is therefore expected to activate MYB target genes[29,66]. MYB is a leucine zipper transcription factor that plays an important role in the control of cell proliferation, apoptosis, and differentiation[68,69], while its target genes include *BCL2* and *GRP78/BIP*, which are essential for cell survival[70]. MYB is a direct target of EG signaling and is highly expressed not only in ACCs, but also in cell lines of ER-positive breast cancers[71,72]. Recently, one study reported that 67% (8/12 cases) of dermal cylindroma displayed the t(6;9) and MYB-NFIB fusion transcripts and that the composition of these chimeric transcripts was identical to that seen in ACC[73].

Approximately 7% of breast cancer cases are related to hereditary conditions and caused by mutations in the *BRCA1* and *BRCA2* genes[3]. Although medullary and metaplastic breast carcinomas, with which ACC shares immunohistochemical and molecular findings, show a frequent promotor methylation of *BRCA1* gene, ACC of the breast usually retains normal *BRCA1* gene function[2,29]. To our knowledge, *BRCA2* gene status has not been investigated in ACCs of the breast.

ACCs of the breast typically do not express the full-length ER-α (ER-α66) and PR[11,14,39-42]. However, several studies have shown that the ACC, apocrine carcinoma, and triple-negative breast cancer of NST exhibited a frequent membranous/cytoplasmic immunoreactivity for ER-α36, a novel ER-α66 splice variant implicated in membrane-initiated estrogen signaling[74-76]. In the experimental cell models of breast cancer, ER-α36 was shown to transduce the membrane-initiated steroid signaling cascade, and served as a dominant-negative modulator of ER-α66 mediated transcription activity[75]. In addition, ER-α36 was reported to be related to non-genomic ER activities, in which activation of the mitogen-activated protein kinase (MAPK/ERK) signaling pathway plays a major role[75]. The MAPK/ERK signaling pathway is activated in response to antiestrogens (*e.g.*, tamoxifen), indicating a subset of ER-α66 (-)/ER-α36 (+) breast carcinomas might still respond to antiestrogen based therapy[74,75]. Finally, ER-α36 protein closely interacts with EGFR protein, which is commonly expressed in ACC and triple-negative breast cancers[75]. Some investigators have reported that ACCs of the breast frequently overexpress EGFR protein in the absence of underlying *EGFR* gene alterations[19,29].

Cancer stem cells have been reported to be associ-

ated with tumor initiation, progression, survival, and resistance to therapy[77]. However, the cancer stem cell field is still fairly controversial and stem cell markers have not been fully elucidated. In the majority of studies, breast cancer cells with a CD44 (+)/CD24 (-) phenotype have been proposed to have tumor-initiating properties with stem cell-like features[78], and Defaud-Hénon *et al*[18] recently reported that a characteristic CD44 (+)/CD24 (-) phenotype is commonly observed in the ACC of the breast. On the other hand, frequent overexpression of c-Kit and EGFR proteins was observed in undifferentiated carcinomas with stem cell-like features[79]. Although several studies illustrated that a consistent c-Kit protein expression was detected in most ACCs[29,40-43], underlying *KIT* gene alterations, such as gene mutations, have not been previously detected[80]. Finally, SOX10 transcription factor appears to support stem-like properties in normal tissues and cancer cells[81]. Recently, Ivanov *et al*[82] described SOX10 as a novel diagnostic marker for ACCs of the salivary gland and breast basal-like carcinomas, indicating that SOX10 expression might be worth examining in ACCs of the breast.

Although triple-negative NST breast cancers usually have high proliferative activity, ACC of the breast exhibits a low proliferation rate using standard Ki-67 labeling index[29,83]. Interestingly, their typical proliferation rate is even lower than that of low-grade conventional breast carcinomas[84]. Mastropasqua *et al*[40] suggested that proliferative indices showed grater values in high-grade ACCs when compared to low-grade lesions. However, another study reported that the proliferative activity is not associated with the outcome of ACC patients with ACC[38]. In addition to low Ki-67 labeling index, ACCs of the breast, including high-grade solid-basaloid lesions, also show low p53 protein expression[29,39,83]. Trendell-Smith *et al*[53] described a slightly higher p53 protein expression in ACC than that in invasive cribriform carcinoma.

Finally there are several recent studies that identified potential breast ACC biomarkers. Insulin-like growth factor-Ⅱ mRNA-binding protein 3 (IMP3) is an oncofetal protein and a component of the insulin-like growth factor-Ⅱ pathway. Studies indicate that it could serve as a biomarker for basal-like breast carcinomas[84-87], and a recent report showed that the IMP3 is commonly overexpressed in ACCs of the breast[88]. In another report, the molecular genetic analysis of a primary ACC of the breast and its renal metastasis revealed *PTEN* and *PIK-3CA* gene mutations[89].

## PROGNOSIS AND TREATMENT

A striking feature of ACC of the breast, which is in stark contrast with other triple-negative, basal-like breast cancers and the ACC of the salivary gland, is its excellent prognosis. As shown in Table 1, the 10-year survival rate is 90%-100%, and lymph node metastasis is rare, as well as distant metastases, which affect mainly visceral organs[11,14-19,90]. Based on its indolent clinical course and favorable outcome, ACC of the breast is generally cured by breast-conserving surgery, such as wide excision or quadrantectomy with or without radiotherapy[11,17,91]. Mastectomy is recommended for invasive lesions when a cosmetically satisfactory excision is not possible, especially when the tumor has a high-grade pattern[4,36,92]. A recent study of a large patient cohort reported a considerable benefit of adjuvant radiotherapy on overall and disease-specific survival in patients with ACC[15]. Moreover, because a high rate of positive surgical margins has been detected following breast conserving surgery, adjuvant radiotherapy may be beneficial[93]. Furthermore, while some clinicians recommend systemic adjuvant chemotherapy for patients with high-grade lesions or axillary lymph node/distant metastasis[36], its role in breast ACC patients remains controversial.

When patients with ACC demonstrate local recurrence or distant metastases, a prolonged and indolent clinical course is still likely[94-97]. However, long-term follow-up is recommended, since their long clinical course carries a risk of secondary malignancies[98,99], and the risk of distant metastases increases with time[100].

As treatment of cancer enters a new stage with the development of targeted therapies, the common *MYB-NFIB* fusion gene may provide new therapeutic avenues for the management of advanced ACC of the breast. Consequently, further functional studies investigating the biological consequences of the *MYB* gene of function due to the *MYB-NFIB* fusion are needed. Gene silencing experiments are also necessary to demonstrate that *MYB* expression is required for the survival of cancer cells with genetically activated *MYB*. Finally, the functional role of the ER-α36 variant in ACC merits further research as experimental evidence in triple-negative breast cancer cell lines suggests that breast cancer cells with ER-α66 (-)/ER-α36 (+) phenotype might still be responsive to antiestrogens[72,73].

## HOUSTON METHODIST EXPERIENCE OF ACC OF THE BREAST

A search of the electronic data base at Houston Methodist Hospital from 2004 to 2010 yielded five cases of ACC of the breast. The clinicopathologic and follow-up status of these five patients are summarized in Table 3. The five female patients ranged from 48 to 76 years in age, with a mean age of 60 years. All tumors had distinct morphologic features of classic ACC: histologic grade 1 with cribriform, trabecular or glandular architectural patterns, and basement membrane deposition. No cases of grade Ⅱ and Ⅲ tumors were identified. Perineural invasion was identified in one case. Lymphovascular invasion was not seen in any of the cases. An associated adenomyoepithelioma was observed in one case. All patients received lumpectomy and two of these patients had axillary lymph node dissections, with no nodal metastasis found. No patients received adjuvant chemotherapy or radiotherapy. Pulmonary metastasis developed in one case (case 2)

seven years after the initial diagnosis. All of the tumors, including the pulmonary metastatic lesion in case 2, were ER/PR negative and did not express Her2. No synchronous/metachronous in-situ carcinoma, invasive ductal/lobular carcinoma, or microglandular adenosis was reported in any of the cases. Four patients without metastasis were alive and showed no evidence of disease for an average (follow-up) of 45.3 mo (range 12-90 mo). The last patient (case 2) who was diagnosed with pulmonary metastasis is alive with disease at 85 mo (one month after metastasis was detected).

## CONCLUSION

The correct classification of the histological special types of breast cancer is not just an academic exercise, as it has both prognostic and predictive implications. Although the majority of triple-negative, basal-like breast carcinomas are high-grade tumors, ACC is a subgroup of low-grade tumors with an indolent clinical behavior that also displays a triple-negative, basal-like phenotype. Because of its low incidence, there have been only few comprehensive studies of ACC of the breast, which is one of the major limitations of this review. However, this review of recent updates, including certain molecular genetic features in breast ACC, herein will hopefully serve as a prognostic and treatment guide for surgical pathologists, breast surgeons, and oncologists, and lead to the development of more specific, personalized therapies for this rare tumor subtype.

## Abstract

Targeted drug delivery to solid tumors is a very active research area, focusing mainly on improved drug formulation and associated best delivery methods/devices. Drug-targeting has the potential to greatly improve drug-delivery efficacy, reduce side effects, and lower the treatment costs. However, the vast majority of drug-targeting studies assume that the drug-particles are already at the target site or at least in its direct vicinity. In this review, drug-delivery methodologies, drug types and drug-delivery devices are discussed with examples in two major application areas: (1) inhaled drug-aerosol delivery into human lung-airways; and (2) intravascular drug-delivery for solid tumor targeting. The major problem addressed is how to deliver efficiently the drug-particles from the entry/infusion point to the target site. So far, most experimental results are based on animal studies. Concerning pulmonary drug delivery, the focus is on the pros and cons of three inhaler types, *i.e.*, pressurized metered dose inhaler, dry powder inhaler and nebulizer, in addition to drug-aerosol formulations. Computational fluid-particle dynamics techniques and the underlying methodology for a smart inhaler system are discussed as well. Concerning intravascular drug-delivery for solid tumor targeting, passive and active targeting are reviewed as well as direct drug-targeting, using optimal delivery of radioactive microspheres to liver tumors as an example. The review concludes with suggestions for future work, considereing both pulmonary drug targeting and direct drug delivery to solid tumors in the vascular system.

**Key words:** Targeted drug delivery; Pulmonary system; Vascular system; Types of drugs and delivery devices; Computational analysis and experimental evidence; Future work

**Core tip:** Targeted drug delivery to diseased areas or solid tumors has the great potential to significantly improve treatment efficacy, minimize side-effects, and reduce health-care cost. The major problem addressed is how to deliver efficiently the drug-particles from the entry/infusion point to the target site. Past and present developments in drug formulation and associated drug-delivery devices are discussed. Examples of optimal drug delivery to pulmonary target sites as well as targeting solid tumors in the vascular system are reviewed.

## INTRODUCTION

In light of the high cost of medicine and potentially devastating side-effects of drug treatment, targeted drug delivery is of great clinical significance. Thus, targeted drug delivery to solid tumors is a very active research area, focusing mainly on improved drug formulation and associated best delivery methods/devices. Drug-targeting has

the potential to greatly improve drug-delivery efficacy, reduce side effects, and lower treatment costs. However, the vast majority of drug-targeting studies assume that the drug-particles are already at the target site or at least in its direct vicinity.

In this review, drug-delivery methodologies, drug types and drug-delivery devices are discussed with examples in two major application areas: (1) inhaled drug-aerosol delivery into human lung-airways; and (2) intravascular drug-delivery for solid tumor targeting. The major problem addressed is how to deliver efficiently the drug-particles from the entry/infusion point to the target site. So far, most experimental results are based on animal studies.

Concerning pulmonary drug delivery, the focus is on the advantages and disadvantages of the three inhaler types, *i.e.*, pressurized metered dose, dry powder and nebulizer, in addition to drug-aerosol formulations. Computational fluid-particle dynamics techniques and the underlying methodology for a smart inhaler system (SIS) are discussed as well.

Concerning intravascular drug-delivery for solid tumor targeting, passive and active targeting are reviewed as well as direct drug-targeting, using optimal delivery of radioactive microspheres to liver tumors as an example.

The review concludes with future work for both pulmonary drug targeting and direct drug delivery to solid tumors in the vascular system.

## PULMONARY DRUG-TARGETING METHODLOGIES

Targeted drug delivery and controlled release are current challenges in pulmonary drug delivery. Three popular drug delivery ways are per oral (pill swallowing), intravenous (drug injection through the vein), and inhalation (breathing into the human lung).

Pulmonary drug delivery therapies, ranging from the treatment of asthma and chronic obstructive pulmonary diseases (COPD) to lung tumors and systemic diseases, have gained great interest in recent years. Advantages of pulmonary drug delivery, when compared with conventional medical treatments include, improvements in efficiency because of the large surface area of the lung (*i.e.*, 100 $m^2$) and the thin epithelial layer thickness (0.2 to 0.7 μm)[1], reduction of systemic drug levels with a decrease in adverse effects, and higher degree of convenience[2-4]. Specifically, as the drug aerosol directly travels to the designated target area, a much lower dose can be used to produce a therapeutic response with negligible side effects[5].

Pulmonary drug delivery therapies are widely used to treat inflammation, asthma, COPD and cystic fibrosis (CF) as well as diabetes and other systemic diseases. For proper treatment the aerodynamic diameters of drug particles/droplets are recommended to be in the range of $0.4 < d_p < 7$ μm[6,7]. However, due to the sophisticated pharmaceutical aerosol formulations and the complex anatomy and physiology of human lung airways, the optimization of pulmonary drug delivery (*e.g.*, drug-targeting delivery in lung airways) is challenging. The major research concern in pulmonary drug delivery is on the utilization of physical or chemical mechanisms, novel particles or drug carriers, and new drug-delivery device developments with improved performance.

In this section, three major classes of pulmonary drug delivery systems, *i.e.*, pressurized metered-dose inhaler (pMDI), dry powder inhaler (DPI) and nebulizer, are introduced and discussed, focusing on their delivery mechanisms, efficacies, and challenges for future developments. Furthermore, this section is also devoted to the foundation of lung-aerosol dynamics, *i.e.*, the transport and deposition of particulate drug carriers, which include the parameters affecting drug aerosol transport and deposition characteristics. It will be followed by a description of state-of-the-art methodologies for the realization of optimal pulmonary drug delivery.

### *Inhalers and drug-aerosol transport*

**Type of inhalers:** There is a rich history of the development of pulmonary drug delivery therapy[8]. Pulmonary drug delivery devices or inhalers are classified into three major types: pMDIs, DPI and nebulizers[3].

pMDIs are devices in which the mixture of drugs and propellants is stored in a canister from which accurate amounts can be released when the device is actuated by human power[3]. Thus, pMDIs provide a fast and cost-efficient solution to deliver pulmonary drug aerosols[9]. A pMDI expels the drug aerosol driven by propellants, such as chlorofluorocarbons (CFC) which, however, is being phased out due to environmental concerns. More recently, hydro fluoroalkanes propel the medicine through a nozzle at high velocities (> 30 m/s)[10]. The typical structure of a pMDI is shown in Figure 1, including canister, metering valve, actuator, and propellant. Detailed functions of each part were presented by Newman[11].

The advantages of pMDIs are: good portability, accurate dosage control, large capacity of medical doses at low cost[12]. Disadvantages of pMDIs include: highly dependent on the coordination of the patient's inhalation[3,13], limited to certain drugs that are physically and chemically inert in the mixture with the propellant, and not efficient to treat deeper lung conditions due to the strong impaction in the upper respiratory system induced by the high jet velocity[5]. For example, only approximately 10%-20% of the medications emitted from CFC-pMDIs are able to enter and deposit in the lung, while the rest deposits in the oropharynx[14]. Additionally, the deposition of the content of drug formulation inside the canister can result in an incorrect dose of medication delivery (en.wikipedia.org/wiki/Metered-dose_Inhaler).

To replace CFC and find a new propellant, hydrofluoroalkane was introduced[12] and approved. To resolve the synchronization problem between device actuation and patient's inhalation, breath-actuated MDIs were developed; for example, the Maxair Autohaler[15]. The devices actuate early during inspiration at an inspiratory flow rate

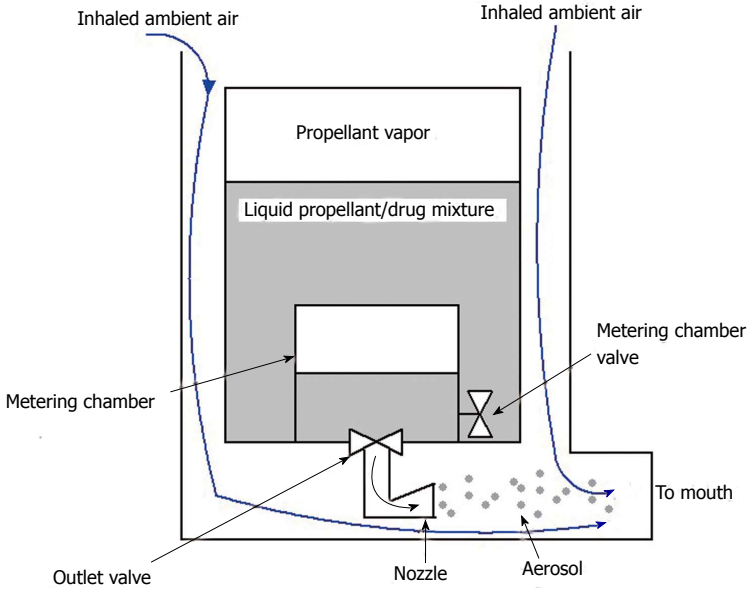

**Figure 1 Typical structure of pressurized metered-dose inhaler[23].** (Reprinted with permission from Ref.[23]).

of 30 L/min and are well accepted by patients[12,16]. It is announced that using breath-actuated inhalers might improve asthma control and reduce overall cost of asthma therapy compared with conventional pMDIs[12,17].

Furthermore, to improve efficacy of drug delivery and avoid synchronization difficulties between patient's inhalation and pMDI actuation, spacer devices have been introduced as an alternative method. The basic design of a spacer contains 3 parts: the open tube, the reservoir/holding chamber, and the reverse flow design in which the pMDI is fired in the direction away from the patient. A one-way valve is used to create a holding chamber after pMDI actuation. Holding chambers serve as particle size filter and produce a fine aerosol because of the stronger inertial impaction of drug-aerosol particles with larger size and particle evaporation of propellant within the chamber. Studies indicated that using a larger-volume (> 750 mL) holding chamber (also called spacer) can provide higher fine-particle doses than a pMDI alone[18]. However, spacers may decrease the portability of pMDIs.

DPIs are an alternative to pMDIs, delivering pulmonary drugs into the respiratory system in the form of dry solid particles[3]. The dispersion of a dry powder aerosol is conducted from a static powder bed. When the patient takes a breath, air is introduced into the powder bed which creates turbulent flow and leads to fluidization of a static powder blend, entering the patient's airways. DPIs contain medicine in a variety of types, *e.g.*, single-dose capsule-based designs, multi-dose units containing the drug in bulk, and multi-dose units containing individual blister packages[19,20]. DPIs can also be divided into two types in terms of its drive force, *i.e.*, a passive DPI dependent on patients' inhalation and an active DPI dependent on external forces[21,22]. Active DPIs have become a preferred method to uniformly distribute drugs independent of the inspiration flow. A typical structure of a unit-dose DPI is shown in Figure 2.

DPIs are small, portable and easy to use. Several advantages were discussed by Sahane *et al*[3]. For example, there is no need for coordination of actuation and inhalation, because the patient's inspiratory force de-aggregates the powder and generates the aerosol. Furthermore, DPIs are able to deliver higher drug payloads to the airways[20].

However, there are several disadvantages of DPIs. For example, if the therapeutic dose of a drug is high, the patient needs to manually reload several individual units per dose, as delivery is limited to a capsule-based or blister-based unit[19]. Also, DPI medications must be stored in a dry place at a temperature of not more than 25 ℃ and humidity between 40%-50% in sealed packages (en.wikipedia.org/wiki/Dry_Powder_Inhaler). Specifically, exposing the powder in a high-humidity environment destroy the medication dispersion ability of the device, implying that the efficacy of a DPI depends mainly on the flow properties of the powder suspension.

Nebulizers are breathing devices that generate droplets in small scales from a liquid in solution/suspension[12], which are used to treat lung diseases. The inhaled drug is in the form of mist aerosols. Nebulizers are often used in situations in which a conventional inhaler is ineffective. In simple targeting cases, nebulizers may limit side effects of certain medication, say, steroids, by delivering the drug directly to the desired site. Several conventional designs of nebulizers are shown in Figure 3.

Atomizers (or jet nebulizers)[23] are the most common ones (Figure 3A). They use compressed gas, or a compressor, to generate high-velocity air streams through a tight opening and across the fluid medication suspension to create particulate/droplet aerosols. The fluid is split up by the airstream and divided into droplets inside the nebulizing chamber. The primary advantage of jet nebulizers is the low operational expense. However, there is always the lack of portability because of the need of compressed gas[12].

Ultrasonic wave nebulizers generate aerosols *via* the vibration of a piezoelectric crystal at a high frequency (> 1 MHz) through the drug liquid (Figure 3B). Contrasted

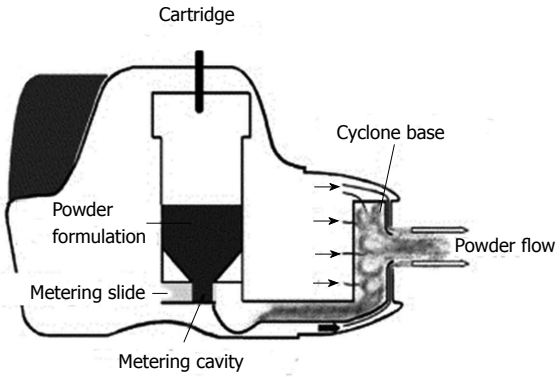

**Figure 2 Typical structure of unit-dose dry powder inhaler.**

with jet nebulizers, ultrasonic nebulizers work with lower noise and provide faster delivery of pharmaceuticals; although due to the complimentary heat generated during the operation, there are several medication restrictions for the ultrasonic wave nebulizers. With both types of nebulizers, the patient inhales vapor through a mouthpiece or face mask. Electronic nebulizers form a subcategory of ultrasonic nebulizers.

Based on the vibrating mesh technology (VMT), smaller portable devices have been developed as advanced nebulizers, *i.e.*, vibrating mesh nebulizers[24]. With the VMT, a mesh/membrane with multiple apertures vibrates at the top of the liquid reservoir (Figure 3C), generating drug aerosols consisting of small-scale droplets. Vibrating mesh nebulizers are claimed to have higher output efficiency, minimal residual volume, and high percentage of fine particulate drugs in the emitting stream[24].

Another type of new-generation nebulizers is called human-powered nebulizers which are breath-enhanced[25]. Their improved designs avoid exhaled loss and apparatus loss of aerosols. Ambient air is entrained through a one-way valve along with the power gas during inspiration, while during exhalation the one-way plastic flapper valve is closed.

As part of the developments of human-powered nebulizers, a dosimetric nebulizer is defined as one that releases aerosols only during inhalation, being the most efficient nebulizer generating aerosols. Comparisons of different types of nebulizers are presented in Table 1[12]. A variety of nebulizer products on the market are summarized in Table 2.

In addition to the three major classes of inhalers, new types of inhalers were designed in order to improve the efficacy. "Soft mist inhaler" is another type of drug delivery device[5,26]. It was developed in order to overcome the limitations of traditional inhaler devices and to meet the need for a convenient propellant-free inhaler[5]. For example, the Respimat® Soft Mist™ inhaler (SMI) utilizes the mechanical force from a spring instead of a fluid-gas propellant to produce a drug aerosol which is suitable for inhalation. The spring system inside the inhaler can guarantee that the aerosol is produced by a reliable and reproducible energy source. Thus, dosage and size distribution of the drug aerosols are insensitive to the inspiratory characteristics of the patient. Medicine delivered by the SMI is stored in a collapsible bag in a sealed plastic container inside the cartridge. With each actuation, the correct dose is drawn from the reservoir and the flexible bag contracts, which is launched by the spring[27]. A recent papers[28] also claimed that SMI can avoid the coordination difficulty between inhalation and actuation. Also, the emitted stream velocity of the aerosol is much slower than that of a pMDI. Theoretically, with the SMI aerosol transport to deeper lung airways is easier due to lower inertial impaction in the upper respiratory system, so that the resulting deposition fraction can reach 40% for adults[19]. However, besides the advantages of SMI, such a device is relatively expensive. Other SMI designs include AERx, and AERx Essence platform (Aradigm, Hayward, California)[29].

**Table 1 Comparisons of conventional categories of nebulizers**

| | Jet | Ultrasonic | Vibrating mesh |
|---|---|---|---|
| Features | | | |
| Power source | Compressed gas or electrical mains | Electrical mains | Batteries or electrical mains |
| Portability | Restricted | Restricted | Portable |
| Treatment time | Long | Intermediate | Short |
| Output rate | Low | Higher | Highest |
| Residual volume | 0.8-2.0 mL | Variable but low | < 0.2 mL |
| Environmental contamination | | | |
| Continuous use | High | High | High |
| Breath-activated | Low | Low | Low |
| Performance variability | High | Intermediate | Low |
| Formulation characteristics | | | |
| Temperature | Decreases | Increases | Minimum change |
| Concentration | Increases | Variables | Minimum change |
| Suspensions | Low efficiency | Poor efficiency | Variable efficiency |
| Denaturation | Possible | Probable | Possible |
| Cleaning | Required, after single use | Required, after multiple use | Required, after single use |
| Cost | Very low | High | High |

MDIs and DPIs are both portable and fast delivering devices for low medication dosages. Another characteristics of both device types is that the aerosol generator and the medication are not detachable. In contrast, nebulizers are able to deliver high medication dosages, and a single device can be used with different drugs[30].

Compared to pMDIs and DPIs, another advantage of using nebulizers for drug inhalation is that no special inhalation techniques are required[12]. However, due to the need of compressed gas or a compressor to operate, conventional nebulizers are generally not portable. Additionally, the drug-delivery efficacy and treatment time using conventional nebulizers are much lower and longer than those for pMDIs and DPIs[31]. However, presently there appears to be a tendency among physicians to prefer to prescribe a pMDI rather than a jet nebulizer which produces more noise and is less portability.

Comparative efficacy of different pulmonary drug delivery devices has been performed by different research groups. Chou *et al*[32] concluded that MDIs can give a

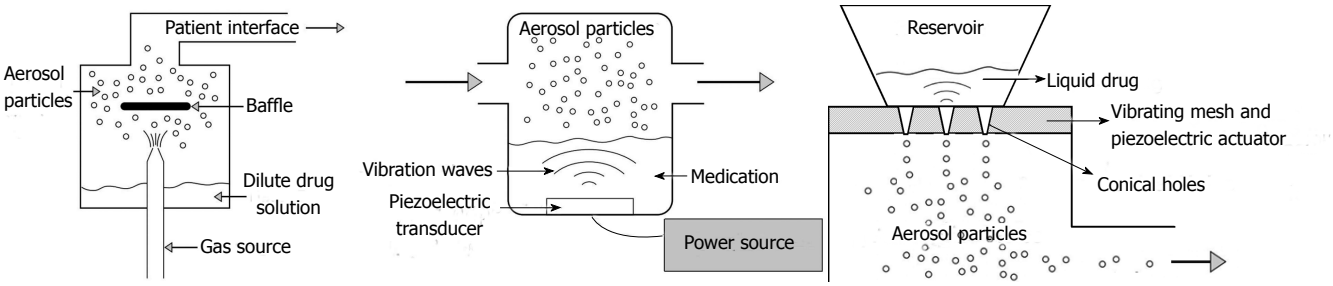

**Figure 3 Typical structures of different nebulizer categories. (Reprinted with permission from Ref.[117].** A: Atomizer (jet nebulizer); B: Ultrasonic wave nebulizer; C: Vibrating mesh nebulizer.

**Table 2 Advantages and disadvantages of different nebulizer products**

| Product name | Type | Pros | Cons |
|---|---|---|---|
| PARI Vios® | Jet nebulizer | Low operational cost, robust in structure, effective in nebulizing suspensions | Relatively bigger in size and heavier in weight; more noisy |
| Omron MicroAir® | Electronic nebulizer | Does not heat the medicine, quiet and fast drug delivery | Comparatively expensive; |
| Omron NE-U17®, Beurer Nebulizer IH30® | Ultrasonic nebulizer | Silent and portable | replaced much more frequently |
| Omron NE-U22V®, Pari E-Flow® | Vibrating mesh nebulizer | Higher output efficiency, minimal residual volume, and High percentage of particles in the emission, small in size | Less efficient in nebulizing aerosols |
| Pari LCD® | Breathe-enhanced nebulizers | Higher output efficiency avoiding apparatus loss and exhaled loss | N/A |
| AeroEclipse® | Dosimetric nebulizer | Higher output efficiency avoiding apparatus loss and exhaled loss | N/A |

faster and more economical approach to deliver bronchodilator drug aerosols for asthma treatment in elder children and adults. A similar conclusion was reported by Batra *et al*[33] for the aerosolized salbutamol in an acute exacerbation of asthma in children. Delgado *et al*[9] investigated nebulizers *vs* MDI with spacers for bronchodilator therapy to treat wheezing in children aged 2 to 24 mo. They drew the conclusion that although younger patients are often unable to coordinate inspiration with activation of the MDI, thereby limiting the effective amount of drug inhaled, MDI with spacers may be as efficacious as nebulizers for the emergency department treatment of wheezing in children aged two years or younger. Dhuper *et al*[34] claimed that using a MDI with a spacer may result in a marked reduction in time and effort, thereby saving the total cost for treatment compared with conventional nebulizers.

While the optimization of treatment using MDIs requires coordination between inspiration and actuation, which is difficult to achieve by patients[13], most DPIs generate and deliver drug aerosols depending on subject-specific inhalation efforts. Indeed, the dose delivered by DPIs is more related to the inspiratory flow rate than by the device[35]. Specifically, MDIs are able to generate more consistent aerosol sizes across a range of inspiratory flow rates. In contrast, the aerosol-size distributions produced by DPIs are reported to be highly dependent on the inhalation patterns, with some being showing more sensitive than others[36].

Not surprising, all drug delivery devices have advantages and limitations. Device selection must consider portability, convenience level for users, therapeutic efficacy as well as low cost and high safety[12]. As mentioned, the therapeutic efficacy is determined by many factors, *i.e.*, the kind of medication used, the aerosol's physical and chemical properties, as well as the patient's inhalation patterns and the physiology of their respiratory systems[30].

The efficacy enhancement of drug delivery devices can be achieved through two major strategies: (1) improved drug formulation; and (2) improved device structure design. The primary goal is to control the agglomeration of drug aerosols inside devices to reduce drug residues in the device, thereby enhancing the efficacy.

**Drug formulation:** The physical and chemical properties (*e.g.*, particle size distribution, shape, surface charge, hygroscopicity, *etc.*) of drug-particles are most important. Usually, drug formulations, including drug-carrier selections, are able to lower inhaler retention and improve transport, the proportion of drugs that reach the desired lung site, and the stability of the drug *in vivo*. Sufficiently strong attractions between carrier and drug must be guaranteed for maintaining the stability of the medication mixture. However, the attractions between carrier and drug must also be sufficiently weak so that the release of the medication from the carrier will not be impeded inside the human respiratory system[3]. Sahane *et al*[3] also discussed the formulation of drugs for DPIs. For example, DPIs are formulated using four types of formulation strategies: Carrier Free, Drug Carrier, Drug Additive, Drug Carrier Additive. Specifically, therapeutic dry powders for inhalation are often composed of fine drug particles and inert coarse carrier particles such as lactose[37].

Sufficient detachment of the drug from its carrier must be guaranteed to improve the delivery efficiency. Improved formulation should reduce the particle-particle interacting forces which are the major cause of the agglomeration between drugs and carriers. Furthermore, adding preservatives and mixing it with other drugs will also influence device output and aerosol characteristics in a good way[38]. Formulations for pMDIs are also necessary. For example, mast cell stabilizers such as cromoglicate or nedocromil are used to extend the duration of the device[11]. In the recent decade, non-hygroscopic mannitol exhibits particularly great promise as an attractive carrier in DPI systems to replace lactose[37,39]. Additionally, it is necessary to minimize the adhesion intensity between the drug particle and the inner wall of the inhalers by using surface treatment to reduce inhaler retention and enhance the drug delivery efficacy[40].

**Device structure:** Device structures can have a strong impact on the velocity field inside the device, thereby influencing the drug suspension characteristics. For example, the design of the actuator plays an important role in the delivered spray characteristics generated by pMDIs[11]. Specifically, the design variables of the actuator are expansion chamber size and shape, nozzle diameter, nozzle path length, mouthpiece length and shape, breath-actuation, spray velocity modification, and spacer attachment[19,41]. For nebulizers, the chamber design using a one-way valve is important to decrease aerosol waste during exhalation[27]. Also, the mouthpiece design is essential to lower the percentage of drugs remaining in the device. For example, increasing the cross-sectional area of the mouthpiece section will decrease the emitting velocity of the drug aerosol thereby lowering the extent of drug deposition in the oral cavity due to the inertial impaction effect[42]. Other factors related to structure which will influence the device performance are flow path design and manufacturing design[7].

The patient's inhalation behavior, in light of the correct utilization of a drug delivery device, is likewise essential for successful therapy. Specifically, it needs to be guaranteed that a patient can easily use the device correctly and properly thereby optimizing the therapeutic efficacy[27]. Therefore, the ideal design of drug delivery devices should include the following characteristics[11,22]: (1) attractive in appearance, easy to use, and easy to carry; (2) accurate and uniform delivery of medication over a variety of patient's inhalation intensities; (3) reliable qualitative drug delivery control throughout the life of the inhaler; and (4) low cost with high efficacy.

Traditionally, the biotechnology and pharmaceutical industries preferred jet nebulizers for novel medication development, considering their capabilities to deliver higher doses of drugs and the lower research and development expenses than other types of devices[19]. However, recently many companies have recognized the long time duration at each treatment experienced by patients. Therefore, to handle that issue they have been starting preclinical development with novel devices based on more efficient and advanced drug delivery technologies.

In the previous two decades, a few innovative inhaler designs have been developed, providing more efficient drug aerosol delivery[12]. New designs and new improvements were presented in several papers[11,12,19,20,43-46]. For example, the improvement of pMDIs is mainly focusing on providing more precise targeting, dose metering, and easy actuation. Related new products are listed by Dolovich *et al*[12]. For new designs of the major three classes of inhalers, Zhang *et al*[20] proposed novel active and multi-dose dry powder inhalers which are able to utilize the compressed air to deliver a small quantity of extra fine particles with high delivery efficacy. A new design for a nebulizer with flow meter function was proposed by Addington *et al*[46]. By changing DPI device structure and drug formulation, Behara *et al*[47] proposed a design option of a DPI which controls the aerosol diameters and increases the emitted drug dose.

**Drug-aerosol dynamics**: Liquid and solid micro/nano-particulate matter (*i.e.*, solid particles and droplets) and vapors are generated by drug delivery devices for therapeutic purposes. The objective of targeting is to guide and deliver drugs from their releasing position to expected deposition regions in the human respiratory system to optimize the medical effectiveness[48]. The fluid-particle dynamics during drug-aerosol transport, deposition, absorption, and clearance are essential for guiding the optimization technique of drug delivery. Specifically, "targeting" can be categorized into three levels[1]: (1) delivery to a specific lung region, *i.e.*, central or peripheral, right or left; (2) delivery to the site of disease; and (3) delivery to distinct cell types with biological barrier transport, *e.g.*, epithelial cells, or cells of the lung associated lymphatic tissue. Traditional targeting activities can be also grouped into passive and active targeting[49].

As discussed in the previous sections, great progress has been made in drug aerosol formulation for better drug-aerosol delivery efficiency, as well as controlling drug aerosol transport before deposition in lung airways. However, it is also necessary to understand the absorption and systemic transport of drug aerosols after the deposition at the air-blood barriers, which has been rarely investigated. In this section, underlying principles for drug-aerosol transport and deposition in human respiratory systems are discussed to provide valuable insight into certain aspects for optimal pulmonary drug-targeting.

Physical and chemical factors which can affect the transport and deposition of drug-aerosols include: initial particle size, shape, density, concentration, as well as release position and velocity; furthermore, the drug-aerosol formulation (*i.e.*, hygroscopicity, charge and surfactant) as well as the geometric characteristics of the patient-specific respiratory system are important[6,41,48].

The underlying principles to describe the complex and coupled fluid-aerosol dynamics inside the human respiratory systems are the physical conservation laws, using the Eulerian or Lagrangian modeling approach. Specifically, the Eulerian approach can be employed to calculate continuity, momentum and energy equations

for the continuous airflow phase, while both Eulerian and Lagrange approaches can be used for the discrete drug aerosol phases[6,48]. Supplementary equations may be necessary for the description of complex mechanisms, *e.g.*, evaporation or condensation of aerosol droplets[50], magnetic-force driven drug-targeting delivery[51], rotational motion of non-spherical particles[52], *etc.* Several computational fluid-particle dynamics (CF-PD) models are available for the calculation of air-drug mixture dynamics[53], such as the discrete phase model (DPM), two-fluid model, mixture model, dense dispersed phase model (DDPM), and the discrete element method (DEM).

The deposition mechanisms of aerosol particles or droplets - impaction, sedimentation, diffusion and combinations in the respiratory tract - have been extensively discussed[6,48,54]. Specifically, for microparticles, the deposition may occur due to: (1) secondary airflow (laminar or turbulent) induced wall impaction; (2) inertial wall impaction; (3) gravity induced sedimentation; (4) particle-particle interaction induced wall impaction; and/or (5) diffusion. For nanoparticles, diffusion, caused by Brownian motion, may become most significant.

Other than treating local diseases in the respiratory system, pulmonary drug delivery is also promising for systemic drug delivery which is intended to utilize the alveolar region to swiftly absorb drug aerosols. However, the processes that take place after an aerosol particle has landed on the pulmonary epithelial surfaces, *i.e.*, the dissolution, absorption, mucociliary clearance, and systemic translocation, still lack information[55]. Using complex pharmacokinetic modeling will be helpful in understanding the absorption process through the lung epithelium, including parcellular transport and transcellular transport. Considering numerical modeling of this process, mass transfer advection-diffusion equations can be employed with proper boundary conditions[56]. Furthermore, systemic drug transport can be modeled using multi-compartment mass transfer models for drug-aerosol migration into the mucus-tissue-blood system[57,58]. Factors affecting drug absorption are physiochemical properties of drug aerosol particles (*e.g.*, hydrophobicity), co-administration conditions, lung pathophysiology, *etc.*[55].

With decreasing computational limitations and the advancements in commercial CFD software development, more realistic numerical models are becoming available for the simulation of dense particle suspensions as well as droplets with heat and mass transfer. Those models can be used for the design of drug delivery devices[59]. Although experiments can provide some information about the airflow field of the drug delivery device[60], using CFD-techniques provide more detailed information when compared to experiments. Specifically, computer simulation models require initial and boundary conditions as well as the geometry of the flow domain of the device. Once fully validated, they are cost-effective tools to analyze factors influencing the performance of drug delivery devices, *e.g.*, turbulence in the inhaler, spray momentum and inlet jet effects, as well as best possible geometric design and operation.

Originally, CFD was only utilized for airflow field analysis of the drug inhalers[61,62]. With the development of numerical multiphase flow methods, simulation techniques were used for the design and analysis. For example, Kleinstreuer *et al*[63] numerically investigated the transport and deposition of drug droplet aerosols from a pMDI into a model of the human respiratory system. The parametric analyses with different propellants, nozzle diameters, and releasing positions were presented. Based on the numerical results, they found that using a smaller nozzle provides a better atomization effect and finer droplets with more uniform dispersion.

Recently, based on the numerical model established by Worth Longest *et al*[64,65], Longest *et al*[13] investigated different aerosol deposition in human lung airways between a specific MDI and DPI. Fluent 12.0 with user-defined functions (UDFs) was employed for the Euler-Lagrange numerical simulations. They claimed that for the specific inhaler models they investigated, MDI is able to deliver significantly more drugs to the tracheobronchial region when compare to DPI. It is worth mentioning that they did not consider any particle-particle interaction effects. Jiang *et al*[66] investigated the design impact on a commercial DPI using the LRN $\kappa$-$\omega$ model in ANSYS Fluent 6.2.16. However, they did not simulate powder transport and subsequent deposition by using any multiphase flow model. Based on CFD analysis, Longest *et al*[67] evaluated associations between aerodynamic parameters and DPI performance for a carrier-free formulation, forming micron/submicron-scale drug aerosols. Factors which may influence the dispersion of aerosol particles were discussed.

With the development of computational fluid dynamics-discrete element method (CFD-DEM), the discrete element method is a robust and computational economic model to simulate the highly dynamic process (*i.e.*, particle-particle interaction) for dense powder dispersions in inhalers[68]. Inhaler developments based on CFD-DEM simulations have been focused on pharmaceutical agglomerate break-up in DPIs[59]. For example, Tong *et al*[68,69] recently employed ANSYS Fluent with in-house UDFs, describing powder dispersion in a commercial Aerolizer® Inhaler model. They also investigated the factors influencing the performance of the inhaler based on their numerical simulation results. They found that at low flow velocities, agglomerates consisting of particulate matters with smaller diameters were more difficult to disperse. They also claimed that the dispersion efficiency is proportional to the ratio of the particle impact energy and particle-particle cohesion energy.

In summary, it is promising to use CFD-DEM or DDPM-DEM for the simulation of dense drug-powder suspensions in pMDIs and DPIs, because of the DEM capability of taking into account the particle-particle contact interaction as well as the computational economy aspect. CF-PD models can also provide guidance for drug delivery and hence enhancing methodology developments which are discussed in Section 2.2. For a recent review see Ruzycki *et al*[70].

### *Design and strategies for direct drug-targeting*

Existing drug aerosol delivery devices, including those that attempt to target specific areas in the lung, exhibit poor efficiencies (*e.g.*, from 5% to 20%). Efforts are being made to improve direct drug delivery through the pulmonary route. The goal is to provide high doses of drugs to lung tumor tissue *via* inhalation, resulting in treatment efficiencies and low adverse side effects.

**Smart inhaler system methodology:** Kleinstreuer *et al*[63] analyzed computationally the performance of pMDIs with and without spacers and compared their deposition efficiencies with that of a smart inhaler system (US Patent 7900625 issued 03/08/2011) based on a new optimal targeting methodology[71]. A novel smart inhaler system (SIS), which achieves up to 85% drug-aerosol deposition efficiency, is being prototyped and experimentally tested. The SIS is a device for directed aerosol delivery to predetermined lung sites, facilitated by an adaptive nozzle and a mechanism for inhalation waveform modulation. The aerosol particles are released through a nozzle which incorporates lightweight, multifunctional shape memory materials that allows to move the nozzle's optimal radial position based on subject-specific numerical data. The SIS is promising to notably improve the aerosol delivery efficiency to specific locations through pulmonary routes, thereby reducing unwanted deposition in healthy lung airways.

**Enhanced deeper lung delivery of nano- and micro-pharmaceutical aerosols *via* condensational growth:** Drug aerosol losses occur because of high deposition in the nasal passages or in the oral cavity due to impaction. To enhance drug-aerosol delivery into deeper lung airways, enhanced condensational growth (ECG) and excipient enhanced growth (EEG) methods have been proposed and validated by experiments *in vitro*[13,72-74]. Based on the fact that the larger mass mean aerodynamic diameter of drug aerosols indicates strong impacting, deposition of particles before entering the trachea as well as most submicron particles inhaled will be exhaled without depositing in the lung airways. Thus one can utilize the high relative humidity of the ambient air or inside the human respiratory system to control the trajectories and depositing sites of the particles in human pulmonary routes, relying on different condensational growth rates of such sub-micron aerosols of different formulations. Specifically, submicron particles are emitted from the inhalers which are able to initially penetrate through the oral or nasal cavity, thereby reducing the deposition before entering the trachea. With the condensation effect, those particles will grow in size and most of them will deposit in deeper lung airways. For ECG, the sub-micron aerosols are inhaled with highly humidified air at a temperature higher than that of the human body. The droplets will grow due to the condensation of surrounding water vapors when they enter the human respiratory system[72]. For EEG, hygroscopic excipients are formulated with the drug and the formulated drug aerosol will absorb water inside the human respiratory system. Although these methods result in higher pulmonary deposition, they are not able to provide location-specific delivery (see Level 2).

**Magnetic nanoparticles for site-specific pulmonary drug delivery**: Another active targeting strategy is magnetic targeting, which can be realized by combining magnetic nanoparticles (*i.e.*, γ-$Fe_2O_3$ and $Fe_3O_4$) with micron particles or droplets[51,75-79]. These types of particles are also called magnetic nano-in-microparticles (NIMs). An external magnetic field will be enforced to guide drug aerosols to specific regions of the lung (Figure 4), thereby reducing undesired side effects, *e.g.*, mitigating deposition on healthy lung tissues. To succeed in direct drug delivery, those magnetic nanoparticles should have characteristics such as mono-dispersity, superparamagnetism, stability and biocompatibility[80].

However, further translation of magnetic nanoparticles may cause potential health problems and need further clinical investigations. The long-term effects of magnetic nanoparticles need to be studied as well[77]. For example, concerns associated with long-term tissue damage, toxicity, carcinogenesis, immunogenicity, and inflammation need to be investigated to improve the production of magnetic nanoparticles[81].

**Shape engineering for novel drug carriers**: For pulmonary drug delivery, the deposition pattern and clearance from deposition sites are two key parameters for a proper design of drug-delivery carriers[82]. For example the particle shape of drug carriers has a profound impact on optimizing performance of drug delivery. Compared to spherical particles, numerical studies have shown that fiber-like particles are more likely to reach the deeper lung airways[52,83]. Also, fiber-like carriers have better internalization abilities than spherical particles for drug delivery[84]. This finding demonstrates that when targeting drugs into deeper lung airways, fiber-like drug carriers may perform more efficiently than spherical ones. A recent study demonstrated that using elongated fine mannitol particles enhance the aerosolization performance of inhalable drugs which may improve the efficiency of drug delivery from the devices[37,85]. It is promising to explore the shape as an important parameter for improved drug delivery performance.

**Multifunctional Nanoparticles**: Today, the size of drug aerosol particles can be reduced from tens of micrometers to tens of nanometers (*i.e.*, less than 100 nm in size), which is a significant technological and medical breakthrough. Drug-delivery systems for nanoparticles have been developed which can potentially enhance the efficacy and reduce side effects for a wide range of drugs. Due to the small inertia of nanoparticles, they can avoid impacting the oral cavity when being inhaled, and hence they are transported deeper into human lung airways. Those nanoparticles with diameters around 50 nm have been reported to be most efficiently internalized by cells[86]. The design of multifunctional nanoparticles for treatment of pulmonary diseases (*i.e.*, lung cancer) is also

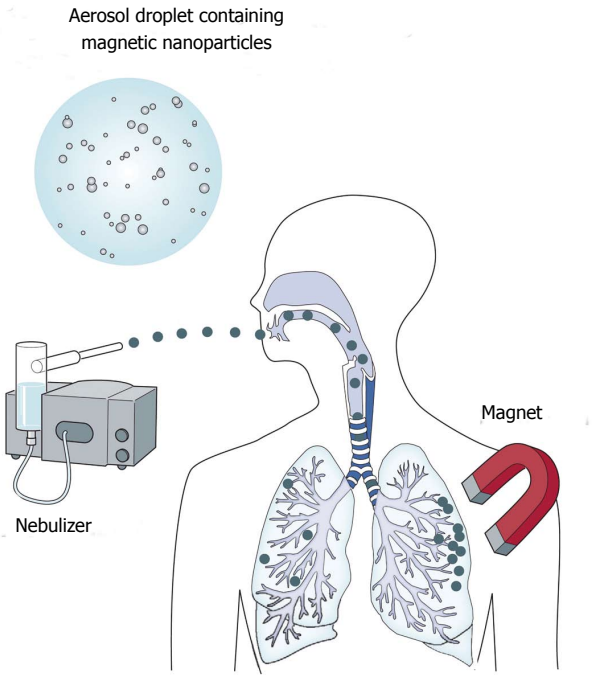

**Figure 4 Targeted deliveries of magnetic aerosol particles.** (Reprinted from Ref.[12], with permission from Elsevier).

a promising methodology. Additional functionality such as image contrast enhancement can be realized by adding other constituents into multifunctional nanoparticles, thereby assisting better drug-targeting control. Multifunctional nanoparticles can be designed for detecting infected cells, and delivering drugs specifically to those cells, and leaving healthy organs and lung cells unaffected[87]. Multifunctional nanoparticles can also deliver multiple therapeutic agents in a single formulation[49]. A multifunctional nanoparticle consists of a surface coating, imaging agent for detection, and therapeutic drugs. The aims of multifunctional nanoparticles are[49]: (1) enable specific targeting and aid in uptake realized by surface modification; (2) avoid fast endothelial system clearance *via* surface coating technology[88], and thereby extending circulation time and enhance uptake; and (3) load higher concentrations of multiple remedial agents that can override multidrug resistance and result in therapeutic effects.

However, more work is needed to understand the fate of nanoparticles after inhalation, including interactions with biological cells and nano-toxicity. Also, in a recent review article, Cheng *et al*[89] discussed the costs and regulatory hurdles for using multifunctional nanoparticles *vs* their potential benefits.

## INTRAVASCULAR DRUG-TARGETING METHODOLOGIES FOR SOLID TUMORS

In addition to drug-targeting in the pulmonary system, much focus has been placed on treating unresectable tumors *via* intravascular therapies. These therapies involve either systemic or local, intra-arterial delivery of therapeutic agents such as chemotherapeutic drugs, multifunctional nanoparticles (NPs), radioactive microspheres, or embolic agents. While micron-sized agents must be delivered locally due to their embolic potential, this local drug administration is also beneficial for delivering higher therapeutic concentrations to cancer cells.

Intra-arterial delivery is often achieved using a locally placed drug-infusion catheter. However, due to the often tortuous and small size of the complex arterial systems leading to tumors, it is difficult or impossible to manually position this catheter directly in tumor-supplying arteries. As a result, therapeutic agents can still deposit in healthy tissue and/or travel to other organs. Thus, techniques are needed to better target predetermined cancer sites from upstream. Some existing methods include passive and active targeting for multifunctional nanoparticles as well as magnetic drug targeting. As will be discussed in the next sections, the shortcomings of these methods are that the nanoparticles must be very close to the tumor for passive and active targeting to be effective, and the magnetic particles must be near the body's surface and in slow blood-flow systems for magnetic drug targeting to be successful. As a result, a direct drug-targeting strategy has been proposed which uses knowledge of the patient-specific, local blood flow field to precisely position a smart microcatheter radially and deliver the therapeutic agents to the tumor directly. Current research is focused on developing and testing such a device.

### *Passive and active targeting*

Being less than 1 μm in at least one dimension, multifunctional nanoparticles can more readily extravasate through tumor vessels and attach to cancer cells with the help of passive and active targeting. Specifically, passive targeting takes advantage of the leaky walls and poor lymphatic drainage of many tumor vessels. This allows NPs to more readily enter the tumor interstitium and linger for extended periods (*i.e.*, the enhanced permeability and retention effect)[90-100]. Active targeting can then enhance tumor accumulation through ligand-receptor binding which is achieved by incorporating ligands on the drug's surface to selectively attach to over-expressed antigens or receptors on tumor cells[101,102]. This targeting can also enhance therapeutic efficacy through receptor-mediated endocytosis.

The limitation of these passive/active-targeting events is that the NPs must come in close proximity to the tumors for both strategies to be effective. Thus, the NPs' size, shape, surface properties, and targeting ligands have been modified in attempts to lengthen their circulation time and increase site specific accumulation[91,103-105]. For example, drug-loaded nanoparticles are often coated with polyethylene glycol to minimize the attraction of proteins which trigger immunogenic responses leading to system clearance. However, while such characteristics are beneficial for prolonging the NPs circulation time, they can also be detrimental once the NPs are near the tumor cells due to their resistance to endocytosis. Thus, the possibility of dynamically altering these characteristics *in vivo* is currently being investigated[106]. Such functionality has

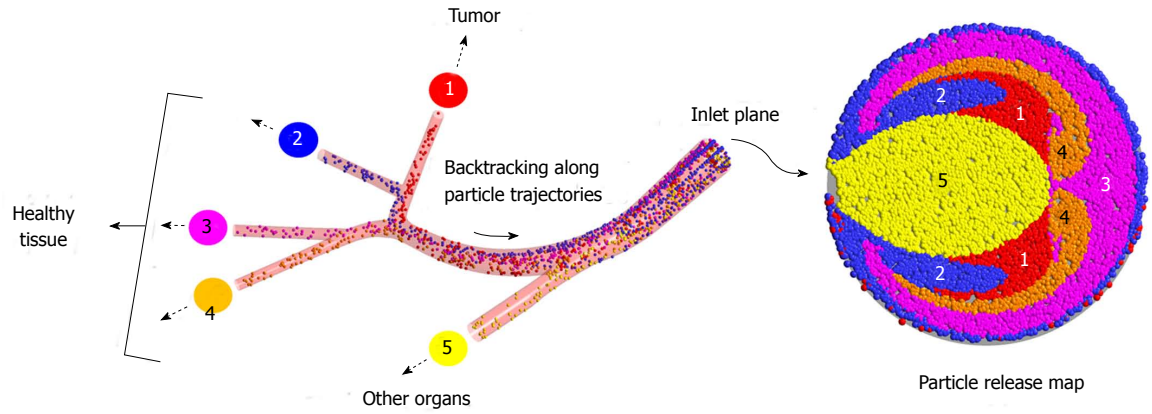

**Figure 5 Illustration of the direct tumor-targeting methodology.** (Reprinted from Ref.[115], with permission from Springer).

been achieved by taking advantage of the different pH, temperature, and enzyme levels in and around tumors. Despite these efforts, NPs still face filtration by non-target organs or clearance by the immune system before reaching the tumor[91,103-105,107].

### *Magnetic drug targeting*

Magnetic drug targeting is one technique for increasing NP accumulation at solid tumors. In this method, drugs are bound to magnetic nanoparticles, and an external magnetic field is applied to attract the particles to a target site. Several studies have demonstrated the feasibility of this approach through computational and animal studies, and a few have demonstrated this targeting in human trials. Recently, studies have focused on obtaining a better understanding of the parameters which affect magnetic targeting success. For example, Kayal *et al*[108] experimentally and computationally analyzed the effects of the flow, magnet, nanoparticle properties, and injection site on deposition efficiency. As expected, they found that the efficiency was lower for increased flow rates, lower magnetic field strength, and smaller NPs. These, and other studies, demonstrate that the current applications are limited due to restrictions on the particle size and magnetic field strength. Specifically, this technique is only applicable when the tumor is located near the body surface and the flow rate is small. To overcome this, implant-assisted magnetic drug targeting has been proposed in which a magnetic implant is inserted near the target site to increase the magnetic field gradient in deep tissue[109]. However, this technique is still not likely to resolve the downstream tumor-targeting problem because it may not be feasible to place these implants as near to the tumor as necessary.

### *Direct drug-targeting*

As an alternative to the current strategies, a novel direct tumor-targeting methodology has been proposed. In this technique, the catheter position (*i.e.*, radial position in the arterial particle-injection plane), infusion speed, and injection timing are precisely controlled so that the injected drug-loaded particles are carried by the blood flow directly to the target site[110]. While previous work has demonstrated that the particle infusion speed should be relatively equal to the surrounding blood flow[111,112], the remaining conditions are determined by computational simulations which mimic the targeted arterial system. Specifically, a vast amount of particles are infused over the selected injection position of the truncated arterial system, and their transport is modeled through the system. By backtracking along the particle trajectories (as indicated in Figure 5), a patient-specific particle release map (PRM) can be generated, which visually links particle injection regions with associated exit branches, some potentially connected to tumors. Such PRMs can then be used to determine radial micro-catheter positions to achieve optimal targeting. For example, in the scenario given in Figure 5, the catheter should be placed in the red zone (zone 1) of the PRM while avoiding the remaining zones. By generating multiple PRMs at subsequent intervals throughout the cardiac cycle, the best injection interval can also be determined[113].

**The computational medical management program:** The Computational Medical Management Program has been proposed to implement this targeting methodology into clinical practice. As illustrated in Figure 6, there are three basic stages in this program: (1) the patient evaluation stage; (2) the computer modeling stage; and (3) the clinical implementation stage.

As in current intra-arterial procedures, the patient evaluation stage includes classification of the tumor and determination of the best treatment route. In the proposed procedure, the patient's geometry and flow conditions are also collected in this stage. In the next stage, computational case studies are run in the truncated geometry to determine the best injection region and interval for targeting as well as the appropriate time to terminate injection. In the final stage, optimal catheter positioning and injection is achieved using the proposed Smart Micro-Catheter (SMC) and Medicine Supply Apparatus (MSA). As in current procedures, success of the treatment is then evaluated.

**SMC system for optimal drug-delivery:** As introduced in the previous section, a SMC and MSA have been

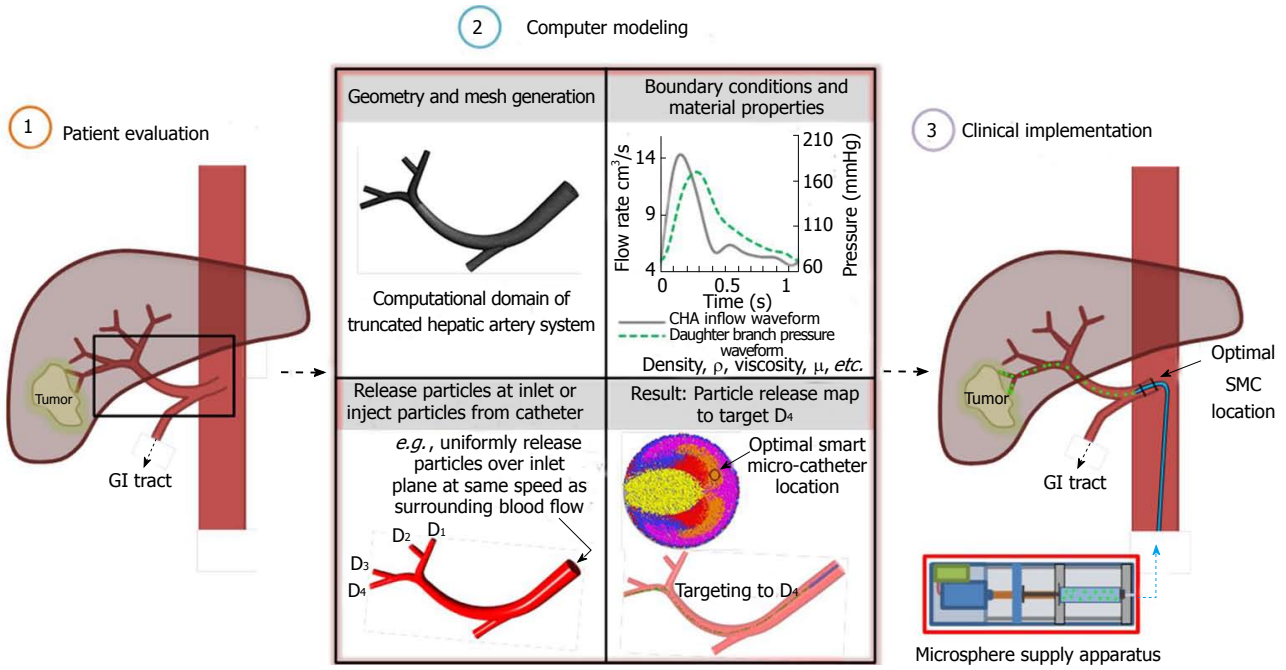

**Figure 6 Computational medical management program. SMC:** Smart micro-catheter.

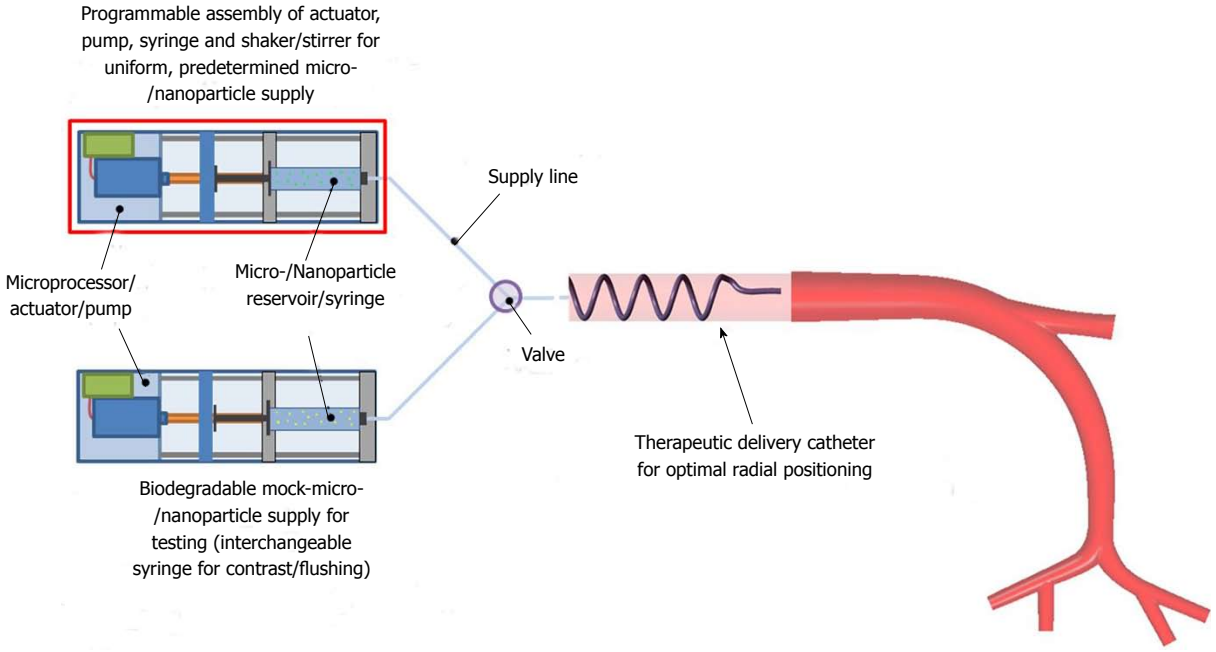

**Figure 7 Proposed components of the medicine supply apparatus.** (Reprinted from Ref.[118] with permission from Elsevier).

proposed to achieve direct tumor-targeting. The main objective of the SMC is to provide precise intra-arterial positioning of the particle injection stream, while the main objective of the MSA is to supply the particle stream to the SMC at the appropriate interval and speed for targeting. Figure 7 illustrates sample concepts for each device.

**Experimental and computational studies:** As an initial validation of this direct tumor-targeting strategy, Richards *et al*[114] performed experimental studies in a scaled-up, rigid hepatic artery system with steady Newtonian-fluid flow. Using the generated particle release map from the corresponding computational simulation, it was demonstrated that specific downstream arteries could be targeted by precisely positioning the particle injection region upstream. While additional computational studies have demonstrated the feasibility of this technique under more realistic conditions such as transient pulsatile flow, a patient-specific geometry, and flexible arterial walls[111-113,115], future experimental studies will need to verify these findings.

## CONCLUSION

In this review article, we compared and discussed different drug-delivery devices and drug-targeting methodologies using pulmonary or intravascular routes, as well as related computational fluid dynamics techniques and applications. Drug-targeting has the potential to greatly enhance drug-delivery efficacy, reduce side effects, and lower treatment cost. However, the vast majority of drug-targeting studies assume that the drug-particles are already at the target site or at least in its direct vicinity.

In this review, drug-delivery methodologies, drug types and drug-delivery devices are discussed with examples in two major application areas: (1) inhaled drug-aerosol delivery into human lung-airways; and (2) intravascular drug-delivery for solid tumor targeting. The major problem addressed is how to deliver efficiently the drug-particles from the entry/infusion point to the target site. Experimental results so far are based on simple laboratory studies and restrictive animal tests. Concerning computational fluid-particle dynamics, further advancements in software and hardware are needed to develop faster, more realistic and accurate computer simulation models.

### *Pulmonary drug targeting*

As mentioned, the selection of drug delivery device and drug aerosol formulation has a critical influence on pulmonary drug-targeting efficiency. To further optimize the pulmonary drug-delivery process and provide more effective therapy, the focus should be on the following aspects: (1) control the aerosol generation process[116]; (2) control the aerosol deposition patterns in lung airways; and (3) control the aerosol transport after penetrating the air-blood barriers. Specifically, due to the scarcity of air-blood barrier transport of drug aerosols *via* the lung route, it is of interest that to know to what extent drug-aerosols can be absorbed or cleared. That will affect the systemic drug delivery effectiveness, including modulation of solubility in the airway-surface layers and the permeability across the epithelial barrier to improve pulmonary bio-availability of the active pharmaceutical ingredients. It should also control the clearance process to prolong the action of the active pharmaceutical ingredients.

### *Solid-tumor targeting*

It is evident that the micron- or nano-drugs have to be delivered directly from the infusion point to the pre-determined tumor site to guarantee high treatment efficiency, minimal side-effects, and low cost. Such a direct drug delivery equates to optimal tumor targeting. Concerning the promising smart micro-catheter system, *i.e.*, a combined and synchronized SMC and MSA assembly, SMC-device miniaturization and system testing in the lab and clinical environment are ongoing and planned projects.

## Abstract

In the current socio-economic scenario characterized by a growing shortage of resources and progressive budget constraints, the need to better coordinate processes in health institutions appears as a relevant aspect to ensure the future sustainability of system. In this sense, Relational Coordination (RC) provides a valuable opportunity for the reconfiguration of clinical guidelines concerning isolated single-level considerations. In this research the RC model has been applied to explain best results in the process of diagnosing and offering clinical treatments for lung cancer. Lung cancer presents the higher rates of tumor's mortality worldwide. Through unstructured and informal interviews with clinicians at both levels (Primary/Specialist Care), a diagnosis of the situation in relation to joint management of lung cancer is provided. Solutions of continuity in terms of coordination are explained due to the observation of lack of effective knowledge transfer between the two levels. It is this disconnection which justifies the introduction of a modified model of RC for the study and implementation of transfer relations between the knowledge holders, in order to structure consolidated and cooperative evidence-based models that lead to a substantial shortening in the response times with a marked outcomes improvement. To our knowledge, the application of this model to a Public Health problem bringing together both levels of care, hasn't been made till now.

**Key words:** Relational Coordination; Lung cancer; Clinical pathway; Dialogic practices; High performance work systems; Healthcare performance

**Core tip:** Innovative managerial frameworks have to be put into practice when treating severe diseases. Relational Coordination makes possible to enhance inter-level knowledge networks to obtain better outcomes from the perspective of the National Health System and the patients. Through systematic revision, it has been checked that only in the fields of Endocrinology and Psychiatry have these frameworks been applied. This model tries to establish a coordinative solution within the field of Oncology, implementing the Theory of Relational Coordination as a tool to get optimal results in lung cancer.

Romero JAV, Señarís JDL, Heredero CDP, Nuijten M. Relational coordination and healthcare management in lung cancer. *World J Clin Cases* 2014; 2(12): 757-768 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/757.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.757

## INTRODUCTION

In the current schemes of complex pathologies manage-

ment, collaborative scenarios are required in order to get to an integral coordination of health problems *via* multi-level strategies[1-3]. This statement acquires higher importance once we consider some concrete disease processes that, due to their increasing incidence and associated costs from both the patient's and the National Health System's (NHS) perspective, constitute core objectives for specific interventions that may reduce time to take accurate decisions headed to resolute, chronify or minimize the pain caused by the disorder. Coordination networks building and optimization of multi-level tacit knowledge transfer, would provide cost containment per patient stay to the NHS and to the social welfare system, contributing this way, to increase Quality Adjusted Life Years decreasing, as well, Disability Adjusted Life Years.

The objective of this study is to apply the Relational Coordination (RC) Model[4-6] to a determined health problem in order to implement the appropriate treatment trajectories based on continual permutation of actions[7] that return positive outcomes on the indicators formerly mentioned. Although, as far as we know, this model has proven very good results in hospitals, nothing has been performed using this model to check out the effectiveness of coordination strategies between levels of care, when considering the design of common pathways to treat successfully neoplasia as a serious Public Health concern.

To enforce this objective, lung cancer has been selected as an example of great relevance disorder. This is due to: its really important Disease Load[8,9], high treatment cost[10,11], social coverage of disabilities, side-effects on productivity[12], assistance discontinuity between Primary (PC) and Specialized Care (SC)[13] and lack of common recognized procedures and pathways between them and within every isolated level.

This study is focused on comparing actual circuits that patients from PC follow until they get to their reference hospital (in this study we consider a high complexity one, Beveridge typology within a National Health System, with its made-to-measure design of Lung Cancer Clinical Pathway), with our proposal of modified, multilevel RC model applied to clinical trajectories that permit assistance continuity.

As a consequence, it is absolutely necessary to build a clinical alert system triggered by proven suspicion of neoplasia. This needs to be in accordance with the next healthcare level (SC) to, under the premise of evidence-based clinical practices, develop quick completion check-lists that enable immediate[14] transference of patients to the adequate level, using information technologies as preferred communication channel[15,16].

With respect to inter-level coordination, we can highlight that this is not a clinical routine. As scientific literature points out, this cooperative strategy is put into practice by medical specialties not or discretely related to Oncology, such as Endocrinology o Psychiatry. Actually, we find no evidence of cooperative inter-level strategies being carried out in the field of Oncology[17]. Difficulties in structuring these kinds of practices lie on the basis of knowledge transfer[18,19] in organizations characterized by the dominance of its tacit component[20,21] that rarely show High-Performance Work Systems (HPWS) practices[22]. Furthermore, organizational designs for effective and efficient management of oncologic diseases have to be both adaptative and dynamic[23] to be aligned with the state-of-the-art advances recognized in gold standards.

To this respect, RC appears as a high-traceable bi-directional tool to provide excellence in neoplastic lung disease treatment. The model theorized by Gittell[5] offers a global coordinative vision of the organizational process, helping to figure out inefficiencies that can be corrected by initializing and implementing cooperative practices and, as a result, proactive organizational designs that tend to rationalize use of resources. Additionally, it contributes to establish optimal relational dimensions for potential efficiencies of scale and scope depending on the attributes of relational and intellectual capital within the organization[24-27].

A noteworthy aspect of the suitability of the model of choice is supported by the complement that offers for the integration of related scientific approaches within the field of Business Organization, such as Operational Management. This will allow the development of further studies to refine reengineering process *via* supply-chain, thus contributing to the optimization of both the intermediate (surrogate-end-points) and the final results observed in patients (outcomes), and in the income mediated by Risk Adjustment Systems[28] used in health financing. Thus, if the inefficiencies inherent in the coordination process of the disease are debugged, additional financial returns (based on capitation criteria related to the number of processes) could be achieved (even from the health organization's perspective with regard to cost-efficiency). Another feature that makes Gittell's[5] model ideal for our purpose, is that it previously develops a series of tables analyzing HPWS practices, correlating its absence or presence with RC and, consequently, with final outcomes. Thus, the same model before being implemented, allows a diagnosis of the situation in terms of the practices mentioned. Once conclusions resulting from field work have been extracted, the implementation of the model can lead to the development of the absent figures, resulting in a multidirectional dynamic feedback identifiable with the continuous improvement cycle[29].

Moreover, and in a methodological approach, given the intangible nature of the concepts that promote operational developments in the organization as well as their interaction and mutual influence, the model enables the application of multivariate analysis techniques focused on structural equations. This has the potential to provide greater rigor and validity when checking the assumptions in a context of real research.

In addition, *via* RC valuable information it would be possible to extend the network (regarding the possibility of generating "Value Networks"[30] in the process) to other stakeholders such as pharmaceuticals and health technology companies, and even to managerial superstructures committed on public health concerns.

Incorporating the principles of Business Organization to the clinical setting is absolutely essential to promote

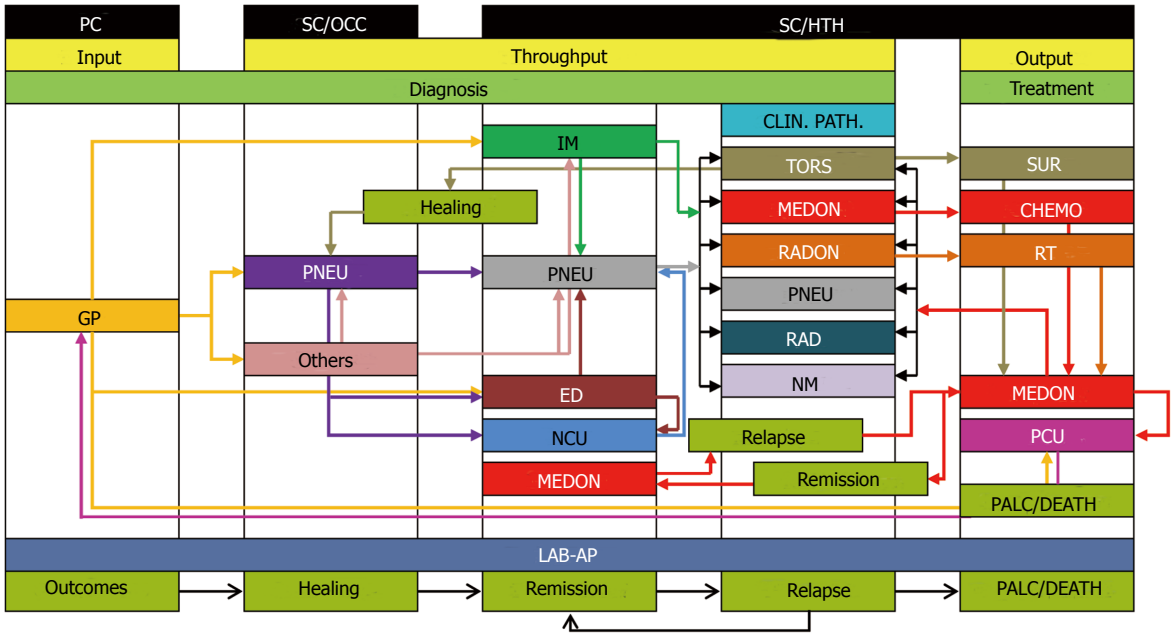

**Figure 1 Inter-level process map.** Source: Authors' own elaboration. PC: Primary Care; SC/OCC: Specialist Care/Outpatient Care Center; SC/HTH: Specialist Care/High-Tech Hospital; GP: General Practitioner; PNEU: Pneumology; IM: Internal Medicine; ED: Emergency Department; NCU: Neoplasia Consulting Unit; MEDON: Medical Oncology; TORS: Thoracic Surgery; RADON: Radiation Oncology; RAD: Radiology; NM: Nuclear Medicine; SUR: Surgery; CHEMO: Chemotherapy; RT: Radiotherapy; PCU: Palliative Care Unit; LAB-AP: Clinical Laboratory and Anatomical Pathology Services; PALC/DEATH: Palliative Care/Death.

the reduction of redundant, iterative processes in traditionally knowledge intensive organizations. These have ignored their role as business managers of a huge amount of resources, in interest of a pretended clinical excellence oriented to complex phenomenology and high media impact in terms of prestige, influence and fund raising, but with little residual value in the generation of efficiencies of scale and scope, given the peculiarities involved in tertiary healthcare.

Given the above, the model postulated by Gittell[4,5] having been tested previously[6] in these types of organizations, is an excellent reference for the detailed study of the relationships involved in designing healthcare procedures between the different levels. It provides the basic tools for understanding and constructing a single treatment line that does not register any undesirable delays attributable to gaps in knowledge and other factors, including relational. The model also facilitates the continuous review of the adequacy of the approaches proposed and its comparison with reference standards in relation to screening, extension study, staging, treatment, monitoring and rehabilitation of lung neoplasia.

## INTER-LEVEL PROCESS MAP AND LUNG CANCER CLINICAL PATHWAY IN A HIGH-TECH HOSPITAL OF A NATIONAL HEALTH SYSTEM

Before accessing the clinical pathway itself, there are many routes to be made by patients in their journey between the two levels of care. This route identifies itself with the diagnosis and treatment of the disease, and represents the transition between access to primary and secondary healthcare (Figure 1). For operational reasons, it excludes access to tertiary level (rehabilitation).

To carry out the process map, unstructured interviews during the months of March, April and May 2012 have been developed with Pneumologists and General Practitioners (GP), as key agents in the user's address to the specific resources for diagnosis and treatment.

The patient's contact with the system starts at the level of PC in the Health Center, where the person requests for consultation to GP due to a series of signs and/or symptoms which may be more or less related to tumors. At this point, a series of basic tests as conventional radiology and blood analytics are required. It is here, where they may be starting to produce the first delayed diagnosis attributable to the transfer of knowledge not based on evidence, since these blood tests not always include non-specific tumor markers, but indicators of malignancy. Furthermore, in many cases, treatment is initiated based on empirical diagnosis of pneumonia, since the neoplastic process can be masked or not being clearly visible by conventional radiology.

From this first GP visit, a second one is requested for reevaluation of improvement and/or worsening of the patient. Also in this second visit, imaging and laboratory results are delivered. This time period can vary from one week to fifteen days (period in which the empirical treatment of antibiotic action produces noticeable changes in the patient's condition and laboratory data). At the persistence of symptoms or onset of signs clearly suggestive of clinical suspicion, inter-consultation part is issued to

the specialty of Pneumology (SC) based at an Outpatient Care Center (OCC). This will lead to an additional delay, although it may be attenuated in case of emergency.

While the above, it should be noted that this path is followed if the clinical manifestations clearly compromise the patient's respiratory status. However, there are not always reliable evidences of pathology as they may be semi-hidden or produce "*a priori*" events unrelated to the disease. This can lead to other specialties not specifically connected with the process, due to the absence of effective knowledge transfer between levels.

Consider, for example, the case in which the disease is indirectly manifested through referred pain in locations as knee or scapula, with inconclusive imaging tests and non-specific tumor markers requested either. In this case, when a person with referred pain consults GP and also has a history of degenerative joint disease, the first inclination is based on the therapeutic application of trauma imaging at the involved location. If this do not show alterations, to an extension diagnosis, the patient maybe referred to other specialties, *via* interconsultation, at the level of OCC, as may be Rheumatology or Traumatology (again, we would have another delay in the issuance of a firm diagnosis). To this must be added, the additional delay in the appointment date for new consultations, delays in the completion of tests that are to be applied in these services and the appointment date for review. Note, that the pain reported by the patient could be produced as a result of neurological compression due to tumor growth.

Once the presence of specific pathology related to other specialties different to Oncology is ruled out, and for a possible occurrence of respiratory and/or systemic signs, the patient may be referred back to the GP (who will likely refer the patient to another specialist in the short-term, as for example an Internal Medicine practitioner at the hospital level) or Pneumologist at OCC level.

It is vitally important to consider that these successive accumulated delays entail delayed diagnosis and may incur progression of the disease from an early stage potentially curable, to an irreversible stage where only palliative measures can be adopted.

Special mention deserves the situation in which the patient attends a first GP consultation when the disease is in an advanced stage. In this case, the GP may take two decisions: one would be immediate referral to the reference hospital emergency department. The other one would be derivation, equally immediate and avoiding waiting list, to Pneumology at OCC.

The tours in both situations are as follow. In the case of referring the patient to the high-tech hospital emergency department considered for the study, the user would be admitted in the lower course of time. Alternatively, the physician at SC may order scheduled or urgent admission according to his criteria, and even *via* emergency if the clinic is accused and limiting.

Returning to the circuit in which the disease is not clearly delimited, and placing the patient back to Pneumology at OCC, application of tumor markers and more specific diagnostic imaging tests with their corresponding waiting times will be issued. This will finally lead to a first diagnosis of neoplastic disease, although in many cases progress is relentless, having passed the tipping point between curability and elongation of survival.

Once the diagnosis has been confirmed (after issuance of radiological and pathological opinion), the Pneumologist at OCC (based on clinical signs) will apply for patient admission at the Respiratory Unit at the reference hospital or at the Neoplasia consulting Unit (staffed by Pneumologists), also located at the hospital but belonging to the outpatient section (OCC/HTH), who predictably will speed his admission to the Respiratory Unit.

It has to be taken into consideration that, as reflected in Figure 1, in cases of nonspecific symptoms the GP or the specialist physician from other disciplines different to Pneumology, can request patient admission at an Internal Medicine Unit. Once there, and after confirming diagnosis, the patient will be placed in charge of the service consulted (Pneumology) or included directly in the clinical pathway in order to be admitted to the Respiratory Unit.

As it has been explained, to reach this clinical decision, the circuits followed by patients are often redundant and inefficient incurring incremental health expenditure and associated loss of productivity, with the aggravating factor of disease progression, which dramatically affects the effective resolution of the process due to a probability increasing of metastatic dissemination. The next step is the inclusion of the patient in the clinical pathway itself.

The Clinical Pathway Commission is a multidisciplinary board delegated by the Chief Medical Officer of the hospital, whose mission is to take collective decisions about the individualized treatment for each patient given the specific types of lung neoplasia presented. It consists of various clinical services such as Thoracic Surgery, Oncology, Radiation Oncology, Pneumology, Radiology and Nuclear Medicine, and meets in session once a week to discern treatment strategies addressing cases that present criteria for inclusion.

Previously, and once the patient has already been admitted in hospital, sequential examinations to limit the spread of the disease and rule out metastasis are conducted.

Once all results are available, which will generate a new lengthening of waiting times due to internal procedures, they are presented in clinical session to elucidate what the best combination of medical and surgical options is. In this regard, it is noteworthy to point out several strategies that, in turn, generate new decisional and time-restricted flows around the patient.

First, and once the kind of broncho-pulmonary neoplastic lesion is typified, in case that the option of surgery is the one chosen, the patient is transferred to Thoracic Surgery (which acts only in relation to the surgical process) being the customer the Respiratory Unit. Upon resolution of this action, the patient can follow two routes

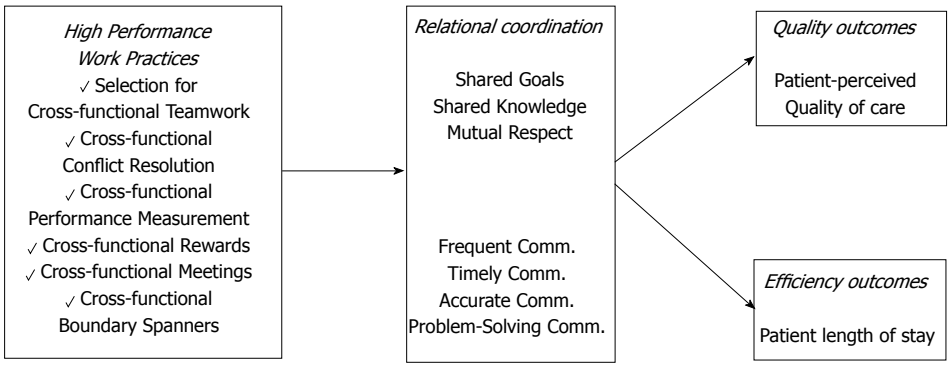

**Figure 2 Relational coordination model.** Gittell[4] (2009).

depending on the characteristics of the disease. If the lesion was curable with just surgery, if it is in a nearly stage, the subject is again brought back to the customer service where periodic reassessments continue on an OCC basis. If clinical pathway was structured in a combined plan of several therapeutic strategies, the patient will be assigned to Medical Oncology and submitted to treatment schemes consisting of chemotherapy and/or radiotherapy (if appropriate), acting as coadjutor service, Radiation Oncology.

Following this, we have to clarify the types and purposes of cancer treatments and their relationship with Thoracic Surgery, as well as with the alternative circuits of patients arising as a result. These treatments can be neoadjuvant or adjuvant. If a neoadjuvant treatment is preferred, the patient will be referred to Medical Oncology from Pneumology, where after receiving the appropriate treatments, will be referred to Thoracic Surgery, and once its performance has concluded, he will be returned to Medical Oncology where the patient will ultimately be assigned. If the *adjuvant* treatment option was considered, the bypass sequence would start from Pneumology to Thoracic Surgery and from the latter to Oncology, where, likewise, the patient would stay finally allocated.

In the case (very common) that Radiation Oncology intervenes, the customer service would be Medical Oncology, and the role of Radiotherapy would be the imposition of costs derived from treatment processes to the original customer.

While all of the above, it is another distinct possibility in case the lesion is unresectable. In this situation, the Commission may choose the administration of chemotherapy and/or radiotherapy to ensure the stabilization of the process. In this sense, the patient is finally moved to Medical Oncology where clinical decisions and treatments are provided, appearing again the interactions described above for the Radiation Oncology department.

After running all the steps above, the circuit would continue in different ways to transfer responsibilities between services and even between levels, depending on the clinical outcome. Thus, we would obtain the following sequences: (1) healing: The patient would return to Pneumology at the OCC level for regular checkups; (2) remission: If partial or complete remission, the patient would be discharged and would attend appointed checkups at Oncology Day Hospital (OCC/HTH); (3) relapse: In this case, the patient re-enters in charge of Medical Oncology, without his case again be subjected to clinical pathway for application of second-and subsequent lines; and (4) palliative Care/Death: For unsolvable progression of the disease, the patient is transferred from Medical Oncology to Palliative Care Unit (PCU), where treatment is merely symptomatic. Nevertheless, depending on the patient's general condition and in respect of his decision making capacity (if this was preserved or had been previously stated), the patient can be treated at home through a collaborative partnership between PCU (SC) and GP.

Restructuring of patient inter-and intra-level flows is absolutely needed. It requires corporate collaborative systems providing knowledge to one medical act. Therefore, the role of the RC model acquires great relevance as it acts as mediator and promotor of joint strategies aimed at improving results ,from both, the patient's and the NHS' viewpoint.

## RELATIONAL COORDINATION MODEL

Based on previous studies grounded in mutual adjustment[31-35] and coordination approaches based on relationships[14,36-40] in corporate environments of high/low interdependence/uncertainty, Gittell develops her model (Figure 2) as a contribution to the study of relational dynamics.

In this sense, Gittell[5] defines her model as a mutually reinforcing process of interaction between communication and relationships carried out for the purpose of task integration. She also states that her theory differs from others due to the proposition of three specific relational dimensions that are necessary for effective coordination.

While many other recent theories emphasize the importance of shared knowledge, RC argues that while this is necessary, is not sufficient. Accordingly, to achieve effective coordination, the members must also be connected through the possession of shared goals and mutual respect.

As mentioned in the previous section, role-based coordination has an advantage over coordination based on

personal ties. While the former may require more investment for being implemented, role-based coordination fosters a role exchange that encourages corporate flexibility to adapt to changing environments within a high uncertainty and interdependence frame over time.

The model is structured around two types of dimensions: Communication and Relationship.

Within the dimensions of communication, we find: (1) frequent communication: Frequent communication helps to establish relationships among roles through the closeness generated as a result of repeated interaction[5]; (2) timely communication: Delays in communication may have negative implications for organizational performance. Hence, the importance of timely communication, and at the right time, for successful development of organizational tasks[41]; (3) accurate communication: Accurate communication, regarding the content of relevant information, plays a critical role in the effectiveness of group tasks performance[42]; and (4) problem-Solving communication: Effective coordination requires that those involved in the task, engage in communication to solve the problems that appear in a group performance characterized by high interdependence (rather than blame others involved or evading the responsibilities). This can lead to negative consequences that singularly affect performance[29].

Within relational dimensions in Gittell's model we find: (1) shared goals: This aspect plays a key role on the coordination of highly interdependent tasks[43,44]. Using a set of shared goals regarding the work process, involved individuals develop ties that allow them to reach conclusions that are compatible with the different ways of thinking and acting as new information is available[5]; and (2) shared knowledge: While Dougherty[45] points out that communication among those involved in the various tasks that constitute a process is not always effective because of different social backgrounds, training and/or experience, Gittell[5] states that when members know how their tasks are related to other members within the same process, it creates a dynamic in which everyone knows the impact that each change will reflect on each task and each role; and (3) mutual respect: Respect for the competence of others involved in the process, provides a powerful tie that will be implemented in a comprehensive way across the whole process generating, as a result, an effective coordination[5].

Through this design, it follows that the RC model turns into a model of intensive coordination in communication and relationships, particularly useful to achieve higher levels of performance under high levels of interdependence among tasks, uncertainty and time constraints. So, it is an example of process improvement that allows a work group department or organization, raise their production possibility frontier to more favorable positions while achieving higher efficiency and quality[5].

It is, therefore, to achieve work processes improvement through improving the quality of labor relations among the actors that play different roles in these processes, thus leading to a higher quality of communication. Through this procedure, it is intended to reduce errors delays and redundancies observable among tasks interdependences within the critical organizational processes.

Model measurement is done through validated surveys to participants in a given process, on the activities of communication and relationships with others involved in the same process, with whom relations of interdependence are kept for achieving the same common objective. Related to the above, the first step would be the selection of a work process that serves a population of interest. Then, the roles or functional groups embroiled in the development of the focal process must be identified. The third step would consist on identifying which of those groups could be accessed by the researcher in order to develop matrices (symmetric/asymmetric) of RC links.

Once the previous steps have been run, likert-type survey would be delivered to the participants consisting of seven questions: four on communication and three concerning relations between different process roles. In order to reduce possible bias attributable to socially desirable responses, RC's survey asks participants about behaviors of other roles, except for organizational behavior feature represented by the frequency of communication. In addition, questions are referenced to habitual patterns of behavior, rather than be directed towards identifying specific events, that are part of the current patterns in the time of evaluation. Thus, avoiding erroneous response patterns based on retrospective response biases.

The characteristics of the model applied to the investigation of coordination practices in the management of interdependent processes, allow multi-functionality in analytical and exploratory orientation, presenting four complementary and inclusive perspectives that give great versatility in building research designs. Thus, the model can be used with the next main purposes: (1) analysis of the effect of RC on organizational performance: Determination of the impact of the model on improving the quality and efficiency of a given process characterized by high levels of interdependence, uncertainty and time constraints; (2) analysis of predictive factors of RC: Determination of the effects of organizational practices to use on the model; (3) analysis of the mediating effect of RC: Determination of the influence of the model on existing organizational practices and their impact on results; and (4) analysis of the moderating effect on RC: Determination of the influence of a/some given factor/s on the effect of the model on organizational performance measurement.

Next, we describe the proposed model for this paper based on RC modified at its core by adding two features of organizational behavior that are interrelated. Also, we introduce two moderating factors to analyze the mediating effect of it and its impact on organizational performance, taking as a critical process multilevel management of health institutions in relation to lung cancer.

To increase consistency and operational development in the future, a comparison with institutional practices currently applied (particularly single level clinical pathways) is made.

## APPLICATION OF A MODIFIED, DOUBLE-MODERATED MODEL OF RELATIONAL COORDINATION IN PERFORMANCE MEASUREMENT OF LUNG CANCER MULTI-LEVEL TREATMENT TRAJECTORY *VS* ISOLATED, SINGLE-LEVEL CLINICAL PATHWAYS

As it has been previously described, the main objective of this paper is the proposal of a modified, double-moderated model of RC (Figure 3), to investigate the degree of development of the theory proposed by Gittell[5] and the impact of its implementation on HPWS practices and outcomes obtained by the institution. In reference to the above, the greatest achievement of this study is supported by theoretically increased times of disease-free survival (DFS) as a consequence of optimal-efficient redesign of coordination strategies between levels involved in diagnosis and treatment. In addition, the potential gains highlighted would imply healthcare costs containment that would return positive savings on other important health problems, being possible to achieve true clinically-oriented corporate strategies.

First, and as a previous step for defining the implications of the proposed model on performance, we need to identify HPWS practices currently observable at health organization level (Table 1) and at the level of diagnosis and treatment of broncho-pulmonary carcinoma (Table 2) for both care providers (PC/SC).

As seen on Table 1, HPWS practices in the health care organization have a wide variability and segmentation that result in continuity of care disconnection. Furthermore, the absence of inter-level operational relations in critical aspects emphasizes the fact pointed out, generating a discontinuity of the care process that could lead to very significant increases in transaction costs, as well as duplication of health expenditure and intangible consumption.

This situation is much more serious when looking at data provided in Figure 2, referred to the specific coordination process of the pathology. In this case, it highlights the virtual absence of joint strategies for the management of the disease. In light of this information, the existence of redundant and iterative processes (that create delays in the effective application of therapeutic measures associated with consequent costs due to disabilities and/or productivity losses), gets verified.

The comparison of data shown in Tables 1 and 2 has been made through unstructured interviews with senior doctors at a health center, which has as reference hospital the one mentioned throughout this work, and that is very representative due to the volume of population served (approximately 22000 health cards).

It justifies the introduction of a modified model of RC for the study and implementation of transfer relations among knowledge holders, in order to structure consolidated, evidence-based cooperative models that would lead to a substantial shortening of response times with a marked improvement in outcomes.

The sequential development of our model is based on the examination of the organizational behavior considered by Gittell, using the methodology annexed to the theoretical approach[5]. Then, it will be complemented by a combination of studies of other authors in the field of management, which postulate the study of trust relationships[21,46] and dialogic practices[14] as effective methods of organizational coordination.

These are especially relevant for high-uncertainty processes requiring quick and adaptative replies.

Related to the above, trust is a predictor and a consequence of interpersonal relationships[21]. In this sense, a higher degree of trust acts as a stimulating factor for communication accessibility, promotes greater effort from those involved in a task and reduces conflict in work teams, fostering better results in performance[47,48]. It could be inferred that it acts as an enhancer of RC.

Moreover, dialogic practices tested in high-uncertainty hospital services[14] appear as coordinative solutions (from a point of view focused on process trajectories[7]), by which cooperative guidelines are structured (Figure 4). This fact is particularly important, given the high variability inherent to the process of diagnosis and treatment, and the consequences of a not entirely optimal assembly of tasks committed with the successful resolution within a framework of time-coordinated action.

Related to approaches focused on trajectories[7], these are described as goal achievement oriented sequences of action that emphasize contingencies and interactions among those involved in, differing from routines in that the latter merely emphasizes a sequence of steps that can't be extrapolated to work situations characterized by novelty, unpredictability and changing environments in relation to tasks, actors and resources[14].

So, it is about measuring the degree of trust that the different professionals at both levels have in dialogic practices, following the methodology used by Dietz and Hartog[46] (Figure 5). This evaluation methodology would be applied to the PC level on the SC level and *vice-versa*.

In a structured way, it would be done a pre-test evaluation of the RC status (for a given level of trust in dialogic practices) at an early stage at both levels, applied to the target health problem. These data would be correlated with the evidence about HPWS developments.

Subsequently, a series of actions would be designed to strengthen relational ties between the two levels. For example, formal assistance on regular basis of one PC-GP to the meetings of the Clinical Pathway Commission (SC), with the aim of promoting the practices mentioned as of excellence, can be suggested. As a consequence,

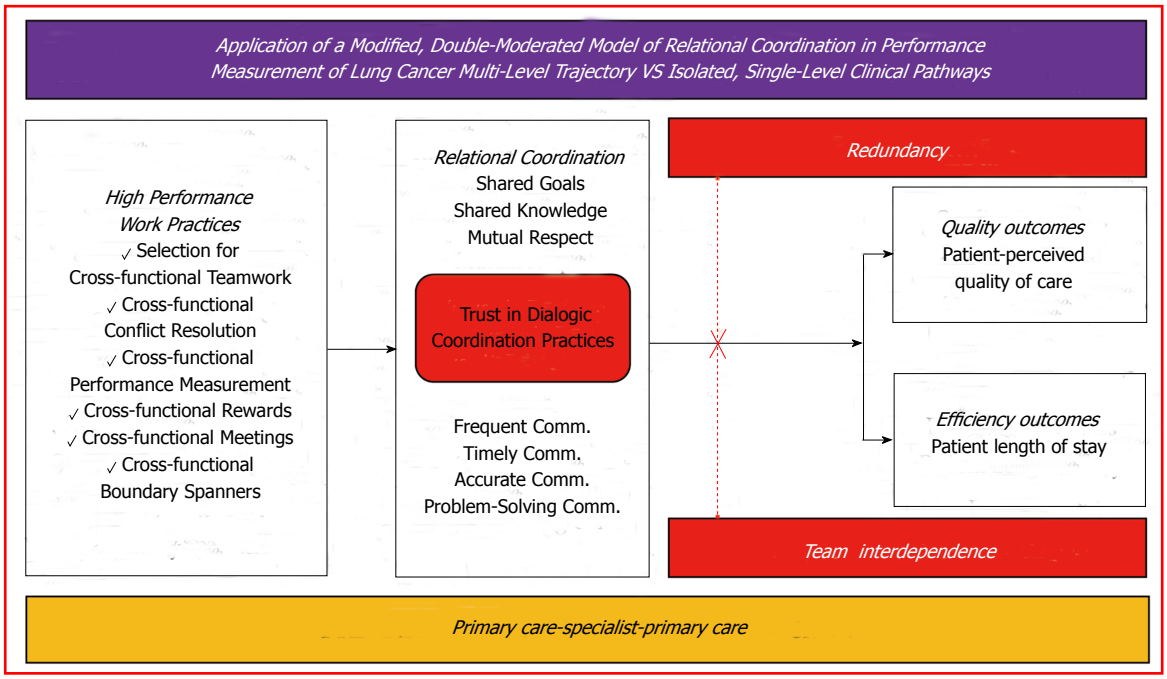

**Figure 3 Modified, double-moderated model of relational coordination.** Source: Authors' own elaboration.

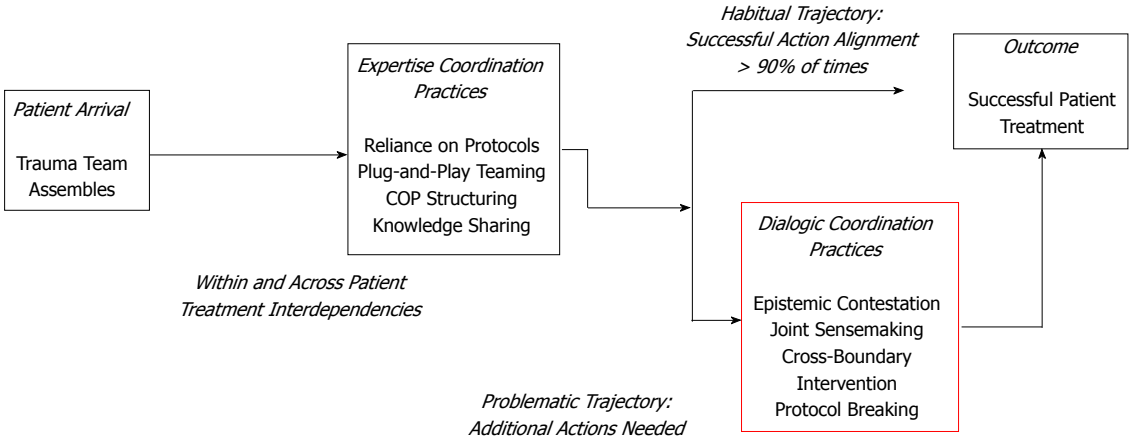

**Figure 4 Coordination-focused model of trauma patient treatment.** Faraj *et al*[14] (2006).

the development of inter-level HPWS practices would be promoted, development that could materialize in creating joint Clinical Practice Guidelines which would contribute to early detection of lung cancer.

Furthermore, to streamline the circuit followed by the patient, direct referring to specific knowledge resources located on SC is intended, always ensuring the traceability of the patient's health status *via* widespread use of shared databases.

In this sense, it is about promoting the representativeness of the Continuity of Care Coordinator (see Table 1) in bidirectional management of patients affected.

Secondly, the interdependence of tasks generated under the prism pointed by Van de Ven *et al*[35] would be considered in terms of work flows at the team level. Participating GP's would be enrolled in a training program of High-Fidelity Clinical Simulation following a methodology of Objective Structured Clinical Examination[49-51] that would be taught by specialist physicians specifically trained in this type of methodology. Once these actions have been carried out, a new post-test measure of the degree of trust in RC and dialogic practices would be done at the same time that HPWS practices are re-evaluated.

From this point on, it is necessary to evaluate (retrospectively/prospectively) the time passed since the first contact with the system takes place until the patient receives the first therapeutic action for treatment, prior to and after the implementation of measures aimed at encouraging the development of RC and dialogic practices. Also, as a control measure that would reinforce the theoretical assumptions (raised by some a priori confirmatory hypotheses for the model proposed vs. single level clinical pathways), TNM staging category (at the time of diagnosis confirmation) and estimation of DFS would be

done. In closing, costs related to hospital stays savings (as a result of early detection) would be calculated.

The proposed model goes from an exploratory qualitative design to (after an inductive process) an explana-

tory type, which generates synergies in the use of scarce resources through coordinative economies of scope.

## CONCLUSION

In the current socio-economic scenario characterized by a growing shortage of resources and progressive budget constraints, coordinated process management in health institutions appears as a relevant need to ensure the sustainability of the medium/long term.

The fact that a health system is strategic for a country (particularly if this system is public and universal), together with the sheer volume of resources associated with healthcare provision, makes mandatory to impose a rational logic in the clinical management of public health concerns. This logic has to be even more intense, when it comes to diseases on the rise and rate of disability and/or mortality as the one we are considering in this paper.

In this sense, RC provides a valuable opportunity for the reconfiguration of clinical guidelines concerning isolated single-level considerations, to turn them into cooperative inter-level ones.

Through unstructured and informal interviews with clinicians at both levels (Primary/Specialist Care), diagnosis of the situation in relation to joint management of lung cancer is made, noting that solutions of continuity (in terms of coordination) are observed due to the lack of effective knowledge transfer between the two levels as a result of RC practices absence[52].

Is in this way, where it is theoretically inferred that delays secondary to ineffective coordination would be attenuated if launching and implementation of cooperative schemes (including relational trust in dialogic practices) had been run. In turn, these strategies would result in the generation of "*ad hoc*" Clinical Practice Guidelines (equivalent to HPWS in other corporate environments), which would strengthen the mission of RC. In this regard, it is worth highlighting the flexibility provided by Gittell's theory[5]. It allows adaptation and modeling of its precepts to the organizational conditions of actual practice, providing a specific management architecture for knowledge intensive organizations that remains under heavy pressure on casuistic, uncertainty and technological changes.

The model proposed in this research, advocates a regularization and training of new skills and relational attitudes arising from the collaboration between the two levels of care involved. This consideration is particularly relevant if we return to the defining characteristics of health systems in which advances in the state of the art occur constantly and must be properly transferred.

The operational implications of the suggested theoretical alternative pursue a dual purpose on results. So on the one hand, facilitating diagnosis in early stages of broncho-pulmonary carcinoma, allows more cost-efficient measures, which will return a decrease in rates of morbidity and mortality and a significant reduction in opportunity costs from the patient's point of view. This would be translated into tangible gains in DFS and the appearance of negative costs obtained from savings in productivity loss avoiding and containment of hospital stays per process.

On the other hand, the second approach is characterized by the impact on health spending of Medical Care Variation. Because physicians are resource allocators, this scheme of coordination is intended to reduce duplication in diagnostic tests and clinical times. Here appears again the concept of opportunity cost, but in this case, from the point of view of the NHS. If the process is clearly predefined, there would be a bidirectional action sequence that would lead up to a regulated and bottom-up asset allocation from an optimum-efficiency criteria based on clinical excellence and non-repetitive processes. The savings generated by this approach can, in turn, be reinvested in the process itself or moved to other singular processes of great clinical significance.

The research model is, therefore, to efficiently redirect health expenditure incurred by the disease through proactive inter-level and inter-professional coordinative solutions, achieving, this way, improvements in quality of life and survival of patients affected.

It should be noted that the health organization is not to stay longer away from the improvement proposals dropped from the corporate world, because it is in itself a great company if we pay attention to budget, employability and management processes underlying their daily operation.

In this sense, this document is made taking into account the feasibility and methodological orientations arising from the healthcare business world and academia, providing a new strategic vision of the organization of clinical processes in high complexity health corporations.

## Abstract

Breast cancer is the most frequent female malignancy worldwide. Current strategies in breast cancer therapy, including classical chemotherapy, hormone therapy, and targeted therapies, are usually associated with chemoresistance and serious adverse effects. Advances in our understanding of changes affecting the interactome in advanced and chemoresistant breast tumors have provided novel therapeutic targets, including, cyclin dependent kinases, mammalian target of rapamycin, Notch, Wnt and Shh. Inhibitors of these molecules recently entered clinical trials in mono- and combination therapy in metastatic and chemo-resistant breast cancers. Anticancer epigenetic drugs, mainly histone deacetylase inhibitors and DNA methyltransferase inhibitors, also entered clinical trials. Because of the complexity and heterogeneity of breast cancer, the future in therapy lies in the application of individualized tailored regimens. Emerging therapeutic targets and the implications for personalized-based therapy development in breast cancer are herein discussed.

**Key words:** Breast cancer; Microenvironment; Signaling molecule; Targeted therapy; Chemoresistance

**Core tip:** Emerging therapeutic targets may overcome chemoresistance in breast cancer.

## INTRODUCTION

The incidence of breast cancer, the most common cancer in women and the second cause of cancer death in women worldwide[1,2], is currently growing[3,4]. Cancers are diseases characterized by aberrant microenvironment and intrinsic signaling causing a continuous proliferation of affected cells ("cancer cells"). Clinical features and

prognosis of cancers vary tremendously according to the tissue and organs they originate from and affect. Breast cancer may start in milk ducts, and can be invasive [invasive ductal carcinoma (IDC)] or not (ductal carcinoma in situ). IDC would represent up to 80% of cases[5,6]. Breast cancer may also start in the lobules, with invasive features (invasive lobular carcinoma) or not (lobular carcinoma *in situ* ). In metastatic breast cancer malignant cells originating from breast primary tumors invade other tissues and organs of the body, resulting in a systemic disease. As disease early detection is associated with better prognosis, screening campaigns involving healthy female subjects are performed worldwide. Notably, mammography, which requires the use of low-dose X-rays to capture images inside the breast, is the current goal standard screening for detection of breast cancer asymptomatic cases[7,8]. However, although the technique requires X-rays, the benefits of the earlier detection of breast cancer outweigh the risk of radiation exposure, which can be associated with the development of breast cancer in previously healthy women is present[9,10]. New approaches for early detection have been proposed, and may also contribute to reducing breast cancer mortality (for review see[11,12]).

Three major therapeutic approaches are used today to treat or control breast cancer: surgical removal of primary tumors, irradiation of cancer cells to stop their growth, and anticancer drugs, which kill cancer cells or inhibit their proliferation. Notably, oncoplastic surgery, a technique combining classical lumpectomy (or partial mastectomy) and plastic surgery techniques have revolutionized breast-conserving surgery for removal of lumps and malignant masses. However, surgery or radiotherapy still requires chemotherapy to eradicate remaining malignant cells and impede relapses. Anticancer drugs are based on three therapeutic approaches: (1) the classical chemotherapy, where cancer cell proliferation is stopped by the indiscriminate targeting of rapid cell divisions in the body; (2) hormone therapy, devised to stop cancer cell growth by targeting the receptors and downstream signaling molecules of hormones pivotal for the proliferation of these cells; and (3) and the emerging and promising targeted therapy, where signaling pathways deregulated in primary breast tumors are specifically targeted. Breast cancer treatment is still challenging, as drugs in use are expensive, have serious undesired effects[13-15], and drug resistance is common, particularly in metastatic cases[16,17], underlying the need for new targeted therapies. Interestingly, recent advances in the understanding of breast cancer biology have highlighted the tumor microenvironment as a major player in breast carcinogenesis and have provided new avenues for targeted therapy.

The present review summarizes and discusses the current understanding of changes affecting breast microenvironment during breast tumorigenesis, with a particular emphasis on signaling pathways currently targeted for therapy and emerging therapeutic targets. Personalized-based targeting implementation is also discussed.

## TUMOR MICROENVIRONMENT IS PIVOTAL FROM BREAST CANCER INITIATION TO METASTASIS

Numerous stromal cell types are found in the extracellular matrix of the breast stroma, including endothelial cells, fibroblasts, adipocytes, and resident immune cells[18]. In addition to these cell types, cancer-affected microenvironment contains malignant cells termed as cancer-associated fibroblasts (CAFs), which are the most numerous cell type, and infiltrating macrophages termed as tumor-associated macrophages (TAMs).

### *Cancer-associated fibroblasts*

CAFs were reported to play key roles in malignant cell proliferation and tumor maintenance[18,19]. An *in vivo* study involving xenograft of MDA-MB-231 breast cells in SCID mice revealed that CAFs induce p53-dependent antimitogenic responses in normal stromal fibroblast[20], at least partly through Notch-dependent mechanisms[21]. In another study, CAFs expressed vascular endothelial growth factor in presence of hypoxia inducible factor 1 α/G-protein estrogen receptor (HIF-1α/GPER) signaling, suggesting a role for these cells in hypoxia-dependent tumor angiogenesis[22]. Under the same conditions, CAFs were shown to express Notch molecules[23], which promotes cancer cell survival, proliferation[24,25], as well as angiogenesis[26]. In addition, Luga *et al*[27] showed that CAFs release exosomes, which stimulate invasiveness and malignant cell metastasis *via* a Wnt11-dependent mechanism. On the same hand, CAFs induced phenotypical changes in adipocytes resulting in the generation of fibroblast-like cells [adipocyte-derived fibroblasts (ADF)], which in turn increased migratory abilities of metastatic cells by releasing high levels of collagen I and fibronectin[28]. Notably, CAF-induced ADF phenotype generation was mediated by reactivation of the oncogenic Wnt/β-catenin pathway in the latter cells in response to Wnt3a produced by the cancer cells, suggesting CAFs and ADFs as potential therapeutic targets in metastatic breast cancer. Furthermore, CAFs may promote breast cancer initiation and progression to metastasis *via* tumor-α9β1 integrin signaling[29] and fibroblast growth factor signaling[30], as well as malignancy orchestration and tumor stroma reprogramming through activation of heat shock factor 1[31], a transcriptional regulator.

Interestingly, Capparelli *et al*[32,33] have hypothesized that senescent fibroblasts may promote tumor growth through an autophagy-dependent mechanism termed as "autophagy-senescence transition". In order to test such hypothesis, these authors introduced autophagy genes such as *bnip3*, *ctsb* or *ATG16L1* in immortalized human fibroblasts that resulted in the induction of a constitutive autophagic phenotype (characterized by mitophagy, aerobic glycolysis, L-lactate and ketone body production) with senescence features associated with increased β-galactosidase activity, increased level of cyclin depen-

dent kinase inhibitor (CDKI) p21, and cellular hypertrophy. Interestingly, "autophagic-senescent" fibroblasts were able to induce tumor growth and metastasis independently of angiogenesis, with stronger effects (up to 11-fold) in autophagic fibroblasts producing large amounts of ketone bodies. These observations were confirmed *in vivo*, as the lysosomal enzyme and biomarker of senescence, β-galactosidase, was also found in human breast cancer stroma. A recent *in vivo* study revealed the ability of CAF autophagy and senescence to promote tumor growth and metastasis increasing the rate of glycolysis and enhancing the generation of mitochondrial fuels including bodies[33] in a compartment-specific fashion, thus supporting the role of CAFs to metabolically regulate tumorigenesis. In this study, the injection of the antidiabetic molecule along with peroxisome proliferator-activated receptor gamma (PPARγ), known to stimulate glycolysis and pro-autophagy, into stromal cells enhanced the growth of co-injected breast cancer cells by 60%, whereas PPARγ injection in cancer cells reduced the growth of breast cancer cells by 40%[34].

### Tumor-associated macrophages

TAMs infiltration into neoplastic tissues is an important negative prognostic factor[35,36], and a hallmark of triple negative breast cancer[37], a chemoresistant subtype of breast cancer[38,39]. Overall, emerging evidence suggests that TAMs are major player in anticancer drug resistance in breast cancer. For instance, Yamashina *et al*[40] recently reported that cancer stem-like cells originating from chemoresistant tumor promote macrophage colony-stimulating factor production *via* an interferon regulatory factor 5 -dependent mechanism, and transform recruited CD14(+) monocytes in tumorigenic M2-macrophages (immunoregulatory), probably through CXCR3 downregulation[41]. Interestingly, the differentiation inducer dimethyl sulfoxide exerted antitumor effects in a mouse breast cancer model (4T1) possibly by inducing M1-phenotype in TAMs[42].

Furthermore, TAMs may promote carcinogenesis and metastasis *via* Wnt signaling, which mediates the angiogenic switch and metastatic processes in breast cancer[43,44]. Notably, TAMs release high levels of the Wnt family ligand Wnt7b[45], and cancer stem-like cells may trigger the metastatic effect of TAMs through enhancement of the β-catenin pathway *via* vitamin D receptor suppression by tumor necrosis factor alpha[46]. In addition, *in vivo* and *in vitro* studies supported a pivotal role for Wnt 5a signaling in TAMs-induced metastasis[47,48], and a strong correlation was found between Wnt5a expression in malignant cells and the number of CD163(+) M2-macrophages[49]. In a relatively recent study investigating the potential of the phosphodiesterase type 5 inhibitor (vasodilator) drug dipyridamole in xenograft mice, anticancer effects were mediated at least partly by decreasing β-catenin cytosolic levels[50]. Altogether, these findings implicated TAMs as a key links between chemoresistance and tumorigenic activities of cancer stem-like cells, and thus, positioning TAMs as potential therapeutic targets for breast cancer. Figure 1 shows the main signaling pathways currently in use for targeted breast cancer therapy, as well as some possible new targets.

## NOTCH SIGNALING

### Notch family of molecules

The Notch family of membrane bound receptors and ligands regulate several cell processes including cell invasion, survival and apoptosis, *via* the Notch signaling pathway. The pathway comprises four receptors (Notch1 through Notch4) and five Notch ligands (Delta-like 1, 3, and 4, and Jagged1 and 2). Notch ligands include an extracellular domain containing multiple epidermal growth factor (EGF)-like repeats and an extracellular DSL where ligand binding occurs, and an intracellular domain with a PDZ-binding motif at C-terminal domain[51,52]. Notch receptors are also made of an extracellular and an intracellular domain covalently linked. Notch receptor extracellular domain also contains EGF-like repeats (26-29 depending on the Notch receptor), whereas Notch intracellular domain (NICD) presents with LIN12/Notch-related repeats preventing ligand-independent signaling, cysteine residues, and a C-terminal transactivation domain containing a PEST sequence with proteolytic activity.

Notch ligands are expressed on the plasma membrane of one cell and interact with Notch receptors on the plasma membrane of a neighboring cell, initiating the cleavage of the receptor by proteases [ADAM (a disintegrin and metalloprotease) and γ-secretase] that culminates in the release of the NICD[53]. Released NICD translocate to the nucleus and forms a transcriptional activator complex with C-promoter binding factor 1/Suppressor of Hairless and Lag-1 (CSL) transcription factor. Together with cofactors like mastermind-like protein, NICD-CSL complex induces the transcription of cell fate key target genes such as *vegfr3* and, *notch1* that regulate angiogenesis and apoptosis, *p21* that regulates the cell cycle, as well as transcription factor genes such as the basic helix-loop-helix and hairy/enhancer of split/-related (*hes* and *hey*) [54,55] (Figure 1).

### Notch signaling as a therapeutic target

As already mentioned (section 2), Notch signaling is used by CAFs to promote cancer cell survival and proliferation. Early reports revealed that upregulation of Notch signaling suffices to transform normal breast epithelial cells in malignant cells *in vitro*, and that high levels of NICD are present in breast primary tumors[56-59]. Notch carcinogenic effects are mediated *via* the silencing pro-apoptotic signaling pathways and growth-inhibitory molecules like TGF-β[58]. Notch-induced TGF-β silencing also promotes bone metastasis[60,61]. In addition, Notch signaling, which is required for physiological angiogenesis, may also be a key player in neoangiogenesis[62]. A Notch 3 addiction of the lymphovascular embolus was reported in a xenograft model of inflammatory breast carcinoma, a subtype of breast cancer whose hallmark is

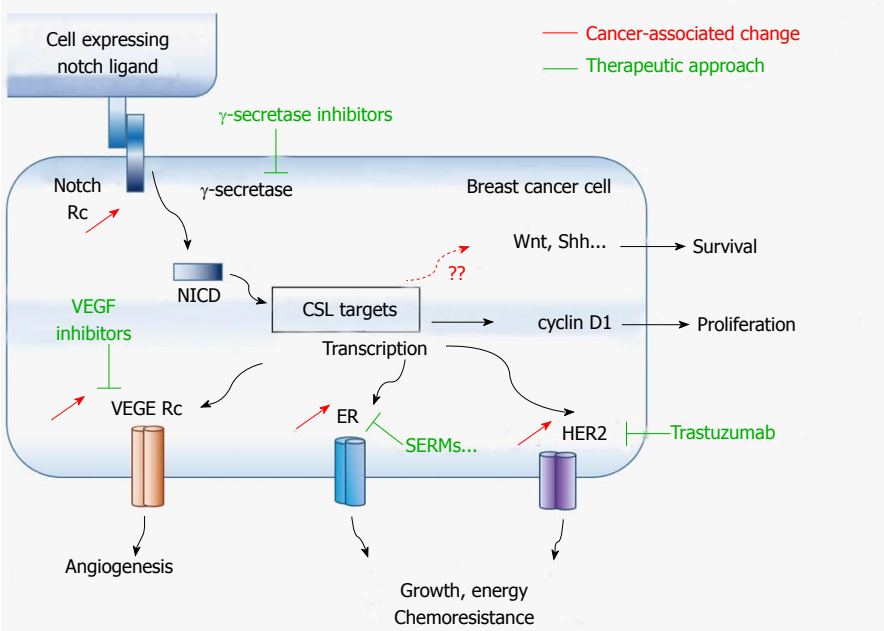

**Figure 1 Notch signaling in breast cancer. In Notch-driven breast cancers, tumor cells and neighboring cells express Notch ligand and receptors.** In presence of ADAM/TACE and γ-secretase enzymatic complex, Notch ligand-receptor interactions result in the release of Notch intracellular domain (NICD), which translocate to cell nucleus and activate CSL transcription factor. Target genes include signaling molecules involve in cancer cell survival, proliferation, angiogenesis, growth, energy metabolism, and chemoresistance. Inhibitors of many of these signaling molecules have been developed and are in use in various cancers, including g-secretase inhibitors, vascular endothelial growth factor inhibitors, estrogen signaling inhibitors, and HER2 inhibitors. ER: Estrogen receptor; HER2: Epidermal growth factor receptor 2; ADAM/TACE: A disintegrin and metalloprotease/tumor necrosis factor-α converting enzyme; CSL: CBF1/Suppressor of Hairless/LAG-1.

lymphovascular invasion[63].

*In vitro* studies in estrogen receptor (ER)-negative breast cancer cells (MDA-MB-231) performed by Lee *et al*[64] revealed that Notch signaling up-regulates the transcription of the apoptosis inhibitor survivin. In another study, these authors showed that Notch-1-survivin functional gene signature is common in basal breast cancer[65]. In addition, crosstalk between Notch and signaling pathways involved in cell growth were reported as well, including the estrogen receptor[66], human epidermal growth factor receptor 2 (HER2)[67], and the metabolic signaling pathways phosphatidylinositol 3-kinase (PI3K)/ protein kinase B (Akt)/mammalian target of rapamycin (mTOR)[68,69] and MAP kinase/ERK[70,71]. Interestingly combined targeting of Notch and EGFR signaling suppressed chemoresistance in a basal-like breast cancer *in vivo* model[72], suggesting that co-targeting of Notch and associated pathways may represent a new avenue for overcoming chemoresistance (Figure 1).

Tumor initiating cells of tumors overexpressing HER2/neu also express high levels of Notch molecules, whose signaling is known to enhance HER2 expression[73]. Chemoresistance to HER2+ breast cancers to trastuzumab, a monoclonal antibody against HER2, is associated with the overexpression of Notch-1 and its ligand Jagged-1[74,75]. Similarly, cancer stem-like cells also achieve resistance against chemotherapy and radiotherapy *via* Notch signaling[76], and targeting of this signaling pathway reduces the stem-like population[77]. The γ-secretase inhibitor MRK-003 induced long-term recurrence-free survival in a transgenic mouse model of HER2+ breast cancer[78]. Similarly, co-targeting of Notch and HER2 signaling pathways prevented breast tumor recurrence in orthotopic breast tumor xenograft using trastuzumab-resistant BT474 cells[79].

Platelet-derived growth factor-D, another marker of breast cancer poor prognosis, may increase breast tumor aggressiveness by activating Notch and NF-κB signaling pathways[80]. Furthermore, Notch-1 and Notch-4, established bio-markers of the chemoresistant breast cancer subtype[81], were reported as novel transcriptional targets in triple negative breast cancer[82,83]. Jagged1/Notch4 signaling was shown to induce epithelial-to-mesenchymal transition[84]. Notch signaling was also reported as a mechanism of resistance to PI3K inhibitors[85] and hormone therapy[86].

### *Clinical evaluation of Notch signaling targeting*

Notch signaling inhibitors have a promising clinical efficacy as they abrogate HER2-Notch axis of chemoresistance. Notch silencing by γ-secretase inhibitors (GSIs) inhibited the proliferation of breast cancer cells partly by causing cell cycle arrest and apoptosis[76], and by sensitizing chemoresistant breast cancer cells to the BH3 mimetic ABT-737[87]. Notably, GSIs induce toxicity to breast cancer both *in vitro* and *in vivo* models, however mechanisms of such cytotoxicity are complex and may involve proteasome inhibition and downregulation of Bax and Bcl-2[88,89].

Following encouraging pre-clinical studies[83,90,91], the oral gamma secretase inhibitor R04929097 recently entered phase- I trial in patients with advanced solid tumors. Early reports of combination therapies with the kinase inhibitor temsirolimus[92], the antimetabolites of the

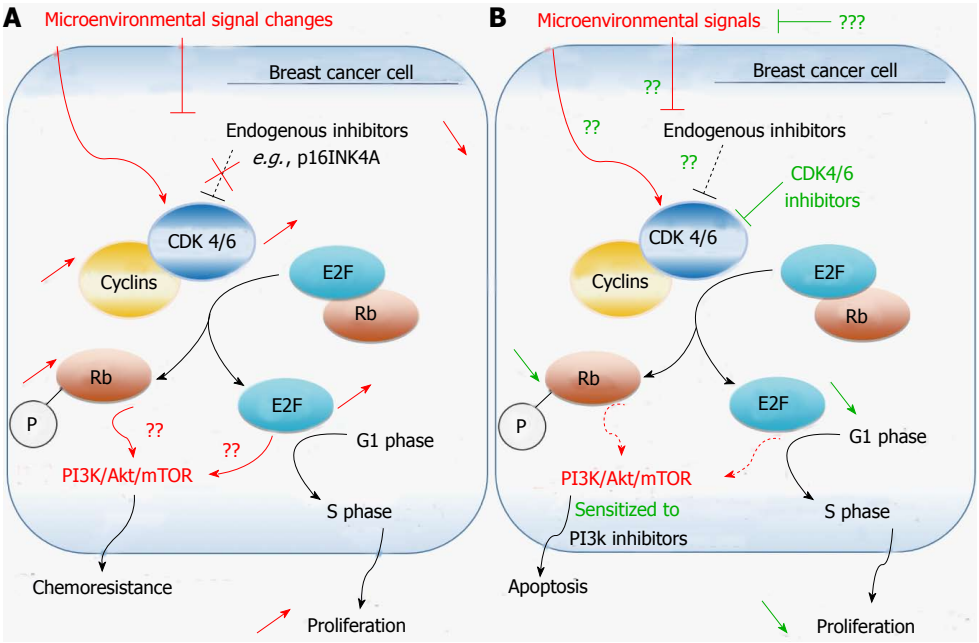

**Figure 2 CDK4/6 signaling in breast cancer.** A: Cyclin dependent kinases (CDK) 4/6 signaling is overexpressed in breast cancer. Such overexpression, which results from the silencing of CDK endogenous inhibitors, participate directly to cancer cell proliferation by triggering G1-S transition, and indirectly to chemoresistance via a PI3K/Akt/mTOR-dependent mechanism; B: CDK4/6 inhibitors sensitize chemoresistant cells to PI3K inhibitors and various other anticancer agents. PI3K: Phosphatidylinositol 3-kinas.

pyrimidine analog family gemcitabine (PHL-078/CTEP 8575)[93] or cediranib (PJC-004/NCI 8503) revealed that the combinations were safe and promising in breast, tracheal, and pancreas cancer patients. However, anemia, diarrhea, fatigue, hypertension, neutropenia, and nausea were observed, among other side effects. GSI reported side effects seem to be mediated primarily through proteasome inhibition[88,94]. Thus, CSL inhibition, which was reported to mediate a more effective inhibition of Notch-dependent carcinogenic processes than GSIs[95], may represent a less toxic approach for Notch signaling targeting.

Another GSI, PF-03084014, also presented promising results in breast xenograft models[96], with gastrointestinal toxicity easily abrogated by glucocorticoids[97]. Other promising pre-clinical observations included a synergistic effect with the antimitotic drug docetaxel in breast cancer[98], colorectal cancer[99], and metastatic pancreatic cancer[100] models. Antiangiogenic effects where also reported in combinations with the tyrosine kinase inhibitor sunitinib in solid tumors[101], whereas in chronic lymphocytic leukemia cells combinations with the nucleoside metabolic inhibitor fludarabine inhibited angiogenesis as well as migration and invasion of Notch 1-mutated cancer cells[102,103]. PF-03084014 therefore appears as an appealing GSI for both solid and blood cancers and may be a good targeted-therapy drug in breast cancer.

## CDK

### CDKs, cyclins and CDKI

Cyclins, CDK inhibitors (CDKIs, *e.g.*, p16INK4, p15INK4B, p18INK4C. p21WAF1/CIP1[104,105]) and CDKs are the three key classes of regulatory molecules that determine cell cycle progression through the G0-G1-S-G2 and M phases[106,107]. Numerous CDKs are found in eukaryotic cells, of which some are pivotal cell cycle regulators, such as CDK1/2/4/6 (Figure 2). CDKs (catalytic subunits, heterodimeric serine/threonine kinase class) associate with cyclins (regulatory subunits) to form an active catalytic complex favoring G1/S cell-cycle progression in mitosis. For instance, CDK1/A2 or CDK1/B1 complexes trigger mitosis in mammalian cells by phosphorylating downstream cell cycle regulatory proteins[108]. Other CDKs are involved in the regulation of cellular transcription, such as CDK7-11[107,109]. A recent proteomic analysis of the CDK family in human cells has identified a CDK5 complex as a key regulator of non-neural cell growth and migration factor[110].

### CDK involvement in breast cancer

Early and emerging evidence suggests that cyclin D1 promotes breast tumorigenesis[111,112]. CDK1 activity was recently reported as a powerful predictor of taxane chemosensitivity, indicating a role for CDK1 in breast tumorigenesis[111]. Notably, taxanes are the drug class most used for breast cancer pre-operative chemotherapy; they induce apoptosis in malignant cells by stopping their replication[113,114]. Moreover, studies investigating genes that are synthetically lethal in Myc-dependent cancer identified numerous CDKs as Myc synthetic-lethal genes[115-117]. Interestingly, in one of such studies CDK1, but not CDK2 or CDK4/6 was selectively lethal to Myc-dependent breast cancer cells[117]. This observation indicates that targeting CDK1 may induce apoptosis in Myc-dependent cancers, where Myc drives cancer cell growth and cycle progression[118]. Increases in activities and levels of other CDK complexes were also reported in breast cancer

primary tumors and experimental models, including CDK4/6 and cyclin E/CDK2 complexes[119-121]. The occurrence of cyclin E/CDK2 proteolytic cleavage products associates with poor clinical outcome in breast cancer patients and increases tumorigenicity in experimental models at least partly by promoting stem-like properties of tumor cells[120]. Transcriptional regulator CDK8 targeting was also recently reported to inhibit both the proliferation and the migration of breast cancer cells[122]. In addition, *BRCA2* gene, whose aberrant activating mutations associate with familial breast cancer[123,124], was reported to induce genomic stability in malignant cells through a CDK-dependent mechanism[125].

A link between the cell cycle and steroid hormone metabolism involving CDK4/6 was recently uncovered in breast cancer primary tumor cells[126]. In this study, malignant cells appeared to control the activity of steroid metabolic enzymes, *i.e.*, the expression of steroid hormone receptors (including ER), by alteration of CDK4/6-levels (overexpression of CDK4 and decrease of its homolog CDK6). Such mechanism may play a pivotal role in the carcinogenesis and chemoresistance of steroid hormone-dependent cancers. In another recent study the newly synthesized compound KU004 that had a potent anticancer effect by targeting HER2 induced a decrease in CDK4 expression[127]. On the same hand, CDK 4/6 inhibitors sensitized *PIK3CA* mutant breast cancer to PI3K inhibitors in a xenograft study[128] (Figure 2), further suggesting a role for CDK4/6 imbalance in breast tumorigenesis.

### *CDK inhibitors*

CDK4/6 inhibitors are more efficient and less toxic antineoplastic agents than molecules targeting other CDKs[129]. The selective cyclin D kinase 4/6 inhibitor palbociclib (PD-0332991) is currently entering phase Ⅲ trial for ER+ breast cancer patients, following encouraging results in progression free survival in phase Ⅱ trials[130]. Using the bioluminescence imaging technology, an early study in xenograft models displaying metastatic progression revealed powerful antimetastatic effects, comparable to avastin, and docetaxel effects[131]. In addition, palbociclib, preferentially inhibited the proliferation of luminal ER+ breast cancer cell lines *in vitro*[132], suppressed malignant cell proliferation in approximately 85% of cases irrespective of ER+/- or HER2+/- statuses[133]. Furthermore, palbociclib induced growth arrest in hormone-resistant MCF-7 breast cancer cells by a mechanism consistent with cellular senescence[134]. This observation is not surprising considering the functional link between tumor microenvironment carcinogenic activity, ageing, and autophagy discussed above (section 2.1), and indicate that the drug may also affect metabolic processes in CAFs and stem-like tumor cells[33,34].

Chemoresistance to CDK4/6 inhibitors has been reported[133,135]. Analyses of primary tumor cells of cases resistant to CDK4/6 inhibitors showed that these cells lack the tumor suppressor retinoblastoma protein (RB)[133], which is necessary for CDK4/6 control of the cell cycle restriction point[135]. Interestingly, RB-deficient chemoresistant breast cancers, such as RB-deficient triple negative breast cancers, are more sensitive to the metabolic inhibitor of the folate analog family methotrexate and to the anthracycline topoisomerase inhibitor doxorubicin compared to RB+ cell lines[136], indicating that combination therapy may improve CDK4/6 inhibitor response in resistant cases. However, a report by Roberts and colleagues cautioned against the use of these agents in combination with DNA-damaging drugs (*e.g.*, doxorubicin, carboplatin), considering the potential genotoxic side effects[129]. The dangers that may result from such combination also emerged in other pre-clinical studies[137,138].

The CDKI dinaciclib (MK-7965), which selectively binds to the ATP site of CDKs and acts as a protein-protein inhibitor of bromodomains[139,140], also displayed encouraging anticancer properties in pre-clinical studies in human cancer models[141,142]. The drug recently entered phase Ⅲ in leukemia[139] and phase Ⅱ trial in solid cancers. The drug is well tolerated in monotherapy, but revealed an antitumor activity whose efficacy was not superior to the nucleoside metabolic inhibitor capecitabine in a phase Ⅱ trial in advanced breast cancer patients[143]. Comparable observations were reported in non-small cell lung cancer where the drug was compared with the protein kinase inhibitor erlotinib[144]. Similar combination therapy studies in progress for breast cancer[143,144] may provide alternative strategies for breast cancer therapy.

## OTHER EMERGING THERAPEUTIC TARGETS

### *Wnt signaling*

A number of reports have suggested that Wnt signaling pathway, which is normally involved in embryonic induction and cell fate[145,146], is aberrantly activated in blood cancers[147-149] and solid cancers, such as head and neck, lung, gastrointestinal, and breast cancer[27,150-155]. Wnt5a and Wnt11 are major players in macrophage-induced malignant invasion in metastatic breast cancer[27,151], and several breast tumors constitutively release-inducible Wnt ligands[156]. In addition, the naturally occurring pentacyclic triterpenoid ursolic acid, which is known to exert antitumor activity in various solid cancers including breast cancer, may act through inhibition of canonical (Wnt/β-catenin) signaling[150]. Similarly, the natural plant polyphenol rottlerin was reported to inhibit Wnt/β-catenin signaling in cancer cells by promoting the degradation of Wnt co-receptor LRP6 (low density lipoprotein receptor-related protein 6)[157]. Such inhibition resulted in cell death in various cancer cell lines, including MDA-MB-231 and T-47D breast cancer cells. Salinomycin, another novel LRP6 inhibitor, induced comparable effects in breast and prostate cancer cell lines, by inhibiting both Wnt/β-catenin and PI3K/Akt/mTOR signaling[158].

The development of specific Wnt inhibitors is in

progress. Recently, a specific inhibitor of Porcupine (PORCN, an O-acyltransferase required for the secretion of Wnt ligands[159]) termed as LGK974 was developed. LGK974 displayed potent anticancer properties in *in vitro* and *in vivo* models of breast cancer and pancreatic adenocarcinoma mediated by reduction of the transcriptional expression of Wnt target genes[147,160]. However, another recent report revealed that Wnt signaling molecules are differentially expressed in breast cancer clinical subtypes and in cancer stem-like cells, indicating that the development of more specific Wnt-targeted therapies in breast cancer may be necessary[161]. Wnt signaling was also reported a major role in malignant cell acquired resistance to classical chemotherapy, including resistance to tamoxifen[162], and in chemoresistant cells from triple negative breast cancer patients[163], suggesting the potential of Wnt inhibitor combination therapies.

### Shh signaling

Early studies have suggested that Sonic Hedgehog (Shh) overexpression, mediated by both NF-κB up-regulation and *shh* promoter hypomethylation in breast cancer[164], is a critical event in the development of various solid cancers[165-167]. For instance, Shh signaling was reported to promote the survival of cancer epithelial cells, but not their normal counterparts[168]. Targeting of Shh transcription activator Gli1 enhanced apoptosis and attenuated migration in inflammatory breast cancer cells[169]. In addition, Shh non-classical activation was reported as a multidrug resistance enhancer, including resistance to Smo inhibitors[170], suggesting that targeting these pathways specifically may abrogate the associated chemoresistance.

Smo inhibitor anticancer drug cyclopamine, which inhibits Shh signaling by antagonizing its downstream target Smo, is metabolically stable and is currently investigated for the treatment of various cancers[171-173]. The chemotherapy drug paclitaxel used in combination with cyclopamine was shown to antagonize chemoresistant breast cancer cells both *in vivo* and *in vitro*[174], suggesting Shh signaling as a candidate for targeted therapy in chemoresistant cancer cells. Similarly, cyclopamine also sensitized chemoresistant tumor cells to taxane drugs in ovarian cancer[175], another hormone-related cancer. Not surprisingly, Shh targeting was reported as a therapeutic option in endocrine-resistant breast cancer due to its ability to sensitize PI3K/AKT signaling-induced tamoxifen chemoresistant malignant cells[176].

Notably, ER-α physiologically regulates non-canonical Shh signaling in the mammary gland, and is essential for mammary gland morphogenesis at puberty[177,178]. However, Gli1 expression also enhances migration and invasion of malignant cells in ERα-negative and triple negative breast cancers, where it represents a predictor of poor prognosis[179]. These observations indicate that Shh signaling involvement in breast cancer cells is complex and therefore targeting Shh in chemoresistant cancer therapy can also compromise its normal physiological function.

## FUTURE DIRECTIONS: PERSONALIZED-BASED THERAPY AND EPIGENETIC TARGETS

### Personalized-based therapy

The major challenges in breast cancer treatment include resistance to chemotherapy, hormone therapy and even targeted therapy (Table 1), which underline the need for developing novel targeted therapies. Although the main molecular events driving cancer involve the activation of proto-oncogenes or the inactivation of tumor suppressors, deregulation of various signaling intermediates and metabolic factors have been well documented[72,77,82,83,149,161]. The events triggering cancer development affect proto-oncogenes such as Notch, Wnt, and Shh, which are the developmental genes driving embryonic induction and organogenesis during fetal life. These genes, whose expression is normally transcriptionally reduced or silenced in most adult tissues (except stem-like cells) by regulator molecules, are aberrantly overexpressed in cancer cells, conferring them stem-like properties[72,77,82,83,149,161].

Concomitantly, neoplastic tissue growth is fuelled by the upregulation and overexpression of receptors such as HER2, ER and, IGF-1R[70,71,180], the upregulation and/or activation of signaling molecules associated with cell proliferation[111,112], cell migration[181,182], oxidative stress, hypoxia and neoangiogenesis[22,26], all which are characteristic of tumor microenvironment. Thus, the complete characterization of all these tumor promoting events will pave the way for the development more efficient and less toxic anticancer drugs. Computational causal network models aimed at improving the current understanding of signaling molecule interactions in breast cancer, which will allow the determination of specific subsets of patients susceptible to a given therapeutic approach, are currently in development[156,183]. Although the complexity of such networks makes this effort challenging, nonetheless, the development of such tool would allow implementation of a highly efficient personalized-based therapy in breast cancer.

### Epigenetic changes drive tumorigenesis

Epigenetics describes heritable alterations in gene expression patterns that do not alter the primary DNA sequence, but play critical roles in normal differentiation and development. Epigenetic alterations include modifications such as DNA methylation, histone modifications and nucleosome remodeling. The plasticity and reversibility of epigenetic events enable a better control of the dynamism of cellular processes. However, deregulation of the normal epigenetic patterns can lead to aberrant expression of cell growth regulatory genes that can culminate in cancer. Epigenetic factors affect gene expression both pre- and post-transcriptionally and probably account for the high inter-individual variability in clinical course and treatment outcome of both blood and solid cancers[184,185]. There is ample evidence linking

**Table 1 Current therapeutics for breast cancer**

| Drug | Trade name | Class | Anticancer mechanism |
|---|---|---|---|
| Classical chemotherapy | | | |
| Methotrexate | Abitrexate®, Mexate®, Folex® | Antimetabolites, folate analogs | Folate receptor competitive antagonist[218] |
| 5-fluorouracil | Adrucil®, Efudex®, Fluoroplex®, prodrug capecitabine/Xeloda® | Antimetabolite, pyrimidine analogs | Inhibition of the phosphatase and tensin homolog thymidylate synthase[219] |
| Gemcitabine hydrochloride | Gemzar® | | |
| Doxorubicin hydrochloride | Adriamycin® | Anthracycline | Deoxyribonuclease inhibitor[220] |
| Epirubicin hydrochloride | Ellence® | | |
| Pamidronate disodium | Aredia® | Nitrogen-containing bisphosphonate | Inhibition of farnesyl pyrophosphate synthase activity[221] |
| Cyclophosphamide | Clafen®, Cytoxan®, Neosar® | Nitrogen mustard alkylating agent | Inhibition of DNA replication by interacting with the alkyl group of DNA guanine base[222] |
| Paclitaxel | Abraxane® Taxol® | Taxanes | Microtubule Inhibitors[223,224] |
| Docetaxel | Docecad®, Taxotere® | | |
| Ixabepilone | Ixempra® | Epothilone B analog | |
| Targeted therapy | | | |
| Everolimus | Afinitor® | mTOR inhibitor | Silencing of PI3K/Akt/mTOR signaling[225] |
| Trastuzumab | Herceptin® | HER2 inhibitor | Anti-HER2 monoclonal antibodies[226,227] |
| Pertuzumab | Perjeta® | | |
| Ado-Trastuzumab Emtansine | Kadcyla® | Antibody-drug conjugate | HER2 inhibitor and cytotoxic agent[228] |
| Lapatinib ditosylate | Tykerb® | Dual tyrosine kinase inhibitor | EGFR/HER2 inhibitor[229] |
| Hormone therapy | | | |
| Toremifene | Fareston® | Selective ER modulator | Silence ER signaling[230,231] |
| Fulvestrant | Faslodex® | ER antagonists | |
| Tamoxifen citrate | Nolvadex® | | |
| Anastrozole | Arimidex® | Aromatase inhibitors | Inhibit estrogen synthesis[232-234] |
| Exemestane | Aromasin® | | |
| Letrozole | Femara® | | |
| Goserelin acetate | Zoladex® | GnRH agonist | |
| Megestrol acetate | Megace® | Progesterone derivative | Progestational and antigonadotropic effects[235] |

the etiology of breast to abnormal genetic and epigenetic events[180,186,187]. Cancer-specific DNA methylation changes and well as dysregulation of histone modification have been characterized as contributors to breast cancer development. Progress in our understanding of epigenetics mechanisms in breast cancer have led to the identification of novel therapeutic targets. Recent therapeutic strategies involving the use of epigenetic agents alone or in combination with chemotherapy and/or endocrine therapy are showing promising results in breast cancer patients including chemoresistant cases[186,188].

The technological breakthrough of "omics era" has allowed the development of high-throughput sequencing technology allowing both global and comprehensive investigations of the interactome, the epigenome, and the transcriptome (*i.e.*, active signaling pathways, cascades of pre- and post-translational changes affecting specific genes, and changes in gene expression)[189-191] at individual level. Epigenetic alterations in cancer constitute appealing therapeutic targets due to their pivotal roles in disease initiation, progression, and chemoresistance, and to their reversibility. For instance, chemoresistance to the ER antagonist fulvestrant is mediated by epigenetic modulation (more specifically hSWI/SNF-mediated chromatin remodeling) of GPER and CDK6 expression[192], suggesting that adjuvant therapy targeting SWI/SNF activity may induce apoptosis in resistant cancer cells. SWI/SNF tumor-dependency has also been reported in other solid cancers and in leukemias[193,194].

**Epigenetic targets in breast cancer:** histone deacetylation and DNA hypermethylation

Studies have shown that the transcriptional expression of various signaling molecules associated with breast cancer and other cancers may result from selective epigenetic silencing of regulator genes mediated by histone deacetylation and gene promoter (DNA) hypermethylation[195-197], among other potential epigenetic mechanisms[186,198]. For instance, the reduction in ER expression observed in various chemoresistant breast tumors may be mediated by epigenetic silencing (*e.g.*, *erβ1* silencing)[199]; and some histone deacetylases (HDACs) such as HDAC3/8 were reported to play pivotal regulatory roles in the proliferation of normal and MDA-MB-231 cells[200].

Data from numerous pre-clinical *in vivo* and *in vitro* studies support the potential of DNA methylation status targeting in breast cancer. Both the HDAC inhibitor (HDACI) trichostatin A and the DNA methyltransferase (DNMT) inhibitor (DNMTI) deoxycytidine (5-aza-2'-deoxycytidine) induced apoptosis in various breast cancer cell lines[201-205]. The HDACI Romidepsin (FK-288) eliminated both primary and metastatic tumors in combination with Paclitaxel in the Mary-X pre-clinical model of inflammatory breast cancer[206]. The green tea-derived

anticancer molecule epigallocatechin-3-gallate suppressed invasiveness in MDA-MB-231 and MCF-7 breast cancer cells by silencing matrix metalloproteinase 2 (MMP2) and MMP-9 and inducing TIMP-3 through increased activities of the enhancer of zeste homolog 2 and HDACs[207]. Suberoylanilide hydroxamic acid, another naturally occurring HDACI, restored radiosensitivity and suppressed breast cancer lung metastasis *in vitro* and *in vivo*[208].

The HDACI Vorinostat sensitized mesenchymal-like triple-negative breast cancer cell lines to hormone therapy by reactivating ERα[209] and PI3K/Akt/mTOR signaling sensitivity[210], corroborating the role of epigenetic alterations in chemoresistance development in breast tumors. Furthermore, the HDACI abexinostat induced cancer-like stem cells differentiation in 16 breast cancer cell lines[211]. Because of these interesting observations, the HDACIs belinostat, panobinostat, and vorinostat, previously used only in blood cancers, have entered phase I and Ⅱ clinical trials in solid tumors, such as lung, prostate, gastrointestinal, ovarian and breast cancer, where they are showing encouraging results (for review see[212]). Various DNMTI are also showing encouraging responses in metastatic and chemoresistant breast cancers in monotherapy and in combination therapies in phase I and Ⅱ trials[213-217].

## CONCLUSION

Targeted therapies are associated with reduced adverse effects and better outcome. Tumor microenvironment cells such as cancer-associated fibroblasts and tumor-associated macrophages undergo aberrant genetic and epigenetic changes that trigger the overexpression of signaling molecules promoting neoplasia and neoplastic tissue survival. Many therapeutic targets have emerged. They include Notch, CDKs, mTOR, Wnt, and Shh, whose inhibitors are showing promising results in ongoing clinical trials, both in monotherapy and in combination therapy. Similarly, epigenetic drugs are also showing encouraging results in breast cancer, particularly in advanced and chemoresistant cases. New technological advances will enable the identification of precise alterations affecting the interactome, transcriptome, and the epigenome, leading to the design of more specific tailored therapies. Such therapeutic approach may also be beneficial in the treatment of chemoresistant breast cancers.

## Abstract

*Acinetobacter baumannii* (*A. baumannii*) is undoubtedly one of the most successful pathogens in the modern healthcare system. With invasive procedures, antibiotic use and immunocompromised hosts increasing in recent years, *A. baumannii* has become endemic in hospitals due to its versatile genetic machinery, which allows it to quickly evolve resistance factors, and to its remarkable ability to tolerate harsh environments. Infections and outbreaks caused by multidrug-resistant *A. baumannii* (MDRAB) are prevalent and have been reported worldwide over the past twenty or more years. To address this problem effectively, knowledge of species identification, typing methods, clinical manifestations, risk factors, and virulence factors is essential. The global epidemiology of MDRAB is monitored by persistent surveillance programs. Because few effective antibiotics are available, clinicians often face serious challenges when treating patients with MDRAB. Therefore, a deep understanding of the resistance mechanisms used by MDRAB can shed light on two possible strategies to combat the dissemination of antimicrobial resistance: stringent infection control and antibiotic treatments, of which colistin-based combination therapy is the mainstream strategy. However, due to the current unsatisfying therapeutic outcomes, there is a great need to develop and evaluate the efficacy of new antibiotics and to understand the role of other potential alternatives, such as antimicrobial peptides, in the treatment of MDRAB infections.

**Key words:** *Acinetobacter baumannii*; Antibiotic resistance; Epidemiology; Genomics; Infection control

**Core tip:** With the current rapid increase in the numbers of studies on Acinetobacter baumannii (*A. baumannii*), the complexity of the entire picture regarding how this superbug copes with its environment and influences human beings is gradually being understood. By conducting a thorough review of this topic, this paper aims to present the relevant literature regarding the antimicrobial resistance of *A. baumannii* and the currently available treatment options for *A. baumannii* infections to highlight possible future research directions.

## INTRODUCTION

### Species identification and current taxonomy

*Acinetobacter spp.* are glucose-non-fermentative, non-motile, non-fastidious, catalase-positive, oxidase-negative, aerobic Gram-negative coccobacilli[1]. Since 1986, the taxonomy of the genus *Acinetobacter* has been modified several times. Currently, the original single species clas-

sification of *Acinetobacter calcoaceticus (A. calcoaceticus)* has been abandoned, and at least 34 genomic species can be distinguished within the genus *Acinetobacter*, 23 of which have been assigned species names[2]. The challenge in the taxonomy of *Acinetobacter* is due to the clusters of closely related species that are difficult to distinguish using phenotypic traits and chemotaxonomic methods. The *A. calcoaceticus-Acinetobacter baumannii (A. baumannii)* complex, comprising *A. calcoaceticus*, *A. baumannii*, and the genomic species 3 and 13TU, is the most well-known example[3]. Because the antibiotic susceptibilities and clinical relevance of the different genomic species are significantly different[4-7], genomic methods for *Acinetobacter* species identification are necessary. A number of genomic fingerprinting methods have been proposed, including pulsed-field gel electrophoresis (PFGE); ribotyping; polymerase chain reaction (PCR)-based fingerprinting techniques, such as random amplified polymorphic DNA analysis; repetitive extragenic palindromic sequence-based PCR (rep-PCR); amplified ribosomal DNA restriction analysis; RNA spacer fingerprinting; and amplified fragment length polymorphism analysis[8]. In addition, new methods, such as 16S-23S ribosomal intergenic spacer, 16S rRNA gene, *rpoB* gene and *gyrB* gene sequence analyses, have been developed for *Acinetobacter* species identification[9,10].

### Common typing methods in outbreak investigations

Of all of the *Acinetobacter* species, *A. baumannii* is the most important member associated with infections in clinical practice and causes most of the reported outbreaks. In addition to chart review and statistical epidemiology, some DNA fingerprinting methods are valuable in outbreak investigations and strain discrimination. Rep-PCR, PFGE, and multilocus sequence typing (MLST) have all been used in previous studies. Rep-PCR has been proven to be a useful and expedient method for the epidemiological characterization of *A. baumannii* nosocomial outbreaks[11]. Rep-PCR has also been used as a tool for determining species lineages of *A. baumannii* in a hospital[12] and for differentiating pan-European, multi-resistant *A. baumannii* clone Ⅲ from clones Ⅰ and Ⅱ[13]. Despite the inter-laboratory variability of rep-PCR, this method has the advantage of being faster to perform than PFGE and MLST. The intra-laboratory clustering of *A. baumannii* has been shown to be well conserved[14] and to correlate well with PFGE[15] or MLST results[16], demonstrating the robustness of rep-PCR. We have found one rep-PCR major cluster (84%) of *A. baumannii* carrying a class I integron that spread among four regional hospitals in northern Taiwan[17]. However, PFGE is still considered the gold standard for typing outbreak-related isolates of *A. baumannii*[18-21], whereas MLST provides a high level of resolution and is an excellent tool for studying the population structure and long-term epidemiology of *A. baumannii*[22]. Recently, the *A. baumannii* MLST database (http://pubmlst.org/abaumannii/) was developed for the BIGSdb genomics platform[23] to assist the broader community in elucidating the structure and function of this microorganism.

### Clinical manifestations

*A. baumannii,* named after Paul Baumann, is ubiquitous in soil and water[24]. Previously, *A. baumannii* was regarded as a low-virulence commensal bacterium. However, it has become a successful pathogen[25] and has emerged as a major cause of healthcare-associated infections, most of which have occurred in critically ill patients in the intensive care unit (ICU) setting[26]. In recent decades, infections caused by *A. baumannii* have also occurred outside the ICU or in trauma patients after natural disasters, and they have even affected patients with co-morbidities in the community[27]. Reports of community-acquired *Acinetobacter* infections have increased over the past decade[28]. Several different types of infections, including pneumonia, urinary tract infections, bacteremia, wound infections and even meningitis, are caused by this organism[29]. These infections often occur in older patients, many of whom have chronic underlying diseases and have previously received antimicrobial treatment[30,31]. The mortality of patients with *A. baumannii* infections in hospitals and in the ICU has ranged from 7.8% to 23% and from 10% to 43%, respectively[32].

### Risk factors

In recent years, many studies have reported the risk factors for acquiring *A. baumannii* infections and have particularly focused on those caused by multidrug-resistant strains. The acquisition of MDRAB is related to multiple factors, including environmental contamination and contact with transiently colonized healthcare providers[33]. The independent risk factors for the acquisition of imipenem-resistant *A. baumannii* (IRAB) include a hospital size of > 500 beds, previous antimicrobial treatment, a urinary catheter, surgery[34], previous ICU stay, and prior exposure to imipenem or third-generation cephalosporins[35]. The only significant independent risk factor for the appearance of imipenem-resistant multidrug-resistant *A. baumannii* (MDRAB) in patients formerly infected with imipenem-susceptible MDRAB is imipenem or meropenem exposure[36]. For extensively drug-resistant *A. baumannii* (XDRAB) infections, the prior use of imipenem, meropenem, piperacillin/tazobactam or fourth-generation cephalosporins and > 30 d of being bedridden have been found to be independent risk factors[37]. A systematic review concluded that the acquisition and spread of *A. baumannii* appeared to be related to a large number of variables, the most important of which were deficiencies in the implementation of infection control guidelines and the use of broad-spectrum antibiotics[38].

The risk factors that are associated with *A. baumannii* bacteremia are immunosuppression, unscheduled hospital admission, respiratory failure at ICU admission, previous antimicrobial therapy, previous sepsis in the ICU, and the invasive procedures index[39]. Resistance to carbapenems, mechanical ventilation, and the presence of malignancy have also been found to be associated with high mortality rates in patients with *A. baumannii* bacteremia[40].

Regarding ventilator-associated pneumonia caused by *A. baumannii*, the risk factors include neurosurgery, adult respiratory distress syndrome, head trauma, and large-volume pulmonary aspiration[41]. Because various studies showed certain differences in the risk factors of acquiring drug-resistant *A. baumannii* bacteremia or pneumonia[42-46], a separate investigation should be performed in each hospital setting to limit the spread of this pathogen[38].

### Virulence factors

Previously, *A. baumannii* was regarded as a low-grade pathogen; however, it contains virulence factors that enhance its bacterial toxicity and pathogenicity. A combined approach of genomic and phenotypic analyses led to the identification of several virulence factors, including extracellular components with hemolytic, phospholipase, protease and iron-chelating activities, biofilm formation, surface motility, and stress resistance[47]. The biofilm formation of *A. baumannii* facilitates its attachment to abiotic and biotic surfaces[48], including those of medical devices and host tissues. The initiation and maturation of biofilms are related to pilus assembly and the production of the biofilm-associated protein (Bap), which is regulated by the two-component system BfmRS[49]. The Bap protein plays a role in adhesion to human epithelial cells[50], and the inhibition of this protein can prevent *A. baumannii* infection[51]. In fact, in a multicenter cohort study, all catheter-related urinary or blood stream infections due to *A. baumannii* were caused by biofilm-forming strains[52]. A 2D proteomic analysis of pellicle-forming *A. baumannii* isolates showed that overexpression of CarO, which is an OprD-homolog, siderophore iron uptake, and pili systems are involved in the development of biofilms[53].

Iron uptake systems are essential to the survival and pathogenicity of bacteria, especially in the low-iron environment of the human host. *A. baumannii* grown under iron-limited conditions undergo major transcriptional changes of not only many iron acquisition-related genes but also of genes involved in motility[54]. *A. baumannii* is well-equipped with metal homeostatic systems that are required for the colonization of a diverse array of tissues[55]. Genome investigations have revealed wide distributions of endogenous siderophores in clinical *A. baumannii* isolates, arguing for their role in pathogenic capabilities[47]. The zinc acquisition system has also been found in *A. baumannii,* which is required for efficient zinc uptake *in vitro* and full pathogenesis *in vivo*[56].

*A. baumannii* adheres to human bronchial epithelial cells *in vitro*, and its prevalent European clone Ⅱ has a relatively high capacity for adhering to these cells[57]. Additionally, the K1 capsular polysaccharide has been shown to prevent *A. baumannii* from being phagocytized by macrophages, to optimize its growth in human ascites fluid and serum, and to enhance its survival in a rat soft tissue infection model[58]. Moreover, several proteins have been implicated as possible virulence factors in *A. baumannii*. Omp38 induces the apoptosis of host cells[59], the absence of the RecA protein decreases survival in response to both heat shock and desiccation[60], and the inactivation of phospholipase D diminishes *A. baumannii* pathogenesis[61]. Importantly, the outer membrane protein A of *A. baumannii* (AbOmpA) is the most abundant surface protein that has been associated with the apoptosis of epithelial cells through mitochondrial targeting[62]. AbOmpA is also the major nonspecific channel in *A. baumannii* and appears to be essential for this organism's high levels of intrinsic resistance to a number of antibiotics[63]. *A. baumannii* can rapidly develop resistance to polymyxin antibiotics through the loss of the lipid A component of lipopolysaccharide[64], which subsequently alters the expression of critical transport and biosynthesis systems associated with modulating the composition and structure of the bacterial surface[65].

## GLOBAL EPIDEMIOLOGY

Two key factors contributing to the significant and ubiquitous dissemination of *A. baumannii* in hospitals are the extent of its antimicrobial resistance and its environmental resilience[66]. The extent of antimicrobial resistance is more severe in *A. baumannii* isolates from patients in Asian and European ICUs than from patients in American ICUs[27], and significant increases in antimicrobial resistance were noted worldwide from 2004 to 2009. The highest resistance rates in 2009 were for ceftriaxone (83.6%), piperacillin-tazobactam (82.0%), and ceftazidime (80.3%) in the Middle East. Increases in resistance were noted for all antimicrobials in isolates collected from the Asia-Pacific Rim, ranging from a 19.1% increase in ceftazidime resistance to a 38.9% increase in levofloxacin resistance. Resistance also increased significantly in Africa (including piperacillin-tazobactam, ceftriaxone, cefepime, amikacin, meropenem, and levofloxacin resistance) and Europe (including piperacillin-tazobactam, ceftriaxone, ceftazidime, levofloxacin, amikacin, minocycline, meropenem, and cefepime resistance)[67].

The first MDRAB isolate resistant to almost all available antibiotics in Taiwan was discovered in 1998[68]. Since then, many MDRAB outbreaks have been reported in Taiwan[69-72]. A Taiwanese surveillance report of antimicrobial resistance in 2000 found that 73% of *A. baumannii* isolates collected from 21 medical centers and regional hospitals were ceftazidime-resistant[73]. Another study conducted during the same year at five major teaching hospitals in Taiwan showed that as many as 22% of *A. baumannii* isolates were not susceptible to imipenem[74]. In 2012, the Taiwan Surveillance of Antimicrobial Resistance program showed that the prevalence of the IRAB complex increased from 3.4% in 2002 to 58.7% in 2010 and that of the XDRAB complex increased from 1.3% in 2002 to 41.0% in 2010[75]. In addition, the proportion of healthcare-associated infections caused by carbapenem-resistant *A. baumannii* (CRAB) significantly increased, compared to infections by all *A. baumannii*, from 14% in 2003 to 46% in 2008 in Taiwan[76]. The local spread of MDRAB has been demonstrated in five proximal hospitals in northern Taiwan, with resistance determinants

distributed widely in clonal and non-clonal isolates[77].

In addition to its prevalence in Taiwan, MDRAB is also prevalent in hospitals in many areas of the world, including Korea[78], Belgium[79], Italy[80], Iraq[81], Israel[82], Greece[83] and America[84]. Furthermore, a one-year study demonstrated that three clones of MDRAB had spread in hospitals in Brazil[85]. In a single institution in Queensland, Australia, sequence type 92 (ST92) was the dominant sequence type and was present for 9 years[86]. Additionally, clonal dissemination among three hospitals located in two different cities has been documented in China, indicating the epidemic potential of MDRAB[87]. Both inter-institutional and intra-institutional transmission of a strain of *A. baumannii* is possible[15]. Several multidrug-resistant clones can coexist endemically in one hospital for several years[31,88], and the same clones often spread on a small scale within a short period of time[31] or can be detected during an outbreak by a close survey of epidemic sources[88]. Furthermore, such outbreaks can occur across national boundaries. For example, Wybo *et al*[89] reported a MDRAB nosocomial infection involving approximately 20 patients in a university hospital in Belgium that was the result of a transfer of two patients from Greece.

In addition to the increasing importance of MDRAB in nosocomial infections, the increasing reports of outbreaks caused by CRAB in recent years have become another frightening reality. The imipenem resistance rate of *A. baumannii* from a worldwide collection between 2005 and 2009 reached resistance rates of greater than 50%[90]. In Brooklyn, New York, citywide surveillance revealed that about 2 of every 3 isolates were resistant to carbapenem antibiotics[91]. One predominant strain type of CRAB has established predominance after being introduced in a university hospital in Chicago in 2005[21]. In addition, molecular epidemiological investigations of sequential outbreaks of *A. baumannii* in an ICU showed the emergence of carbapenem resistance in Italy from 1999 to 2002[19]. The clonal spread of imipenem-resistant *Acinetobacter* spp. accompanied by the wide dissemination of the OXA-23 carbapenemase has been noted in China[92]. The first CRAB outbreak was reported in America in 1991, followed by global CRAB dissemination[93]. Most outbreaks caused by CRAB have occurred in ICU settings[29,94] throughout many countries. An outbreak caused by pandrug-resistant *A. baumannii* (PDRAB) was also reported in a pediatric ICU in a Taiwanese hospital[95].

## COMPARATIVE GENOMICS

In recent years, whole-genome sequencing and comparative genomics have been performed to elucidate the genetic basis of *A. baumannii* resistance, especially regarding the extent of variability and the acquisition and transfer of resistance determinants among different strains. The *A. baumannii* strain AYE, an endemic strain in France, exhibits an 86-kb resistance island in which 45 resistance genes are clustered[96]. Sequence similarities and phylogenetic analyses confirm that most of the resistance genes found in the *A. baumannii* AYE strain have been acquired from bacteria of the genera *Pseudomonas*, *Salmonella*, or *Escherichia*. Using pyrosequencing and transposon mutagenesis, the assembled genome of *A. baumannii* ATCC 17978 has been shown to consist of 3976746 base pairs (bp) and 3830 open reading frames (ORFs), a significant fraction (17.2%) of which are located in 28 putative alien islands[97]. A remarkable number of the islands contain genes implicated in virulence. *A. baumannii* ACICU has a single chromosome of 3904116 bp and two plasmids, pACICU1 and pACICU2, of 28279 and 64366 bp, respectively[98]. As many as 36 putative alien islands (pAs), 15 of which encode genes related to drug resistance, have been detected in the *ACICU* genome. One investigation involving MDRAB strains from hospitals of 10 European countries showed that AbaR3 is the original structure from which the AbaRs, the genomic islands containing many resistance genes, have been derived in European clone I, thus providing the strains of this lineage with a selective advantage[99]. All of these findings indicate that the genome of *A. baumannii* has acquired a large amount of foreign DNA, which has an important role in pathogenesis and antimicrobial resistance.

Currently, the whole-genome sequencing of the widely spread MDRAB strain MDR-ZJ06[100]; an MDR-TJ[101] strain in China; and two other multidrug-resistant strains (TCDC-AB0715, harboring both *bla*$_{\text{OXA-23}}$ and *bla*$_{\text{OXA-66}}$[102], and TYTH-1[103] from Taiwan) has been completed. A comparative genomics analysis has revealed a common strain lineage between the Taiwanese strains (TYTH-1 and TCDCAB0715) and the Chinese strains (MDR-TJ and MDR-ZJ06)[104]. Phylogenetic studies and GC profiles showed that the genome of TYTH-1 was the closest to the genome of MDR-ZJ06, which implies that the dissemination of *bla*$_{\text{OXA-23}}$-carrying CRAB in Taiwan may have been mediated by the transfer of people between Taiwan and China.

Adams *et al*[105] found that the entire multidrug-resistance phenotype of *A. baumannii* can be explained by the acquisition of discrete resistance determinants distributed throughout the genome. A comparison of closely related multidrug-resistant and drug-susceptible isolates suggests that drug efflux may contribute less to the resistance to certain classes of antibiotics than inactivation of enzymes. A resistance island with a variable composition of resistance determinants interspersed with transposons, integrons, and other mobile genetic elements is a significant contributor to the multidrug-resistant phenotype. A whole-genome sequencing analysis of six closely related clinical isolates of *A. baumannii*, including four from one hospital, revealed an extensive divergence of the resistance genotype that correlated with the observed differences in antimicrobial susceptibility[106]. Resistance genes associated with insertion sequences, plasmids, and a chromosomal resistance gene island all showed certain degrees of variability. The dynamic resistance gene pool suggests the rapid evolution of drug resistance in *A. baumannii*. The whole-genome sequencing of three dominant *A. baumannii* strains in an outbreak concluded that

much of their diversification was mediated by homologous recombination across 20% of their genomes[107]. The differences in genomic contents among different *Acinetobacter* spp. are partly shaped by their distinct ecological niches[108]. This notion is further supported by the variable presence of some genes encoding transcription factors and transporters among clinical isolates and their environmental *Acinetobacter* spp.[105].

## RESISTANCE MECHANISMS

### Overview

Currently, centain strains of *A. baumannii* is highly resistant to most antibiotics available in clinical practice. A number of resistance mechanisms to many classes of antibiotics are known to exist in *A. baumannii*, including β-lactamases, multidrug efflux pumps, aminoglycoside-modifying enzymes, permeability defects, and the alteration of target sites[109-111]. Most of these resistance mechanisms can target different classes of antibiotics. However, several different mechanisms can work together to contribute to the resistance to a single class of antibiotics. For example, the resistance mechanisms in CRAB are diverse[112]. In addition to β-lactamases with carbapenem-hydrolyzing activity as a major carbapenem resistance mechanism, which include carbapenem-hydrolyzing class D β-lactamases (CHDLs) and metallo-β-lactamases (MBLs), porins such as CarO[66] and penicillin-binding protein modifications might also be involved in carbapenem resistance[113]. The spread of multidrug-resistance determinants in *A. baumannii* is mostly through plasmid conjugation, transposon acquisition or integron mobilization to gain clusters of genes encoding resistance to several antibiotic families[110]. Furthermore, the functional insertion sequences are important in amplifying antimicrobial resistance and gene plasticity[114-118]. Table 1 shows the various antimicrobial resistance mechanisms of *A. baumannii*. The details are further discussed below.

### β-lactamase

Inactivation of β-lactams constitutes an important part of multidrug resistance in *A. baumannii*, especially for β-lactam antibiotic resistance. All four Ambler classes of β-lactamases (*i.e.*, classes A, B, C and D) can be identified in this organism[66]. Although a wide range of class A β-lactamases, including those of temoneira (TEM)[119-121], sulfhydryl variable (SHV)[122], cefotaxime hydrolyzing capabilities (CTX-M)[123,124], guiana extended-spectrum (GES)[115,125], self-transferable plasmid from *E. coli* (SCO)[126], *Pseudomonas* extended resistant (PER)[127-130], vietnam extended-spectrum β-lactamase (VEB)[96,131-133], carbenicillin hydrolyzing β-lactamase (CARB)[134,135] and *K. pneumoniae* carbapenemase (KPC)[136], have been reported in *A. baumannii* (Table 1), they are generally regarded to play a minor role in its resistance phenotype, especially in carbapenem resistance. Some of these enzymes are narrow-spectrum β-lactamases, *e.g.*, TEM-1[119-121], SCO-1[126] and CARB-4[135]; however, a number of these enzymes are still responsible for the hydrolysis of extended-spectrum β-lactams (ESBL). PER-1 was the first ESBL enzyme identified in *A. baumannii*[137], whereas TEM-92 and CARB-10 were the first reported TEM-type[120] and CARB-type[134] ESBLs, respectively. Later, the chromosomally encoded ESBLs SHV-5[122], PER-2[132] and PER-7[129,130] were also described. *A. baumannii* strains carrying the extended spectrum VEB-1 enzyme were first reported in an outbreak in France[131]. GES-11, an integron-associated GES variant, can even confer reduced susceptibility to carbapenems[115,125]. In addition, CTX-M enzymes are transmitted by integrons or plasmids, indicating the potential dissemination in outbreaks between different strains[123, 124]. Finally, KPC-10 was the first KPC β-lactamase to be identified[136].

Class B β-lactamases can confer resistance to the majority of β-lactams because of their broad range, potent carbapenemase activity and resistance to inhibitors[138]. Although MBLs are not the predominant carbapenemases in *A. baumannii*, verona integron-encoded metallo-β-lactamase (VIM), imipenemase (IMP) and seoul imipenemase (SIM) MBLs have been found contribute to the high-level resistance to carbapenems. The first VIM enzyme was described by Yum in 2002[139]. Thereafter, several other VIM variants, including VIM-1[140-142], VIM-3[143], VIM-4[141,142], and VIM-11[143], were identified in *A. baumannii*. IMP enzymes have also been reported in several Gram-negative bacteria worldwide, including *A. baumannii*. At least nine variants of IMP enzymes have been identified in *A. baumannii*: IMP-1[144], IMP-2[145], IMP-4[146,147], IMP-5[148], IMP-6[149], IMP-8[143], IMP-11[150], IMP-19[150] and IMP-24[143]. SIM-1 is the only SIM enzyme that has been reported in *A. baumannii*[151]. More recently, NDM (new Deli metallo-β-lactamase)-1[152-154] and NDM-2[155] were observed in *A. baumannii*. *bla*$_{NDM-1}$ is integrated in the chromosome within a new transposon structure with two copies of the insertion sequence IS*Aba125* in one clinical strain of *A. baumannii*. Such variability of the genetic environment of *bla*$_{NDM-1}$ likely facilitates its rapid dissemination[153].

The nucleotide sequence of the chromosomal cephalosporinase gene, which encodes an AmpC β-lactamase, in *A. baumannii* was first characterized in a clinical isolate from Spain in 2000[156]. Different isolates of *A. baumannii* have been shown to have almost identical AmpC sequences (no more than two amino-acid substitutions)[157]. A phylogenetic analysis showed that *Acinetobacter ampC* genes are descended from a common ancestor and are more closely related to each other than the *ampC* genes found in other species of bacteria[158]. The class C chromosomal β-lactamase AmpC in *A. baumannii* has a typical cephalosporinase substrate profile[156]. The presence of AmpC β-lactamase plays an important role in β-lactam resistance in *A. baumannii*, and in fact, a high percentage of drug-resistant *A. baumannii* possess *bla*$_{ampc}$[119]. In a study of 23 MDRAB clinical isolates from five proximal hospitals in Taiwan, all isolates had AmpC-type *bla*[77]. The presence of an insertion sequence with a strong promoter upstream of *ampC* in *A. baumannii* clinical isolates has the potential to overexpress AmpC, resulting in high-

**Table 1 Antimicrobial resistance mechanisms in *Acinetobacter baumannii***

level ceftazidime resistance[159,160]. IS*Aba1*-like sequences have been identified immediately upstream of the *bla*$_{ampC}$ gene in ceftazidime-resistant *A. baumannii* isolates but have been shown to be absent in ceftazidime-susceptible *A. baumannii* isolates[157].

Class D β-lactamases were designated OXAs in reference to their preferred substrate oxacillin[161]. Some OXAs are also able to hydrolyze extended-spectrum cephalosporins, and some can even inactivate carbapenems by acting as carbapenemases[66]. At least 121 different variants of class D β-lactamases have been identified at the protein level, and in contrast to other class D β-lactamases, 45 of these variants exhibit carbapenem-hydrolyzing activities[162]. The *bla*$_{oxa}$ genes can be located either on a chromosome or a plasmid and can sometimes be found in integrons[163,164]. Among the four classes of β-lactamases, MBLs and CHDLs are the two main groups of carbapenemases in *A. baumannii*, the latter of which is responsible for the most common type of carbapenem resistance *via* enzymatic degradation[165]. Currently, nine major subgroups of OXA carbapenemases have been identified based on amino acid homologies[166]. Four subgroups of OXA with carbapenemase activity, including the OXA-23, OXA-40/24, OXA-51 and OXA-58 clusters, are prevalent in *A. baumannii*[162,166].

New OXA-type carbapenemases have been frequently discovered since the first clinical isolate of *A. baumannii* with OXA-23 was characterized[66]. The *bla*$_{OXA-23}$ carbapenemase gene has also been disseminated worldwide[167]. The countries that have reported *A. baumannii* with OXA-23 carbapenemase include France[168-170], Germany[171], Bulgaria[172], Romania[173], the United States[105], Colombia[174], Brazil[175], Australia[176], Taiwan[177,178], China[92,179], Korea[180], Singapore[147,181], Italy[182] and Spain[183]. *A. radioresistens* has been proposed as a silent source of *bla*$_{OXA-23}$ for *A. baumannii*[184], and a novel variant, named *bla*$_{OXA-133}$, has been reported by the Asia-Pacific SENTRY surveillance program[185].

OXA-51/69-like β-lactamases are intrinsic chromosomal enzymes in *A. baumannii*[166,186] that emerged as a new subgroup of carbapenemases in MDRAB in 2004[187] and that show increased carbapenemase activity when IS*Aba1* is upstream of the promoter region[188,189]. However, drug export by an efflux pump might be more important in some clinical isolates[190]. A comparative genomics study by Adams *et al*[105] showed that the studied *A. baumannii* strains, including wild-type strains and clinical isolates of MDRAB, all possessed genes belonging to the OXA-51 group. The recently identified OXA-51 group of β-lactamases comprises a novel cluster among the OXA-type carbapenemases, and the cluster includes many variant oxacillinases that have been reported in several studies, including those by Heriter in 2005[186], Brown in 2005[191], Turton in 2006[192], Vahaboglu in 2006[193], Koh in 2007[147], Evans in 2007[194], Naas in 2007[122], Tsakris in 2007[195] and Higgins in 2009[196]. The CHDLs that have been found are listed in Table 1.

The OXA-40/OXA-24 CHDL group is made up of OXA-25, OXA-26, OXA-40, and OXA-72 (an original sequencing error occurred in sequencing OXA-24; it is now known as OXA-40)[166]. These enzymes only differ by a few amino acid substitutions. OXA-40/OXA-24 was originally identified as chromosomally encoded in a carbapenem-resistant *A. baumannii* isolate recovered from Spain[197]. OXA-25, OXA-26, and OXA-27 were later characterized to be associated with carbapenem resistance in clinical isolates of *A. baumannii* from Spain, Belgium and Singapore[198]. Thereafter, the OXA-40/OXA-24 gene in *A. baumannii* was reported in several areas[199], including Spain[188,200,201], Portugal[202] and the United States[203]. The plasmid-mediated *bla*$_{OXA-24}$ gene was noted in the isolates from an outbreak in Spain[204]. Additionally, OXA-72 has been identified in *A. baumannii* isolates from Taiwan[205], China[92] and Croatia[206].

OXA-58 was first identified from an isolate of MDRAB in France[207]. The *bla*$_{OXA-58}$ gene was found to be plasmid borne. Many OXA-58-producing *A. baumannii* isolates were reported worldwide in subsequent years, including isolates in Europe[208-211], Argentina[208], Kuwait[208], the United Kingdom[208], Australia[212], Taiwan[116], the United States[213,214] and China[215]. A number of outbreaks have also been reported in many countries, including Italy[216], Belgium[79], France[217], Turkey[193], Greece[218,219], and the United States[214]. OXA58 can lead to high-level carbapenem resistance in *A. baumannii via* the upstream IS*1008* insertion[116] or the presence of the ISAba825-ISAba3-like hybrid promoter[118]. OXA-97 is a point mutation variant of OXA-58 that shares the same hydrolytic properties and has been recently identified in *A. baumannii* isolates from Tunisia[220]. Another point mutation derivative is OXA-96, which was identified in *A. baumannii* from Singapore[147].

In 2009, a novel CHDL, OXA-143, was identified that shares 88% amino acid identity with OXA-40, 63% identity with OXA-23, and 52% identity with OXA-58[196]. Another novel oxacillinase, OXA-182, was identified in imipenem-nonsusceptible *Acinetobacter* isolates in Korea[221] and showed 93% identity with OXA-143 and 89% identity with OXA-40 based on amino acid sequence alignment. OXA-235, and the amino acid variants OXA-236 and OXA-237, were identified from *A. baumannii* isolates from the United States and Mexico[222]. The deduced amino acid sequences shared an 85% identity with OXA-134, 54 to 57% identities with the acquired OXA-23, OXA-24, OXA-58, and OXA-143, and a 56% identity with the intrinsic OXA-51. Thus, OXA-235, OXA-236 and OXA-237 represent a novel subclass of OXAs. The expression of OXA-235 in *A. baumannii* leads to reduced carbapenem susceptibility, while the cephalosporin minimal inhibition concentrations (MICs) are unaffected.

### Multidrug efflux pumps

While multidrug-resistant efflux pumps have been shown to have roles in bacterial pathogenicity[223], the contribution of efflux pumps to bacterial multidrug resistance is often reported[224,225]. Efflux-based mechanisms are responsible for resistance against many different classes of antibiotics, including tigecycline resistance[226,227] or imipenem resistance[190] in *A. baumannii*. Furthermore, the

linear relationship between the log-transformed expression values of the AdeABC efflux pump genes and the log-transformed MIC values is statistically significant, indicating that overexpression of the AdeABC efflux pump is a prevalent mechanism for decreased susceptibility to tigecycline[228]. The importance of efflux pumps in multidrug resistance in *A. baumannii* is supported by the fact that the presence of efflux pump inhibitors, such as 1-(1-naphthylmethyl)-piperazine[229,230], phenyl-arginine-β-naphthylamide[231,232], or carbonyl cyanide 3-chlorophenylhydrazone[232], can reverse the resistance pattern.

Four categories of efflux pumps, including the resistance-nodulation-division (RND) superfamily, the major facilitator superfamily (MFS), the multidrug and toxic compound extrusion (MATE) family and the small multidrug resistance (SMR) family transporters, have been reported to be related to antimicrobial resistance in *A. baumannii*[233,234]. Of these different pumps, the RND and MFS transporters are mentioned most often. AdeABC, a RND-type efflux pump with a three-component structure, is not only associated with aminoglycoside resistance[235] but is also associated with decreasing susceptibility to several antimicrobials, including tigecycline[226]. Differences in the expression of *adeABC* were shown to contribute to both inter- and intra-clone variation in tigecycline MICs in a study of *A. baumannii* epidemic clones[236]. Both the increase in tigecycline resistance during therapy[236] and the decrease in susceptibility to non-fluoroquinolone antibiotics during an outbreak[237] are mediated by the up-regulation of AdeABC in *A. baumannii*. The AdeABC pump in wild *A. baumannii* is cryptic due to stringent control by the AdeRS two-component system[238]. Point mutations in AdeS and AdeR or a truncation of AdeS due to an IS*Aba1* insertion may be related to the overexpression of AdeABC, which leads to multidrug resistance[238,239]. However, the existence of tigecycline-nonsusceptible and *adeB*-overexpressing *A. baumannii* clinical isolates without known *adeRS* mutations[240] and the low expression of *adeABC* in a clinical strain of *A. baumannii* with the IS*Aba1* insertion in the *adeRS* operon[239] suggest that the regulation of *adeABC* gene expression is complex. Additionally, the cell density-dependent expression of *adeB* suggests the presence of global regulatory mechanisms for the expression of this gene in *A. baumannii*[241]. BaeSR, which functions as an envelope stress response system to external stimuli, is proposed to influence the transcription of *adeAB* and thus tigecycline susceptibility in *A. baumannii* by functioning as a regulator of global transcription[242].

In addition to the AdeABC efflux pump, the inactivation of other RND-type efflux pumps, including AdeFGH[243] and AdeIJK[232,244,245], demonstrates their contribution to multidrug resistance in *A. baumannii*. The AdeABC and AdeIJK efflux systems can contribute synergistically to tigecycline resistance[244]. An open reading frame encoding a LysR-type transcriptional regulator, named *adeL*, is located upstream of the *adeFGH* operon and is responsible for the overexpression of AdeFGH[243], whereas the expression of AdeIJK in *Acinetobacter baumannii* is regulated by AdeN, a TetR-Type regulator[246]. Although the RND efflux pump AdeDE was initially identified in *Acinetobacter* genomic group 3[247], *adeE* was later found to coexist with *adeB* in some clinical isolates of *A. baumannii*[245].

A number of MFS efflux pumps, including TetA[248], CmlA[225], MdfA[233], CraA[249] and AmvA[250], that mediate resistance to different types of antibiotics in *A. baumannii* have been characterized. AbeM, a H-coupled pump that belongs to the MATE family[251], was reported to be present in the clinical isolates of *A. baumannii* in several studies[77,232,245] and to confer resistance to fluoroquinolones or imipenem in *A. baumannii*. *A. baumannii* with a mutant AbeS SMR pump exhibits erythromycin and chloramphenicol resistance[252].

### Aminoglycoside-modifying enzymes

Aminoglycoside-modifying enzymes (AMEs) are the principal mode of resistance to aminoglycosides. This resistance is primarily mediated by three classes of enzymes, including acetyltransferases, adenyltransferases and phosphotransferases, that typically reside on transposable elements; these enzymes chemically modify aminoglycosides[253]. The coding genes for these enzymes can be transferred among different bacterial types through plasmids, transposons, integrons, and natural transformation or transduction[254]. A phenotypic analysis of aminoglycoside resistance profiles indicated that many isolates could produce a combination of aminoglycoside-modifying enzymes[255,256]. The co-carrying of four AME genes, including a novel AME gene *aac(6')-Ib*, was reported in a PDRAB strain from China[257]. The identification of MDRAB isolates harboring genes for the *bla*$_{\text{OXA-23}}$-like genes, AME (*aac(6')-Ib*) and the 16S rRNA methylase (*armA*) implicates AMEs in multidrug resistance[258].

Different types of AMEs have been reported in *A. baumannii*. Amikacin resistance has been reported to be associated with a gene encoding APH(3')-VI phosphotransferase[255]. Furthermore, AME *aac(6')-Iad* plays an important role in amikacin resistance in *Acinetobacter spp.* in Japan[259]. Of the 106 MDRAB isolates identified in one study, 95% possessed at least one type of AME, including *aacA4*, *aacC1*, *aacC2*, *aadB*, *aadA1*, *aphA1* and *aphA6*[256]. In another study in Greece, all of the collected *A. baumannii* strains contained AMEs, which were either *aac(6')-Ib* or *aac(6')-Ih*[260]. Class I integrons containing the gene cassettes *aacA4-catB8-aadA1*, *dhfrXII-orfF-aadA2*, or *aacC1-orfP-orfP-orfQ-aadA1* have been proposed to be associated with the horizontal transfer of diversified aminoglycoside-resistant genes among clinical isolates of *A. baumannii*[17,256,261].

### Permeability defects

Porins, which perform multiple functions in membranes, are proteins that can form channels to allow the transport of molecules across lipid bilayer membranes[233]. These outer membrane proteins not only influence the virulence of *A. baumannii*, *e.g.*, through Omp38-induced epithelial cell apoptosis[59], biofilm formation related to OmpA[262],

OmpA-dependent host cell death[263], and attenuated virulence by the decreased expression of genes encoding CarO- and OprD-like proteins[263], but also play a significant role in the mechanisms of resistance. For example, the loss of a 29 kDa outer-membrane protein, which was later shown to be CarO, contributes to imipenem resistance[263-267]. Several other studies have also identified a number of OMPs involved in the carbapenem resistance of *A. baumannii*. A reduction in the expression of two porins of 22 and 33 kDa was involved in the carbapenem resistance of *A. baumannii* strains in an outbreak in Spain[268]. In one study, CRAB isolates found in New York had reduced expression of the 47-, 44-, and 37-kDa outer-membrane proteins[91], while in other studies, a 33- to 36-kDa OMP was also shown to be associated with carbapenem resistance in *A. baumannii*[269,270]. A 43-kDa OMP, belonging to the OprD family, has been identified as a basic amino acid and imipenem porin through electrophoresis and MALDI-MS analyses[271].

In the presence of OXA carbapenemases, including OXA-51-like or OXA-23-like enzymes, the loss of the 29-kDa outer-membrane protein is associated with a higher imipenem MIC in *A. baumannii*[272,273]. Moreover, a novel insertion sequence, IS*Aba10*, inserted into IS*Aba1* adjacent to the *bla*$_{\text{OXA-23}}$ gene, can disrupt the outer-membrane protein gene *carO* in *A. baumannii*[180]. The loss of lipopolysaccharide (LPS) from the outer membrane, resulting in a decrease in membrane integrity, occurred in a colistin-resistant clinical isolate of *A. baumannii* in Australia[64]. Disruption of the *ompA* gene can lead to decreases in the MICs of chloramphenicol, aztreonam, and nalidixic acid[274].

### Alteration of target sites

Changes in penicillin-binding proteins (PBPs), mutations of DNA gyrase, ribosomal protection by the TetM protein and the involvement of dihydrofolate reductase in trimethoprim resistance all occur *via* mechanisms that alter the target sites for antibiotics[275]. Imipenem resistance has been associated with the overexpression of certain PBPs with a low affinity for imipenem in the absence of other known resistance mechanisms[276]. While an insertion sequence disrupting the gene encoding PBP6b has been identified in an endemic carbapenem-resistant clone, its role must be further evaluated[277]. Furthermore, mutations in DNA gyrase gene *gyrA* and *parC*, which encode topoisomerase Ⅳ, have been reported in an *A. baumannii* outbreak investigation[237]. The *gyrA* mutation at Ser-83 was shown to be associated with quinolone resistance in epidemiologically unrelated isolates of *A. baumannii*[278]. While *tetA* and *tetB* genes are well recognized for their role in tetracycline resistance in *A. baumannii* through efflux pumps[225,279], *tetM* is proposed to be another resistance mechanism that acts through ribosomal protection[280]. Trimethoprim resistance through dihydrofolate reductase in *A. baumannii* is similar to that of other bacteria. Plasmids containing *folA* genes and integrons harboring *dfr* or *dhfr* genes in *A. baumannii* have been found[17,279,281]. Recently, the coexistence of the 16S rRNA methylase *armA* gene and genes encoding OXA carbapenemases were reported in many countries, including China[282], South Korea[253,283], India[284], Italy[285], Japan[286], and Yemen[258], indicating the contribution of the *armA* gene to the multidrug resistance of MDRAB.

### Roles of integrons

The horizontal transfer of resistance genes is a successful mechanism for the transmission and dissemination of multiple drug resistance determinants among bacterial pathogens[287]. Integrons, which are located on either bacterial chromosomes or plasmids, are assembly platforms that incorporate exogenous ORFs by site-specific recombination and convert them to functional genes by ensuring their correct expression[288]. Integrons share common features: a gene encoding an integrase, a specific recombination site that is recognized by the integrase and into which the cassettes are inserted, and a promoter that directs the transcription of the cassette-encoded genes. Currently, there are four classes of integrons, and class 1 integrons are the most common in bacteria[289].

The role of integrons in the development of multidrug resistance relies on their unique capacity to cluster and express drug resistance genes[287]. Many studies regarding integrons harboring different types of resistance genes have been reported worldwide in recent decades. Class I integrons were detected in 52.8% of *A. baumannii* strains in the Nanjing area of China in 2007[290], whereas an epidemic, class 1 integron-carrying MDRAB clone was found to be widespread in Taiwan in the same year[291]. Four different integron structures were detected in 84% of all collected isolates of *A. baumannii* in a Spanish study[255]. However, while no clear antibiogram differences could be associated with the presence or absence of integron structures in the Spanish study, other reports have suggested that integrons play a major role in multidrug resistance in *A. baumannii*[261,291,292]. Additionally, epidemic strains of *A. baumannii* have been found to contain significantly more integrons than non-epidemic strains[293]. Therefore, integrons are regarded as useful markers for epidemic strains of *A. baumannii*, and their typing can provide valuable information for epidemiological studies[294,295].

A study performed in Italy found that 44% of the epidemiologically unrelated *A. baumannii* isolates collected over an 11-year period were integron-positive[296]. Most integron-positive strains carried the same array of cassettes, despite their notable genetic diversity that was identified through a ribotyping analysis, implying that horizontal transfer of the entire integron structure or an ancient acquisition occurred. Additionally, while the same integron can be present in unrelated strains[17], related strains can also have different integrons[297].

Although different relationships exist among different classes of antibiotics and integrons[298,299], most studies have emphasized the association of integrons with cassette genes and aminoglycoside resistance[261]. The diversity of the genes encoding AMEs and their association with class 1 integrons was observed in a study involving

three pan-European clones of *A. baumannii*[256]. Six different class 1 integron variable regions were detected in 74% of the collected strains. Furthermore, Huang *et al*[291] collected 283 MDRAB isolates from three medical centers in Taiwan from 1996 to 2004 and found seven types of gene cassettes, most of which contained AMEs, including *aacA4*, *aacC1*, *aac(6')-II*, *aadA1*, *aadA2*, *aadA4* and *aadDA1*.

Variable CHDL genes, including *bla*$_{OXA-3}$[292], *bla*$_{OXA-10}$[96,290], *bla*$_{OXA-20}$[19,292,296], *bla*$_{OXA-21}$[297], and *bla*$_{OXA-37}$, have been reported in integrons[164,297]. Integron-associated imipenem resistance in *A. baumannii* has also been documented[300]. Genes encoding carbapenemases, such as MBLs *bla*$_{VIM}$, *bla*$_{IMP}$ and *bla*$_{SIM}$, have been found in integrons. *bla*$_{VIM-1}$-carrying integrons[140] and *bla*$_{VIM-2}$-carrying integrons[139] have been noted in Greece and Korea, respectively. In Taiwan, integron-mediated gene spreading has been demonstrated hospitals[301], especially in a unit with high antibiotic selective pressure[302]. *bla*$_{VIM-11}$-carrying integrons have also been identified in MDRAB isolates, and this MBL gene has been postulated to spread among *Pseudomonas aeruginosa* and *A. baumannii* strains[143,291]. Other reported MBLs include *bla*$_{IMP-1}$[303], *bla*$_{IMP-2}$[145], *bla*$_{IMP-4}$[146,147], *bla*$_{IMP-5}$[148], *bla*$_{IMP-8}$[291] and *bla*$_{SIM-1}$[151]. The genes for chloramphenicol resistance in the integrons of *A. baumannii* are *catB2*[135], *catB3*[146,147,151] and *catB8*[294,304].

## CLINICAL IMPACT OF ANTIMICROBIAL RESISTANCE

The clinical impact of *A. baumannii* infections has been a matter of debate[2]. A high mortality rate in immunocompromised hosts with *A. baumannii* infections had been attributed to the patients' underlying diseases rather than to the infections. One Spanish study concluded that there were no differences in mortality among patients with ventilator-associated pneumonia (VAP) caused by imipenem-resistant or imipenem-susceptible *A. baumannii* or by other pathogens[305]. However, other related studies suggest that *A. baumannii* infection itself has a profound influence on high mortality or prolonged length of stay (LOS)[306]. Falagas suggested that the mortality attributed to *A. baumannii* infections should no longer be a controversial issue[307] based on six relevant case-control studies[308-313].

Several previous surveillance[314-317] studies have demonstrated that increasing antimicrobial resistance, especially multidrug resistance, has become a major issue in *A. baumannii* strains in recent years. Whether multidrug resistance is a risk factor for high mortality in *A. baumannii* infections has been a controversial issue. A few studies suggested that MDRAB-related pneumonia or bacteremia is a signal of disease severity and is not related to prolonged LOS or increased mortality[318,319], but more recent studies have shown that MDRAB infections lead to higher mortality. The acquisition of MDRAB was shown to be an independent risk factor for mortality in a burn center in Singapore[320]. A multicenter retrospective study in Taiwan also showed that patients with CRAB infections have a higher mortality rate than those with carbapenem-susceptible *A. baumannii* infections[321], which is consistent with the results of several previous studies[309-311,313,322]. The high impact of imipenem resistance on the mortality rate of patients with *Acinetobacter* bacteremia is chiefly attributable to discordant antimicrobial therapy[311]. Moreover, patients with MDRAB infections have increased hospital and ICU LOS compared to patients with susceptible *A. baumannii* infections and uninfected patients[308]. A mini review of this issue indicated that blood stream infections and nosocomial ICU infections caused by carbapenem-resistant *Acinetobacter* spp. are associated with increased rates of mortality, whereas other types of infections have not clearly been shown to be associated with higher mortality rates but are associated with increased LOSs and hospital costs[323].

## STRATEGIES TO COMBAT THE DISSEMINATION OF ANTIMICROBIAL RESISTANCE

The development of new antibiotics against MDRAB and the implementation of infection control measures are regarded as two methods to aid in controlling the increasing problem of *A. baumannii* infections[307]. When GlaxoSmithKline shared the challenges and difficulties in screening for new classes of antimicrobial agents over a 7-year period, the authors concluded that the pipeline of novel-mechanism antibacterials is still empty and will remain so for a considerable period[324]. Therefore, the importance of following the Association of Professionals in Infection Control and Epidemiology's (APIC) 2010 guide to the elimination of MDRAB transmission in health care settings cannot be overemphasized[325]. This guide includes MDRAB risk assessment and infection surveillance, strict adherence to hand hygiene protocols, implementation of standard and transmission-based precautions, environmental decontamination, outbreak recognition and control, and antibiotic stewardship.

Gastrointestinal or skin colonization of *A. baumannii* develops soon after the pathogen is first isolated from a clinical site[326]. The finding of multidrug-resistant colonized strains compared with susceptible clinical strains without apparent relation to antibiotic use implies that a new onset of MDRAB colonization may not be identified without surveillance. Additionally, the increasing occurrence of multidrug-resistant strains among seriously ill patients emphasizes the importance of continued surveillance as a critical component of any program aimed at preventing and controlling antimicrobial resistance[315]. Environmental contamination, airborne transmission, patient transfer, and cross-contamination are regarded as key factors in causing *A. baumannii* epidemics[327], and clonal expansion has been shown to play a major role in the increase of MDRAB in hospitals[328]. Therefore, barrier infection control measures are necessary to prevent the nosocomial spread of MDRAB[326]. One outbreak

**Table 2 Antimicrobial treatment for MDRAB infections**

| Regimen | Pathogen | Diseases | Outcome[1] | Comparator | Ref. |
|---|---|---|---|---|---|
| CST + RIF | XDRAB | HAP<br>VAP<br>BSI<br>cIAI | The same in<br>CR (mortality) Better in MR | CST | [367] |
| CST + RIF | CRAB | VAP | The same in CR + MR | CST | [366] |
| CST + IPM<br>CST + SAM<br>CST + others | XDRAB | BSI | Better in CR (mortality) + MR | CST | [369] |
| CST + SUL | MDRAB | VAP | The same in CR + MR | CST | [341] |
| TGC based | MDRAB | Pneumonia | Higher mortality | CST based | [349] |
| TGC based | MDRAB | HAIs | The same in mortality[2] Better in MR | IPM + SAM | [352] |
| CT | MDRAB | Infections | The same in mortality | MT | [374] |

[1]"The same" means no significant difference between comparator groups, and "Better" means a significant difference exists between comparator groups; [2]Has a statistically significant favorable outcome. MDRAB: Multidrug-resistant *A. baumannii*; CST: Colistin; IPM: Imipenem; RIF: Rifampicin; SUL: Sulbactam; SAM: Ampicillin/sulbactam; TGC: Tigecycline; HAP: Hospital-associated pneumonia; VAP: Ventilator-associated pneumonia; BSI: Blood stream infection; cIAI: Complicated intra-abdominal infection; HAIs: Healthcare-associated infections; CR: Clinical response; MR: Microbiological response; CT: Combination therapy; MT: Monotherapy.

reported in an ICU in a Greek hospital ceased after the implementation of hygienic measures, complete cleaning and complete disinfection in the ICU[329]. However, cross-infection with *A. baumannii* among patients still occurred, despite the implementation of stringent infection control measures, in a previously reported outbreak; thus, temporary closure of the surgical ward for disinfection was necessary to control the outbreak[330].

Environmental contamination plays an important role in the transmission of MDRAB. One outbreak investigation found that the affected patients had a higher risk of harboring *A. baumannii* after blood transfusion, hydrotherapy or extended use of a respirator, which was possible through the contamination of healthcare personnel and the environment. Another *A. baumannii* outbreak investigation in a surgical ICU at a teaching hospital in Taiwan showed extensive amounts of environmental contamination, including the contamination of bed rails, bedside tables, sinks, ventilator and infusion pump surfaces, and water for nasogastric feeding and ventilator rinsing. Hence, intensified infection prevention control (IPC) measures are needed to terminate an outbreak. The IPC measures include: (1) implementation of enhanced contact isolation precautions; (2) active surveillance cultures; (3) daily environmental cleaning with detergents and phenolic agents; (4) an up-to-date education program for all healthcare workers; and (5) delivery of real-time feedback to healthcare workers regarding IPC compliance[331], which has minimized the spread of colistin-resistant *A. baumannii*. Furthermore, the infection control bundle resulted in a significant reduction in the incidence of nosocomial *A. baumannii* in one burn unit and prevented further outbreaks of this organism, with an 88.8% decrease during the intervention period[332].

Imipenem has been proven to be a strong inducer of multidrug resistance in *A. baumannii*[333]. Many *A. baumannii* isolates exhibit imipenem resistance, which is strongly associated with the prior use of carbapenems[334]. Because of the high mortality rate associated with *A. baumannii* infection, strategies to slow down the emergence of MDRAB in clinical practice by optimizing antimicrobial therapy are necessary. Therefore, antimicrobial stewardship is mandatory in an infection prevention program to prevent the emergence and transmission of MDRAB in health care facilities[325].

## ANTIMICROBIAL THERAPY

Carbapenems, including imipenem or meropenem, have been regarded as effective antimicrobial agents to treat *A. baumannii* infections[314,335]. With many studies reporting increasingly high rates of CRAB in clinical isolates[75,76,90], other classes of antibiotics or combination therapies are urgently needed. Because the choices of antimicrobial treatment for MDRAB are severely limited by resistance, there are only a few effective options available, including polymyxins and tigecyclines[336]. Furthermore, the appearance of PDRAB, which is resistant to all available antibiotics, including polymyxin, implies that more efforts should be devoted to investigating the treatment options for this superbug[27]. Combination therapies with imipenem/sulbactam, colistin/rifampicin, colistin/sulbactam, colistin/tigecycline, colistin/imipenem or meropenem and colistin/teicoplanin have been studied and proposed as possible choices. The recently published reports on the treatment of MDRAB are summarized in Table 2.

### *Sulbactam*

While ampicillin/sulbactam has been shown to be effective in treating blood stream infections caused by MDRAB[337], a later meta-analysis revealed that sulbactam-based therapy is not superior to other therapeutic approaches, including colistin, cephalosporins, antipseudomonas penicillins, fluoroquinolones, minocycline/doxycycline, aminoglycosides, tigecycline, polymyxin, imipenem/cilastatin, and combination therapies[338]. Although sulbactam-based therapy failed to prove its superiority to other regimens for the treatment of *A. baumannii* in-

fections, a case of skin and soft tissue infection caused by CRAB that was treated successfully with ampicillin/sulbactam and meropenem combination[339] raises the possibility of ampicillin/sulbactam as a component of combination therapy against CRAB. The combination of ampicillin/sulbactam with a carbapenem for treating MDRAB bacteremia has been shown to be associated with a better outcome[340], but such beneficial effects were not observed for MDRAB VAP[341].

### Tigecycline-based therapy

In 2004, tigecycline was reported to have a good *in vitro* bacteriostatic effect against *A. baumannii*, including strains resistant to imipenem[342]. Another *in vitro* study using a time-kill assay demonstrated the potential role of tigecycline in the treatment of *A. baumannii* and proposed that doxycycline could be a suitable and cost-effective option in some instances[343]. Tigecycline efficacy was shown to correlate well with the free concentration-time curve of MIC in a murine *Acinetobacter* spp. model[344]. Additionally, several cases affiliated with severe infections by MDRAB were successfully treated with tigecycline in terms of their clinical and microbiological outcomes[345].

With its increasing use, the limitations and adverse aspects of tigecycline in treating MDRAB infections have begun to be realized. Tigecycline was less effective than imipenem in the treatment of pneumonia caused by non-IRAB strains in a murine pneumonia model[346]. In a study consisting of 34 patients with MDRAB infections, the mortality rate reached up to 41%. The authors found that the correlation of clinical and microbiological outcomes was poor and concluded that tigecycline had excellent *in vitro* activity against MDRAB, but its clinical efficacy was still uncertain[336]. One of the possible causes for the discrepancy of treatment outcomes may be variable tigecycline MICs. MIC determination for tigecycline before treatment, with the broth dilution method being favored[347], might increase clinical success[345]. *A. baumannii* isolates with tigecycline MICs of $\geqslant$ 2 mg/L were associated with higher mortality rates; thus, treatment with β-lactams or carbapenems instead of with tigecycline is preferred[348]. This notion was further supported in a matched cohort study in Taiwan that dealt with the effectiveness of tigecycline-based versus colistin-based therapy for the treatment of pneumonia caused by MDRAB[349]. The excess mortality rate of 16.7% in the tigecycline-based group compared with the colistin-based group was mostly attributed to subjects with MIC > 2 μg/mL.

In a meta-analysis of the efficacy and safety of tigecycline, clinical failure, superinfection and adverse events were more frequent with the use of tigecycline[350]. The authors suggested that physicians should avoid tigecycline monotherapy for the treatment of severe infections caused by MDRAB and that they should use it as a last-resort antibiotic. There was no antagonism found when tigecycline was used with other antimicrobials possessing activities against Gram-negative bacteria[351]. However, tigecycline-based therapy for MDRAB infections is not satisfactory. In a study of 266 patients with healthcare-associated MDRAB infections, the mortality rate was not significantly different between those receiving tigecycline-based therapy and those receiving non-tigecycline therapy[352].

While tigecycline has an expanded spectrum of antibacterial activity and a synergic effect with some classes of antibiotics, such as amikacin[353], earlier studies have shown that tigecycline resistance in *A. baumannii* has emerged[354] and is associated with multidrug efflux systems, especially overexpression of the *adeABC* pump[226,227]. The increased expression of the *adeABC* operon can be found in clinical isolates of *A. baumannii* post-tigecycline therapy[236,355]. High resistance rates and high MICs of tigecycline in multiple clones of MDRAB were noted in a medical center in Israel[356]. This phenomenon led to concern regarding the use of tigecycline as one of the few treatment choices for infections caused by MDRAB.

### Colistin-based therapy

Colistin has been described as a last resort for the treatment of MDRAB[357], and this drug is often used in combination therapy. In a report on the clonal spread of MDRAB in eastern Taiwan, antibiotic susceptibility testing showed that 10.4%, 47.8% and 45.5% of MDRAB isolates were resistant to colistin, rifampicin, and tigecycline, respectively, implying that colistin was the only effective antimicrobial agent in that area for treating MDRAB[358]. In addition to its intravenous injection for MDRAB infections, colistin can be given *via* intraventricular and intrathecal routes for meningitis[359] and *via* nebulization for pneumonia[360,361].

Unfortunately, colistin-resistant *A. baumannii* strains have been reported all over the world[357] and are attributed to the loss of lipopolysaccharide[64] or/and phosphoethanolamine modification of lipid A mediated by the PmrAB two-component system[362,363]. Because colistin monotherapy is unable to curb the appearance of resistance, colistin-based combination therapy might be the optimal antimicrobial strategy. Colistin combined with different classes of antibiotics, including tigecycline, cefoperazone/sulbactam or piperacillin/tazobactam, revealed synergistic effects in some CRAB strains[364]. Time-kill assays have also shown that colistin/meropenem, colistin/rifampicin, and colistin/minocycline are synergistic *in vitro* against XDRAB strains[365]. The beneficial effects of colistin and rifampicin combination for patients with VAP caused by CRAB have been documented in terms of clinical and microbiological outcomes[366]. However, another multi-center, randomized clinical trial concluded that 30-d mortality was not reduced by the addition of rifampicin to colistin in serious XDRAB infections[367]. Additionally, such a regimen might be hindered by a high level of rifampicin resistance in *A. baumannii*[368]. Treatment with combination therapy, including colistin/carbapenem and colistin/sulbactam, for XDRAB blood stream infections led to higher microbiological eradication and lower mortality rates in comparison with the colistin monotherapy group[369]. The combination therapy

of colistin and tigecycline has also been proposed as a reasonable treatment of choice for XDRAB pneumonia, especially in the first 48 h, in a rat lung model[370]. Interestingly, a significant synergy has been observed for the combination of colistin and teicoplanin against MDRAB *in vitro*[371]. Telavancin, a similar lipoglycopeptide of teicoplanin, has been shown to be efficacious *in vivo* when used in colistin combination therapy in a *Galleria mellonella* model of *A. baumannii* infection[372].

### Other antimicrobial therapies

Doripenem, a novel broad-spectrum carbapenem, has displayed *in vitro* synergistic activity with tigecycline, colistin and amikacin against MDRAB strains with doripenem resistance[373]. One recent prospective, observational Spanish study did not support an association of combination therapy with reduced mortality in MDRAB infections[374]. Overall, the choice of combination therapy should take several key factors into consideration, including the antimicrobial resistance phenotype, resistance mechanisms, and MIC[375].

## FUTURE PERSPECTIVES

One of the difficulties encountered in understanding the antimicrobial resistance mechanisms of *A. baumannii* lies in the complexity of the involved genes. A DNA microarray, the Check-MDR CT102 microarray, has proven useful in detecting TEM, SHV and CTX-M extended-spectrum β-lactamases and KPC, OXA-48, VIM, IMP, and NDM-1 carbapenemases in some *Enterobacteriaceae* and glucose non-fermentative bacteria, including *A. baumannii*, with 100% sensitivity and specificity for most of the tested genes[376]. The detection of plasmid-mediated cephalosporinases, including CMY-2-like, DHA, FOX, ACC-1, ACT/MIR and CMY-1-like/MOX, was also possible using this assay, suggesting that this DNA array is a powerful high-throughput tool for most common resistance gene identifications and provides a platform for epidemiological or infection-control studies[377].

Bacteria develop resistance to new classes of antibiotics very quickly, and bacteria may even be resistant to new classes of antibiotics before they are introduced to clinical use[378]. Hence, antimicrobial peptides (AMPs) may be another option due to the rare appearance of resistance to AMPs in addition to their antimicrobial and anti-inflammatory effects[379]. AMPs are an important component of host defenses against invading pathogens[380]. They are small, cationic and amphipathic peptides of variable length, sequence and structure. Thus far, more than 750 different AMPs have been identified in various organisms ranging from plants to animals, including humans, most of which exhibit broad-spectrum activity against a wide range of microorganisms by disrupting the plasma membrane and causing cell lysis. Three classes of AMPs, including defensins, cathelicidins, and histatins, have been found in humans[379]. The cathelicidin family is currently limited to a single gene, CAMP. LL-37, which begins with two leucine residues and consists of 37 amino acids, was the first mature peptide isolated from *CAMP* gene products[381].

While only a few studies regarding the use of AMPs in *A. baumannii* have been reported, AMPs might be a potential therapeutic alternative to antibiotics. This hypothesis is supported by the conclusion reached from a study of an LPS-deficient, colistin-resistant *A. baumannii* strain, which showed reduced viability even at a low concentration of LL-37[382]. The human antimicrobial peptide LL-37 and its fragments KS-30 and KR-20 have been shown to have significant antimicrobial activity against clinical isolates of MDRAB, of which the KS-30 fragment exhibits the highest bactericidal ability[383]. Moreover, the prevention of biofilm formation *in vitro* by LL-37, KS-30 and KR-20 adds significance to their efficacy. We predict that AMPs, specifically LL-37, will be promising targets in future research on therapeutics against MDRAB infections.

Because marketing a new antimicrobial is extremely difficult and because bacteria quickly adapt to so-called magic bullets, understanding the interplay between a pathogen such as *A. baumannii* and its hosts may provide another possible solution in the war against bacteria. The microbes that exist in the human body are collectively known as the human microbiota, and this remarkably complex and poorly understood group of communities has an enormous impact on humans[384]. The Human Microbiome Project, funded by the National Institutes of Health, aims to develop tools and databases for the research community to study the role of these microbes in human health and disease. One of the tasks the NIH has set itself is to develop a catalog of the microbial genome sequences of reference strains[385]. For example, the microbiome diversity in the bronchial tracts of patients with chronic obstructive pulmonary disease has been documented[386]. More advances in understanding the pathogenesis of *A. baumannii* using the databases of the Human Microbiome Project can be anticipated.

In conclusion, we hope that this review will aid in understanding the relevant studies regarding the antimicrobial resistance of *A. baumannii* as well as the currently available treatment options for the infections that this pathogen cause, thereby leading to new strategies to combat *A. baumannii*.

## Abstract

Follicular contact dermatitis clinically presents as individual papules that include a central hair follicle. Pathologic features involve the follicle and the surrounding dermis: spongiosis and vesicle formation of the follicular epithelium associated with perifollicular and perivascular lymphocytic inflammation. Using the PubMed database, an extensive literature search was performed on follicular contact dermatitis and neomycin. Relevant papers were reviewed and the clinical and pathologic features, the associated chemicals (including a more detailed description of neomycin), the hypothesized pathogenesis, and the management of follicular contact dermatitis were described. Several agents-either as allergens or irritants-have been reported to elicit follicular contact dermatitis. Several hypotheses have been suggested for the selective involvement of the follicles in follicular contact dermatitis: patient allergenicity, characteristics of the agent, vehicle containing the agent, application of the agent, and external factors. The differential diagnosis of follicular contact dermatitis includes not only recurrent infundibulofolliculitis, but also drug eruption, mite infestation, viral infection, and dermatoses that affect hair follicles. The primary therapeutic intervention for follicular contact dermatitis is withdrawal of the causative agent; treatment with a topical corticosteroid preparation may also promote resolution of the dermatitis. In conclusion, follicular contact dermatitis may be secondary to allergens or irritants; topical antibiotics, including neomycin, may cause this condition. Several factors may account for the selective involvement of the hair follicle in this condition. Treatment of the dermatitis requires withdrawal of the associated topical agent; in addition, topical corticosteroids may be helpful to promote resolution of lesions.

**Key words:** Allergic; Contact; Dermatitis; Follicular; Irritant; Neomycin; Papular

**Core tip:** Follicular contact dermatitis an be elicited by several agents and clinically presents as individual papules that include a central hair follicle. Pathologic features involve the follicle and the surrounding dermis. Hypotheses for the selective involvement of the follicles include patient allergenicity, characteristics of the agent, vehicle containing the agent, application of the agent, and external factors. The differential diagnosis includes dermatoses that affect hair follicles, drug eruption, infundibulofolliculitis, mite infestation and viral infection. Treatment with a topical corticosteroid preparation and/or withdrawal of the causative agent are therapeutic interventions for follicular contact dermatitis.

Cohen PR. Follicular contact dermatitis revisited: A review emphasizing neomycin-associated follicular contact dermatitis. *World J Clin Cases* 2014; 2(12): 815-821 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/815.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.815

## INTRODUCTION

Contact dermatitis can be either allergic or irritant in eti-

ology. Follicular contact dermatitis is a variant of contact dermatitis that has been observed in individuals secondary to incidental exposure or patch testing to the eliciting agent. The allergens and irritants that have previously been reported to cause follicular contact dermatitis are summarized and neomycin-associated follicular contact dermatitis is emphasized.

## CLINICAL MORPHOLOGY AND SYMPTOMS OF FOLLICULAR CONTACT DERMATITIS

Follicular contact dermatitis is usually characterized by individual papules that include a central hair follicle. However, prominent hairs within the papules may not be readily visible when the lesions surround vellus hairs[1]. The papular lesions are frequently pruritic and occasionally painful or burning. The individual lesions have also been described as poral[2,3] or acneiform[1]. In addition, the clinical spectrum of follicular contact dermatitis also includes follicular-based pustules[3].

## PATHOLOGY OF FOLLICULAR CONTACT DERMATITIS

Microscopic examination of the perifollicular papule is similar, regardless of the eliciting contactant. The pathologic changes involve the follicle and the surrounding dermis. There is often spongiosis and vesicle formation of the follicular epithelium or the eccrine sweat ducts or both. In the dermis, predominantly lymphocytic inflammation is noted around the periadnexal vessels, the follicle and/or the eccrine pore. Importantly, the epithelium adjacent to the follicle or pore is normal in appearance[1-12].

## ALLERGIC CONTACT DERMATITIS AND TOPICAL ANTIBIOTICS

Allergic contact dermatitis to topical antibiotics is a relatively common phenomenon. The North American Contact Dermatitis Group reported that among patients referred for patch testing, during 1985 to 2004, the prevalence of allergic contact dermatitis to neomycin ranged from 7.2 to 13.1 percent[13].

Allergic contact dermatitis to topical antibiotics is most commonly observed in certain at-risk populations. These include patients with chronic eczematous dermatoses (such as atopy and stasis dermatitis), chronic otitis externa, chronic venous insufficiency, and post operative or post traumatic wounds. In addition, an occupational risk to develop allergic contact dermatitis to antibiotics occurs more frequently in those individuals who handle them regularly, such as farmers, health care workers, pharmaceutical employees, and veterinary surgeons[13].

## CHEMICALS CAPABLE OF ELICITING FOLLICULAR CONTACT DERMATITIS

Several chemicals, including topical antibiotics, have been described in either individual reports or larger studies to elicit follicular contact dermatitis. The agents associated with the development of follicular contact dermatitis can be allergens (Table 1)[1-10,14-21] or irritants (Table 2)[4,5,11,22-28]. Several metals have been associated with follicular patch test reactions: chromium, cobalt, copper, fluoride, and nickel[3,29]. Allergic and non-allergic development of follicular contact dermatitis has also been observed following exposure to tocopheryl linoleate, a vitamin E derivative[4,5].

### *Neomycin-associated follicular contact dermatitis*

**Neomycin-drug characteristics:** Neomycin is produced by the growth of Streptomyces fradiae. It is an aminoglycoside antibiotic. Its efficacy as an antimicrobial is based upon the drug's ability to irreversibly bind to the 30S ribosomal RNA subunits and inhibit bacterial protein synthesis[13,30-32].

Neomycin can be used as a topical antibiotic and has activity against many aerobic Gram-negative organisms (except Pseudomonas aeruginosa). It is also effective against some aerobic Gram-positive bacteria including Staphylococci. However it is not effective against Streptococci[13,30-32].

Neomycin is usually formulated commercially as 20% neomycin sulfate in a petrolatum vehicle. However, it is often combined with other topical antibiotics such as bacitracin zinc and polymyxin B sulfate. This is done to expand the antimicrobial coverage[13,30-32].

**Neomycin-clinical presentation:** The woman in Figures 1-4 developed follicular contact dermatitis to an antibiotic ointment that contained neomycin sulfate in combination with bacitracin zinc and polymyxin B sulfate. Indeed, individual hair follicules were observed in the center of the papular lesions (Figure 4). Allergic contact dermatitis has been reported to all three components of this antibiotic[33-35]. However, follicular contact dermatitis has only been described in association with neomycin.

**Neomycin-prior observations:** Allergic contact dermatitis to neomycin was initially reported in 1952[36]. Six years later, in 1958, Epstein[9] described contact dermatitis to neomycin as "…an aggravation or "irritation" of a preexisting dermatitis…" and not the obvious picture of an acute contact dermatitis. He considered it to represent a dermal contact sensitivity reaction[9]. The lesions elicited by patch testing clinically presented as papules and histologically demonstrated an intact epidermis with pathologic changes in the dermis[9].

Subsequently, Jillson *et al*[7] reported contact dermatitis to neomycin in 10 patients with atopic dermatitis. One of the patients, a 50-year-old woman had an eczematous dermatitis of her left flexor arm for which prior treatment with neomycin ointment had irritated the dermati-

**Table 1 Agents associated with allergic follicular contact dermatitis**

| Agent | Comment | Ref. |
|---|---|---|
| Ammonium fluoride | A farm helper who sprayed trees with chemical and had an exudative dermatitis and a postal employee with right foot and bilateral popliteal dermatitis; patch test showed folliculoporal reaction | [2] |
| Chromium trioxide | A shoe-shiner with severe hand dermatitis, a plasterer who worked with cement (after a cast had been applied to his hand to treat a fracture), and an electrician with chronic dermatitis flared when he drilled through aluminum coated with zinc chromate primer; all had a folliculoporal patch testing reaction | [2] |
| Cobalt chloride | 103 follicular patch test reactions in 853 heavy metal workers that were tested | [3] |
| Colored permanent pressing sheets chemical | Sheets were 50% cotton and 50% polyester; widely dissmeniated erythematous follicular keratotic papules; primarily on hairy areas with a predominance on legs and forearms. Several washings of sheets did not prevent dermatitis; it persisted up to 8 wk after sheets removed | [10] |
| Copper sulfate | 110 patients patch tested; 8 of 69 who reacted had follicular or poral (folliculoporal) reactions | [2] |
| Cosmetic creams | 5 young women in a 3 mo period; at sites where cream applied following bathing or before sun exposure: extensor limbs (with well developed vellus hairs) were greatly affected | [1] |
| Dander (human) | Patch test reactions to dander histologically showed eczematous changes in the upper parts of hair follicles and clinically consisted of erythema and papules; they were positive in 120 of 181 atopic patients, 2 of 28 allergic contact dermatitis patients, and 1 of 31 normal controls | [14] |
| Formaldehyde | A postal employee with right foot and bilateral popliteal dermatitis; patch test showed folliculoporal reaction<br>2 women developed textile contact dermatitis to a new long sleeved shirt and new pajamas; a hair usually pierced the center of the papular lesions<br>Positive patch test reactions frequently showed a follicular pattern; in some patients, only bright red follicular papules set in a background of normal appearing skin | [2,8,15] |
| Homomenthyl salicylate | Sunscreening chemical in a suntan lotion; 2 women with follicular dermatitis. One of the woman developed consort allergic contact dermatitis from contact with her boy friend who used the lotion; she was originally misdiagnosed as having recurrent disseminated infundibulofolliculitis | [6] |
| Methyl glucose sesquistearate | Follicular dermatitis developed to both a lotion and facial cream that contained this chemical | [16] |
| Neomycin | Repeat topical application on abdomen (current report) and patch test reaction (woman with atopy and left arm dermatitis that flared after applying neomycin ointment | [7,9] |
| Nickel sulfate | A farm helper who sprayed trees with chemical and had an exudative dermatitis; patch test showed folliculoporal reaction<br>29 follicular patch test reactions in 853 heavy metal workers that were tested<br>Female production line worker with dermatitis of hands, chest and face after exposed to metals and cutting fluids and patch test positive to nickel; she developed follicular contact dermatitis in her pubic area 2 d after shaving with a metal razor blade | [2,17,18] |
| Paraphenylenediamine | An atopic woman with recurrent episodes of follicular-based pruritic papules on her face, chest and back beginning 3 wk after starting daily oral hydrochlorothiazide; she had a similar dermatitis after contact with "black hair dye" and positive patch test reaction to paraphenylenediamine (which cross reacts with her new oral antihypertensive) | [19] |
| Polyoxyethylene laurylether | An emulsifier (and an addition of lauryl alcohol and ethylene oxide) used in cosmetics. A woman developed pruritic follicular facial papules after starting to use new cosmetics; both a use test and a patch test for polyoxyethylene lauryether showed a follicular papular reaction | [20] |
| Potassium dichromate | 61 follicular patch test reactions in 853 heavy metal workers that were tested | [3] |
| Selenium salts | In glass industry, 4 employees exposed to barium and sodium selenite suffered from dermatitis and/or conjunctivitis; 2 of the patients developed follicular allergic contact dermatitis with papulo-follicular lesions. Patch testing with sodium selenite confirmed the diagnosis | [21] |
| Sodium tungstate | 3 follicular patch test reactions in 853 heavy metal workers that were tested; heavy metal contains about 90% tungsten carbide | [3,18] |
| Tocopheryl linoleate | Vitamin E derivative added to base formulation of a cosmetic line in Switzerland; 905 patients with papular and follicular dermatitis. Positive patch test reactions to cosmetics and vitamin E linoleate | [4,5] |

tis[7]. Patch testing to neomycin ointment "…was characterized by multiple small (papules of) eczematous areas rather than a confluent eczematous plaque[7]".

The patient in Figures 1-4 developed allergic contact dermatitis to neomycin. Her initial lesions were perifollicular papules. Some of these subsequently developed into confluent plaques.

## PATHOGENESIS OF FOLLICULAR CONTACT DERMATITIS

Several hypotheses have been suggested for the selective involvement of the follicles in follicular contact dermatitis in contrast to the diffuse clinical changes more frequently observed in allergic or irritant contact dermatitis. These include direct penetration of the stratum corneum by the agent *via* the pilosebaceous apparatus, hapten conjugation of the agent to a substance only present in the infundibular region, or both[6]. Other factors may also influence the development of follicular contact dermatitis.

### *Patient allergenicity*

Previously individuals with atopy were considered less likely to be susceptible to allergic contact dermatitis. However, several subsequent studies have demonstrated that atopic patients not only develop contact dermatitis to metals[37], but also more commonly develop follicular contact dermatitis[38,39]. Hence, the patient's diathesis to allergens may influence whether they develop follicular

| Agent | Comment | Ref. |
|---|---|---|
| Beetle toxin | Pederin toxin released as a defensive mechanism from the rove (staphylinid) beetle in hot tropical and moderate climate regions typically limited to uncovered body areas | [22,23] |
| Bis-hydroxyethyl-tallow amine | Antistatic agent used to impregnate plastic tote boxes; outbreak of the hand or arms of 48.3% (14 of 29) of employees of the incoming inspections department of a microelectronic plant. The chemical provoked both follicular and nonfollicular irritant dermatitis; it was also a potential skin sensitizer | [24] |
| Coal-tar products | Hand dermatitis presenting with follicular papules and pustules at the site of exposure to coal-tar oils, creosote, pitch | [25] |
| Croton oil | Occupational source for irritant pustular and follicular irritant contact hand dermatitis | [25] |
| Debromoaplysiatoxin | Occurs after swimming in water contaminated by sea algae (Lyngbya majuscule Gomont); the alga cause a seaweed dermatitis in persons swimming off the coastin Oahu, Hawaii. Topical application of the toxin produces an irritant pustular folliculitis | [26] |
| Fluorine | Antirust solution containing 20% ammonium bifluoride diluted in water; acute irritant contact dermatitis in an atopic child. Rusted buckles of the right shoe cleaned with solution; 12 h later, the 19-mo-old boy developed an erythematous pustular dermatitis on the areas of the treated buckles | [27] |
| Greases | Occupational source for irritant pustular and follicular irritant contact hand dermatitis | [25] |
| Naphthalones | Occupational source for irritant pustular and follicular irritant contact hand dermatitis | [25] |
| Petroleum | Hand dermatitis presenting with follicular papules and pustules at the site of exposure to petroleum derivatives: crude oil and fractions, cutting oils; lesions develop at the contact site to oil-soaked and tar-soaked clothes | [25] |
| Propylene glycol | It is used as a solvent, a plasticizer, a component of household products, a food additive and an ingredient in cosmetics and pharmaceutical preparations. 45138 patients patch tested; only 1044 (2.4%) patients with actual allergic contact dermatitis and 43 (0.10%) patients with non-allergic follicular reactions | [28] |
| Tri-phenyl-tin-fluoride | It is a bioactive organo-tin compound used as agricultural fungicides, general biocides, bactericides, herbicides, insecticides and antifoulant in boat paints (ship bottom coatings); it is moderately toxic to the skin. The patient's forearm accidentally contacted an empty drum that was still contaminated with the chemical; within 2 d he developed multiple follicular keratosis-like red papules evenly distributed over the affected area | [11] |
| Tocopheryl linoleate | Vitamin E derivative added to base formulation of a cosmetic line in Switzerland; 905 patients with papular and follicular dermatitis. In a few patients, the skin reaction appeared after a few applications on discontinuous days or more rarely after a single application suggesting an irritation reaction | [4,5] |

**Figure 1 Neomycin-associated follicular contact dermatitis presenting as follicular papules on the right abdomen, in and around the umbilicus, and the suprapubic region.** The patient is a 59-year-old Asian woman who presented with itchy lesions at the sites of prior incisions on her lower abdomen. Her past medical history was significant for stage Ⅰ, T2N0M0 adenocarcinoma of the sigmoid colon. Her tumor was successfully managed by a laparoscopic anterior resection of the sigmoid colon.

contact dermatitis[17].

### Characteristics of the agent

Heavier molecules are less easily capable of penetrating the epidermis as compared to lighter molecules. Hence, it can be hypothesized that the heavier molecules exhibit a preference for entering the dermis through the pilosebaceous units of hair follicles. For example, cobalt demonstrates an increased number and severity of contact dermatitis reactions at follicles[3]. Neomycin, is a larger molecule than cobalt; therefore, the size of neomycin may account for the observed follicular contact dermatitis to this agent (Figures 1-4).

The concentration of the agent can also influence a predilection for follicular contact dermatitis. Not only cobalt, but also tungstate shows an increase in follicular reactions at higher concentrations[3,18].

### Vehicle containing the agent

Lipophilic irritant agents absorb through the pilosebaceous apparatus[40]. However, water-soluble substances penetrate more easily into and around hair follicles[3]. Yet, in patch test reactions to metals, follicular contact dermatitis is more common when the testing vehicle is petrolatum as compared to water[3].

### Application of the agent

Not only in patch testing, but also in clinical use features regarding the application of the agent can potentially influence the occurrence and severity of follicular contact dermatitis[41,42]. It is reasonable to hypothesize that repeated application and occlusion of the agent may allow for greater contact with larger areas of epithelium instead of only the follicles, resulting in a more confluent dermatitis. Therefore, follicular reactions are less likely to occur when the agent is applied more frequently or is occluded.

### External factors

Follicular contact dermatitis to heavy metals was increased in individuals with hyperkeratosis of their hair follicles;

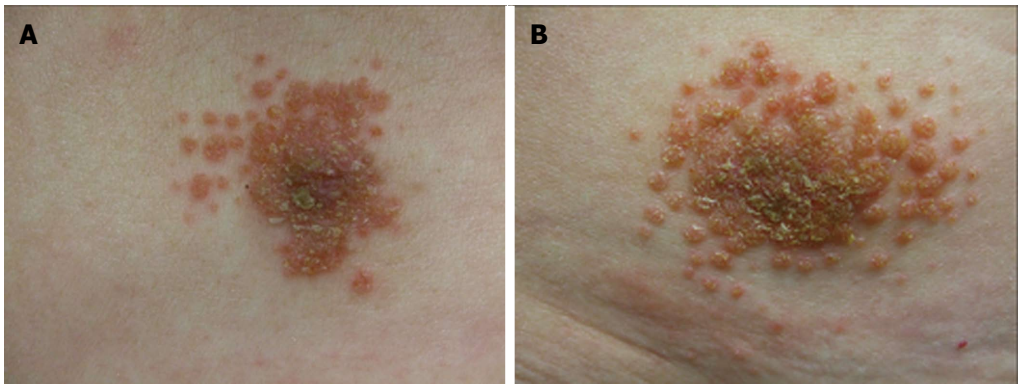

**Figure 2 Closer view of neomycin-associated follicular contact dermatitis on the right mid abdomen (A) and right lower abdomen (B).** The woman noted, one month postoperatively, that there was still some drainage from her surgical wounds. She was instructed to daily clean the sites and apply an antibiotic ointment that contained neomycin sulfate, polymyxin B zinc, and bacitracin zinc (Neosporin ointment). She began to develop small individual lesions at the sites of antibiotic ointment application after 6 wk of daily topical treatment; however, she continued to treat the incision sites for another 4 wk as the individual lesions enlarged and some become confluent-before seeking medical attention.

**Figure 3 Cutaneous examination of her abdomen and suprapubic region (A) showed individual and confluent red-brown pruritic papules where she had been applying the antibiotic ointment to prior incision sites: right mid abdomen, right lower abdomen, umbilicus and periumbilical area (B, distant view and C, closer view) and suprapubic region.**

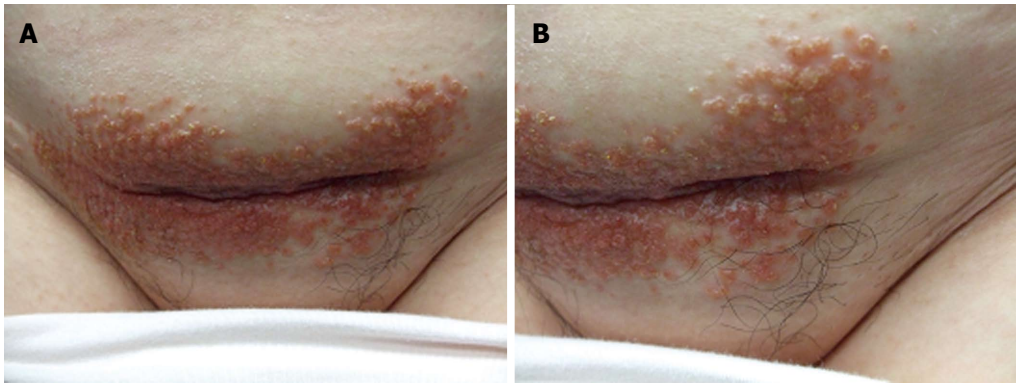

**Figure 4 Distant (A) and closer (B) inspection, particularly of the lesion in her suprapubic area, showed individual hair follicles in the center of the papules. The topical antibiotic was discontinued and flucinonide 0.05% cream was applied twice daily; all of the lesions resolved within 2 wk with residual post inflammatory hyperpigmentation at the sites.**

however, it was not associated with either the presence of acne or sweating[3]. In contrast, not only sweating, but also pressure and friction contributed to the development of follicular contact dermatitis caused by a chemical in colored permanent pressing sheets[10]. These external factors enhanced the penetration of the allergen into the follicles of the patients who developed dermatitis[10].

## DIFFERENTIAL DIAGNOSIS OF FOLLICULAR CONTACT DERMATITIS

Conditions to be considered in the differential diagnosis of follicular contact dermatitis are listed in Table 3[6,10]. Some of the patients with follicular contact dermatitis were initially considered to have disseminated recurrent

**Table 3 Clinical differential diagnosis of follicular contact dermatitis**

| Keratosis pilaris |
| Perforating folliculitis |
| Pityriasis rubra pilaris |
| Scabies |
| Viral exanthema |

infundibular folliculitis-even though they were Caucasian[6,10]. In contrast to follicular contact dermatitis which was characterized by severe itching or areas of erythema and oozing or both in some of the patients, infundibular folliculitis is typically observed in black patients as mild to moderately pruritic or burning, flesh colored, widely distributed, non-inflammatory follicular papules; the papules are typically refractory to treatment and the recurrent episodes persist for weeks to months before spontaneously resolving[43,44].

An individual in whom infundibulofolliculitis was suspected presented with recurrent 2-mm erythematous follicular papules. She was a 24-year-old nurse whose skin eruption partially improved with topical corticosteroids and resolved when her boyfriend moved to another city. However, it recurred when he returned and they went to the beach. Subsequently, the diagnosis of consort follicular contact dermatitis to the homomenthyl salicylate in her boy friend's Coppertone sunscreen lotion was considered and confirmed by positive patch testing to the lotion; additional patch testing to each component of the lotion was only positive for homomenthyl salicylate[6].

The other patients had been exposed to a chemical used in colored permanent-pressed sheets[10]. Not only the distribution and duration of the follicular contact dermatitis, but also the histopathology of the chemical-associated lesions were similar to those observed in individuals with infundibulofolliculitis. However several features permitted the patients with follicular contact dermatitis to be differentiated from those with infundibulofolliculitis: severe itching (as compared to mild or moderate pruritus), the presence of erythematous and even oozing areas (as compared to nonflammatory lesions) and a white patient population (as compared to occurring in African American individuals)[10].

## MANAGEMENT OF FOLLICULAR CONTACT DERMATITIS

The primary management of follicular contact dermatitis is withdrawal of the causative agent. The skin lesions for many of the affected individuals either resolved spontaneously or following treatment with a topical corticosteroid preparation. However, is some of the patients lesions either persisted or recurred even after elimination of the inducing chemical or repetitive washing of the eliciting item from the source of exposure; specifically, follicular contact dermatitis persisted up to 8 wk after exposure to chemical in colored permanent-pressed sheets had been eliminated and new lesions would appear even after the sheets had been washed 3 or 4 times[10].

## CONCLUSION

Follicular contact dermatitis clinically presents as individual papules that include a central hair follicle. Pathologic features involve the follicle and the surrounding dermis: spongiosis and vesicle formation of the follicular epithelium associated with perifollicular and perivascular lymphocytic inflammation. Several chemicals, including topical antibiotics, can elicit follicular contact dermatitis-either as allergens or irritants. Neomycin-associated follicular contact dermatitis was initially reported in 1952. Subsequently, follicular contact dermatitis in additional patients treated with neomycin was observed and the diagnosis was confirmed by patch testing with the agent. Several hypotheses have been suggested for the selective involvement of the follicles in follicular contact dermatitis: patient allergenicity, characteristics of the agent, vehicle containing the agent, application of the agent, and external factors. The differential diagnosis of follicular contact dermatitis includes not only recurrent infundibulofolliculitis, but also drug eruption, mite infestation, viral infection, and dermatoses that affect hair follicles. Withdrawal of the causative agent is the primary therapeutic intervention for follicular contact dermatitis. In addition, treatment with a topical corticosteroid preparation may promote resolution of the dermatitis.

## Abstract

During the incipient steps of periodontal treatment, clinicians are usually asked to predict the prognosis of teeth with compromised periodontium. The aim of this literature review was to investigate the association between periodontal Prognosis, Tooth Loss and risk indicators, such as smoking and genetics. Results showed that the definition of good prognosis has much higher predictability than the one for questionable prognosis. Several risk indicators for periodontal prognosis and tooth loss are discussed as well as different definitions of questionable prognosis and their success in predicting tooth loss. In conclusion, the major focus of future studies should be to construct simplified prognostic models with high predictability that will increase the confidence of dentists and periodontists when assigning teeth prognosis.

**Key words:** Periodontal prognosis; Tooth loss; Risk indicators; Periodontitis

**Core tip:** During the incipient steps of periodontal treatment, clinicians are usually asked to predict the prognosis of teeth with compromised periodontium. Little advancements on this topic have been made in the periodontal literature during the last decade. Current evidence shows that except for good prognosis, the assignment of overall prognosis remains rather dicey. The major focus of future studies should be to construct simplified prognostic models with high predictability that will increase the confidence of Dentists and Periodontists when assigning teeth prognosis.

## INTRODUCTION

During the incipient phases of periodontal treatment, clinicians are usually asked to predict the prognosis of teeth with compromised periodontium[1]. To address this difficult and challenging task, Periodontists have introduced the term "questionable" prognosis. In essence, this term means that a tooth may or may not respond well to treatment and many factors such as patient/host susceptibility, age, location of the tooth and degree of bone loss among others must be weighted to better determine its prognosis.

Scientific attempts to identify risk indicators for tooth loss that can help clarify and better define this term have been reported in the literature. Usually retrospective and cross-sectional studies are employed as these types of investigations allow for access to a large pool of data for analysis without the cost, or the ethical limitations that pertain to interventional studies[2]. The drawback is that it is uncertain whether an observational study can verify the causal role of a true risk factor, yet observational studies are valuable in identifying risk indicators[2].

The aim of this critical review was to investigate the

association between periodontal Prognosis, Tooth Loss and risk indicators. This review paper will discuss how specific risk indicators affect periodontal prognosis and how accurate initial periodontal prognosis can be.

## CRITICAL REVIEW

### *Inceptive definition of questionable prognosis*

Hirschfeld *et al*[3] (1978) presented data of a cross-sectional study that included 600 patients with at least 15 years and up to 50 years of follow-up. This patient cohort was described by the authors as consisting of well-motivated middle-class patients that attended frequent (4-6 mo intervals) recalls.

The authors allocated the patients in three groups based on their response to treatment: well maintained (83.2%), downhill (12.6%), or extreme downhill (4.2%).

In the well-maintained group a mean of 0.68 teeth per patient were lost during the follow-up. The number of teeth lost in the downhill and extreme downhill groups were 5.7 and 13.3 per patient, respectively.

In regards to risk indicators for post-treatment tooth loss, residual mobility was insignificant. The authors' definition of questionable prognosis (furcation involvement, deep non-eradicable pocket, extensive bone loss and/or at least grade 2 mobility with active inflammation) was accurate in depicting clinical reality for the well-maintained group. In this group 80% of the teeth lost had been initially assigned a questionable prognosis. That percentage dropped to approximately 50% in the remaining groups. Almost all of the teeth with questionable prognosis were lost in the extreme downhill group. The authors concluded that tooth loss patterns were case-related and they noted a bilaterally symmetrical pattern. They found a predictable order of likelihood of tooth loss according to position in the arch. Mandibular cuspids and first bicuspids responded most favorable to treatment and maintenance, while maxillary second and first molars and mandibular second and first molars were more susceptible to loss. In this study the characteristics of the extreme downhill group were not identified, so the question of how to predict which patients will lose more teeth remains unanswered.

In a similar study McLeod *et al*[4] (1997) investigated the effectiveness of periodontal treatment in a cohort of patients with moderate to advanced periodontitis that were treated over a period of 29 years. Tooth loss was set as the primary outcome of treatment. The authors utilized the categorization to well-maintained (0-3 teeth lost), downhill (4-9 teeth lost) and extreme downhill (10-23 teeth lost) groups as suggested by Hirschfeld *et al*[3] (1978). The authors defined moderate disease as 4-7 mm of CAL loss and severe as greater than 7 mm of loss. It should be expected that this patient pool would be assigned a diagnosis of severe periodontitis based on contemporary definitions. All patients were treated by means of SRP followed by surgical treatment if indicated and were put on frequent (3-6 mo) recalls. Again, the definition of questionable prognosis was based on Hirschfeld's definition[3]. A total of 2889 teeth were nested in the 114 patients included in this study. After a mean of 12.5 years post-treatment, 220 teeth were lost during maintenance. In agreement with the results of Hirschfeld *et al*[3] (1978), the authors noted a bilateral pattern of tooth loss. They also noted that maxillary and mandibular molars and maxillary first premolars had a higher incidence of extractions. The distribution of patients in the well-maintained, downhill and extreme downhill groups was 84.2%, 13.2% and 2.6%, respectively. Those findings are in remarkable agreement with results from the study of Hirschfeld *et al*[3] (1978). There was a higher rate of tooth loss in teeth with furcation involvement especially in the downhill groups. In regards to questionable prognosis accuracy, 529 teeth were initially assigned to this prognosis group. Sixty-eight of those teeth were lost (12.9%), while the remaining 152 teeth that were lost had not been assigned a questionable prognosis. Therefore, the negative predictive value of that definition of questionable prognosis is brought to question.

This study was novel in attempting to correlate the Hirschfeld *et al*[3] (1978) classification of response to periodontal treatment with the AAP-accepted terminology for periodontal disease. According to the authors: "Nine of the 18 patients in the downhill and extreme-downhill groups had periodontal disease that would be classified as systemic-disease-associated or early-onset periodontitis, and the remaining patients would be classified as having refractory periodontitis". This statement is valuable as it provides an explanation for the response to treatment and maintenance, but does not yield information on how to predict which patients will have a downhill response.

McFall *et al*[5] (1982), replicated the study of Hirschfeld *et al*[3] (1978) in a faculty-practice based patient population ($n$ = 100) that was followed up for at least 15 years. There results were in complete agreement with the previous studies. As in previous studies, maxillary 2$^{nd}$ molars were the most frequently lost teeth and mandibular cuspids and bicuspids were the less frequently lost ones. The definition of questionable prognosis that was utilized in this study predicted only 48.7% of the tooth loss in all groups. From the teeth that were initially assigned questionable prognosis, 62.3% were lost during the follow-up.

A question can be raised as to what benefit, other than a rough estimation of the percentage of poor responders, there is in categorizing patients in groups based on the outcome of treatment. Categorizing patients in a group prior to initiation of treatment, based on specific risk indicators and assessing the accuracy in predicting which patients will exhibit downhill response seems more reasonable.

Chace *et al*[6] (1993) performed a cross-sectional study that specifically aimed to address the fate of teeth that were assigned a questionable prognosis. The authors' definition of questionable prognosis slightly differed from the previous definitions, as it required that the teeth simultaneously exhibited pocket depth greater than 6 mm, mobility greater than 0.5 mm in buccal-lingual direction, poor

root-crown ratio and at least class II furcation involvement. In this study 166 patients, lending 455 questionable teeth to the study, were followed up over up to 40 years. A total of 55 teeth were lost (12%), with an average survival period of 8.8 years. Half of the teeth were bilaterally symmetrical and as in the previous studies most frequently lost teeth mostly groups were maxillary second molars, first molars, first bicuspids, or mandibular molars[3-5]. Even though the accuracy of the assignment of "questionable prognosis" could not be investigated with this study design, results of this study showed that teeth with significant loss of periodontal tissues could be functionally maintained. Yet, factors such as esthetics and patient satisfaction were not discussed.

In another study, Wilson *et al*[7] (1987) focused in investigating the effect of patient compliance on tooth loss. One hundred and sixty-two patients were followed up for at least 5 years and were categorized as "compliant", or "erratic". Results showed that completely compliant patients lost no teeth during the follow-up. Twenty-two patients in the erratic group lost a total 60 teeth, for an average of 0.06/patient/year in that group. The authors claimed a higher percentage of teeth with questionable to poor prognosis being lost, in comparison to teeth that were assigned good or fair prognosis, albeit no statistical test was performed.

## AN EVIDENCED-BASED ATTEMPT TO DEFINE PROGNOSIS: THE ''MCGUIRE AND NUNN'' STUDIES

In 1991 McGuire[1] evaluated the outcome of treatment in 100 patients that were followed up for a mean of 7 years following active treatment. All patients received standard of care non-surgical treatment and all of them received surgical treatment in areas with residual pockets. Patients underwent a stringent maintenance schedule with the first maintenance appointment scheduled at 1 mo post-surgery and at 1-3 mo intervals thereafter. Each tooth was assigned to one of the following five prognosis gradients: good, fair, poor, questionable, and hopeless. The author re-assigned prognosis to each tooth based on the clinical situation at 5 and 8 years post-active treatment. Results showed that the average prognosis of the teeth studied at each interval changed very little from initial to 5 to 8 years.

A 2.1% tooth loss (51/2484) was noted for the study population. The teeth with good prognosis remained relatively stable, while teeth in the fair and poor categories frequently improved. The questionable category generally got better, but a significant number of teeth were lost and teeth in the hopeless category were generally lost. Findings of interest were that prognosis was more accurate for single rooted teeth than multi-rooted, and that 3$^{rd}$ molars and mandibular molars tended to perform worse than expected. The author discussed that the criteria for assigning prognosis in this study were less lenient in downgrading a tooth to questionable prognosis in comparison to the criteria of Hirschfeld *et al*[3] (1978).

In the second part of this study the authors attempted to investigate the accuracy of a statistical model that would consider several explanatory variables such as, furcation involvement, pocket depth, percentage of bone loss, mobility, crown to root ratio and root proximity, based on the data published previously[8]. The model was very accurate in predicting prognosis (approximately 80%), especially in non-molar teeth. When scrutinizing the results, the authors found that the accuracy of the model was significantly compromised when teeth with good prognosis were excluded from the analysis (< 50%). The clinical repercussion of those findings is debatable. It may not be as crucial to determine if a tooth that was assigned questionable prognosis may move to fair, or vice versa. On the contrary it is very valuable the ability to foresee which teeth will shift from the fair, or questionable gradient to hopeless. That question was addressed in the third part of this study that was published later the same year[9].

In the third part of the study the authors extended the follow-up to 16 years. This extended observation time increased the number of teeth lost to 131 of the 2509 initially present. The average survival time for teeth that were lost was approximately 5 years post treatment. In this publication a true endpoint[10] was chosen, tooth loss.

Results showed that both the sensitivity and specificity of the suggested prognosis classification increased when tooth loss was considered as the endpoint.

When questionable and hopeless prognoses were grouped together they were relatively accurate in predicting future tooth loss. The authors also constructed a proportional hazard model that identified initial probing depth, initial furcation involvement, initial mobility, initial percent bone loss, parafunctional habits with no biteguard, and smoking risk indicators for tooth loss.

## CONTEMPORARY VIEWS ON PERIODONTAL PROGNOSIS

New data and studies have initiated a shift in the consideration of risk indicators for periodontal prognosis. A vastly increasing number of new studies are now focusing on risk indicators involving host susceptibility rather than local factors[11,12]. The genetic and host components of periodontal disease and their association with periodontal prognosis are magnetizing the interest of clinicians. The pathophysiologic cascade underlining this relationship has not been clearly elucidated. Yet, there are clear indications of this association. Fardal *et al*[13] (2004) investigated risk factors associated with tooth loss due to periodontal reasons during maintenance phase of treatment in a hundred patients in a Norwegian specialist periodontal practice. This study examined how initial prognosis related to actual outcome as measured by a true point, namely periodontal tooth loss. The patients included in this practice-based study, had comprehensive periodontal treatment and were followed for 9-11 years

during maintenance care. The authors identified that only 36 (1.5%) of the 2436 teeth present at baseline were subsequently lost due to periodontal disease. The majority 27 (75%) of the teeth lost due to periodontal disease had been assigned an uncertain, poor or hopeless initial prognosis. Fardal *et al*[13] found that tooth loss was significantly associated with older age (> 60 years), male gender and smoking, but was not significantly associated with oral health status and family history, and that compliance with maintenance following active periodontal treatment was associated with low levels of tooth loss. Notably, even though the majority of teeth lost due periodontal disease had been initially assigned an uncertain, poor or hopeless prognosis, 9 of the teeth lost (25%) had been assigned a good prognosis at baseline. This indicates that it is not always possible to identify all teeth that are at risk of being lost during the progression of periodontitis. From the interpretation of results of Fardal *et al*[13] (2004) it is evident that risk indicators related with host and genetic components are more predictive of tooth loss, rather than those associated with clinical parameters and local factors. Age and gender were significantly associated with tooth loss in contrast with oral health status, indicating a strong association between tooth loss and the genetic-host component of periodontal disease[13].

A common finding in earlier studies on tooth survival following active treatment and maintenance has shown that furcation involvement is a risk indicator for future tooth loss[1,3-5] and makes assignment of accurate prognosis very challenging[9]. Svärdström *et al*[14] (2000) evaluated 1313 molars in 222 patients in order to analyze the outcome of non-regenerative treatment. They found that from the 899 molars that were deemed maintainable, only 21 (3.5%) were extracted within a 10-year follow-up period. All molars in this group were treated with scaling and root planning followed by modified Widman flap surgery, if indicated. The authors concluded that molar teeth treated with non-resective, non-regenerative approaches have a good long-term prognosis if a frequent recall schedule is followed.

The potential prognostic value of clinical, genetic, and radiographic variables in predicting tooth loss in periodontal patients was assessed in a 10-year retrospective analysis[15]. Sixty periodontal patients were treated according to the standard of care and were placed at 3-4 mo maintenance schedules. In addition to standard clinical and radiographic examination, the patient underwent interleukin-1 genotype assessment. The distance of the bottom of the bony defect to the root apex as well as molar teeth were significant predictors of tooth loss. On the contrary deep intrabony defects had a protective effect. Interleukin-1 test was not efficient as a predictor of tooth prognosis.

Faggion *et al*[16] (2007) also attempted to identify risk indicators to construct a prognostic model. In agreement with the previous studies, teeth with multiple roots were identified as a significant factor. The authors also identified diabetes mellitus, reduced bone levels at baseline, non-vital pulp and tooth mobility as risk indicators for future tooth loss.

A simplification of the McGuire[1] (1991) classification of periodontal prognosis was proposed by Checchi *et al*[17] (2002). This simplified classification includes three prognosis gradients: good, questionable, and hopeless. The authors elected to define prognosis based on residual bone levels and/or furcation involvement. Teeth with more than 75% per cent bone loss were assigned "hopeless" prognosis and teeth that had between 50% to 75% bone loss, or furcation involvement were assigned "questionable" prognosis. If a tooth exhibited both characteristics it was downgraded. Results showed that 0.07% of teeth with good prognosis were lost, 3.63% were lost from the questionable prognosis category and 11.34% were lost from the hopeless prognosis subgroup. While previous prognosis classifications were shown to be accurate for the "good" and "hopeless" prognosis, this simplified approach performed very well for "good" and "questionable" prognosis, but seemed to have been pessimistic in assigning "hopeless" prognosis.

Most of the studies mentioned in this review evaluated the prognosis of teeth that had undergone periodontal treatment and went into a maintenance phase. Neely *et al*[18] (2001) looked into risk indicators for tooth loss in an untreated cohort of 154 Sri Lankan tea laborers. This patient cohort had no access to periodontal treatment and represented a population sample of untreated periodontal disease. Results were very interesting as they showed that plaque index and smoking were not associated with mean attachment loss. Age, gingival index, calculus index and time were associated with attachment loss over 20 years of follow-up.

The same group of researchers published a follow-up paper that evaluated a true endpoint (tooth loss) instead of a surrogate endpoint (attachment loss)[19].

Results were striking as they significantly differed from results of the previous study. In this second part, none of the individual risk indicators had a significant impact on tooth loss. Tooth loss was associated with increasing attachment loss in the presence of use of betel nut. Interestingly, betel nut (a nut containing substances with vasoconstricting properties) was found to be a poor predictor of increase in attachment loss in the first part of the study. These findings point out that even though attachment loss is a well-established surrogate for tooth loss in the treatment of periodontitis, studies that utilize surrogate endpoints should always be reviewed with that limitation in mind[20].

### *Other risk indicators for tooth loss*

Several studies have investigated the effect of single risk indicators, or risk factors, depending on the definition, on tooth loss. Such ones are furcation involvement[21], retained "hopeless" teeth[22], residual deep pockets[23] and maintenance schedule frequency[24].

Axelsson *et al*[24] (1981) assessed the efficacy of a stringent maintenance schedule in patients that had undergone surgical periodontal therapy. All patients were treated with modified widman flap surgery in all four

quadrants. One third of the initial group of 90 patients was referred back to their general dentists for maintenance, while the remaining two thirds underwent a stringent maintenance schedule that included professional debridement once every two months for the first two years post-operatively and once every three months thereafter. Results showed that there was a significant difference in pocket depth maintenance and maintenance of attachment levels around treated teeth between the "recall" and "non-recall" groups. It should be noted that patients in the stringent maintenance group received subgingival scaling at their bimonthly, or trimonthly visits, when indicated. Results on tooth maintenance in each group were not at all that impressive. No significant difference was noted in the number of teeth lost between the two groups. No teeth were lost in the "recall" group and only few teeth were lost in the "non-recall" group. Numerical results were not published. The authors concluded that stringent maintenance is of paramount importance as it can prevent future attachment loss. One could argue that the authors overemphasized results of this study. It is more reasonable to evaluate a true endpoint, such as tooth loss as being more significant over a surrogate, such as attachment loss[10]. On the other hand the sample size on the non-recall group was smaller and as a result the study might have not been powered enough to identify a difference in the incidence of tooth loss, as this is a rare event.

Furcation involvement is another risk indicator that has been highlighted in several studies. Waerhaug[21] (1980) investigated the anatomy and pathophysiology of furcation defects and concluded that if clinicians are aware of specific considerations when treating molar teeth with furcation defects, then their prognosis may be improved.

Interesting findings were that there is significantly increased attachment loss in the furcation area in comparison to the outer surfaces of the root and that the absence of bleeding on probing of the marginal gingiva is not associated with absence of inflammation, or progression of disease in the furcation area.

In a different study, researchers attempted to evaluate the retention of "hopeless" teeth as an indicator for future progression of disease in neighboring sites[22]. In order to define "hopeless" the authors employed a combination of risk indicators such as at least 75% of bone loss, class 3 furcation defect, residual 8mm pocket depth, or repeated periodontal abscesses. Results showed no significant effect of the hopeless teeth on the "adjacent" surfaces of the neighboring teeth in comparison to the "non-adjacent" ones. Pocket depth post-treatment averaged at approximately 3.5 mm around the teeth that were in the vicinity of retained "hopeless" teeth, which indicates that even though no significant increase in surrogate markers for progression of disease was noted, many of the teeth had residual pockets greater than 3 mm. The authors concluded that retained "hopeless" teeth do not affect the periodontium of neighboring teeth as long as patients undergo frequent maintenance.

The influence of residual pockets in the prognosis of teeth has also been a matter of interest. Matuliene *et al*[23] (2008) followed 172 patients with residual pockets after the active phase of treatment for 3-27 years. Progression of disease was defined as at least 3 mm of proximal attachment loss in at least two teeth. During the maintenance phase of treatment the percentage of pocket depths that were less than 5 mm did not change significantly. On the other hand, the percentage of pockets that had an initial depth of at least 5 mm increased from 2.9% to 4.3%. Increased pocket depth was found to be strongly associated with tooth loss in multilevel logistic regression analysis. During the follow-up 1.7 teeth were lost per patient. Residual pockets of at least 6 mm that were left untreated were a significant factor for tooth loss. During the maintenance phase, 43% of all cases were identified as progressing cases based on the definition mentioned above. The authors concluded that residual pockets with depth greater or equal to 6 mm represent incomplete periodontal treatment and are a risk indicator for tooth loss.

## CONCLUSION

Even though this topic has been extensively discussed in the literature a solid definition of questionable prognosis has not been yet established. The importance of assigning an accurate prognosis for teeth prior to initiation of treatment cannot be emphasized enough. Not only it sets the foundation of trust between the therapist and the patient but also prevents legal implications from arising after the treatment process.

The major focus of future studies should be to construct simplified prognostic models with high predictability that will increase the confidence of dentists and periodontists when assigning teeth prognosis.

## Abstract

Patients with interstitial lung disease commonly exhibit abnormal sleep architecture and increased sleep fragmentation on polysomnography. Fatigue is a frequent complaint, and it is likely that poor sleep quality is a significant contributor. A number of studies have shown that sleep disordered breathing is prevalent in this population, particularly in the idiopathic pulmonary fibrosis subgroup. The factors that predispose these patients to obstructive sleep apnoea are not well understood, however it is believed that reduced caudal traction on the upper airway can enhance collapsibility. Ventilatory control system instability may also be an important factor, particularly in those with increased chemo-responsiveness, and in hypoxic conditions. Transient, repetitive nocturnal oxygen desaturation is frequently observed in interstitial lung disease, both with and without associated obstructive apnoeas. There is increasing evidence that sleep-desaturation is associated with increased mortality, and may be important in the pathogenesis of pulmonary hypertension in this population.

**Key words:** Sleep disordered breathing; Interstitial lung disease; Pulmonary fibrosis; Nocturnal hypoxia; Obstructive sleep apnoea

**Core tip:** This article reviews the literature on sleep disordered breathing in interstitial lung disease, seeking to define the important contributing factors and sequelae. The key concepts that are explored include the contribution of nocturnal hypoxaemia to the development of pulmonary hypertension, and the mechanisms behind the observed high prevalence of obstructive sleep apnoea in interstitial lung disease patients.

## INTRODUCTION

The interstitial lung diseases (ILD) are a heterogeneous group of disorders characterized by varying degrees of fibrosis and inflammation of lung parenchyma. Sufferers exhibit lung restriction and exercise intolerance, often developing progressive hypoxia over time. Independent of the presence of daytime hypoxia, many individuals with ILD are observed to desaturate during sleep, with or without associated apnoea.

There is mounting evidence that nocturnal hypoxia and sleep-disordered breathing (SDB) may contribute to adverse outcomes. Aside from resulting in poor sleep quality and daytime fatigue, transient repetitive desaturation and associated sympathetic nervous system activation may play a role in the development of pulmonary hypertension and contribute to increased mortality[1-3].

Existing evidence on aspects of sleep physiology and pathophysiology in ILD will be considered within this review.

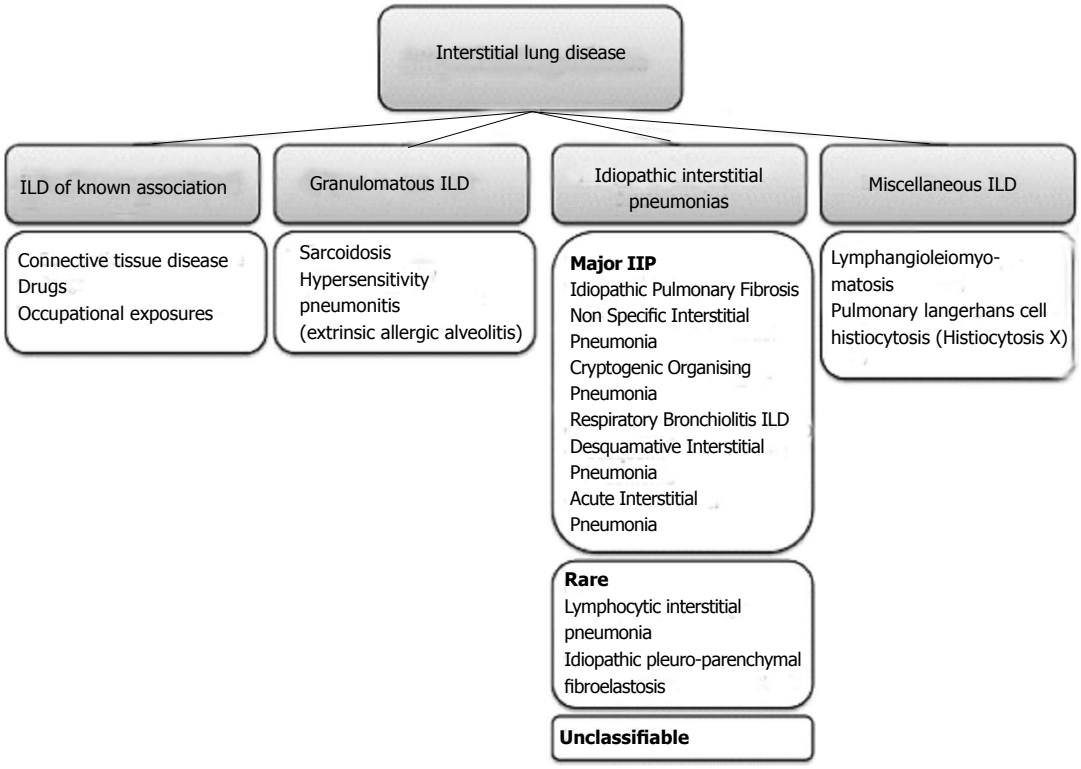

**Figure 1 Classification scheme of interstitial lung disease (Adapted from[4,5]).** ILD: Interstitial lung disease; IIP: Idiopathic interstitial pneumonia.

## POPULATION AT RISK

There are estimates of more than two hundred known causes of ILD, leading to restrictive physiology, dyspnoea and often a pervasive cough. These diseases can be divided into broad subcategories: (1) those with known aetiology such as the pneumoconioses, drug-related ILD, and connective tissue disease-associated ILD; (2) the granulomatous diseases such as sarcoidosis and chronic hypersensitivity pneumonitis; (3) the idiopathic interstitial pneumonias such as idiopathic pulmonary fibrosis (IPF), non-specific interstitial pneumonia, cryptogenic organizing pneumonia (COP); and (4) a miscellaneous group including pulmonary Langerhans cell histiocytosis[4,5]. A classification scheme is depicted in Figure 1.

Many of these diseases evolve from an initial inflammatory process involving the lung interstitium with varying inclusion of the lung vasculature and airways. Over time, inflammation may give way to advancing fibrosis, especially in cases where diagnosis and treatment are delayed and inflammation persists unabated. In contrast, IPF is a distinct entity, in which inflammation does not appear to play an important role in the pathogenesis of fibrosis, which often progresses rapidly and relentlessly.

Irrespective of underlying aetiology, advancing fibrosis often leads to worsening gas exchange across a thickened collagen-dense interstitium, and respiratory failure may eventually ensue. Hypoxic vasoconstriction, endothelial remodelling and vascular obliteration all contribute to the development of pulmonary hypertension, a poor prognostic feature when present in ILD patients[6,7].

## SLEEP CHARACTERISTICS IN ILD

### *Breathing pattern during sleep*

During wakefulness, ILD patients are known to have a rapid, shallow breathing pattern both at rest and with exercise[8,9]. This is thought to be due to increased intrinsic elastic loading of respiratory muscles and stimulation of peripheral mechanoreceptors[8,10]. Even in the face of severely impaired gas exchange, this respiratory pattern allows ILD patients to maintain ventilation and daytime eucapnia until very advanced stages of disease. During sleep, some investigators have found respiratory frequency, *f* to be no different to that when awake[11-14]. Others have shown that *f* falls, but with an attendant increase in tidal volume, so that overall, the increased minute ventilation is preserved during sleep[15].

### *Sleep architecture and sleep quality*

Not surprisingly, sleep quality is comparatively poorer than that of the normal population. Nocturnal cough, medications, breathing difficulties, hypoxia and obstructive apneas have all been implicated in disrupting sleep in this population. Perez-Padilla *et al*[14] in 1985, compared 11 ILD patients with age- and sex-matched controls. They reported decreased amounts of rapid eye movement (REM) sleep as well as significant sleep fragmentation in the patient group[14]. Further prospective studies, with particular focus on IPF confirm these findings, and also report increased stage 1 and 2 sleep, reduced slow wave sleep and poorer overall sleep efficiency[13,15-20]. Sleep characteristics in ILD subjects are shown in Table 1.

**Table 1 Sleep characteristics in interstitial lung disease**

| Sleep characteristic | Abnormality | Patient group | Ref. |
|---|---|---|---|
| Respiratory rate | Decreased | ILD | [15] |
| | Unchanged | ILD, IPF | [11-14] |
| Stage 1/2 sleep | Increased | ILD | [14] |
| | | IPF | [19,20] |
| REM sleep | Reduced | ILD | [11,14,15,25] |
| | | Scleroderma | [26] |
| | | IPF | [2,19,20] |
| Slow wave sleep | Reduced | IPF | [13] |

ILD: Interstitial lung disease; IPF: Idiopathic pulmonary fibrosis; REM: Rapid eye movement.

### Daytime symptoms and quality of life

The symptoms of sleepiness and fatigue often co-exist in ILD patients. Common causative factors include systemic inflammation, treatment side effects, age and comorbidities. Depression and disease-related stressors also affect many. In addition, sleep fragmentation appears to be a substantial contributor, as demonstrated in studies using numerous sleep and health-related quality of life (QoL) questionnaires in ILD subjects. Fatigue is frequently reported, impacting on wellbeing and daytime function[13,21,22]. The Epworth Sleepiness Scale (ESS), and Pittsburgh Sleep Quality Index (PSQI) scores are higher in unselected ILD patients than in normal controls, indicating poorer quality sleep[22-24]. However, in ILD cohorts with polysomnography, the ESS and other tools do not reliably predict severity of sleep-disordered breathing[2,19,25]. The PSQI does appear to correlate with health-related QoL indices, particularly physical function and vitality, highlighting the pervasive influence of sleep fragmentation[22]. Nocturnal hypoxia in ILD patients is also independently associated with a reduction in energy levels, as well as physical and social functioning, as assessed by a variety of QoL instruments[13,21].

### Non-respiratory disturbances to sleep

Increased periodic limb movements and restless legs syndrome (RLS) have been documented in IPF and scleroderma patients[17,26]. A self-reported study in IPF patients and normal controls, however, did not find any difference in the incidence of RLS[27]. Gastro-oesophageal reflux disease may also play a role in sleep disruption, particularly in high-risk groups including scleroderma patients[26].

## OBSTRUCTIVE SLEEP APNOEA IN ILD

Increasing attention has been focused on the prevalence of obstructive sleep apnoea (OSA) in ILD, with much of the cross-sectional data coming from studies in IPF patients. Three prospective studies showed the incidence of OSA in IPF subjects to markedly exceed that reported in healthy age-matched populations, with estimates between 59% and 90%[2,19,20]. This increased risk however, does not appear to be unique to IPF, with studies of mixed ILD populations (and in particular sarcoidosis and scleroderma subgroups) demonstrating similar findings[18,25,28]. These results are summarized in Table 2.

### Association between degree of OSA and severity of lung disease

Although retrospective analyses of ILD subjects suggest an association between the degree of lung restriction and the risk and severity of sleep disordered breathing, this has not been demonstrated in larger, prospective studies[2,17,19,20,25,29]. The only correlation between measured lung volumes and PSG parameters, reported by Mermigkis *et al*[20], was in total lung capacity and REM sleep apnoea hypopnoea index (AHI). Kolilekas *et al*[2] found an association between overall AHI and peak $VO_2$ on exercise testing, but this may simply reflect poorer daytime function and more deconditioning in those with more fragmented sleep.

### Hypotheses for why SDB is increased in patients with ILD

In the general OSA literature, recent attention has been turned towards the inherent characteristics that predispose individuals to sleep disordered breathing. The two key components believed to underscore the pathogenesis of OSA are increased upper airway collapsibility and enhanced ventilatory control system instability[30]. It is useful to consider these processes in the ILD population.

**Upper airway collapsibility:** It is generally believed that restrictive lung disease leads to increased upper airway collapsibility through reduced caudal traction on these structures[31,32]. The inability to demonstrate a relationship between lung function parameters and AHI seems to refute this theory. One limitation with all reported data, however, is the assessment of lung function in the upright position only. There may be more robust associations between supine measurements and SDB, but this is yet to be investigated in ILD subjects. Increased body mass index (BMI) is associated with deposition of adipose tissue around upper airway structures, enhancing collapsibility. BMI correlates with AHI in some, but not all studies of ILD subjects, suggesting that other mechanisms are important[2,18-20,25].

**Ventilatory control system instability:** In sleep, any rise in arterial $CO_2$ (such as occurs with an apnoea) will stimulate carotid and medullary chemoreceptors, resulting in a central respiratory motor output response[33]. The direct activation of respiratory pump muscles and upper airway dilator muscles (*e.g.*, genioglossus) restores upper airway patency, and is often accompanied by an arousal. Some individuals with heightened chemo-responsiveness may overshoot the eucapnic range, by overventilating in response to apnoea-induced hypercapnia. The ensuing hypocapnia will then cause a further apnoea, sometimes leading to a cyclical pattern of repetitive apnoeas as the ventilatory system continues to attempt to achieve ho-

**Table 2 Prevalence of obstructive sleep apnoea in interstitial lung disease populations *n* (%)**

OSA: Obstructive sleep apnoea; BMI: Body mass index; ILD: Interstitial lung disease; IPF: Idiopathic pulmonary fibrosis; SDB: Sleep disordered breathing; PSG: Polysomnography; AHI: Apnoea hypopnoea index; CPAP: Continuous positive airway pressure.

meostasis. This ventilatory system instability is believed to be an important contributing factor in many with OSA[34].

Intermittent hypoxia enhances chemo-responsiveness, and is likely to exacerbate ventilatory instability in susceptible individuals[35]. This may at least partly explain the frequent observation in some ILD patients, where repetitive apnoeas are unmasked during REM sleep when hypoxia is most pronounced[20].

## NOCTURNAL OXYGEN DESATURATION IN ILD

Nocturnal hypoxia is common in ILD, both with and without concomitant OSA. The relative importance of this has been debated, with some early studies concluding that desaturation was minimal, having little clinical impact in ILD[15,16,36]. Other observational studies found that ILD patients experience transient or sustained hypoxia repetitively throughout sleep, leading to a substantial cumulative period of time with $SpO_2$ below 90%[11-14,18,21]. More recently, sleep-desaturation has been found to be an independent predictor of poorer prognosis[1,2].

Whilst obstructive events will undoubtedly be the cause for a proportion of the transient desaturations, there are many other pathophysiologic contributions. Perez-Padilla *et al*[14], did not observe OSA in any of their subjects, but transient desaturation was a frequent occurrence amounting to an average of nearly 50% of total sleep time with $SpO_2$ below 90%. Further studies found the degree of desaturation that subjects experienced during sleep was independent from oxygen desaturation during moderate and maximal exercise[2,11,16].

There are a number of reasons why ILD patients might be more vulnerable to desaturation during sleep than normal subjects, and indeed than sufferers of OSA with normal lungs. Firstly, many patients will be on the steep portion of the oxygen-haemoglobin dissociation curve, whereby small changes in arterial oxygen tension lead to large decrements in saturation. In support of this is the observation of greater degrees of sleep desaturation in those with lower awake resting $PaO_2$ and $SaO_2$[16,21,36,37]. Hypoxia may also occur due to worsening ventilation/perfusion inhomogeneity, and also alveolar hypoventilation, particularly during REM sleep[3]. Findley *et al*[38] studied the effect of lung volume on apnoea-related desaturation in normal subjects lying supine. Apnoeas were initiated at a range of lung volumes between total lung capacity and residual volume. The most severe desaturations occurred with apneas at the lower volumes, presumably because of the greater relative impact of dependent airway closure. This is a further mechanism of sleep-related hypoxia that may be extrapolated to individuals with lung restriction from ILD and concomitant sleep apnoea.

### *Predicting nocturnal desaturation in ILD patients*

As might be expected, daytime hypoxia has been identified as a predictor of night-time desaturation in a number of studies[16,21,36,37]. Severity of lung restriction and degree of desaturation with exercise, on the other hand, do not correlate well with nocturnal hypoxia[1,16,21,37,39]. Respiratory drive during wakefulness, (measured as the change in ventilation in response to changes in $PaCO_2$), shows a tight negative correlation with the degree of desaturation in both REM and NREM sleep in ILD patients[37], suggesting the innate chemo-responsiveness of the individual will also influence susceptibility to hypoxia. It is possible also that repeated severe episodes of nocturnal desaturation will eventually blunt this responsiveness, further perpetuating the problem as the disease advances.

### *Oxygen supplementation during sleep*

Although there is widespread practice to provide supplemental oxygen for chronic lung disease patients with significant sleep desaturation, there is very little supportive evidence. In the COPD literature, the survival benefit derived from continuous oxygen therapy has not been demonstrated with overnight supplementation in those with nocturnal hypoxia only[40-42]. There is some suggestion that pulmonary haemodynamics may be improved in COPD patients with long-term nocturnal oxygen[43].

Only two studies have looked at the acute use of noc-

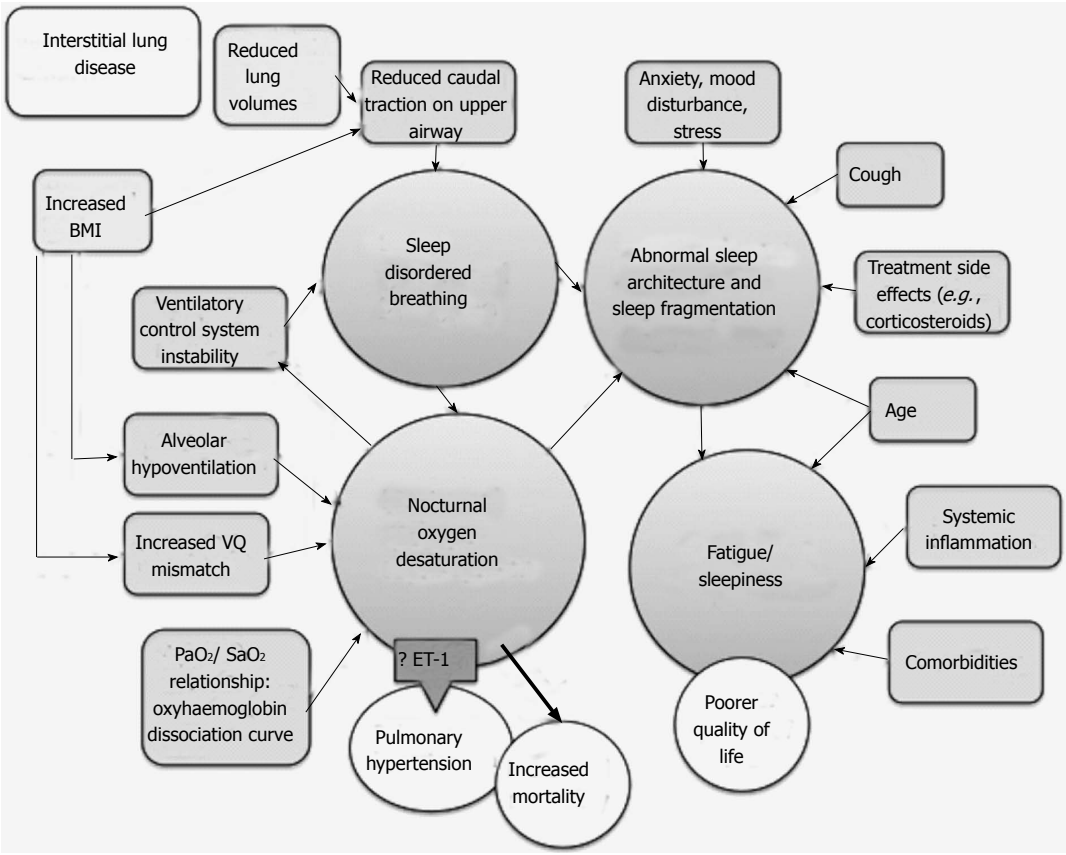

**Figure 2 Mechanisms of sleep-related pathology in interstitial lung disease.** BMI: Body mass index; VQ: Ventilation-perfusion; ET-1: Endothelin-1.

turnal oxygen in ILD. By eliminating sleep-hypoxia with supplemental oxygen, Shea and co-workers were able to demonstrate a fall in both *f* and minute ventilation compared with awake values, approximating those of normal controls[44]. Vazquez studied ILD subjects at 2240 m above sea-level, breathing air or oxygen on two separate nights[45]. Not surprisingly, all were hypoxic at rest (mean $PaO_2$ 51 mmHg). With the addition of low-flow oxygen during sleep, heart rate and *f* were reduced and oxygenation improved. Sleep architecture, efficiency and arousal index were not significantly altered. To date, there have been no studies to address whether sleep quality or haemodynamics may improve with long-term use in ILD.

## NOCTURNAL DESATURATION AND PULMONARY HYPERTENSION

The link between intermittent desaturation and increased pulmonary arterial pressure was hypothesised nearly forty years ago[46,47]. Cross-sectional data in ILD subjects confirms the association between severity of nocturnal desaturation and the presence of pulmonary hypertension on echocardiography and right heart catherisation[1,39,48]. Furthermore, prolonged exposure to transient, repetitive hypoxia in both animals and humans leads to measurable changes in pulmonary haemodynamics[49]. Tatsumi and colleagues studied subjects with both obstructive and restrictive lung diseases, comparing those with significant nocturnal oxygen desaturation (NOD) to those without NOD, but matched for other disease variables[3]. Daytime, supine pulmonary arterial pressures (PAP) and pulmonary vascular resistances (PVR) were significantly higher in the NOD group. Under hypoxic conditions, these differences became more marked. Hyperoxia, on the other hand, improved PVR and PAP, but not to the normal range seen in the non-NOD patients. This experimental data suggests that the effects may last well beyond the acute period, due to permanent structural changes in the vasculature.

### *Biomarkers in pulmonary hypertension*

Serum Endothelin-1 (ET-1), a vasoactive peptide believed to be important in the pathogenesis of pulmonary hypertension, has been measured in ILD patients during sleep, in a novel study by Trakada and colleagues[50]. During wakefulness, ET-1 was significantly higher in those with elevated pulmonary pressures. During sleep, ET-1 rose acutely in all patients during episodes of desaturation below 90%, and correlated with simultaneously measured $PaO_2$ concentrations and pulmonary arterial pressures. This very interesting research highlights a putative mechanistic pathway in the evolution of pulmonary vascular disease in ILD patients.

In summary, there is increasing evidence that nocturnal desaturation is not a benign phenomenon in ILD patients. In a large proportion, NOD occurs transiently and repeatedly throughout sleep, both with and without associated apnoeas. This may promote development of

pulmonary hypertension, and is independently associated with higher mortality. Mechanisms of SDB and NOD are illustrated in Figure 2.

## CONCLUSION

A small but growing body of literature suggests that SDB and NOD are common in patients with IPF and other ILD. There is still much to learn regarding the true impact that these have on the natural history of disease. A large area of uncertainty remains in whether targeted treatment (*e.g.*, positive pressure ventilation, oxygen or other novel therapies) will offer any quality of life or mortality benefits.

## Abstract

$O^6$-methylguanine DNA methyltransferase (MGMT) gene promoter methylation plays an important role in colorectal carcinogenesis, occurring in about 30%-40% of metastatic colorectal cancer. Its prognostic role has not been defined yet, but loss of expression of *MGMT*, which is secondary to gene promoter methylation, results in an interesting high response to alkylating agents such as dacarbazine and temozolomide. In a phase 2 study on heavily pre-treated patients with *MGMT* methylated metastatic colorectal cancer, temozolomide achieved about 30% of disease control rate. Activating mutations of *RAS* or *BRAF* genes as well as mismatch repair deficiency may represent mechanisms of resistance to alkylating agents, but a dose-dense schedule of temozolomide may potentially restore sensitivity in *RAS*-mutant patients. Further development of temozolomide in *MGMT* methylated colorectal cancer includes investigation of synergic combinations with other agents such as fluoropyrimidines and research for additional biomarkers, in order to better define the role of temozolomide in the treatment of individual patients.

**Key words:** Colorectal cancer; $O^6$-methylguanine DNA methyltransferase; Temozolomide; Dacarbazine; Biomarker

**Core tip:** $O^6$-methylguanine DNA methyltransferase (MGMT) methylation is involved in colorectal carcinogenesis and represents a predictive biomarker for alkylating agents in metastatic colorectal cancer. In fact, patients with chemorefractory metastatic colorectal cancer with *MGMT* methylation derived promising response from treatment with dacarbazine or temozolomide, and ongoing research is investigating the efficacy of temozolomide in combination with other chemotherapy drugs for *MGMT*-methylated colorectal cancer. Future challenges include the combination with biologic drugs and the research for additional biomarkers.

Role of MGMT as biomarker in colorectal cancer. *World J Clin Cases* 2014; 2(12): 835-839 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/835.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.835

## ROLE OF MGMT IN THE DEVELOPMENT OF COLORECTAL CANCER

Colorectal carcinogenesis is a complex, multistep and still not completely understood process including both genetic and epigenetic alterations. DNA damage certainly plays a central role in cancer development and progression, especially when the DNA repair machinery is not

efficient.

$O^6$-methylguanine DNA methyltransferase (MGMT) is a DNA repair enzyme codified by the *MGMT* gene at locus 10q26[1]. MGMT removes alkyl groups from the $O^6$-position of the guanine acting itself as an acceptor, and such reaction leads to an irreversible inactivation of the enzyme[2]. *MGMT* transcription is regulated by epigenetic mechanisms. Methylation of the CpG dinucleotides in the promoter region of *MGMT* results in gene silencing, MGMT loss of expression and inability to remove alkyl groups from methylated guanine, with a consequent alteration of the normal DNA structure[3].

While protecting normal cell from carcinogens, MGMT activity also protects tumor cells from lethal effects of chemotherapy with alkylating agents such as dacarbazine (DTIC) or temozolomide (TMZ), widely used for the treatment of melanoma and glioblastoma. In glioblastoma, in fact, *MGMT* methylation has been identified as a relevant prognostic factor and as an independent predictive factor of benefit from TMZ[4,5]. For melanoma, the predictive and prognostic role of *MGMT* methylation status is controversial, but patients with MGMT-methylated melanoma treated with DTIC seem to be at higher risk of treatment-related adverse events[6].

*MGMT* promoter methylation is a frequent and relevant event in colorectal cancerogenesis, with a low expression of MGMT secondary to gene silencing observed in 27 to 40% of metastatic chemorefractory colorectal cancer (mCRC)[7]. However, MGMT loss has been also demonstrated in normal colorectal tissue, suggesting that *MGMT* silencing is only one of several steps needed for the accumulation of DNA damage and cell transformation. MGMT loss has been defined as a "field defect", since it is neither necessary nor sufficient to cancer progression - *i.e.*, in a multistep process, it represents only one of the earlier passages leading to carcinogenesis. In fact, a second level of defense against DNA damage is represented by the mismatch repair (MMR) system which leads cell to apoptosis in presence of serious genomic alterations[8]. Loss of MGMT expression is more frequent in CRC with microsatellite instability, suggesting that methylated *MGMT* select cellular clones with MMR deficient status[9].

However, MGMT loss also plays a role in microsatellite-stable CRC through a mechanism of chromosomal instability[10]. During DNA transcription, methylated guanine is wrongly recognized as adenine causing C:G to A:T transition mutations. MGMT may prevent guanine to adenine transition in ras-family genes, while the loss of MGMT activity may increase the likelihood of *RAS* and *TP53* mutations. In fact, *MGMT* methylation was found in 71% of mCRC with *KRAS* G>A mutations, whereas it was present only in 32% of tumors with non-G>A KRAS mutations and in 35% of tumors with wild-type *KRAS*[11,12]. In *KRAS*-mutant tumors, *MGMT* promoter methylation occurs before *KRAS* mutations and it represents an early event in the adenoma-carcinoma sequence. Therefore, there should be a high concordance of *MGMT* methylation status between primary tumor and distant metastases.

Despite its defined position in the pathogenesis of CRC, the prognostic role of *MGMT* is still controversial. Few studies directed to investigate the prognostic role of *MGMT* methylation have been published with different results. In a series of 116 patients, a reduction of recurrence rate after adjuvant therapy has been reported in *MGMT* methylated patients[13]. Shima *et al*[14] analyzed a group of 855 patients with CRC showing no prognostic value of MGMT loss or gene promoter hypermethylation. No benefit from 5-fluorouracil (5-FU)- or oxaliplatin-based regimens was reported in presence of *MGMT* promoter methylation or *MGMT* loss[15].

## ACTIVITY OF ALKYLATING AGENTS IN MGMT-METHYLATED COLORECTAL CANCER

DTIC and its oral derivative TMZ exert their cytotoxic effects through methylation of DNA at the N3 position of adenine and at the N7 and O6 positions of guanine. Although N7-methyl-guanine and N3-methyl-adenine represent the majority of adducts, cytotoxicity of DTIC and TMZ seems to be mainly due to DNA methylation at the O6-position of guanine, which leads to DNA double strand breaks and subsequent inhibition of DNA replication and apoptosis. As the cytotoxic effect of TMZ is mediated primarily through methylation of O6-guanine, the predominant mechanism of tumor resistance to DTIC and TMZ is *MGMT* expression.

TMZ showed *in vitro* activity against several human malignancies, including colorectal cancer[16]. In a phase 1 study on solid tumors comparing a novel schedule for TMZ given twice a day for more than 5 consecutive days with the standard schedule of a daily administration for 5 consecutive days, the drug activity was quite disappointing with only 1 out of 12 mCRC patients responding to treatment[17]. However, patients enrolled in the trial were not molecularly selected according to the *MGMT* methylation status.

In a pilot study, 66 patients with refractory metastatic cancer were treated according to the molecular tumor profiling, and TMZ was effective in 2 cases of advanced CRC exhibiting loss of *MGMT* expression[18]. Consistently with these data, Schacham-Schmueli and colleagues described 2 patients with mCRC and a low expression of MGMT who were treated with TMZ achieving an impressive clinical response[19]. To explore the hypothesis that in mCRC the activity of TMZ is confined to tumors with low levels of *MGMT*, a phase II trial combined the alkylating drug with lomeguatrib, a nontoxic low-molecular weight pseudosubstrate which inactivates MGMT[20]. Unfortunately, the study was terminated early for futility, after 19 instead of the 30 patient initially planned had been recruited. The main reason why no objective response was observed, as the same authors stated, may be related to the low doses of TMZ and lomeguatrib used in the trial.

**Table 1 Phase 2 clinical trials with alkylating agents in metastatic chemorefractory colorectal cancer**

| Ref. | Schedule | *n* (*MGMT*-m) | RR (*MGMT*-m) | DCR (*MGMT*-m) | PFS mo (*MGMT*-m) | OS mo (*MGMT*-m) |
|---|---|---|---|---|---|---|
| Amatu *et al*[21] | DTIC 250 mg/m$^2$ per day, d 1-4 q21d | 68 (26) | 3% (8%) | 12% (44%) | 1.7 (NR)[1] | NR |
| Hochauser *et al*[22] | TMZ 150 mg/m$^2$ per day 7 d on/7 d off | 37[2] (37) | 3% (3%) | 44% (445) | NR | NR |
| Pietrantonio *et al*[23] | TMZ 150 mg/m$^2$ per day d 1-5, q28d | 32[3] (32) | 12% (12%) | 31% (31%) | 1.8 (1.8) | 8.4 (8.4) |
| Pietrantonio *et al*[26] | TMZ 75 mg/m$^2$ per day, d 1-21 q28d | 21[4] (21) | 24% (24%) | 30% (30%) | 2.2 (2.2) | NR |

[1]Median PFS for *MGMT*-m patients was not reported, but hazard ratio for progression between methylated and non-methylated patients was 0.66 (95%CI: 0.40-1.10), $P$ = 0.0982; [2]The study enrolled 86 patients with MGMT-m metastatic CRC (Mcrc), esophageal, head and neck and non small cell lung cancer; this table reports data of patients with mCRC only; [3]Only MGMT-m patients were enrolled in the study; [4]Preliminary results. DTIC: Dacarbazine; TMZ: Temozolomide; RR: Response rate; DCR: Disease control rate; PFS: Progression-free survival; OS: Overall survival; MGMT-m: MGMT-methylated; NR: Not reported.

Amatu *et al*[21] evaluated the activity of dacarbazine in 68 heavily pretreated mCRC patients. The response rate was only 3% with 2 partial responses, but a preplanned analysis based on *MGMT* methylation status in the individual tumors showed that objective responses only occurred in patients with *MGMT* methylated cancer. In the *MGMT*-methylated group, a significantly higher disease control rate (44% *vs* 6%, $P$ = 0.012) and a trend toward longer progression-free survival (PFS) were also observed (Table 1). These results provided the proof-of-concept that dacarbazine, and consequently its derivative TMZ, are effective only in patients with mCRC harboring methylation in the *MGMT* gene promoter.

Patients with advanced aerodigestive tract and colorectal cancers and methylation of *MGMT* gene promoter were treated by Hochhauser *et al*[22] with TMZ given at 150 mg/m$^2$ per day on a 7-day-on/7-day-off schedule. A low response rate (3%) was reported in patients with mCRC (Table 1), suggesting that *MGMT* methylation may be not the only factor determining response to TMZ. Particularly, cell death induced by TMZ also depends on the integrity of MMR pathways. In this study, all the patients with objective response were MMR-proficient, and most MMR-deficient patients experienced a disease progression, but data were limited to drive definitive conclusions about the correlation between MMR status and response to TMZ.

A phase 2 study run by our research group at the National Cancer Institute of Milan enrolled 32 patients with *MGMT*-methylated mCRC who progressed after all the approved standard therapies including fluoropyrimidines, oxaliplatin, irinotecan and, if *KRAS* wild-type, also cetuximab or panitumumab[23]. All the patients received TMZ at the standard dose of 150 mg/m$^2$ per day for 5 consecutive days every 28 d until disease progression or unacceptable toxicity. This was the first trial of TMZ given to mCRC patients selected for *MGMT* methylation status. The study met its primary end-point of promising activity, with 4 (12%) partial responses and 6 (19%) disease stabilizations; median PFS and overall survival (OS) were 1.8 and 8.4 mo, respectively (Table 1). TMZ was well tolerated, with severe thromocytopenia occurring in only 1 patient and no other grade 3-4 toxicities observed. Dose reduction was necessary in 3 patients, and no patients underwent early discontinuation due to adverse events. The study also explored potential predictive biomarkers, showing that none of the patients with mCRC harboring a mutation in the mitogen-activated protein kinases (MAPK), either *RAS* or *BRAF*, achieved a response. Conversely, four of nine patients with *RAS* and *BRAF* wild-type tumors had an objective response (0% *vs* 44%, $P$ = 0.004). These results confirmed what was already shown for glioblastoma, namely that MAPK signaling may enhance MGMT activity and drive cellular resistance to TMZ[24]. Interestingly, none of the patients included in this trial were MMR-deficient, and this might explain the clinically meaningful response rate observed in this study.

Other trials are currently ongoing, with the aim to shed more light on the role of TMZ as single agent and investigate predictive biomarkers in patients with *MGMT* methylated CRC (Eudract n. 2012-003338-17; 2012-002766-13).

## FUTURE CHALLENGES

It was previously shown that a dose-dense TMZ regimen results in prolonged depletion of MGMT in blood mononuclear cells and possibly in the tumor[25]. This schedule of administration may have enhanced activity due to higher cumulative dose and might be able to restore treatment sensitivity in *RAS* mutant tumors. Preliminary results from a mono-institutional, phase Ⅱ, open label, single arm study with dose-dense TMZ were recently presented by our group[26]. Patients with chemorefractory disease were treated with TMZ at a dose of 75 mg/m$^2$ given daily for 21 consecutive days of a 4-week cycle, up to 6 cycles or until disease progression or unacceptable toxicity. Seventeen out of 21 patients were evaluable for RECIST response. Tumor response, which was the primary endpoint of the study, was 24%. Interestingly, all patients with tumor response had a mutation of either *KRAS* (3 patients) or *BRAF* (1 patient). These preliminary data confirmed the encouraging activity of

TMZ in molecularly selected patients with *MGMT* methylation-positive, chemorefractory mCRC (Table 1). The good safety profile of dose-dense TMZ, as well as the response rate obtained in the *RAS* mutant population, are promising and warrant further prospective randomized confirmation.

There is a strong rationale for combining TMZ with fluoropyrimidines, based on preclinical data in slow-growing carcinoid cell line. It was found that TMZ and 5-FU have synergistic activity in a schedule-dependent manner in which 5-FU exposure preceded TMZ by 5–7 d with maximal synergism at 9 d. When the two agents were delivered concomitantly or if TMZ preceded 5-FU, *in vitro* cytotoxicity was additive but not synergistic. From these translational studies, researchers from the Columbia university formulated the CAPTEM regimen using TMZ for 5 d at 150-200 mg/m$^2$ per day refracted in a BID dosing on days 10-14 and capecitabine 750 mg/m$^2$ BID on days 1-14 of a 28-d-cycle[27]. The TMZ was given twice-a-day instead of the standard daily dosing because the first dose binds MGMT, thus allowing the second dose to methylate guanines in presence of a decreased repair activity of MGMT[17,28]. Given the potential synergy of CAPTEM combination in mCRC, we planned a randomized phase Ⅱ study of second-line CAPTEM *vs* FOLFIRI after failure of prior first-line oxaliplatin-based treatment in patients with advanced, *MGMT* methylated, *RAS* mutated CRC (Eudract n 2014-002417-36). The primary objective of the study is to demonstrate the superiority of CAPTEM over standard FOLFIRI in terms of PFS; secondary endpoints are response rate, safety, quality of life, OS, with an exploratory biomarkers sub-study.

In conclusion, there is growing evidence that *MGMT* methylation status may serve as a predictive biomarker of response to TMZ in mCRC. TMZ is a promising agent for the treatment of *MGMT*-methylated mCRC, and the future research should establish the best schedule of TMZ and should also investigate how to integrate TMZ with the current available therapeutic options for mCRC, whether as single agent in chemorefractory patients or in combination with other active drugs in first or second line. The combination of TMZ with fluoropyrimidines is based on a strong rationale and is currently being investigated, but also the combination of TMZ with irinotecan[29] has been proven to be feasible and it may deserve evaluation in mCRC. TMZ-containing chemotherapy may also provide an interesting backbone for the addition of biologic agents. However, the identification of additional biomarkers is a priority for future research, in order to select individual patients who may benefit the most from alkylating agents.

## Abstract

Necrosis of pancreatic parenchyma or extrapancreatic tissues is present in 10%-20% of patients with acute pancreatitis, defining the necrotizing presentation frequently associated with high morbidity and mortality rates. During the initial phase of acute necrotizing pancreatitis the most important pillars of medical treatment are fluid resuscitation, early enteral nutrition, endoscopic retrograde colangiopancreatography if associated cholangitis and intensive care unit support. When infection of pancreatic or extrapancreatic necrosis occurs, surgical approach constitutes the most accepted therapeutic option. In this context, we have recently assited to changes in time for surgery (delaying the indication if possible to around 4 wk to deal with "walled-off" necrosis) and type of access for necrosectomy: from a classical open approach (with closure over large-bore drains for continued postoperative lavage or semiopen techniques with scheduled relaparotomies), trends have changed to a "step-up" philosophy with initial percutaneous drainage and posterior minimally invasive or endoscopic access to the retroperitoneal cavity for necrosectomy if no improvement has been previously achieved. These approaches are progressively gaining popularity and morbidity and mortality rates have decreased significantly. Therefore, a staged, multidisciplinary, step-up approach with minimally invasive or endoscopic access for necrosectomy is widely accepted nowadays for management of pancreatic necrosis.

**Key words:** Acute pancreatitis; Necrotizing pancreatitis; Surgery; Open necrosectomy; Minimal access retroperitoneal pancreatic necrosectomy; Video-assisted retroperitoneal debridement

**Core tip:** We have recently assisted to a significant change in surgical approach to acute pancreatitis. Infection continues as the most important pillar where surgical indication is established. Nevertheless, from an early consideration for surgery frequently performed by classical open approach, today we have moved to delay the indication and the procedure as much as possible with step-up philosophies trying to deal with "walled-off" necrosis and considering minimally invasive access like video-assisted retroperitoneal or endoscopic. In this paper, most recent therapeutic trends for acute necrotizing pancreatitis are reviewed.

## INTRODUCTION

Gallstones and alcohol are still the most frequent causes of Acute Pancreatitis (AP), a disease with an increasing

**Table 1 Revised definitions of acute pancreatitis (2012)[1,2]**

|---|---|
| Types | |
| Interstitial edematous | Inflammation of pancreatic parenchyma and peripancreatic tissue, without necrosis |
| Necrotizing | Inflammation with pancreatic parenchymal and/or peripancreatic necrosis |
| Grades of severity | |
| Mild | No organ failure<br>Lack of local or systemic complications |
| Moderate | Transient organ failure (< 48 h) and/or<br>Local or systemic complications without persistent organ failure |
| Severe | Persistent single or multiple organ failure (> 48 h) |

incidence in recent decades. Diagnosis is based on the presence of two of the following criteria: (1) characteristic upper abdominal pain radiating in a belt-shaped fashion; (2) amylase or lipase values three times above normal levels; and (3) demonstrative radiologic imaging.

Due to the confusion created by certain terminology derived from the Atlanta classification of AP, a recent revision of the terminology has been developed from an International Consensus, which currently constitutes the reference of the conceptual definition of AP (Table 1). AP is classified into its two forms of presentation (Interstitial Edematous Pancreatitis and Necrotizing Pancreatitis), and according to the severity of the clinical course (mild, moderate and severe). Most AP episodes occur as an interstitial edematous form (80%-90%), usually associated to a mild clinical course, while more clinical severity is frequently associated to the characteristic that defines acute necrotizing pancreatitis (ANP): necrosis, pancreatic or peripancreatic, or a mix of both[1,2].

Local complications associated to the edematous form are defined depending on whether they have or not a well-defined wall and on the time of their arising. Acute fluid collections arise within the first 4 wk of the clinical course and lack a well-defined wall, while pseudocysts are circumscribed fluid collections that occur more than 4 wk after the onset of AP and have a well-defined wall. These complications are out of the scope of the current revision, since their surgical management is not necessary or it is included among elective treatments. On the other part, necrotizing forms may be associated to acute necrotic collections (intra- or extra-pancreatic solid-liquid heterogeneous collection with no defined wall, diagnosed during the first 4 wk of the clinical course) or walled-off necrosis (with similar characteristics but with well-defined wall and with a later diagnosis, above 4 wk). This later concept gathers all previous terms (necroma, pancreatic sequestrum, subacute pancreatic necrosis or pancreatic pseudocyst with necrosis) into a common terminology. Other local complications associated to AP include splenic/portal thrombosis, colon necrosis, retroperitoneal hemorrhage or delayed gastric emptying[1,2].

Physiopathologically, two events may determine the severity of the clinical course. The first of them is the associated Systemic Inflammatory Response Syndrome (SIRS), which involves a complex inflammatory cascade, which can finally cause the characteristic single- or multiorgan failure. Respiratory, renal and cardiovascular are the most frequent organic failures associated to AP. The second event is infection of necrosis, which is usually associated to phenomena of bacteria translocation. Both events constitute critical factors determining the clinical course of AP and they establish even the current indications for surgery in AP; thus, they will be expounded in detail later on[3].

## SURGICAL IMPLICATIONS DURING THE FIRST WEEK

During the first week after the onset of AP, treatment is medical. Frequently, surgeons on duty are called to evaluate patients with AP without response to medical treatment during the initial phase of the disease. For decision making in this context it must be assumed that the reason for lack of response in these patients is based more in the presence and progression of SIRS than in the potential necrosis or pancreatic infection. Thus, surgery is not indicated during this phase, unless a suspicion of ischemia or perforation as a secondary complication arises. Surgery during this first phase aggravates the multiorgan failure and results in a greater rate of complications, such as intestinal hemorrhage or fistula[4].

In this phase, fluid resuscitation is essential during the first 12-24 h, having to be reduced later on trying to avoid intra abdominal hypertension (IAH), frequently associated to AP. A recent review could not find any difference between fluid resuscitation with colloid or crystalloid solutions[5]. Prophylactic antibiotics are not indicated, since they have not shown a clear benefit in previous studies and metaanalysis, and thus, they should not be used until an associated infection is clearly demonstrated[4]. Early (on the first 72 h) Endoscopic Retrograde Cholangiopancreatography has not shown benefits when performed systematically in AP in the absence of cholangitis, although an ongoing clinical trial is analyzing this approach again (APEC trial; ISRCTN97372133). However, in presence of bile duct obstruction it is clearly indicated[6].

During this first week, surgeons are occasionally requested to evaluate patients with AP and IAH, present in 61% of episodes of AP. IAH is the precursor of the Abdominal Compartment Syndrome (ACS) and, thus, of multiorgan failure. Although the beneficial effect of decompression to alleviate ACS is clear in other situations, in AP the ACS seems to be closer related to massive resuscitation, ascites or retroperitoneal fluid accumulation and, thus, treatment strategies with decompressive laparotomy have not shown a clear benefit in terms of morbidity and mortality. Currently, management strategies for AP-associated ACS are directed towards medical support (negative fluid balance, enteral decompression, pharmacological increase of the abdominal wall compliance) and even towards percutaneous drainage of fluid collections (with a related ongoing clinical trial, the DECOMPRESS

**Table 2 Modified Marshall scoring system for organ or multiorgan failure[2,7]**

| Organ system | 0 | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| Respiratory ($PaO_2/FiO_2$) | > 400 | 300-400 | 200-300 | 100-200 | < 100 |
| Renal (Creatinine, mg/dL) | < 1.4 | 1.4-1.8 | 1.8-3.6 | 3.6-5 | > 5 |
| Cardiovascular (mmHg) | > 90 | < 90, fluid responsive | < 90, not fluid responsive | < 90, pH < 7.3 | < 90, pH < 7.2 |

Study; ClinicalTrials.gov NCT00793715). In case abdominal surgical decompression had to be performed during this first phase, in absence of infected necrosis, the retroperitoneum should not be opened[4].

## SURGICAL IMPLICATIONS AFTER THE FIRST WEEK

This is the moment to consider the necessity and indication for surgery of the pancreatic necrosis, on which we will expound extensively. Other local complications may occur at this phase but they are much less frequent and will be mentioned at the end of the chapter.

## SURGERY FOR PANCREATIC NECROSIS

### *Indications*

Most common indications for surgery of pancreatic necrosis are the following: (1) infection. It is a rare event during the first week of clinical course. The diagnosis is based on the association of sepsis signs with compatible radiologic imaging (extraluminal air in intra- or extrapancreatic necrotic areas in CT imaging) and on the occasional support of vascular radiologists with percutaneous fine-needle aspiration for Gram staining and culture. There is universal consensus that a need for therapeutic action exists; (2) single- or multiorgan failure. Organ failure is classified as transient or persistent based on whether it lasts less or more than 48 h, respectively. The most recommended system for its definition (even above the Sepsis-related Organ Failure Assessment -SOFA-) is the Marshall score[7] (Table 2), which is easy and repeatable along the clinical course of AP. It evaluates the three most commonly SIRS-affected systems (respiratory, renal and cardiovascular) and defines organ failure as a score of 2 or more.

A persistent single- or multiorgan failure refractory to support treatment may constitute an indication for surgery. Numerous studies have shown that in this context, oppositely to what happens when infection constitutes the indication for surgery, necrosectomy does not provide a significant benefit regarding mortality, and thus, it must be considered as the last resource in a patient in whom maximum medical support does not result in clear improvement. We can assert the same statements when surgical indication is established on a patient with ANP with no clinical improvement after 4-6 wk of intensive medical treatment.

We must consider that the indication for surgery in the context of AP must derive more from the need to control complications than from the inflammatory process itself. Regarding this, every necrotic and infected tissue must be removed, and pus drained. Material viscosity, as well as the number and localizations of potentially drainable regions constitute determining factors for the selection of the best therapeutic approach. Morbidity associated to pancreatic debridement includes pancreatic fistula (50%), endo- and exocrine pancreatic failure (20%), intestinal fistula (10%) and the common prolonged hospitalization and delay in the incorporation to daily life activities[3,4].

It is important to underline some important concepts before describing the different surgical options: (1) debridement is preferred over resection for two reasons: first, as an attempt to conserve the maximum quantity of functional pancreatic tissue, and second, due to the frequent technical impossibility of pancreatic resection and its associated morbidity in the context of AP[3,4]; (2) unless evident infection of necrosis exists, survival improves as the surgical indication gets delayed. The best results are obtained when the indication may be delayed up to one month after the onset of the clinical symptoms. A better demarcation of necrosis (conversion to "walled-off" pancreatic necrosis) involves less bleeding and less removal of viable tissues[3,4]; and (3) Two different philosophies define the timing of the surgical approach for a patient with AP. "Step-down" consists on the classical immediate surgical approach when there is an established indication, and, later on, a more conservative treatment for the residual disease. However, there is a trend in the most recent medical literature towards a "step-up" type of concept, where more conservative procedures (percutaneous, laparoscopic or endoscopic procedures) constitute the initial treatment of patients with ANP and a final technique is performed later on if necessary, based on poor clinical evolution[8].

### *Options*

**Open necrosectomy:** Open necrosectomy (ON) was considered as the gold standard treatment for decades, and it was usually associated to a therapeutic "step-down" type of approach. Classical ON consists on debridement of the necrotic pancreatic tissue through a midline or subcostal bilateral incision and the access to the pancreatic area through the lesser sac, the gastrocolic omentum or by a transmesenteric access through the transverse mesocolon, depending on necrosis extension and localization. Once the necrosectomy has been performed, the options are: (1) usual closure over drains and relaparotomy depending on clinical course; (2) scheduled laparotomies, usually every 48 h, until debridement has been completed. Open abdomen techniques are recommended if this

approach is selected, but scheduled laparotomies closing the abdomen after each revision have also been reported; and (3) closed technique with abdominal closure over lavage system with large-bore drains in the pancreatic area.

The last one constitutes the most recommended option based on a mortality < 10%, significantly inferior to those associated to the rest of the techniques. Nevertheless, an effective comparison between the different methods is difficult because of the heterogeneity of patients and surgeons[3,4,9].

**Percutaneous drainage:** Several series of patients have reported that management of infected pancreatic necrosis with percutaneous drainage (PD) obtains a high success rate and mortality similar to that of ON treatment. In a systematic review[10], the success rate of PD (defined as survival with no need for additional surgical necrosectomy) was 55%, mortality 17% and morbidity 21%, showing pancreaticocutaneous and pancreaticoenteric fistulas as the most frequent complications associated to the procedure. Although PD constitutes a tempting and efficient therapeutic alternative as a minimally aggressive approach, the truth is that frequently success depends on the availability of large caliber catheters and often repeated procedures are needed. For selected patients, like those with AP and easily accessible single infected necrosis, or as a transient step to surgery in unstable patients, this therapeutic option must be considered. However, PD is not accepted as a useful tool when an extensive necrosectomy is needed[3,4,9].

**Endoscopic approach:** A promising approach for pancreatic necrosis is the transgastric or transduodenal endoscopic approach (EA) under direct vision or with ultrasound support. Very diverse types of instruments are later used to maintain opened the communication between the digestive lumen and the necrosis and to perform the necrosectomy, and frequently repeated procedures are needed. Several series have reported promising results with EA, some as important as the German multicenter GEPARD Study[11] with 93 patients, 81% of clinical success and only 7.5% mortality. The results of EA for necrotizing AP have been recently summarized in a systematic review[12], which reports a success rate of 75% on 260 patients; however, it must be pointed out that data derive from non-randomized studies on selected patients in reference centers.

**Laparoscopic approach:** Laparoscopic approach (LA) for ANP may result particularly attractive because of its potential of obtaining all the advantages of a minimally invasive approach while maintaining access to the whole abdominal cavity (perirenal and retroduodenal spaces and mesenteric root, as well as both paracolic gutters) and the technical possibility of indicating additional techniques (cholecystectomy or jejunostomy). However, the extension of LA in ANP among professionals is still scarce, since its advantages are overpassed by its limitations: infection dissemination, need for pneumoperitoneum in unstable patients, or the possibility of iatrogenic intestinal perforations. Published series of patients have a scarce number of cases and it is still soon to recommend this approach[3,4].

**Retroperitoneal approach:** It constitutes the maximum example of Minimally Invasive Necrosectomy. Retroperitoneal approach (RA) of the necrosis is performed through small incisions and the use of endoscopic material, guided by a percutaneous drainage previously and strategically indicated, placed laterally, avoiding access to the abdominal cavity and providing all the advantages of the minimally invasive approach. Diverse methods for its performance have been described but the most widely accepted are Minimal Access Retroperitoneal Pancreatic Necrosectomy (MARPN) and Video-Assisted Retroperitoneal Debridement (VARD) (Figure 1). This last one consists in the introduction of a laparoscopic camera, through a 5 cm incision, and after the first liquid and solid debris have been removed a vigorous debridement of the necrotic cavity may be performed with the maintenance of a low-pressure pneumoperitoneum. The number of repeated necrosectomies needed later on is significantly lower with VARD than with MARPN.

In a systematic review, incidence of multiorgan failure, incisional hernia and endo- and exocrine failure was significantly lower with RA than with ON, although mortality was similar and no differences were observed regarding local complications, such as intraabdominal bleeding or pancreatic fistula[13].

**Combined approaches with "step-up" philosophy:** Probably, management of pancreatic necrosis in an immediate future will not be based only in one of the methods already mentioned. A combination of them with a decision making based on characteristics of the patient, necrosis grade, extension and localization will be the key for defining the best therapeutic option in ANP. The most illustrative of these approaches is the Dutch PANTER[14] (PAncreatitis, Necrosectomy *vs* sTEp up appRoach) study, a randomized, multicenter, clinical trial in which 88 patients with necrotizing AP who met inclusion criteria, and in whom the need to perform an invasive procedure was established (delayed whenever as possible up to 4 wk from the onset of the clinical symptoms) were divided into two groups: 45 with ON and 43 with "step-up" type minimally invasive approach. Such an approach consisted in placing a percutaneous drainage as the first step (40 retroperitoneal, 1 abdominal and 2 endoscopic), assessing the placement of a second drainage or the performance of RA in the absence of improvement after 72 h, based on clinical and radiologic findings. The morbi-mortality rate of the "step-up" type of approach was significantly lower than that of the ON group (40% *vs* 69%, $P < 0.006$), and so was the multiorganic failure (12% *vs* 40%, $P < 0.002$). In addition, it was defined that more than 30% of patients in the "step-up" group did not need necrosectomy after the percutaneous or endoscopic drainage.

On the same line of therapeutic combination, the on-

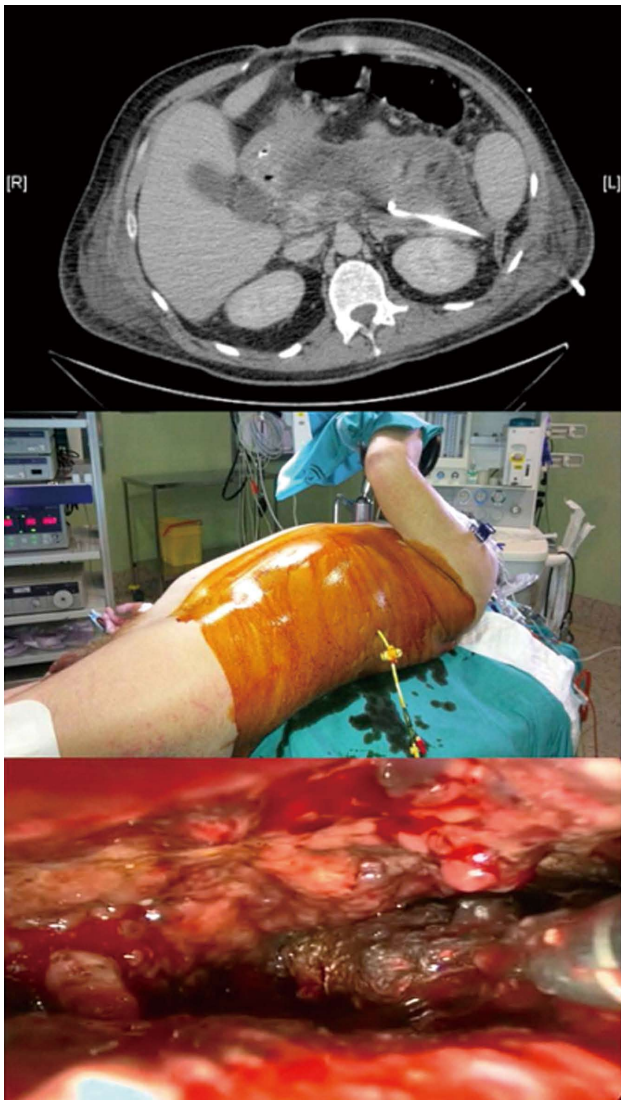

**Figure 1 Video-assisted retroperitoneal debridement: Computed tomography scan with percutaneous drainage into an infected pancreatic necrosis (above); patient's position for necrosectomy (middle); endoscopic view of necrotic pancreatic tissue (below).**

going TENSION study (ISRCTN 09186711) randomizes 98 patients with ANP to receive step-up type endoscopic approach vs surgical approach.

## OTHER SURGICAL INDICATIONS

Disruptions of the main pancreatic duct may derive in internal or external fistulas, pancreatic ascites or pleural effusion. Treatment constitutes an important challenge and, depending on location and clinical manifestation, it can require from PD as the only procedure up to pancreatic resection or Roux-en-Y derivation for what is called the Disconnected Pancreatic Duct Syndrome, although a CPRE approach and transpapillar drainage is usually sufficient[3].

Vascular complications occur in 2.4%-10% of patients with AP, and they derive from bleeding into the peritoneal cavity or into the gastrointestinal tract from pseudoaneurysms of vessels close to the inflammatory process, such as the gastroduodenal or pancreaticoduodenal arteries. Nowadays, embolization is the therapeutic method of choice[3,4].

Colonic complications associated with pancreatitis are infrequent (1% of cases). From reactive ileus to most severe forms with obstruction, necrosis or perforation are associated to poor prognosis and mortality increase. For the majority of cases, resection with proximal ostomy and mucous fistula constitutes the treatment for these complications.

Maybe out of the emergency context but of necessary mention, it must be underlined that there is an indication for cholecystectomy in the first admission after the first mild gallstones pancreatitis. A systematic review reported up to 18% readmissions in patients with mild AP if an early cholecystectomy is not indicated and performed[15]. In severe AP, however, cholecystectomy should be deferred until complete resolution of inflammation[16].

## CONCLUSION

In recent years we have witnessed a change in the management of patients with ANP: from a prematurely indicated surgery, performed open, we are moving to less aggressive procedures, indicated later and with "step-up" strategies, performing first PD, preferably retroperitoneal, and continuing with surgical (considering new access routes) or endoscopic necrosectomy in case of absence of improvement. These concepts require a multidisciplinary approach to ANP with implication of surgeons, gastroenterologists, radiologists, and intensive care unit doctors, and the need for contemplating the referral of patients to reference centers when the needed logistic is not available. Trauma and Emergency Surgery Units in the Departments of General and Digestive Surgery constitute, thus, the ideal setting for the early diagnosis, indication, intervention and follow-up of these patients.

## Abstract

Laparoscopy is one of the most frequently preferred surgical options in gynecological surgery and has advantages over laparotomy, including smaller surgical scars, faster recovery, less pain and earlier return of bowel functions. Generally, it is also accepted as safe and effective and patients tolerate it well. However, it is still an intra-abdominal procedure and has the similar potential risks of laparotomy, including injury of a vital structure, bleeding and infection. Besides the well-known risks of open surgery, laparoscopy also has its own unique risks related to abdominal access methods, pneumoperitoneum created to provide adequate operative space and the energy modalities used during the procedures. Bowel, bladder or major blood vessel injuries and passage of gas into the intravascular space may result from laparoscopic surgical technique. In addition, the risks of aspiration, respiratory dysfunction and cardiovascular dysfunction increase during laparoscopy. Large bowel injuries during laparoscopy are serious complications because 50% of bowel injuries and 60% of visceral injuries are undiagnosed at the time of primary surgery. A missed or delayed diagnosis increases the risk of bowel perforation and consequently sepsis and even death. In this paper, we aim to focus on large bowel injuries that happen during gynecological laparoscopy and review their diagnostic and management options.

**Key words:** Colon; Gynecology; Intraoperative complications; Laparoscopy; Wounds and injuries

**Core tip:** Large bowel injury during laparoscopy is a serious complication because 50% and 66% of bowel and visceral injuries are undiagnosed at the time of primary surgery. A missed or delayed diagnosis increases the risk of bowel perforation and consequently sepsis and death.

## INTRODUCTION

Four decades ago, laparoscopic surgery was being performed by a limited number of surgeons and most of the procedures were limited to diagnostic laparoscopy and tubal sterilization. However, through the years laparoscopy has evolved and become one of the major management choices for many surgical diseases. Cameras and hand instruments with improved visual quality and better manipulation capabilities, respectively, along with the accumulation of the data obtained from previous studies and case reports have contributed to the evolvement of laparoscopy.

Today, laparoscopy is one of the most frequently preferred surgical options in gynecological surgery. In the United States, roughly 350000 bilateral tubal sterilizations and 200000 hysterectomies are performed using

laparoscopy each year. The popularity of laparoscopy has increased around the world and many gynecologists, including inexperienced and junior surgeons in training, have begun to perform laparoscopic procedures. Thus, the number of patients prone to complications during laparoscopy has increased[1].

Laparoscopy has advantages over laparotomy, including smaller surgical scars, faster recovery from surgery, less pain and earlier return of bowel functions. Generally, it is also accepted as safe and effective and patients tolerate it well[2]. However, it is still an intra-abdominal procedure and has the similar potential risks of laparotomy, including injury of a vital structure, bleeding and infection[3-6]. Intra and postoperative complications are below 1% and 4 to 8 patients are lost per 100000 laparoscopic procedures.

Besides the well-known risks of open surgery, laparoscopy also has its own unique risks related to abdominal access methods, pneumoperitoneum created to provide adequate operative space and the energy modalities used during the procedures. Bowel, bladder or major blood vessel injuries and passage of gas into the intravascular space may result from laparoscopic surgical technique. In addition, the risks of aspiration, respiratory dysfunction and cardiovascular dysfunction increase during laparoscopy[5-9]. Blood loss is generally lower than in open surgery; however, in some cases, massive blood loss necessitates immediate laparotomy.

Because of its advantages over laparotomy, such as less pain, hospital stay and recovery time, laparoscopy is generally perceived as a minor surgical procedure by patients. Thus, the medico legal aspects of the complications of laparoscopy are prone to exaggeration. In order to minimize complications and their unavoidable consequences, surgeons should learn the probable complications and their management. In this paper, we aim to focus on large bowel injuries that happen during gynecological laparoscopy and review their diagnostic and management options.

## CLASSIFICATION, EPIDEMIOLOGY AND RISK FACTORS

Complications related to laparoscopic surgery can occur during either intra or postoperative phases. Intraoperative complications can further be divided into complications of access and complications of the operative procedure. More than half of complications occur at the setting up phase, particularly during the creation of the abdominal access pathways necessary for the telescope and trocars[10,11].

The complication rate during the placement of the initial abdominal access port is less than 1%. Complications following the initial access are also rare. In contrast, port site hernia as a late complication can affect 6% of patients[12-14]. Although rare, severe complications including vascular and bowel injuries, may cause serious morbidity and even result in the death of the patient.

The study conducted by Chandler *et al*[10] in 2001 showed that the incidence of injury during abdominal access varied between 5 and 30 per 10000 procedures. Large bowel was the third most frequent injury site after the small bowel and iliac artery, with 12% of all injuries at the large bowel. In their review published in 2012, Jansen *et al*[15] reported that access related bowel injury was seen in 4.4 per 10000 gynecological procedures. In addition, Hasson's open abdominal access technique did not significantly lower the complication rates compared to the closed technique.

Bhoyrul *et al*[16] studied 32 deaths following 629 trocar injuries and found that six patients died following bowel injury. Delay in the diagnosis of gastrointestinal perforation resulted in a mortality rate of 21%.

A history of previous intra-abdominal surgery, vertical incision, endometriosis and pelvic infection increases the risk of bowel injury. Extensive bowel distension obscuring the operative field, large abdominal or pelvic mass (in the case of hysterectomy, uterine size over 500 g) and diaphragmatic hernia increase the risk of complications. In addition, major operative laparoscopy, extensive adhesiolysis and concomitant major surgery are the other factors that increase the risk of complications. Moreover, surgeon experience and the type and the difficulty of the cases also contribute to complication rates[17-21].

## LARGE BOWEL INJURIES DURING THE SETTING UP PHASE OF GYNECOLOGICAL LAPAROSCOPY

Bowel injury may be encountered at any stage of laparoscopic surgery, beginning from abdominal access until the end of port site closure. It is the third most frequent mortal complication of laparoscopy, following anesthesia and major vessel injuries[22]. Gastrointestinal tract injury during laparoscopy ranged between 0.03 and 0.18%[6,23-26] and its incidence was 0.13% in the meta-analysis performed by van der Voort *et al*[27].

Before the study performed by Levy *et al*[28], energy modalities used in laparoscopic surgery were mistakenly considered to be the leading cause of gastrointestinal injuries. However, 30% to 50% of the bowel injuries occur during Veress needle or trocar insertion into the abdominal cavity[6,11,29-31]. Gastrointestinal injuries occur more often at the small bowel; however, other intra-abdominal organs, including the large bowel and stomach, may also be injured. Preoperative bowel preparation and decompression of the stomach with an orogastric or nasogastric tube may prevent potential injuries occurring during abdominal access.

In the retrospective case review study conducted by Chapron *et al*[5], 32.1% of the gastrointestinal injuries occurred during the initial set up procedure. Pneumoperitoneum needle, umbilical trocar and suprapubic trocar were isolated as the causes of injuries in 10.7%, 16.1% and 5.3% of the cases, respectively. Of the 62 gastrointestinal injuries of the 56 patients, 57.2% occurred during the

operative phase of the procedure, and electrosurgery and sharp dissection were the causes of injuries with the rates of 10.7% and 46.5%, respectively. The authors could not define whether the injuries occurred during initial set up or operative phases in 10.7% of the cases.

Of the 62 gastrointestinal injuries of the 56 patients reviewed by Chapron *et al*[5], 30 (48.4%) injuries involving the large intestine had the highest frequency and were followed by the 21 (33.9%) small bowel and 10 (16.1%) epiploon injuries. Of the 30 large bowel injuries, 18 injuries were at the sigmoid colon, followed by four cecum, four rectum and four colon injuries.

It is not clear whether the frequency of bowel injury during abdominal access is affected by the complexity of the operative phase. Some studies reported higher rates of bowel injury during access in diagnostic laparoscopy and laparoscopic tubal sterilizations[30], in contrast to others reporting higher injury rates in major laparoscopic surgeries[6].

The surgeon's experience affects the rate of injury; however, the frequency of injuries during abdominal access is still high for more experienced surgeons[32]. Depending on the fact, investigators are trying to improve the outcomes of abdominal access during laparoscopy by using various access techniques. Blind Veress introduction followed by pneumoperitoneum and the primary trocar, direct trocar insertion and open access techniques are examples. In addition, investigators are trying to improve the already known techniques. As an example, in their recently published study, Ozdemir *et al*[33] used umbilical stalk elevation (USE) technique to improve the success rate of Veress needle insertion in obese patients and concluded that the USE technique seemed safe and required a significantly fewer number of attempts to create pneumoperitoneum.

Excellency in Veress needle and trocar use may prevent some major complications. Although wiggling of the needle movements to ascertain intra-abdominal entry may enlarge the diameter of an injury[32], the correct placement of the needle is usually checked by most surgeons. In addition to the classical safety checks, foul smell, observation of the gastrointestinal contents and asymmetrical abdominal distention due to insufflation of the bowel should raise the suspicion of bowel injury[34]. Moreover, passage of flatus may be a sign of intra-intestinal insufflation.

Although Hasson's open technique did not lower the total complication rates, theoretically open techniques may decrease the risk of life threatening major vascular injuries during abdominal access. In addition, the chance of an earlier diagnosis is higher. In contrast to the theoretical advantages of an open technique, there are articles reporting a higher incidence of bowel injury with an open technique[29,35,36]. However, many surgeons prefer open access techniques for patients with anticipated risks. Thus, in order to avoid selection bias, final judgment will be appropriate after randomized prospective studies.

In addition to their theoretical advantages, open techniques are also used during gasless laparoscopies and may help in lowering the $CO_2$ related risks of laparoscopic surgery. Thus, gasless laparoscopy may decrease some risks of laparoscopic surgery that occur during abdominal access. In our practice, we have experienced the single incision, gasless technique called keyless abdominal rope-lifting surgery (KARS)[37-40] and did not observe any internal organ injury. However, among the various access techniques, the best probably is the one in which the surgeon has more experience and advanced skills.

## LARGE BOWEL INJURIES DURING THE OPERATIVE PHASE OF GYNECOLOGICAL LAPAROSCOPY

During the operative phase of laparoscopy, bowel injury may occur as a result of trauma secondary to tissue dissection and manipulation or electrosurgical energy use. It is a serious complication because 50% and 66% of bowel or visceral injuries are undiagnosed at the time of primary surgery[41]. A missed or delayed diagnosis increases the risk of bowel perforation and consequently sepsis, and even death[6].

In the study conducted by Chapron *et al*[5], of the 56 patients suffering from gastrointestinal injury, 32 had injuries at the operative phase of the procedures and 26 injuries were due to sharp dissections. Thus, experienced surgeons with advanced surgical skills are expected to have lower complication rates. Not surprisingly, experience significantly decreases the complication rates of the operative phase and the surgeon's advanced skills in fine adhesiolysis also decreases the complication rates[6].

Brummer *et al*[42] compared the incidence of injuries of laparoscopy performed between 1992 and 1999 with the injury incidence of 2000 and 2005, emphasizing the importance of the learning curve in laparoscopic and vaginal hysterectomies. The incidence of all kinds of injuries was significantly lower between 2000 and 2005. Similarly, bowel injuries during laparoscopic hysterectomies decreased from 0.14% to 0.09% during the same period and large bowel injuries involved half of all bowel injuries[42]. The use of proper hand instruments while manipulating and dissecting the tissues may decrease the injury rates.

The use of electrosurgical energy during operative laparoscopy causes injury of the target tissue. The injured tissue may become necrotic or heal slowly during the postoperative period[43]. In addition to the target tissue, increased local temperature may cause injury of the nearby vital structures, *e.g.*, the large bowel. Thus, the surgeon should be familiar with the used energy modality. A monopolar current travels through the tissues of the patient; however, a bipolar current passes between the two electrodes of the instrument and thus influences only the tissue between electrodes.

Monopolar energy causes more lateral thermal spread and produces the highest temperatures compared to bipolar electrocautery, the Harmonic scalpel and LigaSure[44]. The degree of lateral thermal spread varies with various energy modalities and is as follows: 2-22 mm for

traditional bipolar, 0-3 mm for ultrasonic cutting and coagulation, 1.1 mm for the Enseal, 1.8 mm for LigaSure and 6.3 mm for Gyrus Plasma Trissector[45-48]. In addition, the monopolar electrosurgical instrument insulating layer is not foolproof and the current may spread to the adjacent tissue[49]. Thus, in a case where the operative field is close to the bowel, the risk of bowel injury increases and the unnoticed injury may present postoperatively.

## PREVENTION, DIAGNOSIS AND MANAGEMENT

Most gynecologists learn traditional gynecological procedures during residency; however, they generally gain skills required for laparoscopic procedures during their postgraduate clinical practice without supervision. The learning curve is lengthy and becomes longer with the advancement of new techniques and instruments. The complication risk is highest during the initial stages of a surgeon's laparoscopic experience[50].

A comprehensive preoperative evaluation, proper consultations, patient selection and risk assessment help lessen the risk of complications. Besides a gynecologist having the required skills for laparoscopic surgery, the operating room staff and assistants should also be properly trained. The operating room should be ready for an emergency laparotomy. The infrastructure required for a multidisciplinary surgical approach should be maintained during the laparoscopic procedures.

During the initial stages of the experience of laparoscopy, it is better for a surgeon to perform minor procedures. Previous studies reported that the complication rates were higher in the first 100 procedures of surgeons beginning to perform laparoscopy.

Sudden and uncontrolled Veress needle and trocar entry can lacerate the rectum and sigmoid colon. The transverse colon may be displaced by the distended stomach and become vulnerable to injuries. A nasogastric tube helps to eliminate this potential risk.

Obliteration of the pouch of Douglas and the presence of dense adhesions between the rectum and uterus increase the chance of bowel injury. In these circumstances, blunt dissection may increase the chance of rectal laceration and thus sharp dissection with scissors or CO2 laser should be preferred. Placement of a probe or finger in both the vagina and the rectum helps to identify the tissue planes. Nezhat *et al*[51] and Redwine[52] advise beginning the dissection lateral to the uterosacral ligaments and proceeding toward the obliterated cul-de-sac. In addition, preoperative bowel preparation may help in cases with high risks for bowel injury.

One to two thirds of bowel injuries can be detected intraoperatively[5] and half of the injuries can be identified between first and seventh postoperative days. Most patients do not have the typical symptoms of bowel injury, such as low-grade fever, nausea, vomiting, ileus, severe abdominal pain, leucopenia or a normal leukocyte count, and the diagnosis is delayed. Thus, in many cases, patients present with peritonitis and the situation increases the rates of morbidity and mortality[10,16]. Sepsis and acute abdominal pain are typically observed 1-2 d after surgery.

Brownish fluid in a saline aspiration test may sometimes diagnose large bowel perforation. In addition, fecal smell strengthens the suspicion. In cases where the suspicion of bowel perforation arises, the Veress needle should be replaced with a sterile one and the field beneath the primary entrance should be examined after the introduction of the telescope. Intraoperative sigmoidoscopy may be helpful in identifying the injury site[53]. Recently, in an experimental study conducted by Ülker *et al*[54], insertion of a rectal catheter attached to a urine bag was recommended to identify large bowel injuries. It was suggested that the accumulation of gas in the connected bag would signal small and hardly demonstrable large bowel injuries. A computerized tomography examination can reveal fecal material outside the large bowel and/or free air in the abdominal viscera. Additional imaging work up, including imaging with a gastrografin enema, can also help to detect an injury site.

Large bowel injuries should be managed at the time when they are recognized, if possible, at the same operative section. Small injuries secondary to a Veress needle may be managed conservatively with close observation in hospital, intravenous hyperalimentation and antibiotics[55]. However, 6% of cases with superficial electrocautery bowel injuries require open exploration due to acute perforation during the observation period and thus intraoperative repair of the damaged bowel is significantly safer and should be performed in every suspicious electrocautery bowel injury.

Most trocar injuries need a primary closure in one or two layers. However, larger injuries with an ambiguous tissue injury may necessitate colostomy. In these conditions, incorporation of a general surgeon experienced with bowel surgery is advisable. Depending on the skills of the surgical team, bowel repair may be performed laparoscopically[56]. Extensive intra-abdominal lavage, use of combined broad-spectrum antibiotics and drainage may decrease the infection risk.

Injury at the right ascending colon generally requires resection of the injured section and a primary anastomosis. Ileostomy with diversion of the intestinal contents speeds up healing. In a case where the bowel is not prepared preoperatively and the descending colon, sigmoid or rectum is injured, primary closure or resection with primary anastomosis are not good treatment options. In these circumstances, a diverting colostomy with resection of the injured portion is recommended. Colonic lacerations of preoperatively prepared bowel can be repaired laparoscopically[50].

## CONCLUSION

Large bowel injuries during gynecological laparoscopy are rare but serious complications. Approximately one third can be diagnosed intraoperatively and delayed diagnosis increases the rates of morbidity and mortality. They

should be managed immediately when recognized, if possible, at the same operative section.

## Abstract

Idiopathic granulomatous mastitis is a rare chronic inflammatory lesion of the breast that can clinically and radiographically mimic breast carcinoma. The most common clinical presentation is an unilateral, discrete breast mass, nipple retraction and even a sinus formation often associated with an inflammation of the overlying skin. The etiology of idiopathic granulomatous mastitis is still obscure. Its treatment remains controversial. The cause may be the autoimmune process, infection, a chemical reaction associated with oral contraceptive pills, or even lactation. Various factors, including hormonal imbalance, autoimmunity, unknown microbiological agents, smoking and α 1-antitrypsin deficiency have been suggested to play a role in disease aetiology. In this review, causing factors in the aetiology of idiopathic granulomatous mastitis are reviewed in detail.

**Key words:** Mastitis; Granulomatous mastitis; Idiopathic granulomatous mastitis; Granulomatous lobular mastitis; Inflammation

**Core tip:** Aetiology of idiopathic granulomatous mastitis has not been fully elucidated. In this article, possible aetiologic factors mentioned in the literature are discussed in detail. Additionally, ethnicity factor which is briefly mentioned previously in the literature are detailed.

## INTRODUCTION

Inflammatory events are frequently seen in the breast, and its can appear in a manner that clinically mimics malignancy, but they are usually benign. In addition, aetiological factors (trauma and breast-feeding) are generally identified after a detailed anamnesis. In cases where the aetiology is defined, it is easy to practice treatment algorithms starting with "limiting or removing the aetiological factor". In cases where the aetiological factor is unknown, the diagnosis, differential diagnosis and treatment steps can become more complicated.

Since idiopathic granulomatous mastitis (IGM) was defined as a distinct clinical entity among benign breast diseases in 1972[1], it has attracted clinicians' attention, particularly those interested in breast diseases.

The differential diagnosis of IGM with breast cancer only clinically without histopathological examination is almost impossible. Therefore, presence of some complaints which can be seen in both disease (like palpable breast mass, nipple retraction, nipple skin hyperemia, erosion and fistula formation) would be more accurate to think of the first diagnosis of malignancy. In histopathological examination, presence of granulomatous inflammation and no malignancy is require performing other tests for the aetiology. Failure various factors which may result in granulomatous reaction in the breast (tuberculosis, certain

parasitic and fungal infections, Wegener's granulomatosis, giant-cell arthritis, polyartheritis nodosum, sarcoidosis, foreign body reaction, *etc*.) will support the diagnosis of IGM.

In this article, we discuss factors that may play a role in the aetiology of IGM.

## DEFINITION

Idiopathic granulomatous mastitis (GM) is a rare, benign, chronic, inflammatory lesion of the breast, and its aetiology has not been fully elucidated. It was defined for the first time in 1972 by Kessler and Woollock and was described in detail in 1977 with a five-case series by Cohen[1,2] .

GM is generally divided into two main groups of specific and non-specific. The term "specific GM" refers to conditions for which the aetiological factor can be identified, whether an isolated inflammatory event only applies to the breast, or the breast is involved in a systemic inflammatory event. Nonspecific GM is also known as idiopathic granulomatous mastitis or granulomatous lobular mastitis, which generally refers to conditions that can lead to a granulomatous reaction in the breast or conditions for which the aetiological factors cannot be determined.

Chronic granulomatous inflammation constitutes 24% of all inflammatory events of the breast that are histopathologically defined[3]. All factors that lead to granulomatous inflammation in the breasts are presented in Table 1[4].

## GENERAL REMINDERS

While IGM mostly emerges in young-middle age women (third and fourth decades), the age range that has been reported in the literature (11-83 years) is considerably wider[5-7]. IGM is usually seen within a couple of years after giving birth, and the majority of patients have a history of at least one live birth and breast feeding[8]. In contrast, specific GM is frequently seen in Asian and African countries and can be detected at any age[9].

IGM may present with clinical findings that mimic the two endpoints of breast diseases such as breast abscess and breast cancer[8]. A palpable mass in the breast is the most common complaint, but nipple retraction, hyperaemia in breast skin, oedema, ulceration and fistule development during the chronic period are also potential complaints[9]. Systemic symptoms such as fever are generally not present[6]. While the incidence is the same in both breasts, the lesion is usually unilateral and cases with bilateral involvement have been reported only rarely[8,10,11].

## PATHOGENESIS

The pathogenesis of IGM is not exactly known, but different steps occur in the disease pathogenesis. One of these steps is nonspecific lobulitis, which involves multiple lobules, and causes reactive lymphoplasmocytic infiltration. A granulomatous formation with central supurative necrosis occasionally occurs because of lobule deformation. Abscesses develop because of an increase in the number of these foci[12].

Some studies have indicated the similarity between IGM and granulomatous inflammation of the testicles or the thyroid gland when IGM was defined for the first time[1]. Considering that mechanical factors are responsible for the formation of granulomas of the thyroid gland in multifocal granulomatous thyroiditis (palpation thyroiditis), the possibility that trauma represents another stage in IGM pathogenesis should not be disregarded[12].

A process starting with non-puerperal secretion has been proposed as the most rational theory for the pathogenesis of IGM. A hormonal imbalance due to a deviation in the oestrogen-progesterone ratio or hyperprolactinemia is believed to cause this secretion and inflammation. Ductal ectasia occurs due to the intra-ductal accumulation of a protein-rich secretion. Permanent inflammation occurs following perforation of the ducti and contact between the secretion and stromal cells. The accumulation of secretion, ductal ectasia, galactoporitis (intraductal inflammation) and chronic GM are steps in the pathophysiological process. Autoimmunity against a secretion that is extravasated from the lobules is also considered to cause this event[6,13,14].

### *Aetiology*

The aetiology of IGM remains unclear. Various factors, including hormonal imbalance, autoimmunity, unknown microbiological agents, smoking and α1-antitrypsin deficiency have been suggested to play a role in disease aetiology.

### *α1-antitrypsin deficiency*

α1-antitrypsin (AAT) is a glycoprotein synthesised by hepatic cells. Similar to anti-thrombin 3, ovalalbumin and thyroid-binding globulin, AAT is a member of the serine-protease inhibitor family. Its primary function is to

prevent the destructive effects of proteases secreted from activated neutrophils (proteinase 3, elastin and cathepsin G). Because AAT level is elevated during inflammation, it is also accepted as an acute phase reactant. Deficiency in AAT leads primarily to lung and liver pathologies[15]. In their case presentation in 2001, Schelfout *et al*[16] demonstrated AAT deficiency in a 37-year-old female patient diagnosed with IGM. According to that study, the authors did not determine any other aetiological factors, and suggested that AAT deficiency could be the aetiological factor; however, further studies were not performed.

### Oral contraceptives

The secretion theory has an important place in the pathophysiology of IGM. Oral contraceptives (OCS) have been considered a potential aetiological factor, as they increase breast secretion[12]. However, a significant association between OCS and IGM has not been determined. Oran *et al*[17] found 10 cases (10/46; 21.7%) that had a history of OCS use; Gurleyik *et al*[18] found eight cases (8/19, 42.1%) that had a history of OCS use; and Al-Khaffaf *et al*[19] found five cases (5/18, 27.7%) that had a history of OCS use. In contrast, Baslaim *et al*[20] reported that none of 20 patients had a history of OCS use. Bani-Hani *et al*[7] found that only two of 24 cases (8.3%) had a history of OCS use, and Asoglu *et al*[21] found that only two of 18 cases (11.1%) had a history of OCS use. In conclusion, the association between IGM and OCS use has been reported to range between 0%-42%.

### Gestation, birth, and breast-feeding

Given that IGM is usually detected in women < 50 years of age, and frequently involves a recent history of birth or breast-feeding, these factors have been considered in the disease aetiology. Hormonal alterations during these processes, secretion, and inflammation have an effect on disease pathophysiology[19,21-28]. Bani-Hani *et al*[7] carried out a study on 24 cases, and found that four had active gestation, four had a history of birth and breast-feeding within 6 months and only two cases did not have a history of gestation. According to a study by Baslaim *et al*[20], all cases had a history of gestation and breast-feeding, whereas two cases were actively breast-feeding, and one case had an active gestation. Similarly, Gurleyik *et al*[18] determined that four of 19 cases had a history of active breast-feeding, and the remaining 15 cases had a history of breast-feeding. Moreover, Oran *et al*[17] reported that only three of 46 cases were nulliparous. Gautier *et al*[14] conducted a case series study on 11 cases and emphasised that all cases except one male case had a history of birth and lactation within the past 5 years.

While almost all studies reported a history of parity, various studies have failed to explain the timing of the parity. It is expected that cases with IGM, which is a reproductive age disorder, have a history of gestation and breast feeding, as gestation occurs between the ages of 20-40 years. In addition to the male case, cases with a wide age range (11-83 years) in the literature make it difficult to hold only gestation, birth and breast feeding responsible for the aetiology of IGM[4,5,14].

### Hyperprolactinemia

Considering the secretion theory, hyperprolactinemia has also been considered responsible for the pathogenesis of IGM, similar to other hormonal disorders[12,29,30]. In a case presentation in 1984, Rowe[29] determined co-morbid prolactinoma in an IGM case. However, future studies did not provide prolactin levels in detail. Bani-Hani *et al*[7] analysed prolactin levels in seven of 24 cases and found elevated prolactin levels in one patient (4.1%). Erhan *et al*[10] carried out a case-series study on 18 women and reported recurrence in three cases (16%), and identified hyperprolactinemia in two of these patients.

### Smoking

While smoking is among the factors considered in the disease aetiology, a definitive association between smoking and IGM has not yet been established. According to a study by Asoglu *et al*[21], 14 of 18 cases (77.8%) had a history of smoking, whereas Baslaim *et al*[20] reported that none of their 20 cases had a history of smoking. In addition, the smoking rate was 34.8% according to Oran *et al*[17], 16.7% according to Al-Khaffaf *et al*[19], and 50% according to Ozel *et al*[31].

### Autoimmunity

A hypothesis that suggests an immunological basis for IGM has received considerable attention. Literature findings, including a good response to steroid and immunosuppressive treatment, patients who had recurrence after surgery showing a good response to steroid treatment, patients with extramammary involvement (such as erythema nodosum, or arthritis) and the demonstration of T-lymphocyte dominance in immunohistochemical studies support the autoimmunity hypothesis[1,2,11-14,32]. Ozel *et al*[31] conducted a study on eight cases and found that six were positive for rheumatoid factor (RF), and two were positive for antinuclear antibody (ANA) and anti-double stranded DNA (anti-dsDNA). In that study, surgery was the preferred treatment option for all patients, and the authors reported recurrence in two patients who were RF-, ANA- and anti-dsDNA-positive, but obtained a positive response after steroid treatment. Erhan *et al*[10] conducted an immunohistochemical evaluation, and determined that 14 of 18 cases had T-cell dominance, and this finding was interpreted as an autoimmune pathophysiological outcome that progressed with reactive T-cell-mediated inflammation and centrilobular granulomas against ductal damage. Furthermore, two IGM cases with erythema nodosum, one IGM case with erythema nodosum and arthritis, one IGM case with Weber-Christian disease and one IGM case with Sjögren's syndrome have been reported in the literature[33-36]. However, cases with a co-morbid autoimmune disorder constitute only a minor fraction of all cases. In contrast to these studies that support the autoimmune hypothesis, classical serological tests, which are used for au-

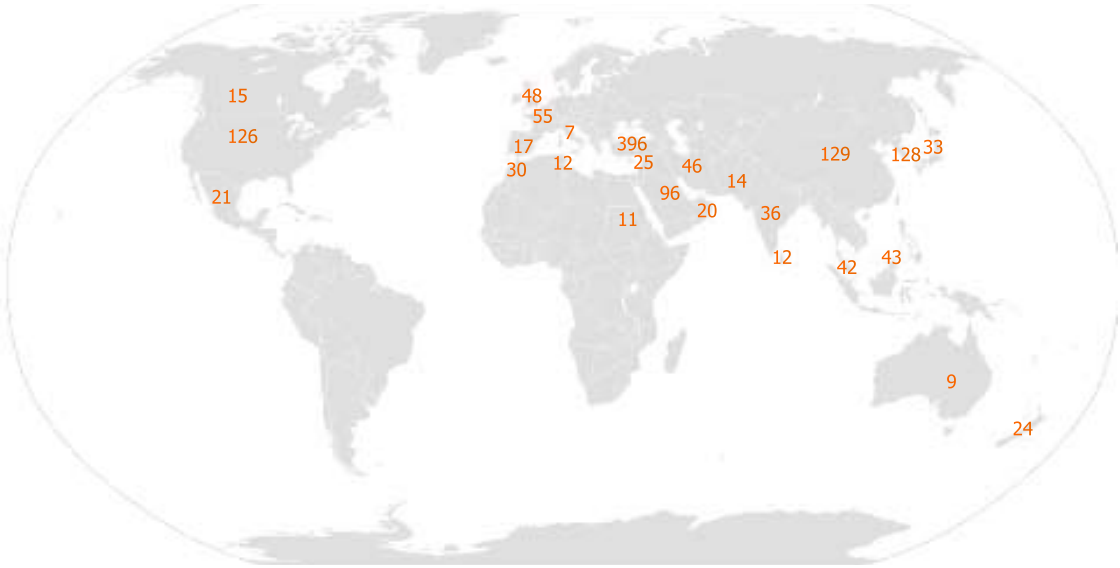

**Figure 1 The distribution of idiopathic granulomatous mastitis cases that were reported in PubMed since 1995 according to country.**

toimmune disorders such as ANA and RF, reveal different results in patients with IGM. Asoglu *et al*[21] conducted a case-series study on 18 cases and determined that all cases were negative for ANA and RF. We conducted a study in our clinic to investigate the autoimmunity hypothesis for IGM aetiology, and evaluated ANA and extractable nuclear antibody levels in 26 cases, but we did not obtain results to support the autoimmunity hypothesis[37].

### Microbiological agents

The normal endogenous bacteria flora of the breast is similar to the skin flora. Dominant organisms include coagulase-negative *streptococci*, *Propiniobacterium sp.* and *Corynebacterium sp*. These findings have been proven through nipple discharge and breast tissue cultures that were collected during mammoplasty[38]. These bacteria are considered to go deeper into the breast tissue *via* the ductal system[13].

*Corynebacteria* cause mastitis in livestock. However, these bacteria are not expected pathogens in humans[13]. These bacteria became the centre of attention in 2003, with detection of corynebacteria in 34 IGM cases by Taylor *et al*[39].

*Corynebacteria* are Gram-positive bacteria and members of the skin flora. It is hard to distinguish whether these organisms cause infection, colonisation or contamination[40]. Despite the difficulty in distinguishing outcome, it is significant to detect purulent matter in an abscess or > $10^4$ CFU/mL dominant *Corynebacterium sp.*[41]. According to a study by Funke *et al*[42], these bacteria could be a possible factor if: (1) a Gram-positive bacillus accompanying polymorphonuclear leukocytes is present; or (2) a *Corynebacterium sp.* is detected in a tissue that is expected to be sterile under normal conditions.

Four different Corynebacterium species have been detected in IGM cases. *Corynebacterium kroppenstedtii* (*C. kroppenstedtii*) is the most frequently observed species, and is different from other corynebacteria due to its lipophilic nature and positive esculin test[39,40].

Taylor *et al*[39] conducted a study of 62 patients who were histologically diagnosed with GM, and detected Corynebacterium in 34 patients (54.8%). A comparison among the remaining 28 cases showed that fever and neutrophilia were more frequently observed in cases that were bacteria-positive, and they had more frequent fistule formation. *C. kroppenstedtii* was the most frequently observed species (14 patients; 41.1%) in that study.

Paviour *et al*[40] isolated Corynebacterium from breast tissue in 24 cases, carried out a histopathological evaluation in 12 of these cases and diagnosed nine cases with IGM. Similarly, *C. kroppenstedtii* was the most frequently isolated species in that study; *C. amycolatum* and *C. tuberculostearicum* were other identified species. In that study, a 3-week intravenous penicillin treatment was tested on one patient; however, when the expected benefit was not observed, the treatment was switched to doxycycline (100 mg, oral), which has better fat solubility. The authors reported that there was no need for surgery after this treatment.

Case presentations in which *Corynebacterium sp.* have been detected are also present in the literature[41,43,44]. A specific species was not reported in two of these studies, whereas Ang *et al*[41] reported that they isolated *C. accolens*. All three studies stated that antibiotherapy was effective for treatment.

In our clinic, we carried out a study on 45 patients with IGM and 34 bacteria using a universal DNA primer, but we did not detect positivity for any microbiological agent (unpublished data).

### Ethnicity

During our search of GM in the PubMed database (1995-2014), we searched the terms "idiopathic granulomatous mastitis", "granulomatous lobular mastitis" and

**Table 2 The distribution of idiopathic granulomatous mastitis cases that were reported in PubMed since 1995 according to country**

| > 100 cases | 20-100 cases | 5-20 cases | < 5 cases |
|---|---|---|---|
| Turkey: > 200 | Saudi Arabia: 96 | Spain:17 | Netherlands: 4 |
| China: 129 | France: 55 | Canada: 15 | Israel: 4 |
| South Korea: 128 | United Kingdom: 48 | Pakistan: 14 | Austria: 3 |
| United States: 126 | Iran: 46 | Sri Lanka: 12 | Belgium: 3 |
| | Brunei: 43 | Tunis: 12 | Taiwan: 2 |
| | Malaysia: 42 | Sudan: 11 | Caribbean: 2 |
| | India: 36 | Australia: 9 | Peru: 1 |
| | Japan: 33 | Italy: 7 | Nigeria: 1 |
| | Morocco:30 | | Kuwait: 1 |
| | Jordan: 25 | | Jamaica: 1 |
| | New Zealand: 24 | | Greece: 1 |
| | Mexico: 21 | | Norway: 1 |
| | Oman: 20 | | |

"granulomatous mastitis" and found approximately 200 articles. We hypothesised that an evaluation based on the location of the centres in which the authors worked would provide a rough estimate of the distribution of the cases. While most of these studies were case presentations, we found that larger case series frequently originated from the Mediterranean region and the developing countries in Asia. Some authors have considered that undiagnosed tuberculosis cases might lead to GM[15,45-48].

According to our search on the PubMed database, the highest number of cases has been reported in Turkey (> 200 cases). This is followed by China (129 cases) and South Korea (128 cases). France had the highest number of cases (55 cases) among European countries, and no other country exceeded 50 cases. In contrast, we found 126 cases in the United States. The total number of cases recorded per country is presented in Table 2 and Figure 1.

According to a Centers for Disease Control and Prevention report, which was published in Morbidity and Mortality Weekly Report in 2009, seven cases were detected in Indiana between 2006 and 2008, and six of these cases were born in Mexico and had a Hispanic. According to the report, this series was the most comprehensive case series reported in the United States[49]. However, Larsen et al. published a study on 54 cases in the same year, but the authors did not evaluate ethnicity[50]. Gautier *et al*[15] carried out a study on 11 cases in Canada and reported that three cases were French, two cases were Canadian of French origin, two cases were Canadian of British origin, two cases were Latin American and one case was Russian. Furthermore, Omranipour *et al*[50] reported a series of 43 cases in Iran, Bani-Hani *et al*[7] reported a series of 24 cases in Jordan and Baslaim *et al*[20] reported a series of 20 cases in Saudi Arabia. In Turkey, different IGM series have been reported by Asoglu *et al*[21] (18 cases), Ozel *et al*[31] (8 cases), Gurleyik *et al*[18], Oran *et al*[17] (46 cases) and Altintoprak *et al*[37] (26 cases). These findings indicate that a previous comprehensive evaluation of ethnicity does not exist, and that more elaborate studies on this topic are required.

## CONCLUSION

In conclusion, while several factors have been considered as potential aetiological factors, these factors are not 'the primary aetiological factors, but rather "secondary factors" that can accompany the process once the primary factor triggers the event, or contribute to the acceleration' of the ongoing process. Given that: (1) a higher number of cases are being reported from certain geographical locations; and (2) patients respond positively to steroid treatment, we believe that the "ethnicity and autoimmunity hypotheses" are the major subjects to focus on. It is possible that our failure in searching for a single aetiological factor will become more evident as details are elucidated; however, the disease is likely to continue to carry the "idiopathic" prefix for a long time.

## Abstract

Allergen-specific immunotherapy (SIT) induces clinical and immunological tolerance as defined by persistence of clinical benefit and associated long-term immunological parameters after cessation of treatment. Although the efficacy of SIT has been shown in terms of reducing symptoms, medication consumption and ameliorating quality of life in both allergic rhinitis and asthma, there has long been some controversies about effectiveness of SIT in the treatment of allergic asthma. The type of allergen, the dose and protocol of immunotherapy, patient selection criteria, the severity and control of asthma, all are significant contributors to the power of efficacy in allergic asthma. The initiation of SIT in allergic asthma should be considered in case of coexisting of other allergic diseases such as allergic rhinitis, unacceptable adverse effects of medications, patient's preference to avoid long-term pharmacotherapy. Steroid sparing effect of SIT in allergic asthma is also an important benefit particularly in patients who have to use these drugs in high doses for a long-time. Symptomatic asthma is a risk factor for systemic reactions and asthma should be controlled at the time of administration of SIT. Both subcutaneous immunotherapy (SCIT) and sublingual immunotherapy (SLIT) have been found to be effective in patients with allergic asthma. Although the safety profile of SLIT seems to be better than SCIT, the results of some studies and meta-analyses suggest that the efficacy of SCIT may appear better and earlier than SLIT in children with allergic asthma.

**Key words:** Asthma; Efficacy; Safety; Subcutaneous immunotherapy; Sublingual immunotherapy

**Core tip:** Allergen specific immuntherapy is the only therapeutic approach that can change the immunologic response to allergens and thus can alter the natural evolution of allergic diseases. Both subcutaneous immunotherapy (SCIT) and sublingual immunotherapy (SLIT) have been demonstrated to be beneficial in reducing of symptoms and drug intake,improving quality of life and preventing patients from possible side effects of high doses of steroids. This review examines the clinical effectiveness and safety of both SCIT and SLIT in patients with asthma by discussing recent studies.

## INTRODUCTION

Asthma is one of the most prevalent chronic conditions affecting roughly 300 million people in the world. It is supposed that asthma will affect an additional 100 million people by 2025[1].

According to data of health statistics in United States, current asthma prevalence is 9.3% and 8%, in children and adults, respectively[2]. This incrementin the prevalence of asthma has been accompanied by an incrementin other allergic disorders like rhinitis and eczema.

Asthma is characterized by chronic inflammation,

which result in recurrent attacks of cough, wheezing, sometimes chest tightness and variable airflow obstruction. As time progresses, thisairflow obstruction may becomeirreversibledue to airway remodelling. Since many years, asthma has been supposed as mainly a Th2 cell-mediated disorder[3,4]. Nevertheless, in recent years, it is also discovered that many other cell types such as Treg, Th1 and Th17 are also involved in pathological process of asthma[3,4].

Drugs, such as inhaled corticosteroids, long-acting beta agonists and montelukast can effectively control asthma symptoms and attacks. However, it is known that, pharmacotherapy can not affect the underlying immune response; when these medications are stopped the symptoms may reccur.

Specific allergen immunotherapy (SIT) is a unique therapy which capable to change the natural evolution of allergic diseases[5]. With this treatment mode, allergens are given to patients in repeated and increasing doses to provide immune tolerance[6].

The effectivenessof both subcutaneous (SCIT) and sublingual (SLIT) immunotherapy is documented for both perennial and seasonal allergic respiratory disease by systematic reviews and meta-analyses[6-11]. For almost 100 years now,subcutaneous route has been used to treat allergic diseases; however, there are many studies to confirm the administration of SLIT because of discomfort of repeated injections and higher risk of adverse reactions.

In most published studies, effectiveness of SIT has been assessed primarily in patients with allergic rhinitis,and the results concerning asthma mostly were given as secondary outcome. Thus, there are a few studies which were organised to evaluate the efficacy of SIT specifically in asthma alone.

In this paper we will review primarily the clinical efficacy and safety of both SCIT and SLIT in patients with allergic asthma in the light of the literature.

## CLINICAL EFFICACY OF SCIT IN ASTHMA

The first of the studies which evaluate the efficacy of SCIT in asthmatic patients published by Abramson in 1995[12].

In the meta-analysis carried out by Ross *et al*[13], 24 prospective, randomized,studies involving 962 asthmatic patients were evaluated. They reported significant amelioration in symptoms and drug intake related with asthma as well as in pulmonary function in the SCIT group in comparison to the placebo. It was deduced that immunotherapy was beneficial in 17 (71%) studies, inefficacious in 4 (17%) studies,and equivocal in 3 (12%) studies. Similar to the previousmeta-analyses, the authors concluded that SIT is effective in patients suffering from allergic asthma.

In a study of Basomba *et al*[14], 55 mild and moderate asthmatic patients (aged 14-50 years) allergic to house dust mites (HDM) were treated with *D pteronyssinus* extract encapsulated in liposomes, in a double-blind placebo-controlled manner. At the end of one year, 45.8% of the patients treated with SCIT decreased symptom and medication scores by at the minimum 60%. There were also notable improvements in results of skin test and allergen-specific bronchial challenge.

In another study, fifteen children aged 6-14 years with asthma due tue HDM were treated with SCIT for three years; the results were remarkable reduction in the number of asthma excelbations and marked decrease in drug intake[15]. Additionally, significant improvement in lung functions and non-specific bronchial hyperreactivity (BHR) wereobserved.

García-Robaina *et al*[16] administered SIT with HDM in 64 adult asthmatic patients and they observed notable amelioration in the active group over placebo in terms of symptom (53.8 %) and medication scores (58%) in addition to improvement in allergen-specific BHR.

Roberts *et al*[17] studied the efficacy of grass pollen SIT in 35 asthmatic patients (aged 3-16 years) over 2 pollen season in a double-blind manner. They found that SIT provided significant decreases in asthma symptom and medication scores, marked improvements in cutaneous ($P = 0.002$), conjunctival ($P = 0.02$), and bronchial ($P = 0.01$) reactivity to allergen.

In the study of Zielen *et al*[18], 65 mite allergic children aged 6-17 years were treated with subcutaneous allergoid immunotherapy plus fluticasone propionate (FP) or FP therapy alone for 2 years. Before starting SIT, asthma control was achieved using inhaled corticosteroids for 5 mo follow-up. Children treated with SCIT plus FP were able to markedly decrease the FP dose, in comparison to the control group given only FP. After 2 years of treatment, the mean daily FP dose decreased from 330.3 μg to 151.5 μg in the immunotherapy group while there was no significant reduction in the control group.

In a recent Cochrane review of SCIT, 88 studies on 3459 subjects with asthma were evaluated; there were 42 trials for dust mites, 27 for pollen, 10 for animal dander, two for molds, two for latex, and six for multiple allergens[19]. It was reported that SCIT improved asthma symptoms, reduced medication use, and diminished BHR. The conclusion of this review was summarized as: "it would require treating three subjects to prevent an exacerbation for one individual, four subjects to improve medication use in one, and four subjects to avoid nonspecific or allergen-specific BHR in one patient, respectively". Additionally, mite and pollen immunotherapy were found more effective on symptom scores.

There are several studies of SCIT (particularly with mites[20,21] or mixed-allergen up to seven aeroallergens[22]) which demonstrated the improvement in asthma symptom and medication scores to a lesser degree than the other published studies. Nevertheless, significant steroid-sparing effect of immunotherapy was shown in moderate persistent asthmatics included in those studies.Thus, it should be kept in mind that the maintenance of asthma control is very important before and during the study in order to obtain optimal benefit of the immunotherapy.

## CLINICAL EFFICACY OF SLIT IN ASTHMA

World Allergy Organization Position Paper on Sublingual Immunotherapydeclared that SLIT is effective in the treatment of allergic rhinitis in adults and in allergic rhinitis and asthma in children[23]. However, it is also stated the presence of some important points about current status of SLIT effectiveness. It is known that there are significant heterogenity between studies included in SLIT meta-analyses, and this may bring significant limitation on the conclusion of them.

The first meta-analysis on SLIT in asthma was conducted by Olaguíbel *et al*[24] and comprised of seven studies in 256 children aged up to 14 years. This study showed marked improvements in symptom scores (SMD: -1.42) and medication requirement scores (SMD: -1.01) related with asthma.

In 2006, a meta-analysis about SLIT in asthma included 25 trials and involved 1706 adults and children[25]. This meta-analysis reported a significant efficacy of SLIT for symptoms and medication use in seven studies, and improvement in pulmonary function in four studies. But, when asthma symptoms and drug intake were analysed as ongoing parameters, the reductions were not significant.

Penagos *et al*[26] evaluated the efficacy of SLIT by conducting a meta-analysis which included nine studies on 441 asthmatic children. Six of these studies were with mites and three of them with pollen. The authors found significant decrease in symptom and medication scores with SLIT in comparison to placebo.

In 2009, Compalati *et al*[10] published a meta-analysis which evaluate nine studies in 452 patients treated with SLIT in HDM-allergic asthma. They reported marked improvement in symptom and medication scores related with asthma. As in SCIT, the steroid sparing effect of SLIT was also demonstrated in some recent published studies[27,28].

In the study of Marogna *et al*[28], 84 asthmatics were randomized to four treatment arms for three years: first group received budesonide 800 μg/d; second group received budesonide 1600 μg/d; third group treated with budesonide 400 μg/d plus montelukast 10 μg/d; and fourth group was given budesonide 400 μg/d plus allergoid of betulaceae pre-coseasonally. Low-dose inhaled corticosteroids plus SLIT provided a marked advantage-over the other options on symptoms plus medications decrease, FEV1 increase, rescue medications usage, and was comparable to low-dose inhaled corticosteroids plus montelukast on MEF25 and BHR.

Similarly, in a study involving 602 mite allergic asthmatic patients, it was shown that daily treatment with SLIT tablet reduced inhaled budesonide more than 80 μg/d in comparison to placebo after 1 year[27].

## HEAD-TO HEAD STUDIES

There are 4 randomized controlled trials with 171 participants which compare SCIT with SLIT directly in asthmatic patients. All these studies enrolled mite allergic patients with rhinitis and/or asthma. Efficacy of SIT was investigated by evaluating the clinical outcomes for both rhinitis and asthma.

In the first of these studies, Mungan *et al*[29], randomized 36 adults with HDM-allergic rhinitis and asthma to receive SCIT, SLIT or placebo. They found that one-year of SCIT improved symptom scores of both rhinitis and asthma while SLIT had benefit only on symptoms of rhinitis. However, medication scores of both rhinitis and asthma decreased significantly in both actively treated groups. After 1 year of immunotherapy, it was also shown marked rises in specific IgG4 concentrations in comparison to the baseline both in SLIT and SCIT groups.

Eifan *et al*[30] evaluatedthe effectiveness of SCIT and SLIT in children with asthma/rhinitis sensitized to mites. Forty eight children were randomized to treat either SCIT, SLIT or pharmacotherapy. This study demonstrated that both SLIT and SCIT have a significant positive effect on symptoms and medication usagerelated with both rhinitis and asthma in comparison to the pharmacotherapy group. Additionally, after 1 year of treatment, Der p 1-driven IL-10 significantly increased in SLIT in comparison to pharmacotherapy, whereas Bet v 1-driven TGF-b increased significantly in SLIT only.

In the study of Keles *et al*[31], 48 patients (aged 5-10 years) with mild persistent asthma and rhinitis monosensitized to mites were randomized to three treatment arms: they received either SLIT ($n$ = 16), SCIT ($n$ = 16) or pharmacotherapy alone ($n$ = 16). After 12-mo of treatment, total asthma symptom scores ($P$ = 0.02) and visual analog scores ($P$ = 0.02) decreased markedly in SLIT when compared with the pharmacotherapy group. Similarly, SCIT also reduced both total asthma symptom-scores ($P$ = 0.04) and visual analog scores ($P$ = 0.001) when compared with the pharmacotharapy group. The percentage of improvement was 100% and 93% in SLIT and SCIT group respectively, in comparison to the pharmacotherapy group. A marked increment was seen in the levels of regulatory and Th1 cytokines both in the SCIT and SLIT groups. Antigen-specific IgG4 levels increased in the SCIT and SCIT plus SLIT groups but not in the SLIT group.

In a recent randomized, placebo-controlled and double- dummy study we investigated the effectiveness of SCIT and SLIT in HDM- allergic children with asthma and/or rhinitis[32]. We showed that one-year SCIT had significant effect on symptom and medication scores related with both rhinitis and asthma. An important observation in this study was the better effect of only SCIT over placebo on reduction of rhinitis and asthma symptoms at the end of one-year-treatment. Bronchial challenge doses and sputum eosinophil increments after bronchial challenge decreased only with SCIT. There was no change in terms of IFN-γ levels in both immunoptherapy groups. Serum sIgG4 levels increased significantly only in the SCIT group. This study then carried on one subsequent year in an open scheme and the placebo group was randomized to treat SCIT or SLIT. Thus, all patients

received active treatment with SCIT or SLIT during one subsequent year[33]. We observed that the effect of SLIT on asthma symptoms and drug intake was less eminent than SCIT in the first year; however this effect was more pronounced in the second year of SLIT. With this study, we concluded that both clinical and immunologic improvement starts earlier with SCIT in comparison to the SLIT in mite-allergic children with rhinitis and asthma.

The summary of these 4 head-to-head studies was shown in Table 1. Recently, a systematic review of studies with head-to-head comparison of SCIT and SLIT in the treatment of allergic rhinoconjunctivitis and asthma was published[34]. Four trials conducted in patients with rhinitis and/or asthma[29-32]. This review demonstrated that low-grade evidence confirms more efficacy of SCIT than SLIT regarding reduction of asthma symptoms and combined measure of rhinitis symptoms and drug intake; moderate-grade evidence confirms more efficacy of SCIT than SLIT for nasal and/or eye symptom reduction. It was deduced that low-grade evidence confirmsthat SCIT is more beneficial than SLIT for reduction in asthma symptoms and moderate-grade evidence for reduction of allergic rhinoconjunctivitis. Further studies are required to support this results for clinical decision making.

## SAFETY OF SCIT AND SLIT

It is known that SCIT has a risk for both local and systemic adverse reactions but, in most of the cases, symptoms are reversible if they are diagnosed early and treated rapidly. All allergen preparations (standardized extracts[35], allergoids[36] or recombinant allergens[37] can cause these side effects.

The incidence of systemic reactions of SCIT varies between 0.06% and 1.01% in those receiving injections[38].

A recent multicenter study suggested that systemic reactions were slightly more frequent in rhinitis with asthma than rhinitis patients alone[39]. Some reports have been suggested that asthma may be a risk factor for severe systemic reactions due to SCIT, notably in patients with uncontrolled asthma. Conversely, another retrospective study reported no significant association between systemic reactions and the presence of asthma[40]. As noted by official documents, the patients's general condition and pulmonary functions should be assesed before injection in order to reduce the risk of anapylaxis[41].

The safety of SLIT seems better than subcutaneous therapy regarding severe systemic reactions. Local side effects (oral itching or mild swelling) may be encountered in three-fourths of patients especially in the early phase of SLIT.

In the study of Dahl *et al*[42] the safety of SLIT investigated specifically in grass pollen allergic patients with asthma. They evaluated side effects which may be related with asthma, *e.g.*, cough, wheezing, and they found no difference in the number of such effects between active and placebo group. Additionally, no asthma exacerbation related with SLIT was reported in this study.

There are also some recommendations about administering of SLIT in patients with systemic reactions after subcutaneous immunotherapy[43]. Nonetheless, some patients suffering from these adverse reactions with subcutaneous route may entertain the same risk for sublingual route of immunotherapy[44]. Thus, our recommendation is that immunotherapy should be customized to each patient on the basis of the degree of sensitization, concomitant allergies, exposures and patient's preference.

## PREVENTIVE CAPACITY OF SIT

SIT builts up clinical and immunological tolerance as shown by persistence of improvement both in clinical and immunologic parameters after the cessation of treatment. Additional long-term benefits of SIT include prevention of new sensitizations and progression from rhinitis to asthma.

There are some studies which demonstrated the preventive effect of SIT in pediatric population. At the 10-year follow-up (7 years after cessation ofimmunotherapy) the children in the immunotherapy group had significantly less asthma in comparison to the control group: 16/64 (25%) with asthma in the immunotherapy group compared with 24/53 (45%) of the untreated control group[45]. The authors concluded that immunotherapy for 3 years with grass and/or birch allergen extracts provides long-term preventive effect on the development of asthma in children with only seasonal rhinoconjunctivitis.

A similar preventive effect was also shown with SLIT in a 3-year open study of 113 children (aged 5-14 years) having grass pollen rhinitis[46]. This study demonstrated that asthma development was 3.8 times more frequent in the control subjects.

There is another study which show no significant difference in symptom and medication scores in the subsequent three pollen seasons after 3-4 years of grass-pollen SCIT[47].

Marogna *et al*[48] have noted that clinical benefit persists for 8 years after SLIT treatment is given for a 4- to 5-year duration; new sensitizations were also reduced in SLIT group.

It has been documented that SCIT with a single allergen has a preventive effect against sensitization to different inhalant allergens[49-52]. There are some studies which reportedsignificantly lower rate of the development of new allergen sensitizations in monosensitized patients who received SCIT in comparison to the controls[49-52]. In these studies, the percentage of the development of new sensitizations were 23%, 24%, 24.7% and 54% in patients treated with SCIT while 68%, 67%, 53.3% and 100% in untreated monosensitized patients.

Recent studies have shown such effects with SLIT[48,53-55]. In a 3-year open study, 5.9 % of 511 patients with allergic rhinitis and asthma treated with SLIT showed new allergen sensitizations, while this rate was 38% in the control patients[55].

**Table 1 Head-to-head studies which included patients with asthma treated by subcutaneous and sublingual immunotherapy[1]**

| Ref. | Year | Study Design | Age | No of patients | Asthma symptom score | | | | Medication score | | | | Findings |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | Before SIT | | After SIT | | Before SIT | | After SIT | | |
| | | | | | SCIT | SLIT | SCIT | SLIT | LSCIT | SLIT | SCIT | SLIT | |
| Mungan *et al*[29] | 1999 | Single-blind, placebo controlled | Adults | SCIT ($n$ = 10) SLIT ($n$ =15) Placebo ($n$ = 11) | 1.2 | 0.63 | 0.59 | 0.41 | 6.8 | 4.93 | 3.9 | 1.97 | Reduction in symptom scores with only SCIT Reduction in medication scores with both SCIT and SLIT |
| Eifan *et al*[30] | 2010 | Open label, randomized, controlled | 5-10 | SCIT ($n$ = 16) SLIT ($n$ = 16) Pharmacotherapy ($n$ = 16) | 0.9 ± 0.7 | 1.4 ± 1.5 | 0.4 ± 0.6 | 0.2 ± 0.4 | 2.4 ± 1.4 | 2.8 ± 1.2 | 1.7 ± 1.4 | 1.2 ± 0.9 | Reducttion in symptom and medication scores and visual analog scores with both SCIT and SLIT |
| Keles *et al*[31] | 2011 | Open label, randomized, controlled | 5-12 | SCIT ($n$ = 11) SLIT ($n$ = 13) SCIT plus SLIT ($n$ = 14) Pharmacotherapy ($n$ = 12) | 0.25 | 0.12 | 0 | 0 | 0.52 | 0.69 | 0.06 | 0.23 | Reduction in symptom scores and visual analog scores with both SCIT and SLIT |
| Yukselen *et al*[32] | 2012 | Randomized, double-blind, double-dummy, placebo-controlled | 6-14 | SCIT ($n$ = 10) SLIT ($n$ = 11) Placebo ($n$ =10 ) | 2.4 | 3.7 | 1 | 2.7 | 2.3 | 2.3 | 1 | 1.7 | Only SCIT was found superior to placebo on reduction of symptom and medication scores |

[1]All studies used HDM immunotherapy. SCIT : Subcutaneous immunotherapy; SLIT: Sublingual immunotherapy; SIT: Specific immunotherapy.

## CONCLUSION

SIT is the only therapeutic approach which capable to modify the natural evolution of allergic respiratory diseases. However, there are some shortcomings in trials conducted in patients with allergic asthma. In most of these studies, efficacy of SIT was not evaluated specifically in allergic asthma alone. Additionally, many of these trials had significant limitations such as low number of patients, difference in treatment protocols and doses, inadequate evaluation of pulmonary functions or absence of a placebo group. Moreover, there is a great heterogenity between studies included in meta-analyses; the most important point in this respect is the assessment of results of SIT with different allergens in the same meta-analysis.

Despite these shortcomings, the clinical efficacy of SIT has been established in allergic asthma in objective and subjective parameters such as titrated skin tests, allergen-specific bronchial hyperreactivity, and symptom and medications scores.

Steroid sparing effect of SIT gives an important advantage for patients who have to use these drugs in high doses in order to control their asthma symptoms for many years.

SIT should be considered in asthmatic patients who experience side effects of medications, to reduce or avoid long-term pharmacotherapy and the economic burden of medications and in the presence of allergic rhinitis and/or other comorbid allergic conditions[41].

Official documents recommend that SIT should not be started in patients with unstable asthma; in these cases, SIT can be initiated after well asthma control with appropriate pharmacotherapy.

Although both SCIT and SLIT have been reported to be effective on allergic asthma, the results of some studies or meta-analyses suggested that the efficacy of SCIT may be better and start earlier than SLIT.

Further studies are needed to discover patients who will benefit more from immunotherapy, novel vaccines and new routes of administration to increase efficacy and safety.

## Abstract

Precancerous lesions of oral mucosa, known as potentially malignant disorders in recent years, are consists of a group of diseases, which should be diagnosed in the early stage. Oral leukoplakia, oral submucous fibrosis, and oral erythroplakia are the most common oral mucosal diseases that have a very high malignant transformation rate. Oral lichen planus is one of the potentially malignant disorders that may be seen in six different subtypes including papular, reticular, plaque-like, atrophic, erosive, and bullous type, clinically. Atrophic and erosive subtypes have the greater increased malignant transformation risk compared to another subtypes. Although there are various etiological studies, the etiology of almost all these diseases is not fully understood. Geographically, etiologic factors may vary. The most frequently reported possible factors are tobacco use, alcohol drinking, chewing of betel quid containing areca nut, and solar rays. Early diagnosis is very important and can be lifesaving, because in late stages, they may be progressed to severe dysplasia and even carcinoma *in situ* and/or squamous cell carcinoma. For most diseases, treatment results are not satisfactory in spite of miscellaneous therapies. While at the forefront of surgical intervention, topical and systemic treatment alternatives such as corticosteroids, calcineurin inhibitors, and retinoids are widely used.

**Key words:** Oral premalignant lesions; Leukoplakia; Erythroplakia; Submucous fibrosis; Lichen planus; Malignant transformation

**Core tip:** Precancerous lesions of oral mucosa are the diseases that have malignant transformation risk at different ratios. Clinically, these diseases may sometimes resemble each other. Thus, the diagnosis should be confirmed by biopsy. In early stages, histopathological findings are distinctive, but if malignant transformation occurs, identical histological features with oral carcinoma are seen. If these diseases left untreated, they can cause many problems, which may affect a patient's social and daily life.

## INTRODUCTION

In a World Health Organization Workshop, held in 2005, the terminology, definitions and classifications of oral lesions with a predisposition to malignant transformation have been discussed and recommended to use the term "potentially malignant disorders" to eliminate terminological confusion[1].

The most common oral precancerous lesions are oral leukoplakia, oral submucous fibrosis (OSMF), and oral erythroplakia. Actinic cheilitis, some miscellaneous inherited diseases such as xeroderma pigmentosum and Fanconi's anemia, and immunodeficiency are another potentially malignant disorders for oral carcinoma as well as these three diseases[1,2]. In a clinicopathological study

**Figure 1 White and red lesions known as erythroleukoplakia are seen.**

designed by Phookan *et al*[3], different oral premalignant lesions were observed in 70 of 320 patients with lower or middle socioeconomic group. Leukoplakia was the most common premalignant disorder (20.65% of patients), while percentages of lichen planus and OSMF were reported equally (0.62% of patients)[3].

The etiology of precancerous lesions of oral mucosa is not well-known[4]. Some risk factors such as tobacco chewing, tobacco smoking, and alcohol play an important role in development of potentially malignant oral conditions. While tobacco chewing is a major risk factor for oral leukoplakia, OSMF, and erythroplakia, tobacco smoking may be a risk factor for oral leukoplakia. Alcohol drinking may increase the risk by 1.5-fold for oral leukoplakia, by 2-fold for OSMF, and 3-fold for erythroplakia. According to Thomas *et al*[2], while alcohol drinking and tobacco chewing may possibly be risk factors for multiple oral premalignant lesions, smoking was not associated with the risk of multiple oral premalignant lesions.

Various studies reported about etiopathogenesis of precancerous lesions of oral mucosa. Vlková *et al*[4] analyzed saliva markers of oxidative stress and reported that salivary thiobarbituric acid reacting substances and advanced glycation endproducts were significantly higher in patients than in control. They also reported that no significant differences were found in salivary advanced oxidation protein products, vascular endothelial growth factor, sialotransferase, and neuraminidase. Total antioxidant capacity and expression of superoxide dismutase were lower in patients than in age-matched controls. Nanda *et al*[5] investigated expression of CK8 and CK18 in potentially malignant disorders such as oral leukoplakia, OSMF, and oral squamous cell carcinoma and they reported that expression of CK8 and CK18 were statistically significant higher than controls. Feng *et al*[6] reported that expression of podoplanin and ABCG2 in oral erythroplakia correlate with oral cancer development. Qin *et al*[7] reported a high prevalence of p53 mutations in premalignant oral erythroplakia. Human papilloma virus (HPV) has been suggested to play a role in the etiopathogenesis of precancerous lesions of oral mucosa[8]. Punyani *et al*[9] reported that there was no statistically significant in salivary IL-8 concentrations among the precancer group and controls.

**Table 1 Risk factors of malignant transformation**

| |
|---|
| Female gender |
| Long duration of leukoplakia |
| Leukoplakia in non-smokers |
| Location on the tongue and/or floor of the mouth |
| Size > 200 $mm^2$ |
| Non-homogenous type |
| Presence of epithelial dysplasia |

Early detection of premalignant lesions and oral cancer is very important. Therefore, miscellaneous modalities such as oral cavity examination, supravital staining, oral cytology and optical technologies including spectroscopy, fluorescence spectroscopy, elastic scattering (reflectance) spectroscopy, Raman spectroscopy, fluorescence imaging, optical coherence tomography, narrow-band imaging, and multimodal optical imaging may be used[10].

We think that the following criteria should be taken into consideration in terms of the importance of early diagnosis: (1) symptomatic and/or non-symptomatic non-healing lesions of oral mucosa; (2) history of smoking, chewing tobacco, alcohol consumption, oral HPV infection, drug use, long-term exposure to sunlight; (3) advanced age; (4) the presence of immunodeficiency; (5) the presence of genetic disease; and (6) poor oral hygiene.

## ORAL LEUKOPLAKIA

Leukoplaki is defined as "A white plaque of questionable risk having excluded (other) known diseases or disorders that carry no increased risk for cancer"[1]. In studies reported in recent years, the prevalence of oral leukoplakia varies between 1.1% and 11.7%, with a mean value of 2.9%[11]. Although leukoplakia can occur at any age, it often occurs in individuals under the age of 40[12]. Leukoplakia is seen six times more among smokers than among non-smokers[1].

Clinically, leukoplakia may be affect any part of the oral and oropharyngeal cavity and can be divided into two subtypes including homogeneous and non-homogeneous types[1]. Homogenous lesions are characterized by uniformly flat, thin, uniformly white in colour and shows shallow cracks of the surface keratin[1,13]. Non-homogenous lesions have been defined as a white and red lesion (known as *erythroleukoplakia*) that may be either irregularly flat (speckled) or nodular (Figure 1). Verrucous leukoplakia is yet another type of non-homogenous leukoplakia[14].

Proliferative verrucous leukoplakia, which is a form of verrucous leukoplakia, was first described by Hansen *et al*[14,15] in 1985 and characterized by multifocal presentation. It has a strong potential for malignant transformation and is resistance to treatment.

Histopathologically, two distinct appearances may be seen as dysplastic or non-dysplastic leukoplakia. Risk factors of malignant transformation are shown in Table 1[14].

Oral leukoplakia should be distinguished from miscellaneous benign and/or potentially malignant disorders

that may be seen white or predominantly white diseases of the oral mucosa. The diseases should be considered in the differential diagnosis including aspirin burn, chemical injury, oral pseudomembranous and hyperplastic candidiasis, frictional lesions, oral hairy leukoplakia, leukoedema, linea alba, lupus erythematosus, morsicatio buccarum, papilloma and allied lesions, mucous patches in secondary syphilis, tobacco-induced lesions, smoker's palate (nicotinic stomatitis), stuff-induced lesion, white sponge nevus, oral lichen planus (OLP), and lichenoid reaction[1,13].

Oral leukoplakia should be confirmed by mucosal biopsy. But before biopsy, some staining methods may be used as a diagnostic aid. Chen *et al*[16] used methylene blue in fifty-eight patients with suspicious oral cavity lesions. They reported that the overall sensitivity of methylene blue uptake in cases with suspected lesions was 90%, specificity 69%, and accuracy 79%. They also reported that the positive predictive value was 74% and the negative predictive value 87%[16].

The most commonly preferred treatment options are surgical excision or $CO_2$ laser therapy. In widespread lesions, photodynamic therapy may be considered[14]. Cryotherapy is another preferred destructive method[17]. Non-surgical treatment modalities might be considered in selected patients. Carotenoids (β-carotene, lycopene), vitamins [L-ascorbic acid (vitamin C), α-tocoferol (vitamin E), retinoic acid (vitamin A), and fenretinide], and bleomycin may be used in patients with oral leukoplakia[18].

Surgical excision should be recommended in the presence of moderate and severe epithelial dysplasia. Reported recurrence ratios after surgery treatment have been varied between 10% and 35%[18]. Kawczyk-Krupka *et al*[19] compared to efficacy of cryotherapy and photodynamic treatment and reported that complete responses were obtained in 72.9% and 89.2% of patients in groups treated by photodynamic treatment and cryotherapy, respectively. Recurrence ratios were reported as 27.1% and 24.3% in groups treated by photodynamic treatment and cryotherapy, respectively[19]. Pietruska *et al*[20] reported significant reduction (on average by 53.8%) of leukoplakia lesions sizes after photodynamic therapy. Among patients treated by topical retinoic acid, while complete response ratio was reported between 10% and 27% of patients, partial response ratio was reported between 54% and 90% of patients. Recurrence of leukoplakia was reported as approximately 50% after withdrawing the topical retinoic acid[21].

## ORAL ERYTHROPLAKIA

Erythroplakia is defined as "A fiery red patch that cannot be characterized clinically or pathologically as any other definable disease". Clinical appearance is characterized by flat or even depressed erythematous change of the mucosa without a patch lesion. Both red and white changes in the same lesion refer to as "*erythroleukoplakia*". Prevalence of erythroplakia varies between 0.02% and 0.83%. It mainly occurs in the middle aged and the elderly. Male gender is most frequently affected. Mostly, a solitary lesion occurs over the surface of any part of the oral cavity. But the most commonly affected areas were reported as the soft palate, the floor of the mouth, and the buccal mucosa[14,22].

Etiopathogenesis is not known exactly[22]. Chewing tobacco and alcohol use are the possible etiologic factors for the development erythroplakia. Hashibe *et al*[23] reported that chewing tobacco and alcohol drinking are strong risk factors for erythroplakia in the Indian population. High prevalence of p53 mutations in premalignant oral erythroplakia was reported in a study designed by Qin *et al*[7].

Clinically, typical lesion of oral erythroplakia is less than 1.5 cm in diameter, but it also be less than 1 cm and larger than 4 cm[22]. Histopathologically, moderate or severe dysplasia was usually seen in lesion with erythroplakia. Malignant transformation rates is very high (vary from 14% to 50%), so it needs to be treated expeditiously[14,22].

Oral erythroplakia should be diminished from any disease which clinically appears red colour in oral cavity. Oral candidiasis, oral histoplasmosis, oral tuberculosis, atrophic OLP, lupus erythematosus, pemphigus, pemphigoids, amelanotic melanoma, haemangioma, telangiectasia, lingual varies, Kaposi's sarcoma, early squamous cell carcinoma, local irritation, mucositis, drug reaction, median rhomboid glossitis, and oral purpura may be confused with oral erythroplakia[22,24].

Owing to the high malignant transformation rate, early effective treatment is mandatory[22]. Surgery, either by cold knife or by laser, is the recommended therapy[1]. Surgical excision may be used in lesions with severe epithelial dysplasia or carcinoma *in situ*[22].

## OLP

Lichen planus was first described by Erasmus Wilson in 1869[25]. The disease is a chronic, autoimmune, inflammatory disease which may affect skin, oral mucosa, genital mucosa, scalp, and nails[26]. Prevalence of OLP varies from 0.5% to 3%[25]. It mainly occurs among female gender and the age of onset is usually between third and sixth decade[25,27].

Although it is believed that OLP is a T-cell mediated autoimmune disease, its cause is partially understood in most cases[28]. Several factors have been proposed for the etiology including genetic background, dental materials (amalgam, metals, gold, and composite restorations), drugs (especially antimalarials, cardiovascular agents, gold salts, non-steroidal anti-inflammatory drugs, hypoglisemics), infectious agents (herpes simplex virus, Epstein-Barr virus, cytomegalovirus, herpes virus-6, hepatitis-C virus, and human papilloma virus), autoimmunity, immunodeficiency, food allergies, stress, habits, trauma, diabetes and hypertension, malignant neoplasms, and bowel disease[26,29,30].

Even though OLP may affect any part of the oral mucosa, most commonly affected areas are dorsum of the tongue (Figure 2), buccal mucosa (Figure 3), and gin-

**Figure 2 Liken planus lesions on the dorsum of the tongue.**

**Figure 3 Reticular pattern lesions on the buccal mucosa.**

giva[26]. Clinically, OLP may be seen as six types including papular, reticular, plaque-like, atrophic, erosive, and bullous type[25]. The most common type is the reticular pattern which present as fine white striae known as "*Wickham's striae*". Typically, lesions present symmetrically and bilaterally, and usually asymptomatic. Atrophic pattern presents as a red lesion. Erosive pattern is usually seen as irregular erosion or ulceration covered with a fibrinous plaque or pseudomembrane. Both atrophic and erosive pattern are generally associated with a burning sensation and pain that exacerbated by trauma and hot, spicy or acidic foods. Plaque type clinically resembles leukoplakia because of its homogenous white nature. The dorsum of the tongue and buccal mucosa are the most affected areas in the oral cavity of patients with plaque type OLP. Multifocal plaque type lesions may be seen. This subtype is more common among tobacco smokers. The papular pattern, which is rarely seen, is characterized by small, white, raised papules with fine white striation at the periphery of the lesion. Bullous pattern is the least common type of OLP that characterized by bullae formation range from a few millimeters to several centimeters in diameter[26].

In 1906, Dubrell first described the histologic features of OLP, but within the next years, it has been revised. Diagnostic histologic features include liquefactive degeneration of the basal cells, colloid bodies (known as *Civatte* bodies), homogenous infiltrate of lymphocytes in a dense, band-like pattern along the epithelium-connective tissue interface in the superficial dermis, cytologically normal maturation of the epithelium, sawtooth rete ridges, and hyperkeratosis. In erosive lichen planus, ulceration may be seen in the surface epithelium[31].

The first case of OLP-related oral carcinoma was reported by François Henri Hallopeau in 1910. Malignant transformation ratio has been reported in 0% to 10% of patients, according to the sample's characteristics and study design, after mean follow-up of 1.5 to 10 years[25]. Increased malignant transformation risk occurs greater in erosive and atrophic forms and in cases of lesions of lateral border of the tongue[27].

If there are Wickham's striae typically, the diagnosis is easy and can be made clinically, especially reticular pattern of OLP. But erosive or atrophic pattern need to be confirmed by biopsy in order to make the correct diagnosis[32]. Direct immunofluorescence may be useful to distinguish from some bullous diseases such as pemphigus vulgaris, benign mucous membrane pemphigoid, and linear immunoglobulin A (IgA) bullous dermatitis[31]. IgA, IgG, IgM or C3 deposition throughout the basement membrane and irregular fibrinogen deposition in the basement membrane are the diagnostic immunofluorescence findings in OLP and positivity rate is 65.8% of the patients with OLP[33]. Indirect immunofluorescence studies are not useful in terms of diagnosis[32].

Patients with reticular and other asymptomatic OLP can be followed without treatment. But if there are any symptoms and/or potential malignant risk, lesions should be treated. Both topical and systemic treatment modalities have been reported for OLP, shown in Table 2[31,34-36].

## ORAL SUBMUCOUS FIBROSIS

Oral submucous fibrosis, was first described by Schwartz in 1952, is chronic and potentially malignant disorder characterized by juxtaepitelial fibrosis of the oral cavity. Fibroelastic change of the lamina propria and epithelial atrophy occur in consequence of juxta epitelial inflammatory reaction, and eventually, stiffness of oral mucosa, trismus and an inability to eat develops[37].

OSMF is usually seen in Asians population (particularly Indians) from the southern states and Taiwanese. Predominantly, it occurs in the second and third decade, and both sexes may be affected[37]. But in patients with pediatric age group were rarely seen[38-40]. Paymaster firstly described its premalignant nature in 1956. This malignant transformation rate was reported 7%-30%[37].

Its etiology is not well-known and thougt to be multifactorial[37]. The strongest risk factor for OSMF is the chewing of betel quid containing areca nut. Other factors like genetic and immunologic predisposition also play a role in OSMF because of reported in families whose members are not in the habit of chewing betel quid or areca nut[41]. Ranganathan *et al*[42] designed a case-control study consisting of 185 patients in Chennai, South India and reported strong association between areca nut

**Table 2 Miscellaneous treatment regimens for oral lichen planus**

| Topical treatments | Systemic treatments | Surgery |
|---|---|---|
| Corticosteroids (triamcinolone, fluocinolone acetonide, fluocinonide, clobetasol, fluticasone propionate, betamethasone sodium phosphate, mometasone furoate) | Corticosteroids | Resection |
| Cyclosporin | Acitretin | Cryotherapy |
| Tacrolimus | Azathioprine | Lasers ($CO_2$, excimer laser) |
| Pimekrolimus | Basiliximab | |
| Rapamycin (sirolimus) | Cyclosporin | |
| Retinoids (tretinoin, isotretinoin) | Dapsone | |
| Aloe vera | Eiconol | |
| Hyaluronic acid 0.2% gel | Enoxaparin | |
| | Glycyrrhizin | |
| | Hydroxychloroquine | |
| | Interferon alpha | |
| | Levamisole | |
| | Mycophenolate mofetil | |
| | Thalidomide | |
| | Tetracycline | |
| | Mesalazine | |
| | Phenytoin | |
| | Griseofulvin | |

use and OSMF. Mehrotra *et al*[43] firstly investigated lipid profile in Indian patients with OMSF, and they observed a significant decrease in plasma total cholesterol, high-density lipoprotein cholesterol (HDL) cholesterol and Apo-A1 in patients with OSMF as compared to the controls. Similarly, Kumar *et al*[44] reported a statistically significant decrease in plasma total cholesterol, LDL and HDL cholesterol in patients with OSMF as compared to controls. Arakeri *et al*[45,46] observed that the mean concentration of copper in the home drinking water of patients with OSMF was significantly higher than in controls. Patients with OSMF also had a significantly higher copper concentration in serum and saliva, and serum ceruloplasmin than controls[45,46]. Aggarwal *et al*[47] reported that the serum beta carotene levels was significantly lower in patients with OMSF than in the controls. From these results, authors suggested that beta carotene plays an important role in the pathogenesis of OMSF and should be treated with a diet rich in beta carotene in order to reduce disease severity and progression towards malignancy[47]. Higher mast cell density as another possible pathogenic factor in patients with OSMF was suggested by Del Vecchio *et al*[48].

Symptoms such as burning sensation and/or intolerance to spicy food are the most common symptoms in the initial phase of the disease. Over time, it gradually progresses and fibrosis develops that can affect mouth opening[37]. Haider *et al*[49] proposed clinical and functional staging of OMSF, shown in Table 3.

Isaac *et al*[50] investigated histopathologic features of OSMF and observed some mucosal and submucosal changes. Mucosal changes such as atrophic changes, pigment incontinence, ulceration with granulation tissue, hyperplastic changes, dysplasia, and carcinoma were seen 74.3%, 62.8%, 40%, 25.7%, 8.6% and 0%, respectively. Submucosal changes such as fibrosis, diffuse chronic inflammatory infiltrate, atrophy of minor salivary glands, skeletal muscle atrophy, bandlike infiltrate, edema and

**Table 3 Clinical and functional staging**

| Clinical stage | Functional stage |
|---|---|
| Faucial bands only | Mouth opening ⩾ 20 mm |
| Faucial and buccal bands | Mouth opening 11-19 mm |
| Faucial, buccal, and labial bands | Mouth opening ⩽ 10 mm |

congestion, and vesicle formation were observed 100%, 100%, 85.7%, 57.1%, 45.7%, 22.8%, and 2.8%, respectively[50].

Three current treatment modalities including surgical, physical, and medical are available for the management of OSMF. Surgical treatments may be used to improve mouth opening and movements. Physical treatment including physical exercise regimen, splints or other mouth opening devices, and microwave diathermy may be useful in some patients with OSMF. There are numerous medical therapy alternatives such as steroids, interferon gamma, placental extracts, immunized milk, pentoxifylline, buflomedil hydrochloride, nylidrin, isoxsuprine, β-carotene, lycopene, vitamins, micronutriens, collagenase, hyaluronidase, chymotrypsin, and aloe vera[37,51-57].

## ACTINIC CHEILITIS

Actinic cheilitis is a potentially malignant disease of the lip caused by exposure solar radiation. It is commonly seen the surface area of the lower lip due to the anatomic proximity. In addition to solar rays, tobacco use, lip irritation, poor oral hygiene, and ill-fitting dentures may play a role in the development of actinic cheilitis. The disease predominantly occurs in men compared to the women[58]. Martins-Filho *et al*[59] reported that the prevalence of actinic cheilitis in farmers in a semi-arid area of Brasil was 16.7%.

While actinic cheilitis shows erythema and edema in the early stages of the disease, diffuse scaling, thickened epithelium with small greyish-white plaques (known as *leukoplakia*), inflammatory areas (known as *erythroleukoplakia*), and linear fissures may present in the late stages of the disease[58]. Malignant transformation rate has been estimated ranging from 1.4% to 36% at an interval of 1 to 30 years[60]. Diagnosis should be confirmed by biopsy to evaluate the degree of dysplasia. Histopathologically, hyperplasia, acanthosis or atrophy of the epithelium, thickening of the keratin layer, and/or dysplasia, which may range from mild to severe, may be shown. In addition to these epithelial changes, in connective tissue, basophilic degeneration of collagen fibers, known as solar elastosis, is usually detected[61].

In treatment, 5-fluorouracil, scalpel vermillionectomy, chemical peel, electrosurgery, cryosurgery, $CO_2$ laser, imiquimod, photodynamic treatment, diclofenac 0.3% gel can be preferred[58,60,62].

## SOME INHERITED CANCER SYNDROMES

In patients with xeroderma pigmentosum and Fanconi's anemia, incidence of oral cancer has increased[1].

## IMMUNODEFICIENCY

In patients with prolonged use of immunosuppressive drugs after solid organ transplants, human immunodeficiency virus-patients, and chronic graft versus host disease after stem cell transplantation are the patients in risk group for oral cancer development[1].

## Abstract

Chronic rhinosinusitis (CRS) is a common disease worldwide, with a prevalence rate of 5%-15% in the general population. CRS is currently classified into two types: CRS with and without nasal polyps. CRS may also be divided into eosinophilic CRS (ECRS) and non-ECRS subtypes based on the presence of tissue eosinophilic infiltration or not. There are significant geographic and ethnic differences in the tissue eosinophilic infiltration, which is predominant in Western white patients and less common in East Asians, despite an increasing tendency for its prevalence in East Asia countries. ECRS differs significantly from non-ECRS in clinical characteristics, treatment outcomes and strategies, and underlying pathogenic mechanisms. ECRS commonly demonstrates more severe symptoms, polyp diseases with a higher incidence of bilateral polyps and sinonasal diseases on computed tomography, and the increase in blood eosinophils. ECRS is considered a special and recalcitrant subtype of CRS, commonly with poor treatment outcomes compared to non-ECRS. The differentiation of specific subtypes and clinical features of CRS will be important for developing novel treatment strategies and improving treatment outcomes for individual phenotypes of CRS. This review discusses clinical features, diagnosis, treatment and prognosis of ECRS in East Asians.

**Key words:** Chronic rhinosinusitis; Eosinophilic chronic rhinosinusitis; Eosinophils; Chronic rhinosinusitis with nasal polyps; Nasal polyps

**Core tip:** Chronic rhinosinusitis (CRS) is a common disease and currently classified into two types based on presence or absence of nasal polyps. CRS may also be subtyped into eosinophilic CRS (ECRS) and non-ECRS according to the presence of predominant tissue eosinophilic infiltration or not. ECRS differs significantly from non-ECRS in clinical characteristics, treatment outcomes and strategies, and underlying pathogenic mechanisms. ECRS is considered a special and recalcitrant subtype of CRS. The identification of ECRS is helpful to develop treatment strategies for this CRS subtype. Herein we review the clinical features, diagnosis, treatment and prognosis of ECRS in East Asians.

## INTRODUCTION

Chronic rhinosinusitis (CRS) is one of the most common chronic diseases worldwide, with a prevalence rate of 5%-15% in the general population in Europe and the United States[1] and 7% in South Korea[2]. CRS remains a significant public health problem with a considerable socioeconomic burden[3]. In the current practice guidelines of Europe, the United States and China, CRS is classified into two types based on the presence or absence of nasal polyps: CRS with nasal polyps (CRSwNP) and CRS without nasal polyps (CRSsNP)[1,4,5]. Eosinophilic inflammation is considered a major pathologic hallmark of CRS. Histological studies demonstrate the predominant tissue eosinophilic infiltration with a high proportion of CRS

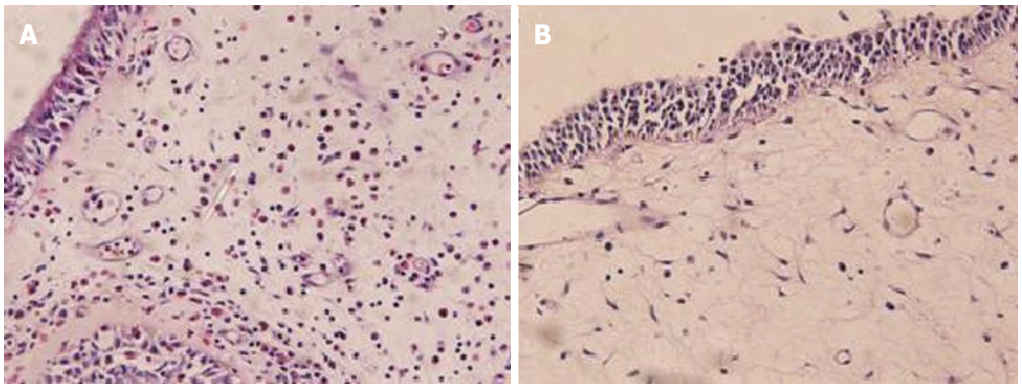

**Figure 1 Hematoxylin and eosin staining for nasal polyp tissues.** Predominant eosinophil infiltration is showed in the subtype of eosinophilic chronic rhinosinusitis with nasal polyps (A), but other forms of inflammatory cell infiltration in the subtype of non-eosinophilic chronic rhinosinusitis with nasal polyps (B) (× 400).

cases, most prominently with CRSwNP cases[1]. Thus, CRS may be classified into two subtypes: eosinophilic CRS (ECRS) and non-eosinophilic CRS (NECRS). Similarly, CRSwNP may also be subclassified into ECRSwNP and NECRSwNP[6-19]. However, the tissue eosinophilic infiltration in CRS shows significant geographic and ethnic differences. Eosinophilic infiltration is predominantly observed in Western white patients with CRS, accounting for more than 80% of CRS cases[1,4,18], while the eosinophilic phenotype is less than 50% of CRS cases in East Asia countries including Japan[13-15,20], South Korea[17,21,22] and China[11,16,23,24]. However, recent studies indicate an increasing tendency for the prevalence of ECRS in these Asia countries[12,13,15,20,21,25]. Studies show that ECRS differs significantly from NECRS in clinical characteristics, underlying pathogenic mechanisms, treatment outcomes and strategies[1,6,10,11,13,15,16,20,26-28]. ECRS is considered a special subtype of CRS[10,13,15] and also a subtype of recalcitrant CRS, which commonly has worse disease severity[8,18,19,29] and poorer treatment outcomes[19,28,30] compared to NECRS. For example, ECRSwNP is refractory to the combined treatments of endoscopic sinus surgery (ESS) and macrolide therapy and shows a strong tendency for recurrence after surgery but responds to systemic steroid therapy[13-15]. Thus, identifying specific subtypes of CRS and underlying pathogenic mechanisms will be important for developing novel treatment strategies and improving treatment outcomes for individual phenotypes of CRS[10,29].

## ROLES OF EOSINOPHILS IN ECRS

CRS is a heterogeneous disease to which numerous etiologies contributed. Although intensive investigations have been performed, the etiology, pathogenesis and underlying mechanisms of CRS are not fully understood[1,15,31,32]. The dominant eosinophilic inflammation for CRS indicates that eosinophils play a key role in the pathogenesis of CRS, especially in CRSwNP[1], although many kinds of other inflammatory cells including neutrophils, mass cells, lymphocytes and plasma cells also have important roles in the pathogenesis of CRS[27,33] (Figure 1).

Eosinophils develop from $CD34^+$ progenitors in the bone marrow and migrate into the bloodstream, and they are recruited to disease sites by chemokines or cytokines, where eosinophils can perform and participate in a variety of functions, including antigen presentation, cytokine or chemokine production, and secretion of granule mediators[34-36]. The ability of eosinophils to process and present antigens has been generally underestimated and this function can be added to the growing list of mechanisms by which eosinophils regulate the immune system[34]. Eosinophils store preformed cytokines in granules that can be released rapidly upon antigenic provocation[36]. These eosinophil-derived cytokines can be T helper 2 (Th2) cytokines such as interleukin (IL)-13 that act directly on T cells, as well as other inflammatory cytokines that can prime antigen presenting cells and the vascular endothelium to secrete chemokines and cytokines that recruit and activate T cells[34].

Studies indicate significant roles of T cell regulation in CRS. CRS appears to be a disease mediated by $CD4^+$ T cells that can be functionally divided into Th1 or Th2 phenotype based on their patterns of cytokine secretion. It is found that among West white patients with CRS, CRSsNP is characterized by Th1 polarization, whereas CRSwNP by predominant Th2, with high levels of Th2-type cytokines including IL-4, IL-5 and IL-13[37]. CRSwNP also is characterized by a Th2-driven eosinophilic inflammation in tissue[37,38]. However, studies suggest that East Asians with CRSwNP present different immunopathologic features compared with West white patients[17,24,39]. For example, CRSwNP in Chinese demonstrates a Th1/Th17 cell pattern with minor eosinophilic inflammation[24]. Th2-dominated reactions can only be found in ECRSwNP instead of all CRSwNP cases, suggesting that Th cell responses may exert different impacts on the pathogenesis of ECRSwNP and NECRSwNP[16,17,24]. There are interactions between T cells and eosinophils. It is conventionally viewed that the T cell–eosinophil interactions are primarily based on the activation of eosinophils by T cells *via* cytokines, but it is suggested that eosinophils also have the capacity to activate T cells to produce cytokines[40,41]. Eosinophils by secreting specific cytokines or chemokines have a more central role in Th2 responses in CRS[34].

**Table 1 Demographic and clinical characteristics of eosinophilic chronic rhinosinusitis with nasal polyps and non-eosinophilic chronic rhinosinusitis with nasal polyps**

| | ECRSwNP | NECRSwNP |
|---|---|---|
| *n* (%) | 27 (45%) | 33 (55%) |

[b]$P < 0.01$ *vs* NECRSwNP. ECRSwNP: Eosinophilic chronic rhinosinusitis with nasal polyps; NECRSwNP: Non-eosinophilic chronic rhinosinusitis with nasal polyps; M/F: Male/female; AR: Allergic rhinitis; VAS: Visual analogue scale; HPF: High power field; CT: Computed tomography.

## CLINICAL FEATURES OF ECRS

Many studies have shown that ECRS differs from NECRS in clinical features[13,14,15]: (1) ECRS often shows the symptom of olfactory dysfunction in its early stage; (2) ECRS commonly demonstrates multiple and bilateral nasal polyps, with highly viscous mucus secretion, while NECRS mostly with mucopurulent discharge; (3) ECRS tends to have bilateral sinus diseases on sinonasal computed tomography (CT), with a predominant disease in the ethmoid sinus especially in early stage, while NECRS in the maxillary sinus; (4) Co-existence of asthma is more common in ECRS; (5) Most of ECRS cases show the increase of peripheral blood eosinophils; (6) ECRS demonstrates dominant tissue eosinophilic infiltration; (7) In medical treatments, local or systemic steroid therapy is more effective for ECRS compared to macrolide therapy, while macrolide is effective for NECRS; and (8) ECRS shows strong tendency for nasal polyp recurrence after surgery, but systemic steroid is effective for the recurrent nasal polyps.

### *Symptoms of ECRS*

Many studies indicate that ECRS commonly has more severe disease and higher symptom score compared to NECRS[8,18,19,29]. A recent study shows the mean severity score of symptoms including olfactory dysfunction, nasal obstruction, and nasal discharge in ECRS is significantly higher than that in NECRS[42]. Previous studies have shown that there is a close correlation between symptoms and tissue eosinophil infiltration in CRS[18,43]. However, a recent study shows no significant differences in the symptom severities of nasal obstruction, nasal discharge, and facial pain aside from smell dysfunction between ECRS and NECRS cases[10]. Another study also shows no difference in visual analogue scale (VAS) score or duration of symptoms between ECRSwNP and NECRSwNP patients[11], suggesting that the two subtypes may have an equivalent severity of symptoms. Similarly, ECRSwNP and NECRSwNP patients may present with comparable symptom scores[44]. In our recent study, a significant difference in the mean VAS score of symptoms between the ECRSwNP and NECRSwNP patients was also not found (Table 1).

CRS is one of the most frequent causes of olfactory dysfunction (reduction or loss of smell) and accounts for 21%-25% of cases with smell loss[45-48]. Meanwhile, olfactory dysfunction affects about 60% of CRS patients[4]. Olfactory dysfunction is related to the severity of CRS, especially when with nasal polyps[49]. A study shows that 38% of CRS patients present with olfactory dysfunction, which is affected by nasal polyps, and the prevalence of olfactory dysfunction is 57% in CRSwNP and 13.7% in CRSsNP, respectively[20]. A recent report indicates that smell dysfunction is a very common symptom in CRSwNP, even accounting for 96.5% of cases[41]. Olfactory dysfunction is a more predominant and characteristic symptom of ECRS and tends to occur in the early stage of ECRS[10,13-15,20,50]. This symptom is more severe and common in ECRS compared to NECRS[42]. A study shows that there is a high prevalence of olfactory dysfunction in ECRS (78.9%) compared to NECRS (25.9%)[20]. Olfactory dysfunction is reported to be associated with olfactory cleft opacification on CT images[51]. Nasal polyps occur more commonly in the olfactory cleft in ECRS compared to NECRS[42]. Edematous swelling or polyposis of the middle turbinate, which is often observed in ECRS patients, increases the opacification of the olfactory cleft and causes olfactory impairments[13]. Studies indicate that olfaction score is influenced by mucosal eosinophilic infiltration, with lower olfaction score in ECRSwNP as compared to NECRSwNP[29,52]. A study shows that there are no statistically significant differences in the VAS scores of nasal obstruction, nasal discharge, headache or overall symptoms, but a statistically significant difference is found in relation to problems of smell between the patients with high and low infiltration of eosinophils in the ethmoidal sinus mucosa[50]. But in our recent study, no statistically significant difference in olfactory dysfunction scores was found between ECRSwNP and NECRSwNP (Table 1). The patients with ECRSwNP seemed to have a shorter duration of symptoms than NECRSwNP patients although this difference was not significant statistically (Table 1).

### *Polyps in ECRS*

ECRS commonly exhibits multiple and bilateral nasal polyps compared to NECRS[13-15], and the polyps commonly exist in the olfactory cleft[42]. Although a previous study shows that there is not a significant difference in endoscopic scores of nasal polyps between ECRSwNP and NECRSwNP subtypes[29], many studies demonstrate that ECRSwNP often present with a higher endoscopic score of nasal polyps compared with NECRSwNP[10,18]. Our recent study showed that ECRSwNP presented with a higher score of nasal polyps and a higher incidence of

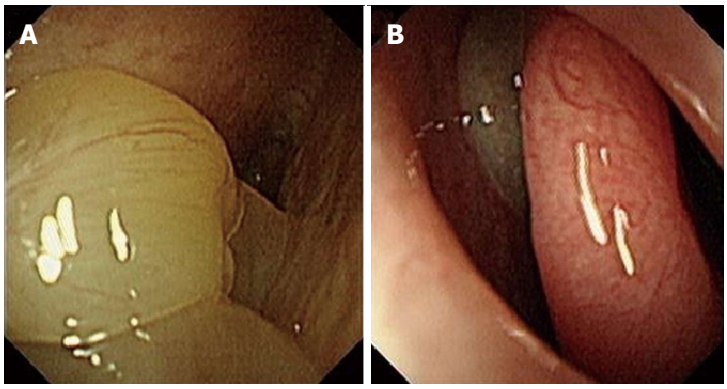

**Figure 2 Nasal endoscopic findings.** Polyps in eosinophilic chronic rhinosinusitis with nasal polyps (A) and in non-eosinophilic chronic rhinosinusitis with nasal polyps (B).

**Table 2 Computed tomography features of eosinophilic chronic rhinosinusitis with nasal polyps and non-eosinophilic chronic rhinosinusitis with nasal polyps**

| | ECRSwNP ($n$ = 27) | NECRSwNP ($n$ = 33) |
|---|---|---|
| Total disease score of sinuses | 14.42 ± 3.84[b] | 9.64 ± 3.37 |
| Number of involved sinuses | 7.88 ± 1.22[b] | 5.64 ± 1.49 |
| Percentage of involvement in all sinuses | 23.1%[a] | 3.0% |
| Incidence of bilateral diseases in individual sinuses | | |
| Frontal | 53.8%[b] | 12.1% |

[a]$P < 0.05$, [b]$P < 0.01$ *vs* NECRSwNP. Scoring for sinus diseases on computed tomography (CT): 0 = normal, 1 = partial opacification, and 2 = total opacification; these points are applied to individual sinuses on each side; OMC is graded as 0 = not occluded, or 2 = occluded; deriving a maximum score of 12 per side. ECRSwNP: Eosinophilic chronic rhinosinusitis with nasal polyps; NECRSwNP: Non-eosinophilic chronic rhinosinusitis with nasal polyps; OMC: Ostiomeatal complex.

bilateral nasal polyps when compared with NECRSwNP (Table 1 and Figure 2).

In addition, endoscopic examination indicates that most of patients with ECRS demonstrate sinonasal mucus secretion with high viscosity, while NECRS is common with mucopurulent discharge[13-15]. It was found in our recent study that more than half (55.6%) of 27 ECRSwNP patients showed highly viscous mucus secretion, but less than a third (30.3%) of 33 NECRSwNP patients presented with this condition.

### *CT findings in ECRS*

The Lund-Mackay scoring system is widely used to evaluate the disease severity of CRS on sinonasal CT[1,4,53,54]. CRSwNP tends to have a higher score of disease on CT compared with CRSsNP[41]. CT imaging also is a powerful tool to differentiate ECRS from NECRS[13]. Studies show that there are significant differences in the disease scores of most sinuses aside from maxillary sinus between ECRS and NECRS[13,15]. ECRSwNP presents with higher disease scores on CT compared to NECRSwNP[18,27], although an obvious difference in CT scores between ECRSwNP and NECRSwNP subtypes is not found in some studies[11,29]. In addition, CT studies show that sinus diseases commonly occur bilaterally in ECRS compared to NECRS[13-15]. Our recent study showed significant differences in the mean score of total diseases in all sinuses, the mean number of involved sinuses, the percentage of cases with involvement of all sinuses, and the incidence of bilateral diseases in individual sinuses between ECRSwNP and NECRSwNP (Table 2 and Figure 3).

In terms of individual sinuses, ECRS patients especially in their early stages often have predominant diseases in the ethmoid sinuses[13-15,20,42]. A previous study shows that there is a significant correlation between the severity of eosinophilic infiltration in the ethmoidal mucosa and the disease on CT[55]. Ethmoidal sinus lesions are readily detected by CT in patients with CRS accompanied by severe eosinophil infiltration[50]. Involvement of the posterior ethmoid sinus is one of the most apparent differences in CT images between ECRS and NECRS. In the early stage of ECRS, CT images can demonstrate the opacification of the posterior ethmoid sinus[15]. A study shows that the posterior ethmoid sinus is more commonly involved in ECRSwNP compared to NECRSwNP, whereas both the anterior and posterior ethmoid sinuses are similarly involved in NECRSwNP, and CT score of the posterior ethmoid has a good accuracy as a predictor of ECRSwNP in a Japanese population[13]. Our recent study showed that ECRSwNP had a higher incidence of bilateral diseases and a higher disease score in the anterior or posterior ethmoid sinus compared to NECRS, but ECRSwNP had similar disease scores in its anterior and posterior ethmoid sinuses, while NECRS showed a higher disease score in the anterior ethmoid sinus compared with the posterior ethmoid sinus (Table 2).

The maxillary sinus is most often involved in CRS. The middle meatus or ostiomeatal complex (OMC) has a fundamental role in the pathogenesis of CRS[1]. As the drainage from the sinus to the middle meatus or OMC is impaired, the sinus becomes secondarily involved. According to this pathogenesis, sinuses that are most likely

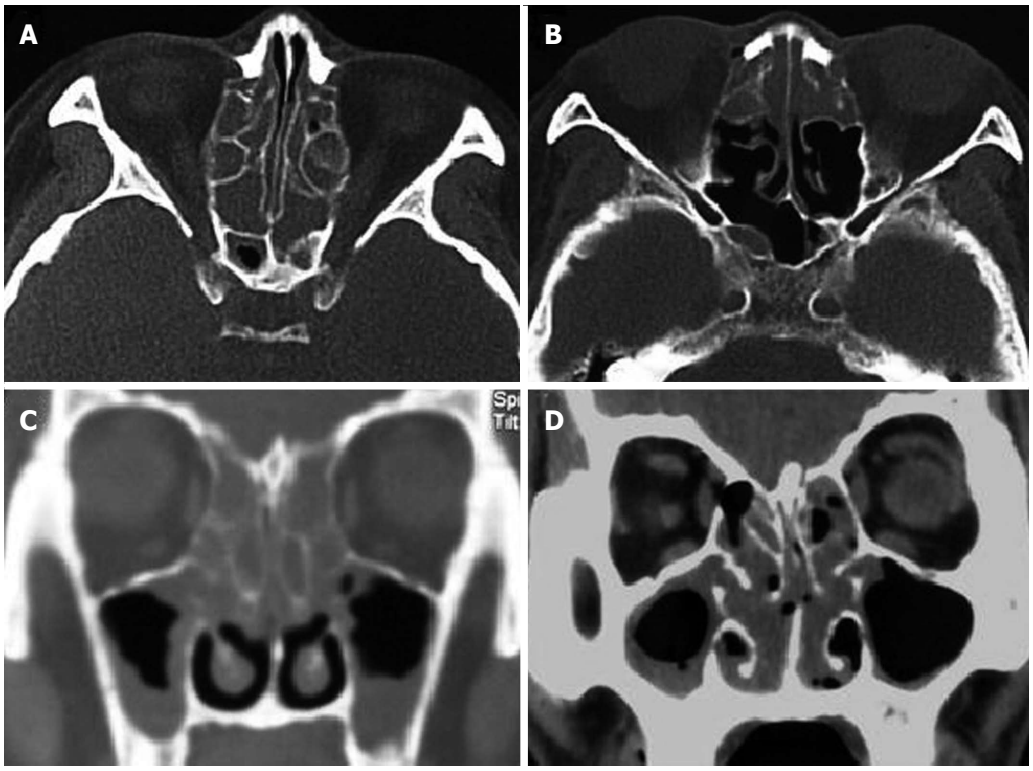

**Figure 3 Computed tomography findings.** Axial and frontal sections in the subtypes of eosinophilic chronic rhinosinusitis with nasal polyps (ECRSwNP) (A and C) and non-eosinophilic chronic rhinosinusitis with nasal polyps (NECRSwNP) (B and D). Predominant diseases in bilateral anterior and posterior ethmoid sinuses are showed in ECRSwNP, while predominant diseases in anterior ethmoid sinuses in NECRSwNP.

to be affected are the maxillary sinus and anterior ethmoid sinus that connect to the middle meatus or OMC through the small ostia. However, ECRS has predominant disease in the ethmoid sinus, while NECRS in the maxillary sinus[13-15,20], and the posterior ethmoid sinus that does not directly connect with the middle meatus is involved in similar to the anterior ethmoid sinus even in the early stage for ECRS patients. This suggests that pathological changes in the middle meatus or OMC may be of less importance for the pathogenesis of ECRS, namely, the pathogenesis of ECRS is different from that of NECRS[15]. A recent study reveals that OMC obstruction is correlated with sinus disease only for patients with CRSsNP but not CRSwNP[56]. It is thought that ECRS may not be associated with OMC occlusion[8].

In contrast to NECRS patients who have often a predominant disease in the maxillary sinus, patients with ECRS have commonly a predominant disease in the ethmoid sinus especially in the early stage[9,13-15,20]. Our recent study showed that ECRSwNP had higher disease scores in frontal, sphenoid, anterior and posterior ethmoid sinuses than NECRSwNP, but there was not a significant difference in maxillary or OMC disease score between ECRSwNP and NECRSwNP (Table 2), which indicated that ECRSwNP had predominant disease in the ethmoid sinus including the anterior and posterior ethmoid sinuses, while NECRSwNP had similar involvement of the anterior ethmoid and maxillary sinuses but with less involvement in the posterior ethmoid sinus.

### *Co-morbid allergic rhinitis or asthma in ECRS*

Inflammation in the upper respiratory tract affects the lower respiratory tract and *vice versa*. The concept of the unified airway is proposed based on evidence from epidemiological, pathophysiological, and treatment outcome studies, indicating the existence of similar inflammatory responses and the shared pathophysiological mechanisms between allergic rhinitis (AR), asthma and CRS[20,57,58].

Some studies demonstrate that 25%-58% of individuals with CRS have AR[59,60]. A recent study shows that 67.2% of 418 patients with CRS have AR, and 76.8% of 190 patients with ECRS and 59.2% of 228 patients with NECRS have AR[42]. However, some studies show that there is not a statistically significant difference in the coexistent rate of AR between ECRSwNP and NECRSwNP[11,22], and a similar finding was also found in our case cohort (Table 1).

The clinical relationship between CRS and asthma has been known for many years. CRS and asthma coexist often clinically and they share some histopathologic features such as chronic eosinophilic inflammation, epithelial damage, and basement membrane thickening of the airway mucosa[61]. It is reported that the prevalence of asthma in CRS patients is 20%-50%[13,18,20,41,42,62,63] and even more than 50%[61]. However, there is a lower prevalence of asthma (2%-3%) in CRS patients in China compared with the Western population[64]. This difference may result from distinct immunopathologic characteristics of CRS in Chinese patients, specifically from lower levels of eosinophilic inflammation[16,24,64-66]. CRS espe-

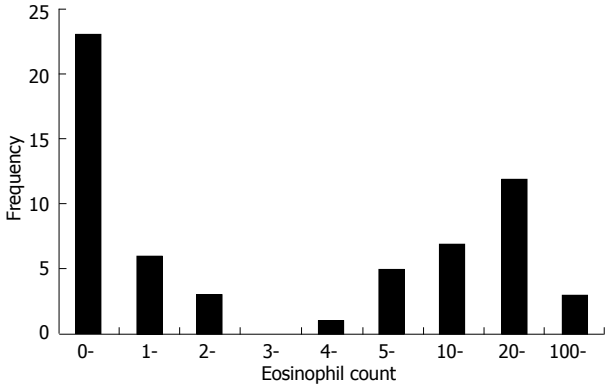

**Figure 4 Frequency distribution and range of tissue eosinophil count per high power field for 60 patients with chronic rhinosinusitis with nasal polyps.**

cially CRSwNP is commonly associated with asthma[31]. The association of CRSwNP and asthma is well established, and CRSwNP in white population of Europe and the United States represents often a form of severe and difficult-to-treat eosinophilic airway inflammation, which frequently is linked to co-morbid asthma[1]. Eosinophilic inflammation is considered a common mechanism in both CRSwNP and asthma[67]. It is reported that among 2176 cases with CRSwNP, 37.5% present with asthma[68]. A recent study shows that among 182 patients with CRSwNP, the percentage of patients with asthma is as high as 94%[69]. Asthma is known to be often concurrent with ECRS[14,42,70]. A study shows that 34.7% of 190 patients with ECRS, but only 9.6% of 228 patients with NECRS, present the coexistence with asthma[42]. Co-morbid asthma is one of typical features for ECRS[13]. Association of ECRSwNP with asthma is widely accepted[12]. Some authors believe that ECRS and asthma share similar histopathologic features and are the same inflammatory process demonstrating in different sites of the respiratory tract[61,67].

A study shows that in Chinese patients with CRSwNP, the incidence of asthma (15.9%) in ECRSwNP is higher than that (3.6%) in NECRSwNP[9]. Another study shows that the prevalence of asthma in ECRSwNP is higher than that in NECRSwNP, but the difference does not reach statistical significance[11]. And also, there are the studies showing no significant difference in the prevalence of asthma between ECRSwNP and NCRSwNP patients[11,22], which may be due to the low prevalence of asthma among CRS patients in China[64]. A statistically significant difference in the incidence of asthma between ECRSwNP and NECRSwNP patients was also not found in our recent study (Table 1). Although asthma is often seen in patients with ECRS, co-morbidity with asthma may not be a diagnostic criterion for ECRS because about half of ECRS cases are not associated with asthma[15].

### *IgE and ECRS*

CRS is a form of eosinophil-dominated inflammation. Some factors result in local production of IgE, which may contribute to severe eosinophilic inflammation. There is a significant correlation between the concentration of IgE and the number of eosinophils in nasal polyp tissue[38]. Some ECRS patients show the elevation of total or specific IgE level[6,15,44]. ECRSwNP patients demonstrate increased blood IgE levels compared with NECRSwNP[11,27]. A study shows that the amount of tissue eosinophils in CRSwNP is related to eosinophilia of the peripheral blood, but no significant correlation exists between elevated serum IgE and the increase of tissue or blood eosinophils, indicating that atopic conditions may play a minor role in the pathogenesis of CRSwNP in Koreans[17]. It is showed that only less than half of CRS patients present with the increased blood IgE and thus eosinophilic inflammation is not likely driven by an IgE mechanism[61]. A study shows the absence of a significant difference in total serum IgE levels between ECRS and NECRS patients, suggesting that systemic IgE does not greatly contribute to the pathophysiology of ECRS[13]. Also, a recent study shows that although total serum IgE in ECRS is higher than that in NECRS (120.3 *vs* 48.0 kU/L), the difference is not statistically significant[10]. Similarly, a significant difference in serum IgE levels between ECRSwNP and NECRSwNP was not found in our recent study (Table 1).

## DEFINITION OR DIAGNOSIS OF ECRS

Currently ECRS is determined primarily based on tissue eosinophilic infiltration, but there is not a well-defined criterion of the tissue eosinophilic infiltration for diagnosis of ECRS. In some studies, ECRS including ECRSwNP is defined as tissue eosinophil count per high power field (HPF) more than 5 eosinophils[18,21,29,64], 10 eosinophils[8,30], or 20 eosinophils[9], even more than 100 eosinophils[27,42], as well as the percentage of eosinophils in tissue-infiltrated inflammatory cells exceeding 5%[17], 10%[16,66,71] or 15%[20]. In our recent study tissue eosinophil count more than 5 eosinophils/HPF was used as a criterion for ECRSwNP based on the frequency of cases with individual eosinophil counts in nasal polyp tissues (Figure 4).

Tissue eosinophilic infiltration, based on which ECRS is determined, is commonly identified after surgery by histopathological examination. Therefore, this approach may be quite unpractical because it is difficult to obtain the diagnostic information before surgery or from the patients treated only with medicines. While peripheral blood eosinophilia has a certain diagnostic value for ECRS[15], because the close correlation between the number of peripheral blood and tissue-infiltrated eosinophils has been shown in several studies[9-11,15,17,18,27,42]. It is easy to understand the close association of blood eosinophils with ECRS because the tissue-infiltrated eosinophils are recruited *via* bloodstream to disease sites of ECRS. Many studies have shown that ECRSwNP presents with a significant increase in the peripheral blood eosinophil count or percentage compared to NECRSwNP[9,11,13,52]. Our recent study also showed the existence of a close correlation between tissue eosinophil count and blood eosino-

**Table 3 Diagnostic sensitivity and specificity of blood eosinophil count or percentage for eosinophilic chronic rhinosinusitis**

ECRS: Eosinophilic chronic rhinosinusitis; AUC: Area under receiver operating characteristic curve.

phil count or percentage in ECRSwNP patients, but not in NECRSwNP patients. Thus, the increased peripheral blood eosinophil count or percentage is considered a good marker or predictor of ECRSwNP[9,11,13,52]. Some studies show that blood eosinophil count or percentage in ECRS subtype is significantly higher than that in NECRS subtype[9,11,13,52]. It is found by receiver operating characteristic curve analysis that blood eosinophil count or percentage has high sensitivity and specificity for the diagnosis of ECRS[9,11,13,52] (Table 3).

Our recent study also showed that there was a statistically significant difference in mean blood eosinophil count or percentage between ECRSwNP and NECRSwNP patients (Table 1). However, it was notable that neither all patients with ECRSwNP had the increased circulating eosinophils nor all patients with NECRSwNP showed a normal level of blood eosinophil count. For example, only 10 of 27 patients with ECRSwNP showed blood eosinophil counts more than normal range and 2 of 33 patients with NECRSwNP had the increase of eosinophil count. Therefore, ECRS or NRECR can not be determined only based on if blood eosinophils increase.

The definition or diagnostic criterion for ECRS is very important since ECRS differs from NECRS in treatment strategy. However, there is not yet a clear definition or diagnostic criterion to differentiate ECRS and NECRS subtypes. Recently, new diagnostic criteria for ECRS have been proposed[13], in which the diagnosis of ECRS is finally determined by the clinical symptoms, nasal endoscopy, sinonasal CT imaging, peripheral blood test, and histological examination[13,15].

## TREATMENT AND PROGNOSIS FOR ECRS

ESS has been used widely for the treatment of CRS. Outstanding short- and long-term results of ESS in CRS have previously been reported in the literature[41,68,72-75]. The impact of ESS on the improvement in CRS-related symptoms postoperatively is remarkable. However, some of CRS patients are inadequately controlled despite receiving combination of maximal medical therapy and ESS[1]. A wide variety of factors contribute to poor disease control, including patient-related factors such as ECRS[76]. It is believed that NECRS can be relatively well controlled with a combination of ESS and macrolide therapy, whereas ECRS is unresponsive to macrolide therapy[13]. Many studies indicate that ECRS commonly has poorer treatment outcomes compared to NECR[14,19,28,30,76,77]. For example, ECRSwNP is refractory to the combined treatment of ESS and macrolide therapy and shows a strong tendency for recurrence after surgery[13-15,27].

However, a recent study suggests that eosinophilic inflammation in CRS may not be related to the surgical outcome in South Koreans[22]. Another study also shows that the presence or absence of tissue eosinophilic infiltration does not impact significantly on the time interval to revision surgery[78]. Our recent study showed that in terms of the short-term efficacy of ESS in CRSwNP, both ECRSwNP and NECRSwNP patients had significant improvement in symptoms aside from smell dysfunction at one-week follow-up after ESS, but there was no significant difference in symptom improvement between the two subgroups.

## CONCLUSION

In conclusion, CRS can be subclassified into two subtypes: ECRS and NECRS. The prevalence of ECRS is increasing in East Asians in the recent years. ECRS differs from NECRS in clinical features and treatment outcomes; however, there is not yet a universally accepted definition or diagnostic criterion for ECRS, and also the underlying pathogenic mechanisms of ECRS are not well-understood. Identification of ECRS subtypes and underlying pathogenic mechanisms is key to developing treatment strategies for the phenotypes of CRS.

## Abstract

**AIM:** To investigate whether congenital lumbar spinal stenosis (CLSS) is associated with a specific degenerative changes of the lumbar spine.

**METHODS:** The lumbar spine magnetic resonance imaging studies of 52 subjects with CLSS and 48 control subjects were retrospectively evaluated. In each examination, the five lumbar levels were assessed for the presence or absence of circumferential or shallow annular bulges, annular tears, anterior or posterior disc herniations, epidural lipomatosis, Schmorl's nodes, spondylolisthesis, pars defects, and stress reactions of the posterior vertebral elements.

**RESULTS:** Compared to control individuals, subjects with CLSS exhibited increased incidence of circumferential and shallow annular bulges, annular tears, disc herniations and spondylolisthesis ($P < 0.05$).

**CONCLUSION:** CLSS is associated with increased incidence of degenerative changes in specific osseous and soft-tissue elements of the lumbar spine.

**Key words:** Congenital lumbar spinal stenosis; Magnetic resonance imaging; Imaging findings; Degenerative changes; Low back pain

**Core tip:** Congenital lumbar spinal stenosis is associated with increased incidence of degenerative changes in specific osseous and soft-tissue elements of the lumbar spine. Describing the spectrum of the respective imaging findings, this article can assist radiologists in providing more detailed magnetic resonance imaging reports.

## INTRODUCTION

Since the first reports describing congenital (or developmental) lumbar spinal stenosis (CLSS), the clinical implications of this entity have been the subject of several scientific studies[1-3]. Based on the original etiological classification described by Arnoldi *et al*[4], CLSS is a developmental narrowing of the spinal canal, which is secondary to a bone dysplasia. Radiographically, the respective subjects have a shorter pedicular length and as a result a smaller cross-sectional spinal canal area[5]. In

usual practice, the above subjects tend to present clinically in the fourth or fifth decade of life with various neurogenic complications and relatively few radiographically evident degenerative spondylotic changes[5]. Except for scattered articles reporting radiographic and cross-sectional measurements to define CLSS, there have been no studies evaluating whether the entity is associated with degenerative changes in specific osseous and soft-tissue elements of the lumbar spine. In our practice with magnetic resonance imaging (MRI) studies of the lumbar spine, we have experienced that individuals with CLSS tend to exhibit an increased incidence of specific imaging features, including foraminal disc protrusions, as well as a particular type of annular disc bulge, in which the posterior concavity of the intervertebral discs is preserved. To validate our observations and potentially extend our understanding of CLSS from an imaging point of view, we investigated the association between CLSS and degenerative changes in various osseous and soft-tissue elements of the lumbar spine.

### Study population

Institutional review board approval was granted and informed consent was waived for this HIPAA-compliant study. The MRI database of our institution was searched for examinations of the lumbar spine performed in adults of less than or equal than 50 years of age, an age limit arbitrarily employed to limit the inclusion of subjects with age-related degenerative spine changes. Two radiologists with 16 (A.C.) and 6 (T.S.) years of radiology experience, respectively, who were blinded to the original reports of the MRI studies, evaluated the examinations in consensus on a picture archiving and communication system workstation (Ultravisual, Emageon, AL, United States). All examinations were performed on 1.5T or 3.0T MR scanners and included axial and sagittal T1- and T2-weighted images, as well as sagittal STIR images of the lumbar spine.

In each study, the T2-weighted images were used to calculate the mid-sagittal spinal canal diameter and mid-sagittal thecal sac diameter at the mid-vertebral levels of all five lumbar vertebrae. Subjects with mid-sagittal spinal canal diameter of less than 14 mm on at least one level were considered as having CLSS and were included in the study group, whereas subjects with mid-sagittal spinal canal diameter of equal or greater than 14 mm at all five levels were included in the control group. Examinations were consecutively evaluated until a study group of 52 subjects and a control group of 48 subjects were formed. Patients with achondroplasia or a known history of spinal surgery, trauma, infection and/or tumor were excluded.

### Image analysis

In each study, the average value of mid-sagittal thecal sac diameter was calculated, and thereafter, the intervertebral levels from L1-L2 to L5-S1 were evaluated for the presence or absence of (1) circumferential annular bulge, defined as generalized extension of greater than 50% of the outer boundary of the intervertebral disc beyond the border of the adjacent bone, with loss of posterior disc concavity; (2) shallow annular bulge, defined as the extension of the intervertebral disc by greater than 50% from the outer boundary of the adjacent bone, with preservation of the posterior disc concavity; (3) annular tear(s), defined as focal area(s) of increased signal intensity within the outer layer of the intervertebral disc on fluid-sensitive images; (4) uni- or bilateral foraminal disc herniation(s), defined as extension(s) of less than 50% of the outer boundary of the intervertebral disc beyond the border of the adjacent bone, centered on one or both foramina; (5) central or paracentral disc herniation, defined as extension of less than 50% of the outer boundary of the intervertebral disc beyond the border of the adjacent bone, protruding centrally or subarticularly within the spinal canal, respectively; (6) epidural lipomatosis, registered when the epidural adipose tissue assumed an anteriorly convex border and a thickness of greater than 7 mm[6]; (7) Schmorl's node(s); (8) spondylolisthesis (antero- or retrolisthesis), registered when the vertebral body exhibited anterior or posterior displacement of equal or greater than 1 mm over the vertebral body below; (9) uni- or bilateral pars defect(s); (10) anterior disc herniation; and (11) stress reaction (increased signal intensity on fluid-sensitive images) of the posterior vertebral elements. For each of the above features, the total incidence observed throughout the five intervertebral levels was documented for each subject.

### Statistical analysis

For all evaluated quantitative parameters, the difference between the study and control groups was assessed using Student's $t$ test, whereas sex distribution was evaluated using $\chi^2$ test. A probability level of 0.05 was accepted as statistically significant. All data were stored on a spreadsheet (Excel 2010, Microsoft, Seattle, WA, United States) and analysis was performed using a commercially available statistical package (MedCalc 8.0, Mariakerke, Belgium).

## RESULTS

Table 1 summarizes the demographics of the study population, the incidences of the features evaluated, as well as the results of the various statistical comparisons between the study and control groups. The two groups were similar in terms of age and sex distribution. Subjects with CLSS exhibited increased incidence of circumferential and shallow annular bulges, foraminal and anterior disc herniations, annular tears, and spondylolisthesis. There was no difference between the two groups regarding the incidences of central and paracentral disc herniations, epidural lipomatosis, Schmorl's nodes, pars defects, and stress reaction of the posterior vertebral elements.

## DISCUSSION

CLSS has been attributed to an abnormal anatomic de-

**Table 1 Demographics of the 100 patients of the study along with the imaging features which were evaluated on the respective magnetic resonance imaging studies**

| Parameter | Subjects with CLSS | Control subjects | *P* |
|---|---|---|---|
| Subjects | 52 | 48 | - |
| Age | 38 ± 10 | 38 ± 8 | 0.4930 |
| Sex (males/females) | 28/24 | 22/26 | 0.2742 |
| Average mid-sagittal thecal sac diameter | 1.31 ± 0.13 | 1.51 ± 0.18 | – |
| Circumferential annular bulges | 59 (1.13 ± 0.95) | 35 (0.73 ± 0.79) | 0.0116[1] |
| Shallow annular bulges | 80 (1.54 ± 1.06) | 47 (0.98 ± 0.93) | 0.0031[1] |
| Foraminal disc herniations | 31 (0.60 ± 0.82) | 13 (0.27 ± 0.54) | 0.0111[1] |
| Central/paracental disc herniations | 22 (0.42 ± 0.70) | 15 (0.31 ± 0.55) | 0.1917 |
| Epidural lipomatosis | 33 (0.63 ± 1.09) | 17 (0.35 ± 0.76) | 0.0701 |
| Schmorl's nodes | 24 (0.46 ± 1.00) | 13 (0.27 ± 0.68) | 0.1352 |
| Spondylolisthesis | 53 (1.02 ± 0.96) | 29 (0.60 ± 0.71) | 0.0081[1] |
| Pars defects | 0 (0.00 ± 0.00) | 2 (0.04 ± 0.20) | 0.0699 |
| Annular tears | 56 (1.08 ± 1.01) | 25 (0.52 ± 0.80) | 0.0004[1] |
| Anterior disc herniation | 63 (1.21 ± 1.16) | 25 (1.51 ± 0.18) | < 0.0001[1] |
| Posterior elements stress reaction | 4 (0.08 ± 0.33) | 2 (0.04 ± 0.20) | 0.2644 |

Subjects and sex are expressed are number of cases, age as yr ± SD, and spinal and thecal sac diameters as average value in cm ± SD. All imaging parameters are presented as total incidence (average incidence ± SD). Features marked with an asterisk ([1]) indicate significant difference between the two groups. CLSS: Congenital lumbar spinal stenosis.

**Figure 1 Mid-sagittal T2-weighted (3230, 120) image of the lumbar spine in a 50-year-old male with congenital lumbar spinal stenosis.** The lumbar spine shows loss of the lordotic curve, multilevel spondylolisthesis, and degenerative disc disease manifested as loss of disc height, circumferential disc bugles, anterior disc herniations, Schmorl's modes and a central disc protrusion. In this subject, the mid-sagittal spinal canal diameter ranged from 1.45 cm at the L1 level to 1.03 cm at L4 level. The average mid-spinal canal diameter was 1.26 cm.

velopment of the spinal canal. The etiology of the entity is unknown, except from some cases which are induced by achondroplasia[5,7]. CLSS differs from degenerative lumbar spinal stenosis in that the spinal canal stenosis is not limited to one or two intervertebral levels, but is uniformly distributed throughout the lumbar spine (Figure 1). As a result, the surgical treatment of CLSS commonly necessitates multi-level intervention, as opposed to degenerative lumbar spinal stenosis, which requires more focal procedures[5]. Subjects with CLSS are vulnerable to even minimal degenerative changes that compromise the already narrowed spinal canal, and tend to experience symptoms in the fourth and fifth decades of life, as opposed to patients with degenerative lumbar spinal stenosis, who demonstrate symptoms primarily after the sixth decade of life[5,7].

Although the incidence of CLSS in the general population is unknown and probably varies among different races and ethnic groups, MRI readers commonly encounter this entity in studies of the lumbar spine. CLSS has been described as early as the 1950s[3], however the imaging evaluation of this entity has been limited to delineating radiographic and cross-sectional criteria for its definition, and reporting limited degenerative spondylotic changes as a typical radiographic feature of the respective subjects. The definition of CLSS is not uniform across authors, with studies suggesting cut-off values of mid-sagittal spinal canal diameter varying between 10 and 17 mm, and not clarifying whether spinal canal narrowing needs to be documented on at least one or more spinal levels[4,7-10]. Some authors consider the cross-sectional area of the spinal canal as the criterion to define CLSS, a measurement, probably more accurate, but also time-consuming and impractical for everyday use. In addition, all previous studies have been limited in the vague description of osseous degenerative changes, and mostly using radiographs[1-3,5,7]. This study focused on specific osseous and soft tissue elements of the lumbar spine and employed a mid-sagittal spinal canal diameter of less than 14 mm on at least one mid-vertebral level to define CLSS. The latter value "summates" previous reports, has been illustrated in a large previous study by Singh *et al*[5] and is the one used by radiologists and orthopaedic surgeons in our institution. A recent study which compared subjects with and without CLSS by means of MRI and antero-posterior radiographs of the lumbar spine, reported that, in the CLSS cohort, global pathology and multilevel involvement with L3, L4, and L5 segments were involved more commonly and severely, whereas severe stenosis, at L1, L2, and S1 occurred infrequently. The authors also described three spinal canal morphologies in the CLSS group: (1) "flattened" canal with predominantly reduced spinal canal AP diameter; (2) spinal canal with predominantly reduced interlaminar angle; and (3) global reduction of all canal parameters[11].

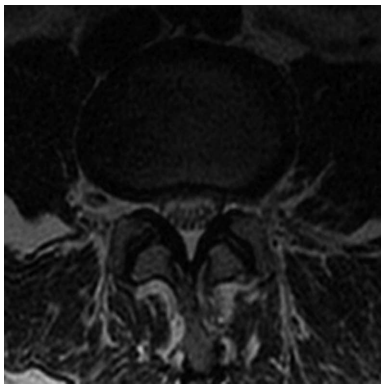

**Figure 2 Axial T2-weighted (5000, 102) images of the lumbar spine in a 48-year-old female with congenital lumbar spinal stenosis exhibits a shallow annular disc bulge.**

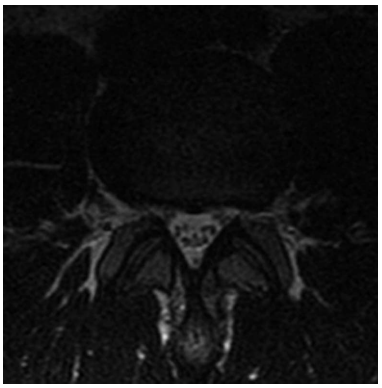

**Figure 3 Axial T2-weighted (3516, 115) image of the lumbar spine in a 29-year-old male with congenital lumbar spinal stenosis demonstrates a circumferential disc bulge with a superimposed left foraminal disc protrusion.**

We found that young and middle-aged individuals with CLSS demonstrate increased incidence of degenerative changes in the specific osseous and soft-tissue elements of the lumbar spine. In particular, these subjects exhibit increased incidence of "shallow annular bulges", a term which has not been previously established, but has been used in our practice to describe a particular type of disc bulge, which involves greater than 50% of the disc boundary, but does not meet the strict definition of circumferential bulge, in which a loss of the posterior disc concavity is also present (Figure 2). Shallow annular bulges preferentially narrow the neural foramina, similar to foraminal herniations. It may be speculated that, in CLSS, the thecal sac becomes less pliable due to the uniformly narrowed spinal canal, as well as less compressible due to the opposing intrinsic pressure of the cerebrospinal fluid. As a result, the thecal sac demonstrates increased resistance against posterior disc bulges or herniations in the initial stages of degenerative disc disease. In the above setting, a degenerated disc, acquiring the path of least resistance, tends to project into the foramina rather than the spinal canal. Consequently, the disc potentially maintains its posterior concavity and a shallow annular bulge is established. The above hypothesis could also explain the increased incidence of foraminal protrusions and anterior disc herniations in CLSS. The spectrum of findings is completed with increased incidence of circumferential annular bulges and spondylolisthesis (Figure 3).

Knowledge of the spectrum of MRI findings in CLSS could not only extend our understanding of the latter entity, but also assist radiologists in providing more detailed lumbar spine MRI reports. In most situations, radiologists begin the assessment of lumbar spine MRI studies from a quick evaluation of the mid-sagittal image, therefore establishing CLSS could alert readers for the presence of the aforementioned features.

This study has certain limitations. First, all studied subjects reported back pain, therefore the incidence of degenerative disc disease was probably high in this biased group, and may have affected the results. Second, all MRI examinations were evaluated in consensus by the two readers, therefore the inter-observer variability could not be estimated. Third, due to the absence of a widely accepted cut-off value of mid-sagittal canal diameter to define CLSS, we used a cut-off value that "summates" previous reports, and probably provides a good trade-off between specificity and sensitivity for detecting CLSS. However, the use of an absolute dividing line between subjects with and without CLSS is probably arbitrary, and a continuous zone between the two groups most likely exits.

In conclusion, CLSS is associated with early development of degenerative changes in specific osseous and soft-tissue elements of the lumbar spine, which could reflect altered spinal biomechanics. The spectrum of imaging findings includes the shallow annular bulge, in which the posterior concavity of the intervertebral disc is preserved. Knowledge of the above spectrum could extend our understanding of CLSS, and assist radiologists in providing more detailed lumbar spine MRI reports.

## COMMENTS

### *Background*

Congenital lumbar spinal stenosis (CLSS) is a developmental narrowing of the spinal canal, which is associated with early neurogenic complications and relatively few radiographically evident degenerative spondylotic changes. This article investigates the association between CLSS and degenerative changes in various osseous and soft-tissue elements of the lumbar spine.

### *Research frontiers*

Evaluation of subjects with CLSS by means of magnetic resonance imaging to investigate the spectrum of early degenerative changes of the lumbar spine in the respective entity.

### *Innovations and breakthroughs*

This is the first article to describe the spectrum of early degenerative changes of the lumbar spine in subjects with CLSS.

### *Applications*

Providing knowledge of the spectrum of early degenerative changes of the lumbar spine in subjects with CLSS this article extends our understanding of the entity and nay assist radiologists in providing more detailed MRI reports.

### *Peer review*

This is a very interesting article describing uncertain entity as congenital lumbar stenosis is.

## Abstract

**AIM:** To determine the incidence of appendiceal Crohn's disease (CD) and to summarize the characteristic histologic features of appendiceal CD.

**METHODS:** We reviewed the pathology files of 2179 appendectomy specimens from January 2007 to May 2013. The computer-assisted retrieval search facility was utilized to collect specimens. We selected those cases that were diagnosed as CD or chronic granulomatous inflammation and defined the final diagnosis according to the histologic findings of CD, including transmural lymphocytic inflammation, non-caseating epithelioid granulomas, thickening of the appendiceal wall secondary to hypertrophy of muscularis mucosa, mucosal ulceration with crypt abscesses, mucosal fissures, and fistula formation.

**RESULTS:** We found 12 cases (7 male and 5 female patients, with an average age of 29.8 years) of appendiceal CD. The incidence of appendiceal CD was 0.55%. The chief complaints were right lower quadrant pain, abdominal pain, lower abdominal pain, and diarrhea. The duration of symptom varied from 2 d to 5 mo. The histologic review revealed appendiceal wall thickening in 11 cases (92%), transmural inflammation in all cases (100%), lymphoid aggregates in all cases (100%), epithelioid granulomas in all cases (100%), mucosal ulceration in 11 cases (92%), crypt abscesses in 5 cases (42%), perforation in 2 cases (17%), muscular hypertrophy in 1 case (8%), neural hyperplasia in 5 cases (42%), and perpendicular serosal fibrosis in 8 cases (67%).

**CONCLUSION:** A typical and protracted clinical course, unusual gross features of the appendix and the characteristic histologic features are a clue in the diagnosis of appendiceal CD.

**Key words:** Appendix; Appendectomy; Acute appendicitis; Crohn's disease; Prognosis

**Core tip:** Appendiceal Crohn's disease (CD) is relatively rare and is indistinguishable from acute appendicitis. Appendiceal CD shows a favorable clinical outcome with a low recurrence rate. The differential diagnosis includes intestinal tuberculosis, foreign body reaction, diverticulitis of the appendix, sarcoidosis, actinomycosis, and *Yersinia* infection. Atypical and protracted clinical course, unusual gross features of the appendix and the characteristic histologic features are a clue in the diagnosis of appendiceal CD.

## INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory bowel

disorder characterized by a transmural inflammatory reaction and non-caseating small granulomas and may involve all parts of the gastrointestinal (GI) tract from the mouth to the anus[1-7]. The most common sites of involvement are the ileum and colon[8]. Appendiceal CD is a rare disease but has been well summarized in the various reports[9-14]. The incidence of appendicitis with granulomatous reaction varies from 0.1% to 2.0%[15]. Since Meyerding *et al*[16] had reported an interesting case of appendiceal CD without demonstrable involvement of the adjacent GI tract in 1953, many additional cases of appendiceal CD have been demonstrated in the literature to date.

The purpose of this retrospective review study was to determine the exact incidence of appendiceal CD in patients who underwent appendectomy and to summarize the common characteristic histologic findings along with a review of the literature.

## MATERIALS AND METHODS

### Ethics

The materials used in our study are human appendix tissue samples, which are products of surgical procedures. Our study contains no private information relating to the patients, and so ensures their anonymity. Therefore, our study has no problems in causing any ethical issue or encroachment of human rights.

### Patient tissue

A retrospective review of 2179 appendectomy specimens from January 2007 to May 2013 was conducted. All patients underwent appendectomy at the Hanyang University Hospital (Seoul, South Korea). The computer-assisted retrieval search facility was utilized to collect appendectomy specimens. Appendices resected for acute appendicitis and those removed as a part of right hemicolectomy and gynecology procedures were collected and reviewed. We selected those cases that were diagnosed as CD or chronic granulomatous inflammation and defined the final diagnosis according to the common histologic findings of CD, including transmural lymphocytic inflammation, non-caseating small epithelioid granulomas, thickening of the appendiceal wall secondary to hypertrophy of muscularis mucosa, mucosal ulceration with crypt abscesses, mucosal fissures, and fistula formation. No evidence of parasitic, fungal and mycobacterial disease, foreign body, or systemic sarcoidosis was found in any patient. The clinical information including age, gender, clinical data, and data about the surgical procedure for each case as well as follow-up data including colonoscopic evaluation was collected. The special staining technique such as Ziehl-Neelsen staining and special molecular technique such as tuberculosis polymerase chain reaction (Tb-PCR) were performed to rule out *Mycobacterium tuberculosis*.

## RESULTS

Out of these 2179 appendectomy specimens, 12 cases (0.55%) were classified as appendiceal CD. The clinicopathologic characteristics of the appendiceal CD patients are summarized in Tables 1 and 2. Out of these 12 patients, there were 7 male and 5 female patients. The age of patients ranged from 11 to 51 years (average age of 29.8 years). The chief complaints of patients were right lower quadrant (RLQ) pain, abdominal pain, lower abdominal pain, and diarrhea. The duration of symptom with which patients presented varied from 2 d to 5 mo. There was no systemic clinical manifestation such as arthralgia, uveitis, or arthritis. No history of tuberculosis of any organ was found in these patients. There was also no clinical evidence of systemic sarcoidosis. The initial clinical impression was acute appendicitis in all of these 12 patients along with perforation in 2 among these 12 patients. All patients underwent appendectomy. The final pathologic report was CD in all of these 12 cases. All cases showed a negative result for *Mycobacterium tuberculosis* in Ziehl-Neelsen staining and Tb-PCR. The histologic review of these 12 cases revealed appendiceal wall thickening in 11 cases (92%), transmural inflammation in all cases (100%), lymphoid aggregates in all cases (100%), epithelioid granulomas in all cases (100%), mucosal ulceration in 11 cases (92%), crypt abscesses in 5 cases (42%), perforation with abscess formation in 2 cases (17%), muscular hypertrophy in 1 case (8%), neural hyperplasia in 5 cases (42%), and perpendicular serosal fibrosis in 8 cases (67%). The representative microphotographs are shown in Figure 1. There is no evidence of disease recurrence in these 12 patients to date.

## DISCUSSION

Crohn first described that CD stops at the ileocecal valve with sparing of the colon and appendix. However, this theory was disproved as patients with CD often have involvement of the colon and appendix[5]. The first isolated appendiceal CD was reported by Meyerding *et al*[16] in 1953. Since Meyerding *et al*[16] had reported a case of CD arising in the appendix, many case reports and some collective reviews have been reported in the literature. The incidence of appendiceal CD is variable[17-21]. Prieto-Nieto *et al*[4] described that approximately 0.2% of patients (10 out of 4468 appendectomies performed during 20 years) had appendiceal CD. In our review, 12 cases (0.55%) out of 2179 appendectomy specimens were revealed as appendiceal CD.

Appendiceal CD is usually found among young patients, however, it can occur at any age[3,12]. Yang *et al*[14] described the age with onset of disease in 14 patients with appendiceal CD, ranged from 10 to 45 years (average age of 21.1 years). Prieto-Nieto *et al*[4] reported the disease onset-age in 10 patients with appendiceal CD, ranged from 10 to 33 years (average age of 29 years). The difference in incidence of disease in males and females has been reported, with male predominance[4,14]. In our study, the age ranged from 11 to 51 years, with an average age of 29.8 years. Among 12 patients, 7 were male, reflecting more male patients with the disease described

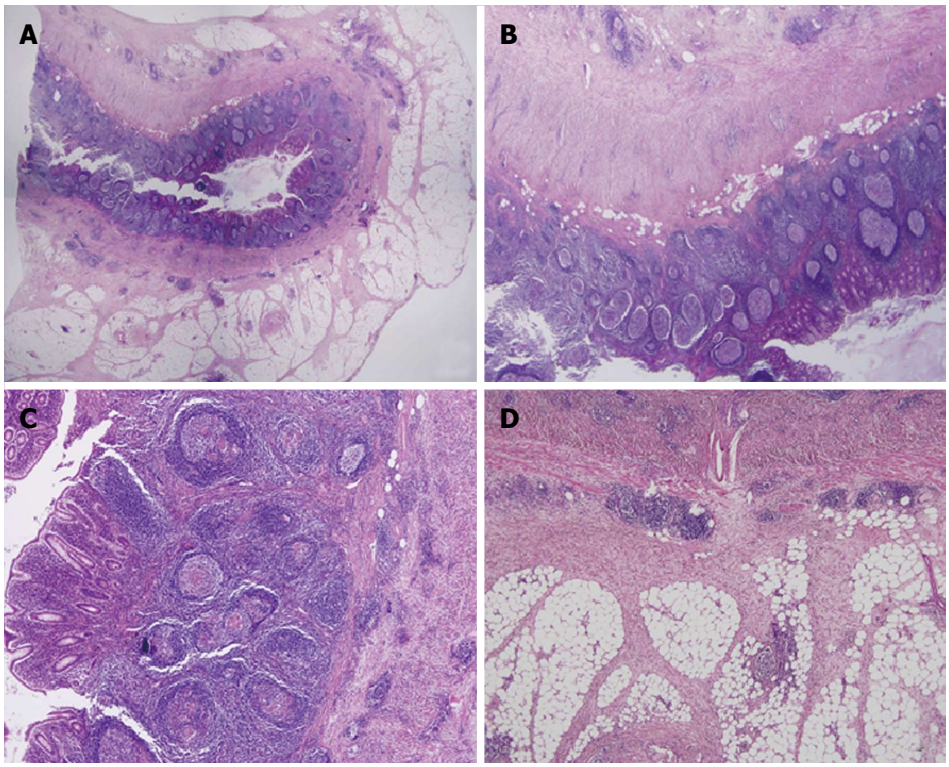

**Figure 1 Appendiceal Crohn's disease.** A: The appendix with Crohn's disease shows transmural inflammation with markedly thickened wall; B: There is a prominent lymphoid hyperplasia in the mucosa and serosa; C: The mucosa shows many small non-caseating granulomas; D: The serosa shows creeping fat with perpendicular thick fibrous bands.

**Table 1 Summary of the patients with appendiceal Crohn's disease**

| Case No. | Sex | Age (yr) | c/c | SD | Clinical impressions | AFB | Tb-PCR |

previously.

The clinical presentation of appendiceal CD is variable. The most common presenting symptom is acute lower abdominal pain especially in the RLQ, which is very similar to the lower abdominal pain presented in patients with acute appendicitis[4,13,22]. Approximately 25% of appendiceal CD patients show chronic abdominal pain in the right lower abdomen[13]. The symptoms may be more protracted or recurrent than in the usual case of acute suppurative appendicitis. Appendiceal CD should be suspected when the patients show atypical or protracted unusual clinical course[2,13]. In our study, most patients presented with the pain in the RLQ. The initial clinical impression was acute appendicitis in all 12 patients. Most patients had symptoms for two or more days, and 8 patients (67%) presented with these symptoms for over a week.

Appendiceal CD usually shows an enlarged appendix with marked thickening of the appendiceal wall and fibrous adhesion to the periappendiceal soft tissue[2,22,23]. Microscopically, the histologic features are characterized by transmural chronic inflammation with marked fibrous thickening of the wall, lymphoid aggregates, small non-caseating granulomas, ulcerative mucosal change, crypt abscesses, muscular hypertrophy, and neural hyperplasia[13,24-26]. In our study, the features were similar to the

**Table 2 Summary of histologic features of appendiceal Crohn's disease**

| Histologic features | Number of cases | % |
|---|---|---|
| Wall thickening | 11/12 | 92 |
| Transmural inflammation | 12/12 | 100 |

| Epithelioid granuolmas | 12/12 | 100 |
| Mucosal ulceration | 11/12 | 92 |
| Crypt abscess | 5/12 | 42 |
| Perforation | 2/12 | 17 |
| Muscular hypertrophy | 1/12 | 8 |
| Neural hyperplasia | 5/12 | 42 |
| Perpendicular serosal fibrosis | 8/12 | 67 |

previously described histologic characteristics. Interestingly, we found that appendiceal CD had the characteristic perpendicular serosal fibrous band formation in 8 out of 12 cases.

The differential diagnosis includes intestinal tuberculosis, foreign body reaction, diverticulitis of the appendix, sarcoidosis, actinomycosis, and *Yersinia* infection[10,13,22,24,25]. Appendiceal tuberculosis results in the formation of epithelioid granulomas, however, the granulomas in tuberculosis are larger with a central caseous necrosis and less discrete than those in Crohn's disease[10,27-29]. If a foreign body is present, histologic examination should reveal the offending material and diverticular disease may be excluded via careful examination[14,27]. Intestinal sarcoidosis is extremely rare and does not occur as an isolated finding[13,30]. Actinomycosis also results in a vague granulomatous tissue reaction, however, actinomycosis shows neutrophilic abscess formation with floating bacterial colonies (sulphur granules)[31-34]. *Yersinia* infection results in necrotizing granulomatous reaction in the appendiceal mucosa or submucosa and shows microabscess formation[35,36].

The treatment of choice for appendiceal CD is appendectomy[30]. Appendiceal CD shows lower recurrence rate compared with CD arising in other parts of the intestine[25]. The prognosis of appendiceal CD seems to be much better than that of CD arising in the small or large bowel[14].

In conclusion, we described the incidence of appendiceal CD in patients who underwent appendectomy and summarized the common characteristic histologic findings along with a review of the literature. Atypical and protracted clinical course, unusual gross features of the appendix and the characteristic features are a clue in the diagnosis of appendiceal CD.

## COMMENTS

### Background

Appendiceal Crohn's disease (CD) is a rare disease. Since Meyerding *et al* had reported an interesting case of appendiceal CD without demonstrable involvement of the adjacent gastrointestinal tract in 1953, many additional cases of appendiceal CD have been demonstrated in the literature to date.

### Research frontiers

The incidence of appendicitis with granulomatous reaction varies from 0.1% to 2.0%. The incidence of appendiceal CD is variable. The purpose of this study was to determine the exact incidence of appendiceal CD in patients who underwent appendectomy and to summarize the common characteristic histologic findings along with a review of the literature.

### Innovations and breakthroughs

The histologic features are characterized by transmural chronic inflammation with marked fibrous thickening of the wall, lymphoid aggregates, small non-caseating granulomas, ulcerative mucosal change, crypt abscesses, muscular hypertrophy, and neural hyperplasia. In this study, the features were similar to the previously described histologic characteristics. However, the authors found that appendiceal CD had the characteristic perpendicular serosal fibrous band formation in 8 out of 12 cases.

### Applications

With the characteristic clinical presentation and the typical pathologic findings, the clinicians and pathologists can consider the possibility of appendiceal CD. Atypical and protracted clinical course, unusual gross features of the appendix and the characteristic histologic features are a clue in the diagnosis of appendiceal CD.

### Terminology

CD is a chronic inflammatory bowel disorder characterized by a transmural inflammatory reaction and non-caseating small granulomas and may involve all parts of the gastrointestinal tract from the mouth to the anus.

### Peer review

The authors described appendiceal CD clinically presenting as acute appendicitis. This is an interesting review and CD in appendix is a rare condition. Whenever it is encountered, the surgeon must know what to do and be aware of its prognosis. This paper will lead surgeons to this condition.

## Abstract

**AIM:** To conduct a detailed systematic review of the current evidence on the administration and efficacy of tranexamic acid in patients with menorrhagia due to uterine fibroids.

**METHODS:** We conducted an electronic search on the following databases PubMed and Medline (1950-2013); (1980-2013); Cochrane library (1993-2013).

**RESULTS:** A total of 36 articles were retrieved after the initial electronic search. Careful assessment of the retrieved studies led to the final selection of 5 articles for inclusion in the review.

**CONCLUSION:** Tranexamic acid may reduce blood loss perioperatively in myomectomies. It may reduce the menorrhagia in patients with fibroids, however a stratification of fibroids by size and location is required to define the responses. It is safe in general, with mild adverse effects observed in some cases. More studies with a double-blind randomized design and larger numbers of participants are necessary to reach more precise and safe conclusions.

**Key words:** Tranexamic acid; Uterine fibroids; Fibrinolysis; Menorrhagia; Myomectomy

**Core tip:** Uterine fibroid tumors are the most common gynecologic causes for menorrhagia. Tranexamic acid is a safe non-hormonal medication that significantly reduces abnormal menstrual bleeding. We conducted a systematic review of the contemporary evidence on the administration and efficacy of tranexamic acid in patients with menorrhagia associated with fibroid tumors of the uterus. Antifibrinolytic treatment may reduce blood loss perioperatively in myomectomies, and reduce menorrhagia in patients with fibroids. More double randomized studies with larger numbers of participants are necessary to reach more precise and safe conclusions.

Peitsidis P, Koukoulomati A. Tranexamic acid for the management of uterine fibroid tumors: A systematic review of the current evidence. *World J Clin Cases* 2014; 2(12): 893-898 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/893.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.893

## INTRODUCTION

Worldwide, approximately 235 million women are affected by uterine fibroids and about 20%-40% of women will be diagnosed with leiomyomas at some point in their life, though only a fraction of those will cause problems or require treatment[1]. Uterine fibroid tumors or leiomyomas very often lead to abnormal menstrual bleeding or menorrhagia[2]. Menorrhagia is abnormal extensive menstrual bleeding in cases where the quantity of the overall blood loss exceeds 80 mL in every menses[3].

The treatment of uterine leiomyoma may be surgical or conservative. Surgical management consists of total

or subtotal hysterectomy and myomectomy, but in some cases less invasive procedures, such as uterine artery embolization are successful[3].

Data show the presence of extensive fibrinolysis in the menstrual blood of women suffering from menorrhagia, and this has triggered the use of antifibrinolytic drugs as a therapeutic option[4]. Tranexamic acid (cyklokapron) is a non-hormonal medication that decreases menstrual hemorrhage and it is an excellent therapeutic option in patients with menorrhagia who opt for nonhormonal management[5]. Tranexamic acid achieves hemostasis and elicits its antifibrinolytic action by reversible block of the locus that connects with lysine on plasminogen molecules. It inactivates the plasminogen activator of the endometrium and thus stops fibrinolysis and degradation of the clotting complexes[6]. Tranexamic acid has been administered on a daily basis to reduce excessive hemorrhaging and the need for transfusion during and after major cardiac or orthopedic surgeries[7].

In the international literature, several randomized clinical trials have been published which have evaluated and reviewed the efficacy of tranexamic acid in the management of abnormal gynecological hemorrhagic conditions. It is not certain how efficient tranexamic acid is in treating women with normal reproductive function and diagnosed with abnormal bleeding caused be uterine fibroids[8].

### Aim

The aim of the study was to conduct a systematic review of the current evidence on the administration and efficacy of tranexamic acid in patients with menorrhagia caused by uterine myomas. The administration of tranexamic acid during the preoperative and postoperative period as a method of reducing blood loss is also reviewed. No previous systematic review of the use of tranexamic acid in women with fibroids has been reported.

## MATERIALS AND METHODS

### Search strategy

We conducted an electronic search on the following databases PubMed and Medline (1950-2014); EMBASE (1980-2013); Cochrane library (1993-2014). The *Medical Subject Headings* which were utilized were as follows: "tranexamic acid" and "fibroids" and "myomas" and "leiomyomas" and "myomectomy".

Manuscripts written in English or French languages were selected for inclusion in the study. The retrieved studies were scrutinized and their references were examined carefully in order to reveal any relevant studies not identified initially by the electronic search. The included studies were reviewed independently by two authors (PP and AK). In cases of discrepancy and lack of evidence, the corresponding authors of the studies were contacted to provide further information and clarification. Studies from conferences and scientific meetings were also searched.

From each study, we gathered the following clinical data: author and year of publication; country of origin of study; type of study; number of participants in the study; aim of the study; dosage, type and length of administration of tranexamic acid; data about adverse effects and the conclusion of study results. The clinical data were collected and presented in a table according to chronological order of publication.

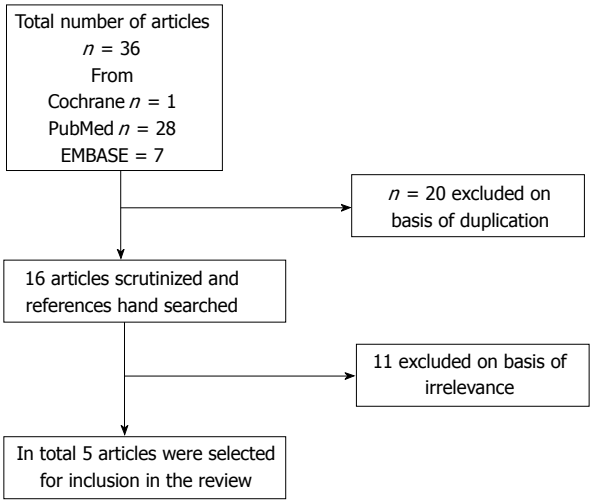

**Figure 1 Flowchart of the selection of studies.**

### Inclusion criteria

All the studies reported the administration of tranexamic acid for treatment of hemorrhage in women of reproductive age with symptomatic fibroids. In addition, studies that reported the administration of tranexamic acid preoperatively or postoperatively to myomectomy procedures were selected for inclusion.

### Exclusion criteria

Studies that reported the use of tranexamic acid in pregnant women and in women diagnosed with malignant gynecological disease were excluded. Also studies in women with non-symptomatic fibroids, postmenopausal women and women with hemorrhage related to reasons other than fibroids (dysfunctional uterine bleeding; hematological disorders) were not included in the review.

### Quality assessment of studies

The quality assessment of studies was performed according to the guidelines reported from The Scottish Intercollegiate Guidelines Network (SIGN)[9].

## RESULTS

A total of 36 articles were retrieved after the initial electronic search. These 36 articles were scrutinized for duplicate results. The flowchart diagram of the selection process is shown in Figure 1. Eleven articles were excluded because they were not concerned with management of menorrhagia in women with fibroid tumors. Careful assessment of the retrieved studies led to the final selection of 5 articles to be included in the study. A summary of the selected articles is presented in Table 1[10-14]. The

**Table 1 Summary of the selected studies**

| Ref. | Country | Type of study | Mean age | Symptom-atology | Participants | Aim of the study | Regimen administration | Results | Adverse effects | Comment |
|---|---|---|---|---|---|---|---|---|---|---|
| Lakhani *et al*[10] | United Kingdom | Longitudinal Prospective | 42.8 | Menorrhagia Pelvic pain | $n$ = 12 | Ultrasound assesment of PI and RI of UA in women with TA administration | Tranexamic acid P.O. 1 g x 3 for 2 cycles | No significant changes in blood loss or PI and RI | Not reported | No changes in UA-PI resistance in women with fibroids |
| Caglar *et al*[11] | Turkey | Prospective randomized double-blind placebo | 34.2 | Menorrhagia Pelvic pain | $n$ = 50 (TA) $n$ = 50 (Placebo) | To compare the perioperative blood loss in patients undergoing myomectomy and taking TA with patients not taking TA | Tranexamic acid 10 mg/kg *iv* (max 1 g) 15 min before incision | Significant statistical differences in two groups postoperative, total blood loss and duration of surgery ($P$ < 0.01) in favor of TA | Not reported | TA does not reduce perioperative blood loss nor Hb levels. It reduces postoperative and total blood loss and surgery time in correlation with myoma size. However further investigations required |
| Ip *et al*[12] | Hong Kong | Observational | 43.8 ± 25 | Menorrhagia Pelvic pain | $n$ = 22 | Pathology assesment of fibroid specimen in women receiving TA | Tranexamic acid Per os dosage not reported | Necrosis and infarcts in resected fibroids. Larger daimeter fibroids more prone to necrosis changes. Size is an independent factor | Not reported | Authors emphasize the necrosis and thrombosis in fibroids but suggest precaution for complications |
| Lukes *et al*[14] | United States | Randomized double-blind placebo | 36.5 | Menorrhagia Pelvic pain | $n$ = 42 (TA) $n$ = 26 (Placebo) | To assess the efficacy and safety of TA for heavy menstrual bleeding | Tranexamic acid Per os 1.3 g daily for 5 d up to 6 cycles | Reduction in menstrual blood loss in women receiving TA compared to placebo. No statistically significant changes in blood loss in patients with fibroids | Mild adverse effects Menstrual cramps Gastrointestinal allergies | TA was effective in the treatment of heavy menstrual bleeding regardless of the presence or absence of fibroids |
| Eder *et al*[13] | United States | Randomized double-blind placebo | 38 | Menorrhagia Pelvic pain | $n$ = 96 (TA) $n$ = 51 (Placebo) | To compare the menstrual blood loss in women with fibroids and TA and women with fibroids not taking TA. consisting placebo group | Tranexamic acid Per os 3.9 g/d for 5 d up to 6 menstrual cycles | Menstrual blood loss reduced in women receiving TA ($P$ < 0.001) | 3 patients in TA group and 3 in placebo group reported headache | TA was well tolerated and reduced menstrual blood loss |

TA: Tranexamic acid; UA: Umbillical artery; UA-PI: Umbillical artery pulsatility index.

reviewed studies originated from Europe[10,11]; Asia[12] and America[13,14]. All articles were written in English. The studies were published between 1998 and 2013. The total study population from the 5 studies was 349 women; 206 patients were treated with tranexamic acid and 101 patients were allocated to the placebo groups. All patients were premenopausal with a mean age of 37.65 ± 3.2 years. All patients in the study groups presented with menorrhagia and pelvic pain due to uterine fibroids. Three studies had a double-blind randomized design[11,13,14], one had an observational design[12] and one had a prospective longitudinal design[10]. Tranexamic acid was administered orally in four studies[10,12-14], and intravenously in one study[11]. Tranexamic acid reduced the blood loss perioperatively in women undergoing myomectomy in comparison to women not receiving tranexamic acid according to the authors[11]. Management of excessive bleeding during the menstrual cycle with tranexamic acid decreased hemorrhage despite the existence of myomas[13].

Furthermore, tranexamic acid reduced the quantity of bleeding in patients with menorrhagia in a pivotal phase Ⅲ randomized double blind study[14]. The authors reported that they estimated the quantity of blood *via* a validated alkaline hematin method in patients with sonographically confirmed fibroids[14]. Tranexamic acid did not alter the pulsatility index during ultrasound assessment of women with fibroids[10]. Significant pathologic changes were noted in specimens from women who received tranexamic acid and underwent myomectomy. Very mild complications of treatment were seen in 2 studies[13,14], and 3 women in a single study reported headache[14].

### *Quality of the studies*

The quality assessment of the selected studies according to SIGN criteria is shown in Table 2. Three studies were graded 2++ (high quality studies)[11,13,14] and 2 studies were graded 2+ (well conducted studies)[10,12]. All studies were conducted in University teaching hospitals[10-14], 3 were conducted in a single setting[10-12], and 2 were conducted in multicenter settings[13,14]. Three studies received financial support from pharmaceutical companies[10,13,14].

## DISCUSSION

In practice, tranexamic acid has been administered in many clinical situations in which the inhibition of fibrinolysis has shown beneficial effects in managing hemorrhage. The use of tranexamic acid in Obstetrics and Gynecology as a conservative method for reducing blood loss has been extensive[15]. TA provides a non-hormonal, treatment for patients with excessive hemorrhage during the menstrual period[13]. How tranexamic acid manages menorrhagia provoked by leiomyoma is still unclear and unknown due to the limited data.

In the current review, according to the reported studies, tranexamic acid is a safe treatment and may reduce menorrhagia in women with fibroids. It reduces the blood loss perioperatively with no adverse effects in women undergoing laparotomy and myomectomy. Tranexamic acid causes necrosis in myomas but does not alter pulsatility indices in ultrasound assessment. However, the current review has some limitations because of the quantity and quality of studies published in the literature and the presence of bias related to the size and location of fibroids.

Despite the fact that tranexamic acid administration has shown a risk for complications like thrombosis and embolism due to its antifibrinolytic effect, thromboembolic events were not been reported in the selected studies. Only mild headaches, allergies and discomfort were reported in a small population of patients[13,14]. In the study by Lukes *et al*[14], the authors did not specify the exact type and number of adverse effects in patients with fibroids, and stated that the most common adverse effect was menstrual discomfort.

Tranexamic acid has been administered widely in Scandinavian and European countries in general as a first-line management option for menorrhagia since the 1970s, and data have shown no increase in the frequency of adverse clotting disorders[16,17]. However, the optimal dose and duration of treatment with tranexamic acid has not been established[18].

The efficacy and safety of tranexamic acid when given intravenously for peri- and postoperative hemorrhage has been investigated more in orthopedic and cardiovascular surgical interventions[19]. In the study by Caglar *et al*[11], the authors reported that tranexamic acid succeeded in decreasing perioperative blood loss during excision of myomas; however, they emphasized the importance of various parameters such as type of surgery, surgical skills, and duration of surgery for perioperative blood loss. In the same study, the location and type of myoma (subserous, intramural, submucous) were highlighted and also the number and size of fibroid tumors. Multiple fibroid tumors may increase the duration of surgery in contrast to a single large myoma > 6 cm[12].

Ip *et al*[12] concluded that tranexamic acid induced necrosis of fibroids. Larger fibroids were more prone to necrosis. The authors emphasized the significance of tranexamic acid in conservative management of fibroids, thus sparing unnecessary surgical interventions. However possible complications such as pelvic pain and low grade fever maybe present in these patients[12].

It has been reported in clinical studies that the levels of plasminogen activator are elevated 30 min after the initiation of surgery, and this mechanism may elicit a reduction in bleeding in surgical patients[11,19].

One randomized study investigated whether tranexamic acid was effective in comparison with placebo for the management of menorrhagia in patients with no pathological findings in the pelvis[13]. The factual limitations of this study were that in women diagnosed with fibroid tumors, myomas were not found in large numbers and their size was not significant to justify surgical removal. Although the goal of this trial was not to assess the effect of tranexamic acid on abnormal vaginal bleeding caused by myomas, outcomes showed that tranexamic acid was effective in treating heavy menorrhagia, and this was not related

**Table 2 Quality assessment of the studies according to Scottish Intercollegiate Guidelines Network guidelines**

to the presence of absence of myomas. However, based on the design of the study, it is hard to postulate that treatment with tranexamic acid is influenced by the size and type of the fibroids[18]. In the study by Lakhani *et al*[10], women with fibroids were found to have no significant changes in various sonographic parameters. However, these findings may exhibit bias and limitations because the women were not divided into different groups with different sizes and types of myomas[18].

The Food and Drug Administration approved tranexamic acid 650 mg (Lysteda-Ferring) in November 2009. Treatment with tranexamic acid while using hormonal contraceptives may increase the risk of developing thrombosis, cardiac complications, and stroke[20].

Tranexamic acid has been used extensively in patients with heavy menstrual bleeding with good results, and enough evidence is available to support its use. Tranexamic acid may reduce blood loss perioperatively in myomectomies, and may reduce menorrhagia in patients with fibroids, but stratification of fibroids by size and location is required to define the responses to tranexamic acid. Physicians should be aware that tranexamic acid may cause drug-induced necrosis of fibroids and surgical management can be avoided, but complications such as pelvic pain and low grade fever can be present in these patients. It is safe in general, and mild adverse effects are observed in some cases. More studies of a double-blind randomized design and larger numbers of participants are required to reach clearer conclusions about the use of tranexamic acid in patients with fibroids.

## COMMENTS

### Background

Menorrhagia due to fibroid tumors of the uterus is one the leading causes of abnormal menstrual bleeding. Tranexamic acid is non-hormonal and has been used previously for the treatment of dysfunctional uterine bleeding. The role of tranexamic acid in the treatment of abnormal menstrual bleeding due to uterine fibroid tumors in unclear. The authors have reviewed the literature and demonstrated that tranexamic acid may reduce bleeding in myomectomies and also may reduce the amount of bleeding in patients with menorrhagia caused by uterine fibroids.

### Research frontiers

Tranexamic acid may reduce blood loss in patients with menorrhagia due to fibroids. It may cause drug-induced necrosis of fibroids and surgical management can be avoided, but complications such as pelvic pain and low grade fever can be present in these patients.

### Innovations and breakthroughs

The study showed that tranexamic acid reduced blood loss in patients undergoing myomectomy. It may cause necrosis in fibroids and may reduce the menorrhagia due to fibroids. Tranexamic acid has shown mild adverse effects during its administration. It may be used in patients who do not want hormonal treatment.

### Applications

To ensure that tranexamic acid can be used in patients with menorrhagia caused be uterine fibroids, further double-blind randomized studies are required in order to ensure that the regimen is safe, efficient and does not cause severe effects.

### Terminology

Tranexamic acid is a hemostatic agent that elicits its antifibrinolytic action by reversibly blocking the lysine-binding sites on plasminogen molecules. It inactivates the plasminogen activator in endometrial cells and thus stops fibrinolysis and degradation of the clotting complexes. A number of studies have reported the use of tranexamic in reducing blood loss in cardiac and orthopedic operations. Tranexamic acid has been used to decrease blood loss in patients with menorrhagia. Menorrhagia is abnormal extensive menstrual bleeding where the quantity of overall blood loss exceeds 80 mL in every menses.

### Peer review

The authors here performed a systematic review of the current evidence on the administration and efficacy of Tranexamic acid for these patients.

## Abstract

Non-salvageable extremities have been utilized for harvesting fillet flaps as part of the "spare parts" concept in traumatic and oncologic settings. Here we report on the use of a pedicled fillet flap of the upper arm for chest wall reconstruction after excision of a malignant peripheral nerve sheath tumor in a patient with neurofibromatosis. Pedicled flaps as part of the "spare parts" concept provide the advantage of reduced donor-site morbidity, immediate closure, intact vasculature, and adequate soft tissue coverage of large defects. Malignant peripheral nerve sheath tumor is a rare aggressive tumor with a poor prognosis that may result in large defects post resection. Limited data describes the use of pedicled fillet flaps of the upper extremity. We report the use of a pedicled fillet flap of the upper arm as a viable option that can be successfully used for coverage of soft tissue defects of the shoulder and chest wall post complex resections in an oncologic setting.

**Key words:** Reconstruction; Flaps; Neurofibromatosis; Malignant Peripheral Nerve Sheath Tumor; Sarcoma

**Core tip:** Here we present a rare case on the use of a pedicled fillet flap of the upper arm for chest wall reconstruction after excision of a malignant peripheral nerve sheath tumor in a patient with neurofibromatosis. This case report describes a reconstructive procedure that is rarely described in the literature as a viable option for soft tissue coverage of shoulder and chest wall defects after an oncologic resection.

## INTRODUCTION

The use of non-salvageable extremities for harvesting fillet flaps has been utilized for reconstruction as part of the "spare parts" concept in traumatic and oncologic settings. Fillet flaps have been extensively characterized based on their clinical value and can be used as pedicled or free flaps[1], however there is limited data describing the use of fillet flaps of the upper extremity[2]. Here we report a rare case of harvesting a pedicled fillet flap of the upper arm for chest wall reconstruction after excision of a malignant peripheral nerve sheath tumor (MPNST) in a patient with neurofibromatosis.

## CASE REPORT

A 42-year-old female with a history of neurofibromatosis presented to plastic surgery clinic with complaints

**Figure 1 Left shoulder mass at initial presentation.**

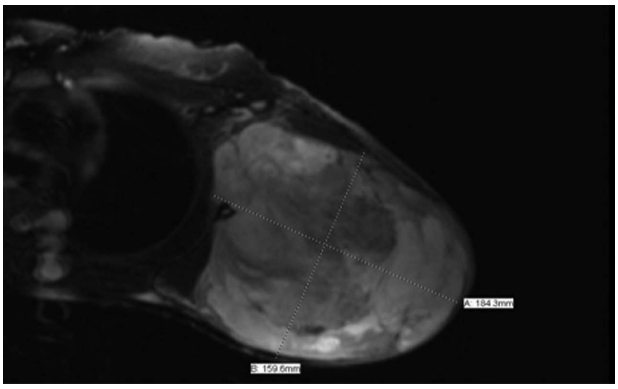

**Figure 2 Magnetic resonance imaging of left shoulder, Mass: 18.4 cm × 15.9 cm × 20 cm.**

of a left shoulder mass growing for the past two years that caused significant pain with movement (Figure 1). Magnetic resonance imaging (MRI) revealed 18.4 cm × 15.9 cm × 20 cm mass concerning for possible malignant degeneration of a neurofibroma based on size and clinical history (Figure 2). Neoadjuvant chemoradiation per National Comprehensive Cancer Network guidelines for resectable soft tissue sarcomas with potential for adverse functional outcomes[3] was discussed. Patient was lost to follow up after initial planning and when she returned, she was unable to lay supine secondary to pain from the tumor, which had obvious necrosis with bleeding. Chest computerized tomography (CT) revealed a left large axillary mass with scapular erosion as well as small pulmonary nodules suggestive but not diagnostic of metastatic disease. A decision was made to abandon neoadjuvant therapy and surgically resect the axillary mass followed by adjuvant therapy with close observation of pulmonary lesions.

After the scapula was disarticulated and the tumor excised, it became clear that the arm would be of limited functional use and a modified forequarter amputation with vascular preservation of the upper extremity was performed. A regional flap could not be done due to the wide defect and need for post-operative radiotherapy. Use of a pedicled latissimus dorsi was contraindicated due to tumor invasion, therefore in order to provide immediate closure, without the added time and risk of performing a free flap, a musculocutaneous pedicled fillet flap of the left upper arm was chosen for reconstruction.

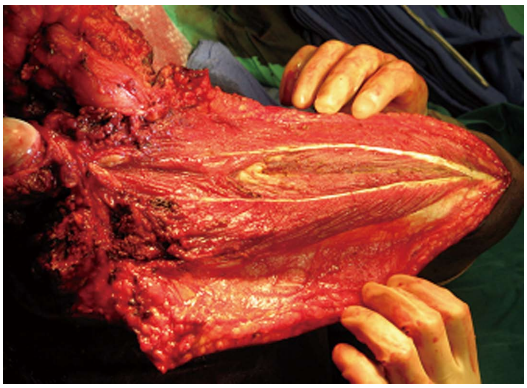

**Figure 3 Fillet flap of the upper arm post subperiosteal dissection and removal of the humerus.**

An incision was made on the posterior aspect of the left upper extremity starting at the shoulder joint and extending below the elbow. Skin and triceps muscles were dissected in the midline and then a subperiosteal dissection was performed (Figure 3). Next, the humerus was removed and the arm transected just below the elbow after identifying and ligating the neural and vascular structures. The flap was rotated into the defect without any tension (Figure 4).

Post-operative pathology report demonstrated a T2bN0 grade 2 or stage Ⅱb[5] MPNST. The tumor was 24 cm × 24 cm × 19 cm in size with focally positive margins. After meeting with radiation and medical oncology, the patient agreed to undergo adjuvant chemoradiation. The patient was initiated on a chemotherapy regimen consisting of doxorubicin and ifosfamide and scheduled for radiation therapy. However, three months after surgery, patient had local recurrence of a mass at her left shoulder. Patient was referred to an outside facility closer to home for adjuvant therapy and this was delayed secondary to patient compliance. CT of the chest and shoulder revealed large recurrent solid and cystic mass in the left shoulder region and left upper anterolateral chest wall. The patient died 5 mo postoperatively from hemorrhagic conversion of metastatic lesions in the brain.

## DISCUSSION

The use of fillet flaps from non-salvageable or amputated extremities has been successfully used for reconstruction as part of the "spare parts" concept[1]. Pedicled musculocutaneous flaps are commonly used for reconstruction; however, the use of a pedicled fillet flap of the upper arm has not been well reported in the literature[2].

Forequarter amputations may be necessary for locally aggressive bone and soft tissue tumors invading the axilla, shoulder or scapula[4]. However, multiple variables, such as size and location of the defect, exposure of nerves, tendons, vessels and bones, as well as need for post-operative radiation, must be taken into consideration when deciding on type of reconstruction. Skin grafts do not

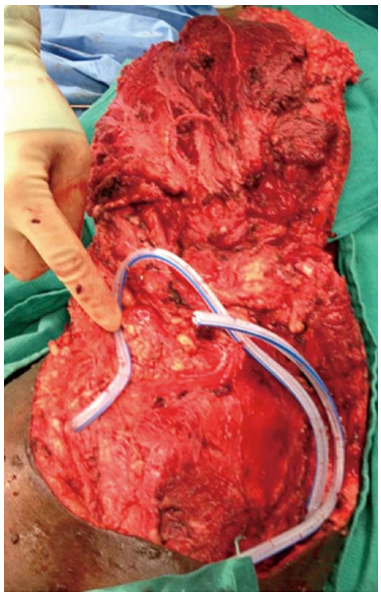

**Figure 4 Fillet flap with drains, prior to closure.**

provide adequate coverage for large, deep wounds, and are not durable in patients needing post-operative radiation. Therefore, flap coverage with either a pedicled or free flaps are the appropriate choice to provide adequate, immediate coverage post-resection in order to initiate adjuvant radiation therapy[5]. In patients undergoing an amputation, the use of fillet flaps as part of the "spare parts" concept provides these similar advantages with the added benefit of reduced donor-site morbidity[1,5].

Previous studies describe the use of free forearm fillet flaps in patients who underwent an upper extremity amputation for cancer, however the use of an upper arm pedicled fillet flap has not been well reported[2,6]. The use of an upper arm flap may have been contraindicated due to local invasion of the tumor[2]. However, in our patient, the lack of tumor invasion into the upper arm or into the vascular inflow in the axilla allowed the opportunity to perform a pedicled fillet flap. Not only did the upper extremity flap allow for adequate, tension free coverage, it reduced the risks associated with a free flap. Chao and colleagues demonstrated that patients who received adjuvant radiotherapy after free fillet flaps were significantly more likely to have graft loss as compared to those who received neo-adjuvant radiation[7]. Since our patient was not appropriate for neo-adjuvant radiation, performing an upper-extremity pedicled fillet flap allowed us to reduce the risk of post-operative wound complications associated with adjuvant radiation therapy. Pedicled latissimus dorsi flaps for reconstruction after forequarter amputations have also been described[8], but due to tumor invasion in our patient as well as added donor site morbidity, an upper arm fillet flap was decided to be the most appropriate choice for reconstruction.

MPNST is a rare primary chest wall tumor with an incidence of 0.001% in the general population. It commonly presents as an enlarging painful mass and arises from Schwann cells or neural crest cells in a peripheral nerve or its sheath. Patients with NF-1 are at increased risk of developing MPNST through malignant degeneration of plexiform neurofibromas[9]. MPNSTs are considered highly malignant, associated with a poor prognosis, have a high risk of local recurrence, and are associated with distant metastasis, most commonly to the lungs[9,10]. MRI remains the gold standard for diagnosis after which the treatment of choice is surgical resection[9]. Definite wide excision, negative surgical margins, with neo-adjuvant or adjuvant radiotherapy is currently recommended for treatment of resectable tumors in patients with MPNSTs[3,9]. Poor prognostic indicators include tumor size greater than 5 cm, local recurrence, high tumor grade, positive surgical margins, association with neurofibromatosis type I (NF-1), and truncal location[9]. Patients with NF-1 should be educated about the increased risk for developing MPNST and be advised to contact their physician should rapidly enlarging masses, pain, or neurologic changes occur. Given the poor prognosis for MPNST, early initiation of treatment provides the best chance for survival[9].

Overall, this case represents a rare description of the use of a pedicled musculocutaneous flap from the upper arm for reconstruction after resection of MPNST. Given that MPNST is an aggressive tumor that may present with large defects post resection, the use of a pedicled fillet flap of the upper arm is a viable option that can be successfully used for coverage of soft tissue defects of the shoulder and chest wall[9]. The advantage of immediate wound closure, avoidance of donor-site morbidity, and reduced operative time over a free flap makes this procedure a reliable method for complex reconstructions in an oncologic setting[1].

## COMMENTS

### *Case characteristics*

A 42-year-old female with a history of neurofibromatosis presented to plastic surgery clinic with complaints of a left shoulder mass growing for the past two years that caused significant pain with movement.

### *Clinical diagnosis*

Patient has a tense, large, protruding mass over her left scapula that is excruciatingly tender with intact flexor and extensor function of the hand and elbow and gross sensation but limited shoulder function secondary to significant pain.

### *Differential diagnosis*

Malignant peripheral nerve sheath tumor, cellular schwannoma, fibrosarcoma, synovial sarcoma.

### *Laboratory diagnosis*

White blood cell: 9.80 k/μL; hemoglobin: 9.9 g/dL.

### *Imaging diagnosis*

Magnetic resonance imaging revealed 18.4 cm × 15.9 cm × 20 cm mass concerning for possible malignant degeneration of a neurofibroma based on size and clinical history and chest computerized tomography revealed a left large axillary mass with scapular erosion.

### *Pathological diagnosis*

Post-operative pathology report demonstrated a T2bN0 grade 2 or stage IIb malignant peripheral nerve sheath tumor and the tumor was 24 cm × 24 cm × 19 cm in size with focally positive margins.

### *Treatment*

Surgical resection of the mass using a pedicled upper arm fillet flap was performed and post operatively, the patient was initiated on a chemotherapy regimen consisting of doxorubicin and ifosfamide and scheduled for radiation

therapy.

### Related reports

Pedicled musculocutaneous flaps are commonly used for reconstruction; however, the use of a pedicled fillet flap of the upper arm has not been well reported in the literature.

### Term explanation

A pedicled flap contains tissue that remains attached to the original donor site with intact vasculature and is transposed to a new location which is in contrast to a free flap where tissue is detached from its original donor site and transferred to another location.

### Experiences and lessons

The advantage of immediate wound closure, avoidance of donor-site morbidity, and reduced operative time over a free flap makes the use of a pedicled fillet flap of the upper arm a viable option that can be successfully used for coverage of soft tissue defects of the shoulder and chest wall for complex reconstructions in an oncologic setting.

### Peer review

This case report describes a novel reconstructive procedure that can be used to cover the amputated upper arm with a pedicled fillet flap.

## Abstract

Cecal bascule is a rare cause of bowel obstruction in which a mobile cecum folds anteriorly and superiorly over the ascending colon. Herein, we present the first case of internal herniation of a cecal bascule into the lesser sac through the foramen of winslow, aiming at discussing radiological findings, differential diagnosis, and surgical management of this uncommon condition. A 75-year-old female presented to the emergency room with an 18-h history of sudden onset sharp, progressively worsening abdominal pain associated with vomiting. Physical exam revealed abdominal distention and epigastric tenderness while initial laboratory tests were unremarkable. Computed tomography of her abdomen and pelvis showed a loop of distended colon within lesser sac without signs of bowel ischemia or perforation. On exploratory laparotomy, a cecal bascule was found herniating into lesser sac *via* foramen of winslow. Upon reduction, the cecum appeared viable therefore a cecopexy was performed without bowel resection. Unlike cecal volvulus, cecal bascule consists of no axial rotation of the bowel with no mesenteric vascular compromise and therefore ischemia would only occur from intraluminal tension or extraluminal compression from the borders of foramen of winslow. The management of internal herniation of a cecal bascule is always surgical including anatomic resection or cecopexy.

**Key words:** Cecal; Bascule; Hernia; Internal; Foramen; Winslow

**Core tip:** Cecal bascule is a rare and overlooked cause of large bowel obstruction in which a mobile cecum folds anteriorly and superiorly leading to obstruction of ascending colon. Although cecal bascule has been described in association with mechanical bowel obstruction in the literature, its association with this type of internal hernia has never been described before. The management of internal herniation of a cecal bascule is always surgical even in the absence of peritonitis, either cecopexy or right hemicolectomy depending on the viability of the bowel segment involved.

Makarawo T, Macedo FI, Jacobs MJ. Cecal bascule herniation into the lesser sac. *World J Clin Cases* 2014; 2(12): 903-906 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/903.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.903

## INTRODUCTION

Cecal bascule is an extremely rare condition in which the bowel folds anteriorly and superiorly over the ascending colon[1]. Its similarity with cecal volvulus has led to misdiagnosis, although the absence of axial rotation of the bowel in cecal bascule is an importance difference that influences presentation. In cecal bascule, patients usually present with less critical illness than those with cecal volvulus as there is no torsion of the mesenteric vasculature[2]. Symptoms are therefore mostly related to bowel obstruction, particularly in the presence of a functional ileocecal valve causing a closed-loop obstruction. Diagnosis is often challenging because of equivocal image findings in addition to its rare occurrence. We, herein, present a rare case of cecal bascule herniating into the lesser sac in a patient with obstructive signs, and discuss the diagnosis, and operative management of this rare

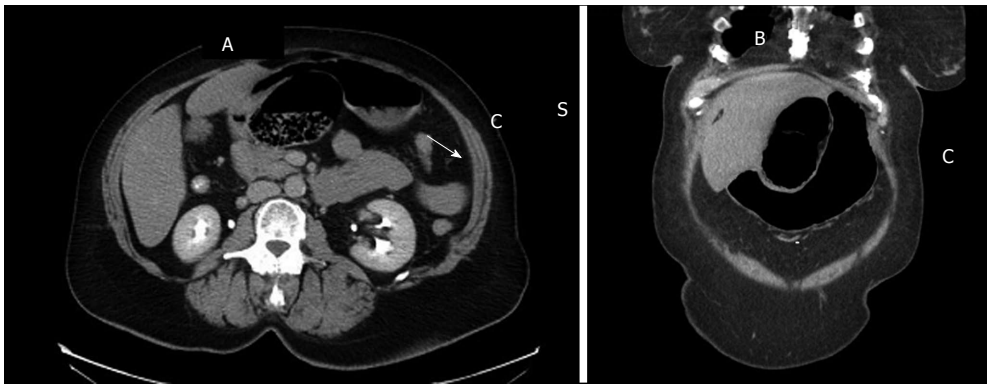

**Figure 1 Computed tomography of abdomen and pelvis showing a loop of distended colon within lesser sac without bowel ischemia or perforation.** Radiological features include: (1) the cecum herniated (C) into the lesser sac behind the stomach (S) (A and B); (2) the presence of mesentery (white arrow) between the portal vein and inferior vena cava (A); and (3) the presence of gas or fluid in the lesser sac with its 'beak' directed toward the foramen of winslow (B).

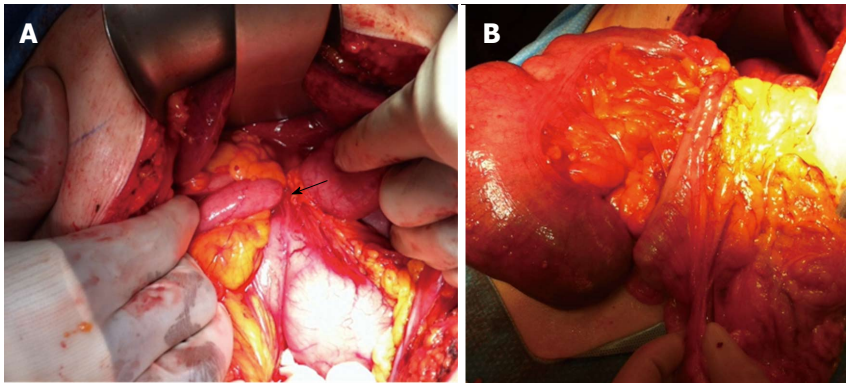

**Figure 2 Intraoperatively, a cecal bascule was found herniating into lesser sac *via* foramen of winslow (A). Upon reduction, the cecum appeared viable (B).**

condition.

## CASE REPORT

A 75-year-old female presented to the emergency room with an 18-h history of sudden onset, progressively worsening abdominal pain associated with vomiting. The patient had a previous history of hiatal hernia with gastroesophageal reflux symptoms and previous hysterectomy and tonsillectomy. The patient presented with abdominal distention and epigastric tenderness without diffuse peritoneal signs. Laboratory tests were unremarkable, with no leukocytosis but computed tomography (CT) of the abdomen and pelvis showed a loop of distended colon within lesser sac with no signs of bowel ischemia or perforation (Figure 1).

The patient underwent exploratory laparotomy during which the cecum was noted to be folded anteriorly over the ascending colon and herniating into lesser sac *via* the foramen of winslow (Figure 2A) resulting in colonic obstruction. To reduce the internal hernia, the lesser omentum was incised revealing the absence of underlying adhesive bands tethering the cecum in place, hence allowing the gentle withdrawal of the bowel back through foramen of winslow. Upon reduction, the cecum and terminal ileum appeared viable (Figure 2B). Therefore, lysis of a single adhesive band to the terminal ileum was performed prior to cecopexy with fixation of the cecum inferolaterally to the right lateral abdominal wall, negating the need for bowel resection.

The patient made an uneventful post-operative recovery, tolerating full oral intake within 48 h of the surgery and being discharged on post-operative day four. The patient has had no further episodes of bowel obstruction, remaining symptom-free after almost a year of follow-up.

## DISCUSSION

Cecal bascule is a rare and overlooked cause of large bowel obstruction in which a mobile cecum folds anteriorly and superiorly leading to obstruction of ascending colon. It has been estimated that approximately 10% to 15% of labeled "cecal volvulus" episodes were actually cecal bascules[3]. The formation of a cecal bascule is secondary to hypermobility of the cecum and intestinal distention[4,5]. This excessive mobility can occur as a result of defective retroperitoneal fixation of the cecum due to incomplete intestinal rotation during embryogenesis, or the persistence of ascending mesocolon. It may also occur postoperatively after dissection of peritoneal attachments[6]. The formation of adhesions may also play a role by creating a point of fixation, allowing the formation of

the bascule.

The clinical presentation of cecal bascule is usually similar to postoperative ileus including nausea, vomiting and abdominal distention and pain. However, unlike in cecal volvulus, the patients are not as critically ill because there is no axial torsion of the mesenteric vasculature, which leads to bowel ischemia. However, it must be noted that delay in diagnosis with unrelieved bowel obstruction causing increased intraluminal tension or extraluminal compression from an internal hernia would ultimately result in bowel ischemia and eventual perforation. Diagnosis is often challenging due to its rare nature. Plain abdominal X-rays may show a dilated cecum in the right upper quadrant with or without small bowel obstruction. CT scan of the abdomen, which is more helpful, may demonstrate a dilated cecum anterior to the ascending colon and an ileocecal valve located in the right upper quadrant[4]. In our case, the CT scan did show an internal hernia containing a loop of distended colon within lesser sac, although it was unclear whether it was transverse colon or ascending colon that had herniated through the foramen of winslow.

Herniation of abdominal viscera through the foramen of winslow into the lesser sac occurs rarely, accounting for 8% of all internal hernias[7]. Hernias through this foramen have been described as containing small bowel, right colon, and rarely, gallbladder or transverse colon. Potential predisposing factors include hypermobile mesentery, enlargement of the foramen of winslow, or absence of fusion of the ascending colon to the posterior abdominal wall[7,8]. Although cecal bascule has been described in association with mechanical bowel obstruction in literature, its association with this type of internal hernia has never been described before[8-14]. Indeed, it is possible that the term 'bascule' which is derived from a French word meaning "a bridge with a movable section hinged about a horizontal axis", is not widely applied, and therefore underdiagnosed as a cause for cecal herniation.

The management of bowel obstruction secondary to cecal bascule should be surgical. In this case, simple reduction and cecopexy was technically feasible, safe, and had a satisfactory outcome. Although right hemicolectomy has also been advocated even with the cecum being viable to prevent recurrence[9], there are no reported cases of recurrence of cecal bascule following cecopexy only[10-12]. Therefore, we would recommend that segmental resection be reserved for cases with associated ischemia or perforation. Closure of the foramen has also not been advocated due increased risk of portal vein thrombosis or hepatic artery and/or bile ducts injury[13,14].

In conclusion, we presented a rare case of an internal hernia containing a cecal bascule into the lesser sac through the foramen of winslow. Despite its rare occurrence, cecal bascule should be in the differential diagnosis armamentarium of bowel obstruction, especially in patients with a markedly distended cecum in the absence of peritoneal signs. The management of internal herniation of a cecal bascule is always surgical even in the absence of peritonitis, and includes either cecopexy if the cecum is viable or right hemicolectomy if it appears ischemic or non-viable.

## COMMENTS

### Case characteristics

A 75-year-old female presented to the emergency room with an 18-h history of sudden onset, progressively worsening abdominal pain associated with vomiting.

### Clinical diagnosis

On physical examination, she had abdominal distention and epigastric tenderness without diffuse peritoneal signs.

### Differential diagnosis

Mechanical obstruction due to adhesions, ileus, cecal volvulus, cecal bascule.

### Imaging diagnosis

Computed tomography of abdomen and pelvis showing a loop of distended colon within lesser sac without bowel ischemia or perforation.

### Treatment

The patient underwent exploratory laparotomy, reduction of cecal herniation into the lesser omentum and cecopexy.

### Term explanation

Cecal bascule occurs when a mobile cecum folds anteriorly and superiorly leading to obstruction of ascending colon. The term "bascule" is derived from a French word meaning "a bridge with a movable section hinged about a horizontal axis", is not widely applied, and therefore may be underdiagnosed.

### Experience and lessons

This is the first case in the literature describing a hernia into the lesser sac from a cecal bascule. The management of bowel obstruction secondary to cecal bascule should be surgical.

### Peer review

This manuscript highlights the clinical presentation of a rare cause of large bowel obstruction and provides insights into the management of cecal bascule.

## Abstract

Dural arteriovenous fistula (DAVF) is a rare type of cerebral arteriovenous malformation. Common presenting symptoms are related to hemorrhage. However, rarely these patients may present with myelopathy. We present two cases of DAVF presenting as rapidly progressive myelopathy. Two treatment options are available: microsurgical interruption of the fistula and endovascular embolization. These treatment options of DAVFs have improved significantly in the last decade. The optimal treatment of DAVFs remains controversial, and there is an ongoing debate as to whether primary endovascular or primary microsurgical treatment is the optimal management for these lesions. However, despite treatment a high percentage of patients are still left with severe disability. The potential for functional ambulation in patients with DAVF is related to the time of intervention. This emphasizes the important of early diagnosis and early intervention in DAVF. The eventual outcome may depend on several factors, such as the duration of symptoms, the degree of disability before treatment, and the success of the initial procedure to close the fistula. The usage of magnetic resonance imaging and selective angiography has significantly improved the ability to characterize DAVFs, however, these lesions remain inefficiently diagnosed. If intervention is delayed even prolonged time in rehabilitation does not change the grave prognosis. This review outlines the presentation, classication and management of DAVF as well as discussing patient outcomes.

**Key words:** Dural arteriovenous fistula; Myelopathy; Vascular malformation; Cognard classification; Microsurgery; Onyx embolization

**Core tip:** Tentorial dural arteriovenous fistulas (DAVF) are an uncommon entity, and myelopathy as a result of these AV fistulas is even more uncommon. We present two cases of myelopathy as a result of dural AV fistulas. This review highlights the classification of dural AV fistulas, the various diagnostic modalities available for diagnosis and management strategies employed for the treatment of DAVF. We also stress the importance of a timely diagnosis and its impact on patient outcomes and recovery.

Tentorial dural arteriovenous fistula presenting as myelopathy: Case series and review of literature. *World J Clin Cases* 2014; 2(12): 907-911 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/907.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.907

## INTRODUCTION

Dural arteriovenous fistulas (DAVF) constitute 10% to 15% of all intracranial vascular malformations[1,2]. Tentorial DAVFs account for 8.4% of intracranial DAVFs[3]. Cranial dural arteriovenous fistulas may give rise to myelopathy due to spinal perimedullary venous drainage causing intramedullary venous hypertension[4]. However, this is very uncommon, with only 38 cases reported in the literature[5]. We describe two cases of tentorial dural AV fistulas causing significant myelopathy.

## CASE REPORT

### *Case 1*

A 69-year-old male presented to our institution with 3 d of progressively worsening bilateral lower extremity weakness and urinary retention. These symptoms had been preceded by bilateral hand and forearm pain that lasted for 2 d. The patient was presumptively diagnosed with Guillian-Barre Syndrome and treatment started. Magnetic resonance imaging of the brain and of the cervical, thoracic, and lumbar spine showed increased T2/STIR signal intensity in the pons, medulla, and upper cervical spine and multiple small flow voids in the dorsal cervicothoracic spine suggestive of dural arteriovenous malformation (Figure 1). Neurological exam revealed significant weakness in bilateral lower extremities, most pronounced in bilateral hamstrings and in the left tibialis anterior. The upper extremity strength testing was normal. There were no sensory abnormalities. Deep tendon reflexes were increased in the lower extremities. This presentation was thought to be consistent with myelopathy from venous congestion related to a dAVF. He underwent angiography, which confirmed a Cognard V tentorial dAVF fed by the left middle meningeal, tentorial branch of the left ICA, and dural branches of the occipital and posterior auricular arteries, with drainage into cervical spinal veins (Figure 2). The AVF was successfully embolized with Onyx (Covidien Inc., Mansfield, MA) without any residual filling seen following embolization (Figure 3). The patient was discharged to rehab on hospital day 5. He was seen in follow-up 10 wk later, at which point he was noted to be walking independently, without urinary symptoms and only mild proximal lower extremity weakness bilaterally with manual muscle testing grade of 4 out of 5 in bilateral iliopsoas and hamstrings. The Aminoff-logue scale changed from 6 preintervention, to 1 after embolization of dural AV fistula.

### *Case 2*

A 34-year old woman presented with progressively worsening bilateral upper and lower extremity weakness over 1 wk. Past medical history was significant for temporal pilocytic astrocytoma resection with subsequent whole brain radiation at age 12. Examination revealed quadriparesis and hyperreflexia in all 4 extremities. Initial presumptive diagnosis made was transverse myelitis with high cervical cord involvement, and the patient was started on steroid therapy. MRI Brain revealed dilated tortuous vessels posterior to the spinal cord between the foramen magnum and the upper thoracic spine. It also showed asymmetric expansion and T2/FLAIR signal abnormality of the left side of the brainstem at the cervicomedullary junction, as well as diffuse expansion and mild diffuse T2 signal abnormality within the cervical and upper thoracic spinal cord (Figure 4).

Cerebral angiogram showed a left transverse sigmoid junction dAVF fed by the left occipital artery (Figure 5). This fistula drained into the superior petrosal sinus, going to the tributaries of the petrosal vein and to the anterior medullary vein. From the anterior medullary vein it then drained down to the anterior spinal and cervicomedullary veins. This venous drainage was thought to be responsible for venous hypertension and the subsequent quadriparesis that the patient was experiencing. This DAVF was successfully embolized with Onyx (Covidien Inc., Mansfield, MA). Three month follow-up angiogram revealed no opacification of the fistula with left occipital artery injection (Figure 6). Clinically the patient had regained complete strength in all 4 extremities and was back at work performing manual labor. The Aminoff-logue scale changed from 7 preintervention, to 0 after embolization

of dural AV fistula.

## DISCUSSION

dAVFs are rare vascular lesions that can come to clinical attention as either intracranial hemorrhage (intraparenchymal, subarachnoid, subdural) or as a consequence of venous hypertension. In the latter situation, presenting symptoms are varied and can include pulsatile tinnitus, dementia, seizures, encephalopathy, parkinsonism, intracranial hypertension, and myelopathy[4]. Here we have presented two cases of rapidly progressive myelopathy related to dAVFs. All fistulas have one or more feeding arteries, derived from the dural arteries or meningeal branches of cerebral arteries, with venous drainage into a venous sinus, leptomeningeal, or spinal veins.

The classification of intracranial DAVFs has evolved over time, based on venous drainage, natural history, and arterial feeders. Cognard classification divides DAVFs in 5 types ( I -V). This classification is based on the direction of dural sinus drainage (antegrade or retrograde), the presence or absence of cortical venous drainage, and venous outflow architecture (nonectactic cortical vein, ectactic cortical vein, or spinal perimedullary vein)[6,7]. The higher the type, the more likely the DAVF is to be symptomatic as a result of increased venous congestion. Both our cases were classified as Cognard Type V lesions. Type V DAVF usually have aggressive symptoms with progressive myelopathy due to spinal cord venous hypertension. The perimedullary venous drainage can extend down to the thoracic or lumbar levels.

The etiology of DAVFs is not entirely clear. It is generally accepted that DAVFs in adults are acquired. Trauma, prior surgery, sinus thrombosis, and stenosis have been proposed as possible etiologies[3,4,8,9]. An atypical presentation can lead to delays in accurate diagnosis, as clinicians may first think of other causes of rapidly progressive weakness, such as Guillian Barre syndrome and transverse myelitis. Both the cases we have presented were suspected to be suffering from similar neurological ailments. Only after failure to improve with standard therapy were further investigations conducted and the dAVF discovered on MRI imaging. This goes to underscore the importance of an accurate and timely diagnosis and the value of MRI in the acute setting since delayed diagnosis leads to grave neurologic and functional prognosis[10].

MRI findings can be subtle and difficult to interpret. These include prominent perimedullary flow voids as well as T2 signal intensity in the brainstem and spinal cord

indicating the presence of venous congestion and edema. Diffuse signal change in the brainstem and spinal cord, with dilated perimedullary veins combined with a presentation of progressive myelopathy should always raise the suspicion of a DAVF[8]. Cerebral angiography is the gold standard for diagnosis. Arterial feeders to DAVFs can originate from branches of the external carotid artery such as the occipital artery, posterior meningeal artery, middle meningeal artery, as well as meningeal branches of pial arteries[9,11,12]. When the arterial phase of spinal angiography is negative, an extended observation of the venous phase should be performed looking for venous stagnation which is a sign of venous hypertension.

The optimal management strategy for DAVF is still controversial. It is recommended that DAVF be managed at a center with multidisciplinary experience in endovascular therapy, microsurgery and radiosurgery. Although both of our patients were successfully treated endovascularly, there is still a major role of conventional microsurgery in selected patients. Surgical therapy involves ligation and disruption of the arterio-venous fistulous connection, with success rates of 87.5% to 100% reported in literature[1-3,12]. Embolization with Onyx can be used as a first line therapy in many patients, with reportedly high rates of durable cure and low rates of complications[13,14]. There is some evidence to suggest that surgical ligation may offer permanent cure without any recurrence compared to endovascular therapy where recurrence may occur[15].

Endovascular and surgical therapies are associated with significantly improved symptoms once the definitive diagnosis of SDAVF is made, with studies showing significant improvement in patient outcomes measured on the Aminoff-Logue scale. The Aminoff-Logue scale is a disability scale comprising of three subcategories which score the patient on their gait, micturition and bowel control. Literature supports post-treatment improvement particularly in the subcategories of micturition and gait[16].

In conclusion, DAVFs are rare but aggressive and potentially fatal vascular malformations. Atypical presentation can mimic other more common neurologic disorders delaying diagnosis. Early diagnosis is important in these cases as a prompt intervention can result in great functional outcomes as evidenced by our cases.

## COMMENTS

### Case characteristics

The authors present two cases of dural arteriovenous fistula presenting as rapidly progressive myelopathy.

### Clinical diagnosis

In one instance the patient demonstrated bilateral lower extremity weakness, whereas the second patient had quadparesis with significant weakness of all 4 extremities.

### Differential diagnosis

Differential diagnosis includes Guillian Barre syndrome, transverse myelitis and various other demyelinating illnesses.

### Imaging diagnosis

MRI showed T2 signal change in the spinal cord as well as prominent dorsal flow voids. Cerebral angiogram showed the presence of a dural arteriovenous fistula in both cases.

### Treatment

Both patients were treated with Onyx embolization that resulted in complete resolution of the dural AV fistula.

### Related reports

This is an unusual presentation of tentorial dural AV fistulas which normally present as hemorrhage and not many cases have been reported in the literature.

### Term explanation

Dural arteriovenous fistulas are abnormal connection between arteries within the dura mater and veins that normally drain brain tissue.

### Experience and lessons

Dural AV fistulas are rare vascular lesions and can be classified using the Cognard classification. This case report highlights two cases of tentorial dural AV fistulas presenting as progressive myelopathy and discusses treatment options available.

### Peer review

Very interesting case reports. It is worth to publish.

## Abstract

Relapsing polychondritis (RP) is a rare autoimmune disease with chronic inflammatory/destructive lesions of the cartilaginous tissues. In one third of the cases it is associated with other autoimmune disorders, mostly with anti-neutrophil cytoplasmic antibody (ANCA) associated vasculitis (AAV). We report three cases of RP with p-ANCA positive AAV. In the first patient RP developed 1.5 years after the onset of AAV. In the others the signs of RP were present before the onset of severe crescent glomerulonephritis. Patients responded well on steroid and cyclophosphamide. In dialysis dependent cases plasmapheresis was also used successfully. During the 2 and 1.5 years of follow up, they were symptom-free, and had stable glomerular filtration rate. The first patient died after four years of follow-up due to the complications of sudden unset pancytopenia, which raises the possibility of associated hemophagocytic syndrome. In the setting of RP or AAV physicians should always be aware of the possibility of sudden or insidious appearance of the other disease.

**Key words:** Relapsing polychondritis; Anti-neutrophil cytoplasmic antibody; Anti-neutrophil cytoplasmic antibody-associated vasculitis; Rapidly progressive glomerulonephritis; Immunosuppressive treatment

**Core tip:** Relapsing polychondritis (RP) is a rare disease usually diagnosed late when serious symptoms occur. Appearance of renal symptoms significantly increases the possibility of associated associated vasculitis (AAV). We present three cases of RP in whom AAV occurred at different times during the illness. AAV caused rapidly progressive glomerulonephritis (RPGN) in the second and third patient. Aggressive immunosuppression resulted in remission of both RP and AAV. In the RPGN cases dialysis could be discontinued.

## INTRODUCTION

Relapsing polychondritis (RP) is a rare disease characterized by recurrent inflammatory flares of cartilaginous structures of ear, nose, joints, larynx and tracheobronchial tree[1-4]. The aetiology of RP is not clearly defined, but the pathogenesis should involve an autoimmune response to cartilage[5]. About one third of RP cases can be associated with other multi-system diseases, of which

**Figure 1 Red and swollen ear of patient 1. The inflammation spares the lobule.**

primary systemic vasculitides are the most common. antineutrophil cytoplasmic antibody (ANCA) may be present in up to 25% of patients with RP[6]. Some of these patients show a classical clinical picture of one of the ANCA associated vasculitides (AAV) and polychondritis is usually thought to be a secondary phenomenon[7-9]. However many RP patients with ANCA positivity do not have any, or only limited, vasculitic symptoms[6] and the occurrence of RP may precede AAV[10-12]. It is possible that the development of ANCA could be provoked by RP, as it was seen by us in rheumatoid arthritis patients[13].

Whatever is the sequence of disease manifestations, the occurrence of renal symptoms significantly raise the possibility of (underlying or secondary) AAV, the need for more aggressive treatment, and indicates worse prognosis[14-17]. We present three cases of RP in whom AAV occurred at different times during the illness. Two patients developed rapidly progressive glomerulonephritis (RPGN). The aggressive treatment resulted in dialysis independence in both cases.

## CASE REPORT

### *Case report 1*

In March 1998 microscopic polyangiitis was diagnosed in a 58 years old male, based on four weeks' history of fever, anaemia, purpura, arthralgia, episcleritis, axonal neuropathia, and p-ANCA positivity of 38 U/mL (normal < 3 U/mL). Glomerular haematuria, granular casts and mild proteinuria were also present. The serum creatinine was normal, therefore a kidney biopsy was not performed. Renal angiography did not find any aneurysms. Skin biopsy verified small vessel vasculitis. Per os treatment with 1 mg/kg steroid and 2 mg/kg cyclophosphamide resulted in quick resolution of symptoms and p-ANCA negativity, but 2 mo later severe leucopenia and herpes infection of the skin developed, therefore cyclophosphamide was withdrawn. The patient was well on a low dose steroid, but after tapering the dose to 4 mg/d in November 1999 episcleritis reoccurred. Painful swelling and redness of both auricles with sparing of the ear lobe had also developed (Figure 1). Auricular polychondritis spontaneously diminished, but in the next months it relapsed twice. Less severe inflammation of the nose bridge was also present. Based on these clinical symptoms the diagnosis of relapsing polychondritis was established. ANCA remained negative and no other signs of systemic vasculitis reoccurred. Increased steroid dose and azathioprine resulted in remission of polychondritis, therefore six month later azathioprine was withdrawn and only 4-8 mg of methylprednisolone was applied. In June of 2002 fever, weakness and purpura reoccurred. Severe thrombocytopenia (24 G/L), leucopenia (1,2 G/L) and anaemia (Hb 78 g/L) were also present. Bone marrow biopsy showed hyperregenerative cell lines but also a delay in cell maturation thus leading to pancytopenia. Occasionally macrophages containing red blood cell fragments within their cytoplasm were also present. No primary haematological disease was seen and ANCA was negative. Pulse steroid treatment was given resulting in quick improvement of pancytopenia. In August 2002 pancytopenia suddenly reoccurred and the patient died within 24 h after admission into another institution. No autopsy was performed.

### *Case report 2*

A 63-year old woman was admitted to our Department in July 2012 with two months' history of 6 kg weight loss, fatigue, subfebrility, elevated C-reactive protein and normocytic anaemia. She had renal failure as well and needed urgent haemodialysis (serum creatinine 1040 μmol/L). Urinalysis disclosed proteinuria and glomerular haematuria, ultrasound showed normal size kidneys. Rapidly progressive glomerulonephritis was suspected. The renal biopsy demonstrated pauci-immune necrotizing glomerulonephritis with fibrocellular crescents being present in 70% of glomeruli (Figure 2). She had elevated anti-MPO titer: 21 U/mL (normal < 5 U/mL). The diagnosis of ANCA associated systemic vasculitis was established. Typical signs of auricular chondritis were also present, her ears were tender and had cauliflower appearance. She complained of dizziness, hearing loss, and compromised smell. Her bilateral mixed hearing loss was diagnosed 8 years earlier. In the recent years she had migrating transient polyarthralgia, recurrent nasal obstruction and red eyes, but medical consultation was not sought except due to hypertension in 2010. These signs and symptoms led to the diagnosis of relapsing polychondritis. Pulse steroid of 3 × 1 g was given and five sessions of plasmapheresis were performed. Treatment resulted in immediate resolution of the inflammatory symptoms. Maintenance immunosuppression was continued in a dose of 0.5 mg/kg per day prednisolone and 1.5 mg/kg per day cyclophosphamide per os. Renal function improved, in February 2013 dialysis could be discontinued, cyclophosphamide was

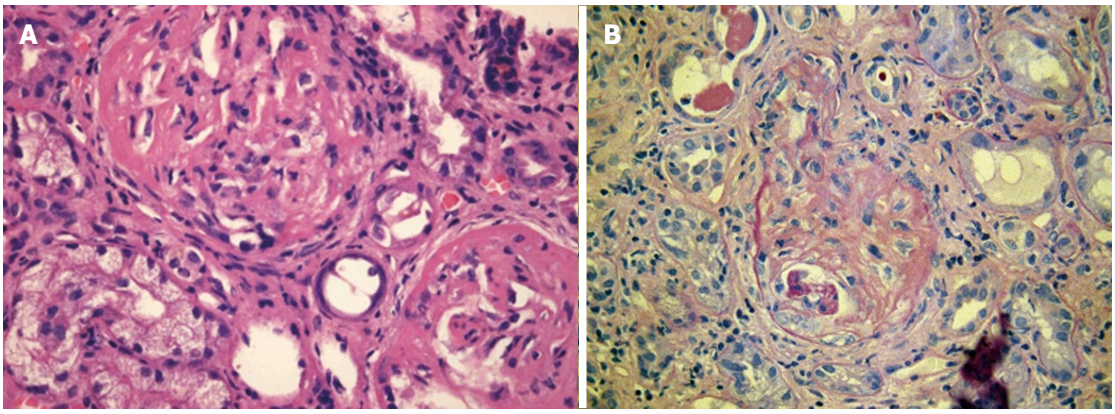

**Figure 2 Renal biopsy of the second patient: extensive fibrocellular crescents in the glomeruli.** A: Haematoxilin-eosin × 40; B: Periodic acid-Schiff × 40.

withdrawn. Prednisolone was stopped in June 2014 (estimate GFR 20 mL/min per 1.73 $m^2$, proteinuria 0.5 g/L). During the 2 years of follow-up, no relapse of vasculitis or polychondritis was observed. Anti-MPO level remained negative, her hearing and the shape of her ears returned to normal.

### *Case report 3*

A 56-year-old woman - with a ten year history of hypertension - was referred to our Department in October 2012 due to RPGN requiring dialysis. ANCA associated glomerulonephritis was established based on > 100 U/mL anti-MPO (normal < 5 U/mL) and pauci-immune glomerulonephritis (fibrocellular crescents in 10 of 32 of glomeruli) seen in the kidney biopsy. In recent years she repeatedly experienced hoarseness, sore throat, laryngotracheal pain, swollen, tender, painful ears and low grade fever. Symptoms sometimes disappeared spontaneously, sometimes she was treated with antibiotics and analgesics. She also had migrating arthralgia. Based on these signs preceding polychondritis was also diagnosed. Before the start of her complaints she punctured her finger while vaccinating rabbits against myxomatosis. At that time (September 2011) laboratory tests revealed normal renal function without proteinuria and haematuria. In September 2012 her throat and ear complaints reoccurred accompanied by fever, fatigue, weight loss, macroscopic haematuria and oliguria. Considering this acute episode she was started on the following therapy: pulse prednisolone (4 × 0.5 g), plasmapheresis (5 session), and 1.5 mg/kg oral cyclophosphamide. The treatment resulted in resolution of the inflammatory symptoms, renal function improved, and dialysis could be discontinued. Anti-MPO level decreased to 16 U/mL. The patient was discharged in good condition with 0.8 mg/kg per day methylprednisolone and 1.5 mg/kg per day cyclophosphamide. After three weeks she needed admission to our intensive care unit due to high fever, repeated convulsions, agitation and unconsciousness. ANCA titer was normal, renal function has not deteriorated, and her ears and throat did not show signs of inflammation. Therefore cerebral symptoms were suspected not caused by a vasculitic episode but rather by an immunosuppression-related cerebral infection. Herpes encephalitis was diagnosed by liquor herpes simplex virus polymerase chain reaction positivity. Intravenous acyclovir and immunoglobulin was administered, the steroid dose increased and cyclophosphamide discontinued. This therapy resulted in a slow but full recovery regarding cerebral symptoms. The steroid was gradually tapered and stopped after 1 year. There was no relapse of polychondritis or vasculitis during the 18 mo follow-up, eGFR stabilized about 20 mL/min per 1.73 $m^2$, there was no proteinuria, and ANCA tests were negative.

The most important laboratory findings are presented in the Table 1.

## DISCUSSION

We present three cases of ANCA associated vasculitis, who also merit the diagnostic criteria for RP. They are not exceptional cases, because vasculitis can be seen in 14% of RP patients[1], ANCA positivity in up to 25% of RP patients[6]. The annual incidence of AAV and RP (which is about 10-30/million and 3.5/million population respectively) makes it unlikely that these cases represent simple coincidence.

About one third of RP cases can be associated with other autoimmune diseases, of which vasculitis is the most common[1-4]. All types of vasculitis were already reported with RP, including microscopic polyangiitis[10,14], polyangiitis with granulomatosis[18], eosinophil granulomatosis with polyangiitis[19], among them most frequently AAV. In our three cases microscopic polyangiitis was diagnosed based on the general and renal signs of systemic vasculitis, the absence of eosinophilia, allergic rhinitis/asthma or sinusitis/otitis. The p-ANCA, anti-MPO positivity is also characteristic for MPA.

There are no specific clinically applicable tests to confirm the diagnosis of RP. Antibodies against type II collagen and matrilin-1 (cartilage matrix protein prominent in tracheal, auricular, and nasal cartilages) can be detected in sera of patients with RP, however their sensitivity and specificity is very low[5]. Therefore the diagnosis of RP is based on clinical signs[20]. Currently the diagnosis of

CRP: C-reactive protein; GFR: Glomerular filtration rate.

RP requires the presence of a proven inflammation in at least 2 of 3 of the auricular, nasal, or laryngotracheal cartilages, alternatively, a proven inflammation in one of the above cartilages and two other signs including ocular inflammation, hearing loss, vestibular dysfunction, or seronegative arthritis[21].

In our cases the auricular chondritis was the diagnosis-raising sign, but there were other signs in every case to meet the diagnostic criteria of RP. In the first patient recurrent polychondritis developed 1.5 years after the onset of typical vasculitis (neuropathy, purpura, haematuria) when the steroid dose was tapered off. This supports the concept, that RP is a secondary phenomenon of underlying AAV. However, at that time vasculitis was not active, furthermore ANCA was negative. This observation is counter to the findings outlined in a recent case report[9].

In Case 3 the ear and throat symptoms preceded the vasculitis by one year. Her symptoms started after an accidental needle-puncture while vaccinating rabbits against myxomatosis. It is possible that the attenuated *Myxoma virus* was the trigger activating the immune system by molecular mimicry. In Case 2 AAV and auricular chondritis occurred at the same time, but her hearing loss preceded them by eight years. From that time she had recurrent auricular, nasal and ophthalmological symptoms, which raises the possibility of RP. The diagnosis of RP is difficult in the early stage because the incidence of each symptom is less than 50% at the onset[1]. The diagnosis is usually delayed by 3 years[22] but the delay can be as long as 10 years[23]. Extremely precise case history and clinical evaluation is needed. In this case the biopsy of an involved cartilage could help. Biopsies, however, often show only nonspecific granulation tissue, so the pathognomonic findings for RP may be not be easy to obtain[24].

In spite of the fact that glomeruli do not contain type II collagen, renal involvement was reported in 29/129 cases in the Mayo Clinic study[17]. Haematuria was the most frequent abnormality occurring in 26% of 337 patients[1]. It was observed in all our cases, indicating a proliferative glomerulonephritis. Rapid decline in glomerular filtration rate (GFR) was seen in two cases raising the suspicion of pauci-immune crescentic glomerulonephritis, which was verified by a kidney biopsy. This type of glomerular lesion is diagnostic for AAV-s, even if ANCA is not present. In the early phase of kidney damage only focal segmental glomerular necrosis can be present. These lesions were the most frequently observed pathological finding in RP and rose the suspition of vasculitis even decades earlier when ANCA was not yet available[14-17]. Less frequently other types of glomerulonephritides, such as IgA nephropathy[25], membranous nephropathy[26] had also been reported. We think that these lesions could not to be linked to RP. When renal signs appear it is very important to differentiate renal vasculitis from other causes: *e.g.*, membranous nephropathy could be caused by non-steroid anti-inflammatory drugs, used for the treatment of arthralgia in RP.

Renal vasculitis indicates a worse prognosis and the need for more aggressive immunosuppressive treatment. Due to the poor response of AAV to steroids alone, first-line regimes used in patients with RP/AAV overlap should include additional cyclophosphamide or other immunosuppression. Our patients responded well on steroid and cyclophosphamide treatment. In dialysis-dependent cases we combined it with plasmapheresis. This regime resulted in dialysis independence in spite of the advanced histological picture. The patients became symptom-free both regarding RP and AAV. They have severely decreased GFR, which could have been prevented had they been referred to us earlier. The first patient died after four years of follow-up due to the complications of sudden unset pancytopenia. No primary haematological disease was seen on bone marrow biopsy. Therefore it was thought to be a result of a flare of the underlying autoimmune disease, which was supported by the fact that pulse steroid treatment had been effective. The presence of hemophagocytosis and the recurrence of pancytopenia with sudden respiratory failure raise the possibility of hemophagocytic syndrome. Its association with adult onset autoimmune disease has recently gained attention[27,28]. The association of RP and AAV can lead to critical conditions and treatment needs to be initiated promptly and undertaken by an experienced team. RP patients need a regular and prolonged follow up for renal symptoms and ANCA-s as well.

### Recommendation

In any case of RP or AAV physicians should be aware of sudden or insidious appearance of the other disease.

## COMMENTS

### Cases characteristics

A 58-year-old male diagnosed with microscopic polyangiitis experienced painful swelling and redness of both auricles, a 63-year-old woman had renal failure, tender and cauliflower-like ears, a 56-year-old woman -with a history of relapsing polychondritis-presented with rapidly progressive glomerulonephritis.

### Clinical diagnosis

Swelling and redness of both ears, arthralgia, red eyes, hearing loss, tracheobronchial pain pointed to relapsing polychondritis, while purpura, general (fever,

fatigue, weight loss), and renal (haematuria, oliguria) symptoms to vasculitis.

### Differential diagnosis

Microscopic polyangiitis, polyangiitis with granulomatosis, eosinophil granulomatosis with polyangiitis, other vasculitides, systemic lupus erythematodes, other causes of rapidly progressive glomerulonephritis (RPGN) can be considered.

### Laboratory diagnosis

High C-reactive protein, anaemia, p-anti-neutrophil cytoplasmic antibody/anti-MPO positivity, haematuria, proteinuria, elevated serum creatinine, decreased glomerular filtration rate (Table).

### Imaging diagnosis

Chest X-ray was unremarkable, abdominal ultrasound showed normal size kidneys.

### Pathological diagnosis

Skin biopsy of the first patient showed small vessel vasculitis, renal biopsy of the other two patients was consistent with pauci-immune crescentic glomerulonephritis.

### Treatment

Immunosuppressive treatment with steroid, cyclophosphamide, azathioprine; in the RPGN cases plasmapheresis was the specific medication.

### Related reports

There are only scattered case reports about the association of relapsing polychondritis (RP) and associated vasculitides (AAV).

### Term explanation

Pauci-immune glomerulonephritis is diagnosed based on extensive extracapillary proliferation (leading to crescent formation) and necrotic lesions in the capillary tuft with negative immunofluorescent and electron microscopic finding.

### Experiences and lessons

In any case of RP or AAV physicians should be aware of sudden or insidious appearance of the other disease.

### Peer review

It is properly writen article on case series of relapsing polychondritis and vasculitis.

## Abstract

Bezoars are accumulations of human or plant fiber located in the gastrointestinal tract of both humans and animals. Patients remain asymptomatic for several years, and the symptoms develop as these accumulations increase in size to the point of obstruction or perforation. We report the case of a 21-year-old patient at 10 d postpartum, who presented with acute abdomen associated with sepsis. Given the urgency of the clinical picture, at no point was the presence of a giant bezoar at gastric level suspected, specifically a trichobezoar. The emergency abdominal and pelvic ultrasound revealed only unspecific signs of perforated hollow viscus. Diagnosis was therefore made intraoperatively. A complete gastric trichobezoar was found with gastric perforation and secondary peritonitis. The peritoneal fluid culture revealed *Candida glabrata*.

**Key words:** Bezoar; Postpartum period; Acute abdomen

**Core tip:** This case report describes the presentation of a gastric trichobezoar as an acute abdomen in puerperal woman with a detailed clinical description and images. The discussion provides an extensive analysis on the various types of treatments that exist today and their results, as well as evaluating its association with specific psychiatric diseases, and the finding of Candida infection in the patient evolution.

Gastric trichobezoar associated with perforated peptic ulcer and *Candida glabrata* infection. *World J Clin Cases* 2014; 2(12): 918-923 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/918.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.918

## INTRODUCTION

The trichobezoar is a rare medical condition composed of a mass of hair in the proximal gastrointestinal tract, which can cause obstruction, and almost exclusively affects young women[1,2]. Its prevalence ranges from 0.06% to 4% in the general population[3]. It is considered a re-

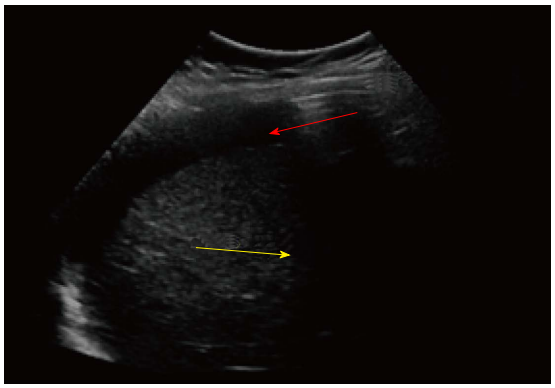

**Figure 1 Abdominal ultrasound at epigastric level shows moderate amount of free fluid (yellow arrow) and reverberation artifact immediately under the abdominal wall compatible with intraperitoneal free air (red arrow).**

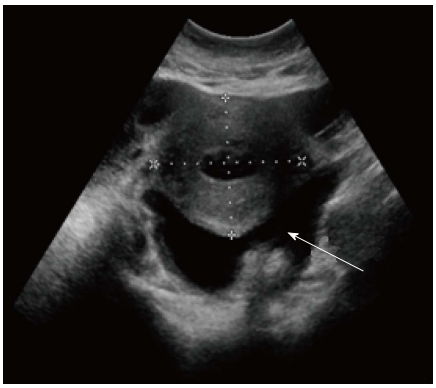

**Figure 2 At pelvic level, enlarged uterus is observed associated with free fluid, which presents echogenic material within suggestive of pus (white arrow).**

sult of trichotillomania, a psychiatric disorder linked to compulsively removing hair from the head and body in general[4]. When hair is ingested, it resists digestion and peristalsis, which is why it accumulates in the folds of the gastric mucosa. Mostly it remains confined to this level; but on some occasions it passes the pylorus, reaching the jejunum, ileum and even the colon. This condition was described for the first time by Vaughan *et al*[5] in 1968, and was called Rapunzel syndrome. The aim of this work is to report the clinical case of a patient with acute abdomen involving perforated hollow viscus associated with sepsis during the post-Cesarean period, who presented with a giant trichobezoar intraoperatively, and to review the clinical presentation, study through imaging, risk factors, complications and treatment.

## CASE REPORT

Patient, 21 years of age, female, with a history of insulin resistance with no current pharmacological treatment. She came to the emergency room of the Clínica Alemana Temuco, Chile ten days after an uneventful Cesarean section, referred from the hospital in Angol due to acute pain in her left side with 24 h of evolution, colicky in nature and with an intensity of 10/10 on the pain scale, without radiation, associated with sweating and involvement of her general state. In the initial evaluation, she was described as endomorph (BMI: 26), with altered vital signs in the range of systemic inflammatory response syndrome: blood pressure 124/80 mmHg; mean blood pressure 87 mmHg; heart rate 150 beats per minute in sinus rhythm; temperature 36 ℃; respiratory rate 21 breaths per minute; oxygen saturation 98% with 3 L/min of oxygen *via* nasal prongs. On physical examination she was alert, focused and responsive (Glasgow Scale: 15 points), pale in skin and mucosa, vesicular murmur reduced in both lung fields, and abdomen distended with no sounds, yielding to the touch with diffuse tenderness with signs of peritoneal irritation. The laboratory examinations on admittance were as follows: hematocrit 34.7%; leukocyte count: 16100 K/uL; platelets: 984000 K/uL; erythrosedimentation rate: 41 mm/h; C-reactive protein: 502 mg/L; creatinine: 1.52 mg/dL; uremia: 64 mg/dL; prothrombin percentage/thromboplastin time: 55.7%/42.1 s; INR: 1.3; sodium: 134 mmol/L; potassium: 5.5 mmol/L; chlorine: 105 mmol/L. The abdominal-pelvic ultrasound taken in the emergency room revealed a moderate amount of free fluid and pneumoperitoneum; the uterus was enlarged due to purulent fluid at the bottom of the Pouch of Douglas (Figures 1 and 2). The patient was admitted to the ICU with diagnoses of: (1) Acute abdomen; (2) Systemic inflammatory response syndrome (SIRS); (3) Early postpartum 10$^{th}$ day Cesarean section; and (4) Acute renal dysfunction.

Support began with conservative therapy: zero regimen, oxygen therapy and resuscitation with fluids. Follow-up tests 3 h later: hematocrit: 23.5; leukocytes: 10500; platelets: 735000. The patient received antibiotic prophylaxis (2 g ceftriaxone and 500 mg metronidazole) and a transfusion of 2 UI of deep frozen fresh plasma. Through imaging, the patient was considered to be in post-Cesarean period with acute abdomen, abdominal sepsis and possible perforated hollow viscus. An exploratory laparotomy was performed, which found purulent fluid in 4 quadrants, a left subphrenic abscess, cecal appendix with the end phlegmonous and ulcerated, two perforated gastric ulcers, one in the anterior wall and another in the posterior wall, with a collection of gastric fluid in the omental bursa, and complete gastric trichobezoar involving the stomach and duodenum (weight: 1090 g) (Figure 3). The technique used was an anterior gastrotomy and bezoar extraction (Figures 4-6), closing the wound, including the ulcer, with a running stitch of 3-0 polydioxanone, single-layer suture and running stitch with 2-0 silk. Closing the ulcer in the posterior wall was done with 3-0 polydioxanone and an omental patch, fixing it with 3-0 silk.

The patient evolved favorably in the early postoperative phase, but at 3 d she began with a fever up to 38.9 ℃, for which empirical antibiotic treatment was introduced. She remained hospitalized 25 d and in total and four days in intensive care unit. Peritoneal fluid culture

**Figure 3 Trichobezoar extracted weighing 1.09 kg.**

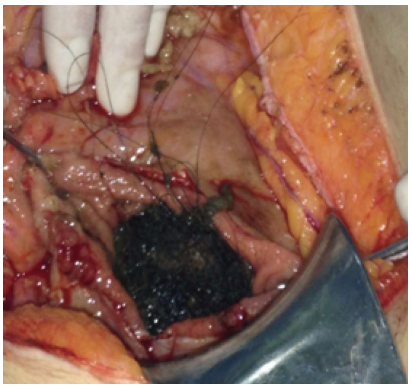

**Figure 5 Gastric opening for extraction of trichobezoar.**

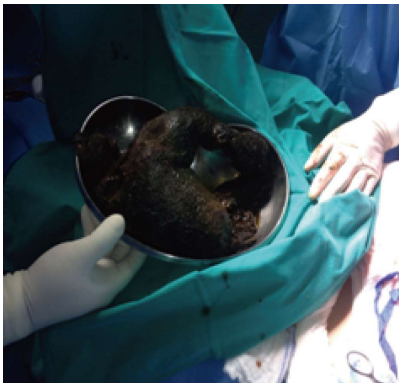

**Figure 6 Trichobezoar mass taking the shape of the stomach and part of the duodenum.**

was positive for *Candida Glabrata*; therefore, infectology assessed the case and decided to initiate anti-fungal drugs due to the presentation in the case of a hollow viscus rupture in conjunction with a bezoar. During hospitalization a psychiatric evaluation, during an interview of the patient and her mother, revealed that she had exhibited trichotillomania and trichophagia daily since the age of 12. The behavior decreased during pregnancy, and she was therefore diagnosed with moderate anxiety disorder with trichotillomania and inactive trichophagia. The methylene blue test was negative on the seventh postoperative day. Antibiotic therapy with ertapenem in addition to caspofungin was completed after two weeks. Evolution was good, with a good response, so discharge was given, completing oral anti-fungal treatment with voriconazole for three weeks.

## DISCUSSION

A bezoar is defined as a mass of ingested foreign material accumulated in the digestive tract. It means "protection against poison" or antidote, given its use for curative purposes and even superstitions associated with good luck[6,7]. The first recorded case was in 1779, when Baudamant described the presentation in a woman[8]. Bezoars are classified into 5 groups according to the substance that comprises it: phytobezoar, pharmaco-bezoar, trichobezoar, lactobezoar and foreign body bezoar[9].

Bezoars are described as occurring in 1% of the population, associated mainly with gastric disorders such as hypomotility, hyposecretion with hypochlorhydria, and a history of resection[10]. In one retrospective study, 87 cases of intestinal bezoars were presented, in which diagnosis was made using the clinical history plus an endoscopy. The results included the presence of a prior surgery in 76 of the cases. In 3% of the cases, the most widely used technique was the bilateral truncal vagotomy with a pyloroplasty (75.8%). Other factors to consider would be an excess of plant fiber ingestion in 39.5%, and alterations in teething and chewing in 24%[11].

In our case it was more important specifically to investigate the presence of trichotillomania, a disorder listed in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders, in the section on Obsessive-Compulsive and Related Disorders[12]. Although its prevalence and comorbidity have not been clearly determined, different series of cases describe from 5% to 30% of patients with trichotillomania as having associated trichophagia[13-15], while 1% to 37.5% of these will develop a trichobezoar[13,15-17].

The clinical presentation generally occurs with symptoms and signs of acute abdomen and intestinal obstruction. This includes abdominal pain, nausea, bilious vomiting, hematemesis, anorexia, early satiety, weakness, weight loss and an abdominal mass[18-20]. Associated systemic

complications include anemia, due either to nutritional deficit or gastrointestinal bleeding, and gastric ulcers have been documented in cases of gastric bezoars[21]. Imaging, such as ultrasound, can be useful in the detection of an abdominal mass, although computed tomography is more precise in assessing the characteristics of a bezoar and will allow the additional identification of bezoars in other places in the gastrointestinal tract. The diagnosis is established by endoscopy[2,18,22], and sometimes this can be effective as a treatment as we will analyze later.

In terms of surgical approach, this is where most of the debate lies with respect to management. Laparotomy, laparoscopy, endoscopic removal and even chemical dissolution in the case of phytobezoars have all been proposed. The choice is made on the basis of the size and composition of the bezoar[6,23].

The endoscopic removal of a trichobezoar has not been standardized, and a variety of techniques have been described in the literature, among which the following have been emphasized: fragmentation and removal with forceps, polypectomy snare, hydrolysis, neodymium-doped yttrium aluminum garnet laser, mechanical lithotripsy, electrohydraulic lithotripsy or extracorporeal shock wave lithotripsy[9,24-27]. The first report of the successful endoscopic removal of a trichobezoar was for one that weighed 55 g[28]. An analysis of case reports where endoscopy was used as a first approach revealed a success rate of only 5%[29]. The difficulties of this technique are due to an unsuccessful fragmentation that might be explained by the size trichobezoars can reach, as well as by the density and hardness of the formed mass[30,31]. The repeated introduction of the endoscopy to achieve removal of all the fragments can cause esophagitis, pressure ulcers and even esophageal perforation[32]. Even in cases like ours of large trichobezoars, the attempt at fragmentation may allow the bezoars to migrate beyond they pylorus and cause an intestinal obstruction. The search for satellites in the intestine is not optimal with endoscopy, and their removal is impossible. Thus the role of endoscopy has advanced more towards diagnostic management than treatment. It allows us to differentiate, in the context of a gastric mass of an unknown nature, between a trichobezoar and foreign bodies that can be extracted or fragmented *via* endoscopy[33].

As far as surgical removal is concerned, it is important to differentiate between the classic and the laparoscopic approaches. The first report of a successful result of laparoscopy for a trichobezoar was published in 1998 regarding a 7-year-old girl[21]. To date the case reports endorsing this technique have been few, mainly in the pediatric population, limited mainly by the size and the presence of satellites in the intestine[29,30,32,34-37]. The combination of techniques has been used, implementing fragmentation laparoscopically and removal endoscopically[38]. The advantages of laparoscopy as it relates to a trichobezoar are a lower rate of postoperative complications, a reduced hospital stay, and a better cosmetic result. The disadvantages are a longer operating time, greater complexity in the review of the intestine in search of satellites, and the risk of contaminating the abdominal cavity with hair fragments[39].

The laparotomy has been successful in most cases: over 100 cases of successful results with this technique have been described[40]. Complications with this technique are described in 12% of the cases[40], and these include intestinal perforation during removal of the trichobezoar[41,42], infection of the surgical wound[43], pneumonia, and paralytic ileum[44].

Another interesting point to analyze in our case is the *Candida Glabrata* infection. One study reported on the cases presented for one year with a diagnosis of peritonitis due to a perforated peptic ulcer. There were 62 cases in all, of which 23 (37.09%) had peritoneal fluid cultures that tested positive for *Candida*, ten (16.12%) for isolated bacteria and the rest were negative. That analysis concluded there were no significant risk factors for developing the different species. In addition, they marked an important prognostic factor with an up to 21.7% likelihood of mortality for the case of *Candida* peritonitis, compared to the results for bacterial peritonitis and negative cultures, which were 0% and 3.4% respectively. The specific case of *Candida Glabrata* peritonitis was second in frequency (13.04%) in this series, surpassed by *Candida Albicans* peritonitis with 78.26%[45]. Other reports associate the gastric mycotic infection as a factor related to gastric perforation[46]. This point emphasizes the importance of taking a peritoneal fluid culture in patients with secondary peritonitis.

After the anti-fungal treatment, the patient in our report presented a good clinical evolution and was discharged with no associated morbidity.

## COMMENTS

### Case characteristics

Abdominal pain in a puerperal woman associated with systemic inflammatory response syndrome.

### Clinical diagnosis

Acute abdomen.

### Differential diagnosis

The principal differential diagnosis was the complications of previous cesarean section , as an uterine rupture or large bowel perforation.

### Laboratory diagnosis

Laboratory signs of systemic response.

### Imaging diagnosis

Pneumoperitoneum and free fluid suggestive of pus.

### Pathological diagnosis

Tricobezoar.

### Treatment

Anterior gastrotomy and bezoar extraction.

### Related reports

Psychiatric diseases in relation with tricobezoar.

### Term explanation

Association with Candida Glabrata infection.

### Experiences and lessons

The authors need a high level of diagnostic suspicion, and use the anamnesis to find trichotillomania in antecedents to supply our diagnosis.

### Peer review

The case-report is interesting and so is the complication and super infection.

## Abstract

Ectopic liver tissue (ELT) is a rare condition, which is usually not diagnosed preoperatively, but coincidentally during abdominal surgery. While the location of ELT can vary, it is usually localized on the gallbladder wall or in close proximity. ELT is associated with various complications, a major complication being extrahepatic hepatocellular carcinoma. A 59-year-old female underwent elective surgery for chronic cholecystitis with stones. During laparoscopic exploration, a 2-cm-diameter ELT was detected in the anterior gallbladder wall and a laparoscopic cholecystectomy was performed. The case is presented due to the rare nature of ELT and as a reminder of ELT-related complications.

**Key words:** Ectopic liver tissue; Laparoscopic cholecystectomy; Hepatocellular carcinoma

**Core tip:** Ectopic hepatic tissue is a rare condition and it has been reported in several sites, such as the gallbladder, gastrohepatic ligament, adrenal glands, and esophagus. It is usually clinically silent and found incidentally. Ectopic hepatic tissue carries an increased risk of malignant degeneration to hepatocellular carcinoma. It should be discovered and removed by the surgeon to prevent a higher risk of complications and malignant transformation.

Rare entity: Ectopic liver tissue in the wall of the gallbladder - A case report. *World J Clin Cases* 2014; 2(12): 924-926 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/924.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.924

## INTRODUCTION

Congenital localization anomalies of the liver are rare, and can be classified into two major subgroups: those that are connected to the main liver tissue mechanically, and those that are not[1]. Ectopic liver tissue (ELT) is a subtype that is not connected to the main liver tissue, and it can be present in any intra-abdominal or supradiaphragmatic location. The most frequent intra-abdominal location is the gallbladder, and ELT is generally identified by recognizing extra tissue on the gallbladder wall that is of the same color as liver tissue[2].

First defined in 1922, ELT can vary in size, from microscopic scales to 3 cm in diameter. Despite its small size, since it is liver tissue histopathologically, it is prone to parenchymal diseases of the liver, including carcinoma development. Due to its small size, ELT is generally not noticed during routine radiological examinations; however, when noticed, it might be necessary to differentiate it from various conditions, including gallbladder cancer[3].

Here, we present a case of ELT on the gallbladder wall, which was detected during surgery, and review the relevant literature.

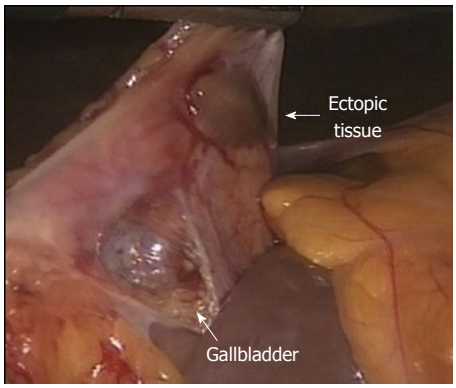

**Figure 1 Laparoscopic exploration: A 2 cm × 1 cm cm tissue mass located at the gallbladder wall, which had the same color as the liver.**

**Figure 2 Laparoscopic cholecystectomy material with ectopic tissue.**

## CASE REPORT

A 59-year-old female presented to the general surgery clinic with occasional epigastric pain and dyspeptic complaints for 2 mo. She had no history of systemic disease, previous abdominal surgery, or regular medication use, and her physical examination and laboratory tests were normal. Abdominal ultrasonography (USG) revealed a large number of millimeter-size stones in the gallbladder lumen, and she was scheduled to undergo an elective cholecystectomy. Laparoscopic exploration revealed a 2 cm × 1 cm tissue mass located in the fundus of the anterior gallbladder wall, which had the same color as the liver (Figure 1). The patient was diagnosed as having ELT on the gallbladder wall, and underwent a laparoscopic cholecystectomy (Figure 2). She did not have any postoperative problems, and was discharged on the second day. Following histopathological examination, the tissue attached to the gallbladder wall was confirmed to be ELT. The specimen examination showed that it was a truly ectopic liver and was not connected to the mother liver. The patient has been followed without any problems for 5 mo.

## DISCUSSION

Ectopic liver tissue is a rare condition that is usually detected coincidentally during a post-mortem examination or abdominal surgery. According to the literature, the incidence of ELT at laparoscopy or laparotomy is 0.24%-0.47%[4]. In a 5500-case autopsy series, the incidence of ELT was 0.05%[5], while its incidence was 0.47% in a 1060-case laparoscopic surgery series[6]. During the past 5 years, 5000 patients underwent abdominal surgery at our clinic for various reasons and ELT was observed in a single patient (0.02%), the case presented here.

The most frequent localization of ELT is the gallbladder, although other sites have been reported, including the adrenal glands, pancreas, spleen, falciform ligament, pylorus, umbilicus, retroperitoneum, thorax (intrapleural/extrapleural), and pericardium[2]. ELT is generally asymptomatic, but it can present with recurrent abdominal pain due to torsion, hemorrhagic necrosis, or rupture, or with pressure symptoms due to mass formation as a consequence of malignant degeneration[7]. We believe that our patient's non-specific complaints were due to cholecystopathy, and not associated with the ELT, because there was not pathological appearance of ELT such as torsion, necrosis.

Various theories have been presented to explain the development of ELT at different sites, and ELT can be seen together with biliary atresia, caudate lobe agenesis, omphalocele, and certain congenital cardiac anomalies[8]. We did not observe any comorbid anomalies in our case. It is a truly ectopic liver and is not connected to the mother liver. The ectopic liver tissue presents resulting from liver tissue migration to fundus of gallbladder during embryogenesis.

Ectopic liver tissue is not noticed during radiological examinations, as it is generally asymptomatic, rare, small in size, or the examiner is not aware of this entity. The diagnosis of ELT should be considered when a soft-tissue mass is detected on the gallbladder wall using USG or computed tomography. Color Doppler USG and angiography can show the blood vessel feeding the liver. However, the incidence of radiological detection is low, and the number of reported cases for which a preoperative diagnosis has been made is very limited[2,3]. When noted radiologically, the exact diagnosis is made by showing the presence of hepatic tissue in a percutaneous biopsy; however, this is not a suggested method for diagnosis, due to the bleeding risk and malignant degeneration[4].

The normal progression of ELT is not known. Since it is liver tissue, it is affected by the same risk factors affecting the liver, and lipid infiltration, cirrhotic changes, chronic active hepatitis, hemosiderosis, metastatic tumors, and hepatocellular carcinoma (HCC) have been reported to develop in ELT[8]. The development of HCC is the most important condition, and involves a higher risk of neoplastic transformation that is independent of the main liver tissue. The lack of complete functional structure for neoplastic transformation in small ELT, absence of vascular and ductal systems, and possible metabolic insufficiency are believed to contribute to the carcinogenetic process[4,9].

In conclusion, ELT is a rare condition, and it is difficult to make a radiological diagnosis. When seen during

a surgical intervention, it should be excised because of the possibility of developing a malignancy.

## COMMENTS

### *Case characteristics*

Patient presented to the general surgery clinic with occasional epigastric pain and dyspeptic complaints for 2 mo.

### *Clinical diagnosis*

Patient had no history of systemic disease, previous abdominal surgery, or regular medication use, and her physical examination was normal.

### *Laboratory diagnosis*

Laboratory tests were normal.

### *Imaging diagnosis*

Abdominal ultrasonography revealed a large number of millimeter-size stones in the gallbladder lumen.

### *Pathological diagnosis*

Following histopathological examination, the tissue attached to the gallbladder wall was confirmed to be liver tissue.

### *Treatment*

The patient was underwent a laparoscopic cholecystectomy.

### *Related reports*

Laparoscopic exploration revealed a 2 cm × 1 cm tissue mass located in the fundus of the anterior gallbladder wall.

### *Experiences and lessons*

Ectopic liver tissue is a rare condition, and it is difficult to make a radiological diagnosis. When seen during a surgical intervention, it should be excised because of the possibility of developing a malignancy.

### *Peer review*

This paper was concise and well-written.

## Abstract

A 49-year-old female patient consulted us for a cardiac evaluation before undergoing colon adenocarcinoma surgery. Three years prior, the patient underwent coronary angiography for dyspnea. The coronary angiography examination revealed a fistula originating from the left anterior descending artery and left main coronary artery, which had soft aneurysmal sacs and most likely drained into the pulmonary artery. Parasternal short axis echocardiography revealed a color flow that could be related to the fistula, but the other echocardiographic findings were normal. The patient did not accept the proposed examination and invasive treatment.

**Key words:** Left main coronary artery; Left anterior descending; Fistula; Swinging aneurysmal sacs

**Core tip:** (1) Acquire technical and surgical skills; (2) Learn the coronary anatomy and its variations; and (3) Learn the methodology of for treating coronary anomalies.

Emre E, Aktas M, Sahin T, Ural E, Ural D. Rare multiple fistulas with large saccular aneurysms originating from left anterior descending artery and left main coronary artery. *World J Clin Cases* 2014; 2(12): 927-929 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i12/927.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i12.927

## INTRODUCTION

Coronary artery fistulas are rare anomalies that open into the heart chambers, large vessels and other structures by bypassing the myocardial capillary network. Coronary artery fistula is detected in 1.21%-5.60% of all patients undergoing coronary angiography[1]. Left main coronary artery fistula is extremely rare[2]. Not all coronary-pulmonary artery fistulas are hemodynamically significant, however some may cause myocardial ischemia, myocardial infarction, congestive heart failure, pulmonary arterial hypertension, aneurysmal fistula rupture and sudden death[3]. Here we present a case with an angiographically documented coronary artery fistula that originating from the left main coronary artery (LMCA) and dividing into two branches. In addition, another fistula that originated from the left anterior descending artery (LAD) combined with the LMCA fistula and created a new line of fistula, with large saccular coronary sacs, that drained into the pulmonary artery. This type of coronary artery fistula is most rares.

## CASE REPORT

A 49-year-old female patient consulted us for a cardiac evaluation before undergoing colon adenocarcinoma surgery. Three years prior, the patient underwent coronary angiography for dyspnea. The coronary angiography examination revealed, a fistula originating from the LMCA which could be interpreted as draining into the pulmonary artery. Upon examining the coronary angiography in detail, in addition to the LMCA fistula, another fistula

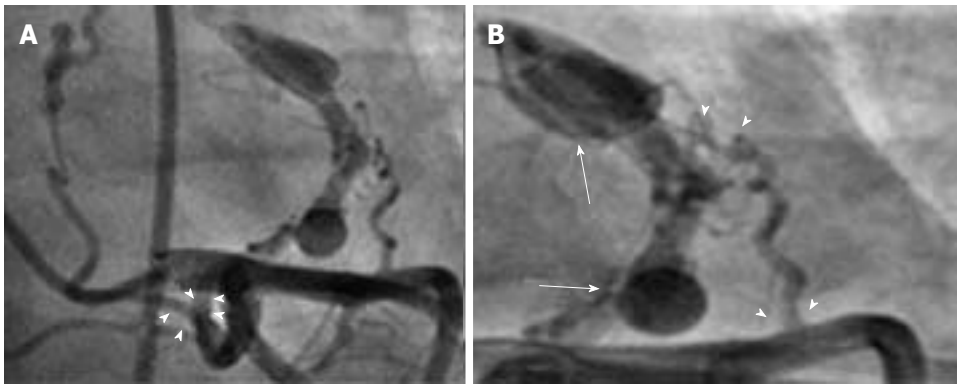

**Figure 1 A: The fistula emerging from the left main coronary artery is divided into two branches after the fold (arrowhead); B: An angiographic view showing the combination of a small fistula emerging from left anterior descending artery, the fistula from left main coronary artery (arrowhead) and large saccular sacs on the fistula line (arrow).**

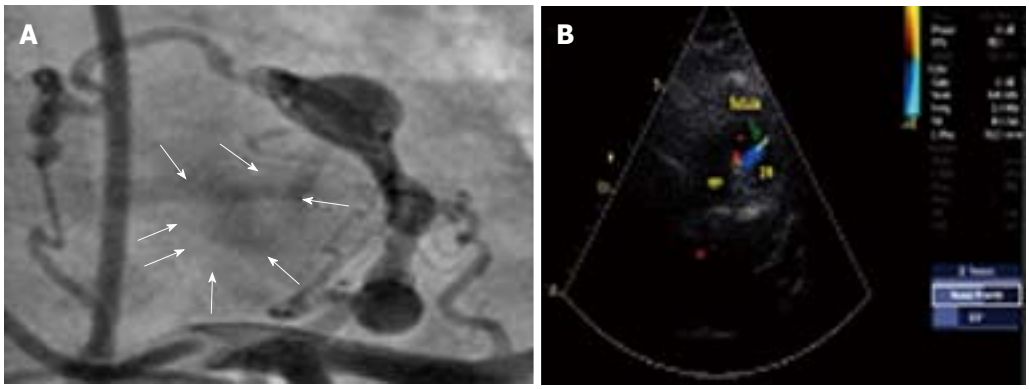

**Figure 2 The passage of the contrast agent formed by the fistula (A), parasternal short axis echocardiography revealed the color flow associated with the fistula (B).**

emerged from the LAD combined with the LMCA fistula and there was an aneurysmal sac swinging on fistula line (Figure 1). It was thought that the fistula was draining into the pulmonary artery (Figure 2A). Parasternal short axis echocardiography revealed a flow that was most likely caused by the fistula (Figure 2B). There were no regional wall motion abnormalities or systolic dysfunction. Because of excessive fatigue, the stress test was terminated at the end of step 3. The target heart rate and blood pressure were reached and there were no arrhythmia or ST-T wave changes. After further investigations and evaluations were performed, the patient was informed about the the possibility of a cardiac operation. The patient did not accept the treatment proposals and further investigation was not planned. The medical risks were explained to the patient and outpatient follow-up was scheduled with full oral medical treatment.

## DISCUSSION

Coronary artery fistulas are rare anomalies that open into the heart chambers, large vessels and other structures by by-passing the myocardial capillary network[1]. The first case of coronary arteriovenous fistula was reported by Krause[4] in 1865. Coronary artery fistula is detected in 1.21%-5.60% of all patients undergoing coronary angiography[5]. A fistula from the coronary arteries to the pulmonary artery is observed in 0.1%-0.2% of coronary angiographies[6]. Atotal of 92% of coronary artery fistulas drain into the right heart chambers and 8% drains into the left heart chambers. The origins of the fistulae are vary, as follows: right coronary artery (50%-60%), left anterior descending artery (25%-42%), both coronary arteries (5%), circumflex artery (18%), diagonal artery (1.9%), marginal arteries (0.7%). Left main coronary artery fistula is extremely rare[2]. Although coronary artery fistulas are often congenital, they may occur after chest trauma, angiography and bypass surgery[7].

Coronary artery anomalies often affect hemodynamic parameters. Not all coronary-pulmonary artery fistulas are hemodynamically significant, However some may cause myocardial ischemia, myocardial infarction, congestive heart failure, pulmonary arterial hypertension, aneurysmal fistula rupture and sudden death[3].

Although two-dimensional echocardiography (transesophageal echocardiography complements two-dimensional echocardiography) is valuable in revealing the fistula, it is operator dependent and because it does not have a good acoustic window, determining the fistula location may be insufficient[8].

Until recently, using conventional coronary angiography to detect coronary anomalies was the preferred diag-

nostic method. However invasiveness, acquisition plane images, the lack of angiographic projection angle and concerns about the contrast load limit this method[9]. Multislice computed tomography (MSCT) can better reveal aneurysms, occlusion; as well as the direction of the fistula and its relationship with the cardiovascular structures along the fistula compared with coronary angiography[8]. MSCT imaging is the recommended technique for the diagnosis and follow up of coronary artery anomalies[10].

The treatment of asymptomatic patients without significant shunts is still a matter of debate[11]. The presence of ischemic symptoms or a positive stress test, aneurysmal dilatation with or without mural thrombus and overload of heart chambers due to excessive blood flow are the indications for fistula closure[12]. In the literature, similar early efficiency, mortality and morbidity rates are observed for both the surgical and transcatheter approaches[13].

In this case, although the fistula did not affect the hemodynamic parameters and the exercise test for ischemia was negative and because there was a large thrombosed aneurysm sac on the fistula line, transcatheter closure of the fistula was considered. The patient did not accept any attempt at surgical treatment, thus, further examination and treatment.could not be performed. The patient was discharged with with full oral medical treatment and recommendations. The patient has the risk of sudden death due to aneurysmal sac rupture and thromboembolic event due to aneurysm sac thrombus. Because of progression in the shunt system, a reduction in functional capacity and heart failure may develop. Coronary artery fistula is a possibility because of the degree of shunt or the patient's symptoms; in addition, aneurysmal sacs and thrombus in the fistula line are possible[5,12].

## COMMENTS

### Case characteristics

The main symptom of the patient was exertional dyspnea.

### Differential diagnosis

The authors took into consideration the diseases , comorbidities and patient's age which causes exertional dyspnea (*e.g.*, coronary artery disease, pulmonary diseases, structural heart diseases, endocrine disoerders).

### Laboratory diagnosis

The authors made routine laboratory tests including BNP, pro-BNP, serum creatinine, urea, electrolytes, aspartate aminotransferase, alanine aminotransferase, complete blood count.

### Imaging diagnosis

Color doppler echocardiography and coronary angiography.

### Treatment

Transcatheter and surgical closure; Heart failure treatment; Nitrates, Acetylsalicylic acid, angiotensin converting enzyme inhibitor.

### Term explanation

***Coronary artery fistula*:** a sizable communication between a coronary artery and a chamber of the heart (coronary-cameral fistula) or any segment of the systemic or pulmonary circulation (coronary arteriovenous fistula).

### Experiences and lessons

The authors have learned how to diagnose a coronary fistula, manage its complications and treatment and searched the literature about its frequency and treatment modalities.

### Peer review

Interesting case report of a rare congenital coronary artery anomaly. This case represents the dilemmas of diagnosis, treatment and follow up of this rare cases.

## Abstract

Long-term cannabis use may be associated with attacks of severe nausea and vomiting, and a characteristic learned behavior of compulsive hot bathing, termed cannabinoid hyperemesis syndrome (CHS). Long-term follow-up and prognosis of CHS have not been reported previously. A 44-year-old Caucasian man with a long history of addiction to marijuana presented with chronic abdominal pain complicated by attacks of uncontrollable vomiting for 16 years. He had a compulsion to take scalding hot showers, as many as 15 times a day, to relieve his symptoms. All previous therapies had been ineffective. However, abstinence from marijuana led to rapid and complete resolution of all symptoms and his compulsive hot showering behavior. He has been followed for nine years, and is still doing well without recurrence of symptoms. Physicians should have a high index of suspicion for this under-recognized condition, as excellent long-term prognosis of CHS can be achieved when abstinence is maintained.

**Key words:** Cannabinoids; Hyperemesis; Prognosis; Abdominal pain; Adverse drug effect

**Core tip:** Cannabinoid hyperemesis syndrome (CHS) can be diagnosed with characteristic clinical features, including long-term cannabis use, severe cyclical abdominal pain, nausea and vomiting, and temporary relief of symptoms with hot showers or baths. Excellent long-term prognosis of CHS can be achieved when abstinence from cannabinoid is maintained. Physicians should have a high index of suspicion in patients with unexplained chronic abdominal pain and vomiting.

## INTRODUCTION

According to the World Health Organization, drug abuse remains prevalent around the globe, and about 27 million individuals worldwide are addicts[1]. Although legal recreational drugs, such as tobacco and alcohol, boast higher rates of consumption, cannabis is the most commonly used illegal recreational drug in the world[2,3]. In some patients, long-term cannabis use is associated with severe episodes of nausea and vomiting, and a characteristic learned behavior of compulsive hot bathing. So-called cannabinoid hyperemesis syndrome (CHS) was first described in 2004 by Allen *et al*[4] and its features were confirmed by several other subsequent reports[5,6]. This condition may be underdiagnosed because of relatively recent recognition and lack of awareness. Physicians should be vigilant for this unique cluster of symptoms to avoid misdiagnosis even after a protracted, invasive and costly workup. Long-term follow-up and prognosis of

CHS has not been previously reported, therefore we now present a case of CHS with follow-up of nine years.

## CASE REPORT

A 44-year-old Caucasian man with a long history of marijuana use presented to our clinic with chronic episodic abdominal pain complicated by attacks of uncontrollable vomiting for the past 16 years. His abdominal pain centered in the epigastrium or periumbilical region, occurred abruptly without provocation, was often aggravated by eating in the morning, and lasted anywhere from three hours to two days. Because of his abdominal pain, his weight fluctuated between 50-68 kg. In recent years, all his symptoms had increased in intensity and frequency. He had a compulsion to take scalding hot showers, as many as 15 times a day, to relieve his symptoms. When he ran out of hot water at home, he would drive to his mother's house, his sister's house, or visit his neighbors, even in the middle of night. Four years prior to his presentation to us, he had been hospitalized with second degree burns on his back because of the showers. In the last few years, he had undergone a massive workup from five previous gastroenterologists, and had visited the emergency room more than 20 times. He denied tobacco, alcohol or illegal drug use, with the exception of regular marijuana use for the past 20 years, consuming at least 4-8 marijuana doses ("joints") per day. He had no specific family history, except for Crohn's disease in a cousin.

His previous gastrointestinal workup had been extensive, including numerous abdominal and pelvic computerized tomographs (CTs), at least two small bowel follow-through studies, multiple abdominal ultrasounds, and a barium swallow and head CT. All were negative. Twenty-four hour urine porphyrin levels were normal and urinalysis did not show occult blood. Three years ago, he underwent upper endoscopy and colonoscopy, which were also unremarkable. In the past, treatment attempts had been made with psychotropic and neuromodulatory medications (including amitriptyline, paroxetine hydrochloride, sertraline and tegaserod), dietary manipulation, and alternative medical therapies. However, all of these efforts had been ineffective. This condition adversely affected all aspects of his life, including his relationship with family, friends and peers, making him unemployable. His workup was estimated to have cost tens of thousands of dollars.

He was thin with a weight of 50 kg, and his physical examination was otherwise unremarkable. His laboratory and radiological tests were within normal limits. Blood tests showed no abnormalities, including a liver functional panel, amylase and lipase. Stool occult blood tests were negative. Repeat abdominal ultrasound and abdomen and pelvic CT were normal. A repeat small bowel follow-through and capsule endoscopy were performed to exclude small bowel Crohn's disease, as he had a history of unexplained perirectal fistulae as well as a distant relative with Crohn's disease. The small bowel follow-through was negative, but multiple small ulcerations scattered throughout the small intestine were noted on capsule endoscopy. However, the mucosa did not appear to be inflamed, and there were no strictures, masses, or signs of bleeding, therefore the small ulcers were considered an incidental finding. The gastric emptying time for the capsule was only three minutes. A urine toxicology screen was done to rule out other recreational drugs, and was negative.

He was asked to stop marijuana use because of the concern for CHS. Abstinence led to a dramatic improvement within one week, with complete resolution of all symptoms and compulsive hot showering behaviors. Since then, he has gained 20 kg, completed a college degree, found employment, gotten married and started a family. We have had 9 years of follow-up so far, and he is still doing well without recurrence of symptoms. He speaks at educational events on the impact of marijuana on his life.

## DISCUSSION

Large, population-based surveys suggest that illicit drug use is relatively common in the population, with initial use typically starting in mid to late adolescence: cannabinoids are the most commonly used illegal substances[7,8]. Cannabinoids have also been used for the treatment of nausea, vomiting, anorexia and anxiety[5]. Its mechanism of action for inhibiting nausea and vomiting is not precisely known, but is probably related to stimulation of cannabinoid receptors in the brain. Given the nationwide increase in cannabinoid use for recreational and medical reasons, adverse drug effects associated with cannabinoid have become more prominent.

Chronic use of cannabinoids in some individuals can paradoxically cause severe episodic abdominal pain, nausea and vomiting[4]. Recently, Simonetto proposed clinical criteria for CHS[6]: Major diagnostic features include long-term cannabis use, severe cyclical abdominal pain, nausea and vomiting, resolution with cannabis cessation, and temporary relief of symptoms with hot showers or baths. The patient in our case report demonstrated all these features; in particular, he indulged in compulsive hot bathing behavior during acute attacks, a phenomenon prominently seen in almost all prior reports in the literature[9-14]. Supportive diagnostic features include age younger than 50 years, weight loss of greater than 5 kg, morning predominance of symptoms, normal bowel habits and negative findings on diagnostic testing. Our case also showed all the secondary features, with his social and work life severely affected by CHS. In the past, long-term follow-up and prognosis for this condition have not been reported because CHS has only recently been recognized and the recidivism rate is high in patients who are not determined to get better. It should be noted that some patients are psychologically addicted to marijuana and exhibit considerable denial when confronted with the possibility that marijuana, which has purported anti-nausea properties, may be the cause of their chronic nausea and abdominal pain symptoms. Patients who are not determined to get

better may have difficulty maintaining abstinence from marijuana for long periods of time. Our case demonstrates that prolonged abstinence leads to sustainable improvements in all symptoms over a period as long as nine years.

The mechanism of CHS is still unknown. Most cannabinoids act through two receptors, CB1 and CB2, which reduce anterior pituitary hormone and increase corticotrophin release[15]. Disturbances of the hypothalamic-pituitary-adrenal axis and the presence of autonomic instability have been proposed as possible mechanisms of CHS[6]. The central effect of long-term cannabis use is thought to be similar to that seen in cyclic vomiting syndrome, which is characterized by the increased secretion and activation of corticotrophin-releasing factor[16]. In addition, relief of symptoms with compulsive hot bathing might be due to impairment of physiologic thermoregulatory mechanisms by cannabinoids[6], as CB1 receptors of the preoptic area have been reported to be involved in the hypothermic effects of cannabinoids[17,18]. As peripheral CB1 receptors in the gastrointestinal tract have also been implicated in slowing gastrointestinal transit[19], it is suggested that slowed gastric emptying might be responsible for the severe vomiting seen in CHS[4]. However, only 30% of CHS patients had delayed gastric transit, with the majority having either normal or increased gastric transit on gastric scintigraphy[6].

The diagnosis of CHS can be made if there is a high index of suspicion; the pathognomonic feature of compulsive bathing is particularly useful because this phenomenon is not seen in any other condition. As diagnosis of CHS is based on only clinical criteria[6], laboratory or radiological data are not required for its diagnosis except to rule out other gastrointestinal conditions. Although blood or urine cannabinoid metabolites were not measured in our case, they may be helpful in ruling out the use of other recreational drugs. The correct diagnosis can often prevent an extensive and fruitless medical workup and lead to complete resolution of symptoms once abstinence from marijuana is achieved. Therefore, the index of suspicion amongst the medical profession should be raised, as this may be only the tip of the iceberg given the increasing use of marijuana associated with its legalization in several American states[1].

In conclusion, physicians should have a high index of suspicion in patients with unexplained chronic abdominal pain and vomiting, because an excellent long-term prognosis of CHS can be achieved when abstinence is maintained. Since the mechanism by which cannabis induces hyperemesis is unknown, further research is required in patients with CHS.

## COMMENTS

***Case characteristics***

A 44-year-old man with a history of marijuana use presented with chronic abdominal pain complicated by attacks of uncontrolled vomiting for 16 years.

***Differential diagnosis***

Cyclic vomiting syndrome or small bowel inflammatory bowel disease.

***Laboratory diagnosis***

All laboratory findings were unremarkable, including normal 24-h urine porphyrin levels and urinalysis.

***Imaging diagnosis***

Repeat abdominal ultrasound, abdomen and pelvic computerized tomograph as well as small bowel follow-through were all normal.

***Treatment***

All previous treatments were ineffective, including psychotropic and neuromodulatory medications (amitriptyline, paroxetine hydrochloride, sertraline, and tegaserod), dietary manipulation, and alternative medical therapies, however, abstinence of marijuana led to a dramatic improvement of all symptoms within one week.

***Related reports***

Cannabinoid hyperemesis syndrome (CHS), which is caused by chronic use of cannabis, may be associated with severe episodes of nausea and vomiting, and a characteristic learned behavior of compulsive hot bathing. This condition may be underdiagnosed because of relatively recent recognition and lack of awareness. Physicians should be aware of this unique cluster of symptoms to avoid misdiagnosis even after a protracted, invasive and costly workup.

***Term explanation***

CHS can be diagnosed based on major clinical features including long-term cannabis use, severe cyclical abdominal pain, nausea and vomiting, resolution with cannabis cessation, and temporary relief of symptoms with hot showers or baths.

***Experiences and lessons***

This case report highlights the excellent prognosis of CHS when abstinence from cannabis is maintained. Physicians should have a high index of suspicion for this rare condition in patients with unexplained chronic abdominal pain and vomiting. This report provides useful information on a rare disease as the cause of chronic abdominal pain and vomiting.

***Peer review***

This is an interesting case study of cannabinoid hyperemesis syndrome, which is characterized by chronic, heavy use of cannabis, recurrent episodes of severe nausea and intractable vomiting, and abdominal pain. Overall, the paper is well written.

## Abstract

We report a case of an 11-year-old boy with diagnosed but uncorrected tetralogy of Fallot presented to us for brain abscess drainage. The child was managed successfully with scalp block with sedation.

**Key words:** Tetralogy of Fallot; Brain abscess; Ketamine; Scalp block; Congenital heart disease

**Core tip:** We present a case report describing the use of scalp block combined with sedation for brain abscess drainage in a child with uncorrected tetralogy of Fallot. The goal should be to maintain hemodynamic stability and avoid any increase of a right to left shunt. Therefore, we decided to perform scalp block combined with sedation in this child. We used $O_2$ inhalation, analgesia and sedation with fentanyl, midazolam and ketamine to alleviate anxiety and increase systemic vascular resistance, pulmonary perfusion and oxygenation.

## INTRODUCTION

Tetralogy of Fallot (TOF), with an incidence of 10% of all congenital heart diseases[1], is the commonest cyanotic congenital heart disease[1] and has a dilated aorta which overrides the large ventricular septal defect along with right ventricular outflow tract (RVOT) obstruction and hypertrophy of right ventricle. RVOT can be valvular, infundibular or both[2]. There have been several case reports of successful management of TOF presenting for brain abscess drainage, cesarean section and major abdominal surgeries[3-5]. We present a case report describing the use of scalp block combined with sedation for brain abscess drainage in a child with uncorrected TOF.

## CASE REPORT

An 11-year-old male child weighing 44 kg presented to us in the emergency department with a history of fever up to 102 °F, headache and vomiting for 10 d. The child was a known case of TOF but had not undergone any surgical repair. His effort tolerance was poor. He had a history of cyanotic spells since childhood but was not on any medication. On examination, the child was conscious, irritable and crying. The child did not show any signs of raised intracranial pressure. Central cyanosis and clubbing were present. He had a pulse rate of 76 per minute with a blood pressure of 110/60 mmHg. On examination of the cardiovascular system, the apex beat was found in the left 5th intercostal space in the midclavicular line and was associated with a left parasternal heave. 1$^{st}$ and 2$^{nd}$ heart sounds and a loud pulmonary component of the 2$^{nd}$ heart sound were audible, along with a pansystolic murmur (Grade 4/6) at the left lower sternal border. No focal deficit was found on neurological examination. The

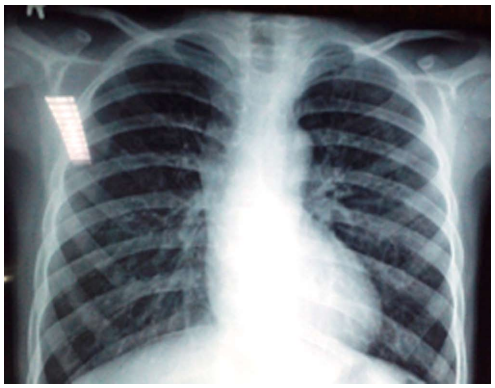

**Figure 1 Chest X-ray of the patient showing enlarged cardiac silhouette.**

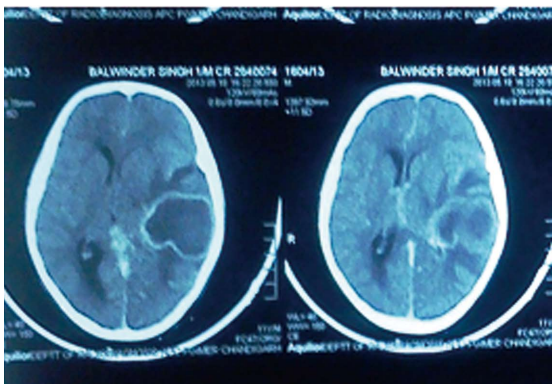

**Figure 2 Contrast-enhanced computed tomography of the patient showing left temporoparietal abscess.**

respiratory and gastrointestinal systems were normal on examination.

Chest X-ray (Figure 1) showed an enlarged cardiac shadow with left ventricular hypertrophy and dilated pulmonary arteries. Electrocardiogram (ECG) revealed sinus rhythm with right ventricular hypertrophy. Echocardiography (ECHO) showed a large ventricular septal defect (VSD) of 13 mm, 60% overriding of the aorta, right ventricular hypertrophy and right ventricular tract outflow obstruction and ejection fraction of 0.6. Cardiac catheterization was not done. Contrast-enhanced computed tomography (Figure 2) showed a left temporoparietal abscess with no uncal herniation, along with a midline shift of 2 mm. His hematocrit was 58% with a platelet count of 105 × $10^9$/L. The child's serum electrolytes, coagulation studies and renal function tests were within normal limits. The baseline Arterial Blood Gas analysis revealed pH 7.419, $Po_2$ 35.5 mmHg, $Pco_2$ 31.8 mmHg, $HCO_3$ 20.1 mEq/L, $SPO_2$ 68.7% and base excess -3.3. The child received infective endocarditis prophylaxis prior to the surgery, was allowed oral intake of fluids up to 2 h before surgery and normal saline was used as the maintenance fluid thereafter in the ward. In the operation theater, standard monitoring was done with noninvasive blood pressure, pulse oximetry, ECG and temperature. A NeoStar™ triple lumen central venous catheter was in situ as it was inserted when the child presented to us in the emergency department. A 20 G arterial cannula (Becton Dickinson Critical Care Systems, Singapore) was inserted into the radial artery under local anesthesia. The baseline heart rate was 70 beats per minute with an invasive blood pressure of 116/68 mmHg and a central venous pressure (CVP) of 10 cm of $H_2O$. The child had 64% $SPO_2$ with 50% $O_2$ with a Venturi face mask. Normal saline was used as maintenance fluid with the dose of 4 mL/kg per hour.

The scalp block was given with 20 mL of 0.75% ropivacaine without adrenaline (3-4 mL for each nerve) to block the supratrochlear, supraorbital, zygomaticotemporal, auriculotemporal, greater and lesser occipital nerve. The block was supplemented with fentanyl 20 μg *iv*, followed by ketamine 20 mg *iv* and midazolam 0.2 mg *iv* at the time of the burr hole. The child was kept on spontaneous respiration throughout the procedure with a 50% oxygen and air mixture. At the time of dural opening, intravenous ketamine 20 mg was repeated. Normal saline was administered to keep CVP in range of 14-16 cm of $H_2O$. The procedure lasted for 30 min and the intraoperative course was uneventful, with maintenance of hemodynamic parameters and acid base status within normal limits and a $SPO_2$ of 69.5%.

## DISCUSSION

For the anesthetic management of these patients, one should be careful about the drugs and events that may increase the R-L shunt[6]. The severity of the disease directly correlates with the size of VSD, severity of pulmonary stenosis and functional status of the right ventricle[7]. Complications of right to left shunts include chronic hypoxia leading to pulmonary vasoconstriction, altered acid base status, polycythemia, coagulopathy, infective endocarditis and cerebral abscess due to increased risk of paradoxical emboli. The reported incidence of brain abscess in patients with cyanotic heart disease is between 5% and 18.7%[8].

Anesthetic management of these patients is always a challenge for the anesthetists because of the cardiopulmonary and coagulation abnormalities, dehydration and electrolyte imbalance, along with abscess-induced complications of seizures, meningitis and raised intracranial pressure[4].

General anesthesia with controlled ventilation has the advantage of better oxygenation but can be associated with the risk of hemodynamic instability, along with compression of pulmonary vessels, impaired gas exchange and academia[9].

Most of the agents used for induction and maintenance of general anesthesia may also lead to myocardial depression, along with reduction of SVR.

The goal should be to maintain hemodynamic stability and avoid the changes that would increase the right to left shunt. Therefore, we decided to perform scalp block combined with sedation in this child.

Factors such as thorough preoperative examination, ECHO, treatment of any chest infections, cardiologist consultation, documentation of preoperative cardiac and neurological status and correction of any coagulopathy were necessary and taken care of in our child.

Prolonged fasting is better avoided in these patients and intake of clear fluids up to two hours prior to the surgery should be allowed. We followed the same guidelines in our patient with normal saline as a maintenance fluid in the ward. Prevention of dehydration is also important as these patients have an increased hematocrit. Patients with a hematocrit ⩾ 60% are susceptible to develop coagulopathy and preoperative phlebotomy is beneficial in such cases. Our child had a hematocrit of 58% and preoperative phlebotomy was not performed as it was an emergency procedure, but adequate precautions to prevent dehydration and liberal fluid administration were done to keep the CVP in the range of 14-16 cm of $H_2O$. Fluid boluses of 20 mL/kg may be required to increase the blood pressure and RV preload[10].

Air bubbles are also a preventable cause of perioperative morbidity in patients with shunting as air or particulate matter may be shunted directly into the arterial bed[11,12] and we took measures to prevent this.

We used $O_2$ inhalation, analgesia and sedation with fentanyl, midazolam and ketamine to alleviate anxiety and increase SVR, pulmonary perfusion and oxygenation. Although $O_2$ inhalation, fentanyl and midazolam cannot increase SVR, they avoid increasing PVR. Ketamine may increase SVR at some level or more importantly can prevent lowering of SVR and it helped our patient by decreasing the left to right shunt.

Ketamine has also been shown to be better in children with pulmonary hypertension[13,14] although this is not the cause of cyanosis in these patients but it is the fall in SVR leading to left-right shunt which causes hypoxia. In one study of 18 neonates who had complex cardiac defects, ketamine was used most commonly when intubation was not required for surgery[15]. Anesthetic agents like sevoflurane, isoflurane and fentanyl/midazolam infusions have no effect on the shunt fraction of children with shunts[16-18].

Scalp block is a well-established technique for craniotomy, increasingly being used for epilepsy surgery, temporal lobectomy where the excision encroaches on eloquent cortex areas[19].

Scalp block may be given preoperatively to reduce the hemodynamic response to pin holder application and postoperatively before the emergence to decrease the severity of postoperative pain. They also decrease intra and postoperative opioid requirement[20,21].

We used 0.75% ropivacaine without adrenaline for administering scalp block as the addition of adrenaline may cause tachycardia which is very dangerous in patients with uncorrected TOF because it may cause infundibular spasm and a cyanotic spell.

Scalp block along with sedation is being used successfully in our institute for patients with chronic subdural hemorrhage. Since the patient we encountered had to undergo an emergency procedure with no time for cardiac catheterization and medical optimization of the patient, we decided to proceed with regional anesthesia with sedation and invasive monitoring in the patient.

The avoidance of general anesthesia due to medical reasons in selected patients and with the thorough anatomical knowledge of nerve blocks, this underestimated regional technique of scalp block with sedation may be considered as an alternative technique in selective patients with unrepaired TOF and has proved to be an extremely rewarding procedure for the neuroanesthetist whilst offering the best possible outcome for the patient.

## COMMENTS

### *Case characteristics*

An 11-year-old male, a known case of tetralogy of Fallot (TOF), presented with fever (up to 102 ºF), headache and vomiting for the past 10 d.

### *Clinical diagnosis*

On examination, the child had central cyanosis, clubbing, loud P2 and grade IV pansystolic murmur but there were no signs of raised intracranial pressure and no neurological focal deficit.

### *Differential diagnosis*

A known case of TOF who had not undergone any surgical repair and presented with brain abscess.

### *Laboratory diagnosis*

The patient had a high hematocrit with a normal coagulation profile. The baseline Arterial Blood Gas analysis revealed pH 7.419, $Po_2$ 35.5 mmHg, $Pco_2$ 31.8 mmHg, $HCO_3$ 20.1 mEq/L, $SPO_2$ 68.7% and BE -3.3.

### *Imaging diagnosis*

Echocardiography revealed a large ventricular septal defect of 13 mm, 60% overriding of aorta, right ventricular tract outflow obstruction and ejection fraction of 0.6, while contrast-enhanced computed tomography (Figure 2) showed a left temporoparietal abscess with no uncal herniation and a midline shift of 2 mm.

### *Pathological diagnosis*

The patient was diagnosed as a brain abscess with uncorrected TOF.

### *Treatment*

Child was not on any medication and presented to us in the emergency department. The child received infective endocarditis prophylaxis prior to the surgery.

### *Experiences and lessons*

Uncorrected TOF presents as a challenge to anesthetists and a thorough knowledge about the physiological and pathological changes occurring with the disease is essential for the safe management of the patient in the perioperative period. Regional anaesthesia should be considered as an alternative to general anesthesia when feasible.

### *Peer review*

A good paper that can be accepted.

## Abstract

The authors have presented a technique of full occlusal rehabilitation in a case of severe dental fluorosis. In this technique, maxillary and mandibular anterior teeth were simultaneously prepared and restored first. This was followed by simultaneous preparation of maxillary and mandibular posterior teeth that were restored in canine guided occlusion. The technique and sequence followed here is unique and is not available in dental literature. This technique reduces number of appointments while fulfilling all objectives. Periodontal follow-up over 3 years was satisfactory. A restorative treatment protocol has been devised for fluorosis which will act as a guide for the dental practitioners.

**Key words:** Occlusal rehabilitation; Dental fluorosis; Treatment protocol; Restorative management; Occlusal plane

**Core tip:** A novel technique of full occlusal rehabilitation is illustrated here. It is a simple procedure which adheres to all the principles of occlusal rehabilitation. Rehabilitation of dental fluorosis using the treatment protocol suggested here will systematize and streamline the clinical technique and it is hoped that this approach will benefit the patients and act as a guide for dentists. Although the technique described here is skill sensitive, it is the author's belief that it is a new paradigm in full mouth occlusal rehabilitation.

## INTRODUCTION

There are hardly any documented cases in dental literature where dental fluorosis is treated by full occlusal rehabilitation. Restoration of dentitions affected by dental fluorosis is a challenging prospect. The presence of dental hypoplasia, the severity of discoloration, associated symptoms like hypersensitivity and attrition makes treatment planning extremely critical. The majority of fluorosis patients usually have mild to moderate fluorosis[1,2] wherein the main symptoms are discoloration and/or very mild hypoplasia[3,4]. These may be managed by simple restorative procedures like bleaching or composite filling. Some patients have moderate fluorosis which requires veneers or an occasional crown[5-8]. Very rarely, patients with severe fluorosis require full occlusal rehabilitation. The protocol for treatment of dental fluorosis has been formulated in this article.

**Figure 1 Baseline pre-treatment intraoral photograph.**

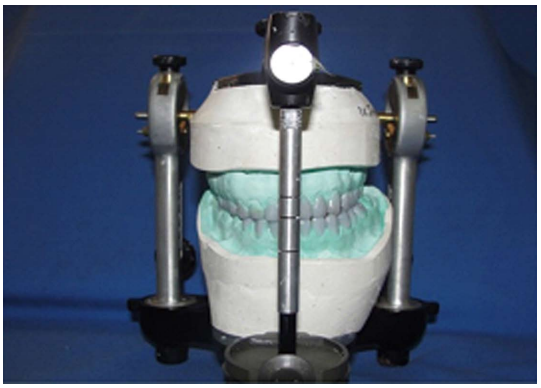

**Figure 2 Centric relation and centric occlusion was verified in a semi adjustable Hanau articulator.**

This article documents a case of severe dental fluorosis with intraoral findings such as severe attrition, anterior open bite and unilateral cross bite, which was treated by full occlusal rehabilitation. Novel clinical and technical modifications were employed which may help to simplify the procedure of full occlusal rehabilitation.

## CASE REPORT

A 28-year male patient reported to the Department of Prosthodontics, with a chief complaint of inability to chew food and discoloration of teeth. A detailed personal history revealed that the patient belonged to one of the fluoride belts of India. Clinical findings included protruded mandible, concave facial profile, severe dental fluorosis (Level 4 on Dean's Modified Index)[9], maxillary midline not coinciding with mandibular midline, anterior open bite, unilateral crossbite with a few centric stops on left side, generalized severe attrition of teeth with moderate sensitivity (Figure 1). However, there was no loss of vertical dimension which could be attributed to passive eruption to compensate for the attrition. Diagnostic impressions were made using irreversible hydrocolloid (Zelgan 2002, Dentsply, India) and casts poured using dental stone (Kalabhai Karson Pvt. Ltd., India). Face bow (Hanau Springbow, Waterpik Technologies, United States) transfer was done and the casts were mounted using a centric relation record on a semi-adjustable articulator (Hanau H2, Whip Mix Corp, United States). All the clinical findings were confirmed by diagnostic mounting of the casts. Diagnostic wax up was done based on findings of clinical examination, diagnostic mounting and diagnostic wax up. Full occlusal rehabilitation using ceramometal crowns [Meta Cast (V), United States], without changing the vertical dimension at occlusion, was decided as the treatment of choice. The limitations of this treatment option viz., inability to coincide the maxillary and mandibular midline, inability to improve the facial profile and persistence of crossbite on left side were explained to the patient and his approval was obtained for the treatment plan. Maxillary and mandibular anterior teeth were prepared simultaneously to receive individual ceramometal crowns. Impressions were made using Vinyl Polysiloxane (GC America Inc, Made in Japan) by the putty-wash technique[10]. Individual temporary crowns (DPI, India) were fabricated using the indirect technique[11] and were used to establish the anterior guidance in the patient's mouth in such a way that anterior temporaries provided canine guided occlusion. This was transferred to the semi-adjustable articulator and a custom incisal table was fabricated. The anterior metal try-in was carried out and ceramic (Vita VMK 95, Germany) build up was done according to the anterior guidance obtained from the patient. These definitive anterior restorations were seated in the patient's mouth, the canine guided occlusion verified and finally the anterior individual crowns were cemented using glass ionomer luting cement (Ketac Cem, 3M ESPE, Germany). The maxillary and mandibular midlines got close but could not be coincided. In the next phase of treatment, all the posterior teeth (maxillary and mandibular) were prepared simultaneously in a single appointment and a centric relation record was obtained. Impressions were made and master casts poured using die stone (Kalrock, Kalabhai Karson Pvt Ltd, India). The casts obtained were mounted on the semi-adjustable articulator. The horizontal and lateral condylar guidances were set arbitrarily at 20° and 15° respectively[12]. The metal copings were fabricated and tried in the patient. Before the ceramic build up was started, the occlusal plane had to be established. This was set at the midpoint between the prepared maxillary and mandibular posterior teeth. After ceramic build up, the definitive restorations were tried in the patient, harmony of centric relation and centric occlusion was verified (Figure 2), canine guided occlusion was confirmed and the restorations were cemented.

### *Follow up*

Follow up of the restorations and surrounding tissues was done for 3 years. Gingival and Periodontal component of Periodontal Disease Index (PDI)[13] and Plaque component of PDI (Shick and Ash modification) was recorded at the beginning of treatment, every 3 mo for 1 year post treatment and every 6 mo for next 2 years (Figure 3). The Gingival and Periodontal component of PDI score before treatment was 2, in the first year post treatment it was 1 and for the next two years it was 0. Plaque

**Figure 3 Follow up of the restorations and surrounding tissues.** A: One year post-treatment intraoral photograph; B: Two year post-treatment intraoral photograph; C: Three years post-treatment extra oral photograph.

**Table 1 Restorative treatment protocol for dental fluorosis of varied severity**

| Modified dean's fluorosis index score | Clinical findings | Suggested treatment options |
|---|---|---|
| Normal (0) | Enamel represents usual transparency, semi-vitriform type of structure. The surface appears smooth, glossy and usually of a pale, creamy white colour | No treatment |
| Questionable (0.5) | Few flecks to occasional white spots | No treatment/bleaching |
| Very Mild (1) | Small, opaque, paper white areas scattered over < 25% of the tooth surface | No treatment /bleaching |
| Mild (2) | White opaque areas in enamel of the teeth are more extensive, but do not involve as much as 50% of the tooth | Bleaching/composite restoration |
| Moderate (3) | All enamel surfaces of the teeth are affected and surfaces subject to attrition show wear. Brown stain is frequently a disfiguring feature | If discolorations accompanied by wear: Full coverage<br>If only discoloration without any wear:<br>1 Bleaching or<br>2 Veneers (Direct or indirect) or<br>3 Bleaching followed by Veneers (Direct or indirect) |
| Severe (4) | All enamel surfaces affected, severe hypoplasia, discrete or confluent pitting. Brown stains are widespread and teeth often present a corroded-like appearance | Full coverage |

component of PDI score before treatment was 2 and for the next three years it was 1. This indicated high compliance of oral hygiene instructions post-treatment by the patient and successful integration of the restorations in harmony with the periodontal apparatus. The patient expressed satisfaction with treatment and esthetics and restorations were sound and asymptomatic (no sensitivity to heat or cold, no pain/tenderness) at the follow-up visits. This three year follow up has reinforced that the treatment plan was sound and objectives of full occlusal rehabilitation were fulfilled while addressing all the pre-treatment problems of the patient.

## DISCUSSION

Dental fluorosis is seldom so severe[14-16] as to warrant full occlusal rehabilitation. In addition, complexities such as unilateral cross bite on left side, minimum occlusal contacts on right side, anterior open bite (as found in the present case) makes the prosthetic rehabilitation of such a patient challenging. Every attempt was made in this case to provide the best possible functional and aesthetic rehabilitation of the patient.

The dentition in full occlusal rehabilitation cases are restored variously following different principles and philosophies. The canine guided occlusion is the favoured occlusal scheme, most often adopted in full occlusal rehabilitation[17-24]. In this technique, the posterior teeth contact only in centric relation, the incisors are the only teeth contacting in protrusion and the canines are the only teeth contacting in mandibular lateral movements. In this patient, the canine guided occlusal scheme was implemented.

In canine guided occlusion the orientation and location of occlusal plane is not critical as long as it allows the anterior guidance to do its job. In this case, the occlusal plane was planned to be located midway between the prepared posterior teeth. This concept was relatively easy to apply as both the maxillary and mandibular posteriors were prepared at the same time and made the technician's job much easier. Since the technician received both maxillary and mandibular final casts with prepared posterior teeth, it was easier for her to establish proper contours and height of opposing restorations making optimum use of the available space. This technique is especially advantageous in cases of full occlusal rehabilitation restored using canine guided occlusion. In the present case, a technique has been attempted which simplifies the clinical and laboratory procedures of full occlusal rehabilitation while fulfilling all its objectives[12,25].

The restorative procedures were divided into two components: anterior segment restoration followed by posterior segment restoration. The maxillary and mandibular anterior restorations were fabricated at the same time. Establishing the anterior guidance was also easier. Any adjustments and trimming could be done easily. When the posterior restorations were fabricated, developing the occlusal plane was greatly simplified as both the maxillary and mandibular segments were simultaneously prepared. The occlusal level was then set at the midpoint between the prepared maxillary and mandibular posterior teeth on the articulated casts.

Some occlusal rehabilitation philosophies recommend the restoration of posterior teeth prior to that of anterior teeth (*e.g.*, Hobo Twin-Stage procedure[26] -Conditions 1 and 2). Other philosophies of full occlusal rehabilitation, including the Panky-Mann-Schyuler concept modified by Dawson[12] recommend the sequential restoration of mandibular anterior segment, maxillary anterior segment, mandibular posterior and finally the maxillary posterior segment. The approach discussed in this article is unlike any other philosophies of full occlusal rehabilitation, is simple, requires least number of appointments, is unique and novel, and yet it fulfils all the requirements of full occlusal rehabilitation.

Hence clinical work is greatly simplified and patient appointments are limited to just 6 as follows: Appointment 1: Diagnostic impression, face bow transfer. Appointment 2: Preparation of maxillary and mandibular anterior teeth, impressions, temporization of anteriors. Appointment 3: Anterior metal try-in. Appointment 4: Cementation of anterior ceramometal crowns, selective grinding, finishing, polishing; preparation of all posterior teeth; impressions, face bow transfer, temporization of all posterior teeth. Appointment 5: Metal try-in of posterior restorations; Appointment 6: Cementation of posterior ceramometal crowns selective grinding, finishing, and polishing. Appointment 4 may be split into two depending on convenience of operator and/or patient.

Depending on the Modified Dean's Fluorosis Index[9] which is the gold standard for quantifying dental fluorosis, a treatment protocol is herewith suggested (Table 1) which is meant as a guide; the operator may follow any treatment modality given in the protocol depending upon the skill-philosophy-convenience-preference.

The technique of full occlusal rehabilitation illustrated here simplifies the procedures while adhering to all its principles. Rehabilitation of dental fluorosis using the treatment protocol suggested here will systematize and streamline the clinical procedure and it is hoped that this approach will benefit the patient and act as a guideline for dentists.

## COMMENTS

### Case characteristics

This is a report of a case of severely discolored teeth, secondary to dental fluorosis; with generalized sensitivity, inability to chew food from both sides and deformed esthetics due to anterior open bite.

### Clinical diagnosis

The patient had a concave facial profile with severe dental fluorosis (level 4 on Dean's Modified Index), with prognathic mandible, maxillary midline not coinciding with mandibular midline, anterior open bite, unilateral cross bite with a few centric stops on left side, and severe generalized attrition with moderate sensitivity.

### Differential diagnosis

The differential diagnosis can be hypoplasia secondary to trauma to the teeth and jaws, any infections during pregnancy or infancy, poor pre-natal and post-natal nutrition, hypoxia, exposure to toxic chemicals and a variety of hereditary disorders, irregular vitamin D metabolism (vitamin D-resistant rickets) or chronic kidney failure at the time of tooth development.

### Laboratory diagnosis

The tests included intra oral periapical and extra oral panoramic radiographs, diagnostic model mounting, pulp vitality testing of all teeth that confirmed the clinical findings of permanent hypoplastic teeth with sensitivity that were severely attrided and in malocclusion.

### Imaging diagnosis

Imaging techniques used were orthopantomograph and intraoral periapical radiographs which showed generalized hypoplastic teeth, malocclusion, and anterior open bite.

### Treatment

The treatment given was a full mouth rehabilitation using a specialized, simplified technique which is novel.

### Term explanation

All terms are standard and established which have been used empirically.

### Experiences and lessons

The approach to a full mouth rehabilitation case has to be holistic, patient specific and should fulfill all the criteria of scientific treatment protocol.

### Peer review

This is an interesting and well written article. Methods are appropriate. Results are clearly presented. Discussion and Conclusions are really interesting.
