**AIM AND SCOPE**

*World Journal of Clinical Cases* (*World J Clin Cases*, *WJCC*, online ISSN 2307-8960, DOI: 10.12998) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

The primary task of *WJCC* is to rapidly publish high-quality Autobiography, Case Report, Clinical Case Conference (Clinicopathological Conference), Clinical Management, Diagnostic Advances, Editorial, Field of Vision, Frontier, Medical Ethics, Original Articles, Clinical Practice, Meta-Analysis, Minireviews, Review, Therapeutics Advances, and Topic Highlight, in the fields of allergy, anesthesiology, cardiac medicine, clinical genetics, clinical neurology, critical care, dentistry, dermatology, emergency medicine, endocrinology, family medicine, gastroenterology and hepatology, geriatrics and gerontology, hematology, immunology, infectious diseases, internal medicine, obstetrics and gynecology, oncology, ophthalmology, orthopedics, otolaryngology, pathology, pediatrics, peripheral vascular disease, psychiatry, radiology, rehabilitation, respiratory medicine, rheumatology, surgery, toxicology, transplantation, and urology and nephrology.

## Abstract

To report the first case of dellen-like keratopathy with superior corneal thinning associated with implantation of glaucoma drainage devices. A 70-year-old male with a history of primary open angle glaucoma and dry eye disease underwent placement of glaucoma drainage devices with antimetabolite application in both eyes. Prior to placement, minimal refractive error was noted on manifest refraction. Several years later, the patient was referred for decreased vision and corneal irregularity. Examination showed pathologic corneal curvature, superior corneal thinning, and epithelial demarcation lines immediately anterior to the glaucoma drainage devices in both eyes. The epithelium remained intact with no evidence of limbal stem cell deficiency. Manifest refraction revealed a large change in both eyes. Topography was used to confirm the presence of irregular corneal curvature anterior to the glaucoma drainage devices. Dellen-like keratopathy with superior thinning is a rare sequela after implantation of a glaucoma drainage device that must be considered in elderly patients who undergo glaucoma surgery. It is likely related to a combination of tear film alteration related to previously large anterior blebs, antimetabolite application, and aqueous humor flow patterns around the drainage devices. Treatment should focus on lubrication.

**Key words:** Dellen-like keratopathy; Delle; Glaucoma drainage device; Corneal thinning

**Core tip:** Corneal abnormalities are not uncommon findings in patients with longstanding glaucoma. Topical medication-related and antimetabolite-related keratopathies are conditions that have been well documented. This case report identifies an entity related to glaucoma drainage devices. Dellen-like keratopathy is a condition similar in appearance to that of a delle, but larger in size. Early identification is important in preventing excessive corneal thinning and irregular corneal curvature.

Fenzl CR, Moshirfar M, Gess AJ, Muthappan V, Goldsmith J. Dellen-like keratopathy associated with glaucoma drainage devices. *World J Clin Cases* 2014; 2(1): 1-4 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i1/1.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i1.1

## INTRODUCTION

Dellen keratopathy is characterized by localized thinning and dryness in the cornea. It often develops adjacent to areas of ocular surface changes and elevation, such as pterygia. Chronic dellen formation can lead to diffuse thinning. This is the first reported case of delle-like keratopathy with superior corneal thinning resulting from the implantation of glaucoma drainage devices.

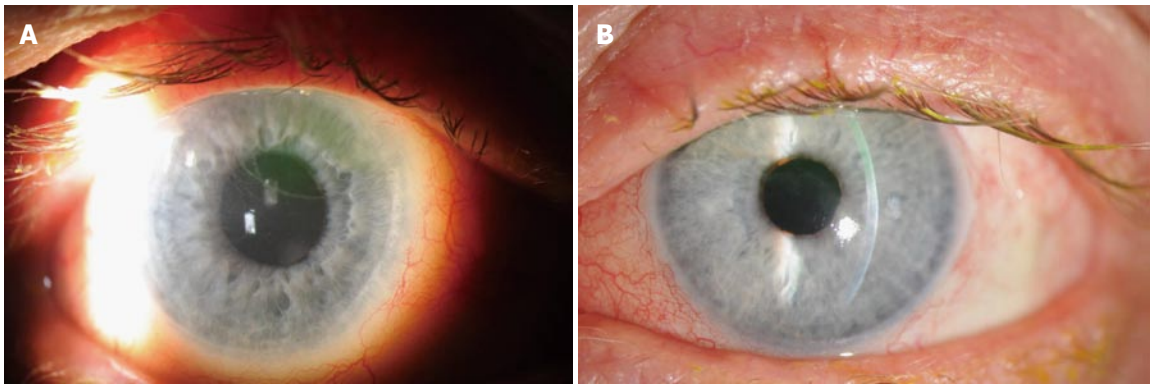

**Figure 1 Photograph of right eye demonstrating epithelial demarcation line, fluorescein pooling, and ExPRESS shunt immediately below superior eyelid margin (A) and photograph of left eye showing epithelial demarcation line, superior stromal thinning, fluorescein pooling, and Ahmed valve immediately below superior eyelid margin (B).**

## CASE REPORT

A 70-year-old male was referred by his glaucoma specialist for gradual worsening of vision in both eyes. The patient had a history of primary open angle glaucoma for ten years for which he underwent multiple surgeries. He also suffered from moderate dry eye disease for which he was being treated with frequent topical lubrication. The right eye had placement of ExPRESS shunt (Alcon Laboratories, Fort Worth, TX) with use of mitomycin-C (MMC), which required two subsequent revisions in the right eye, both of which also used MMC. The left eye underwent a trabeculectomy with MMC, followed by Ahmed tube shunt (New World Medical, Rancho Cucamonga, CA). The patient was also pseudophakic in both eyes and denied any history of refractive surgery, excessive eye rubbing, bleb massage, and collagen vascular disease.

Eleven months prior to presentation he had stable best corrected visual acuity of 20/40 in the right eye and 20/50 in the left eye. Manifest refraction was -1.25 + 1.50 × 010 and -0.75 + 0.75 × 080 respectively.

At the time of presentation, the patient was being treated with brinzolamide twice daily, brimonidine/timolol combination twice daily, latanoprost once daily, and preservative free artificial tears three times per hour in both eyes. The patient's best-corrected visual acuity was 20/70 in the right eye and 20/100 in the left eye with significantly increased astigmatism on manifest refraction: -6.25 + 7.75 × 060 in the right eye and +2.25 + 2.50 × 047 in the left eye. Intraocular pressure was 34 mmHg in the right eye and 18 mmHg in the left eye. Central corneal thickness was 511 microns in the right eye and 533 microns in the left eye.

Externally, no eyelid pathology was present. Anterior segment examination revealed thinning of the superior one-third of the corneal stromal with an clear epithelial demarcation line in each eye (Figure 1). The epithelium was intact bilaterally. A slight elevation of the conjunctiva was present posterior to the limbus in each eye, but no perilimbal bleb was identified. The glaucoma drainage device tubes inside each anterior chamber were in appropriate posterior position with no corneal contact. Topographic analysis with Pentacam (Optikgerate GmbH, Wetzlar, Germany) revealed diffuse corneal thinning as well as irregular corneal curvatures adjacent to the glaucoma drainage devices. At the thinnest point, the right cornea was 421 microns and the left cornea was 450 microns (Figure 2).

## DISCUSSION

Corneal dellen are localized areas of drying and thinning in the peripheral cornea, usually adjacent to an area of ocular surface abnormality. With chronic dellen, a keratopathy mimicking ectasia can occur with a combination of drying, thinning, and a reduced corneal tensile strength.

Keratopathy resulting from glaucoma surgery is exceedingly rare. To our knowledge, only two cases of keratopathy after glaucoma surgery have been documented in the literature, both following trabeculectomy (there are no reported cases after tube shunt surgery). One reported case utilized MMC[1] and the other used 5-Fluorouracil (5-FU)[2]. In one bilateral case of superior corneal changes observed 15 years after surgery, the cause was thought to be due to either bleb compression from prominent avascular blebs or chronic corneal toxicity from MMC application[1]. The other case of keratopathy following trabeculectomy was attributed to excessive eye rubbing[2].

MMC and 5-FU have long been used adjunctively in trabeculectomy to improve surgical outcomes. Resultant epitheliopathy is common due to the effect of antimetabolites on actively replicating tissue[3], and effects are seen well beyond the time of surgery[4]. Stromal keratocytes are also affected by antimetabolite medications; in an *in vitro* human cornea model, Rajan *et al*[5] documented a significant delay in keratocyte repopulation as well as decreased anterior stromal thickness four weeks after photorefractive keratectomy combined with MMC.

In our patient, thinning and significant alteration in the corneal curvature were present in a location immediately anterior to each drainage device. Given this patient's history of multiple glaucoma surgeries, it is likely that dellen

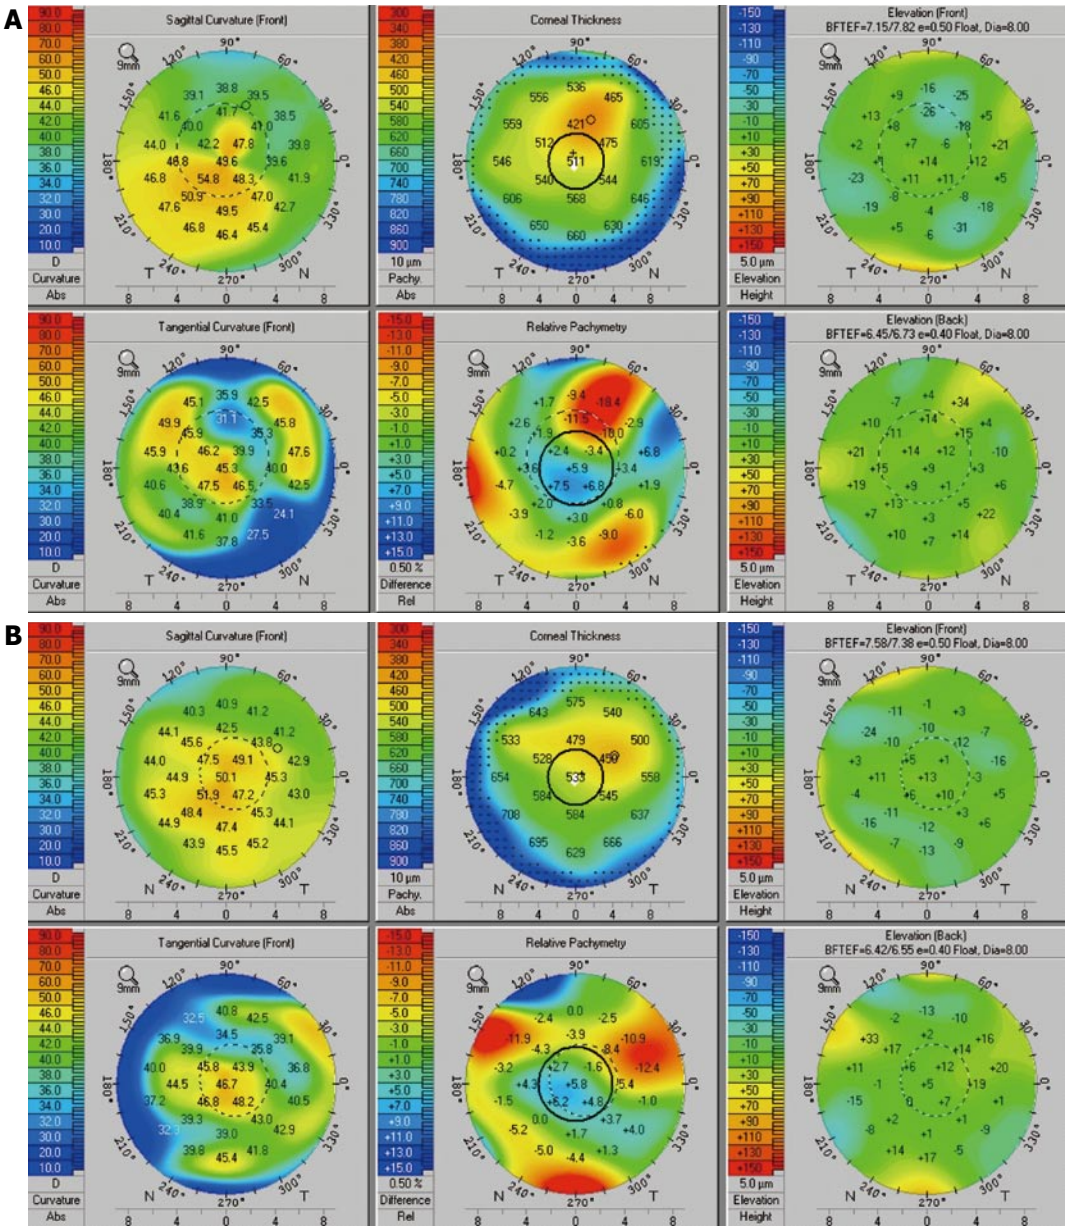

**Figure 2 Oculus Pentacam of right eye (A), left eye (B) showing corneal thinning and irregular curvature.**

formed at some stage in each eye. This may have been the result of previously large, anterior blebs causing tear film alteration[6]. In the left eye, a tissue allograft placed adjacent to the limbus during the Ahmed valve placement may have provided a nidus for delle formation. The antimetabolite use during these surgeries may have accelerated this process. It is also possible that the fluid dynamics of the aqueous humor at the opening of the drainage device may play a role in inducing thinning superiorly through low grade inflammation that may impair normal corneal healing, repair, and maintenance functions. Retrograde flow of inflammatory cells has also been postulated as a source of corneal complications[7], and focal endothelial irregularities related to drainage devices have been reported[8].

A combination of chronic dellen formation and low grade inflammation in the posterior cornea likely led to the diffuse superior corneal thinning and resultant astigmatism in this patient. We term this a dellen-like keratopathy, rather than a dellen keratopathy, due to the diffuse nature of the thinning that covered nearly 50% of the superior cornea and encroached into the visual axis, mimicking a superior keratoconus. To the patient, we recommended continued use of frequent lubrication and fitting for rigid gas-permeable contact lenses to maximize his visual potential. He has not followed up with us since his initial visit.

This is the first reported case of glaucoma drainage device associated keratopathy, a rare but serious complication of glaucoma surgery. Keratopathy resulting directly from device placement cannot be proven, and is likely multifactorial. The focal thinning immediately adjacent to both drainage devices suggests a causal relationship. Glaucoma and cornea specialists should be aware of this

possibility in patients presenting with worsening vision and corneal changes after glaucoma surgery.

## COMMENTS

### *Case characteristics*

The main symptom was blurry vision.

### *Clinical diagnosis*

The main clinical findings include corneal thinning, epithelial demarcation lines, and pathologic corneal curvature.

### *Differential diagnosis*

The differential diagnosis focuses on potential causes of corneal thinning and change in corneal curvature including dellen-like phenomena, antimetabolite complications, and aqueous humor fluid dynamics at the opening of the drainage devices.

### *Laboratory diagnosis*

No laboratory testing was performed.

### *Imaging diagnosis*

Imaging revealed dramatic change in refraction as well as irregular corneal curvature identified by topography.

### *Pathological diagnosis*

No specimens were obtained for pathology.

### *Treatment*

Treatment includes frequent lubrication and gas-permeable contact lenses.

### *Related reports*

Similar reports are included as references one and two.

### *Term explanation*

A delle is an area of localized thinning and dryness of the cornea adjacent to an elevated area.

### *Experiences and lessons*

Dellen-like areas of corneal thinning can occur anterior to glaucoma drainage implants and should be treated in a similar manner as dellen.

### *Peer review*

Strengths include evidence of change in manifest refraction as well as significant corneal curvature abnormalities on topographic imaging.

## Abstract

Inflammatory pseudo-tumour (IPT) of the liver is a rare condition with the appearance of a tumour-like space occupying lesion. Aetiology and natural history is not known for these benign lesions, as they are commonly diagnosed as malignant lesions and frequently undergo surgical resection since spontaneous resolution is very rare. Multifocal IPT involving both lobes of liver are rarely reported. Here we report a unique case of multifocal IPT of the liver which resolved spontaneously within 5 wk period.

**Key words:** Multifocal; Inflammatory pseudo-tumour of liver; Spontaneous regression

**Core tip:** Inflammatory pseudo-tumour (IPT) is extremely rare pre-operative diagnosis. It's a benign condition which does not require surgical management and it rarely self resolves. Our case so unique in appearance that IPT generally are solitary and if multiple generally confined on lobe of liver. In our case this tumour mimicked metastasis and presented in bilobar presentation. It resolved in 5 wk something which is never reported in medical literature.

Puri Y, Lytras D, Luong TV, Fusai GK. Rare presentation of self-resolving multifocal inflammatory pseudo-tumour of liver. *World J Clin Cases* 2014; 2(1): 5-8 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i1/5.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i1.5

## INTRODUCTION

Inflammatory pseudo-tumours (IPTS) represent a challenging clinico-pathologic entity due to their similarity with malignant lesions. Histo-pathologically these tumours are inflammatory myofibroblastic tumours or plasma cell granulomas. They were initially observed in the lung by Brunn *et al* in 1939, and subsequently in the liver by Pack *et al*[1] in 1953. Although in the liver they may rarely lead to biliary obstruction, portal hypertension and even cirrhosis, their clinical importance is primarily related to the difficult differential diagnosis from malignant tumours[2]. For this reason the main pattern of diagnosis is on post-resection histopathological processing. However, spontaneous resolution of these lesions has been reported as well. Here we present a case of multifocal liver IPT, which spontaneously resolved without any type of therapeutic intervention.

**Figure 1 Computed tomography at presentation demonstrating multiple liver lesions.**

## CASE REPORT

A 37-year-old Caucasian female was referred to our tertiary hepatopancreatobiliary surgical unit with symptoms of weight loss and malaise since one month. There are no pre-existing medical co-morbidities. Bloods results showed derangement of liver function tests with alkaline phosphatase of 174 U/L (normal range: 38-126), aspartate transaminase of 40 U/L (9-36), alanine transaminase of 43 U/L (10-28), and normal bilirubin. Regarding inflammatory markers only erythrocyte sedimentation rate was raised at 58 mm/h (2-12). Abdominal ultrasound revealed multiple bilobar lesions in the liver with maximum size of 3.5 cm adjacent to the porta hepatis. Multiditector computed tomography with a liver protocol demonstrated 5 lesions, non-enhancing and of low attenuation highly suspicious of metastatic origin (Figure 1). According to decision of the multidisciplinary team meeting, the patient was considered harbouring metastatic diseases of unknown primary and she underwent detailed investigations with upper gastrointestinal endoscopy, positron emission tomography (PET) scan, mammography, chest computed tomography scan and tumour markers as well. Apart from an abnormal uptake in the right lobe of the liver on PET scan there was no pathology revealed in any other study.

After failure in locating the primary, a percutaneous biopsy of a liver lesion was decided as next step in the diagnostic workup. Histopathology revealed a parenchyma of normal architecture but replaced by collagenous stroma admixed with inflammation. The stroma was composed of dense areas of fibrosis, myofibroblasts and

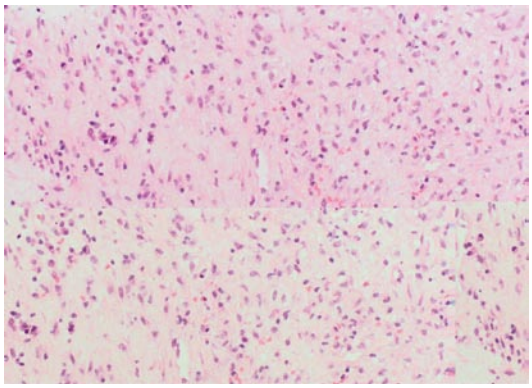

**Figure 2 Lesional area composed of cytologically bland, spindle- or stellate-shaped cells arranged in a collagenous stroma with scattered inflammatory cells with predominance of plasma cells.**

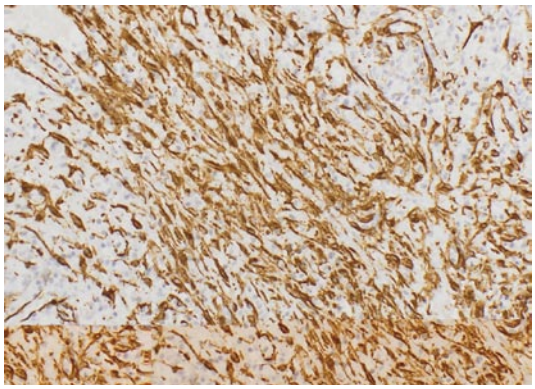

**Figure 3 Immunostaining for smooth muscle actin shows that many of the spindled cells are myofibroblasts.**

fibroblasts. The inflammation consisted of a mixture of plasma cells, lymphocytes and eosinophils. Aggregates of xanthomatoushistiocytes were also seen. There was mild portal inflammation. Also few epithelioid granulomas were seen. Immunohistochemistry showed positivity of the spindle cells for smooth muscle actin and negativity for ALK-1 (Figures 2 and 3). Epstein barr virus and cytomegalovirus immunostains were negative as well. Ziel-Neelsan showed no evidence of acid-fast bacilli in specimen. The tissue sample was considered as highly suggestive of inflammatory pseudo-tumour.

Based on the existed evidence and according to patient's consent, a wait and watch policy with follow-up imaging in 3 wk was decided. Magnetic resonance imaging (MRI) demonstrated significant reduction in the size of all liver lesions, measuring a maximum diameter of 1.5 cm as compared to the previous 3.5 cm. Follow-up MRI at two months showed almost complete resolution of the lesions. She was put on annual follow up with liver MRI and she remains asymptomatic and without evidence of any lesions on 2 year follow-up (Figure 4).

## DISCUSSION

An IPT is a benign, tumour like lesion characterised by

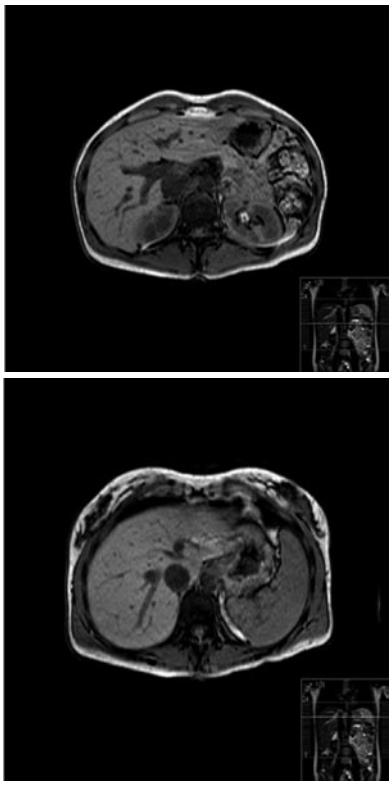

**Figure 4 Magnetic resonance imaging of the liver at 2 year follow up demonstrating complete resolution of liver lesions.**

presence of certain chronic inflammatory cells namely plasma cells, lymphocytes and eosinophils. Although uncommon in presentation, they represent a challenge in differential diagnosis since they might lead to unnecessary surgical interventions if they are interpreted as malignant disease[3].

Their aetiology remains unclear. IPTs are known to be associated with chronic inflammatory conditions like Crohn's disease[4], autoimmune disorders related to IgG4[5] or infective agents like *Escherichia coli*[6]. The main location in the liver is the right lobe but multifocal IPTs although extremely rare have been described as well[7]. In the present case, there was multifocal, bi-lobar distribution of these lesions while there was no association with any chronic condition. This is first of its kind case report from our unit who performs around 100 liver resections per year.

Diagnosis of IPT is considered quite difficult since the radiological features of these tumours are often mistaken as of malignant origin[1,8]. Definitive diagnosis is only possible following fine needle aspiration cytology or core biopsy[9]. Histologically, these tumours appear as densely hyalinised structures with dense collagen matrix and a whorl like pattern infiltrated by chronic inflammatory cells[10]. Similar histological pattern was observed in the present case.

Natural history of IPT is not well defined since the current evidence is mainly after an incidental radiological diagnosis which often leads to surgical resection. However complete spontaneous resolution of these lesions has been also observed within months[10]. Raised values of tumour markers as CA19-9 might confuse further the final diagnosis, but this was not observed in our case.

In conclusion, IPT might represent a considerable diagnostic challenge requiring high index of suspicion. The characteristic of spontaneous resolution highlights the necessity of regular, short-term, imaging follow-up in order to avoid aggressive unnecessary interventions.

## COMMENTS

### *Case characteristics*

A 37-years-old female without any medical co morbidities presented with short term history of weight loss and malaise and diagnosed with multiple liver lesions.

### *Clinical diagnosis*

Multiple liver lesions.

### *Differential diagnosis*

Metastatic disease in liver, multifocal hepatocellular carcinoma, inflammatory pseudotumour.

#### *Laboratory diagnosis*

Bloods results showed derangement of liver function tests with alkaline phosphatase of 174 U/L (normal range: 38-126), aspartate transaminase of 40 U/L (9-36), alanine transaminase of 43 U/L (10-28), and normal Bilirubin. Erythrocyte sedimentation rate was raised at 58 mm/h (2-12). Other blood tests including tumour were normal.

### *Imaging diagnosis*

Multiditector computed tomography with a liver protocol demonstrated 5 lesions, non-enhancing and of low attenuation highly suspicious of metastatic origin.

### *Pathological diagnosis*

Histopathology revealed a parenchyma of normal architecture but replaced by collagenous stroma admixed with inflammation. The stroma was composed of dense areas of fibrosis, myofibroblasts and fibroblasts. Immunohistochemistry showed positivity of the spindle cells for smooth muscle actin.

### *Treatment*

This patient did not require any treatment as inflammatory pseudo-tumour self-resolved completely and patient was completely asymptomatic even at 2 years follow up.

### *Related reports*

There are very case reports of this particular condition but these lesions are more frequently diagnosed because of routine use of cross sectional imaging. It is important to be aware of this particular condition to spare patient of major surgical procedure.

### *Experiences and lessons*

The biology pathophysiology and disease history of this particular condition is not completely known. This case report highlights importance of serial radiological examinations and unique place of fine-needle aspiration cytology in diagnosis of inflammatory pseudo tumours.

### *Peer review*

This is a brief, easy to read and interesting case report in which the authors show a patient with a usual clinical presentation.

## Abstract

Gastrointestinal stroma tumours (GIST) are the most common mesenchymal tumour in the digestive tract and commonly found in the stomach. The patient described in this report presented with collapse and a palpable abdominal mass. He was found to have a large gastric GIST that penetrated through the mesocolon. Resection of the GIST was technically challenging but facilitated by a new generation ultrasonic scalpel device. In resection of gastric cancer the use of ultrasonic scalpels has been shown to reduce operating time, blood loss and length of stay. We feel that in technically challenging cases of gastric GIST the use of an ultrasonic scalpel device may be justified as well.

**Key words:** Gastrointestinal stroma tumours; Ultrasonic scalpel; Harmonic; Giant tumour; Stomach

**Core tip:** This case report about a giant gastric gastrointestinal stroma tumours focuses on surgical technique. Because of its bulk the giant tumour was penetrating through the transverse mesocolon. Dissecting the tumour of the mesocolon and avoiding a concomitant colectomy was facilitated by using a new generation ultrasonic scalpel device.

Schneider C, Hewin DF. Resection of giant gastric GIST with a new generation ultrasonic scalpel device. *World J Clin Cases* 2014; 2(1): 9-11 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i1/9.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i1.9

## INTRODUCTION

Gastrointestinal stromal tumours (GISTs) are the most common mesenchymal tumour of the digestive tract. Most GISTs are found in the stomach and although bleeding is a frequent complication, they usually present with non-specific symptoms[1]. We present a case of a giant gastric GIST in a patient presenting with collapse and a palpable abdominal mass. Intra-operatively the tumour was found to penetrate the transverse mesocolon. Resection of the GIST without requiring a colectomy was facilitated using a new generation ultrasonic scalpel device (HARMONIC ACE®+).

## CASE REPORT

This 71-year-old man with a past medical history of hypertension and peptic ulcer disease was admitted to the local Emergency Department with a sudden onset of abdominal pain followed by collapse. Clinical examination revealed a large epigastric abdominal mass. The patient was haemodynamically stable and initial full blood count and biochemistry tests were unremarkable. The patient

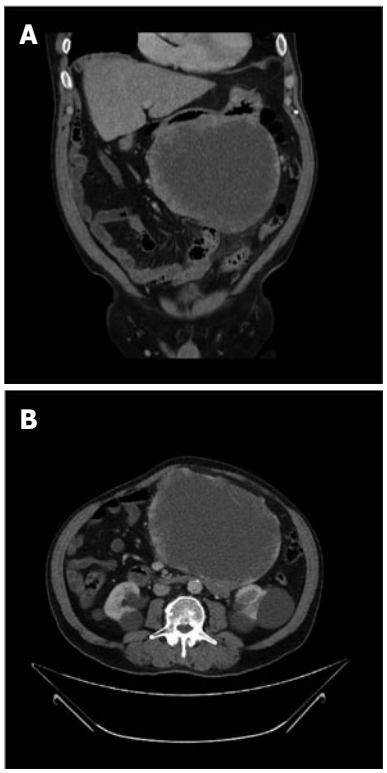

**Figure 1 Preoperative computed tomography scan of the abdomen and pelvis showing a large mass inseparable from the greater curve of the stomach.** A: Coronal view; B: Axial view.

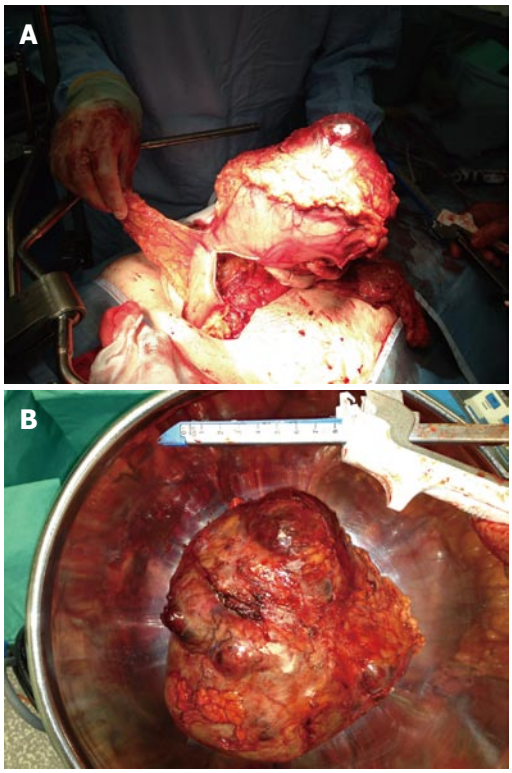

**Figure 2 Fully mobilised gastrointestinal stroma tumours attached to the distal stomach (A) and Resected specimen (B).**

was discharged home and booked in for an ultrasound scan (USS), which revealed a large heterogeneous soft tissue mass extending from the epigastrium into the pelvis. CT scan of the abdomen and pelvis was performed immediately, revealing a large mass inseparable from the greater curve of the stomach and the body of the pancreas. A large proportion of the tumour had low attenuation indicating cystic change or necrosis. The Radiology report concluded that the differential diagnosis should include cystadenocarcinoma of the pancreas, neuroendocrine tumour and GIST (Figure 1). The patient was urgently referred to the oesophago-gastric department. After multi-disciplinary discussion and outpatient review the patient was scheduled for surgery.

### Surgery

The operation was performed *via* a midline laparotomy. Intraoperative findings were that of a large tumour arising from the greater curve of the stomach. The tumour was firmly attached and penetrating completely through the mid-portion of the transverse mesocolon, without invading it. It was difficult to establish a safe plane of dissection between tumour and colonic vessels. At this stage the HARMONIC ACE®+ proved valuable as it aided in the careful separation of tumour and mesocolon. A novel feature added to the latest generation of the device is the audible "tissue sensing" feedback. As the device is activated a constant tone starts, similar to older versions. The dissecting shears "sense" when tissues have been divided and the quality of tone changes which signals to the surgeon to stop activation of the device. In our view the main benefits of this feature were reduced heat dissipation thereby enabling us to dissect the tumour off the transverse mesocolon without inadvertently damaging the colonic blood supply. There was also a marked increase in speed of dissection as the audible feedback reduced the overall activation time during dissection.

The gastro-colic omentum was divided and the tumour dissected from the mesocolon where possible. Several densely adherent branches of the middle colic vessels were sacrificed and the transverse colon checked for viability. The tumour was carefully dissected from its attachments to the duodenum and pancreas. A standard distal gastrectomy with a retrocolic Roux-en-Y reconstruction was carried out.

The patient made an unremarkable recovery and was discharged on the seventh postoperative day. He was re-admitted on the 19$^{th}$ postoperative day with haematemesis. Gastroscopy was performed and showed ulcerations around the staple line of the gastro-jejunal anastomosis but no active bleeding was found. The patient remained haemodynamically stable throughout his second admission and was discharged after two days.

### Postoperative outcome

Histopathological macroscopic examination revealed a greyish, pale, soft tumour with cystic haemorrhagic and necrotic areas. Tumour weight was measured at 2.6 kg and dimensions were 19 cm × 18 cm × 16 cm (Figure 2). A massive central area of haemorrhage was noted. On

immunostaining the tumour stained positive for KIT (CD 117) and CD 34. Mitotic rate was seven out of ten and immunostaining for Ki-67 showed an increased proliferation index of seven percent. Microscopic examination and immunostaining were compatible with a GIST of the spindle cell type. Resected lymph nodes did not show any metastatic spread. All of the above histopathological findings were congruent with a completely excised GIST with high risk for malignant potential. Following further multidisciplinary team discussion the patient was referred to oncology services for adjuvant chemotherapy.

## DISCUSSION

This case highlights an unusual clinical presentation of a Gastrointestinal Stromal Tumour and a successful approach to the intraoperative challenges.

The patient presented with acute collapse and an abdominal mass. Only a small number of GIST presenting as a palpable abdominal mass have been reported in the world literature[2]. The patients collapse was probably a result of an acute bleed into the tumour; however no clinical or haematological signs of haemodynamic compromise were evident on presentation to emergency services.

The challenges of the operation described above were the large size of the tumour and the penetration of its bulk through the transverse mesocolon. The tissue sensing properties of the HARMONIC ACE®+ enabled us to preserve most of the middle colic vessels, thereby avoiding the added trauma of a concomitant colectomy.

To our knowledge, use of an ultrasonic scalpel has not been reported in open surgery for gastric GIST, however its benefits have been reported in the open resection of gastric cancer. One group found the device to decrease operating time, blood loss and operator stress during lymphadenectomy[3]. These findings were recently confirmed in a trial that, in addition to the above, showed a shorter length of hospital stay and a higher number of lymph nodes harvested in the group undergoing gastrectomy with an ultrasonic scalpel[4]. Overall hospitalisation costs were found to be equal between the traditional and ultrasonic scalpel surgery groups.

This technically challenging case demonstrates that utilisation of the new generation ultrasonic scalpel in the open resection of giant GIST of the stomach is feasible. The device's tissue sensing technology may help in preserving vital structures and therefore may lessen the extent of resection, reducing morbidity.

## COMMENTS

### *Case characteristics*

A technically challenging case of a giant gastric gastrointestinal stromal tumours (GIST) resection facilitated by the HARMONIC ACE®+ ultrasonic scalpel.

### *Clinical diagnosis*

A giant gastric GIST presenting with collapse and a palpable abdominal mass.

### *Differential diagnosis*

The main differential diagnosis in a patients presenting with collapse and an abdominal mass is an abdominal aortic aneurysm rupture.

### *Laboratory diagnosis*

Routine blood tests performed on admission included a full blood count, liver function tests, urea and electrolytes and C-reactive protein; all of which were unremarkable.

### *Imaging diagnosis*

The abdominal ultrasound scan showed a large abdominal mass and computer tomography revealed a large tumour inseparable from the greater curve of the stomach with a central necrotic area.

### *Pathological diagnosis*

Histopathological macroscopic examination revealed a greyish, pale, soft tumour which on microscopic examination and immunostaining was compatible with a GIST.

### *Treatment*

Resection of the GIST was performed *via* a midline laparotomy and following multidisciplinary team discussion adjuvant treatment with Imatinib was commenced.

### *Term explanation*

GIST. Ultrasonic scalpel - a surgical device that cuts and coagulates tissues by generating friction.

### *Experiences and lessons*

Dissection in proximity to vulnerable structures may be facilitated by the HARMONIC ACE®+ ultrasonic scalpel.

### *Peer review*

Authors describe a case of a giant gastric GIST respected by HARMONIC ACE+ (as stated in the title). The manuscript is well written. Gastric GISTs are very well known entity.

## Abstract

We report a case of a traveler who visited Uganda for 8 d, and took mefloquine one tablet/week for malaria prophylaxis. After the second dose, he suffered from two episodes of loss of consciousness with seizures, therefore mefloquine was discontinued. During the flight back after full recovery, seizures reoccurred while he was on board, he was disembarked in Addis Ababa and then transferred to Nairobi. After repatriation to Italy, he experienced four other similar episodes. The patient was still on full dose anticonvulsant therapy one year and a half after, as any attempt at reduced dose was unsuccessful. Currently, three agents (mefloquine, atovaquone/proguanil, and doxycycline) are recommended for malaria chemoprophylaxis, with similar efficacy but different adverse event profiles, regimens, and prices. Considering that mefloquine is associated with a higher risk of neurologic and psychiatric adverse events than the alternative regimens, we suggest considering mefloquine as a second line choice after atovaquone/proguanil and doxycycline for short-term travelers.

**Key words:** Mefloquine; Neuropsychiatric disorders; Epilepsy; Antimalarial chemoprophylaxis; Side effects

**Core tip:** We report a case of epilepsy due to mefloquine chemoprophylaxis. Considering that mefloquine is associated with a higher risk of neurologic and psychiatric adverse events than the alternative regimens, we suggest considering mefloquine as a second line choice after atovaquone/proguanil and doxycycline for short-term travelers.

## INTRODUCTION

According to most international guidelines[1-4], atovaquone/proguanil, doxycycline and mefloquine are all indicated as the first choice for the chemoprophylaxis of *Plasmodium falciparum* malaria. The efficacy of the three drugs seems to be comparable[5], but side effects and costs are different. Although a causal relationship between the drug intake and a severe side effect is usually difficult to demonstrate, it is well known that mefloquine is associated with a high risk of neurologic and psychiatric disorders (NPD). Weinke *et al*[6] estimated that one of 13000 travelers receiving mefloquine chemoprophylaxis suffers from serious central nervous system reactions. Barrett *et al*[7], in a postal and telephone survey, reported that 0.7% of

travelers taking mefloquine had disabling NPD.

Adverse events related to mefloquine mostly occur in people with a past history of seizures or manic-depressive illness[8], but in literature there are reports of cases of seizures in travelers, with no previous personal or family history of epilepsy, after taking mefloquine for treatment[9] or prophylaxis[10].

## CASE REPORT

A 40-year-old Italian traveler visited Uganda for 8 d, and took mefloquine one tablet/week for malaria prophylaxis. His weight was 70 kg. His clinical history was unremarkable and he had no history of alcohol or tobacco abuse. He was vaccinated against yellow fever, hepatitis A and tetanus-diphtheria. Upon arrival in Kampala, after the second dose of mefloquine, he suffered from two subsequent episodes of grand mal seizure, therefore mefloquine was discontinued. The duration of the two episodes was about 5 min and the patient remained unconscious for 10 min. During the flight back after full recovery, seizures reoccurred while he was on board, so he was disembarked in Addis Ababa. One further episode occurred at the airport and another one upon urgent admission to the hospital. He was then transferred to Kenya Nairobi Hospital under suspicion of meningitis or cerebral malaria (both were later ruled out), where he started on phenytoin 100 mg twice a day.

After repatriation to Italy, two weeks after the first crisis, an electroencephalogram showed diffuse epileptiform abnormalities, while a brain-RM was negative. Then, he experienced four similar episodes and was treated with diazepam. Moreover, phenytoin was replaced by levetiracetam 500 mg twice a day. Levetiracetam was stopped after 6 mo, but subsequent seizure episodes required another course of anticonvulsivant prophylaxis, with sodium valproate 500 mg twice a day. The patient was still on full dose anticonvulsant therapy one year later, as any attempt at dose reduction was unsuccessful.

## DISCUSSION

Currently, three drugs (mefloquine, atovaquone/proguanil, and doxycycline) are recommended for malaria chemoprophylaxis, with similar efficacy but different adverse event profiles, regimens, and prices[5]. The choice of the different drugs depends on the levels of malaria transmission and presence of drug resistance in the destination area, on specific characteristics of the traveler (*e.g.*, underlying health conditions, possible pregnancy, compliance to daily/weekly therapies), on the duration and purpose of travel and on costs. Jacquerioz *et al*[11], in a review of drugs for preventing malaria in travelers, conclude that atovaquone-proguanil and doxycycline are the best tolerated agents and mefloquine is associated with adverse NPD. NPD includes two categories of symptoms: central and peripheral nervous system disorders (including headache, dizziness, vertigo, seizures) and psychiatric disorders (including major psychiatric disorders, anxiety and sleep disturbances)[12]. Controlled studies have shown a significant excess of NPD in mefloquine users[5,13-16]. Moreover, in a recent study, van Essen *et al*[17] suggest that mefloquine disturbs motor learning skills. Considering NPD as potentially severe and dangerous adverse side effects and the availability of drugs with equivalent efficacy, the new Italian indications for malaria prophylaxis[18] proposed mefloquine as a second line choice after atovaquone/proguanil and doxycycline for short-term travelers. However, mefloquine keeps playing a fundamental role for specific groups of travelers: pregnant and breastfeeding women, long-term travelers, adults and children visiting friends and relatives (VFR)[19]. Travelling to malaria endemic areas during pregnancy is contraindicated because this disease is an important cause of stillbirth, spontaneous abortion or maternal death[20]. However, for pregnant women who cannot defer their travel (mostly VFR), mefloquine is the only option, as doxycycline is contraindicated in pregnancy and, although proguanil is considered safe and no teratogenicity has been observed in animal studies using atovaquone, there are no sufficient data about safety of atovaquone/proguanil. In fact, mefloquine has been proved to be safe in the first trimester: according to Schlagenhauf *et al*[21], birth defect prevalence and fetal loss after mefloquine exposure in pregnancy were comparable in prospectively monitored cases to background rates. For long-term travelers (nonimmunized travelers who visit malaria endemic areas for a period of six mo or longer), malaria chemoprophylaxis is controversial. Although the risk of malaria increases with longer stays, the adherence to chemoprophylaxis decreases over time. Steffen *et al*[22] reported that compliance with chemoprophylaxis was reported by 57.0% of travellers who spent less than 3 mo in Africa, compared with 29.2% who stayed for 3-12 mo. In case chemoprophylaxis is recommended, mefloquine, if well tolerated, remains a good option in alternative to doxycycline: the weekly dose facilitates a good adherence. Long-term atovaquone/proguanil is now registered in Italy, but a long-term chemoprophylaxis is too expensive. van Riemsdijk *et al*[16] found that NPD occurred more frequently in females and were more common in first-time users. Usually females weigh less than males, so we suggest to modulate the mefloquine dosage by body weight (*i.e.*, people weighing between 40 and 60 kg should take 75% of the tablet)[4]. For a traveler who takes mefloquine for the first time, it is advisable to start chemoprophylaxis 3 wk before travelling, because adverse effects usually appear at the first dose. Lobel *et al*[23] found that the frequency of these events declined with the increasing duration of prophylaxis. Travelers who have taken mefloquine before and had no NPD can usually take this drug again. For many VFR families,

who stay long in high-risk areas, mefloquine represents a good option because of its low cost and weekly administration. Moreover, mefloquine is effective and well tolerated in children weighing < 20 kg[24]. Considering that mefloquine is often the only drug that can be prescribed for young children VFR, because doxycycline is contraindicated in children < 8 years and atovaquone/proguanil is generally too expensive, mefloquine is considered the best option for VFR families.

In conclusion, we suggest considering mefloquine as a second choice for short-term (less than one mo) travelers; however, mefloquine remains a good option, in alternative to doxycycline, for long-term travelers and the first choice for pregnant women and VFR families.

## COMMENTS

### *Case characteristics*

Grand mal seizures after taking mefloquine for malaria prophylaxis.

### *Clinical diagnosis*

The duration of each of the two episodes of grand mal seizures was about 5 min and the patient remained unconscious for 10 min.

### *Differential diagnosis*

Epilepsy due to other causes.

### *Imaging diagnosis*

Electroencephalogram showed diffuse epileptiform abnormalities, while a brain-RM was negative.

### *Treatment*

The patient was treated with phenytoin 100 mg twice a day, then with levetiracetam 500 mg twice a day, and then with sodium valproate 500 mg twice a day.

### *Related reports*

Adverse events related to mefloquine mostly occur in people with a past history of seizures or manic-depressive illness, but in literature there are also reports of cases of seizures in travelers who had no previous personal or family history of epilepsy, after taking mefloquine for treatment or prophylaxis.

### *Experiences and lessons*

Authors suggest considering mefloquine as a second choice for short-term (less than one mo) travelers; however, mefloquine remains a good option, in alternative to doxycycline, for long-term travelers and the first choice for pregnant women and visiting friends and relatives families.

### *Peer review*

This article highlights possible severe side effects of mefloquine and suggest to consider other drugs as a first choice for malaria chemoprophylaxis.

## Abstract

Gullo's syndrome is a newly identified condition characterized by a chronic elevation of pancreatic amylase and/or lipase in the absence of pancreatic disease. Until now, only one case of benign isolated hyperlipasemia in children has been recorded. We describe two children with benign and not familial increase of serum lipase. Case 1: a six year old girl presented with occasional discovery of serum lipase elevation. Medical history was silent for pancreatic hyperenzymemia. The screening for possible causes for elevated lipase (genetic, autoimmune and infectious diseases) was normal. The serum lipase increased three fold over the upper limit (193 U/L; reference range 0-60 U/L), with daily fluctuation of values. Both ultrasound scan and magnetic resonance imaging were normal. The genetic mutation associated with chronic pancreatitis was negative. We followed up this patient for two years with blood tests every six months and she did not show any signs or symptoms of pancreatic disease, except for the high level of lipase serum. Case 2: an eight year old girl complained of nausea, vomiting and severe abdominal pain in the epigastric region after eating for the last two weeks. Full blood count, electrolytes, C-reactive protein, liver and renal function were normal. Serum lipase was 96 U/L (reference range 0-60 U/L). The screening for the possible causes of pancreatic disease was negative. Endoscopy of the upper gastrointestinal tract, ultrasound, computed tomography scan and magnetic resonance imaging were normal. One year after the presentation of the symptoms, the patient became asymptomatic although the level of serum lipase continued to be high.

**Key words:** Amylase; Lipase; Pancreatic hyperenzymemia; Gullo's syndrome; Benign hyperlipasemia

**Core tip:** Benign hyperlipasemia is a rare condition in children. The identification of this condition could be very useful for pediatricians in the diagnosis and management of hyperlipasemia. The cause of pancreatic hyperenzymemia seems to be related to a defected pathway from the trans-Golgi network to basolateral cell membrane. It has been hypothesized that a defect in this pathway could be responsible for the increased passage of enzymes into circulation. "Gullo's syndrome" remains a diagnosis of exclusion and clinicians still need to be vigilant of the wide-ranging conditions that can manifest initially with elevations in lipase/amylase.

Lionetti E, Francavilla R, Leonardi S, Tomarchio S, Gennaro A, Franzonello C, La Rosa M. Two rare cases of benign hyperlipasemia in children. *World J Clin Cases* 2014; 2(1): 16-19 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i1/16.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i1.16

## INTRODUCTION

Gullo first described in adults a new syndrome character-

ized by a benign chronic increase of serum pancreatic enzymes in the absence of pancreatic or other pathologies[1]. This condition is often familial, although sporadic cases have also been described[2]. In another study, the same investigator found that this syndrome can also be present in children. In the majority of cases (95%), the hyperenzymemia concerns all pancreatic enzymes; in 5% of cases it is possible to observe an increase of only the amylase and rarely of only the lipase[3]. In this report, we describe two pediatric cases of the rare form of benign hyperlipasemia.

## CASE REPORT

### Case 1

A six year old girl came to our outpatient department for the occasional discovery of serum lipase elevation with normal amylase level during routine blood tests. She was third born by normal delivery of non-consanguineous parents. Her medical history was silent except for a surgery because of funicular hernia when she was one year old. There was no familial history of pancreatic hyperenzymemia or of other relevant diseases. At physical exam, her weight, height and body mass index were 20.8 kg, 123.5 cm and 14 kg/m$^2$ (10$^{th}$ centile), respectively; there was no clinical sign of pancreatic or other diseases. Routine blood tests were normal (full blood count, serum glucose, liver and renal function tests, total and fractioned blood bilirubin, blood iron subset and immunoglobulin). In order to assess a possible cause for the elevated lipase level, the following tests were done: lipid subset, cytomegalovirus serology and cultures, Ebstein-Barr, toxoplasma, rubella, parvo and herpes virus serology, autoimmunity profile, including anti-transglutaminase antibodies, perinuclear antibodies, antineutrophil cytoplasm and anti-Saccharomyces cerevisiae antibodies, C-peptide and islet cell antibodies, fecal elastase, serum trypsinogen, IgG4 and sweat analysis; they all were within the normal range. Amylase and pancreatic isoamylase as well as serum lipase concentrations were determined by an enzymatic colorimetric method (Beckman Instruments, Fullerton, CA) and the only abnormal parameter was the serum lipase, increased three fold over the upper limit (193 U/L, reference range: 0-60 U/L), with daily fluctuating values. Due to the persistence of increased lipase, abdominal ultrasound scan and magnetic resonance imaging were also performed and did not show any pathological signs. The genetic mutations associated with chronic pancreatitis, including mutations for autosomal recessive cystic fibrosis transmembrane conductance regulator (CFTR) [by two validated commercial kits (INNO-LiPA CFTR 19 and INNOLiPA CFTR 17 Tn polymorphism, Innogenetics *N.V.*, Ghent, Belgium), which simultaneously detect 36 mutations and the Tn polymorphism], autosomal dominant PRSS1 and pancreatic trypsin SPINK1, were also negative, such as the familial screening for pancreatic hyperenzymemia. Having ruled out all the common causes of hyperlipasemia, we decided to follow up this patient with blood tests every six months. For the entire 2 years of follow up, the child did not show signs or symptoms of pancreatic or other diseases, and blood tests as well as the ultrasound morphology of her pancreas continued to be normal, except for blood lipase levels that fluctuated widely during the whole period of follow up [lipase median value: 194 U/L (reference range: 0-60 U/L) (range: 179-218 U/L); mean ± SD: 195.8 ± 12.9 U/L. Pancreatic isoamylase median value: 34.5 U/L (reference range) (0-46 U/L) (range: 30-43 U/L); mean ± SD: 35.2 ± 4.5 U/L].

### Case 2

An eight year old girl was referred to our outpatient clinic for abdominal pain for the last two weeks. She complained of nausea, vomiting and severe abdominal pain of short duration localized at the epigastric region, occurring mainly after eating; there was no history of abdominal trauma. On medical examination, she was afebrile, the abdomen was slightly distended and tender; her weight, height and body mass index were 25 kg, 130 cm and 14.8 (25$^{th}$ centile), respectively. No weight loss preceded the onset of pain. To exclude organic causes, the following investigations were performed and were normal: full blood count, liver and renal function tests, serum glucose and electrolytes, total cholesterol and fractions, erythrocyte sedimentation rate and C-reactive protein. Serum amylase and lipase concentrations were 124 U/L (reference range 0-46 U/L) and 96 U/L (reference range 0-60 U/L), respectively. Salivary isoamylase and urinary amylase were normal. Amylase became normal in the following five days, while lipase concentrations remained elevated (4-5 fold above the reference value). The diagnostic work-up for pancreatic diseases was started and all the following tests returned within normal range: serology for infective diseases, autoimmunity, fecal elastase, serum trypsinogen, IgG4, sweat test and genetic markers for chronic pancreatitis. Endoscopy of the upper gastrointestinal tract with antral and duodenal biopsies did show any alteration to the esophagus, stomach and duodenal bulb. Morphological assessment (ultrasound scan and magnetic resonance imaging) showed normal pancreatic parenchyma and biliary and pancreatic tree. Familial screening for pancreatic hyperenzymemia was also negative.

During hospitalization, the child recovered from the abdominal pain in the following two days; however, the serum level of lipase remained elevated although it fluctuated. One year after presentation, the patient became asymptomatic although the serum lipase remained elevated [lipase median value: 240 U/L (reference range: 0-60 U/L) (range: 96-480 U/L); mean ± SD: 264 ± 166.6 U/L. Pancreatic isoamylase median value: 41.5 U/L (reference range 0-46 U/L) (range: 37-124); mean ± SD: 264 ± 166.6 U/L].

## DISCUSSION

Pancreatic hyperenzymemia is a rare finding in children; it can be due to different pathological conditions, the most frequent being acute or chronic pancreatitis[4,5]. Other causes of serum lipase elevation have been identified in a

**Table 1 Principal causes for increased serum levels of pancreatic enzymes**

| Causes | Suggested work-up |
|---|---|
| Pancreatic diseases | Full blood count, erythrocyte sedimentation rate, PCR, immunoglobulin |
| Drugs | Liver function tests |
| Infections | Fecal elastase |
| Tumors | Serum trypsinogen |
| Autoimmunity | IgG4 |
| Trauma | Cytomegalovirus serology and cultures, Ebstein-Barr, toxoplasma, rubella, parvo and herpes virus serology |
| Anatomic anomalies | Sweat analysis |
| Gene mutation | Genetic analysis (CFTR, PRSS1, SPINK1) |
| Cystic fibrosis | US |
| Viral hepatitis | CT scan |
| Surgery | |
| Biliary diseases | Full blood count, erythrocyte sedimentation rate, PCR, immunoglobulin |

number of conditions, such as acute cholecystitis, Gilbert syndrome, hypertrigliceridemia, intestinal infarction, duodenal ulcer, obstruction or inflammatory bowel disorders, liver diseases, abdominal trauma[6], diabetes ketoacidosis[7] and renal insufficiency (Table 1)[8].

Interestingly, Gullo *et al*[2] have recently shown the existence of a benign pancreatic hyperenzymemia defined as an abnormal increase in serum pancreatic enzymes that occurs in healthy adults or children in the absence of pancreatic or other disease; it is asymptomatic and persists over time with considerable fluctuation in serum enzyme concentrations. At least 1-2 years must pass after the initial finding of the hyperenzymemia before it can be considered benign. It can be familial (when the patient has at least one family member with the same anomaly) or sporadic. The authors studied this condition in 15 children with hyperenzymemia. Among them, 13 were found with high levels of all pancreatic enzymes, one with normal range of enzymes, and only one was found with an increased level of the only lipase. The condition was familial in 12 children and sporadic in three of them. To our knowledge, there are no other studies in children reporting the isolate benign increase of serum lipase, while two studies recorded one case each of familial hyperamylasemia[9,10].

In this report, we described the second two cases in the literature of benign hyperlipasemia. During the whole period of follow-up, the two children did not present with any signs or symptoms of pancreatic or other diseases, and blood tests as well as the ultrasound morphology and the imaging study of their pancreas remained normal, showing the benign nature of this abnormality. A limitation of the present case report may be the non-availability of the nasal potential difference test for the diagnosis of subclinical form of cystic fibrosis, although genetic screening and sweat analysis were negative. In the second case, initial elevations of both amylase and lipase with ongoing persistence in lipase may suggest a pancreatic origin, but not detectable based on limitations of current available tests. It is important to point out that, even if rarely (1%-2% of cases), an apparently benign pancreatic hyperenzymemia can be the first clinical sign of a pancreatic tumor, which may declare itself in the following years[2].

In our experience, these cases were sporadic, considering that familial enzymes were normal. The cause of pancreatic hyperenzymemia and the reason for its fluctuating behavior is not known. It has been shown that there is a direct, constitutive-like pathway from the trans-Golgi network to the basolateral cell membrane, by which newly synthesized enzymes reach the circulation. It has been hypothesized that a defect in this pathway could be responsible for the increased passage of enzymes into circulation[2].

The fluctuating behavior could depend on the degree of the cellular defect, with the passage of enzymes being sporadic when the defect is mild and more frequent when it is more severe or extensive[2].

"Gullo's syndrome" remains a diagnosis of exclusion and clinicians still need to be vigilant of the wide-ranging conditions that can manifest initially with elevations in lipase/amylase. However, clinicians should be aware that failing to diagnose the cause, the condition of idiopathic hyperlipasemia (or hyperamylasemia) can be diagnosed and is usually associated with a benign course. According to Gullo, we believe that the knowledge of this condition should be helpful to the pediatrician in diagnosis and management, assuring the clinician and alleviating the concern of the child's parents[1]. A larger cohort of patients and longer follow-up are needed to evaluate the exact proportion of this clinical chemical constellation and to better understand the etiology, natural history and the real benign nature of this condition.

## COMMENTS

### *Case characteristics*

The two cases of benign hyperlipasemia have a different clinical presentation; while the first case was asymptomatic, the second case showed nausea, vomiting and severe abdominal pain at the epigastric region.

### *Clinical diagnosis*

Medical examination was silent for pancreatic diseases.

### *Laboratory diagnosis*

The screening for possible causes for elevated lipase and amylase (genetic, autoimmune and infectious diseases) was normal.

### *Pathological diagnosis*

In the second case, endoscopy of the upper gastrointestinal tract with antral and duodenal biopsies did show any alteration to the esophagus, stomach and duodenal bulb.

### *Related reports*

It is very important to know this condition because an apparently benign pancreatic hyperenzymemia can be the first clinical sign of a different pathological condition.

### *Experiences and lessons*

Benign hyperlipasemia remains a diagnosis of exclusion and clinicians still need to be vigilant of the wide-ranging conditions that can manifest initially with elevations in lipase/amylase.

### *Peer review*

This report describes the second two cases in the literature of benign hyperlipasemia but a larger cohort and longer follow-up are needed to better understand the natural history of this condition.

## Abstract

We present the case of a 74 year old woman suffering from severe mitral valve incompetence and rapid atrial fibrillation. After an appropriate vitamin K antagonist (VKA) therapy, the patient underwent mitral valve replacement by bioprosthesis. Then, the patient was re-hospitalized for jaundice. Suspecting hepatotoxicity, VKA was discontinued and fondaparinux was started. During this treatment, the patient developed a symptomatic atrial thrombus. After exclusion of a hepatic disease, VKA was re-established with hemodynamic and liver enzymes normalization and atrial thrombus resolution. Caution has to be used when considering fondaparinux as an alternative strategy to VKA in patients with multiple thrombotic risk factors.

**Key words:** Mitral valve; Thrombus; Prosthetic valve; Atrium; Hepatotoxicity

**Core tip:** Thromboembolism represents an important complication following heart valve replacement. This case report shows that although vitamin K antagonist (VKA) treatment represents the elective therapy in patients with left atrial thrombosis without mitral valve dysfunction, it may not be sufficient to avoid thrombogenesis. We also recommend that the discontinuation of VKA during the first three months after mitral valve surgery has to be carefully considered, especially in high thromboembolic risk patients.

Left atrial thrombosis in an anticoagulated patient after bioprosthetic valve replacement: Report of a case. *World J Clin Cases* 2014; 2(1): 20-23 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i1/20.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i1.20

## INTRODUCTION

Thromboembolism represents an important complication following heart valve replacement. The international guidelines on the management of valvular heart disease recommend postoperative anticoagulation therapy (AT)[1].

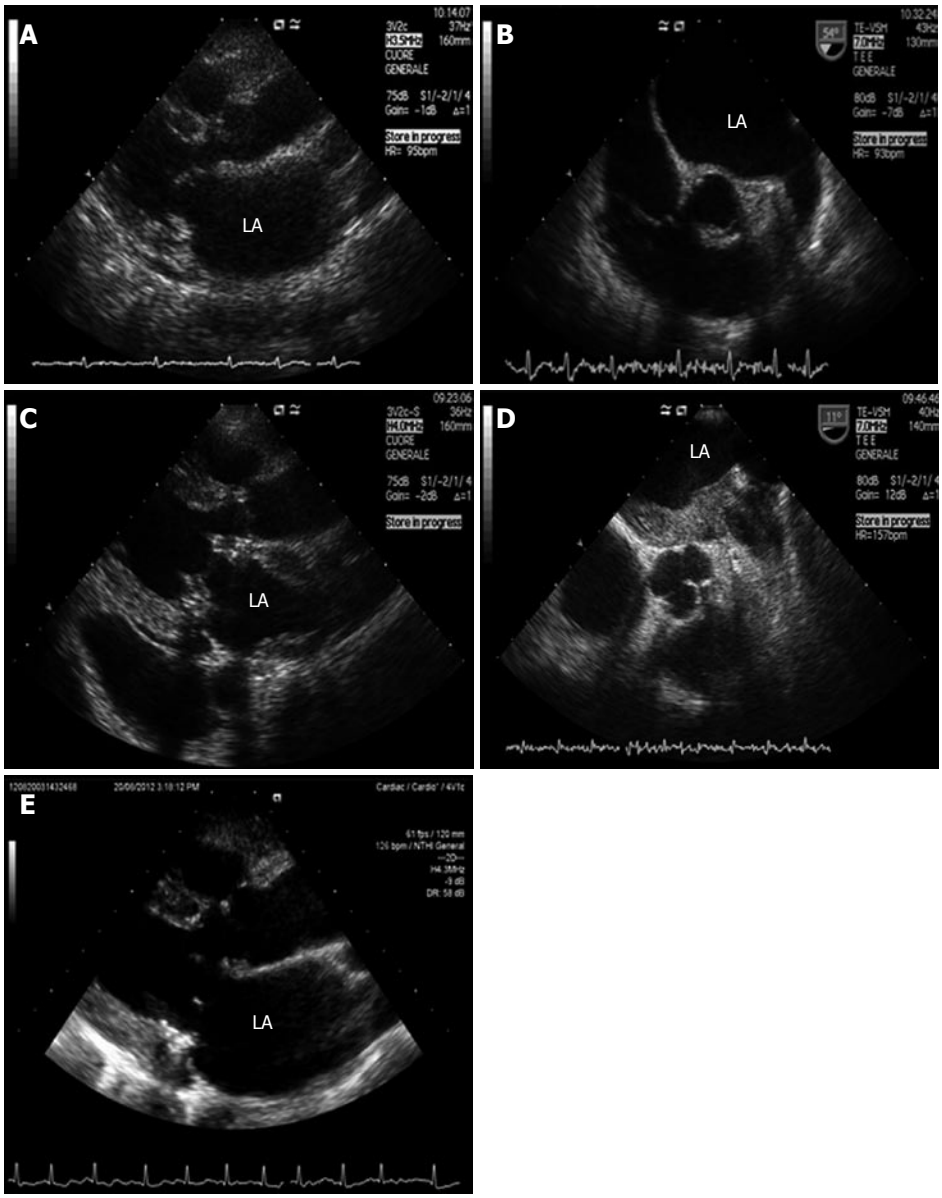

**Figure 1 Echocardiographic image.** A: Left parasternal long axis transthoracic echocardiography; B: Upper transesophageal views of the aortic valve in short axis; C: Left parasternal long axis transthoracic echocardiography; D: Upper transesophageal views of the aortic valve in short axis; E: Left parasternal long axis transthoracic echocardiography. LA: left atrium.

While mechanical valves require lifelong anticoagulation therapy, bioprosthetic valve (BV) recipients can avoid long-term use. Owing to the higher frequency of thromboemboli in the first 3 mo after BV insertion, three months of AT is recommended for patients not receiving antithrombotic therapy, especially for those who undergo bioprosthetic mitral valve replacement[2]. However, in the presence of atrial fibrillation (AF), heart failure and impaired LV function (ejection fraction < 30%), AT has to be continued for life.

## CASE REPORT

A 74 year old woman with a history of valvular rheumatic disease, acute myocardial infarction, autoimmune thrombocytopenia and paroxysmal atrial fibrillation presented with palpitations and rapid worsening of dyspnea. She was on antithrombotic therapy with acetylsalicylic acid. EKG showed rapid atrial fibrillation. Transthoracic echocardiography (TTE) demonstrated severe mitral valve incompetence and mild stenosis, enlarged left atrium and right chambers, and severe tricuspid regurgitation (Figure 1A). Appropriate vitamin K antagonist (VKA) therapy was administered.

Transesophageal echocardiography (TEE) showed no thrombus in the left atrium (LA) or in the left atrial appendage (Figure 1B). Since the pharmacological therapy was unable to control the rhythm, the patient was successfully submitted to electrical cardioversion. Five weeks later, the patient underwent mitral valve replacement by Carpentier-Edwards Perimount Magna bioprosthesis (Edwards Lifesciences, Irvine, CA, United States) and tri-

cuspid valve annuloplasty.

In June 2012, the patient was re-admitted because of jaundice and abdominal pain. EKG showed atrial fibrillation. Liver and biliary tract diseases were ruled out despite hyperbilirubinemia and cholestasis indexes (bilirubin was 15.63 mg/dL, γ-glutamyltransferase 1638 U/L, alkaline phosphatase 621 U/L, aspartate aminotransferase 30 U/L, alanine aminotransferase 63 U/L). VKA was discontinued due to suspected hepatotoxicity and fondaparinux was subcutaneously administered (5.0 mg/d). Due to peripheral edema, jugular turgor and hepatomegaly, TTE was repeated over the following days. We found a mass stratified on all the atrial walls (Figure 1C). TEE confirmed that the image was suggestive of thrombus (Figure 1D). Diagnostic workup excluded a thrombophilic state, viral/autoimmune liver disease, cancer or biliary duct pathology. In the first days of July 2012, VKA treatment was re-started and fondaparinux was stopped. In August 2012, the patient showed hemodynamic stability and normalization of the liver function and enzymes, while TTE excluded the presence of a thrombus in the left atrium (LA) (Figure 1E). During 5 mo of follow up, the patient remained asymptomatic.

## DISCUSSION

Unlike mechanical heart valves, BV insertion is associated with a very low rate of thrombosis (approximately 0.03% per year)[3]. After BV implantation, AT is recommended for the first 3 mo and for life only in the presence of atrial fibrillation, heart failure, impaired left ventricular function or history of thromboembolism. Currently, the only oral drugs approved for AT are VKAs.

There is no scientific evidence that the new oral antithrombotic agents (*e.g.*, dabigatran, rivaroxaban and apixaban) are effective in these patients. Nevertheless, these drugs could represent a new interesting option because of their elevated safety and efficacy due to their pharmacodynamic profile and the absence of drug-to-drug interactions. The only possible alternatives to VKAs are unfractionated heparin (UFH) and low molecular weight heparins (LMWHs), but they must be administered intravenously or subcutaneously[1]. Our patient was admitted nearly 40 d after mitral valve surgery when anticoagulation therapy is considered mandatory. Since she was at high thrombotic risk (*e.g.,* age, left ventricular dysfunction, atrial fibrillation, left atrial enlargement with atrial contractile failure), on the basis of the current guidelines, she should have continued AT indefinitely. This treatment strategy is mandatory for the primary prevention of cardioembolic ischemic stroke in patients with cardiac disorders (such as atrial fibrillation). Cardioembolic stroke is considered a high-risk complication and it represents the subtype of ischemic infarct with the highest in-hospital mortality (20%)[4].

Clinical practice shows that VKA therapy is very effective but long-term administration may be difficult, especially in elderly patients due to the variability in drug metabolism, drug-drug and drug-food interactions, patient compliance and risk of bleeding events.

The beginning of VKA therapy is burdened by a prothrombotic state, so we associated LMWH for few days until reaching the international normalized ratio (INR target), as recommended by international guidelines to avoid thromboembolism.

Our case confirmed this aspect: INR was 4.6 following heart surgery and 1.5 at re-hospitalization after four weeks of therapy at home. Thus, we had to improve anticoagulation by VKA therapy but our concern was related to the increased bilirubin levels and cholestatic indexes suggestive of an acute hepatitis with liver damage.

First of all, we excluded the most frequent causes of acute liver disease. No evidence of viral hepatitis, cholelithiasis and no use of hepatotoxic drugs or toxin ingestion were found. Thus, we theorized that the cause of increased bilirubinemia and cholestatic index levels could be related to the right heart failure with hepatic blood stasis and secondary liver dysfunction.

On the other hand, in accordance with previous reports[5], we did not continue administering VKAs. Furthermore, we could not administer UFH or LMWH due to the history of immune thrombocytopenia and, moreover, we found some reports of LMWH-induced hepatotoxicity. Thus, we decided to administer fondaparinux. We found little evidence (two experimental models[6,7] and a case report[8]) supporting the administration of fondaparinux (7.5 mg once per day) to prevent thrombosis in patients with mechanical heart valves. At that time, we speculated on the potential usefulness of a concomitant antiplatelet therapy (APT). However, we excluded this option considering that there was no evidence of improved efficacy and only an increased hemorrhagic risk.

During an echocardiogram that was carried out to investigate the clinical signs of right heart failure, we found a giant left atrial thrombosis.

These findings, together with the normalization of the hepatobiliary function indexes, suggested to us to discontinue fondaparinux and re-start VKA treatment. Another issue supporting this therapeutic strategy was represented by the concomitant presence of atrial thrombosis without valve dysfunction.

After one month of correct VKA therapy (INR target: 2-3), we not surprisingly found a normally functioning prosthetic valve, accompanied by the resolution of atrial thrombosis. Whether oral anticoagulation may result in the lysis of a thrombus is not clear. Studies carried out for cardioversion in atrial fibrillation have shown that 3-4 wk of warfarin therapy leads to complete resolution of atrial thrombi in 80%-90% of cases without evidence of clinical thromboembolism or residual organized adherent thrombus[9]. In our patient, this thrombus remodeling may have favored its re-absorption.

Although VKA treatment represents the elective therapy in patients with left atrial thrombosis without mitral valve dysfunction, this case shows that it may be not suit-

able for avoiding thrombogenesis. This case shows that in very high thromboembolic risk patients, VKA therapy never must be discontinued.

This case also suggests that discontinuation of VKAs during the first three months after mitral valve surgery has to be carefully considered, especially in high thromboembolic risk patients. Although we used fondaparinux as an alternative strategy, the efficacy of this drug requires further validation in larger clinical trials.

## COMMENTS

### *Case characteristics*

A 74 year old woman with high thromboembolic risk (including atrial fibrillation and previous mitral valve replacement) presented with peripheral edema, jugular turgor and hepatomegaly after withdrawal of the vitamin K antagonist, replaced by fondaparinux.

### *Clinical diagnosis*

Left atrial thrombus and right heart failure.

### *Differential diagnosis*

Left atrial thrombus spontaneous formation or promoted by vitamin K antagonist withdrawal.

### *Laboratory diagnosis*

The metabolic panel that led to the vitamin K antagonist withdrawal showed an increase of bilirubinemia (total bilirubin 15.63/dL), γ-glutamyltransferase (1638 U/L), alkaline phosphatase (621 U/L), aspartate aminotransferase (30 U/L) and alanine aminotransferase (63 U/L).

### *Imaging diagnosis*

Transthoracic echocardiography found a left atrial mass consistent with a thrombus. Transesophageal echocardiography confirmed this insight.

### *Treatment*

The re-initiation of therapy with the vitamin K antagonist led to complete thrombus resolution.

### *Related reports*

Potential liver toxicity induced by the vitamin K antagonist should be considered in clinical practice due to the wide distribution of this drug.

### *Experiences and lessons*

In expectation of new oral antithrombotic agents, the vitamin K antagonist remains the first choice for preventing thrombotic event in high-risk patients. In addition, these patients require a long-term therapy.

### *Peer review*

This article recommends a long-term anticoagulant therapy in high-risk patients and identifies the vitamin K antagonist as the most effective drug.

## Abstract

Jejunogastric intussusception is a rare long term complication of Billroth Ⅱ gastrectomy. The case reported here is a 50 year old man with history of a Billroth Ⅱ gastrectomy and Braun's side-to-side jejunojejunal anastomosis who presented with hematemesis. On abdominal examination, there was a mass in the left iliac fossa. Computed tomography scan showed a retrograde jejunogastric intussusception across the gastrojejunostomy. On laparotomy, a retrograde intussusception of the distal jejunum through the jejunojejunal anastomosis and across the gastrojejunostomy with a gangrenous intussusceptum was found. The jejunojejunal anastomosis was taken down, the gangrenous segment was resected and bowel continuity was restored with two jejunojejunal anastomoses, proximal and distal to the gastrojejunostomy. The gastrojejunostomy was preserved. This case brings out an unusual type of retrograde gangrenous intussusception which occurred at two points of a previous anastomosis, *i.e.*, jejunojejunostomy and gastrojejunostomy simultaneously, which could be managed with jejunal resection.

**Key words:** Retrograde; Intussusception; Billroth Ⅱ gastrectomy; Jejunojejunostomy

**Core tip:** Retrograde jejunojejunal and jejunogastric intussusceptions are rare. The occurrence of retrograde intussusception across two anastomoses has not been reported in the literature. A high index of suspicion and timely investigations like an esophagogastroscopy or a computed tomography scan will help to clinch the diagnosis early. Emergency surgical intervention can help to prevent clinical deterioration and save the life of the patient. We would like to emphasize the fact that a high index of clinical suspicion should be maintained in patients with gastroenteric anastomosis who present with hematemesis for the possibility of a retrograde jejunogastric intussusception; the results can be gratifying.

Gopal R, Elamurugan TP, Hage S, Muthukumarassamy R, Kate V. Retrograde jejunogastric intussusception following Braun's jejunojejunostomy. *World J Clin Cases* 2014; 2(1): 24-26 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i1/24.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i1.24

## INTRODUCTION

Retrograde jejunogastric intussusception is a potentially fatal complication of Billroth Ⅱ gastrectomy[1,2]. It is a rare complication of this procedure, with only just over 200 cases reported[2]. Retrograde jejunogastric intussusception can present with varied clinical presentations, like abdominal pain, vomiting, hematemesis, gastric outlet or intestinal obstruction and gangrene gut[1,3-6]. There are limited case reports of jejunojejunal intussusception through a Braun's jejunojejunostomy in cases of total gastrectomy[7]. To the best of our knowledge, there are

**Figure 1 Computed tomography scan of the abdomen showing the intussusceptions of jejunum into the stomach *via* the gastrojejunostomy.**

no reported cases of hematemesis presenting in a patient with retrograde jejunogastric intussusception through a Braun's jejunojejunostomy. We present a case that brings out an unusual type of retrograde gangrenous intussusception which occurred across two points of previous anastomosis, *i.e.,* jejunojejunostomy and gastrojejunostomy simultaneously, and presented with hematemesis.

## CASE REPORT

A 50 year old gentleman who had undergone a Billroth Ⅱ gastrectomy and Braun's side-to-side jejunojejunal anastomosis five years ago for gastric outlet obstruction presented to our emergency department with a one day history of hematemesis. He had five episodes of vomiting altered blood. He gave no history of anything similar in the past. The patient was hemodynamically stable. Abdominal examination did not show any peritoneal signs. An 8 cm × 8 cm mass was palpable in his left iliac fossa. There was no palpable hepatosplenomegaly. An upper gastrointestinal endoscopy was attempted but visualization was poor due to the pooled altered blood. An emergency computed tomography (CT) scan of the abdomen revealed a retrograde intussusception of the jejunum into the stomach across the gastrojejunostomy (Figure 1). The patient was stabilized and taken up for emergency laparotomy. The findings of the CT scan were confirmed intraoperatively. The patient had a gastrojejunostomy and a diverting Braun's side-to-side jejunojejunal anastomosis. The efferent limb of the jejunum distal to the jejunojejunal anastomosis was seen telescoping across the jejunojejunostomy (Figure 2A) into the stomach through the gastrojejunostomy. Schematic representation of the normal anatomy and the retrograde intussusception is shown in Figure 3. The intussuscepted segment was gangrenous (Figure 2B) and there was around 500 mL of altered blood in the stomach but there was no obvious peritoneal contamination. The rest of the bowel, including the intussuscipiens segment, appeared viable. The jejunojejunal anastomosis was taken down and the contents reduced. The gangrenous segment of the jejunum was resected and the gastrojejunostomy was preserved. The bowel

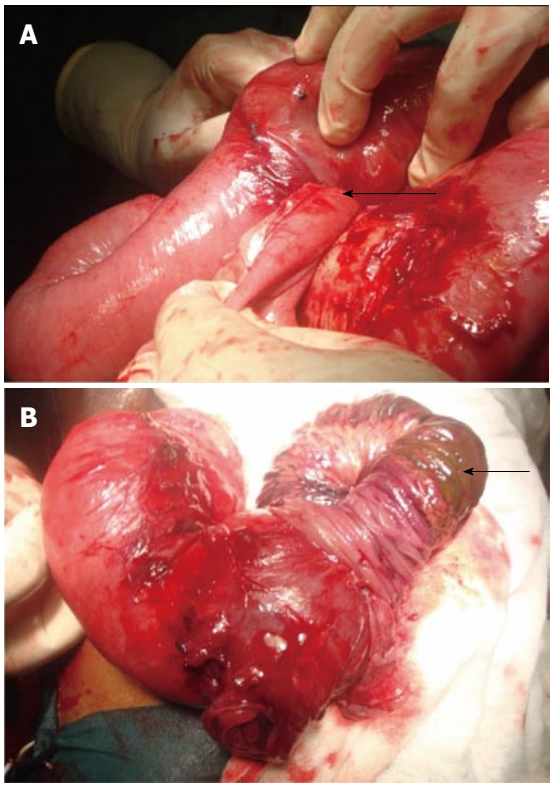

**Figure 2 Intraoperative pictures.** A: Showing the distal jejunum telescoping into the proximal limb across the Braun's jejunojejunal anastomosis; B: Showing the gangrenous intussusceptum after it was reduced from the proximal jejunum.

continuity was restored with two jejunojejunal anastomoses, one proximal and one distal to the gastrojejunostomy. A Witzel's type of feeding jejunostomy was placed distal to the second anastomotic line in the efferent loop. The postoperative period was uneventful. The patient's bowel activity returned to normal on the fourth postoperative day. He was initially started on jejunostomy feeds on the fifth postoperative day, on oral diet in the second postoperative week and discharged from hospital after removal of the feeding jejunostomy tube. The patient was asymptomatic at the first and second month follow-up visits.

## DISCUSSION

Retrograde jejunojejunal and jejunogastric intussusceptions are rare but dangerous long term complications of Billroth Ⅱ gastrectomy and gastrojejunostomy. Jejunogastric intussusception is more common than the jejunojejunal variety[8]. There have also been reports of retrograde intussusception in patients who have undergone Roux-en-Y gastrointestinal anastomosis after gastrectomy[9] but the occurrence of retrograde intussusception across two anastomoses has not been reported in the literature. A high index of suspicion and timely investigations like an esophagogastroscopy or a CT scan will help to clinch the diagnosis early. Emergency surgical intervention can help to prevent clinical deterioration and save the life of the patient[2]. All the reported cases of retrograde intussusceptions of jejunum into the stomach through a gastroje-

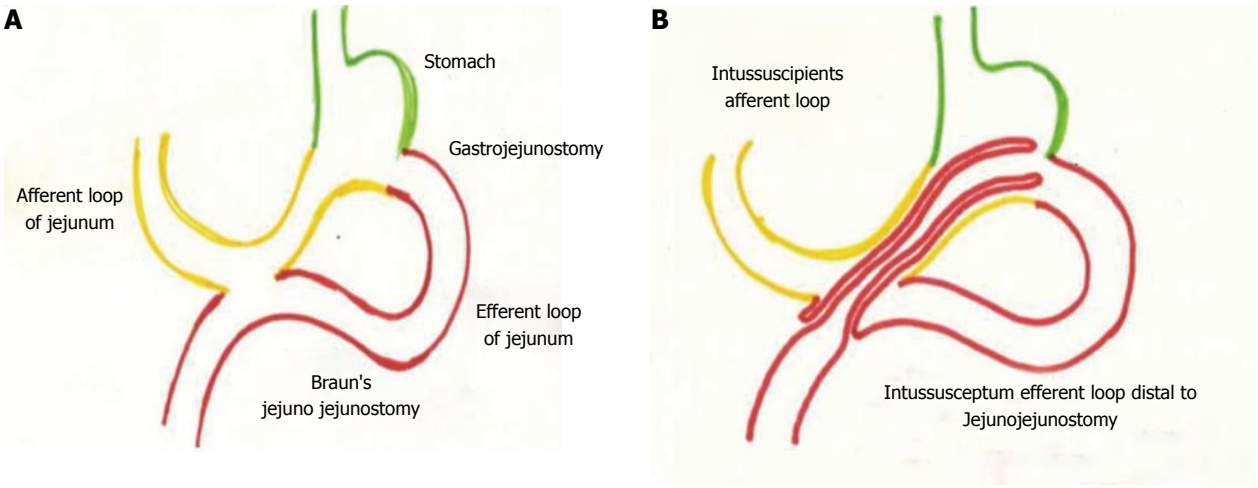

**Figure 3 Schematic representation.** A: The original anastomotic status of the patient; B: Intussusceptions across the jejunojejunostomy and the gastrojejunostomy.

junostomy have been managed by emergency laparotomy and appropriate resection procedures. In our case also, the relatively early presentation, the clinical suspicion and timely imaging helped in the early diagnosis and proper management and survival of the patient. We would like to emphasize the fact that a high index of clinical suspicion should be maintained in patients with gastroenteric anastomosis who present with hematemesis for the possibility of a retrograde jejunogastric intussusception; the results can be gratifying.

## COMMENTS

### *Case characteristics*

A 50 year old man with history of a Billroth II gastrectomy and Braun's side-to-side jejunojejunal anastomosis presented with hematemesis and mass in the left iliac fossa.

### *Clinical diagnoses*

Unusual type of retrograde gangrenous intussusception which occurred at two points of previous anastomosis, *i.e.*, jejunojejunostomy and gastrojejunostomy simultaneously.

### *Differential diagnosis*

Clinical examination, upper gastrointestinal endoscopy and imaging methods can help in arriving at the diagnosis.

### *Imaging diagnosis*

Computed tomography scan showed a retrograde jejunogastric intussusception across the gastrojejunostomy.

### *Treatments*

The jejunojejunal anastomosis was taken down, the gangrenous segment of jejunum was resected and bowel continuity was restored with two jejunojejunal anastomoses, proximal and distal to the gastrojejunostomy.

### *Term explanation*

Braun's gastrojejunostomy: gastrojejunostomy with diverting jejunojejunal anastomosis.

### *Experiences and lessons*

A high index of clinical suspicion should be maintained in patients with gastroenteric anastomosis who present with hematemesis for the possibility of a retrograde jejunogastric intussusception.

### *Peer review*

This is an interesting subject with very good pictures.

## GENERAL INFORMATION

*World Journal of Clinical Cases* (*World J Clin Cases*, *WJCC*, online ISSN 2307-8960, DOI: 10.12998) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

### *Aim and scope*

The primary task of *WJCC* is to rapidly publish high-quality Autobiography, Case Report, Clinical Case Conference (Clinicopathological Conference), Clinical Management, Diagnostic Advances, Editorial, Field of Vision, Frontier, Medical Ethics, Original Articles, Clinical Practice, Meta-Analysis, Minireviews, Review, Therapeutics Advances, and Topic Highlight, in the fields of allergy, anesthesiology, cardiac medicine, clinical genetics, clinical neurology, critical care, dentistry, dermatology, emergency medicine, endocrinology, family medicine, gastroenterology and hepatology, geriatrics and gerontology, hematology, immunology, infectious diseases, internal medicine, obstetrics and gynecology, oncology, ophthalmology, orthopedics, otolaryngology, pathology, pediatrics, peripheral vascular disease, psychiatry, radiology, rehabilitation, respiratory medicine, rheumatology, surgery, toxicology, transplantation, and urology and nephrology.

*WJCC* is edited and published by Baishideng Publishing Group (BPG). BPG has a strong professional editorial team composed of science editors, language editors and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15 471 editorial borad members or peer reivewers, and is a world first-class publisher.

### *Columns*

The columns in the issues of *WJCC* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future research directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers; (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, *etc.*; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in clinical research; (12) Clinical Practice: To briefly report the novel and innovative findings in clinical practice; (13) Meta-Analysis: Covers the systematic review, mixedtreatment comparison, meta-regression, and overview of reviews, in order to summarize a given quantitative effect, e.g., the clinical effectiveness and safety of clinical treatments by combining data from two or more randomized controlled trials, thereby providing more precise and externally valid estimates than those which would stem from each individual dataset if analyzed separately from the others; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJCC*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of clinical medicine; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

## SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

***Biostatistical editing***
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

***Conflict-of-interest statement***
In the interests of transparency and to help reviewers assess any potential bias, *WJCC* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

***Statement of informed consent***
Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

***Statement of human and animal rights***
When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

## SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### *Online submissions*

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/2307-8960/g_info_20100722180909.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjcc@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

## MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### *Title page*

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive foundations should be provided, *e.g.*, Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, *e.g.*, Telephone: +86-10-85381892 Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

### *Abstract*

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/…"), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, *e.g.*, $6.92 \pm 3.86$ *vs* $3.61 \pm 1.67$, $P < 0.001$), and CONCLUSION (no more than 26 words).

### *Key words*

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### *Core tip*

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

### *Text*

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both.

### *Illustrations*

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of

the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: …*etc*. It is our principle to publish high resolution-figures for the E-versions.

### *Tables*

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### *Notes in tables and illustrations*

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of $P$ values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of $P$ values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as $^{1}$F, $^{2}$F, $^{3}$F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

### *Acknowledgments*

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### *Coding system*

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### *PMID and DOI*

Pleased provide PubMed citation numbers to the reference list, *e.g*., PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

### *Style for journal references*

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### *Style for book references*

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### *Statistical data*

Write as mean ± SD or mean ± SE.

### *Statistical expression*

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as $\chi^2$ (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### *Units*

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; $CO_2$ volume fraction, 50 mL/L $CO_2$, not 5% $CO_2$; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/2307-8960/g_info_20100725073806.htm.

### *Abbreviations*

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

### *Italics*

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

### *Examples for paper writing*

All types of articles' writing style and requirement will be found in the link: http://www.wjgnet.com/esps/NavigationInfo.aspx?id=15

## RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

### *Language evaluation*

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

### *Copyright assignment form*

Please download a Copyright assignment form from http://www.wjgnet.com/2307-8960/g_info_20100725073726.htm.

### *Responses to reviewers*

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/2307-8960/g_info_20100725073445.htm.

### *Proof of financial support*

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

## STATEMENT ABOUT ANONYMOUS PUBLICATION OF THE PEER REVIEWERS' COMMENTS

In order to increase the quality of peer review, push authors to carefully revise their manuscripts based on the peer reviewers' comments, and promote academic interactions among peer reviewers, authors and readers, we decide to anonymously publish the reviewers' comments and author's responses at the same time the manuscript is published online.

## PUBLICATION FEE

*WJCC* is an international, peer-reviewed, OA online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium and format, provided the original work is properly cited. The use is non-commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 600 USD per article. All invited articles are published free of charge.

## Abstract

According to the current definition of neuropathic pain ("pain arising as a direct consequence of a lesion or disease affecting the somatosensory system"), the demonstration of a lesion or disease involving the somatosensory system is mandatory for the diagnosis of definite neuropathic pain. Although several methods are currently available for this aim, none is suitable for every type of disease (or lesion). Neurodiagnostic skin biopsy (NSB) is a relatively new technique for the diagnosis of peripheral nerve lesions. It is an objective method, completely independent from the patient's complaining, based on immunohistochemical staining techniques that allow measurement of the density of the epidermal nerve fibers, currently considered the free nerve endings of small diameter (A-delta and C) afferent fibers. NSB has the important property of being used to investigate the skin, allowing obtaining a diagnosis of small fiber axonal neuropathy of peripheral nerves supplying every body part covered by skin. This feature appears to be very important, particularly in cases of unilateral nerve lesions, because it allows going beyond the possibilities of neurophysiological tests which are available only for a limited number of peripheral nerves. All these characteristics make NSB a precious instrument for the diagnosis of peripheral unilateral neuropathic pain.

**Key words:** Skin biopsy; Neuropathic pain; Diagnosis; Peripheral nerve lesion; Innervation

**Core tip:** The demonstration of a lesion or disease involving the somatosensory system is mandatory for the diagnosis of definite neuropathic pain. Unfortunately, none of the currently available methods is suitable for every type of nerve lesion. Neurodiagnostic skin biopsy (NSB) is an objective method to measure the density of epidermal sensory small fibers. In case of unilateral nerve lesions, it goes beyond the diagnostic possibilities of neurophysiological tests, allowing the diagnosis of axonal neuropathies of peripheral nerves supplying every body part covered by skin. For these reasons, NSB represents a precious tool for the diagnosis of peripheral unilateral neuropathic pain.

Buonocore M. Unilateral peripheral neuropathic pain: The role of neurodiagnostic skin biopsy. *World J Clin Cases* 2014; 2(2): 27-31 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i2/27.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i2.27

## UNILATERAL NEUROPATHIC PAIN

In 2008, the special interest group for neuropathic pain of the International Association for the Study of Pain (IASP) proposed a new definition of neuropathic pain: "pain arising as a direct consequence of a lesion or disease affecting the somatosensory system"[1]. This new definition was accepted by the IASP and is now largely used all over the world. According to it, neuropathic pain conditions have several possible mechanisms which ex-

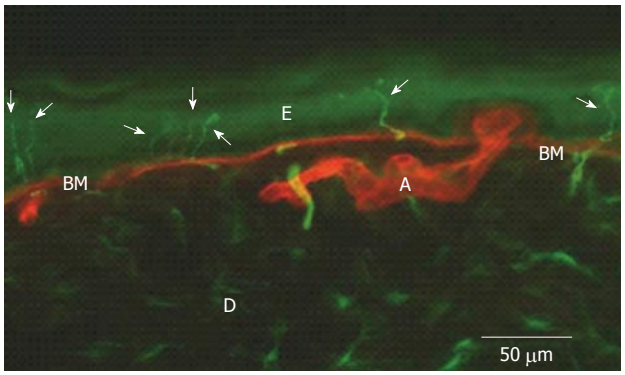

**Figure 1 Epidermal nerve fibers (arrows) identified by immunofluorescence in the distal leg of a normal subject (in green, PGP 9.5 staining of nerve fibers; in red, type Ⅳ collagen staining of basement membrane and blood vessels).** E: Epidermis; D: Dermis; BM: Basement Membrane; A: Artery.

press different phenotypes and clinical presentations. On this basis, neuropathic pain has to be divided into at least central and peripheral neuropathic pain, depending on which part of the nervous system is involved. Peripheral neuropathic pain is sustained by peripheral nerve lesions that can have various types of presentation[2]. In particular, among the multiform pathophysiological expressions, one of the main differences is based on symmetrical or asymmetrical pathology sustaining the painful clinical syndromes. Nerve lesions associated with neuropathic pain can indeed be symmetrical, *e.g.*, polyneuropathies, or asymmetrical, *e.g.*, herpes zoster neuropathy. Although there are well-documented contralateral effects following a painful lesion[3], only asymmetrical nerve lesions sustain the so-called unilateral neuropathic pain.

Several forms of unilateral peripheral nerve lesions are possible[2,4]. They can be roughly divided into mononeuropathies, radiculopathies and plexopathies. The most common clinical presentation is mononeuropathy, *i.e.*, a lesion involving only one peripheral nerve, such as the median nerve lesion in the carpal tunnel syndrome. Another common clinical presentation of unilateral peripheral nerve lesion is radiculopathy, a frequent consequence of an intervertebral disk herniation or other pathologies of the lumbar or cervical spine. Plexopathies are rarer than other unilateral nerve lesions, the most frequent being brachial plexopathy, commonly caused by trauma or disorders involving neighboring structures.

## CLINICAL NEUROPHYSIOLOGICAL TESTS FOR THE DIAGNOSIS OF UNILATERAL PERIPHERAL NERVE LESIONS

In cases of suspected peripheral unilateral neuropathic pain, in order to demonstrate the presence of a peripheral nerve lesion sustaining the painful condition, the first diagnostic step following the clinical examination is usually the execution of neurophysiological tests, in particular electromyography (EMG) and electroneurography (ENG or nerve conduction studies)[5-8]. Unfortunately, those tests have two major limitations. The first is the impossibility of using them in every part of the body (*e.g.*, the trunk) and the second is the fact that they investigate only large diameter fiber functions, part of the lemniscal system which is only one of the two tracts of the somatosensory system, the lesion (or disease) of which is mandatory for the diagnosis of neuropathic pain[1]. Another possible tool to test the function of peripheral large diameter/lemniscal fibers are somatosensory evoked potentials[7,9,10] that can be useful to study the proximal parts of the peripheral nervous system, but substantially share the same limitations of EMG and ENG. The small diameter fibers' functions can be neurophysiologically investigated by Laser Evoked Potentials[10-12], although this test is still confined to specialized neurophysiological labs, is time consuming and currently is not used for routine diagnostic evaluation.

Finally, another test for evaluating small fiber afferent function is Quantitative Sensory Testing[13-15]. The controlled application of thermal stimuli indeed allows investigating the spinothalamic functions, both in its A-delta (cold stimuli) and C component (warm stimuli). The major limit of this method is the necessity for the patient's cooperation. On the other hand, the most important advantage is the possibility of studying the entire body surface and above all to identify and measure hypersensitivity phenomena, such as thermal allodynia and hyperalgesia.

## NEURODIAGNOSTIC SKIN BIOPSY

Neurodiagnostic skin biopsy (NSB) is a relatively new technique for the diagnosis of peripheral neuropathies[16-18]. It is an objective method based on a skin biopsy performed by a circular punch, usually 3 mm diameter, and on immunohistochemical staining techniques that allow identifying the epidermal nerve fibers. To this aim, both bright-field and immunofluorescence (Figure 1) can be used, allowing calculation of the Epidermal Nerve Fiber Density (ENFD)[19]. It is important to underline that epidermal nerve fibers are currently exclusively considered the free nerve endings of small diameter (A-delta and C) afferent fibers[20], a part of the spinothalamic tract physiologically conveying thermal and painful sensations from the periphery to the brain. Interestingly, among all the nerve fibers present in a peripheral nerve, the great majority are just small diameter fibers[21].

## NSB FOR THE DIAGNOSIS OF PERIPHERAL NEUROPATHIES IN BODY PARTS IMPOSSIBLE TO INVESTIGATE BY CLINICAL NEUROPHYSIOLOGICAL TESTS

Due to the continuous advances in knowledge that have occurred in the last ten years, NSB is currently considered an important diagnostic tool for neurologists[22,23].

NSB has the important property of being used to in-

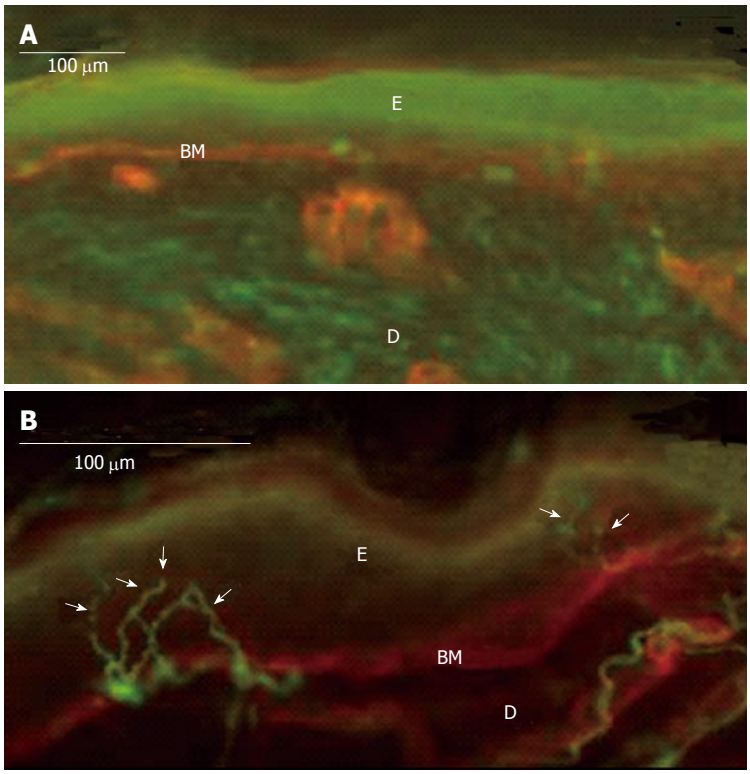

**Figure 2 Complete denervation of epidermis (and dermis) in an 82-year-old patient with a severe post-herpetic neuralgia (A), normal, contralateral, mirror skin innervation (13 fibers/mm) (B).** Immunofluorescence method: In green, PGP 9.5 staining of nerve fibers; in red, type Ⅳ collagen staining of basement membrane and blood vessels; Arrows: Epidermal nerve fibers; E: Epidermis; D: Dermis; BM: Basement Membrane.

vestigate the skin, allowing obtaining a diagnosis of small fiber axonal neuropathy of peripheral nerves innervating every body part covered by skin[24,25].

This feature appears to be very important because it allows going beyond the possibilities of neurophysiological tests which are available only for a limited number of peripheral nerves. It follows on that NSB allows reaching a diagnosis of neuropathy for "difficult" nerves, such as those of the trunk or occipital nerves frequently (and irregularly) involved in post-herpetic neuralgia[26]. An example of NSB clinical use is given in Figure 2 which shows a severe, unilateral decrease of ENFD in the neck skin of a patient with post-herpetic neuralgia.

Another important property of NSB is the ability to identify lesions involving small branches of peripheral nerves which cannot be investigated by neurophysiological tests. This feature of NSB appears to be particularly important in post-traumatic peripheral nerve lesions where one lesion is different from another.

In this context, it is important to highlight a recent paper where NSB showed a significant asymmetry in a spinal cord injury patient complaining of a bilateral burning and pricking pain at the level of injury[27]. Interestingly, NSB not only allowed demonstration of the presence of two different mechanisms leading to identical symptoms, but also to justify a different efficacy of the same treatment in the two sides. Continuing to talk of possible pain mechanisms, in a very recent paper, NSB findings suggested skin hyperinnervation as a possible cause for the development of dynamic mechanical allodynia following finger amputation[28].

Another recent study confirmed that NSB can allow getting information from the skin of several parts of the body. In that study, the epidermal innervation was studied in burn patients with unilateral injuries, allowing to suggest a possible correlation between the residual cutaneous innervation and the development of chronic pain[29].

NSB can also be useful in other clinical contexts. For example, it can also be used in differentiating neuropathic from referred pain, as demonstrated in a very recent paper in patients with endometriosis and unilateral thigh pain[30]. Moreover, it has been used for assessing the involvement of the peripheral nervous system in a dermatological manifestation of neurological disease, such as a dyshidrotic eczema in a patient with ulnar neuropathy or a unilateral pruritus on the paretic side of a stroke patient[31]. Finally, NSB can also be used to exclude a neuropathic pathophysiology of a clinical pain, as demonstrated in Parry-Romberg syndrome, a rare painful condition characterized by progressive hemifacial atrophy and unilateral facial pain[32].

Considering the current evidence on NSB and the well-known specific diagnostic properties of neurophysiological tests, it is possible to suggest a diagnostic sequence that can be useful to confirm the diagnosis of unilateral peripheral neuropathic pain (Figure 3).

## EPIDERMAL INNERVATION SYMMETRY RATIO

One of the main disadvantages of NSB is that it is very difficult to obtain robust normative data for any part of the body because of their different epidermal innervation patterns. This problem can be elegantly solved in cases of unilateral peripheral nerve lesions by comparing the neuropathic skin ENFD with the contralateral, normal side ENFD. To this aim, a bilateral biopsy is necessary

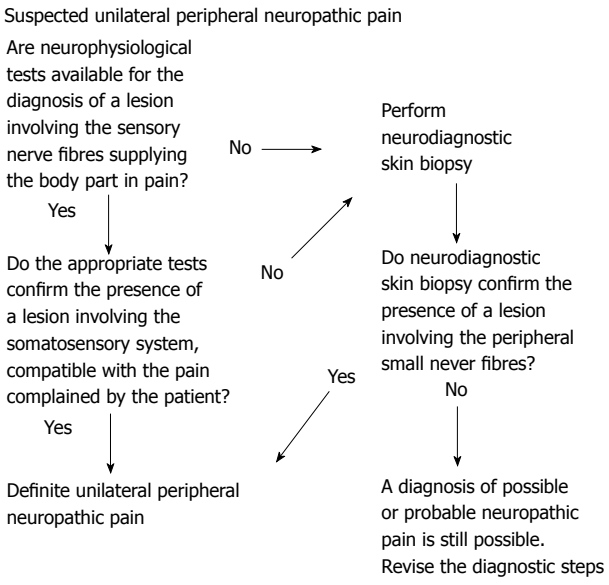

**Figure 3 Suggested diagnostic sequences for the confirmation of a peripheral nerve lesion sustaining a definite, peripheral, unilateral neuropathic pain.**

**Figure 4 Figure exemplifies the bilateral biopsy needed for comparing the epidermal nerve fiber density of two symmetrical, mirror skin parts.**

(Figure 4). It is well known that the two sides of the body of a normal subject are only theoretically symmetrical and a significant asymmetry can be frequently found in several types of biological measures. NSB is not an exception. For this reason, a ratio (the Epidermal Innervation Symmetry Ratio) was developed to compare the epidermal innervation of two symmetrical, mirror parts of the body in normal subjects. Preliminary data were obtained from 133 normal subjects[33]. In particular, when comparing the ENFD of the right with the left side, the ratio showed a normal distribution (mean 1.02; median 1.01; standard deviation 0.21; asymmetry 1.86, kurtosis -0.97). Moreover, when confronting the lower with the higher (contralateral) ENFD, the ratio was quite constant and surprisingly reproducible, also considering different parts of the body (Figure 5).

## LIMITATIONS

As with any other diagnostic method, the use of NSB for investigation of the peripheral nerve system has some

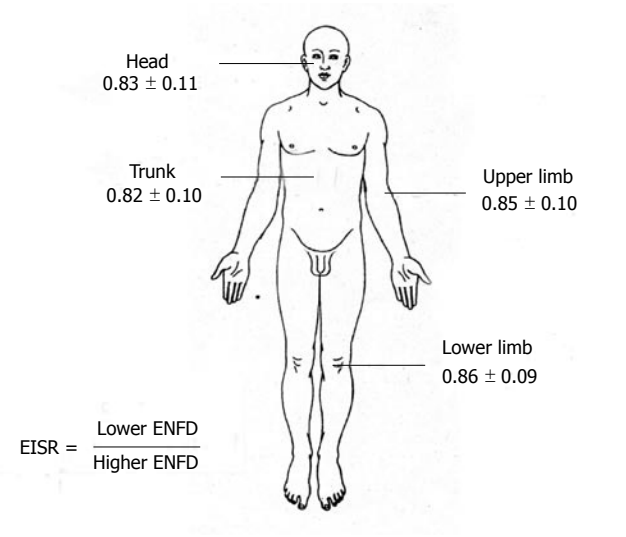

**Figure 5 Figure shows the values of epidermal innervation symmetry ratio obtained for different body parts in 133 normal subjects.** ENFD: Epidermal Nerve Fiber Density.

limitations. First of all, it is important to mention that NSB is surely not useful for the diagnosis of entrapment neuropathies, particularly in their early phases when only large diameter fibers are involved. Another important limitation is that NSB is a time-consuming method; calculating the time for specimen processing and the manual counting of two blinded investigators and the time for obtaining a reliable medical report, it is usually not less than two weeks. Finally, NSB is currently confined to a small number of specialized diagnostic units.

## CONCLUSION

The demonstration of a lesion or a disease involving the somatosensory system is mandatory for the diagnosis of definite neuropathic pain and objective diagnostic tools play an important role to reach the aim. To this end, several methods are currently available but none is suitable for every disease (or lesion). NSB can be an important diagnostic method for the demonstration of peripheral nervous system involvement, with a special reference to small fiber neuropathies and to peripheral nerves not evaluated by other tests. For these characteristics, NSB can be considered a precious instrument for the diagnosis of peripheral unilateral neuropathic pain.

## ACKNOWLEDGMENTS

The author would like to thank the neuropathophysiology technicians Michela Canti and Rosa Bagnasco for their essential role in drafting the paper and Dr. Anna Maria Gatti for helping with the preparation of figures.

## Abstract

Left ventricular (LV) thrombus is a life-threatening complication of severe LV dysfunction. Ventriculotomy has been a commonly performed procedure for LV thrombus; however, it often further decrease LV function after surgery. We present an alternative approach to thrombectomy in order to minimize the postoperative LV dysfunction. A 37-year-old female with a postpartum cardiomyopathy found to have poor LV function and a large left ventricular apical thrombus (3 cm × 3 cm) attached to the apex by a narrow stalk. Given her severe LV dysfunction, the LV thrombus was approached *via* left atriotomy under cardiopulmonary bypass. The LV thrombus was easily extracted with gentle traction *via* the mitral valve. Postoperatively, the patient was discharged home without any embolization event or inotropic support. LV thrombectomy *via* left atriotomy through the mitral valve could be an alternative option for the patients with poor LV function with a mobile LV thrombus.

**Key words:** Left ventricular thrombus; Atriotomy; Cardiomyopathy; Surgical thrombectomy; Pedunculated thrombus

**Core tip:** We successfully treated the patient of a large pedunculated left ventricular (LV) thrombus with poor LV function *via* left atriotomy. Compared to conventional ventriculotomy, left atrial approach would be more suitable for emergency LV thrombectomy for highly mobile thrombi because the left atriotomy may not further decrease the LV function and would preserve the LV apex for future ventricular assist device placement.

## INTRODUCTION

Left ventricular (LV) thrombus is a life-threatening complication of severe left ventricular dysfunction. Possible treatment options include anticoagulation, thrombolysis and surgical thrombectomy[1,2]. Small immobile thrombi can be safely managed with anticoagulation; however, treatment for large mobile thrombi is often problematic. LV thrombus is usually associated with poor LV function[3]. Therefore, surgical approaches such as left ventriculotomy, which potentially cause further deterioration of LV function, should be avoided if possible. We present an alternative approach of LV thrombectomy in order to preserve the remaining LV function.

## CASE REPORT

A 37-year-old female with a history of postpartum cardiomyopathy and multiple pulmonary embolisms in the

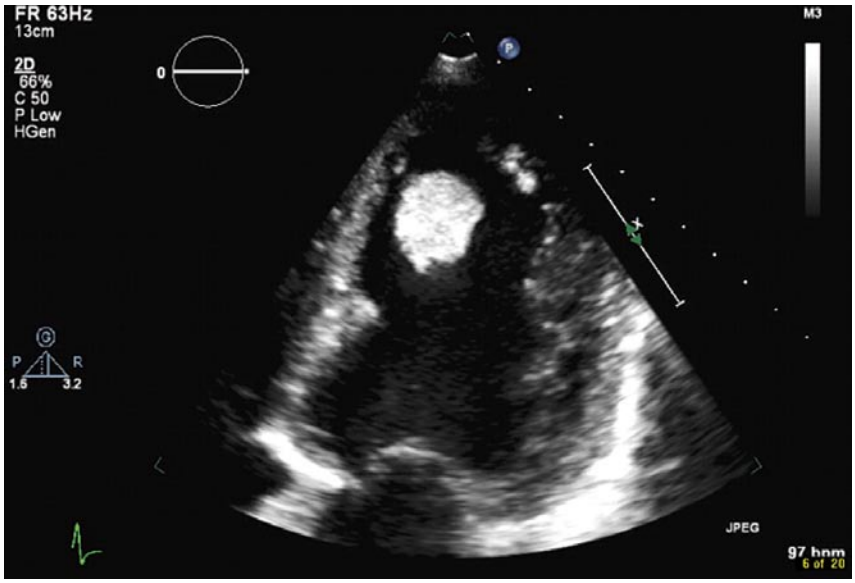

**Figure 1 Transthoracic echocardiogram demonstrated a large left ventricular thrombus.** It was highly mobile and the risk of embolization was considered to be high.

past presented to an outside hospital with worsening dyspnea on exertion and fatigue 3 mo after her second delivery. She stated that she ran out of her medications for several weeks including rivaroxaban which was prescribed for her possible hypercoagulable state. At the outside hospital she complained of chest pain and underwent right and left heart catheterization, which disclosed a cardiac index of 1.5 L/min per square meter and nonobstructive coronary disease. She was initiated on inotropic support for low output cardiac failure. Her transthoracic echocardiogram followed by transesophageal echocardiogram showed worsening LV function with an ejection fraction of 10%, which was previously 20%, and a large apical pedunculated LV thrombus measuring 3 cm × 3 cm (Figure 1). She was therefore transferred to our hospital for further management.

Considering a narrow stalk and large size of the LV thrombus, the risk of embolization was considered to be high. Emergent surgery was thus undertaken. Under cardioplegic cardiac arrest and cardiopulmonary support, the left atrium was opened at Waterson's groove. A Cosgrove retractor was placed to optimize the exposure of the mitral valve. The LV thrombus was visualized through the mitral valve and was located at the apex connected to the ventricular wall only with a small stalk, which was divided at the base of the papillary muscle. The thrombus was extracted with gentle traction through the mitral valve without difficulty. The LV cavity was extensively irrigated, and then the left atrium was closed. The cross clamp time was 20 min and there was no issue weaning from cardiopulmonary bypass. Postoperatively, the patient was on minimal inotropic support which was successfully weaned off by postoperative day 4. She developed transient atrial fibrillation on postoperative day 3, which was converted to sinus rhythm by medical therapy. The postoperative echocardiogram revealed a small residual mural thrombus measuring 3 mm × 4 mm with left ventricular function of 40% (Figure 2). Hematology was consulted for workup of a possible hypercoagulable state, however all studies were negative. She was placed on coumadin therapy for the residual LV thrombus and was discharged home on postoperative day 10 without an embolic event. Pathologic workup of the mass revealed a large thrombus without any malignant component. Throughout her postoperative course, she has remained symptom free 6 mo after surgery.

## DISCUSSION

First line of treatment for a LV thrombus is anticoagulation; however, a large mobile thrombus as is in this case often requires urgent surgical thrombectomy. The concern with surgical removal of a large LV thrombus is ventricular function, since it is often seen in patients with poor LV function. The conventional approach to LV thrombus is left ventriculotomy[4,5]. Ventriculotomy provides direct visualization of the thrombus; thus it has been considered the standard approach for complete removal of the thrombus. This may be best utilized for mural thrombus which is adhered to the ventricular wall. However, LV ventriculotomy often causes further deterioration of the LV function[6], and should be avoided in cases of poor LV function if possible. Furthermore, if once the left ventriculotomy was performed, future placement of the ventricular assist device in case of further deterioration of the LV function would be more complicated. Another possible approach is thrombus extraction *via* aortotomy. This trans-aortic approach has been reported in conjunction with the video-assisted thoracoscopy to facilitate visualization[7]. However, the size of the thrombus is often the limiting factor in this approach and was too large to pass through the aortic valve in this case.

A left atrial approach does not require incision to the LV, thus theoretically preserves the remaining LV function. This approach also provides adequate visualization of the thrombus and trans-mitral valve extraction allows extraction of a larger thrombus than the trans-aortic ap-

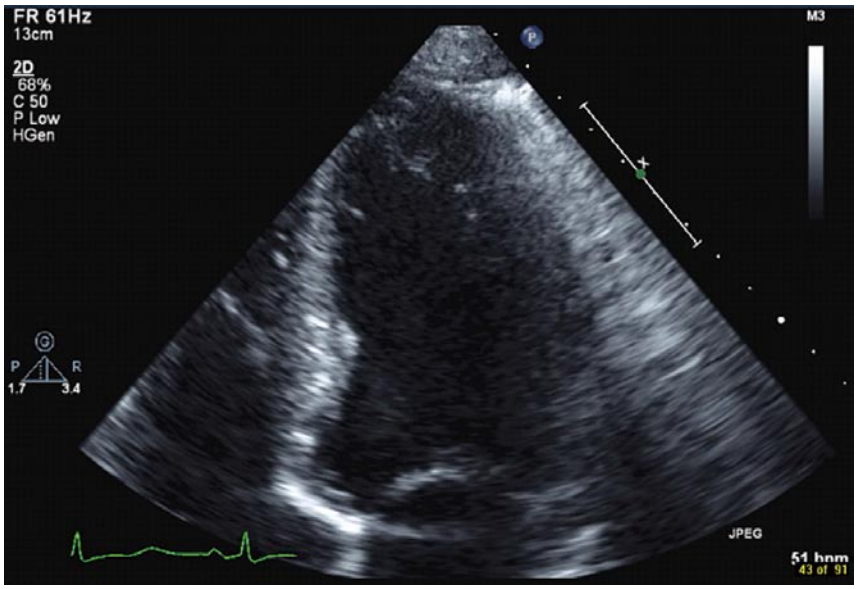

**Figure 2 Postoperative transthoracic echocardiogram demonstrated only minimally remaining mural thrombus.**

proach[8-10]. The potential disadvantage of the left atrial approach would be limited room for maneuvering of the thrombus and should be reserved only for one that is loosely connected to the ventricular wall with a narrow stalk, which is exactly the case that emergent thrombectomy is usually indicated. When surgical thrombectomy is indicated for mural thrombi, which can usually be managed with anticoagulation, the left atrial approach should not be selected because extensive debridement is expected. These cases should be operated semi-electively with a standby left ventricular assist device since further deterioration of the LV function is expected after ventriculotomy. Therefore, we advocate left atriotomy as an alternative approach for emergent LV thrombectomy.

## COMMENTS

### *Case characteristics*

A 37-year-old female with a history of postpartum cardiomyopathy presented with chest pain and dyspnea 3 mo after her second delivery.

### *Clinical diagnosis*

Echocardiogram showed worsening left ventricular (LV) dysfunction (ejection fraction of 10%) with a large left ventricular apical thrombus (3 cm × 3 cm) attached to the apex with a narrow stalk.

### *Differential diagnosis*

Differential diagnosis included intracardiac thrombus, primary or metastatic tumor and cardiac myxoma.

### *Laboratory diagnosis*

The patient's cardiac index was 1.5 L/min per square meter and ejection fraction of 10%.

### *Imaging diagnosis*

Echocardiogram showed a large left ventricular apical thrombus (3 cm × 3 cm) attached to the apex with a narrow stalk.

### *Pathological diagnosis*

The removed mass was found to be a thrombus.

### *Treatment*

The left ventricular thrombus was removed via the right-sided left atrium though the mitral valve.

### *Related reports*

Conventional LV thrombectomy by left ventriculotomy; may this decrease the left ventricular function after surgery.

### *Experiences and lessons*

Compared to conventional ventriculotomy, left atrial approach would be more suitable for emergency LV thrombectomy for highly mobile thrombi because the left atriotomy may not have any effect on the left ventricular function and would preserve the left ventricular apex for future ventricular assist device placement.

### *Peer review*

Left ventricular thrombectomy *via* the left atrium though the mitral valve would be most feasible for the thrombus connected to the left ventricle with a narrow stalk.

## Abstract

Variations in the bile duct and pancreatic duct opening are related to the process of rotation and recanalization during embryologic development. Complete non-union of distal common bile duct and pancreatic duct gives rise to double papillae of Vater. The separation of the drainage of the main pancreatic duct and bile duct can be appreciated by careful assessment at the time of endoscopic retrograde cholangiopancreatograpy. The cranial orifice is a bile duct opening, whereas the caudal orifice is a pancreatic duct opening. The separate orifice finding can be confirmed by cholangiogram and pancreatogram with no communication between the two orifices. Endoscopists should be aware of this rare variant because late recognition can result in unnecessary manipulation and contrast injections of the main pancreatic duct and biliary cannulation failure.

**Key words:** Double major papillae; Double orifices; Cannulation; Bile duct; Endoscopic retrograde cholangiopancreatography

**Core tip:** Drainage of the main pancreatic and bile duct as two separate orifices is a recognized, but very rare anatomical variant. It is also referred to as double major papillae.

Chavalitdhamrong D, Draganov PV. Unexpected anomaly of the common bile duct and pancreatic duct. *World J Clin Cases* 2014; 2(2): 36-38 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i2/36.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i2.36

## INTRODUCTION

The common bile duct and the pancreatic duct coalesce into one duct at the level of the ampulla, before they open into the duodenum *via* a single orifice. A variation in the bile duct and pancreatic duct opening causing two separate orifices is a rare anatomical variant as they fail to coalesce (also known as double papillae). This variant does not predispose to any pancreatobiliary disease, but recognition at the time of endoscopic retrograde cholangiopancreatography (ERCP) is crucial to ensure the procedures technical success. We present a case of a patient with separate drainage orifices of the bile and pancreatic duct which initially was not appreciated. This resulted in obtaining unnecessary pancreatograms, a prolonged procedure and increased risk for post-ERCP pancreatitis.

## CASE REPORT

A 27-year-old presented 3 wk post-partum with acute right upper quadrant abdominal pain associated with elevated liver function tests (aspartate aminotransferase of 396 U/L, alanine aminotransferase of 364 U/L, total bilirubin of 1.5 mg/dL, and alkaline phosphatase of 510 U/L). Abdominal ultrasonography revealed a dilated common bile duct of 12 mm and mild intrahepatic ductal

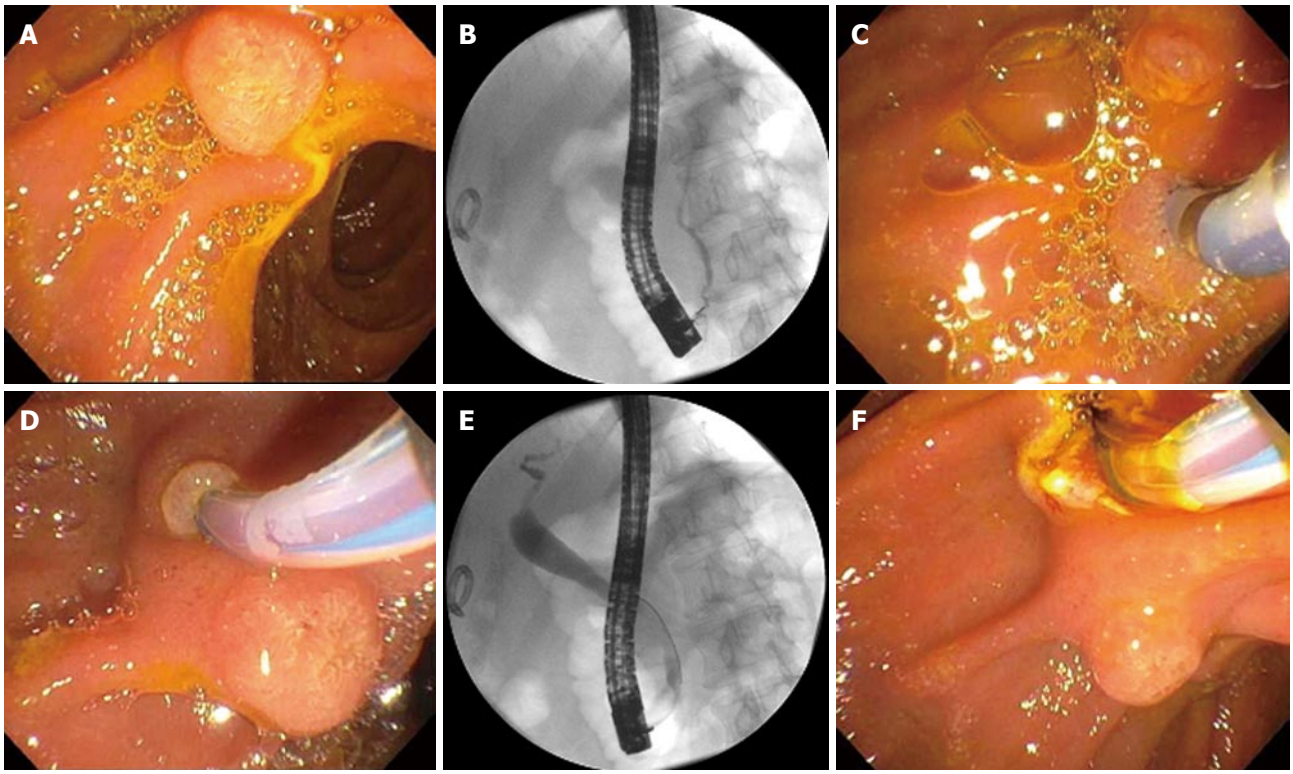

**Figure 1 The patient underwent an endoscopic retrograde cholangiopancreatography for stone removal.** A: The major papilla appeared normal; B: Normal pancreatogram; C: The major papilla was re-examined; D: Cannulation of the bile duct through the second orifice; E: Biliary tract with biliary stone within the distal common bile duct; F: Biliary sphincterotomy.

dilatation. Magnetic resonance cholangiopancreatography showed a four millimeter stone in the distal common bile duct.

The patient underwent an ERCP for stone removal. The major papilla appeared normal (Figure 1A). Multiple cannulation attempts resulted in repeat pancreatograms (Figure 1B). The major papilla was re-examined, and what originally was thought to be the minor papilla was found to be located at the roof of the major papilla (Figure 1C). This appearance raised the possibility of two separated orifices of the bile duct and the main pancreatic duct, which independently drain with a separation of 10 mm. Indeed, that was confirmed after cannulation of the bile duct through the second orifice (Figures 1D and E). Biliary sphincterotomy was preformed (Figure 1F) and the biliary stone was easily extracted. Rectal indomethacin was given as a prophylactic measure for prevention of post-ERCP pancreatitis[1]. The patient later underwent a cholecystectomy, and her hospital course was uneventful.

## DISCUSSION

Drainage of the main pancreatic and bile duct as two separate orifices is a recognized, but very rare anatomical variant. It is also referred to as double major papillae. The two separate openings are usually not apparent without close inspection[2]. The cranial orifice communicates with the common bile duct and the caudal orifice communicates with the duct of Wirsung[3]. Double papilla of Vater cannulation of the common bile duct and pancreatic duct could be accomplished through either orifice independently[4,5]. Endoscopists should be aware of this rare variant because late recognition can result in unnecessary manipulation and contrast injections of the main pancreatic duct. Fortunately, our patient did not develop post-ERCP pancreatitis. Furthermore, inability to recognize this anatomic variant can lead to biliary cannulation failure.

## COMMENTS

### *Case characteristics*

This case demonstrates a rare endoscopic finding of papilla during endoscopic retrograde cholangiopancreatography.

### *Clinical diagnosis*

A non-union of the bile duct and pancreatic duct opening causes two separate orifices.

### *Differential diagnosis*

The confirmation of two separate ampullary structures can differentiate double major papillae of Vater from other diagnoses.

### *Laboratory diagnosis*

Cannulation of both orifices can prove that they are the openings of the common bile duct and the pancreatic duct.

### *Imaging diagnosis*

Cannulation of the cranial orifice shows cholangiogram, whereas cannulation of the caudal orifice shows pancreatogram.

### *Pathological diagnosis*

Cannulation of each orifice can evaluate the biliary or pancreatic abnormality.

### *Treatment*

Therapeutic interventions by endoscopic retrograde cholangiopancreatography (ERCP) can be performed after proper cannulation.

### *Related reports*

A literature search revealed only a few documented cases of double papillae of Vater.

### *Term explanation*

Double major papillae of Vater are separate drainages of the common bile duct and the pancreatic duct. The cannulation of the common bile duct and pancreatic duct can be achieved through either orifice independently.

### *Experiences and lessons*

The unnecessary pancreatograms are associated with increased risk for post-ERCP pancreatitis. Fortunately, the patient did not develop post-ERCP pancreatitis.

### *Peer review*

Careful inspection of the ampulla finding the two openings can lead to appropriate cannulation of the common bile duct and pancreatic duct through either orifice independently.

**Key words:** Sciatic neuropathy; Lotus neuropathy; Sciatic nerve

**Core tip:** In this case history we report on a patient with a severe isolated sciatic neuropathy with a foot drop, a complication of prolonged sitting in a modified lotus position. Although rare, similar reports of sciatic nerve injury due to external compression as a result of prolonged or repeated sitting in the same position have been reported. A so-called "lotus neuropathy" should be included in the differential diagnosis in patients presenting with a isolated sciatic neuropathy.

Bosma JW, Wijntjes J, Hilgevoord TA, Veenstra J. Severe isolated sciatic neuropathy due to a modified lotus position. *World J Clin Cases* 2014; 2(2): 39-41 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i2/39.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i2.39

## Abstract

A 51-year-old man presented to our hospital with progressive pain and weakness in his right leg. Neurological examination revealed atrophy of all muscles of the right leg, unilateral foot drop and paralysis of the anterior tibial and gastrocnemicus muscles. Electromyography confirmed a severe isolated sciatic neuropathy in the thigh. For unclear reasons, our patient habitually used to sit in a modified lotus position. We concluded that this position, in literature known as "lotus neuropathy" had resulted in the sciatic neuropathy. After more than a year our patient was referred again to our outpatient clinic. At that time there was only minimal improvement, now with an achilles tendon contracture and pes equinus due to immobility.

## INTRODUCTION

Isolated sciatic nerve injury is a common clinical situation. Several mechanisms are responsible for sciatic neuropathies. In this case report we describe a patient with complete paralysis of the right leg due to prolonged sitting in a modified lotus position.

## CASE REPORT

A 51-year-old male fugitive from Iran with post-traumatic stress disorder and schizophrenia presented to our hospital with progressive pain and weakness in the right lower extremity and with difficulty in walking. The symptoms had been present for 6 mo and there was no history of a trauma. The patient denied back pain, bowel or bladder

**Figure 1 Photograph of our patient sitting in a modified lotus position.** We hypothesized that repeated sitting in this position, with the right thigh on the heel of the left foot, had lead to compression and subsequent injury of the right sciatic nerve.

incontinence or sexual dysfunction. He drank alcohol occasionally.

General physical examination was unremarkable. Neurological examination demonstrated atrophy of all muscles of the right lower extremity. He ambulated with a steppage gait associated with an unilateral foot drop and ankle instability. Patient complained of dysesthetic pain, described as a constant burning sensation in the distal sciatic nerve distribution. Pinprick sensation was diminished in the distribution of the right peroneal nerve. The anterior tibial and gastrocnemicus muscles were paralysed (grade 0 MRC scale). Strength was normal in the more proximal sciatic innervated muscles. The right ankle reflex was absent.

His general practitioner mentioned that, for unclear reasons, our patient habitually used to sit in a modified lotus position (Figure 1). We hypothesized that repeated sitting in this position, with the right thigh on the heel of the left foot, had lead to compression and subsequent injury of the right sciatic nerve. Magnetic resonance imaging of the spine was normal. Electromyography and nerve conduction studies confirmed a severe isolated sciatic neuropathy in the thigh of the right lower extremity (Figure 2).

## DISCUSSION

The causes of sciatic mononeuropathy can be divided into those occurring in the hip and the thigh region. Only the minority of sciatic neuropathies are localised in the thigh and several mechanisms can lead to sciatic nerve damage in this region[1]. Most frequently the nerve injury is the result of a femur fracture, posterior thigh compartment syndrome, laceration, nerve infarction, mass lesions or acute external compression. Prolonged external compression of the sciatic nerve results in nerve damage from ischemia or from direct mechanical laceration of the nerve.

In literature similar cases with development of sciatic nerve injury due to external compression as a result of prolonged or repeated sitting in the same position have been reported. Sciatic neuropathy occurring as an intraoperative pressure palsy is a well-known complication of

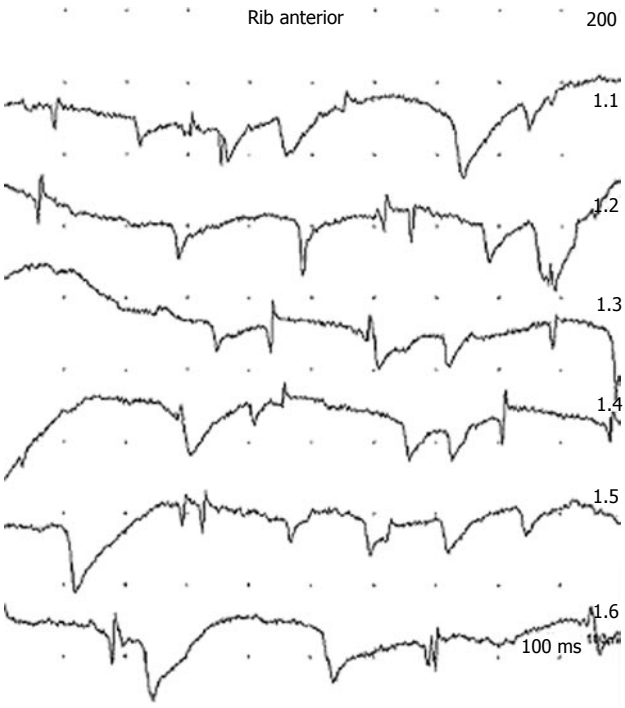

**Figure 2 Needle electromyography revealed spontaneous muscle fibre activity due to denervation in the paralysed right tibial anterior muscle.**

surgery[2]. "Toilet seat" sciatic neuropathy as a complication of gluteal compartment syndrome has been reported in alcoholic intoxicated people falling asleep on a toilet[3]. Furthermore, injury of the sciatic nerve after yoga meditation is a known entity, called "lotus neuropathy"[4,5].

Our patient was managed conservatively and subsequently failed to follow up after discharge, but was finally referred again to our outpatient department after more than a year. At that moment there was a minimal improvement of neurologic function of the leg. Additionally, an achilles tendon contracture and pes equinus had developed due to immobility.

In conclusion, in this paper we report a patient with an isolated sciatic neuropathy due to compression of the thigh as a result of sitting in a modified lotus position.

## COMMENTS

### *Case characteristics*

This patient complained of progressive pain and a 6-mo history of weakness in the right lower extremity and with difficulty in walking.

### *Clinical diagnosis*

Further examination revealed a complete and isolated sciatic neuropathy due to compression of the thigh as a result of sitting in a modified lotus position.

### *Differential diagnosis*

The differential diagnostic considerations were nerve injury as a result of a femur fracture, posterior thigh compartment syndrome, laceration, nerve infarction, mass lesions or acute external compression.

### *Imaging diagnosis*

Magnetic resonance imaging of the spine was normal. Electromyography and nerve conduction studies confirmed a severe isolated sciatic neuropathy in the thigh of the right lower extremity.

### *Treatment*

The patient was managed conservatively and referred to a physiotherapist, but

subsequently failed to follow up.

### *Term explanation*

"Lotus neuropathy" is an entity due to injury of the sciatic nerve after yoga meditation.

### *Experiences and lessons*

Although rare, a so-called "lotus neuropathy" should be included in the differential diagnosis in patients presenting with a isolated sciatic neuropathy.

### *Peer review*

The authors report an interesting clinical case with a novel clinical entity. Presentation is extremely clear.

## Abstract

Malignant melanoma is a malignancy of pigment-producing cells (melanocytes) located predominantly in the skin. Nodal metastases are an adverse prognostic factor compromising long term patient survival. Therefore, accurate detection of regional nodal metastases is required for optimization of treatment. Computed tomography (CT) and magnetic resonance imaging (MRI) remain the primary imaging modalities for regional staging of malignant melanoma. However, both modalities rely on size-related and morphological criteria to differentiate between benign and malignant lymph nodes, decreasing the sensitivity for detection of small metastases. Surgery is the primary mode of therapy for localized cutaneous melanoma. Patients should be followed up for metastases after surgical removal. We report here a case of inguinal lymph node enlargement with a genital vesicular lesion with a history of surgery for malignant melanoma on her thigh two years ago. CT and diffusion weighted-MRI (DW-MRI) were applied for the lymph node identification. DW-MRI revealed malignant lymph nodes due to malignant melanoma metastases correlation with pathological findings.

**Key words:** Diffusion-weighted imaging; Magnetic resonance imaging; Inguinal lymph node; Malignant melanoma; Metastasis; Apparent diffusion coefficient

**Core tip:** Diffusion-weighted magnetic resonance imaging (DW-MRI) measures differences in tissue microstructure based on the random displacement of water molecules. The differences in water mobility are quantified using the apparent diffusion coefficient which has an inverse relationship with tissue cellularity. As such, the technique is able to differentiate between tumoral tissue and normal or necrotic tissue. In this paper, we present an inguinal lymph node metastasis of malignant melanoma after surgery, with DW-MRI findings.

Bayraktutan U, Kantarci M, Pirimoglu B, Ogul H, Okur A, Gursan N. Utility of diffusion-weighted imaging in the diagnosis of inguinal lymph node metastasis with malignant melanoma. *World J Clin Cases* 2014; 2(2): 42-44 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i2/42.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i2.42

## INTRODUCTION

Malignant melanoma is located predominantly in the skin but also found in the eyes, ears, gastrointestinal tract, leptomeninges and oral and genital mucous membranes. Melanoma accounts for only 4% of all skin cancers; however, it causes the greatest number of skin cancer-related deaths worldwide. Early detection of thin cutaneous melanoma is the best means of reducing mortality[1]. We present a case with inguinal lymph node enlargement with a genital vesicular lesion with a history of surgery

**Figure 1 Axial T1 weighted image (A), T2 weighted image (B) and contrast enhanced fat saturated T1 image (C) showing contrast enhancing inguinal conglomerated lymph node enlargement (arrows).**

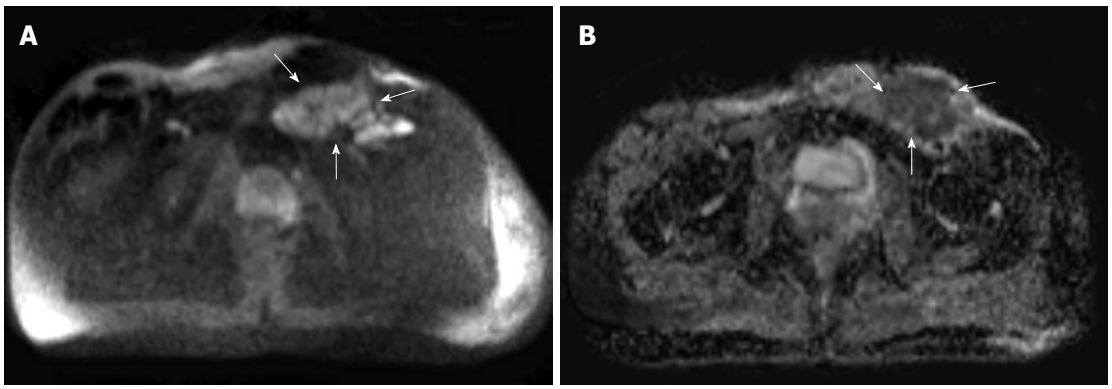

**Figure 2 Diffusion weighted images b800 (A) and apparent diffusion coefficient map (B) showing diffusion restriction in inguinal conglomerated lymph nodes (arrows).**

for malignant melanoma two years ago.

## CASE REPORT

A 38-year-old woman was admitted to our hospital complaining of a mass on her left inguinal region for about 1 mo. On physical examination there was left inguinal lymph node swelling and a genital vesicular lesion. The patient had a history of malignant melanoma on her thigh 2 years ago. Computed tomography (CT) scans showed inguinal conglomerated lymph node enlargement that may be inflammatory due to a genital lesion or malignant melanoma metastases. Magnetic resonance imaging (MRI) also showed inguinal conglomerated lymph node enlargement (Figure 1). Diffusion-weighted MRI revealed reduced apparent diffusion coefficient (ADC) values in these lymph nodes consistent with malignancy (Figure 2). After removal of the mass by surgery, histopathological examination showed evidence of malignant melanoma metastases (Figure 3).

## DISCUSSION

Malignant melanoma arises from melanocytes, the cells

that give skin its color, and can spread to nearby lymph nodes and, eventually, distant sites in the body. Approximately 50000 new cases of malignant melanoma occur in the United States every year and about 8000 people die from this most lethal form of skin cancer. If untreated, malignant melanomas can spread rapidly, sometimes causing death within months of diagnosis. However, the five year cure rate of early, superficial lesions is nearly 100%[1,2].

Melanomas can occur on mucous membranes of the mouth, genital regions and anus. Sun-exposed areas are at higher risk than shielded areas. Although melanomas can occur anywhere on the body, and some types are more likely to be found in some areas than others, women tend to develop more melanomas on their legs, while men's arise more frequently on the torso[2].

Risk factors for malignant melanoma are sun exposure, white race, first degree relatives with a history of melanoma (may increase one's risk by up to eight times), personal history of previous melanoma, dysplastic nevus syndrome, large congenital melanocytic nevi, lentigo maligna ("Hutchinson's freckle"), history of other non-melanoma skin cancers, immunosuppression and higher numbers of melanocytic nevi (moles)[3].

Surgical removal of melanomas that have not metastasized or penetrated to deeper layers of skin is often curative. Metastatic disease is generally inoperable. Lymph node dissection, immunotherapy, vaccine therapy, chemotherapy and hyperthermia are among the modalities used to treat metastases[4]. Current the National Comprehensive Cancer Network guidelines do not recommend surveillance laboratory or imaging studies for asymptomatic patients with stage ⅠA, ⅠB and ⅡA melanoma (*i.e.*, tumors ≤ 4 mm depth). Imaging studies (chest radiograph, CT and/or positron emission tomography-CT) should be obtained as clinically indicated for confirmation of suspected metastasis or to delineate the extent of disease and may be considered to screen for recurrent/metastatic disease in patients with stage ⅡB-Ⅳ disease, although this latter recommendation remains controversial. Routine laboratory or radiological imaging in asymptomatic melanoma patients of any stage is not recommended after 5 years of follow-up[5].

CT and MRI facilitate detection of lymph nodes; however, both modalities rely on size-related and morphological criteria to differentiate between benign and malignant lymph nodes. Diffusion-weighted imaging measures differences in tissue microstructure based on the random displacement of water molecules. The magnitude of water molecule movement is expressed as an ADC value. Its usefulness in the diagnosis of malignant tumors has gained interest. The technique is able to differentiate between tumoral tissue and normal or necrotic tissue[5,6]. The improved nodal identification may aid treatment planning and further nodal characterization[7]. In conclusion, DWI is recommended for evaluation of lymph node metastasis in patients with malignant melanoma.

## COMMENTS

### *Case characteristics*

A 38-year-old woman was admitted to the hospital with complaint of a mass on her left inguinal region for about 1 mo ago.

### *Clinical diagnosis*

On physical examination there were left inguinal lymph node swelling and a genital vesicular lesion.

### *Imaging diagnosis*

Computed tomography (CT) scans showed inguinal conglomerated lymph node enlargement, may be inflammatory due to genital lesion or malignant melanoma metastases.

### *Treatment*

CT and diffusion weighted-magnetic resonance imaging (DW-MRI) were applied for the lymph node identification, DW-MRI revealed malignant lymph nodes due to malignant melanoma metastases correlation with pathological findings.

### *Experiences and lessons*

DWI is recommended for evaluation of lymph node metastasis in patients with malignant melanoma.

### *Peer review*

Presentation and readability of the manuscript is good, the paper is brief, concise, the text is clear and easily comprehensible, adequately describes the course of the disease, its diagnostics and treatment of the patient.

## Abstract

A 67-year-old male presented with a gradually progressive low back pain of 2 years duration. The patient was leading a retired life and there was no history of chronic fever or significant trauma. There was no radiation of pain or any features suggestive of claudication. There was no history of any comorbidity. The pain was aggravated with extension of the spine and relieved with flexion. There was no swelling or neurological deficit, but muscle spasm was present. Radiographs of the spine revealed degenerative changes in the lumbosacral spine, along with articulation of spinous processes at in lumbar spine at all levels level suggestive of Baastrup's disease, commonly known as "kissing spine". Routine blood investigations were within normal limits. The patient was managed conservatively. He was given a week's course of analgesics and muscle relaxants and then started on spinal flexion exercises, with significant improvement being noted at 6 months follow up.

**Key words:** Baastrup's disease; Neoarthrosis; Spinous process; Kissing spine; Osteophytes; Low back ache; Back pain

**Core tip:** Baastrup's disease, although not a rare entity, is often misdiagnosed and wrongly treated due to poor knowledge. Complete evaluation and a detailed examination of radiographic images are crucial for a proper diagnosis and to avoid mismanagement of the condition, including a hasty surgical intervention.

Singla A, Shankar V, Mittal S, Agarwal A, Garg B. Baastrup's disease: The kissing spine. *World J Clin Cases* 2014; 2(2): 45-47 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i2/45.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i2.45

## INTRODUCTION

Baastrup's disease (kissing spine) is a relatively common entity characterized by degenerative changes of spinous processes and inter-spinous soft tissues. It involves the formation of hypertrophic spinous processes, an important cause of mechanical back pain, and accompanying degenerative disc disease. Most of the cases previously described in the literature were managed either surgically or with fluoroscopy image guided steroid injections. To the best of our knowledge, this is the first case showing significant improvement with only conservative management.

## CASE REPORT

A 67-year-old male presented with gradually progressing low back pain of 2 years duration. The pain was aggravated with extension of the spine and relieved with flexion. There was no evidence suggestive of radiation of pain or any clinical features suggestive of claudication. The patient had no additional comorbidity. There was no history of chronic fever or significant trauma. Radiographs of the spine revealed degenerative changes involving the lumbosacral spine, along with articulation of spinous processes at at multiple levels level (Figure 1),

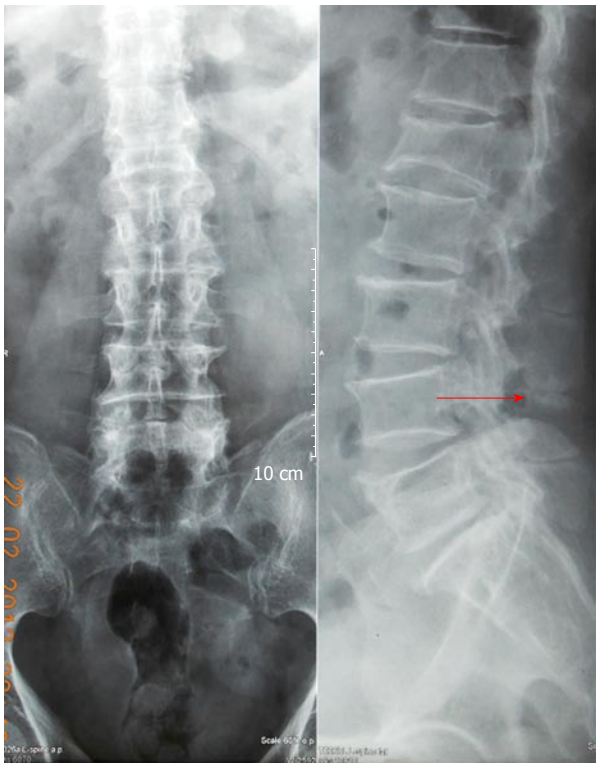

**Figure 1 Radiographs of lumbar spine in anterior-posterior and lateral views showing Baastrup's disease at at multiple lumbar level.**

commonly known as "kissing spine" and strongly suggestive of Baastrup's disease in the absence of any other features. The patient was managed conservatively with muscle relaxants and analgesics for one week and, once the pain subsided, was started on physiotherapy with spinal flexion exercises. The treatment plan involved conservative management with a close follow up. The option of intralesional steroid injections and bursal excision was to be considered if conservative treatment failed. The patient was monitored at the outpatient department at regular intervals and at 6 mo follow up was found to have significant improvement with physiotherapy alone and hence was asked to continue the exercises.

## DISCUSSION

This condition was first described as a neoarthrosis between adjacent spinous processes by Mayer[1]. Brailsford[2] demonstrated the same entity and labeled it "kissing spines". Baastrup[3] described this condition again in detail and subsequently this condition came to be known as Baastrup's disease. It was noted clinically in 6.3% of college athletes[4], most commonly gymnasts, and was thought to be related to the repetitive flexion and extension attributed to the sport. In a recent study by Kwong *et al*[5], Baastrup's disease was found in 413 (41.0%) patients (diagnostic criteria being close approximation and contact between apposing spinous processes and sclerosis of the superior and inferior portions of adjacent processes on computed tomography) with an incidence of 81.3% among patients older than 80 years, whereas Maes *et al*[6] reported an overall incidence of 8.2% with the presence of a bursa between spinous process as a diagnostic criteria based on magnetic resonance imaging.

Two cohort studies have demonstrated conflicting reports of clinical improvement following surgical intervention. This included one early study of 10 patients by Franck[7] in 1944 in which the patients undergoing surgical excision of the spinous process for Baastrup's disease demonstrated improvement. A later study by Beks *et al*[8] in 1989 in which 64 patients who underwent either partial or total surgical excision of the lumbar spinous processes demonstrated that surgery does not always alleviate the patient's pain. Their research suggested that "kissing spine" might not be a disease entity itself but an additional pathology, specifically spondylosis with osteophyte formation. A case has been reported of atrophy and fatty replacement of the paraspinal musculature in a patient with Baastrup's disease on X-ray[8]. Pain can be attributed to multiple factors in Baastrup's disease, including mechanical pain secondary to the hypertrophic spinous processes coming into contact with each other, secondary to degenerative disc disease, and interspinous bursal fluid collections extending through the ligamentum flavum, leading to central canal stenosis[9]. In 2004, Pinto *et al*[10] reported 2 cases of spinous process fractures in patients with Baastrup's disease and proposed that close proximity of the spinous processes resulted in its fracture and hence pain. Management includes decompression and posterior spinal instrumentation surgery or fluoroscopically guided interspinous steroid injections[11].

In conclusion, Baastrup's disease is not a rare cause of back pain in the elderly but it is frequently missed on radiographs due to lack of knowledge about the disease on the part of physician and overexposure of spinous processes in most X rays. Most of the management suggested in the literature is invasive, *i.e.,* surgery or intralesional injections. However, conservative management can also produce good results. Hence, it is imperative that the treating physician must attempt a conservative line of management before moving onto invasive modalities. Since this condition is one of the few treatable causes of back pain in the vast spectrum of spinal conditions, one must be aware of the condition to correctly diagnose and institute a line of treatment most beneficial to the patient.

## COMMENTS

### *Case characteristics*

A 67-year-old male presented with a gradually progressive low back pain of 2 years duration.

### *Clinical diagnosis*

Baastrup's disease is not a rare cause of back pain in elderly, with pain aggravated on extension and relieved on bending forward.

### *Differential diagnosis*

Common differential diagnoses include lumbar spondylosis, muscle strain, spondylolisthesis, fracture of the spinous process, vertebral compression fractures and infectious etiologies of the spine.

### *Imaging diagnosis*

Radiographs showing articulation of spinous processes, *i.e.*, the kissing spine.

### *Peer review*

The authors present a nice case report.

## Abstract

Ameloblastic carcinoma is a rare odontogenic tumor exhibiting histological evidence of malignancy in the primary or recurrent tumor. It is characterized by rapid, painful expansion of the jaw, unlike conventional ameloblastomas. The tumor most frequently involves the mandible. The expanding lesion causes perforation of the buccal and lingual plates of the jaw and invades the surrounding soft tissue. Rapidly growing large tumor mass may cause tooth mobility. A mandibular tumor involving the mental nerve leads to paresthesia of the nerve. A maxillary tumor can produce a fistula in the palate and paresthesia of the infraorbital nerve. Most ameloblastic carcinomas are presumed to have arisen de novo with a few cases of malignant transformation of ameloblastomas. Although rare, these lesions have been known to metastasize, mostly to the regional lymph nodes or lungs. A case of ameloblastic carcinoma in a 60-year-old man is reported here and its clinical, radiological and histological features are discussed.

**Key words:** Ameloblastic carcinoma; Squamous metaplasia

**Core tip:** Clinically, ameloblastic carcinoma is more aggressive than most typical ameloblastomas, with extensive local destruction, perforation of the cortical plate, extension into surrounding soft tissues, numerous recurrent lesions and metastasis, usually to cervical lymph nodes. Histologically, the tumor cells resemble cells seen in ameloblastoma but show cytological atypia, cellular pleomorphism, nuclear hyperchromatism, mitoses and vascular and neural invasion. These identifying features of ameloblastic carcinoma must be known and recognized by dental practitioners. It is probable that ameloblastoma, like other tumors (such as carcinoid tumors and epithelial tumors of the ovary), shows a spectrum of histological and biological behavior, ranging from benignity at one end to frank malignancy at the other.

Srikanth MD, Radhika B, Metta K, Renuka NV. Ameloblastic carcinoma: Report of a rare case. *World J Clin Cases* 2014; 2(2): 48-51 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i2/48.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i2.48

## INTRODUCTION

Malignant odontogenic tumors are very uncommon and ameloblastic carcinoma is a rare odontogenic carcinoma, with very few such cases being reported so far. The frequency of malignant change in ameloblastomas is difficult to establish but probably may be less than 1% among all cases of ameloblastomas[1].

The terminology for these lesions is somewhat controversial. The term malignant ameloblastoma should be used for a tumor that shows the histopathological

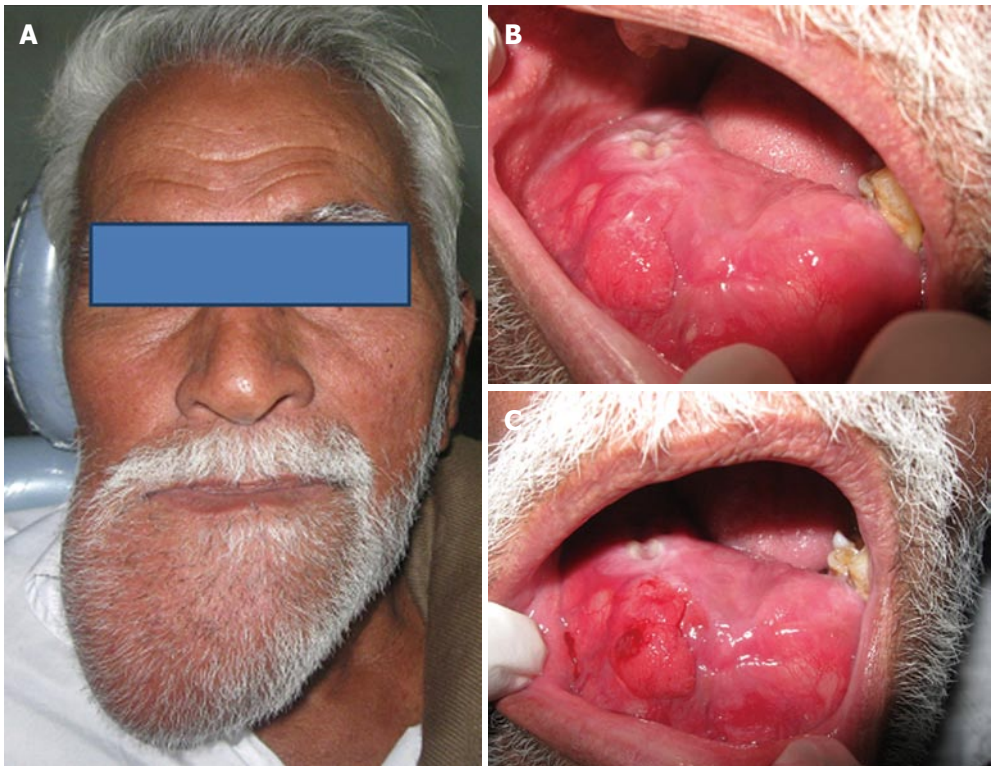

**Figure 1 Extra (A) and intra oral photograph of swelling with labial, buccal and lingual cortical expansion (B, C).**

features of ameloblastoma, both in the primary tumor and in the metastatic deposits[2]. However, the term ameloblastic carcinoma should be reserved for an ameloblastoma that has cytological features of malignancy in the primary tumor, in a recurrence, or in any metastatic deposit[3]. These lesions may follow a markedly aggressive local course but metastases do not necessarily occur[4].

Odontogenic carcinoma signifies the primary malignant epithelial tumors of the terms that are so poorly differentiated that they bear little or no resemblance to any of the odontogenic apparatus. With the presence of many clear cells in conjunction with the other patterns and histological features considered to be indicative of malignancy in these lesions and in keeping with the guidelines of World Health Organization (WHO) classification of odontogenic tumors, some authors even prefer to designate these tumors as clear cell ameloblastic carcinoma or ameloblastic carcinoma, clear cell variant.

## CASE REPORT

A 60-year-old male patient came to the department of oral medicine and radiology with a chief complaint of swelling over the right side of the face for 10 years (Figure 1A). History revealed that he first noticed a small intra oral swelling at the labial aspect of lower right canine region which gradually increased in size. Initially he noticed pain in that region but subsequently but there was no pain and the swelling increased progressively to the present size. The patient also noticed development of paresthesia of the lower lip with pain over the swelling.

On examination, a huge extra oral swelling was found, measuring around 23 cm × 11.5 cm in size, extending from the right side of mandible and crossing the midline with well defined margins, hard in consistency, with tenderness over the swelling. Intra oral examination revealed complete obliteration of the buccal and labial vestibule on the right side, with the swelling extending in to the anterior region of the floor of the mouth (Figure 1B). It had a normal mucosal color and 31-33 and 41-47 teeth were missing. The intra oral swelling was hard in consistency and tenderness was present on palpation (Figure 1C).

In light of the above findings and the nature and duration of the lesion, a provisional diagnosis of ameloblastoma was considered and odontogenic myxoma and osteosarcoma were considered for a differential diagnosis.

The patient had an orthopantomograph (OPG), computed tomography (CT) mandible and magnetic resonance imaging. OPG showed huge multilocular radiolucency with the septa giving an appearance of a soap bubble or honeycomb extending from the ramus molar region on right side, crossing the midline to the lower left premolar region (Figure 2A). CT dental scan showed an enlarged tumor extending from the ramus region of 48 to the 35 region (Figure 2B). The tumor caused severe expansion of the buccal and lingual cortical plates with a multilocular appearance.

Excisional biopsy revealed numerous epithelial follicles spread out in a scanty connective tissue stroma. The epithelial nests showed typical (tall) columnar peripheral cells with apically placed nuclei and vacuolated cytoplasm. The central cells showed squamous metaplasia

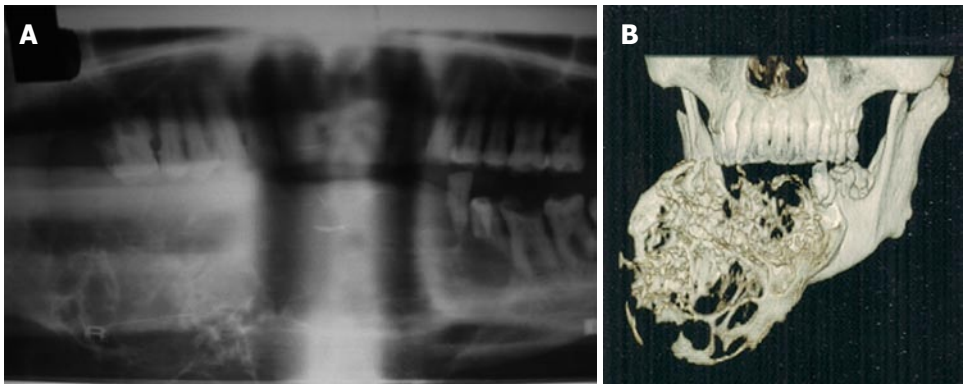

**Figure 2 Orthopantomograph (A) and 3D computed tomography (B) showing honeycomb lesion.**

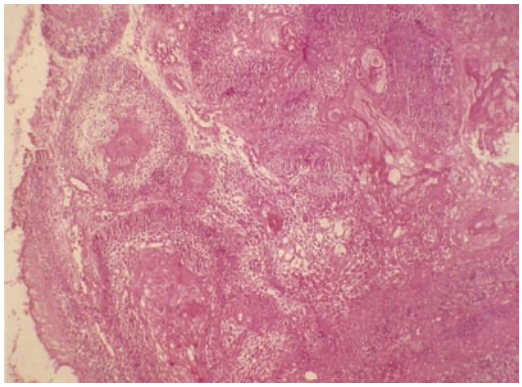

**Figure 3 Histopathology specimen showing epithelial follicles with squamous metaplasia and numerous keratin pearls.**

and numerous keratin pearls. A few cells showed features of dysplasia, such as irregular aggregation, cellular and nuclear pleomorphism with nuclear hyperchromasia (Figure 3).

The histological features were consistent with ameloblastic carcinoma. Myxomas radiologically show honeycomb variant and fine trabeculations within the small lobules not present in ameloblastoma. Osteosarcoma is a common primary malignant tumor affecting the jaw and radiologically a sunray appearance is present. Hence, they were excluded and a final diagnosis of ameloblastic carcinoma was made. The patient underwent surgical resection of the tumor by microvascular reconstructive surgery with complete resection of the mandible and reconstruction of the mandible was done by fibula graft (Figure 4). The patient is being followed up closely.

## DISCUSSION

Ameloblastic carcinoma is a rare neoplasm that represents a challenge in its diagnosis, treatment and prognosis. Information regarding its clinical features is scanty[5]. The demographic data of ameloblastic carcinoma reported in the literature suggests that it is more common in males (M:F 1.5:1) and the site of distribution is in the mandible, particularly in the posterior mandible[1]. The age range of occurrence shows a large variation with an average age of 39.8 years. However, a few authors have stated that the sixth decade is the predominant age group. Ameloblastic carcinoma has been reported to arise either de novo or from a preexisting odontogenic cyst or ameloblastoma[5]. The common clinical signs and symptoms include swelling, pain, trismus and dysphonia[6] and there are several classifications: (1) WHO classification of odontogenic carcinomas: malignant ameloblastoma; primary intraosseous carcinoma; malignant variants of other odontogenic tumors; and malignant changes in odontogenic cysts; (2) Classification of odontogenic carcinomas according to Slootweg and Muller: primary intraosseous carcinoma, *e.g.,* odontogenic cyst (Type Ⅰ); malignant ameloblastoma (type ⅡA); ameloblastoma carcinoma, arising *de novo*, *e.g.,* ameloblastoma, or *e.g.,* odontogenic tumor (type ⅡB); and primary intraosseous carcinoma arising *de novo* (type ⅢA: non keratinizing; type ⅢB: keratinizing); and (3) LJ Slater, Oral and Maxillofacial Clinics of North America - odontogenic carcinomas: metastasizing ameloblastoma; ameloblastic carcinoma; carcinoma, *e.g.*, ameloblastoma; primary intraosseous carcinoma; solid; cystic (*e.g.*, odontogenic cyst); central mucoepidermoid carcinoma; ghost cell odontogenic carcinoma; and clear cell odontogenic carcinoma.

### *Odontogenic sarcoma: Ameloblastic fibrosarcoma*

The diagnostic criteria of an ameloblastic carcinoma that differentiate from ameloblastoma are based on cytological atypia and an increased mitotic index[5]. The histological changes should include a higher proliferative index emphasized by higher mitotic activity, higher proliferating cell nuclear antigen expression and higher ki67, atypia such as nuclear pleomorphism and basilar hyperplasia, hyperchromatic nuclei of basaloid cells, and other features of malignancy, such as peripheral or perivascular invasion. This should be correlated with the clinical features. The four important characteristics include[5] growth rate, the propensity for ameloblastic carcinoma to perforate the cortex, pain, as a third of patients with ameloblastic carcinoma experience pain or discomfort, and sensory disturbance, such as paresthesia which is rare with ameloblastoma.

Ameloblastic carcinoma is an aggressive neoplasm

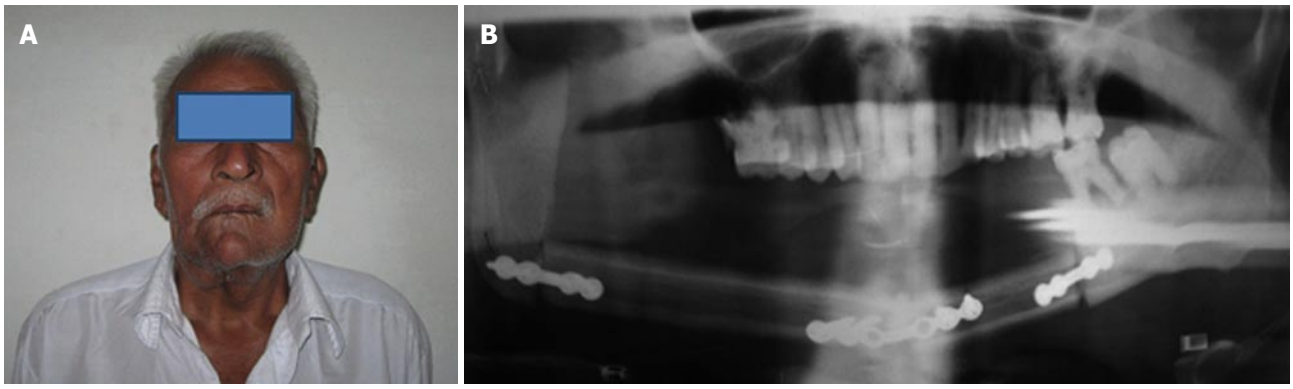

**Figure 4 Post-op photograph (A) and orthopantomograph (B) of patient after surgical resection of the tumor by microvascular reconstructive surgery and reconstruction with a fibula graft.**

that is locally invasive and can spread to regional lymph nodes or distant metastatic sites such as long bones. It is managed with wide local excision, elective or therapeutic neck dissection and post operative radiation therapy[5]. Radiotherapy and chemotherapy seem to be of limited value. The prognosis is poor and hence close follow up of the patient is needed.

Although the reported cases of ameloblastic carcinoma are scarce, the above features can be applied to diagnose an ameloblastic carcinoma at an early stage to enable early intervention and better treatment[7].

## COMMENTS

### *Case characteristics*

A case of ameloblastic carcinoma in a 60-year-old man is reported here and its clinical, radiological and histological features are discussed.

### *Imaging diagnosis*

The patient had an orthopantomograph (OPG), computed tomography mandible and magnetic resonance imaging. OPG showed huge multilocular radiolucency with the septa giving an appearance of a soap bubble or honeycomb extending from the ramus molar region on right side, crossing the midline to the lower left premolar region.

### *Pathological diagnosis*

Excisional biopsy revealed numerous epithelial follicles spread out in a scanty connective tissue stroma.

### *Treatment*

The patient underwent surgical resection of the tumor by microvascular reconstructive surgery with complete resection of mandible and the reconstruction of the mandible was done by a fibula graft.

### *Experiences and lessons*

It is probable that ameloblastoma, like other tumors (such as carcinoid tumors and epithelial tumors of the ovary), shows a spectrum of histological and biological behavior, ranging from benignity at one end to frank malignancy at the other.

### *Peer review*

Ameloblastic carcinoma is a rare malignant tumor. This report is very interesting.

## Abstract

**AIM:** To investigate cancer cell absence or presence in wide excision after biopsy of squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) patients.

**METHODS:** 200 patients (100 BCC and 100 SCC) from the same dermatology clinic, who had positive margin upon biopsy, were selected from a computer generated randomized report. All selected patients had wide excision following biopsy. To determine the correlation of gender, age distribution and cancer absence, BCC and SCC cases were separated based on excision-cancer absent or present after wide excision. $\chi^2$ tests, Fisher's exact tests were used to analyze the ratio of male to female between excision-cancer absent and excision-cancer present patients, while Mann-Whitney *U* test were used to compare the age distribution in the two groups. Statistical analyses were performed using SPSS version 16.0 for Windows.

**RESULTS:** Our retrospective chart review of the patients showed that cancer cells were absent in 49% of BCC patients ($n$ = 100) and 64% of SCC patients ($n$ = 100) who had previously had positive margins upon biopsy. Gender analysis showed the ratio of male to female (M/F) in the BCC arm was significantly higher compared with the SCC arm in those with excision-cancer absent (2.06 *vs* 0.66; $P$ = 0.004; $\chi^2$ test). But M/F of excision-cancer absent and excision-cancer present in neither BCC nor SCC patients was statistically significant. Age adjustment showed no significant difference between excision-cancer absent and excision-cancer present in BCC and SCC patients. Nevertheless, in excision-cancer absent cases, the age distribution showed that the BCC patients were younger than SCC patients (average age 67 *vs* 74; $P$ < 0.001; Mann-Whitney *U* test). In addition, our data also indicated that in the patient group of 71-80 years old, there were more SCC patients who showed excision-cancer absence (67.6% *vs* 39.4%; $P$ = 0.02; $\chi^2$ test).

**CONCLUSION:** Our study indicates that approximately 50% or more of BCC and SCC patients with positive margins found on biopsies did not have cancer cells present at the time of wide excisions.

**Key words:** Biopsy; Histology; Positive margin; Skin cancer; Wide excision

**Core tip:** Wide excisions are performed for skin cancers when malignant cells extend to the margins of biopsy. It is expected that cancer cells will appear in the excised tissue at the time of wide excision. However, an analysis of wide excision tissue samples from 200 patients revealed that approximately 50% or more basal and squamous cell carcinoma patients with cancer cells that extended to the margins in biopsy did not have

cancer cells present on wide excision. This finding suggests that the wound caused by the biopsy itself may trigger a body response to eliminate cancer cells.

Yuan Y, Duff ML, Sammons DL, Wu S. Retrospective chart review of skin cancer presence in the wide excisions. *World J Clin Cases* 2014; 2(3): 52-56 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i3/52.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i3.52

## INTRODUCTION

The incidence and mortality rates of skin cancer are increasing in the United States and many other countries[1]. Of these skin cancers basal cell carcinoma (BCC) is the most common type followed closely by squamous cell carcinoma (SCC)[2]. The incidence of BCC is 200/100000 in men and 100/100000 in women[3]. BCC incidence increases with age; the median age for diagnosis is 68 years old[4]. SCC incidence is 100/100000 in men and 50/100000 in women[3]. Clinically if skin cancer is suspected, a biopsy is taken. The biopsy shows a small sample of the lesion, which can be looked at microscopically by a pathologist. The pathology report will describe the type of cancer and if the cancer extends to the border (positive margin) or is completely excised (negative margin) in the tissue sample[5] (Figure 1). If the lesion is completely removed, no further surgery is needed. For lesions with a positive margin, a wide excision surgery is done to remove the remaining cancer. This wide excision is a common and essential way to treat skin cancer, and incomplete excision may lead to cancer recurrence[6-8]. Theoretically, all the tissue samples from wide excision should contain cancer cells. However, pathological analyses of tissue samples from wide excision in our clinic often only show evidence of scar with no cancer cells remaining. All lesions had photos to ensure the correct lesion was excised. This observation has not been reported. In this study, we systematically analyzed the cancer cells absence or presence in wide excision after biopsy by subtype as well as sex and age from 100 SCC and 100 BCC patients. Our results will provide guidance for future determination of potential mechanism that leads to the disappearance of cancer cells in surrounding tissues of biopsies.

## MATERIALS AND METHODS

### Patients' data extraction

Chart review of 200 patients (100 BCC and 100 SCC) was obtained from a single dermatology office. The patients were selected from a computer generated randomized report of those who had SCC and a separate list for those who had BCC. Only patients who had a positive margin at the time of biopsy were included. Patients were excluded if pathology was unavailable for either biopsy or wide excision. In cases where patients with more than one biopsy or wide excision, the first lesion from the list was chosen, this was the case unless there was no corresponding wide excision; or location of biopsy and wide excision did not match. There was no exclusion of patients who had SCC and BCC.

**Table 1 Patients characteristics**

| | BCC | SCC | Total patients |
|---|---|---|---|
| No. of cases | 100 | 100 | 200 |
| Sex | | | |
| Male | 62 | 43 | 105 |
| Female | 38 | 57 | 95 |
| Male/female | 1.63 | 0.75 | 1.11[1] |
| Median age (range) | 69 (42-92) | 77 (45-95) | 73 (42-95)[2] |
| Biopsy margins positive | 100 | 100 | 200 |
| Excision-cancer absent | 49 | 64 | 113[3] |

*P* value (BCC *vs* SCC): [1]$P = 0.007$; [2]$P = 0.003$; [3]$P = 0.032$. BCC: Basal cell carcinoma; SCC: Squamous cell carcinoma.

### Statistical analysis

In this chart review, $\chi^2$ tests were used to compare the difference of gender distribution and excision-cancer absent percentage in assigned groups. When the sample size was less than 40, Fisher's exact tests were used instead. All the difference of age distribution was evaluated by Mann-Whitney *U* test. $P < 0.05$ was considered as statistically significant. These statistical analyses were performed using SPSS version 16.0 for Windows.

## RESULTS

### Clinical characteristics

First, the characteristics of the selected patients were analyzed (Table 1). Among the 200 cases that were reviewed, including 100 BCC and 100 SCC patients, SCC was more common than BCC among female patients (57% *vs* 38%; $P = 0.007$; $\chi^2$ test) while BCC was more common than SCC among male patients (62% *vs* 43%; $P = 0.007$; $\chi^2$ test). Despite a similar age range, the average age of SCC patients were 8 years older than BCC patients (77 years *vs* 69 years old; $P = 0.003$; Mann-Whitney *U* test). All skin cancer patients showed a positive margins upon biopsy. However, cancer cells were found to be absent in excised tissue of 49% of the BCC patients and 64% of the SCC patients. In addition, excision-cancer absent percentage in SCC patients was significantly greater than that in BCC patients (64% *vs* 49%; $P = 0.032$; $\chi^2$ test). Analyses of the excision-cancer absent in the different subtypes of BCC and SCC indicated that there was no statistic significant difference in percentage among the analyzed subtypes of BCC or SCC (Table 2).

### Gender distribution of excision-cancer absence with positive margins

To evaluate if cancer cells absence or presence after wide excision was associated with gender, BCC and

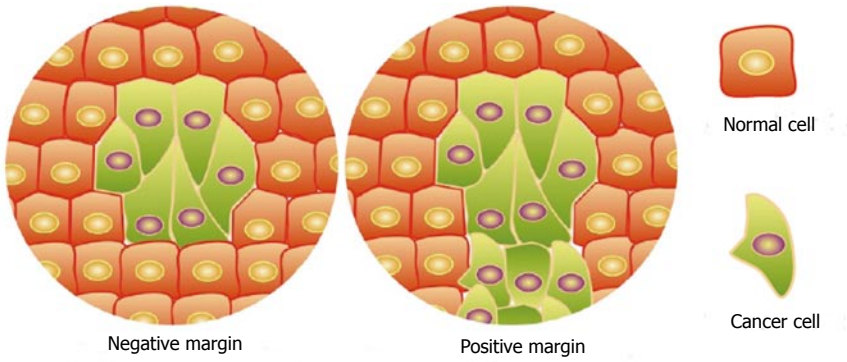

**Figure 1 Appearances of negative and positive margins in biopsies.**

[1]Include following complex subtypes, intraepidermal epithelioma pattern, *in situ*-intraepidermal epithelioma pattern, *in situ* and invasive, *in situ*-well differentiated, moderately to poor differentiated, *in situ* acantholytic and focally invasive, *in situ* and focally superficial invasive, keratinizing well differentiated, and unknown types. BCC: Basal cell carcinoma; SCC: Squamous cell carcinoma.

**Table 3 Gender distribution between excision-cancer absent and excision-cancer present cases of basal cell carcinoma and squamous cell carcinoma *n* (%)**

| | | M | F | Total | M/F | *P* value |
|---|---|---|---|---|---|---|
| BCC | Excision-cancer absent | 33 (67.3) | 16 (32.7) | 49 | 2.06 | 0.280[1] |
| | Excision-cancer present | 29 (56.9) | 22 (43.1) | 51 | 1.32 | |
| SCC | Excision-cancer absent | 25 (39.7) | 38 (60.3) | 63 | 0.66 | 0.382[1] |
| | Excision-cancer present | 18 (48.6) | 19 (51.4) | 37 | 0.95 | |
| Excision-cancer absent cases | BCC | 33 (67.3) | 16 (32.7) | 49 | 2.06 | 0.004[2] |
| | SCC | 25 (39.7) | 38 (60.3) | 63 | 0.66 | |

*P* value: [1]In BCC or SCC cases, the percentage of male (female) patients in excision-cancer absent *vs* present groups; [2]In excision-cancer absent cases, the percentage of male (female) patients in BCC *vs* SCC. BCC: Basal cell carcinoma; SCC: Squamous cell carcinoma; M: Male; F: Female.

SCC patients were grouped based on excision-cancer absence/presence and then the ratio of male to female was calculated respectively (Table 3). Despite the fact that a higher ratio of male to female was found in excision-cancer absent BCC patients than that in excision-cancer present BCC patients, the difference was not statistically significant (2.06 *vs* 1.32; $P = 0.28$; $\chi^2$ test). A close ratio of male to female SCC patients was observed in excision-cancer absent and present groups (0.66 *vs* 0.95; $P = 0.382$; $\chi^2$ test). However, in excision-cancer absent cases, the ratio of male to female in BCC was significantly higher compared with SCC (2.06 *vs* 0.66; $P = 0.004$; $\chi^2$ test).

### *Age distribution of excision-cancer absence with positive margins*

To evaluate if the malignancy presence after excision was associated with age, BCC and SCC patients were grouped based on cancer presence/absence, and then the median and average ages for the patients in each group were calculated (Table 4). Our data indicated that while there was no statistically significant difference in ages for excision malignancy present and absent patients in both BCC ($P = 0.191$) and SCC ($P = 0.534$), the patients' ages of excision-cancer absent cases for SCC were 8 years older than that for BCC (74 years *vs* 67 years old; $P < 0.001$; Mann-Whitney *U* test), which is similar to the difference between average age of SCC and BCC patients (Table 2). Further evaluation of the percentage of excision-cancer absence in BCC and SCC based on age distributions (< 60, 61-70, 71-80 and > 80 years old) revealed that while the percentage of excision-cancer absence cases among the elderly SCC patients was increased, the percentage among the elderly BCC patients was decreased (Figure 2). Our data indicated that in the patient group of 71-80 years old, SCC showed significantly higher percentage compared with BCC (67.6% *vs* 39.4%; $P = 0.02$; $\chi^2$ test).

## DISCUSSION

While currently there are limited reports linking local immune response and cutaneous carcinoma regression after biopsy, it is noteworthy that the local immune cells might contribute to eliminating residual skin cancer cells. For instance, dendritic cells (DCs), the typical antigen-presenting immune cells which consist dermal DCs, Langerhans cells and plasmacytoid DCs, are abundant in both epidermal and dermal tissues and play central role in initiating immune response[9-11].

Despite DCs being present in human carcinomas, the potential to initiate an immune response is largely diminished by tumor environment[12,13]. Tumors suppress the function of DCs significantly by exploiting different cytokines, including interleukin-6 (IL-6), macrophage colony-stimulating factor, IL-10 and IL-13[14-16]. It was reported that the number of Langerhans cells decreased in

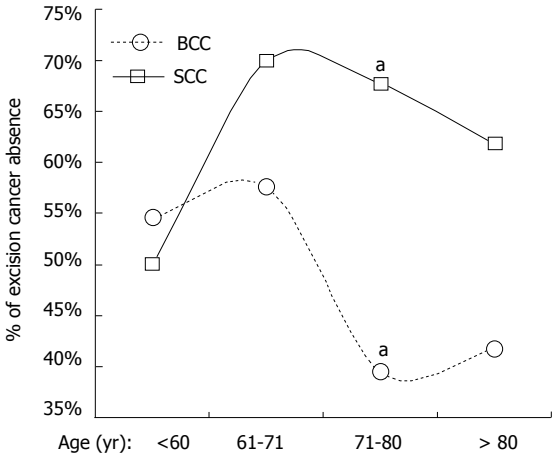

**Figure 2 Age distribution and percentage of excision-cancer absence in basal cell carcinoma and squamous cell carcinoma.** Basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) cases were divided into four groups based on age, including cases younger than 60, 61-70, 71-80 and older than 80 years old. The percentage of excision-cancer absence in each group is shown as squares (SCC) and circles (BCC). [a]*P* = 0.02, percentage of excision-cancer absence in BCC *vs* SCC in 71-80 years old group.

SCC, though the mechanism is not fully understood[17-19]. In addition, SCC-associated DCs have much lower potential to stimulate proliferation of T-cells compared with DCs derived from normal tissue[20]. In view of this tumor mediated suppression of DCs, stimulating their function becomes a promising way to fight against skin cancer, as a limited number of DCs are sufficient to induce an immune response[21,22].

During the original biopsy of the SCC or BCC, a substantial part of the cancer tissue, as well as adjacent tumor-associated DCs and macrophages, were removed. This "tissue injury" would cause inflammation, accompanied with both innate and adaptive immune responses in the wound healing process[23-25]. Neutrophils, followed by monocytes, infiltrate the wound where monocytes would differentiate into DCs or macrophages. On the one hand, the immune cells which were either suppressed by the tumor or benefit the tumor growth were removed so that local immune suppression is relieved. Fresh healthy immune cells would then enter the wound area to "clean" the environment. Macrophages are the most abundant cells before fibroblast proliferation, which induced cancer cell apoptosis by producing nitric oxide or inducing nitric oxide production in tumor cells[26-30]. It is possible that the residual cancer cells were killed by these immune responses during the initial wound healing, leading to excision-cancer absence. Further research is needed to understand the underlying mechanism.

In a conclusion, wide excisions from nearly 50% or more BCC and SCC patients with positive margins at biopsy appeared to be absent of cancer cells. The excision-cancer absence is more frequently observed in SCC than BCC patients. No significant correlation between gender and cancer absence is found. However, while the percentage of excision-cancer absence was increased in elder SCC patients, it was decreased in elder BCC patients. These findings might provide evidence for a study on the specific mechanism of cancer cell absence resulting from a biopsy induced immune response.

**Table 4 Age distribution between excision-cancer absent and excision-cancer present cases of basal cell carcinoma and squamous cell carcinoma**

| | | Median age (range), yr | Average age, yr | *P* Value |
|---|---|---|---|---|
| BCC | Excision-cancer absent | 66 (45-92) | 67 | 0.191[1] |
| | Excision-cancer present | 72 (42-90) | 70 | |
| SCC | Excision-cancer absent | 76 (48-95) | 74 | 0.534[1] |
| | Excision-cancer present | 78 (45-91) | 75 | |
| Excision-cancer absent | BCC | 66 (45-92) | 67 | < 0.001[2] |
| | SCC | 76 (48-95) | 74 | |

*P* value: [1]In BCC or SCC cases, age distribution of excision-cancer absent *vs* present cases; [2]In excision-cancer absent cases, age distribution of BCC *vs* SCC. BCC: Basal cell carcinoma; SCC: Squamous cell carcinoma.

The authors would like to thank Mr. Rui Zhang (Nanjing University) for his assistance in statistic analysis.

## COMMENTS

### *Background*

When examining patients for suspected cancer, biopsies are performed to confirm that the lesion is in fact cancer, which type of cancer, as well as to determine if the cancer is confined to the biopsy or extends to the margins (positive margins). For biopsies which show positive margins, wide excision will be performed. It is expected that cancer cells will appear in the excised tissues of wide excisions. However, clinically this is not always the case.

### *Research frontiers*

As the classic treatment for skin cancer, the wide excision is necessary after the positive margin is confirmed in biopsy. Biopsy is indispensable to define the risk factors of skin cancer. The research hotspot in this field is how to determine the excision margins of different types of skin cancer based on result of biopsy.

### *Innovations and breakthroughs*

This retrospective chart review provided evidences that 49% basal cell carcinoma (BCC) and 64% squamous cell carcinoma (SCC) patients did not have cancer cells left in the original location where the positive margin was reported in biopsy. Although the correlation between excision-cancer absence and gender or age distribution was excluded in both SCC and BCC patients, the analysis revealed that in excision-cancer absent cases, there were more male patients in BCC than that in SCC while SCC patients were older than BCC patients.

### *Applications*

The data provided in this study suggests a potential role of immune response caused by biopsy in removing residual cancer cells. The high percentage of excision-cancer absence might cushion the SCC and BCC patients against the fear of biopsy and promote compliance of them with biopsy demanded by dermatologists.

### *Terminology*

Excision-cancer present SCC or BCC patient means that cancer cells were found in the widely excised tissue which contained positive margin which had been reported previously in biopsy. Excision-cancer absent SCC or BCC means no cancer cells were found in wide excision containing previously defined positive margin.

### *Peer review*

The work is well written and focuses on an interesting aspect of skin cancer surgery.

## Abstract

Chordomas are malignant tumors arising from notochordal remnants. They are the most frequent tumors of the spine after plasmacytomas. Only 6% of chordomas are localized to the cervical level. In young patients, chordomas are rare and unpredictable. Despite this, the treatment of choice remains the total resection, as much as possible, followed by proton beam radiation. This case was managed using a precarotid and retrocarotid approach at the same time. The tumor was completely resected with the edges free from disease. The cervical spine was stabilized with an anterior plating C2-C4. Eighteen months after surgery the patient is still free from illness. Multilevel oblique corpectomies are an available and safe option for the treatment of upper cervical chordomas.

**Key words:** Cervical chordoma; Multilevel oblique corpectomy; Surgery; RXT; Retrocarotid approach

**Core tip:** In young patients, chordomas are rare and unpredictable. Despite this, the treatment of choice remains the total resection, as much as possible, followed by proton beam radiation. When there is a precarotid and retrocarotid extension, the removal by a multilevel oblique corpectomy seems to be a feasible and safe surgical technique.

Multilevel oblique corpectomies as an effective surgical option to treat cervical chordoma in a young girl. *World J Clin Cases* 2014; 2(3): 57-61 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i3/57.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i3.57

## INTRODUCTION

Chordomas are malignant tumors arising from notochordal remnants and are the most frequent tumors of the spine after plasmacytomas. Only 6% of chordomas are localized at cervical level[1,2]. The treatment of choice is total resection, or removing as much as possible of the tumor, followed by proton beam radiation. As emphasized in previous studies, total resection and, in particular, *en bloc* removal are not always possible, especially in the upper cervical localization and when the tumor englobes the epidural space (as in our case). This is a consequence both of the fact that the cervical chordoma infiltrates the nearby structures and that the margins of the total resection include unresectable structures. In young patients, chordomas are rare and unpredictable. We describe a rare case of an extensive cervical chordoma in a 14-year-old girl treated simultaneously by a precarotid and retrocarotid approach.

## CASE REPORT

A 14-year-old girl was referred to our institution with cervical pain, dysphagia, hyperreflexia and weakness of

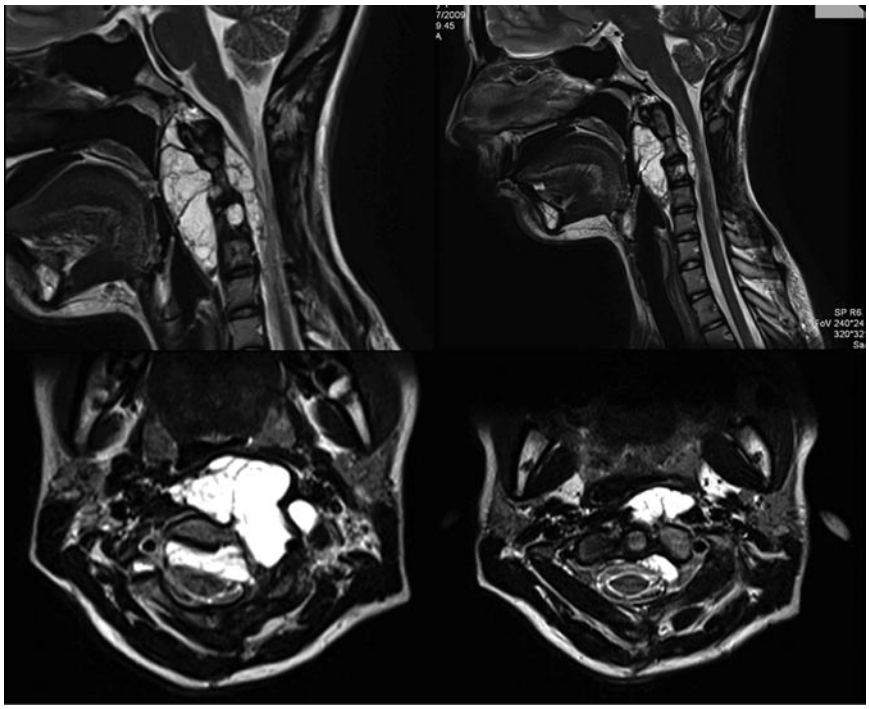

**Figure 1 Sagittal and axial T2-weighted magnetic resonance imaging showed diffuse increased signal of a lesion of C2-C3-C4 with important retropharyngeal portion.**

the four limbs for 8 mo. The preoperative magnetic resonance imaging (MRI) showed a lesion of C2-C3-C4 with marked retropharyngeal and epidural space involvement (Figure 1). The tumor extended from the C1 anterior tuberculum as far as the C5 superior plate. Since biopsy had been performed in another institute *via* C2-C3-C4 interhemilaminectomy, the definitive result of the biopsy was not available.

A pre-operative CT showed erosion of the C2-C3-C4 vertebral bodies (Figure 2). An angio-MRI with gadolinium administration pointed out that the left vertebral artery (VA) was encapsulated and displaced without reduction of the vessel diameter. The tumor showed a spare contrast enhancement with gadolinium and in DWI was hyperintense in DWI sequences. Relating to the clinical and radiological features, there were two diagnostic hypotheses, either an epidermoid cyst or chordoma. The tumor was classified IB according to the Enneking classification[3]. It was distributed to layers A-F and sectors 4-7 according to the Weinstein Boriani Biagini Classification[4].

### *Surgical procedure*

Surgical strategy consisted of a precarotid and retrocarotid approach during a single operation. The patient was positioned in the supine position with her head rotated 30° to the right. A presternocleidomastoid longitudinal skin incision was performed starting from left mastoid process. Firstly, the precarotid approach was performed through which the retropharyngeal portion was removed (Figure 3). Infiltrated bone, the portion around VA and the epidural space component were removed *via* the second approach, *via* multilevel oblique corpectomies. During surgery we employed ecodoppler monitoring to control the vertebral artery, as well as the operative microscope and the cavitron ultrasonic surgical aspirator, to remove the epidural component of the tumor. The retropharyngeal component was removed by an *en bloc* excision, while an intralesional excision was performed to remove the residual tumor. The tumor was completely resected together with the disease-free borders. A C2-C3 and C3-C4 discectomy with apposition of synthetic bone was performed to improve and speed up fusion and the cervical spine was stabilized by means of C2-C4 anterior plating.

A post-operative computed tomography (CT)-scan confirmed the correct position of the plate and the screws (Figure 4). The second day after surgery, the patient was free of any neurological deficit and was able to stand up and started to walk. The patient was discharged from hospital the seventh day after surgery. Twenty days after surgery, a post-operative MRI showed total resection of the tumor. A Shantz cervical collar was fitted for 45 d. Forty days after surgery, the patient received postoperative

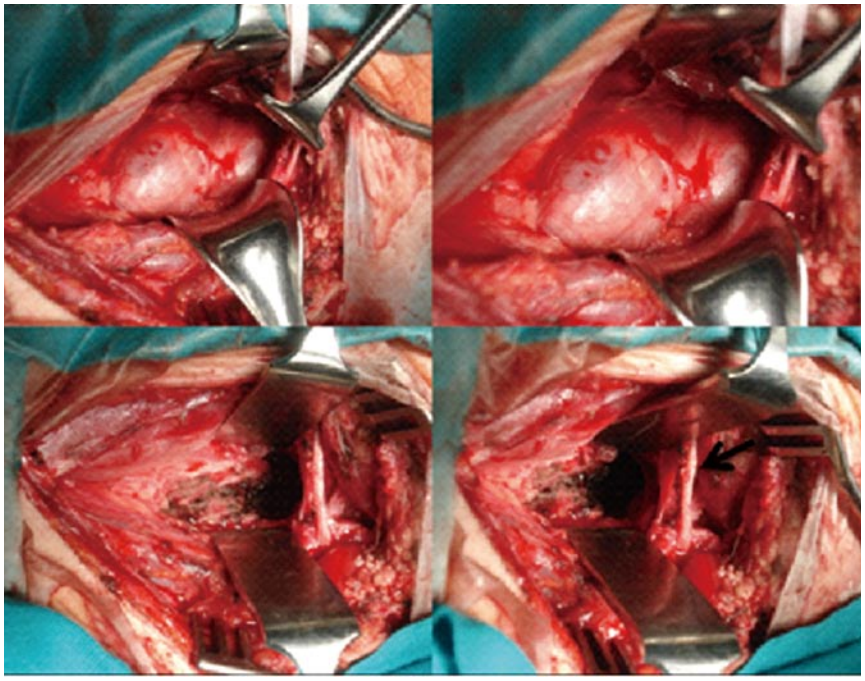

**Figure 3 Intraoperative photos shows before (above) and after (below) *en bloc* excision of the retropharyngeal portion.** The arrow points to the hypoglossal nerve.

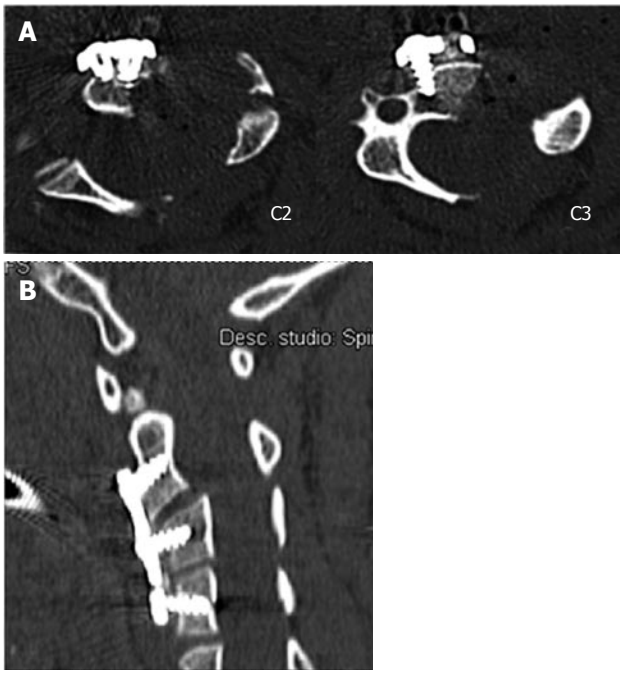

**Figure 4 Postoperative axial (A) and sagittal (B) reconstructed computed tomography scans of the cervical spine shows the oblique corpectomies and a fixation with an anterior plating C2-C4.**

proton beam radiation therapy. A clinical and radiological control, consisting of cervical MRI with gadolinium, was performed every 6 mo. Twenty days after surgery, the patient returned to school and at present leads a normal life. Fusion was documented at 40 d. No recurrence or metastasis was observed 48 mo after the operation (Figure 5).

## DISCUSSION

Chordoma is a low-grade malignant tumor which is rare (incidence of 0.51 cases/million), and is generally slow-growing, radioresistant and has a high tendency of recurrence[4]. Chordomas arise from remnants of the notochord, especially at the two end portions. 32% of chordomas arise from the clivus, 33% from the spinal cord, 29% from the sacrococcygeal region and just 6% from the cervical spine[1]. The treatment of choice is *en bloc* total resection followed by radiation therapy. The chordoma is sensitive to a high dose of "standard" radiation. However, the Bragg peak effect of a proton beam is useful for delivering a high radiation dose without damaging the tissue around the tumor and the spinal cord[1,5]. Total resection and, above all, *en bloc* removal are not always possible, especially in the upper cervical localization and when the tumor englobes the epidural space (as in our case). This is a consequence of the fact that the cervical chordoma infiltrates the nearby structures; moreover, the margins of the total resection include non-resectable structures like the vertebral artery. However, as pointed out by Boriani *et al*[6], "*en bloc* removal of a bone tumor is possible for a tumor arising in the scapula (scapulectomy) and tibia (above knee amputation), but it is absolutely impossible for a spinal tumor. In this sense, even if the spinal cord is sectioned above and below, the epidural space represents a compartment extending from the skull to the coccyx. A trial of aggressive chemotherapy is warranted in patients with metastatic chordomas. In the literature[7-9], two protocols were primarily used, consisting of ifosfamide or imatinib mesylate. Several approaches for treating upper cervical chordoma have been described in the literature: the anterior precarotid cervical approach (bilateral or not); the anterolateral retrocarotid approach; the transoral approach[10]; and anterior fixation or anterior and posterior fixation[11].

In the case described here, an anterior precarotid and an anterolateral retrocarotid (presternocleidomastoid) ap-

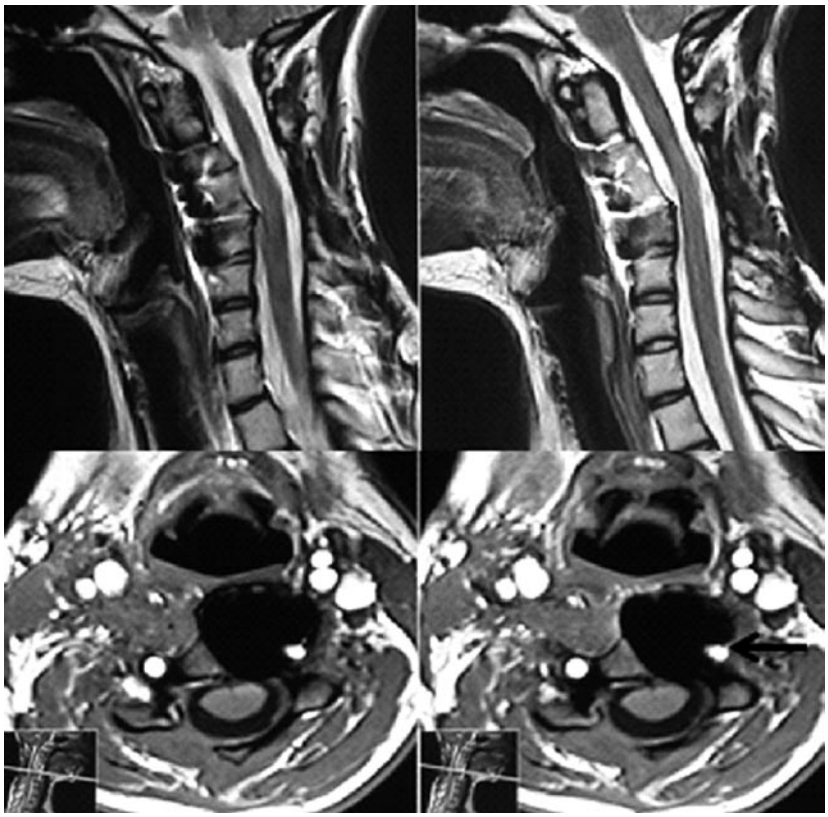

**Figure 5 T2 (above) and T1 with gadolinium contrast (below) magnetic resonance imaging shows total resection of the tumor.** The arrow underlines the left vertebral artery.

proach were performed at the same time. The advantages of this technique were good control of the left vertebral artery, multilevel oblique corpectomies, removal of the epidural space component of the chordoma and the possibility of anterior plating. It was impossible to perform an *en bloc* excision for the epidural space component because the tumor enclosed the left VA[1]. The procedure that we performed avoided binding of the VA and injuring the cervical roots, with a better outcome in comparison to some recent works[10,12]. Moreover, only anterior fixation was necessary because we performed multilevel oblique corpectomies, thus sparing the posterior structures of the cervical spine. This procedure made it possible to avoid occipitocervical fixation in a 14-year-old girl and the consequent limitations in movement.

In our opinion, a more aggressive strategy (multiple spondylectomy), which has a high morbidity, is justified for the treatment of cervical chordoma because chordomas are tumors whose biological behavior is difficult to predict. Despite this, the most recent publications[1,10-19] have shown that there are no important differences between patients operated on using an aggressive strategy (spondylectomy) and those submitted to corpectomies. So in our opinion, multilevel oblique corpectomies seem to be a feasible and safe surgical technique to treat a cervical chordoma.

## COMMENTS

### *Case characteristics*

A 14-year-old girl was referred to our institution with cervical pain, dysphagia, hyperreflexia and weakness of the four limbs for 8 mo.

### *Imaging diagnosis*

The preoperative magnetic resonance imaging showed a lesion of C2-C3-C4 with marked retropharyngeal and epidural space involvement.

### *Treatment*

Surgical strategy consisted of a precarotid and retrocarotid approach during a single operation.

### *Experiences and lessons*

Multilevel oblique corpectomies seems to be a feasible and safe surgical technique to treat a cervical chordoma.

### *Peer review*

This is well written case report presenting a rare condition which is explained well.

## Abstract

The case of a 32-year-old black woman of African descent who suffered from repeated episodes of acute pancreatitis, initially triggered when flying on airplanes, is reported. She did not drink alcohol or smoke. Genetic analysis was negative for cationic trypsinogen, serine protease inhibitor Kazal type 1 and chymotrypsin C. However, hemoglobin F was elevated. Sequencing of the thalassemia gene revealed a novel alteration in the 5′ region indicative of a functional abnormality of the molecule. Sequencing the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene revealed a heterozygote sequence variant. The combination of a hemoglobin gene mutation known for thalassemia in conjunction with the hitherto undescribed *CFTR* mutation is suggested to pave the road for initial and repetitive pancreatitis attacks. This will be discussed.

**Key words:** Acute pancreatitis; Hypoxia; Flying; Thalassemia; Hemoglobin; Cystic fibrosis transmembrane conductance regulator; Hereditary persistence of fetal hemoglobin

**Core tip:** This is a discussion case with two genetic alterations, one in a pancreatitis-related gene and one in an unrelated gene that might influence the oxygenation in the pancreas.

Löhr JM, Haas S. Can a polymorphism in the thalassemia gene and a heterozygote *CFTR* mutation cause acute pancreatitis? *World J Clin Cases* 2014; 2(3): 62-66 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i3/62.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i3.62

## INTRODUCTION

Within the group of younger patients suffering from recurrent episodes of acute pancreatitis, those not drinking alcohol impose a special diagnostic challenge. Many of these patients, who were coined to suffer from idiopathic pancreatitis even without a family history, may have mutations in the genes known to be associated with this disease[1]. Among genes identified to convey the risk of developing pancreatitis are cationic trypsinogen (PRSS1)[2], serine protease inhibitor Kazal type 1 (SPINK1)[3], chymotrypsin C (CTRC)[4] and cystic fibrosis transmembrane conductance regulator (CFTR)[5], whereas mutations in the anionic trypsinogen gene[6] appear to be protective. Some who may be negative for genetic factors may have anatomical abnormalities, such as pancreas divisum or other branching disorders[7]. Still then, a small subgroup is left with no identifiable reason. Those may suffer from rare metabolic conditions or syndromes, however, normally present with other symptoms indicative of the underlying disease. Beyond those conditions, there are rather exotic reasons for suffering from acute pancreatitis. We here report on the combination of two hitherto undescribed mutations in both an extrapancreatic and a

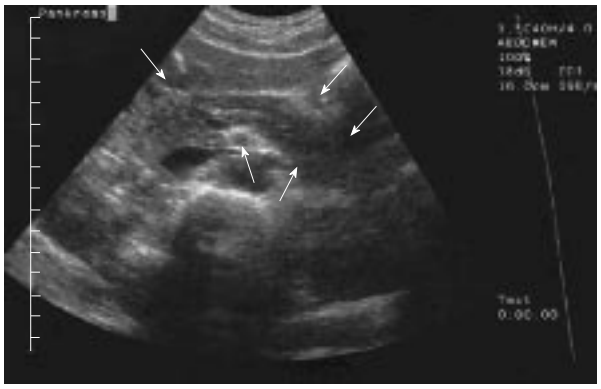

**Figure 1 Transabdominal ultrasound depicting a pancreas (arrows) of normal size with slightly enhanced echogenicity.**

pancreatic gene that might explain the repetitive attacks of pancreatitis.

## CASE REPORT

### Previous history

The 31-year-old black woman, who was brought up in Kenya but had been living in Germany for the last 8 years, presented with repeated episodes of acute abdominal pain which started in the middle epigastric region and would eventually radiate into the back, suggestive of acute pancreatitis. These episodes initially occurred after flying on regular commercial aircrafts. She was hospitalized eight years prior to this attack when 23 years old for cystitis and pyelonephritis when a diagnosis of acute pancreatitis was established *via* computer tomography. At that time, she also suffered from iron-deficient anemia [hemoglobin (Hb) 10.7 g/dL, mean corpuscular volume 69.4 μm, iron 28 mg/dL, ferritin 23 ng/mL].

### Recent history prior to referral

Abdominal ultrasound and computed axial tomography scan were reported to be normal; endoscopic retrograde cholangiopancreatography showed a slightly irregular main pancreatic duct (grade 0); however, no pancreas divisum and no papillary abnormalities. No overt gallstones, microlithiasis or sludge was present. After the last episode, when the diagnosis of acute pancreatitis was established by laboratory tests (elevated serum amylase and lipase) and abdominal ultrasound (swollen pancreas), the patient was referred to our outpatient pancreas clinic about one week after the last episode.

### Current presentation

The patient denied any abdominal pain or discomfort, fever or occasional night sweating. Appetite was normal. Bowel movements were reported to be regular with normal stool consistency and she reported no weight loss. There was no family history of pancreatitis or unclear abdominal pain. The patient denied any alcohol intake, smoking or experience with other drugs. There were no known allergies, prescription medicine or over-the-counter drugs. The patient is a graduate student.

The patient was in no apparent distress. The physical exam was completely normal, vital signs stable and specifically, the abdomen was not tender. Bowel sounds were normal.

### Laboratory tests

In the blood, amylase and lipase were elevated (Table 1). All other parameters were within normal limits (Table 1). Infectious pathogens known to be associated with pancreatitis (cytomegalovirus, Epstein-Barr virus, mumps, adenovirus, varicella zoster virus, rubella, human immunodeficiency syndrome, Coxsackie, Legionella, leptospira, echinococcus, filariasis, fasciolosis, toxocara, bilharzia) could be excluded by serology. She did not have and had no history of malaria. Autoantibodies against nuclei, mitochondria and smooth muscle were negative, as were rheumatoid factors. All immunoglobulins, especially total immunoglobulin G (IgG) and IgG4, were within normal limits. Fecal elastase-1 (985 μg/g) and fecal chymotrypsin (14.7 U/g) were well within the normal range.

### Imaging

The pancreas appeared almost normal on ultrasound. Notably, the echogenicity was slightly elevated towards a so-called "white pancreas"[8] (Figure 1). There was a normal arterial blood supply to the pancreas. As the patient was slender, the transabdominal ultrasound had a good visibility: no gallstones, sludge or microlithiasis could be detected in the gallbladder or the bile duct all the way down into the pancreas.

### Hematological and genetic tests

Since the history of present illness together with the ethnic background of the patient was pressing, we performed further analysis with regard to a possible hemoglobinopathy. The ordinary complete blood count with blood smear was normal.

Hemoglobin F was slightly elevated at 0.92%, suggesting a "hereditary persistence of fetal hemoglobin" (HPFH). Molecular analysis of the hemoglobins resulted in the finding of a heterozygous transition at -158 C → T within the 5' non-coding region of the $^{G}$gamma globulin gene (HPFH Swiss)[9,10]. Sequencing of the $^{A}$gamma globulin gene did not reveal any abnormalities. Other genetic abnormalities associated with HPFH [HPFH-1 (black), HPFH-2 (Ghana), HPFH-3 (Indian), HPFH-7 (Kenya)] could not be detected. Sequencing of the β-thalassemia gene revealed no abnormalities. Sequencing the *CFTR* gene revealed a heterozygote sequence variant (c.2882T>C; p.M961T (ATG>ACC). Sequencing of *PRSS1*[2], *SPINK1*[3] and *CTRC*[4] did not reveal any additional mutations in these pancreatitis genes.

### Further course

During a six year follow-up, the patient did not develop any further episodes of pancreatitis. According to our recommendation, she resisted from flying.

**Table 1 Laboratory values upon presentation to the pancreas outpatient clinic**

| Parameter | Unit | Value | Range |
|---|---|---|---|
| WBC | 10E9/L | 4.5 | 3.6-11.0 |
| RBC | 10E12/L | 4.73 | 3.8-5.2 |
| Hb | g/dL | 14.8 | 12-16 |
| Hct | | 43.9 | 35%-47% |
| MCV | fL | 92.9 | 80-100 |
| Na | mmol/L | 139 | 135-144 |
| K | mmol/L | 4.28 | 3.5-5.2 |
| Ca | mol/L | 2.18 | 2.25-2.60 |
| Albumin | g/L | 36.4 | 35-52 |
| Blood glucose | mg/dL | 74 | 70-115 |
| Bilirubin (total) | mg/dL | 0.31 | 0.2-1.4 |
| Uric acid | mg/dL | 3.2 | 2.5-5.7 |
| Cholesterol | mg/dL | 173 | 130–260 |
| Triglycerides | mg/dL | 36 | < 200 |
| BUN | mg/dL | 18.8 | 16.7-45.8 |
| Creatinine | mg/dL | 0.7 | 0.6-1.1 |
| Alkaline phosphatase | U/L | 80 | 55-160 |
| γGT | U/L | 9 | 4-18 |
| GPT/ASAT | U/L | 5 | 5-19 |
| GOT/ALAT | U/L | 13 | 5-15 |
| Cholinesterase | U/L | 4238 | 2800-7400 |
| HbA1C | | 1.51 | 1.2-4.6 |
| Zinc | mmol/L | 34 | 16-50 |
| Amylase | U/L | 183 | 25–115 |
| Lipase | U/L | 202 | 114-286 |
| Chymotrypsin | U/g | 14.7 | > 6 |
| Elastase-1 | μg/g | 985 | > 200 |
| HbF | | 0.92 | < 0.5% |
| HbA | | 92.73 | 87%-94% |
| HbA2 | | 2.14 | 1.6%-3.1% |
| Anomalous Hb | | Not detectable | |
| ALA | μmol/d | 24 | 2-49 |
| Porphobilinogen | μmol/d | 6.6 | 0.5-7.5 |
| Total porphyrines | μg/d | 41.7 | < 145 |

WBC: White blood cells; RBC: Red blood cells; Hb: Hemoglobin; Hct: Hematocrit; MCV: Mean corpuscular volume; BUN: Blood urea nitrogen; GOT/ASAT: Glutamic oxaloacetic transaminase; GPT/ALAT: Glutamic pyruvic transaminase; HbA1c: Hemoglobin A1c; ALA: Alpha lipoic acid.

**Table 2 Summary of key findings**

| Etiology | Parameter | Negative/ normal | Positive | Finding |
|---|---|---|---|---|
| Metabolic parameters | TSH, PTH, α-AT, lipids | X | | |
| Immunological parameters | IgG/IgG4; AMA, ANA, ASMA, RF | X | | |
| Pancreatotrophic virus | Adenovirus, Coxsackie, CMV, EBV, hepatitis, HIV, measles, mumps, Rubella, VZV | X | | |
| Pancreatitis genetics-acinar | PRSS1, CTRC, SPINK1 | X | | |
| Pancreatitis genetics-ductal | CFTR | | X | c.2882T > C; p.M961T (ATG > ACC) |
| Hemoglobin | HBs | | X | Elevated |
| HPFH | $^{G}$gamma-hemoglobin gene | | X | -158 C → T (HPFH Swiss) |
| | $^{A}$gamma-hemoglobin gene | X | | |

HIV: Human immunodeficiency syndrome; ANA: Autoantibodies against nuclei; AMA: Autoantibodies against mitochondria; ASMA: Autoantibodies against smooth-muscle; CMV: Cytomegalovirus; EBV: Epstein-Barr virus; VZV: Varicella zoster virus; PTH: Parathyroid hormone; TSH: Thyroid-stimulating hormone; IgG: Immunoglobulin G; RF: Rheumatoid factor; PRSS1: Pancreatitis cationic trypsinogen; SPINK1: Serine protease inhibitor Kazal type 1; CTRC: Chymotrypsin C; CFTR: Cystic fibrosis transmembrane conductance regulator; HBs: Hepatitis B surface; HPFH: Hereditary persistence of fetal hemoglobin.

## DISCUSSION

In adolescent and young adult patients presenting with signs of pancreatitis, associations with genetic abnormalities are pressing[1]. Even in sporadic cases, mutations in the genes known to cause hereditary pancreatitis such as PRSS1 have been reported. More recently, mutations in SPINK1 and CTRC have been reported in patients with idiopathic pancreatitis. Those were all normal/negative in this patient. The earlier history of present illness with flying to and from Kenya triggering the episodes of pancreatitis made us suspicious of other mechanisms underlying the etiology of her pancreatitis. The ethnic background led to further analysis of hemoglobinopathies, which revealed elevated hemoglobin F. Elevated fetal hemoglobin is not uncommon: it has been detected in around 10% of teenage high school students[11], a few of them with abnormalities. Amongst these, the $^{G}$gamma-globulin gene (HPFH Swiss) alteration is most frequent amongst females, all of them described as of Caucasian origin[11]. Detailed studies of our young black female patient revealed this heterozygous transition at -158 C → T within the 5' non-coding region of the $^{G}$gamma-globulin gene (HPFH Swiss) (Table 2). No other abnormalities could be detected. Notably, the patient did not suffer from clinically overt thalassemia, not having the typical mutations in the hemoglobin A (β-chain). Since this particular variant is considered to be minor[12], this could not have been expected. Nevertheless, associations with rather complex hereditary traits have been described in these hemoglobinopathies[13].

Classical thalassemia is reported to be associated with acute pancreatitis; however, the etiology is biliary as gallstones are typical in these patients. Indeed, in a series of 43 juvenile patients with acute pancreatitis, 30 suffered from choledocholithiasis caused by thalassemia[14].

Sequencing the *CFTR* gene revealed a heterozygote sequence variant that has not been described previously (Table 2). The pathophysiological meaning, especially in relation to pancreatitis, is therefore unknown.

Whereas neither of these heterozygote mutations per se might have been sufficient to cause or contribute to pancreatitis, it is suggestive that the minor alterations in two genes, one pancreatic (CFTR) and one extrapancreatic (hemoglobin), might have culminated in a two-step mechanism leading to pancreatitis: impaired hemoglobin,

causing a certain degree of oxygen deficiency which is known to cause pancreatitis, *e.g.*, during iatrogenic ischemia or heart-lung machine usage, imposed on a heterozygote mutation in the *CFTR* gene. This two-hit hypothesis is speculative as we did not investigate the functional changes imposed by such a transition in the non-coding region in the hemoglobulin and the *CFTR* mutation alone or in combination.

There is only one study reporting on a small series of patients with clinically overt thalassemia, gallstones and biliary pancreatitis[14]; however, our patient did not have overt thalassemia or gallstones/sludge or microlithiasis.

The pathological oxygen saturation of hemoglobin in thalassemia has been described[15,16]. Hypoxemia and ischemia have been demonstrated to be able to induce experimental pancreatitis[17]. Microcirculatory disturbances are today considered to play an important role in the exacerbation of acute pancreatitis[18]. Reduced perfusion of the pancreatic gland leading to hypoxia and ischemia is a well-described mechanism causing[19] or worsening pancreatitis[20]. Even in sickle-cell anemia, the acute pancreatitis is considered to be caused by microvascular occlusion[21]. Conversely, hyperbaric oxygen therapy has been demonstrated to ameliorate acute pancreatitis[22]. The combination of an alteration in a gene altering oxygen saturation with a gene altering pancreatic secretion represents the rendezvous of two genes, each in itself not sufficient to induce thalassemia or pancreatitis, an extrapancreatic and an intrapancreatic. This is supported by the finding in our patient during the initial, most severe acute pancreatitis when she was also found to have anemia (Hb 10.7 g/dL). We speculate that such combinations may be responsible for a number of hitherto undefined causes of juvenile pancreatitis. This has been observed in patients with pancreas divisum with CFTR or SPINK1 mutations, also conditions that on their own might not be sufficient to cause pancreatitis[23].

## ACKNOWLEDGMENTS

We thank the patient for permission to publish her case and to conduct the genetic analyses. We thank Heiko Witt, Munich and Jonas Rosendahl, Leipzig, for performing the genetic analyses.

## COMMENTS

### Case characteristics

The case of a 32-year-old black woman of African descent who suffered from repeated episodes of acute pancreatitis, initially triggered when flying on airplanes, is reported.

### Laboratory diagnosis

Genetic analysis was negative for cationic trypsinogen, serine protease inhibitor Kazal type-1 and chymotrypsin C. However, hemoglobin F was elevated.

### Pathological diagnosis

The combination of a hemoglobin gene mutation known for thalassemia in conjunction with the hitherto undescribed *CFTR* mutation is suggested to pave the road for initial and repetitive pancreatitis attacks.

### Treatment

Sequencing of the thalassemia gene revealed a novel alteration in the 5' region indicative of a functional abnormality of the molecule.

### Experiences and lessons

Sequencing the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene revealed a heterozygote sequence variant.

### Peer review

This is indeed an interesting case that needs to be published to increase awareness of more uncommon causes.

## Abstract

Hutchinson-Gilford progeria syndrome (HGPS) is a rare dysmorphic syndrome characterized by several features of premature aging with clinical involvement of the skin, bones, and cardiovascular system. HGPS has an estimated incidence of one in four million to one in eight million births. The main clinical features of HGPS include short stature, craniofacial dimorphism, alopecia, bone fragility, and cardiovascular disorders. The most frequent cause of death is myocardial infarction at a mean age of 13 years old. Dental manifestations include delayed development and eruption of teeth, discoloration, crowding and rotation of teeth, and displaced teeth. Cone beam computed tomography images revealed the absence of the sphenoid, frontal, and maxillary sinus, flattening of the condyles and glenoid fossa, and bilateral hypoplasia of the mandibular condyles. The disease is caused by mutations in lamin A/C (*LMNA*). Here, we present a case report of an 11-year-old boy with classical features of HGPS, which was caused by a *de novo* germ-line mutation (C1824T, G608G) in exon 11 of the *LMNA* gene. Some uncommon HGPS-associated features in our patient, such as alterations in the facial sinuses and hypoplasia of the condyles, contributed to the expansion of the phenotypic spectrum of this syndrome from a dentomaxillofacial perspective.

**Key words:** Cone beam computed tomography; *LMNA* mutation; Craniofacial anomalies; Temporomandibular joint

**Core tip:** Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic syndrome characterized by the accelerated appearance of aging in children. We report a case of an 11-year-old boy with HGPS with uncommon HGPS-associated dentomaxillofacial features. Alterations in the facial sinuses and hypoplasia of the condyles were recognized in our patient, expanding the phenotypic spectrum of this syndrome.

## INTRODUCTION

Hutchinson-Gilford progeria syndrome (HGPS; OMIN #176670) is an uncommon genetic disorder characterized by accelerated aging with clinical involvement of the skin, bones, and cardiovascular system[1,2]. The prevalence of HGPS is one in four million to one in eight million live births; males are more frequently affected than females, and the intellect of the affected children is unimpaired[3]. Clinically, individuals with HGPS demonstrate short stature, prominent eyes, micrognathia, craniofacial disproportion, loss of subcutaneous fat, alopecia, beaked nose, coxa valga, pathologic bone fractures, radiolucent terminal phalanges, hearing loss, photophobia, hypertension, hyperlipidemia, atherosclerosis, and cardiovascular disorders. The most frequent cause of death is myocardial infarction at a mean age of 13 years old[4-11]. Oral alterations include high rates of tooth decay, crowding, delayed tooth development and eruption, tooth discoloration, hypodontia, maxillary and mandibular hypoplasia, and small mouth opening[5-7,12,13]. Recognition of dentomaxillofacial features of HGPS may allow oral health problems to be readily identified and aid in implementation of preventative treatment plans to improve quality of life[14,15]. Although HGPS demonstrates both autosomal dominant and autosomal recessive modes of inheritance, most cases are due to sporadic mutations[16]. Mutations in the lamin A/C (*LMNA*) gene are responsible for HGPS[17-19].

Here we report a case of HGPS in an 11-year-old boy with an uncommon phenotype and a *de novo* heterozygous silent mutation at amino acid 608 (G608G) of the *LMNA* gene.

## CASE REPORT

An 11-year-old boy with a clinical diagnosis of HGPS was referred to the Clinical Department, School of Dentistry, Federal University of Pará, Brazil for oral health care. He was suffering from angina, peptic ulcer disease, and limited joint mobility. His current medications were pravastatin (5 mg/d) to prevent cardiovascular disease and ranitidine (150 mg/d) for the treatment of the peptic ulcer. The patient had normal neurodevelopment and showed the classical clinical features of HGPS, including short stature, low weight/height ratio, thin and inelastic skin, eyes slightly open when sleeping, photophobia, osteoporosis in the femur region, generalized alopecia, prominent scalp veins, small face with a beaked nose, and high-pitched voice (Figure 1). The patient had no apparent hearing loss. Echocardiogram and electrocardiogram results, blood pressure, pulse, and oxygen saturation were within normal limits. A hand-wrist radiograph showed radiolucencies of the terminal phalanges and the skeletal maturity of a 14-year-old boy with a chronological age of 11 years and 8 mo.

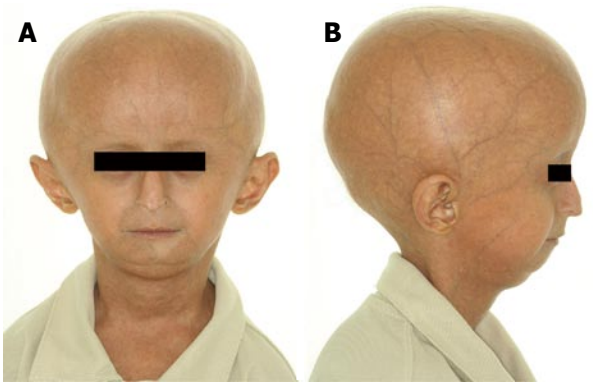

**Figure 1 Clinical features of the patient at 11 years of age.** A: Facial features were characterized by a deformed head, generalized alopecia, a small face, a beaked nose, and thin and inelastic skin; B: In the lateral view, prominent scalp veins and micrognathia are evident.

His height and weight were 1.1 m and 17.4 kg, respectively, which is well below the 3rd percentile for his age and only 4.4 kg greater than expected for a normal 4.5-year-old boy. Oral examination revealed micrognathia, class II malocclusion, and chronic trimus. Erupted teeth were of normal size, shape and color, but the permanent incisors were lingually erupted. The patient had gingivitis and low salivary flow, but had no dental caries and brushed his teeth while supervised by the mother. An orthopantomographic radiograph showed reduced dimensions of both arches with consequent lack of space for the correct positioning of the permanent teeth, mandible with a steep mandibular angle, eruption of the permanent teeth, and congenitally missing left upper second premolar and both lower second premolars (Figure 2). To better visualize the craniofacial features, cone beam computed tomography (CBCT) was performed. CBCT images revealed the absence of the sphenoid, frontal, and maxillary sinuses (Figure 3A and B), flattening of the condyles and glenoid fossa, and bilateral hypoplasia of the mandibular condyles (Figure 3C). Panoramic and axial images confirmed the dental alterations (Figure 3D-F).

To confirm the clinical diagnosis of HGPS, DNA sequence analysis was performed. The parents gave informed consent before the genetic study began. Mutation analysis of the *LMNA* gene with genomic DNA extracted from oral mucosa cells was performed according to a published protocol[20]. The patient demonstrated a heterozygous C-to-T transition at nucleotide 1824 in exon 11 of *LMNA*, which created a silent point mutation at codon 608 (GGC>GGT, G608G) (Figure 4). A similar mutation was not observed in the patient's parents or sister.

## DISCUSSION

This case highlights some common and uncommon dentomaxillofacial features associated with HGPS. Tooth size was essentially normal but the eruption sequence was complicated by both incomplete mandibular and

**Figure 2 Panoramic radiograph showing delayed eruption of the permanent teeth, hypodontia of the left upper second premolar and both lower second premolars, and temporomandibular joint malformation.**

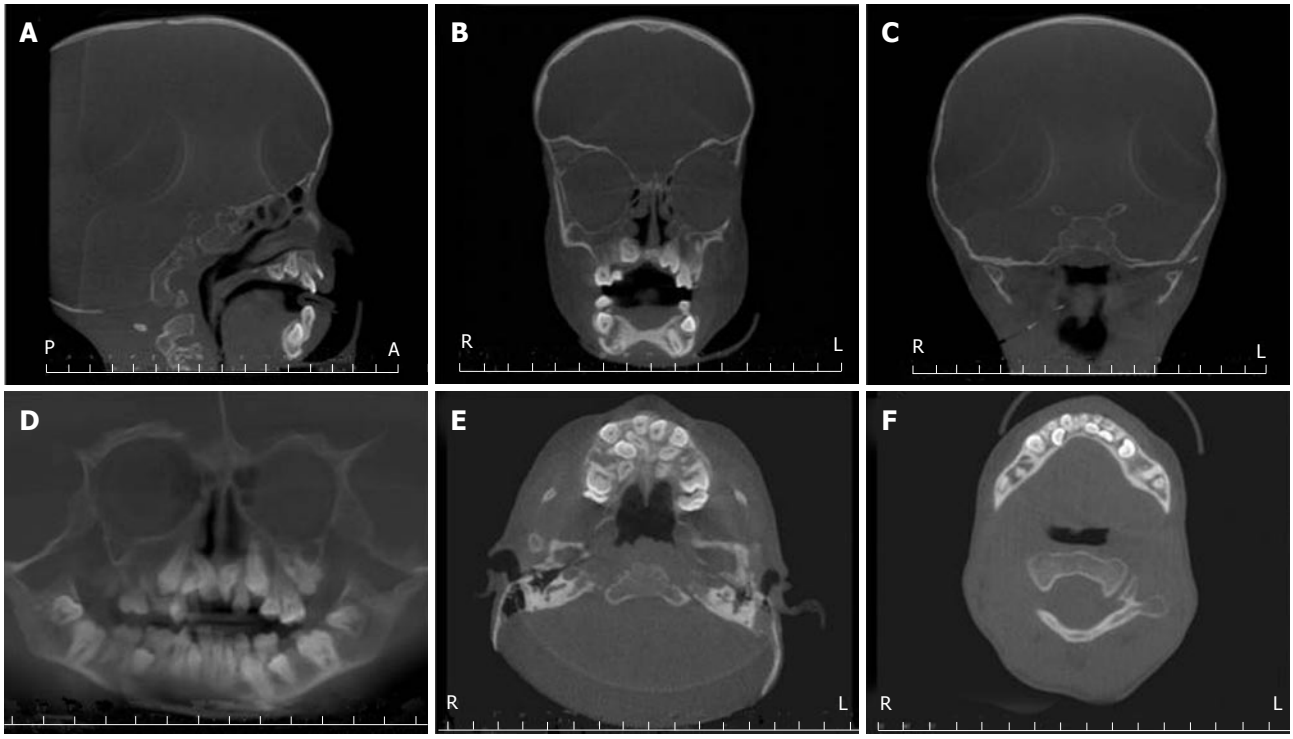

**Figure 3 Craniofacial features of the Hutchinson-Gilford progeria syndrome patient detected by cone beam computed tomography.** A, B: On sagittal (A) and coronal (B) images, hypoplasia of the sphenoid, frontal and maxillary sinuses was evident; C: This view depicts the temporomandibular joint alteration, which was characterized by flattening of the condyle and glenoid fossa and bilateral hypoplasia of the condyles; D: Panoramic view of the cone beam computed tomography (CBCT) revealing impaction of several permanent molars and hypodontia of the premolars; E, F: Axial slices of the CBCT showed malocclusion and lingual eruption of permanent teeth.

maxillary growth and micrognathia, which contributed to dental impactions. Despite radiographic evidence of normal root development, tooth eruption appeared to be delayed by three years. In addition, the permanent incisors had erupted lingually, and two premolars were absent (hypodontia). Delayed eruption, malocclusion associated with lower anterior dentition crowding, and hypodontia are consistent findings in patients with HGPS, as well as enamel hypoplasia and discoloration[15,20-22]. The permanent teeth in the current case were macroscopically normal in shape and color. Patients who do not present alterations in the joints of the hands can carry out oral hygiene perfectly, but adult supervision is required along with the use of a toothbrush with a small head due to the small oral cavity and limited mouth opening. Interestingly, CBCT images revealed the absence of the sphenoid, frontal and maxillary sinuses, shallow glenoid fossae, and bilateral hypoplasia of the mandibular condyles and articular eminences. After evaluating radiographs of 21 children aged newborn to 14.6 years old, Gordon *et al*[14] concluded that articulation deformities are not a common feature of HGPS. Chen *et al*[11] reported a similar case to ours and highlighted that craniofacial anomalies of HGPS contribute to increased number of caries, severe malocclusion, and problems with swallowing, feeding, and speech. However, Ullrich *et al*[23] evaluated 25 patients with HGPS and identified short mandibular rami in combination with flattened mandibular condyles, shallow glenoid fossae, and hypoplastic or absent articular eminences. The significance of the sinus alterations was unclear; however, patient- and parent-related chronic trismus can occur after a long period of regular dental

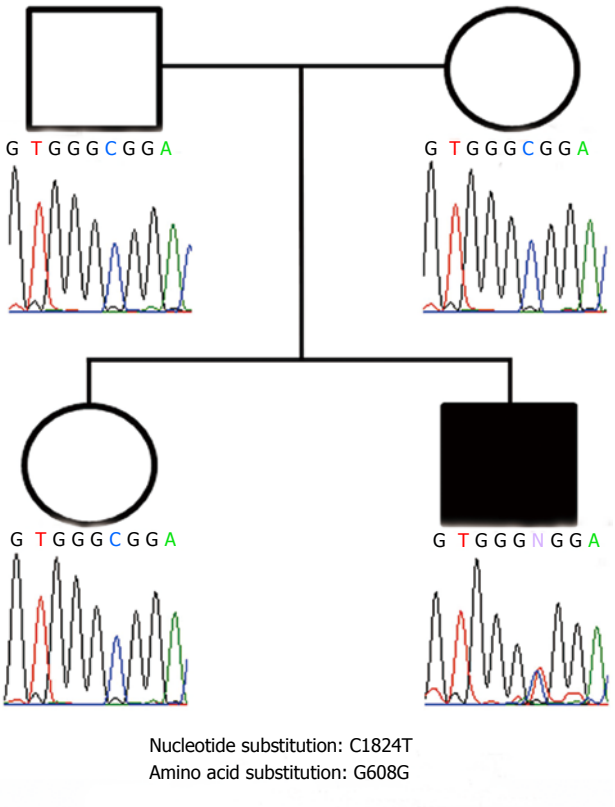

**Figure 4 Detection of the *LMNA* mutation in the Hutchinson-Gilford progeria syndrome patient.** Shown here are portions of the DNA-sequence electropherogram of the LMNA exon 11 of the affected patient, his parents and older sister. Compared to the normal sequence, the affected patient has a heterozygous C-to-T substitution at nucleotide position 1824 in the *LMNA* gene, which does not change the amino acid (G608G).

treatment. Thus, HGPS patients should be evaluated for temporomandibular joint (TMJ) disorders, and dentists need to be aware of the possible TMJ complications after a long period of regular dental treatment.

Despite the reported clinical characteristics, HGPS may be confused with other syndromes that include some features of premature aging, including neonatal progeroid syndrome (Weidemann-Rautenstrauch syndrome), acrogeria, Cockayne syndrome, Hallermann-Streif syndrome, gerodermia osteodysplastica, Berardinelli-Seip congenital lipodystrophy (congenital generalized lipodystrophy), Petty-Laxova-Weidemann progeroid syndrome, Ehlers-Danlos syndrome, progeroid form, and Werner syndrome[10,21]. Since an overlap in the clinical features of the patients affected by progeroid syndromes is common, the diagnosis of HGPS is based on the recognition of common clinical features and the detection of mutations in the *LMNA* gene and eventually in the *ZMPSTE2* gene, a metallopeptidase involved in processing of lamin A. *LMNA* mutations are present in more than 95% of cases, and genetic testing should start with analysis of the p.G608G mutation at exon 11, in which 62% of the defects reside[12]. DNA sequencing from the patient reported here revealed the p.G608G silent mutation. Although this mutation does not change the encoded amino acid, it results in the activation of a cryptic splice site and causes a truncated lamin A protein (50 amino acids shorter than normal), which is essential for the conversion of normal lamin A from prelamin A[18]. Since HGPS patients develop severe atherosclerosis and death usually occurs as a result of the complications of cardiac or cerebrovascular diseases during adolescence, early diagnosis of HGPS is important. To promote survival of HGPS patients, annual analysis of the vascular status is recommended using baseline electrocardiogram, echocardiogram, and carotid duplex scans to evaluate stenosis and intimal thickness. Additional tests include a skeletal X-ray to evaluate common associated features (*e.g.*, acroosteolysis, clavicular resorption, and coxa valga), dual-energy X-ray absorptiometry to assess bone mineral density, standard goniometry to assess global joint mobility, and nutritional assessment to optimize caloric intake[24].

In summary, we report one patient affected by HGPS who demonstrated unusual features, including the absence of the sphenoid, frontal and maxillary sinuses and bilateral hypoplasia of the mandibular condyles. Proper characterization of the clinical features and genetic defects is of utmost importance for correct diagnosis and timely clinical management. Furthermore, early intervention by a multidisciplinary team can increase the quality of life and survival of HGPS patients.

## COMMENTS

### *Case characteristics*

An 11-year-old boy with a diagnosis of Hutchinson-Gilford progeria syndrome (HGPS) presented with a need for oral health care.

### *Clinical diagnosis*

The patient exhibited classical clinical features of HGPS, including short stature, low weight/height ratio, thin and inelastic skin, eyes slightly open when sleeping, photophobia, generalized alopecia, prominent scalp veins, small face with a beaked nose, and high-pitched voice.

### *Differential diagnosis*

Differential diagnosis included neonatal progeroid syndrome (Weidemann-Rautenstrauch syndrome), acrogeria, Cockayne syndrome, Hallermann-Streif syndrome, gerodermia osteodysplastica, Petty-Laxova-Weidemann progeroid syndrome, and Werner syndrome.

### *Imaging diagnosis*

Cone beam computed tomography (CBCT) images revealed absence of the sphenoid, frontal and maxillary sinuses, flattening of the condyles and glenoid fossa, and bilateral hypoplasia of the mandibular condyles.

### *Pathological diagnosis*

DNA sequence analysis and mutation analysis of the lamin A/C (*LMNA*) gene was performed with genomic DNA extracted from oral mucosa cells. The patient demonstrated a heterozygous C-to-T transition at nucleotide 1824 in exon 11 of *LMNA*, which created a silent point mutation at codon 608 (GGC>GGT, G608G).

### *Treatment*

The patient received medical and dental treatment to improve his quality of life.

### *Related reports*

Recognition of dentomaxillofacial features of HGPS may allow for early identification of oral health problems and for the development of preventive treatment plans to improve quality of life.

### *Term explanation*

Hutchinson-Gilford progeria syndrome is an uncommon genetic disorder characterized by accelerated aging with clinical involvement of the skin, bones, and cardiovascular system.

### *Experiences and lessons*

Proper characterization of the clinical features and genetic defects of HGPS is of utmost importance for correct diagnosis and initiation of timely clinical man-

agement; early intervention by a multidisciplinary team can increase the quality of life and survival of these patients.

### *Peer review*

This article reports a case of Hutchinson-Gilford progeria syndrome in an 11-year-old boy with an uncommon phenotype and a *de novo* heterozygous silent mutation at amino acid 608 (G608G) in the *LMNA* gene.

## Abstract

Resuscitation measures performed at the scene of the event have the ultimate impact on the outcome of a cardiac arrest. We analysed six case histories of those sudden cardiac arrest patients who were revived in the field and were subsequently admitted to the intensive care unit during a six-month period. All were known cardiac patients and were under the care of healthcare providers. Four of those were discharged home from the hospital and did not suffer any residual damage where as one died of multi-organ failure and the other was declared brain dead. The outcome was good in patients who received early intervention in the form of basic life support. The family members of non-survivors witnessed the cardiac arrest at home but were not familiar with the concept or procedures of basic life support. We propose that physicians who care for cardiac patients should undertake the task of increasing family member awareness and knowledge in the techniques of basic life support.

**Key words:** Heart disease; Cardiac arrest; Cardiopulmonary resuscitation; Physicians; Family members; Education and training

**Core tip:** Resuscitation measures performed at the scene of the event have a major impact on the outcome of cardiac arrest. There is no specific strategy in place to motivate family members of cardiac patients to learn life-saving basic life support techniques. We propose that the physicians who care for cardiac patients should undertake the task of increasing family member awareness and knowledge of basic life support.

Ajmal M. An additional responsibility for physicians caring for cardiac patients: Insight from a case series. *World J Clin Cases* 2014; 2(3): 72-74 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i3/72.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i3.72

## INTRODUCTION

Successful revival following sudden cardiac arrest depends on patient characteristics and resuscitation measures[1]. Heart disease is the most common cause of sudden cardiac arrest, and its risk can be reduced by long-term efforts initiated by patients and their healthcare providers. However, "resuscitation measures" performed at the scene of the event have a major impact on the outcome of cardiac arrest[2]. Recently, we reviewed a series of out-of-hospital adult cardiopulmonary resuscitations carried out in the communities served by our regional hospital. An insight of the outcome of that case series is reported.

## CASE REPORT

We analysed six case histories of cardiac arrest patients who were revived in the field and were subsequently admitted to the intensive care unit during a six-month period. The patient characteristics and resuscitation measures are shown in Table 1.

In this series, cases 5 and 6 did not survive. Case 5

**Table 1 Patient characteristics and resuscitation measures**

| Case | Age (yr) | Gender | Cardiac disease | Initial diagnosis | BLS/ ACLS | Initial treatment | In-hospital management |
|---|---|---|---|---|---|---|---|
| 1 | 68 | Male | Yes | VFib | Immediate | BLS, ACLS | Ventilation antiarrhythmic inotropes |
| 2 | 58 | Male | Yes | VFib | Immediate | BLS, ACLS | ventilation thrombolytic inotropes |
| 3 | 79 | Male | Yes | PEA | Immediate | BLS, ACLS | ventilation thrombolytic inotropes |
| 4 | 64 | Male | Yes | VFib | Immediate | BLS, ACLS | ventilation antiarrhythmic |
| 5 | 74 | Male | Yes | VFib | Delayed | ACLS | ventilation antiarrhythmic hemofiltration |
| 6 | 56 | Female | Yes | VFib | Delayed | ACLS | ventilation antiarrhythmic therapeutic hypothermia |

ACLS: Advanced cardiac life support; BLS: Basic life support; PEA: Pulseless electrical activity; VFib: Ventricular fibrillation.

died of multi-organ failure, and case 6 was declared brain dead. The other four patients were discharged home and did not suffer any residual damage. Though limited in number, this series reveals some patterns with regard to characteristics and resuscitation measure outcome: (1) all were known cardiac patients under the care of healthcare providers; (2) in five of the six patients, cardiac arrest was due to ventricular fibrillation, which is a shockable rhythm and requires the immediate use of a defibrillator, such as automated external defibrillator; (3) the outcome was good in patients who received early intervention in the form of "basic life support" (BLS); and (4) the family members of cases 5 and 6 witnessed the cardiac arrest at home but were not familiar with the concept or procedures of BLS. Two of the four patients who survived suffered from cardiac arrest while they were enjoying in a pub/bar and were able to receive BLS or even defibrillation immediately. One patient who collapsed on his own street was taken care of by paramedical professionals employed at the local hospital who happened to be passing by, and one victim suffered cardiac arrest at a doctor's appointment and was resuscitated by his primary care physician. One of the patients who did not survive was the youngest (56 years old) in this case series but did not receive cardiopulmonary resuscitation until an ambulance arrived twenty minutes later. We asked the families of the survivors about their awareness and ability to provide BLS, and three of the four families acknowledged that they did not know how to implement these measures.

## DISCUSSION

Many social organizations actively promote public and community awareness about BLS. Healthcare employees and those that work at public facilities (*e.g.*, airports, restaurants/pubs) are required to complete BLS training. However, there is no specific strategy in place to motivate family members of cardiac patients to learn life-saving BLS techniques[3]. We propose that physicians who care for cardiac patients should undertake the task of increasing family member awareness and knowledge of BLS[4]. Anesthesiologists can motivate families of cardiac patients who undergo anesthesia or intensive care unit admission. This can be accomplished through direct communication with individual families or in the form of combined educational sessions with multiple families[5]. This strategy is especially important in remote areas where ambulance response times are long.

## ACKNOWLEDGMENTS

A special "thank you" goes to Niall Fanning, Anesthesiologist, St. James's Hospital, Dublin, Ireland and Michael Carey, Anesthesiologist and Director Perioperative Medicine, Coombe Women and Infants University Hospital, Dublin, Ireland, for their ongoing support and encouragement for the author to continue academic activities in the field of Anesthesiology and Acute Care Medicine.

## COMMENTS

### *Case characteristics*

A series of six out-of-hospital sudden witnessed cardiac arrests in cardiac patients.

### *Clinical diagnosis*

Return of spontaneous circulation following sudden cardiac arrest.

### *Differential diagnosis*

Intact cerebral function, cerebral damage, and brain death.

### *Laboratory diagnosis*

Post cardiac arrest.

### *Imaging diagnosis*

Post cardiac arrest in five cases, severe cerebral damage (brain death) in one case.

### *Pathological diagnosis*

Post cardiac arrest.

### *Experiences and lessons*

Family members of cardiac patients should learn life saving basic life support techniques and health care providers involved in their care should motivate family members to learn these techniques.

### *Peer review*

The author who analysed six case histories of cardiac arrest victims proposes that physicians who care for cardiac patients should undertake the task of increasing family member awareness and knowledge of "basic life support". The cases are not rare but the content is worth publishing.

## Abstract

Ehlers-Danlos syndrome (EDS) is a group of inherited connective tissue disorders caused by collagen synthesis defects. Several hemostatic abnormalities have been described in EDS patients that increase the bleeding tendencies of these patients. This case report illustrates a patient with an unusual presentation of a patient with type Ⅳ EDS, platelet δ-storage pool disease and factor Ⅴ Leiden mutation. Young woman having previous bilateral deep vein thrombosis and pulmonary emboli coexisting with ruptured splenic aneurysm and multiple other aneurysms now presented with myocardial infarction. Presence of factor Ⅴ Leiden mutation raises the possibility that the infarct was due to acute coronary thrombosis, although coronary artery aneurysm and dissection with myocardial infarction is known to occur in vascular type EDS. This is the first report in the medical literature of factor Ⅴ Leiden mutation in an EDS patient which made the management of our patient challenging with propensity to both bleeding and clotting.

**Key words:** Ehlers-Danlos syndrome; Factor V Leiden; Platelets; Coagulopathy

**Core tip:** Hemostatic abnormalities that have already been described in Ehlers-Danlos syndrome patients include platelet abnormalities (release defects, δ-storage pool disease) as well as clotting factor deficiencies that increase the bleeding tendencies of patients. The coexistence of platelet δ-storage pool disease and factor Ⅴ Leiden mutation in our patient manifested as having aneurysms of the splenic, renal, hepatic, gastric, mesenteric arteries and diffuse aneurysms of the upper and lower extremities as well as bilateral lower extremity deep vein thromboses and pulmonary emboli. This propensity to both bleeding and clotting made the management of our patient challenging on this presentation with acute anterolateral myocardial infarction.

## INTRODUCTION

Ehlers-Danlos syndrome (EDS) is a group of heterogeneous heritable diseases that cause hyperextensibility of the skin, hypermobility of the large joints and easy bruising. It is classified in regard to main symptoms, the causative gene and the inheritance pattern. Among the eleven described types of EDS, type Ⅳ EDS known as vascular form, is a rare autosomal dominant inherited disorder with a 100% phenotypic penetrance caused by a mutation of the *COL3A1* gene encoding type Ⅲ collagen. EDS has an estimated prevalence of 1:5000 to 1:250000 births, and among all, vascular type accounts for 5%-10% of cases[1,2]. The vascular type is the most severe because

of vascular system complications as type Ⅲ collagen rich systemic arteries may undergo dissection, aneurysm, or rupture. Vascular rupture or other organ rupture are the presenting signs in 70% of patients with vascular EDS and the mean age for first major arterial or gastrointestinal complication is 23 years[1]. As for the hemostatic abnormalities previously reported in EDS, patients have more tendency to bleed due to platelet abnormalities (release defects, δ-storage pool disease) and clotting factors deficiencies. We report a case of a 40-year-old female with type Ⅳ EDS, platelet δ-storage pool disease and factor V Leiden mutation. Patient who had multiple previous complications including rupture splenic aneurysm and multiple other aneurysms in addition to coexisting bilateral deep vein thrombosis and pulmonary emboli, presented with acute myocardial infarction.

## CASE REPORT

The patient is a 40-year-old woman previously diagnosed with Ehlers-Danlos syndrome type Ⅳ and aneurysms of the splenic, renal, hepatic, gastric, and mesenteric arteries as well as diffuse aneurysms of the upper and lower extremities. She was transferred emergently from an outside hospital with nausea, vomiting, chest pain, shortness of breath, productive cough, and fever of two days duration. Her history was significant for coagulopathy associated with platelet storage pool defect, factor V Leiden with large bilateral lower extremity deep vein thromboses and pulmonary emboli, and diet controlled diabetes mellitus. Further history obtained from the patient and medical record revealed a healthy childhood and generally good health in early adulthood. The patient noted that she had always been "double jointed" in her hands. She had excessive bleeding after cesearian section and deep vein thrombosis in her twenties that prompted hematologic evaluation. This revealed a prolonged bleeding time and platelet storage defect, and factor V Leiden homozygous mutation. The patient denied a tobacco smoking history.

At the age of 33 she was hospitalized for abdominal pain and underwent appendectomy for presumed appendicitis. Approximately one month later she presented again with further abdominal pain and was found to have a ruptured splenic artery aneurysm and multiple aneurysms of the hepatic, renal, gastric, and mesenteric arteries. She underwent emergent splenectomy. Extensive vascular adhesions were found on laparotomy at that time. Four days later she developed a left arm compartment syndrome due to an automated sphygmomanometer and underwent emergent vascular reconstruction of her brachial artery. That hospitalization was further complicated by post-op intrabdominal bleeding requiring repeat laparotomy and Jackson-Pratt drainage placement, and hematochezia due to anal fissures. During recovery from these acute events she developed thigh pain and pleuritic chest pain and was found with large bilateral deep vein thromboses and small pulmonary emboli. Surgical pathological examination of the splenic artery aneurysm with molecular and biochemical analysis were diagnostic of Ehlers-Danlos syndrome type Ⅳ.

Initial examination was significant for a woman in moderate distress, pulse of 115 bpm, blood pressure of 80/40 mmHg, respiratory rate of 24 per minute with 96% oxygen saturation on 15 L/min non-rebreather, and temperature of 101.7 F. She had elevated jugular venous pressure to 6 cm above the angle of Louis, and diminished breath sounds in the right lung with right basilar rales. Her cardiac exam revealed no visible heave, a diminished point of maximum intensity, a rapid regular rhythm, and a normal first and second heart sound with no audible S3. She had a holosystolic Ⅱ/Ⅵ murmur loudest at the left sternal border that did not vary with respiration, and she had no pericardial rub. Her extremities were warm, and distal pulses were normal except for a diminished left radial pulse. She had a large surgical scar running the medial length of her left arm from axilla to distal forearm. She had no peripheral edema. Further physical examination was notable for prominent veins of the extremities with a transparent appearance of the skin. Her finger, hand, and wrist joints were hypermobile with passive range of motion.

Electrocardiogram revealed sinus tachycardia with 2 mm ST elevations and Q waves in the antero-lateral leads consistent with acute antero-lateral myocardial infarction. Initial laboratory evaluation was significant for troponin I of 189 ng/mL. Chest X-ray was significant for bilateral hazy infiltrates. The patient was offered emergent cardiac catheterization but declined. She also declined all antiplatelet and anticoagulant medications. Echocardiogram was performed revealing severely decreased systolic function with severe hypokinesis of the anterior wall, septum, apex and inferior wall. The remaining segments were hypokinetic. Right ventricular size and function and estimated pulmonary artery pressures were normal, and mild to moderate mitral regurgitation was present. Her mental status, blood pressure, and chest pain improved with supportive measures including empiric antibiotics for community acquired pneumonia. The patient's recovery from anterolateral myocardial infarction and pneumonia was complicated by parapneumonic effusion. She tolerated percutaneous pleural drainage well and was discharged home.

## DISCUSSION

Among the eleven described types of EDS, type Ⅳ EDS, also known as vascular form, is a rare autosomal inherited disorder of connective tissue due to a mutation of the *COL3A1* gene encoding type Ⅲ collagen. It presents a decreased amount of type Ⅲ collagen and therefore an increased vascular friability and fragility. The vascular morbidity this patient has experienced is typical of patients with vascular EDS type Ⅳ who do not express the typical hyperextensible skin and joints[3]. In fact, it is the most severe form and leads to premature death due to hemorrhage from the rupture of the major and visceral arteries. Besides the connective pathology responsible for the bleeding tendency, several hemostatic abnormalities have been described in EDS patients. These include platelet abnormalities (release defects, δ-storage pool

disease) as well as clotting factor Ⅷ, Ⅸ, XI and XIII deficiencies[4-6]. However, cause of the acute anterolateral myocardial infarction remains unclear in this unfortunate young woman with the combination of platelet storage pool defect with coagulopathy and factor Ⅴ Leiden mutation with history of deep vein thromboses and pulmonary emboli. Coronary artery aneurysm and dissection with myocardial infarction is known to occur in vascular type EDS[7-14]. The coexistence of factor Ⅴ Leiden mutation further raises the possibility that the infarct was due to acute coronary thrombosis, although a clear association between MI and factor Ⅴ Leiden in non-smokers has not been established[15]. Coronary artery aneurysm with or without dissection as an anatomic substrate for acute coronary thrombosis in this individual with factor Ⅴ Leiden is one possibility that could tie together her vascular and hematologic abnormalities that resulted in acute anterolateral myocardial infarction. This patient had an unusual combination of pathologies. This rare association of EDS type Ⅳ, platelet δ-storage pool disease and factor Ⅴ mutation is not previously described. As our patient illustrates, this association predisposes to bleeding and clotting tendencies. While there is no therapy for EDS, desmopressin acetate reduces the bleeding time in patients with EDS type Ⅳ and platelet δ-storage pool disease[16].

## COMMENTS

### *Case characteristics*

A 40-years-old female diagnosed with Ehlers-Danlos syndrome (EDS) type Ⅳ presented with chest pain, shortness of breath and productive cough.

### *Clinical diagnosis*

Diminished breath sounds in the right lung, holosystolic Ⅱ/Ⅵ murmer loudest at left sternal border and elevated jugular venous pressure to 6 cm above the angle of Louis.

### *Differential diagnosis*

Myocardial infarction, pulmonary embolism, pneumonia.

### *Laboratory diagnosis*

Troponin I 189 ng/mL.

### *Imaging diagnosis*

Electrocardiogram (ECG): 2 mm ST elevations and Q waves in anterolateral leads; chest X-ray: Bilateral hazy infiltrates; echocardiogram: Decreased systolic function with severe hypokinesis of anterior wall, septum, apex and inferior wall.

### *Pathological diagnosis*

ECG and troponin suggestive of anterolateral myocardial infarction.

### *Treatment*

Patient declined both emergent cardiac catheterization and antiplatelet/anticoagulation medications.

### *Related reports*

Patients with type Ⅳ Ehler-Danlos are reported to have increased tendency to bleed rather than having hypercoagulability state.

### *Experiences and lessons*

This case report shows unusual coexistence of platelet storage disease and factor Ⅴ Leiden mutation in EDS, predisposing our patient to bleeding and clotting tendencies.

### *Peer review*

This article reports an interesting factor Ⅴ Leiden mutation in an Ehlers-Danlos patient.

## Abstract

Stroke is an important cause of death and disability in adults. However, effective treatments for patients with acute ischemic stroke are limited. Intravenous recombinant tissue plasminogen activator (*iv* rtPA) within 4.5 h after onset has been approved as a standard treatment for patients with acute ischemic stroke. However, due to time constraints, less than one percent of acute ischemic stroke patients in Thailand are able to obtain *iv* rtPA. Although endovascular interventional therapy has not yet been approved as standard treatment in acute ischemic stroke, it is the one of the potentially effective treatment options. There are several reliable methods of endovascular therapy for acute ischemic stroke patients. Endovascular interventional therapy has rarely been done in Thailand. We report seven patients with successful recanalization after endovascular treatment in acute large vessel stroke from a single stroke center in Thailand. Patient screening and selection with multimodal imaging protocol and multimodality methods of endovascular interventional therapy are described.

**Key words:** Acute ischemic stroke; Intra-arterial thrombolysis; Endovascular therapy; Mechanical thrombectomy

**Core tip:** We report seven patients with successful recanalization after endovascular treatment in acute large vessel stroke from a single stroke center in Thailand. Patient screening and selection with multimodal imaging protocol and multimodality methods of endovascular interventional therapy are described.

Jongsathapongpan A, Raumthanthong A, Muengtaweepongsa S. Successful recanalization with multimodality endovascular interventional therapy in acute ischemic stroke. *World J Clin Cases* 2014; 2(3): 78-85 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i3/78.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i3.78

## INTRODUCTION

Stroke is the leading cause of adult disability, particularly in the elderly, and remains the third most common cause of death in the developing world, as well as in Thailand[1,2]. Despite improving the quality of stroke management, morbidity and mortality related to stroke remain significant[3]. Intravenous recombinant tissue plasminogen activator (*iv* rtPA) is a standard treatment for patients with acute ischemic stroke[4]. The NINDS study shows that *iv* rtPA given within 3 h of stroke onset improves the modified Rankin Scale (mRS) at 90 d[5]. The recent

F: Female; M: Male; ICA: Internal carotid artery; BA: Basilar artery; NIHSS: National Institutes of Health Stroke Scale; *iv* rtPA: Intravenous recombinant tissue plasminogen activator; *ia* rtPA: Intra-arterial recombinant tissue plasminogen activator; NA: Not available; Y: Yes; N: Not.

ECASS3 trial expands indication of intravenous rtPA to 4.5 h[6]. Clinical benefit from *iv* rtPA to Thai stroke patients has been shown in studies[7,8]. However, most stroke patients are still not able to get *iv* rtPA due to delayed arrival and tight exclusion criteria[9].

Identification of ischemic penumbra with diffusion-perfusion mismatch by magnetic resonance imaging (MRI) may have a role in patient selection for further treatment in acute ischemic stroke[10,11]. However, the benefit on clinical outcomes of this imaging selection for endovascular treatment in patients with acute ischemic stroke is still controversial[12].

Intra-arterial thrombolysis is a viable option to some patients who arrive after the 3 h[13]. The PROACT Ⅱ trial showed that recanalization rate and functional outcomes are better with intra-arterial thrombolysis[14]. Mechanical thromboembolectomy in acute ischemic stroke has received intense interest in recent years. The multi MERCI trial shows that clot removal with the device, which can be done up to 8 h after stroke onset, raises the recanalization rate up to 60%[15]. The Penumbra Pivotal trial shows that continuous thrombus aspiration with a Penumbra catheter can improve the recanalization rate to more than 80%[16]. The SWIFT trial shows that clot extraction with the Solitaire device in large vessel occlusion, including internal carotid artery (ICA), middle cerebral artery part 1 (M1), middle cerebral artery part 2 (M2) and basilar artery (BA), also provides a recanalization rate of up to 80%[17]. Unfortunately, the two most recent trials published in a landmark journal do not show any benefit in functional outcomes from endovascular treatment in acute ischemic stroke[18,19].

In Thailand, endovascular interventional therapy rarely has been performed in patients with acute ischemic stroke. Intra-arterial recombinant tissue plasminogen activator (*ia* rtPA) is an option in some medical centers. Imaging selection is also optional for decision making in some centers. Recently, Solitaire and Penumbra devices have been available for commercial use. We report our initial experiences with these procedures.

Phyathai 2 is a private hospital located in central of Bangkok. This 200 bed hospital provides 20 intensive care unit beds for medical intensive conditions, including acute ischemic stroke. The medical records of patients who received endovascular interventional therapy for acute large vessel occlusion (ICA, M1, M2 and BA) in Phyathai 2 Hospital during February 2010 to January 2013 were reviewed.

### Endovascular interventional therapy protocol

Acute ischemic stroke patients who were not eligible for *iv* rtPA or who still had significant deficits after *iv* rtPA were evaluated by the stroke neurologist (SM). A stroke interventional team (Jongsathapongpan A, Raumthanthong A) was alerted. Multimodal MRI (conventional MRI with MRA and MR perfusion) was done on an emergency basis. If the diffusion-perfusion mismatch was more than 20%, the patient would be transferred to the catheterization lab for endovascular treatment. The anesthesiologist was standing by in the catheterization lab.

The right femoral artery was cannulated with an 8 F sheath. Selective angiography of the carotid or vertebral artery was done with a 5 F Simmon 1 or a 5 F JR4 catheter. The aortic arch angiogram and 4 vessel DSA were not routinely performed. If an occluded artery was confirmed, a 6 F 90 cm sheath was placed as far as a distal cervical ICA or a distal V2 segment. A 018 microcatheter was advanced over the guidewire to the occlusion site. Low dose *ia* rtPA (less than 5 mg) was given. If no clot lysis was seen, continuous clot aspiration using a Penumbra device or clot extraction with a Solitaire device was performed.

## CASE REPORT

We identified 7 cases. Age ranged from 56-87 years. National Institutes of Health Stroke Scale (NIHSS) ranged from 9-30. Multimodal MRI was done in 6 of 7 cases (86%). There were 2 patients with ICA occlusion, 2 with middle cerebral artery (MCA) occlusion and 3 with BA occlusion. Carotid stenting was performed in one case. *ia* rtPA, mechanical thrombectomy and combined treatment were done in 4, 5 and 3 cases, respectively. Solitaire and Penumbra devices were used in 2 and 3 cases, respectively. Only 1 patient received intervention after intravenous thrombolysis. Case presentation and treatment are summarized in Table 1.

### Case 1

**Left distal ICA occlusion opened with *ia* rtPA and**

**Solitaire device:** A 56-year-old female presented with right hemiparesis and aphasia. She arrived at hospital 1 h after onset. Emergency computed tomography (CT) brain showed cord sign in left MCA and distal ICA. Initial NIHSS was 20. Electrocardiography (EKG) showed normal sinus rhythm. Echocardiography showed no intracardiac thrombus. *iv* rtPA was given 90 min after onset. No neurological improvement was noted. Two hours after *iv* rtPA, angiography was done. We found distal ICA occlusion. Balloon inflation with a 2.0 mm × 15 mm coronary balloon was attempted without success. Eight milligrams of *ia* rtPA was infused. No clot lysis was seen. Then, a 4.0 × 15 Solitaire device was deployed 5 h after onset. Immediate angiography showed thrombolysis in cerebral infarction (TICI) 2 flow. The Solitaire was slowly pulled back and a large thrombus was removed. Residual stenosis of mid M1 persisted but it resolved after 1 mg of nimodipine. Final angiography showed TICI 3 in M1 and anterior cerebral artery part 1 (A1). Occlusion of anterior cerebral artery part 2 (A2) was noted. No further intervention was attempted. Six months after the procedure, mRS was 2 (Figure 1A and B).

### Case 2

**BA occlusion opened with *ia* rtPA and Penumbra device:** An 80-year-old female presented with alteration of consciousness. She had hypertension and chronic AF. Warfarin had been discontinued during the last month for unknown reasons. Immediate CT brain showed hyperdense basilar artery. MRI and MRA brain revealed small right cerebellar infarction and occlusion of mid basilar artery. Patent bilateral fetal type posterior cerebral artery was noted. Echocardiography showed no intracardiac thrombus. She was transferred to the catheterization lab 5.5 h after onset. Angiogram showed near occlusion of mid BA. Continuous thrombus aspiration with a 032 Penumbra catheter was done. TICI 3 was seen from proximal to mid basilar artery and bilateral superior cerebellar artery. Occluded distal basilar artery could not be opened. MRI brain on the next day showed bilateral superior cerebellar infarction. No intracranial hemorrhage was seen. After 3 mo mRS was only 4. Four months later, she suffered from a left MCA stroke despite dabigatran maintenance. No thrombolytic drug was given because of late presentation (Figure 1C and D).

### Case 3

**Tandem ostial left ICA and distal M1 occlusion opened with carotid stent:** A 64-year-old male was admitted for prostate surgery. Two days after the operation, he developed a right hemiparesis and dysphasia. Initial NIHSS was 10. MRI and MRA brain showed small left MCA infarction and severe ostial left ICA stenosis. Because of symptom fluctuation, *iv* rtPA was not given. Endovascular treatment was done because of a large diffusion-perfusion mismatch (> 20%). Angiography was done 5.5 h after onset. Critical ostial ICA stenosis and occlusion of supraclinoid ICA were seen. After deployment of a distal protection device, carotid stenting was done using 7.0 mm × 30 mm WALLSTENT™. Angiogram showed good flow of left ICA. Occluded distal M1 was noted. No further intervention was attempted because of good collateral flow. Two days after the procedure, NIHSS was 1 and mRS was 1 (Figure 1E and F).

### Case 4

**Basilar artery occlusion opened with Solitaire device:** An 81-year-old male presented with left hemiparesis. He arrived at hospital 7 h after onset. He had hypertension, dyslipidemia and chronic atrial fibrillation. Echocardiography revealed no intracardiac thrombus. MRI and MRA brain showed small right cerebellar infarction and mid basilar artery occlusion. He was transferred to the catheterization lab 13 h after onset. Angiography showed tortuous left vertebral artery and occluded proximal BA. We failed to advance a 5 F hydrophilic catheter over the left vertebral artery. Then, a homemade 90 cm shortened JR 7 F guiding catheter was placed at the proximal vertebral artery. A 4.0 mm × 15 mm Solitaire was deployed at the basilar artery. After thrombus extraction, TICI 3 flow of basilar was noted. Some residual thrombus remained in the basilar artery. No further intervention was attempted. He regained full consciousness the next day. Final NIHSS was 1 and mRS was 0 (Figure 1G and H).

### Case 5

**Left distal M1 occlusion opened with *ia* rtPA:** A 61-year-old male presented with right arm weakness and dysphasia. He arrived at hospital 1 h after onset. Initial NIHSS was 9. EKG was sinus rhythm. Echocardiography showed no intracardiac thrombus. MRI and MRA brain revealed small infarction in the left MCA area and left distal M1 occlusion. A large diffusion-perfusion mismatch was seen. He was transferred to the catheterization lab 4 h after onset. Angiography showed occlusion of superior M2 and slowed flow in the inferior M2 branch. Good pial collateral flow to the left superior M2 area was seen. Five milligrams of *ia* rtPA was given. TICI 3 flow of M1 and inferior M2 was noted. The superior M2 branch was still occluded. No further intervention was attempted. CT brain on the next day showed small spot hemorrhage in the left temporal lobe and small infarction of the left corona radiata. Right hemiparesis improved after the procedure. Three months later, he had only mild dysphasia and mRS was 0 (Figure 1I and J).

### Case 6

**BA occlusion opened with *ia* rtPA and Penumbra device:** An 87-year-old female patient was referred to our hospital because of loss of consciousness. Initial CT scan showed no significant hypodense area. EKG showed atrial fibrillation. MRI and MRA brain showed left pontine infarction and small bilateral cerebellar infarction. She was transferred to the catheterization lab 5 h after onset.

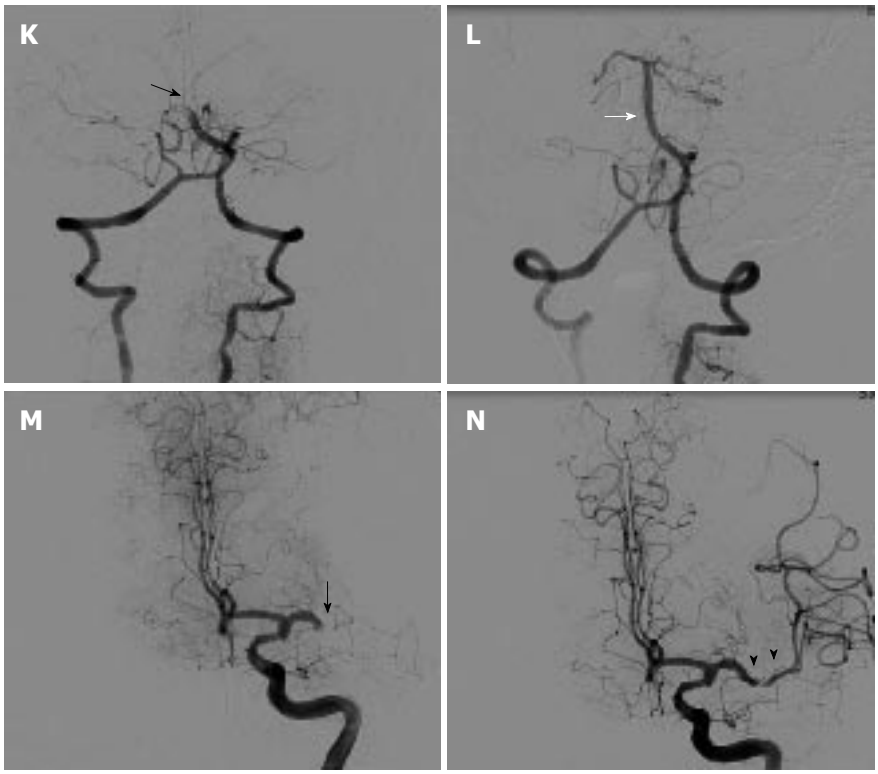

**Figure 1 Case angiogram.** A: Pre-procedure imaging showed occlusion of distal left internal carotid artery (black arrow); B: Post-procedure imaging showed good flow of middle cerebral artery (MCA) and A1 (white arrow), occlusion of A2 (arrowhead) was noted; C: Pre-procedure imaging showed near total occlusion of mid basilar artery (BA) (black arrow); D: Post-procedure imaging showed improved in mid BA, distal BA (arrowhead) still occluded; E: Pre-procedure imaging showed critical stenosis of ostial left including internal carotid artery (ICA) (black arrow); F: Post-procedure imaging showed mild residual stenosis of proximal ICA after carotid stenting (arrowhead); G: Pre-procedure imaging showed proximal BA occlusion (black arrow); H: Post-procedure imaging showed patent BA with some residual thrombus in proximal part (arrowhead); I: Pre-procedure imaging showed thrombotic occlusion of superior M2 branch and slow flow of inferior M2 branch (black arrow); J: Post-procedure imaging showed good flow of inferior M2 branch, superior M2 branch still occluded and that area was supplied from pial collateral (arrowhead); K: Pre-procedure imaging showed occlusion of distal BA (black arrow); L: Post-procedure imaging showed patent BA (white arrow) and right posterior cerebral artery (PCA), with left PCA still occluded (arrowhead); M: Pre-procedure imaging showed occlusion of distal left M1 (black arrow); N: Post-procedure imaging showed good flow of left MCA (arrowhead) and all branches.

Angiogram showed occlusion of distal BA. *ia* rtPA 5 mg was given without improvement. Four minutes of continuous thrombus aspiration with a Penumbra 041 catheter was done. Complete clot removal was seen. FU CT brain on the next day showed no intracranial hemorrhage but a new right occipital lobe infarction was seen. Despite the good angiographic outcome, she only had mRS 4 on the final visit (Figure 1K and L).

### *Case 7*

**Left M1 occlusion opened with *ia* rtPA and Penumbra device:** A 70-year-old male patient was referred to our hospital because of stupor, right hemiplegia and aphasia. He had diabetes, hypertension and was post coronary artery bypass surgery. EKG showed normal sinus rhythm. Echocardiography showed no intracardiac thrombus. Initial CT scan showed old cerebral infarction and so *iv* rtPA was not given. MRI and MRA brain showed occlusion of left M1. DWI showed no acute infarction. He was transferred to the catheterization lab 5 h after onset. Angiogram showed occlusion of left distal M1. *ia* rtPA 5 mg was given via a Rebar microcatheter without success. Three minutes of continuous aspiration with Penumbra 041 catheter was done. Complete clot removal was seen. CT brain on the next day showed small subarachnoid hemorrhage in the left sylvian fissure. No new infarction was seen. Three months later, he had only mild weakness of the right arm and mRS was 2 (Figure 1M and N).

## DISCUSSION

We described 7 cases of endovascular treatment with successful recanalization in acute ischemic stroke patients. Good outcome, defined by mRS less than 2, were found in 5 of 7 cases (71%). When mechanical thromboembolectomy devices were used, successful recanalization rate and good outcome were found in 80% and 60%, respectively, which are comparable to 81% and 25%, respectively in the PENUMBRA pivotal trial and 61% and 58%, respectively in the SWIFT trials. There was no mortality in our series, compared to 38% in the PENUMBRA pivotal trial and 17% in the SWIFT trial. In our series, intracranial hemorrhage and symptomatic intracranial hemorrhage were found in 28% and 0%, respectively, which is comparable to 28% and 11%, respectively in the

PENUMBRA pivotal trial and 17% and 2%, respectively in the SWIFT trial[16,17]. In our case series, younger (less than 80 years old) patients and good collateral supply were good prognostic indicators. We observed that in patients under 80 years old, all patients had good outcome (4 of 4) and in the presence of collateral supply (case 3 and case 5) a good outcome may be achieved even if the direct flow cannot be restored.

Multimodal MRI is the most reliable study to select the patients[20,21]. Patients with a small infarct core but large diffusion-perfusion mismatch are more likely to have better outcomes[21-23]. There is evidence that multimodal CT is also able to identify the infarct core and penumbra area[21,24]. However, high dose of iodinated contrast usage during CT may be contra-indicated in some patients[25]. Application of the ASPECT score with multimodal CT may be helpful for patient selection and outcome prediction[26,27].

Intra-arterial thrombolysis is one of preferred treatments in some centers[13,28]. Based on the PROACT trial, patency rate (TICI 2, 3) was 66% and mRS less than 2 at the 90$^{th}$ day was 40%, but in our case series, no clot lysis was found in any case[14]. It might be due to the limited dose of rtPA we used (less than 5 mg) and that the waiting time was too short (average 10-20 min). Anyway, we believed that *ia* rtPA still had a role in some patients, such as patients with small thrombus burden and patients with very tortuous neck arteries. However, it is likely that the role of *ia* rtPA will be surpassed by high efficacy mechanical devices in the near future[29].

Recently, mechanical thrombectomy devices in acute stroke have received intense interest[29,30]. High patency rate (61%-86%) and improved clinical outcome were reported in the SWIFT, PENUMBRA and TREVO trials[16,17,31]. However, individual devices may have their own technical issues. A stent based device, using a dragging method, may cause thrombus embolization into new territory. The possible solutions for this problem are to allow the device to "ingest" the thrombus for few minutes, to slowly pull back (1 cm/min) and to add aspiration force through the sheath or guide catheter. The advantage points of stent based devices are small delivery profile and speed of recanalization[32].

Continuous thrombus aspiration using a Penumbra device has one inherited problem, that is "profile"[33]. Because of a larger profile, it may require delivery in triaxial fashion over the guidewire and microcatheter. The strong advantage of a Penumbra device is more complete clot removal and less embolization into new territory[33]. This could benefit the patients with large thrombus burden and in the situation with residual thrombus after the dragging method. The aspiration method, compared to the dragging method, is perceived to result in less vessel trauma. Clinical trials reported no difference in intracranial hemorrhage, compared to the Solitaire device[29,30,33].

We plan to reduce time to recanalization in our center. Focused stroke MRI protocol may shorten it by a few minutes in this critical condition. Using multimodal CT instead of MRI may also be a time saver. An interventionist should be available 24/7. Activation of the interventional team during the imaging study is crucial. Using mechanical thromboembolectomy as a first line treatment, instead of intra-arterial thrombolysis, should be of benefit.

## COMMENTS

### *Case characteristics*

The authors report seven patients with successful recanalization after endovascular treatment in acute large vessel stroke from a single stroke center in Thailand.

### *Clinical diagnosis*

There were 2 patients with internal carotid artery occlusion, 2 with middle cerebral artery occlusion and 3 with basilar artery (BA) occlusion.

### *Imaging diagnosis*

Multimodal magnetic resonance imaging was done in 6 of 7 cases (86%).

### *Treatment*

Carotid stenting was performed in one case. Intra-arterial recombinant tissue plasminogen activator, mechanical thrombectomy and combined treatment were done in 4, 5 and 3 cases, respectively. Solitaire and Penumbra devices were used in 2 and 3 cases, respectively.

### *Related reports*

Multimodal magnetic resonance imaging (MRI) is the most reliable study to select the patients.

### *Experiences and lessons*

Focused stroke MRI protocol may reduce time by a few minutes in this critical condition. Using multimodal computer tomography instead of MRI may also be a time saver.

### *Peer review*

The manuscript is a nicely written collection of 7 cases of acute ischemic stroke that were treated with various endovascular techniques. The report is worthy of being published.

## Abstract

Endoscopic hemorrhoidal band ligation is a well-established nonoperative method for treatment of bleeding internal hemorrhoids (grade 1 to 3). It is a safe and effective technique with a high success rate. Complications with this procedure are uncommon. Although rectal ulceration due to band ligation is a rare complication, it can cause life-threatening hemorrhage especially when patients are on medications which impair hemostasis like aspirin or non steroidal anti-inflammatory drugs. We present 2 cases of massive lower gastro-intestinal bleeding in patients who had a band ligation procedure performed 2 wk prior to the presentation and were on aspirin at home. Both the patients were hemodynamically unstable requiring resuscitation. They required platelet and blood transfusions and were found to have rectal ulcers on colonoscopy done subsequently. The rectal ulcers corresponded to the site of band ligation. The use of aspirin by these patients would have caused defects in the hemostasis and may have predisposed them to massive bleeding in the presence of rectal ulcers occurring after the band ligation procedure. Managing aspirin before and after the ligation may be difficult especially since adequate guidelines are unavailable. Stopping aspirin in all the cases might not be safe and the decision should be individualized.

**Key words:** Hemorrhoids; Rubber band ligation; Rectal ulcers; Massive bleeding; Aspirin

**Core tip:** Rubber band ligation is known to be a relatively safe procedure. Massive bleeding and rectal ulceration is a very rare complication of this procedure. We came across two cases of severe, life-threatening lower gastrointestinal hemorrhage following endoscopic hemorrhoidal band ligation in patients on aspirin. The use of aspirin and other non-steroidal anti-inflammatory drugs can predispose to massive hemorrhage. The case report aims at creating awareness about these complications and that it may be advisable to avoid aspirin and non steroidal anti-inflammatory drugs immediately after band ligation.

Rectal ulcers and massive bleeding after hemorrhoidal band ligation while on aspirin. *World J Clin Cases* 2014; 2(4): 86-89 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i4/86.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i4.86

## INTRODUCTION

Hemorrhoids are dilated or bulging veins in the rectum

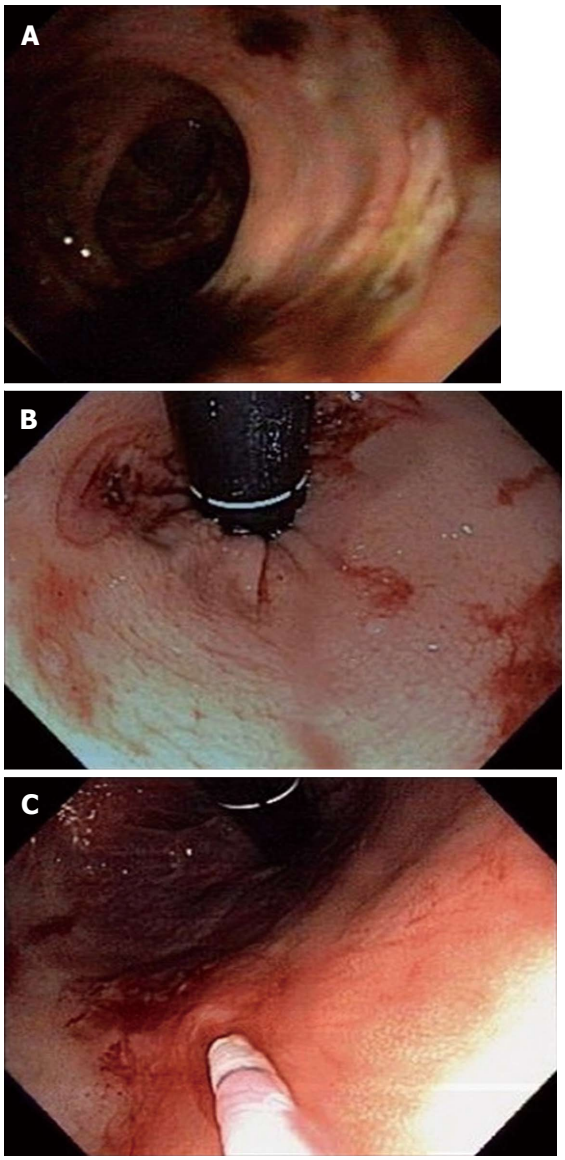

**Figure 1 Endoscopic pictures of the rectal ulcers.**

and/or anus caused by increased pressure in the rectal veins. They are believed to be normal anatomic structures, as demonstrated by their presence in babies[1]. Frequently, they can become a source of significant morbidity if they get inflamed or swollen. The estimated prevalence rate of symptomatic hemorrhoids in the United States is 4.4% of the adult population. More than one million individuals are affected annually by hemorrhoidal conditions[2,3]. The prevalence peaks between the ages of 45-65 and declines thereafter. It is more commonly found in whites more than blacks and the rates are higher in people from higher socioeconomic background[2].

Elastic band ligation is a well-established nonoperative method for treatment of bleeding internal hemorrhoids (stages Ⅱ-Ⅲ). Usually, one or two bands are placed at a single session by using rigid instruments. Endoscopic hemorrhoidal band ligation is a safe and effective technique used in the management of hemorrhoids, with a high success rate[4]. Blaisdell[5] and Barron[6] described and refined the band ligation therapy. Complications with this procedure are uncommon.

Massive bleeding and rectal ulceration due to band ligation is a very rare complication. The use of aspirin (acetylsalicylic acid, ASA) and other non-steroidal anti-inflammatory drugs (NSAID) can predispose to massive hemorrhage. We came across two cases of severe, life-threatening lower gastrointestinal hemorrhage following endoscopic hemorrhoidal band ligation in patients on aspirin.

## CASE REPORT

### *Patient 1*

A 52-year-old white man with a past medical history of anxiety and a recent band ligation for hemorrhoids 15 d prior to presentation came to the emergency room (ER) complaining of bleeding from his rectum for 2 h. He was in his usual state of health when he suddenly had a large bowel movement with bright red blood and clots. He had no other complaints such as abdominal pain, coffee ground vomiting or black stools. His medications included aspirin (81 mg/d) for preventing cardiovascular disease and Sertraline for his anxiety. His blood pressure (BP) was 130/76 mmHg, temperature was 98.3 F, respiratory rate was 16/min and the heart rate (HR) was 96/min. His abdomen was soft, with normal bowel sounds and no tenderness or guarding. His rectal exam revealed reduced sphincter tone and bright red blood. His BP subsequently dropped to 80/40 mmHg with a HR of 140/min within an hour. He became unresponsive and was subsequently intubated for airway protection in the ER. His initial blood work revealed a hemoglobin of 12 g/dL and platelets of 199000. Due to hemodynamic collapse and the large volume of blood seen in the stool, he received fluids, 2 units of packed red blood cells and 1 unit of platelets after which his vital signs stabilized. ASA was discontinued. He underwent a colonoscopy (Figure 1A) which showed two clean based rectal ulcers measuring 3 cm and 1cm with overlying exudates 7 cm from the anal verge. The location of the rectal ulcers corresponded to the site of band ligation. The rectal ulcer biopsy revealed active chronic inflammation with surface exudates and attached fragment of granulation tissue. Bleeding subsequently stopped and the patient was extubated on day 2 of admission and later discharged after an otherwise uncomplicated hospital course.

### *Patient 2*

A 67-year-old white man presented to the ER with complaints of bleeding from his rectum for 4 h. He was known to have symptomatic hemorrhoids for which he underwent band ligation 2 wk prior to the presentation. He denied abdominal pain, nausea, vomiting, black stools or any other complaints. His past medical history was significant for hypertension, hyperlipidemia, coronary artery disease for which he underwent Coronary Artery Bypass Graft surgery in 2004 and stroke with no residual

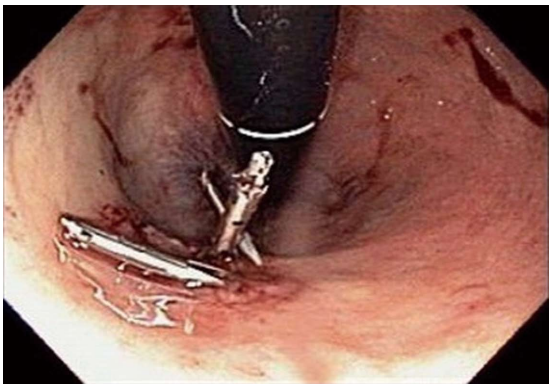

**Figure 2 Status post Endoscopic clip placement of the hemorrhoidal ulcer.**

neurological deficits in 2005. His medications included Aggrenox (aspirin/Dipyridamole -25/200 mg twice a day for stroke prevention), Amlodipine, Metoprolol, Atorvastatin and Ezetimibe. On arrival, he was afebrile with a BP of 80/50 mmHg and a HR of 62 beats per minute. The absence of tachycardia was presumed to be due to the beta blockade. His abdomen was soft, with normal bowel sounds and no tenderness or guarding. The rectal exam revealed bright red blood with clots, normal sphincter tone and no palpable masses. His initial hemoglobin was 14 g/dL and platelet count was 187000. His hemoglobin decreased to 10 g/dL over 10 h and he continued to have rectal bleeding. Due to ongoing bleeding and hemodynamic instability he received fluids, 2 units of packed red blood cells and 1 unit of platelets. An emergent colonoscopy was then performed which showed a solitary rectal ulcer (Figure 1B and C) of 1 cm size with a visible vessel proximal to the dentate line. The visible vessel was successfully clipped endoscopically (Figure 2). The location of the rectal ulcer corresponded to the site of band ligation. No further bleeding was noted and the patient was subsequently discharged home.

## DISCUSSION

Initial treatment for mild to moderate hemorrhoidal disease consists of increased fiber intake[7], oral hydration, use of NSAIDs for pain, avoidance of straining during defecation, and sitz baths[8]. Hemorrhoids that fail to respond to medical management may be treated with rubber band ligation, sclerosis, and thermotherapy by using infrared beam, electric current, $CO_2$ laser, or ultrasonic energy. Surgery is reserved for those who fail to improve with conservative measures.

Rubber band ligation is found to be the most effective method to treat symptomatic internal hemorrhoids (grade 1 to 3) that have failed to respond to conservative management[4,9-11]. Complications associated with ligation are uncommon (< 2%) and usually benign which may include pain, rectal bleeding from early dislodgment, vasovagal response or infection[12,13]. Bleeding after ligation may occur immediately after the procedure or 3-10 d after the rubber band and the ligated tissue fall off. Rectal ulcers after the band ligation are extremely rare complication. The exact incidence is unknown. These ulcers can lead to massive life threatening bleeding especially in the patients taking antiplatelet agents like aspirin. ASA and other NSAIDs inhibit platelet production of thromboxane A2. ASA irreversibly acetylates the platelet enzyme so that a single dose impairs hemostasis for five to seven days hence causing hemostasis defects[14]. Recovery of the platelets after discontinuing these drugs is slow and is equivalent to the lifespan of the platelets. The other NSAIDs are competitive and reversible inhibitors with more transient effects.

A prospective study of 512 patients by Bat *et al*[15] who underwent hemorrhoidal rubber band ligation over a seven-year period were followed up for any complications. Most of the patients, who had hemorrhoidal band ligation, had a successful event free outcome (82%). Minor complications were found in 24 patients (4.7%) including painful, thrombosed hemorrhoids, slippage of bands, minor rectal bleeding, chronic longitudinal ulcers and priapism. Major complications were noted in 13 patients (2.5%) who had either delayed massive bleeding or severe complicated thrombosis of the hemorrhoids. Five of the six patients who had massive bleeding, had the onset of symptoms 10 d or more after the procedure similar to our 2 patients. Three of the six patients with massive bleeding required transfusions. Two of the three patients who were transfused were taking aspirin regularly.

Both our cases developed massive bleeding 2 wk following the banding procedure requiring platelet and blood transfusions. The use of aspirin by these patients would have caused defects in the hemostasis and may have predisposed them to massive life-threatening hemorrhage in the presence of rectal ulcers occurring after the band ligation procedure. The first patient was taking ASA for preventing cardiovascular diseases and aspirin could have been safely stopped atleast 1 wk prior to the procedure. On the contrary, the second patient had a history of coronary artery bypass graft and a stroke, stopping ASA in him abruptly might have caused more harm. Managing ASA before and after the ligation may be difficult especially since adequate guidelines are unavailable. Stopping ASA in all the cases might not be safe and the decision should be individualized.

The cases we report are an example of a rare and life threatening complication of a procedure known to be relatively safe. Use of aspirin may have been a coincidence or would have predisposed the patient to a massive bleeding. It may be advisable to avoid ASA and NSAIDs immediately after band ligation.

## COMMENTS

### *Case characteristics*

Two men, age 52 and 67, on aspirin at home came to the emergency room with bright red blood per rectum 2 wk after a hemorrhoidal band ligation.

### *Clinical diagnosis*

The authors came across two cases of severe, life-threatening lower gastrointestinal hemorrhage following endoscopic hemorrhoidal band ligation in patients

on aspirin.

### Differential diagnosis

Diverticular disease, hemorrhoids, colitis, bleeding ulcers.

### Laboratory diagnosis

Patient one had a hemoglobin of 12 g/dL and platelets of 199000 on admission. Patient 2 had a hemoglobin of 14 g/dL and a platelet count of 187000 initially. Both patients were losing blood rapidly leading to drop in the hemoglobin subsequently.

### Imaging diagnosis

Colonoscopy was performed in both the cases which showed two clean based rectal ulcers measuring 3 cm and 1 cm with overlying exudates 7 cm from the anal verge in the first case and a solitary rectal ulcer of 1 cm size with a visible vessel proximal to the dentate line in the second case.

### Pathological diagnosis

In the first case, rectal ulcer biopsy revealed active chronic inflammation with surface exudates and attached fragment of granulation tissue. No biopsy was performed in the second patient.

### Treatment

Treatment mainly included platelet and blood transfusions. The second patient had a rectal ulcer with a visible vessel which was endoscopically clipped.

### Related reports

There are a very few case reports which have described massive bleeding after hemorrhoidal band ligation in patients on aspirin.

### Term explanation

Rubber band ligation is a procedure performed endoscopically in which rubber bands are tied off at the base of the hemorrhoids hence, cutting off the blood flow to the hemorrhoids.

### Experiences and lessons

Massive bleeding is a rare but life threatening complication of a fairly safe procedure which may be avoided if we attempt to tailor the use of aspirin pre and post band ligation according to individual patient conditions.

### Peer review

This is an easy to read, well written and an interesting case report worth highlighting in the surgical community since rubber band ligation is a very commonly performed procedure.

## Abstract

Left ventricular (LV) pseudoaneurysm is a rare complication that is reported in less than 0.1% of all patients with myocardial infarction. It is the result of cardiac rupture contained by the pericardium and is characterized by the absence of myocardial tissue in its wall unlike true aneurysm which involves full thickness of the cardiac wall. The clinical presentation of these patients is nonspecific, making the diagnosis challenging. Transthoracic echocardiogram and cardiac magnetic resonance imaging are the noninvasive modalities whereas coronary arteriography and left ventriculography are invasive modalities used for the diagnosis. As this condition is lethal, prompt diagnosis and timely management is vital.

**Key words:** Chest pain; Myocardial infarction; Transthoracic echocardiogram; Left ventricular aneurysm; Left ventricular pseudoaneurysm

**Core tip:** Left ventricular pseudoaneurysm is a rare and lethal condition. It can be challenging to diagnose as it has an ambiguous clinical presentation. Timely recognition and management is critical and can be lifesaving.

Alapati L, Chitwood WR, Cahill J, Mehra S, Movahed A. Left ventricular pseudoaneurysm: A case report and review of the literature. *World J Clin Cases* 2014; 2(4): 90-93 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i4/90.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i4.90

## INTRODUCTION

Left ventricular (LV) pseudoaneurysm is a lethal condition, but the diagnosis and differentiation from LV true aneurysm is challenging as the clinical presentation of LV pseudoaneurysm is non-specific. We describe a 75-year-old patient who presented with symptoms and signs of myocardial infarction and was diagnosed to have LV pseudoaneurysm.

## CASE REPORT

A 75-year-old african american female with hypertension, diabetes, hyperlipidemia, peripheral vascular disease, gout, status post coronary artery bypass graft and aortic valve replacement with bio-prosthetic valve performed a year ago, presented to the emergency department two weeks after mitral and tricuspid valve repair surgery, with shortness of breath, cough and chest pain for 2-3 d.

Her medications included aspirin, hydrochlorthiazide, irbesartan, simvastatin, verapamil and metformin. Vital signs on presentation were heart rate 74/min, blood pressure 127/56 mmHg, respiratory rate 16/min, temperature of 97.4 F and oxygen saturation of 98% on room air. On physical examination, patient had normal S1 and S2, grade 2/6 systolic murmur heard over the aortic area, no

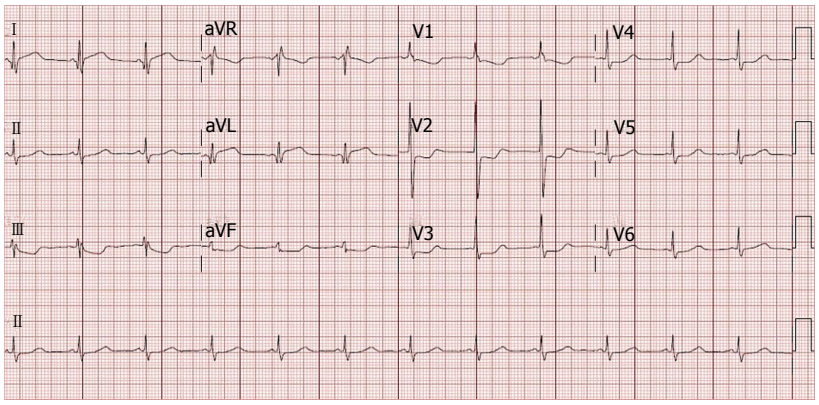

**Figure 1 Electrocardiogram shows 1.5 to 2 mm ST elevation in Ⅰ, aVL, 1 to 2 mm ST depression in Ⅱ, aVF, V1 to V4, and R/S ratio > 1 in V1 and V2.**

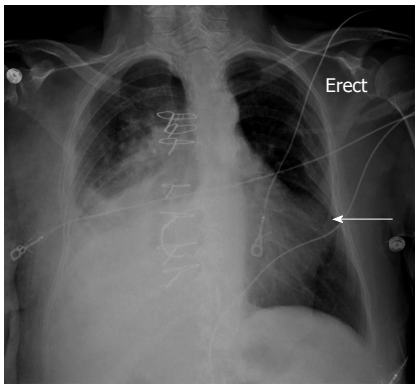

**Figure 2 Chest X-ray: Convexity on the lateral wall of the cardiac silhouette (white arrow).**

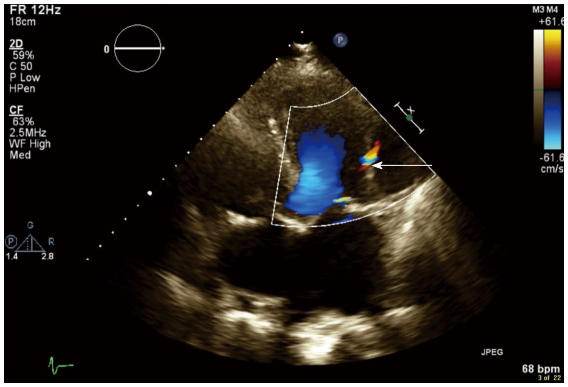

**Figure 3 Transthoracic echocardiogram: Apical modified 4/5 chamber view showing bidirectional shunt through the left ventricular wall (white arrow).**

gallops, no rub, and no jugular venous distension. There were diminished breath sounds in the mid and lower right lung fields and crackles over the left lower lung field. Trace bilateral lower extremity edema was present. Her white blood cell count: 13.50 k/μL, hemoglobin: 10.2 g/dL, hematocrit: 31.2%, platelets: 334 k/μL, creatinine: 0.74 mg/dL, troponin: 4.00 ng/mL, total creatinine phosphokinase: 75 U/L, creatinine kinase myocardial band: 10.4 ng/dU. An electrocardiogram showed 1.5 to 2 mm ST elevation in Ⅰ, aVL, 1 to 2 mm ST depression in Ⅱ, aVF, V1 to V4, and R/S ratio > 1 in V1 and V2 (Figure 1). A chest radiograph showed right sided consolidation and pleural effusion and a convex out pouching along the left heart border (Figure 2).

The patient was started on nitroglycerin drip but continued to have chest pain. Transthoracic echocardiogram (TTE) showed dyskinesis and marked thinning of mid and basal anterior-lateral segments consistent with infarction in the distribution of the left circumflex artery. It also showed a ruptured ventricular wall with a large pericardial effusion adjacent to the dyskinetic segment. On doppler, a bidirectional shunt across the lateral left ventricle is seen, indicative of LV aneurysm (Figure 3). The width of the neck is 5.8 mm and the maximal internal diameter of the aneurysmal sac is 48 mm with the neck to sac ratio of less than 0.5 (about 0.12) which is strongly suggestive of pseudoaneurysm. Coronary angiograpy showed left anterior descending artery free of angiographic disease, left circumflex with 90% disease ostially and proximally. The right coronary artery (RCA) was 100% occluded ostially. Saphenous vein graft to RCA was patent with normal flow. Saphenous vein graft to the first obtuse marginal (OM1) with a jump graft to second obtuse marginal (OM2) were patent but there was distal disease in both the OM1 and OM2 up to 80%.

Subsequently, transesophageal echocardiogram (TEE) and cardiac magnetic resonance imaging (MRI) were done and the diagnosis of LV pseudoaneurysm was confirmed (Figures 4 and 5). Intra-operatively, the patient was found to have a LV lateral pseudoaneurysm with approximately 1.5 cm diameter free wall perforation; the LV pseudoaneurysm contained a thrombus and was communicating with the LV cavity. The LV pseudoaneurysm was repaired with a bovine pericardial patch. She was discharged to a rehabilitation center on post-operative day 7. Four weeks post operatively, she was discharged from the rehabilitation center and was performing very well.

## DISCUSSION

LV pseudoaneurysm also referred to as contained LV wall rupture is a rare complication that is reported in less than 0.1% of all myocardial infarction patients. It is catastrophic causing death in 48% of patients without surgical intervention[1]. LV pseudoaneurysm is a result of cardiac rupture contained by the pericardium and is characterized by the absence of myocardial tissue in its wall

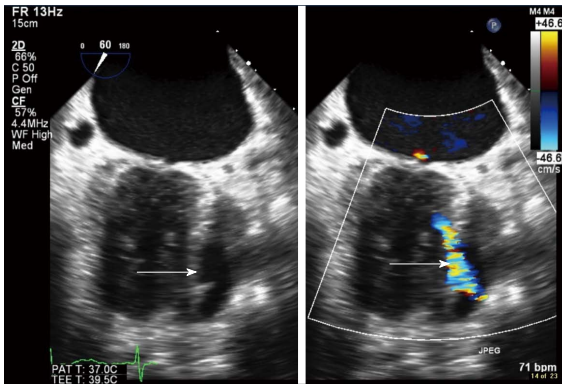

**Figure 4 Transesophageal echocardiogram: 2 chamber view confirming the to and fro flow between left ventricle and the pseudo aneurysm (white arrow).**

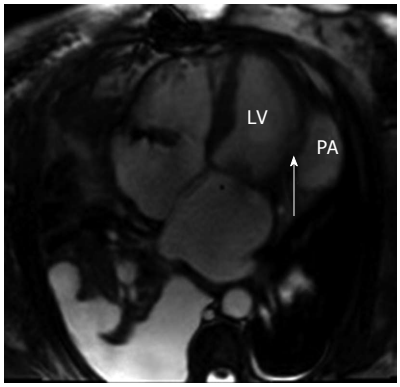

**Figure 5 Cardiac magnetic resonance imaging: 4 chamber view showing the connection between the left ventricular cavity and the left ventricular pseudo aneurysm (white arrow).** LV: Left ventricular; PA: Pseudoaneurysm.

unlike true aneurysm which involves the full thickness of the cardiac wall.

Frances *et al*[2] in 1998 reviewed data from 290 patients and reported the most common etiology of LV pseudoaneurysm to be myocardial infarction followed by cardiac surgery. The risk factors for the LV pseudoaneurysms are older age, female sex, hypertension and inferior and lateral wall myocardial infarction. The common location for LV pseudoaneurysm is postero-inferior followed by postero-lateral and anterior, in contrast to true LV aneurysm which is more commonly located in the anterior and apical walls[2]. The patients with LV pseudoaneurysm usually present within 2 mo of a myocardial infarction[3].

The clinical presentation of patients with LV pseudoaneurysm is not specific and can mimic myocardial infarction or heart failure. Patients could be asymptomatic (12%) or could have persistent or recurrent chest pain (30%), shortness of breath (25%) or non-specific symptoms like dizziness or altered mental status, and 3% of the patients could have sudden death as a presenting symptom[4].

The physical examination is nonspecific with soft heart sounds, pericardial friction rub and a new systolic murmur. Electrocardiogram changes in most cases include sinus bradycardia, junctional rhythm and changes reflecting ischemia or infarction. A convexity or a mass adjacent to the cardiac silhouette can be present on the chest radiograph in more than half of the cases (Figure 2). None of these findings are specific for LV pseudoaneurysm which brings the focus to the cardiac imaging modalities.

It can be challenging to diagnose LV pseudoaneurysm with the ambiguity in its clinical presentation and the nonspecific physical findings. However, prompt diagnosis is essential as LV pseudoaneurysm is associated with a cardiac rupture risk of 30%-45%[4]. Therefore, cardiac imaging plays a very significant role in the diagnosis of LV pseudoaneurysm. Currently, various cardiac imaging modalities are available for diagnosis of LV pseudoaneurysm.

TTE has increased the number of diagnosed LV pseudoaneurysm cases. Being a noninvasive technique, TTE is routinely used for initial assessment in suspected patients as it helps in diagnosing LV pseudoaneurysm and also in determining the infarction. A ratio of $< 0.5$ between the width of the neck and the maximal internal diameter of the aneurysmal sac[5] or the presence of bidirectional turbulent flow through the neck by color and pulsed Doppler study[6], are suggestive of a LV pseudoaneurysm. TEE further assists in improving the accuracy of diagnosing LV pseudoaneurysm because in TTE there can be field of view limitation for visualization of the LV inferior wall.

Cardiac MRI is a non-invasive modality that enables the diagnosis of LV pseudoaneurysm. It is useful in identification of the pericardium, detection of thrombi, and in distinguishing between necrotic and normal myocardium. It provides morphological definition of a LV pseudoaneurysm location, extension and relation to adjacent structures. Delayed enhancement enables accurate assessment of the location and extent of the infarcted area and of viable myocardium, all of which are essential to determine optimal management. Cardiac MRI being a non invasive modality without risk of radiation exposure, has an enormous value in differentiating between LV aneurysms and LV pseudoaneurysms, with the ability to obtain cross sectional views in any plane. Cardiac MRI has a sensitivity of 100% and a specificity of 83%[7].

Cardiac computed tomography is another non invasive imaging modality used for acquiring the three-dimensional anatomical and functional information on the myocardium and pericardium[8]. However, the limited temporal resolution, the usage of iodinated contrast and exposure of the patient to ionizing radiation, makes it less favorable.

Left ventriculography demonstrates the narrow neck connecting the ventricle to the cavity in which contrast liquid remains for several beats following the injection. Though left ventriculography is considered the gold standard modality with a diagnostic accuracy of about 85%[9], it is seldom used because of the concern for thrombus dislodgement.

Once the diagnosis is confirmed, urgent surgical in-

tervention is necessary in acute LV pseudoaneurysm[10] as the risk of rupture outweighs the risk of surgery. Small retrospective studies have shown that patients with incidental finding of chronic small LV pseudoaneurysm less than 3 cm in size[10] and patients with increased surgical risk[11] can be managed conservatively. But until large studies confirm the favorable outcomes of medical management over surgical intervention, the preferred approach would remain surgical management.

In conclusion, since it is challenging to diagnose LV pseudoaneurysm because of the ambiguity in its presentation, diagnosis in a timely manner is crucial. High clinical suspicion and early utilization of the non-invasive modalities for detection of LV pseudoaneurysm are essential to improve the outcome in these patients.

## COMMENTS

### *Case characteristics*

A 75-year-old female patient with history of coronary artery bypass graft and aortic valve replacement presenting with cough, shortness of breath and chest pain.

### *Clinical diagnosis*

Grade 2/6 systolic murmur over the aortic area, no gallops, no rub, and no jugular venous distension. Diminished breath sounds in the mid and lower right lung fields and crackles over the left lower lung field and trace bilateral lower extremity edema.

### *Differential diagnosis*

Myocardial infarction, congestive heart failure, left ventricular (LV) aneurysm, LV pseudoaneurysm, pericarditis.

### *Laboratory diagnosis*

White blood cell count: 13.50 k/μL, hemoglobin: 10.2 g/dL, hematocrit: 31.2%, platelets: 334 k/μL, creatinine: 0.74 mg/dL, troponin: 4.00 ng/mL, total creatinine phosphokinase: 75 U/L, creatinine kinase myocardial band: 10.4 ng/dU.

### *Imaging diagnosis*

Transthoracic echocardiogram with doppler showed a bidirectional shunt across the ruptured lateral left ventricle. The width of the neck is 5.8 mm and the maximal internal diameter of the aneurysmal sac is 48 mm.

### *Treatment*

Surgical repair of LV pseudoaneurysm.

### *Related reports*

The diagnosis of LV pseudoaneurysm is challenging requiring high clinical suspicion for timely diagnosis and management.

### *Experiences and lessons*

This case report presents a rare case of pseudoaneurysm and the use of advanced imaging modalities in the diagnosis.

### *Peer review*

LV pseudoaneurysms are a rare finding mainly in patients after myocardial infarction; difficult to diagnose and are associated with a high mortality. The case report demonstrates very nicely the main diagnostic findings in this setting.

## Abstract

Varicocele has been implicated as a cause in 35%-50% of patients with primary infertility and up to 81% of men with secondary infertility. Although a large number of reports have shown improvement in the semen parameters after correction of varicocele, other studies have suggested no benefit. We report the first case of azoospermia after surgery in a young infertile male patient with left-sided varicocele and severe oligozoospermia undergoing laparoscopic varicocelectomy. A pregnancy was only achieved with assisted reproductive technology because semen cryopreservation was performed before surgery. In the light of the above, the deterioration of sperm count after varicocele repair in patients with severe oligozoospermia could be due to irreversible impairment of spermatogenesis of such patients, together with the possible temporary damage of the surgical repair. This possible complication could therefore turn the severe oligozoospermia into an indication to perform cryopreservation before surgery, on both clinical and medico-legal grounds. Further research is needed before drawing definitive conclusions regarding the management of varicocele-related severe oligozoospermia.

**Key words:** Varicocele; Fertility; Semen; Cryopreservation; Oligozoospermia

**Core tip:** We report a case of deterioration of sperm count after varicocele repair in a patient with severe oligozoospermia. ## INTRODUCTION

Varicocele has been implicated as a cause in 35%-50% of patients with primary infertility and up to 81% of men with secondary infertility. Numerous studies have shown that varicocele is associated with testicular hypotrophy, impaired spermatogenesis, increased apoptosis of germ cells at the seminiferous tubules, oxidative stress pattern and a progressive damage to testicular biology over time[1]. Although a large number of reports have shown

improvement in the semen parameters after correction of varicocele, other studies have suggested no benefit[2].

## CASE REPORT

We reported a case of a 34-year-old infertile male patient with left-sided varicocele. On physical examination, the patient's varicocele was categorized as grade 3 according to a three grade scale (grade 1: detectable during Valsalva maneuver only; grade 2: palpable at rest; grade 3: visible at rest). The reflux during color Doppler ultrasound, classified into three grades (slight and brief reflux, ending before the Valsalva maneuver was completed; lasting throughout the Valsalva maneuver; and severe reflux, already present with the patient supine at rest) was detected as severe with reflux at rest.

A basic infertility evaluation including a detailed history and a complete physical examination was undertaken and the infertility was defined on the basis of a failure to establish a pregnancy within 1 year with unprotected intercourse. No history of smoking, drug abuse or other systemic disease was reported. Hormonal parameters before and after surgery were normal. Semen analysis, conducted according to the World Health Organization recommendations, showed a severe oligozoospermia. The median value of the percentage of progressive motile sperm was 18%, while the median value of the percentage of normal forms was 11%. Nevertheless, the woman was normal, based on history, hormonal levels and hysterosalpingogram.

The surgical approach used was laparoscopic ligation of the spermatic vein. The spermatic cord at the internal ring was identified and then the parietal peritoneum overlying the spermatic cord was incised with scissors. The engorged internal spermatic veins were then identified, dissected, ligated and divided. The venous ligation was performed by a freehand intracorporeal knot-tying technique with 3-0 silk ligature. The lymphatic vessels and testicular artery were meticulously identified and preserved. The post-operative course was uneventful and the patient was discharged after 24 h. The patient underwent physical examination 1 mo after surgery and spermatic color Doppler and semen analysis 6 mo after surgery.

The size of the left testis before and after surgery was 3.2 cm and 3.3 cm respectively. Although no complications or recurrence were noted, a deterioration in sperm concentration was recorded and the patient became azoospermic. A pregnancy has only been achieved with assisted reproductive technology because semen cryopreservation was performed before surgery.

The patient underwent another semen analysis 1 year after surgery but it was not necessary to perform a testis biopsy before varicocelectomy.

## DISCUSSION

The Practice Committee of the American Society for Reproductive Medicine recently published recommendations for the evaluation and treatment of varicoceles[3,4]. This report was previously published as a peer-reviewed consensus jointly with the Male Infertility Best Practice Policy Committee of the American Urological Association. The committee concluded that varicocelectomy should be offered to the male partner in couples attempting to conceive only when all of the following conditions were present: a palpable varicocele, documented couple infertility, a female partner with normal fertility or potentially correctable infertility, and a male partner with one or more abnormal semen parameters or test results showing abnormal sperm function.

Concerning the operative technique, data in the literature do not show significant differences in seminal parameter improvements comparing the different surgical, microsurgical or interventional radiological techniques. According to the main international guidelines, currently it is not possible to identify a gold-standard treatment and the most appropriate technique is the one that the surgeon is most confident with or that is the easiest to perform in each hospital setting. Furthermore, it is demonstrated that accidental ligation or injury of the testicular artery during primary varicocele repair has no deleterious effect on post-operative semen and pregnancy outcomes[5]. The predictors of varicocele repair outcome are high-grade varicocele, normal serum FSH, total motility > 60% and total motile sperm count > $5 \times 10^6$ before varicocelectomy. These good prognostic indicators may only help in identifying those men with a better prognosis for varicocelectomy[6]. Nevertheless, such predictors cannot be evaluated as a contraindication of performing a varicocelectomy. In fact, in the past 10 years, some studies have shown that also nonobstructive azoospermic patients with varicocele identified on physical examination may benefit from varicocele repair[7].

We reported, to the best of our knowledge, the first case of azoospermia after laparoscopic varicocele repair in a young infertile male patient with left-sided varicocele and severe oligozoospermia.

Few studies have shown deterioration or azoospermia after surgery. Moreover, they do not analyze the characteristics of the patients with semen deterioration or justify this complication[8,9].

In our case, all of the indications to perform varicocelectomy were present and therefore, in such a case, malpractice cannot be a cause of this complication. Moreover, there were no complications with intercourse and no reflux was identified with the echographic evaluation after surgery.

The reason for a deterioration after varicocelectomy is not clear as it is not reported in the literature at all. In the light of the above, the deterioration of sperm count after varicocele repair in patients with severe oligozoospermia could be due to irreversible impairment of spermatogenesis of such patients, together with the possible temporary damage of the surgery repair. This possible complication could therefore turn the severe oligozoospermia

into indications to perform cryopreservation before surgery, on both clinical and medico-legal grounds. Further research is needed before drawing definitive conclusions regarding management of varicocele-related severe oligozoospermia. A randomized clinical trial on these patients with severe oligozoospermia and varicocele would be useful to evaluate the effectiveness of varicocelectomy.

## COMMENTS

### *Case characteristics*

Young infertile man with varicocele and severe oligozoospermia.

### *Clinical diagnosis*

Asymptomatic patient.

### *Laboratory diagnosis*

Semen analysis showed a severe oligozoospermia and the median value of the percentage of progressive motile sperm was 18%, while the median value of the percentage of normal forms was 11%.

### *Imaging diagnosis*

The reflux during color Doppler ultrasound was detected severe with reflux at rest.

### *Treatment*

A pregnancy has only been achieved with assisted reproductive technology because semen cryopreservation was performed before surgery.

### *Experiences and lessons*

In the light of the above, the deterioration of sperm count after varicocele repair in patients with severe oligozoospermia could turn the severe oligozoospermia into an indication to perform cryopreservation before surgery, on both clinical and medico-legal grounds.

### *Peer review*

The manuscript reported the first case of azoospermia after laparoscopic varicocelectomy in a young infertile patient with left-sided varicocele and severe oligozoospermia, which is contrary to most others that have been published in the literature.

## Abstract

We report a case of a 54-year-old patient who was denied surgical replacement for severe aortic stenosis because of complicated acquired immunodeficiency syndrome and who successfully underwent transcatheter aortic valve implantation at our institution.

**Key words:** Severe aortic stenosis; Acquired immunodeficiency syndrome; Transcatheter aortic valve implantation; Heart team; Periprocedural complications

**Core tip:** The present case report describes the feasibility and safety of transcatheter aortic valve implantation for patients with acquired immunodeficiency syndrome, evaluated after the heart team decision.

Salizzoni S, D'Ascenzo F, Moretti C, Bonora S, Calcagno A, Omedè P, Montrucchio C, Cerrato E, Colaci C, Sheiban I, Marra S, Rinaldi M, Gaita F. Transcatheter aortic valve implantation in a 54-year-old patient with aggressive HIV. *World J Clin Cases* 2014; 2(4): 97-99 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i4/97.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i4.97

## INTRODUCTION

The transcatheter aortic valve implantation (TAVI) procedure is currently considered a valid alternative to surgery in patients with severe aortic stenosis not eligible for valve replacement or with high operative risk, as demonstrated by the recent PARTNER[1] trial, which showed similar results between surgery and TAVI. For this reason, it may represent an attractive option for patients whose surgical risk is difficult to assess, like immunocompromised ones.

## CASE REPORT

We report the case of a 54-year-old male (82 kg, 178 cm) with a diagnosis of post-transfusion HIV infection in 1990, who had taken six different antiretroviral drugs because of a virus with several resistances. In October 2009, the patient was hospitalized for Listeria meningitis and he suffered from several episodes of acute heart failure, after which severe aortic stenosis was diagnosed by transthoracic echocardiography (TTE), with a mean gradient of 55 mmHg and an ejection fraction of 50% without coronary disease at the angiography. The patient was

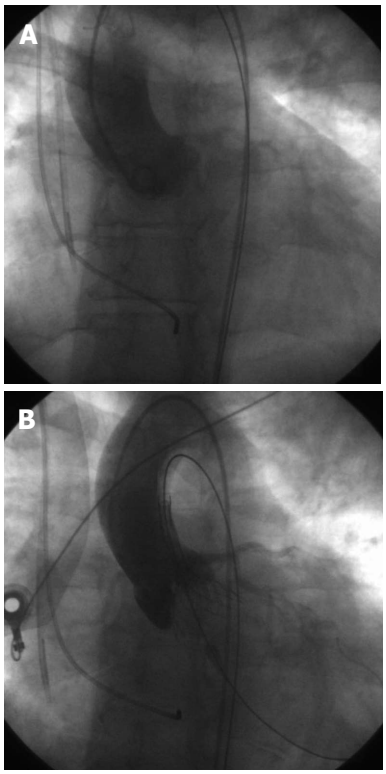

**Figure 1 Positioning image.** A: Pig tail positioning before transcatheter aortic valve implantation; B: Valve after positioning.

consequently referred to cardiac surgeons who refused to do the procedure due to a high operative risk, with a Cd4 cell count of 400 cell/cc and low count of platelets. Nevertheless, from December 2010 he became symptomatic (NYHA Ⅲ) and had several syncopal episodes, the last of which led to a leg fracture.

The patient was referred again to our surgeons who considered him for TAVI, despite his age and low risk detected by common scores (Logistic EuroSCORE 1.51%, STS 3%). Multidisciplinary discussion, including the infectious diseases specialist who foresaw at least a 2-year survival and a high risk of potential life threatening peri-intervention infections at the same time, led to the decision of a percutaneous transfemoral approach to minimize all potential sites of infection, both for the patient and the operators. He was successfully treated with a 29 mm CoreValve and discharged uneventfully on post-operative day nine (Figure 1). His TTE showed a mean gradient of 12 mmHg and mild paraprothesic aortic insufficiency. His cardiovascular therapy consisted of aspirin, clopidogrel and furosemide 25 mg.

Two weeks after discharge, he presented to the emergency department because of angina (CCS Ⅱ) and repeated episodes of gingival bleeding and melena. ECG was unchanged but important anemia (Hb 8 g/dL) was detected, so clopidogrel was stopped.

At the 12 mo follow-up, he was in NYHA I and had no further syncope or angina. Ejection fraction was 51%, with a mean transprothesic gradient of 12 mmHg and still mild paraprothesic aortic insufficiency on echocardiography.

## DISCUSSION

The numbers of immunocompromised patients with aortic stenosis will increase because of longer survival for HIV patients[2-4].

Despite some encouraging reports from patients with uncomplicated HIV[5], their management can be really tricky: for patients, because of a high infective risk, high prevalence of renal disease and consequently a risk of bleeding or thrombosis[4-6], and for surgeons, due to contamination risk[7]. Moreover, accurate tools to correctly assess risk in immunocompromised patients (not appraised by EuroSCORE and only partially by the STS score[8,9]) are lacking and no data are reported about in hospital and midterm follow up complications. This medical issue will become more and more relevant due to the increase in survival of patients with immunodeficiency (both HIV or after transplant). It must be remembered that in some countries, such as the United States, the TAVI procedure is still considered to be in an initial phase and this can affect the lack of data regarding this population. To the best of our knowledge, this is the first HIV patient with severe aortic stenosis treated by TAVI, which was chosen mainly due to the infective risk. TAVI, with an accurate treatment of in-hospital complications, may represent a feasible choice for those with HIV/AIDS.

## COMMENTS

### *Case characteristics*

Aggressive acquired immunodeficiency syndrome (AIDS) in a patient referred for invasive cardiac surgery to improve his life expectancy.

### *Clinical diagnosis*

NYHA Ⅲ: reduced second heart sound with systolic murmur heard. Electrocardiogram (ECG) with left ventricle hypertrophy and echocardiogram confirming severe stenosis.

### *Differential diagnosis*

After syncope, ECG monitoring did not show any atrioventricular block.

### *Laboratory diagnosis*

The lymphocyte typing detected a significant reduction in the lymphocyte subpopulation of $CD3^+$, $CD4^+$ and $CD19^+$.

### *Imaging diagnosis*

Transthoracic echocardiography showed the left ventricle with concentric hypertrophy and FE of 55%; severe aortic stenosis with AVA 0.8 $cm^2$ and mean transvalvular gradient of 55 mmHg without coronary disease at angiography.

### *Pathological diagnosis*

HIV-positive patient treated with anti-retroviral therapy, suffering from symptomatic severe aortic stenosis.

### *Treatment*

Transfemoral transcatheter aortic valve implantation (TAVI).

### *Term explanation*

*Core Valve* is a valve prosthesis, comprised of 3 porcine pericardial tissue leaflets mounted in a self-expanding nitinol frame. This valve has only been used in a retrograde approach, either *via* transfemoral, subclavian or direct aortic access.

### *Experiences and lessons*

TAVI can be considered a therapeutic option for severe aortic stenosis in a severe immunosuppressed status, as for patients with AIDS treated with antiretroviral therapy.

### *Peer review*

The argument could be considered a strong point because in the literature, this is not treated; in fact, this was the first TAVI procedure on a patient affected by

AIDS at high risk for valve surgical replacement. So, this case report represents an example for an alternative therapeutic option, giving an opportunity for these patients to be cured despite their important comorbidity.

## Abstract

We present a case of a 33-year-old female who sustained multiple injuries of her spine, including spinous process fractures of C5 to C7 and a lamina fracture of C6 and C7. Her thoracic spine showed transverse process fractures of T4 to T10, a compression fracture and lamina fracture of T3, spinous process and transverse process fractures of T4 and T5, a rotation injury of T6, as well as a compression fracture of L1. Thirteen months after posterior thoracic spinal instrumentation, a pedicle screw was suspected to be in contact with the aorta, which was proved by computed tomography angiograms. Consequently, implant removal was planned with direct exposure of the aorta in order to allow for immediate repair if needed. So far, studies that compare different techniques to remove pedicle screws that are suspected to penetrate the aorta are missing. However, different techniques have been described in case reports, mainly minimally invasive endovascular techniques *vs* open techniques such as thoracotomy.

**Key words:** Spine; Pedicle screw; Aorta; Bleeding; Implant removal; Hemorrhage

**Core tip:** Large vessel damage is described during spinal surgery and can lead to perforation of the aorta by misplaced pedicle screws. However, misplaced pedicle screws are often seen within postoperative computed tomography scans, only resulting in elective pedicle screw removal/exchange. Different techniques are available. We describe the use of a thoracotomy to prevent lethal hemorrhage. The importance of preoperative planning is highlighted, including pondering the advantages and disadvantages.

Decker S, Omar M, Krettek C, Müller CW. Elective thoracotomy for pedicle screw removal to prevent severe aortic bleeding. *World J Clin Cases* 2014; 2(4): 100-103 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i4/100.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i4.100

## INTRODUCTION

Damage to large vessels like the aorta is a major complication in spinal surgery. This is a rare but life-threatening event. It is not uncommon that pedicle screws can penetrate the anterior cortex, therefore posing a risk of trauma to the aorta[1]. The anterior vertebral body is convex which increases the risk of penetration by the pedicle screws. As there is no biomechanical benefit from penetration of the anterior cortex with a pedicle screw, spinal surgeons generally do not strive for it[2].

Research has shown that the posterior spinal approach poses less risk for severe aortic bleeding than that of anterior surgery. Liljenqvist *et al*[3] reported 99 patients of whom only one underwent pedicle screw exchange because of its proximity to the aorta[4-6].

Major arterial bleeding has also been reported after lumbar disc surgery[7]. In particular, aortic damage has been reported after pedicle screw instrumentation. Most

**Figure 1 Severe rotation injury of T6 in the coronal and sagittal plane.**

authors favor minimally invasive endovascular treatment using a femoral artery approach to implant a stent for a misplaced pedicle screw that penetrates the aorta before implant removal[8-11].

In the event of aortic bleeding during the removal of pedicle screws, the patient is at a particularly high risk for exsanguination. Different invasive strategies are available to protect the patient from life-threatening bleeding, of which thoracotomy with direct visualization of the aorta and endovascular approaches with the use of stents are the main strategies.

Whilst there are several reports on endovascular treatment of aortic damage due to spinal instrumentation, reports regarding thoracotomy are rare[12,13]. We present a case of a displaced pedicle screw with a concern of penetration of the aorta. Elective thoracotomy was performed during implant removal for best visualization and to give the opportunity for immediate aortic clamping in case of severe bleeding.

## CASE REPORT

A 33-year-old woman was admitted to our emergency department with multiple injuries during a roll-over accident with her car. Endotracheal intubation was performed at the site of the accident without complications. No neurological deficit was reported. She suffered from severe thoracic trauma with several rib fractures on both sides, lung contusions, a hemopneumothorax, as well as a left forearm fracture. She also suffered from multiple severe spinal injuries. Her cervical spine had spinous process fractures of C5-C7 and a lamina fracture of C6-C7. Her thoracic spine showed transverse process fractures from T4 to T10, a compression fracture and lamina fracture of T3, spinous process and transverse process fractures of T4 and T5, a rotation injury of T6 (Figure 1), as well as a compression fracture of L1. We performed pedicle screw instrumentation from T2 to T10, as well as a laminectomy of T6 and posterior fusion on the day of injury (Figure 2). Three weeks later, an anterior interbody fusion of T5 to T7 was performed with an autologous iliac crest bone graft using a thoracoscopic approach. The postoperative computed tomography (CT) showed correct positioning of all pedicle screws, as well as the bone graft. Wound healing was regular without complications. She was discharged 23 d after admission and directly started rehabilitation. The patient stayed on our intensive care unit during the complete hospital stay. We allowed full weight-bearing. Follow-up care was performed by resident physicians. Thirteen months after anterior fusion, she presented in our outpatient clinic and a CT scan was performed to evaluate fracture healing as well as integration of the bone graft. There was a concern that the left pedicle screw of T7 was in contact with or could potentially perforate the aorta. This was not seen on the previous CT scan (Figure 3). Transesophageal sonography could not exclude an intraaortic position of the tip of the pedicle screw. Consequently, we planned the implant removal which was performed two weeks after the CT scan. This was done with the help of the vascular

surgeons.

The patient was placed in the right lateral position. Using a median approach, we first removed the cross connector, the rod as well as all the pedicle screws on the right side. A thoracotomy was then performed through the 6th and 7th intercostal space. Anterior preparation of the T7 left pedicle screw, which penetrated the anterior cortex of the corpus vertebrae, was done for optimal visualization before implant removal; the screw did not penetrate the aorta. The aorta was pulled across using a retractor so that it did not cover the screw of T7. We then removed the left rod as well as all the pedicle screws. No bleeding was observed with removal of the T7 pedicle screw. The incision was closed in layers after irrigation and placement of a chest tube and drains at the back. One month later, the patient needed revision surgery because of a seroma at the back. The seroma had been apparent since discharge from the hospital after implant removal and was punctured in our outpatient clinic three times before revision surgery. Afterwards, to our knowledge no further complication occurred. However, wound healing was monitored by a resident physician between the initial surgery and the implant removal.

## DISCUSSION

When surgeons suspect that a pedicle screw affects the aorta, one should keep in mind that implant removal should not be performed with the patient in a prone position without further precautions. Instead, intensive preoperative planning is needed and vascular surgeons should be contacted in advance if the trauma or orthopedic surgeon is not qualified to manage large vessel damage. Preoperative planning should include good visualization of the spatial relationships of the tip of the screw as well as the involved vessels. Different techniques are available, mainly minimally invasive endovascular techniques as well as a thoracotomy[8-13]. Clear guidelines as to which technique is best are missing so far. In this case, we decided to perform a thoracotomy to directly visualize the left T7 pedicle screw as we were afraid of not being able to control bleeding in case of aortic rupture using an endovascular approach. Although this is a very invasive technique, it provides the best visualization as well as access for a fast intervention like aortic clamping in the event of aortic injury. Nevertheless, alternatives such as preoperative implantation of femoral arterial access for quick endovascular intervention have to be considered and extensively discussed with the patient and the team preoperatively. When pedicle screw removal is planned because of its proximity to the aorta, the patient should be clearly informed about the risk of bleeding, as well as the various options to prevent life-threatening bleeding. We recommend a multi-disciplinary discussion of these surgeries to evaluate which technique is best. Generally, surgeons should decide depending on two main aspects. First, the technique has to be safe to prevent lethal hemorrhage and surgeons have to feel safe. Second, the surgery should be as minimally invasive as possible. *E.g.*, a thoracotomy[12,13] is very invasive and should be avoided whenever possible. In conclusion, this is a very subjective decision. Clear data that help to decide which technique is best in which situation is missing and, in contrast, the decision-making process depends on individual surgical competence and experience.

## COMMENTS

### Case characteristics

The patient described did not show any symptoms 13 mo after posterior instrumentation of multiple spinal fractures. However, a computed tomography (CT) scan did raise suspicion that a pedicle screw could perforate the aorta.

### Clinical diagnosis

Like in the CT, intraaortic positioning of the pedicle screw could not be excluded by transesophageal sonography.

### Treatment

The authors planned implant removal using a thoracotomy for direct visualization of the aorta which did not appear to be perforated.

### Related reports

Thoracotomy is a very invasive technique that provides the best visualization during surgery but there have also been reports that described minimally invasive endovascular treatment.

### Term explanation

The authors experienced the importance of intensive preoperative planning, as well as a multidisciplinary approach to discuss all available treatment options to reduce the risk of lethal hemorrhage during surgery.

### Experiences and lessons

The strength of this case report is that it describes a rare situation that can, however, be seen by every spine surgeon. Although the authors describe a very invasive technique, other techniques have also been described. Nevertheless, the decision of which technique to use is very subjective as experience with this specific topic is low.

### Peer review

The study reported how a 33-year-old patient underwent a thoracotomy for pedicle screw removal due to suspected contact with the aorta. It is an unusual but not unheard of occurrence which is valuable to review.

## Abstract

A case of osteoid osteoma of the elbow in a patient with hemophilia A is described. This male patient presented with chronic and nocturnal pain of the left elbow which was alleviated with acetaminophen. Besides pain, he also complained of stiffness. Before these complaints, he had recurrent bleedings in the elbow because of hemophilia. A delayed diagnosis of osteoid osteoma in the proximal part of the left ulna was established by a bone scan and a multislice spiral computed tomography (CT) scan. The lesion was surgically removed under CT-guidance. The histopathological analyses did not show specific features of osteoid osteoma. Two months after the operation, the complaints decreased and the range of motion of the left elbow improved. A diagnosis of osteoid osteoma of the elbow should be considered in young adult patients with persistent elbow pain and histological confirmation is not always necessary.

**Key words:** Elbow; Osteoid osteoma; Surgery; Hemophilia; Diagnosis

**Core tip:** Two issues are emphasized by reporting this case. Firstly, it is important to recognize the possibility of osteoid osteoma in a young adult patient with persistent chronic and nocturnal elbow pain which is alleviated with nonsteroidal anti-inflammatory drugs. Secondly, histopathological confirmation is not always possible and necessary to establish the diagnosis of osteoid osteoma.

## INTRODUCTION

Osteoid osteoma is a benign tumor in young adults and is relatively common, accounting for approximately 10%-12% of all benign skeletal neoplasms[1-3]. Jaffe[4] first described this entity in 1935 as a distinct osteoblastic skeletal tumor. It usually occurs in the second and third decade of life and the male/female sex ratio is approximately 3:1[1,3]. This tumor is curable by surgical excision. About 50% to 60% of osteoid osteomas occur in the long bones of the lower extremities and the femoral neck is the single most frequent anatomic site. In these cases, the diagnosis is usually typical. However, in the upper extremities where the bones of the elbow are the most frequent anatomic site, the clinical and imaging picture may be misleading, often mimicking other entities. This poses a challenge to the diagnosis which is often delayed, resulting in a significantly negative impact on the patient's quality of life[3,5]. Making the diagnosis is especially difficult when the patient is known to have other joint pathology. We describe a case of osteoid osteoma mimicking

arthropathy of the elbow in a patient with hemophilia.

## CASE REPORT

A 29-year-old man presented with chronic pain of the left elbow that was alleviated with painkillers. The pain had started suddenly 1.5 years ago after lifting a weight. The patient had locking complaints, nocturnal pain and pain at rest. He also had hemophilia A with recurrent bleedings in the elbow and progressive extension deficit of the elbow. A previous arthroscopy was performed but without improving the range of motion and diminishing pain. Physical examination of the left elbow revealed mild crepitus and no hydrops of the joint. Flexion of the elbow was possible until 110 degrees and there was an extension deficiency of 30 degrees. Pronation and supination was possible until 60 and 80 degrees respectively. Palpation of the lateral epicondyle and the proximal ulna was painful. There were no neurological or vascular abnormalities.

A plain radiograph (Figure 1) and a computed tomography (CT) scan performed in April 2007 revealed only osteoarthrotic changes without visualization of a nidus. A magnetic resonance imaging (MRI) scan showed a synovitis and hydrops and therefore a synovectomy was performed, without improvement in motion and pain.

A bone scan showed a circumscript hyperemic and metabolic active focus in the proximal part of the left ulna. These findings match the diagnosis of osteoid osteoma, cartilage lesion, osteomyelitis and a fissure or fracture. In December 2007, a multislice spiral CT scan showed early degenerative changes of the left elbow joint with signs of arthritis. It also confirmed the diagnosis of osteoid osteoma in the proximal ulna with a clearly calcified central nidus just distal from the proximal radioulnar joint and with surrounding periost reaction. The measurement of the lesion was 12 mm × 8 mm.

The patient was given clotting factor Ⅷ preoperatively and a CT-guided surgical excision of the lesion was performed (Figure 2). The histological analyses showed cancellous bone with sclerotic changes without specific features. A second opinion was sought from the national committee on bone tumors at Leiden University medical center and by consensus they confirmed the diagnosis osteoid osteoma, although histological analyses did not establish it.

Two months after the operation, the pain had decreased and the function of the elbow had improved. Flexion was possible until 120 degrees and there was an extension deficiency of 20 degrees. A plain radiograph of the left elbow performed after the operation showed a decrease of sclerotic changes in the proximal ulna. One year after surgical excision of the lesion the patient was discharged from follow up.

## DISCUSSION

The general clinical presentation is the persistence of a dull, diffuse, aching pain of increasing severity. The pain is frequently worse at night and is alleviated by nonsteroidal anti-inflammatory agents[1,3,5]. Because clinical features precede imaging, there is frequently a delay in the diagnosis and patients are often treated for and suspected of having other conditions. Osteoid osteoma of the elbow may masquerade as a non-specific synovitis. However, the possibility of osteoid osteoma must be considered in the presence of persistent pain with diminished range of movement of unknown etiology[2,5].

**Figure 1 A plain radiograph revealed osteoarthritic changes without visualization of a nidus.**

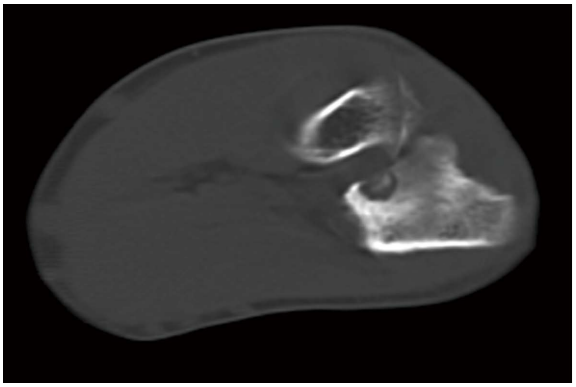

**Figure 2 The nidus is computed tomography-guided surgically removed.**

Osteoid osteoma is a benign tumor that consists of a well-demarcated osteoblastic mass called a nidus that is surrounded by a distinct zone of reactive bone sclerosis. The zone of sclerosis is not an integral part of the tumor and represents a secondary reversible change that gradually disappears after the removal of the nidus. The nidus tissue has a limited local growth potential and usually is less than 1 cm in diameter[3]. The elbow is a rare location in which to find osteoid osteoma. Bruguera *et al*[6] identified only four osteoid osteomas among all primary tumors of the elbow in the Leeds Regional Bone Tumour Registry.

Our patient had a history of hemophilia A. This is an X-linked inherited bleeding disorder characterized by a deficiency of clotting factor Ⅷ[7,8]. Arthropathy caused by recurrent intra-articular hemorrhages is a common complication of severe hemophilia. The elbow joint is

the second most common site of arthropathy in the hemophilic patient. Severe arthropathy of the elbow is complicated by pain, stiffness, reduced range of motion and chronic synovitis[9,10]. This comorbidity complicated and delayed the diagnosis of osteoid osteoma in the described case.

The radiological features of osteoid osteoma of the elbow include the following triad: (1) osteosclerosis, usually a dominant feature at initial imaging and typically enveloping the nidus; (2) joint effusion; and (3) a periostal reaction that can involve both the bone in which the osteoid osteoma arises and adjacent bones. Awareness of these features will facilitate making the correct diagnosis, thereby facilitating timely and appropriate treatment[2]. About a quarter of osteoid osteomas are not detected on plain radiographs. CT scan, bone scintigraphy and MRI are useful to make an early and correct diagnosis. Although MRI is not very helpful in diagnosing osteoid osteoma, it can be beneficial in showing the inflammatory reaction produced by osteoid osteoma and in excluding other associated pathologies[1,3,11].

In the described case the nidus was not observed on plain radiographs. Because of persisting complaints and clinical symptoms with normal radiographic examination, a bone scintigram was performed which showed an increased uptake of radioisotope. Additionally, a multislice CT scan was performed which localized the nidus, accurately disclosing its relationship with the surrounding anatomical structures, thus beneficial for the pre-operative planning[5].

The histology of osteoid osteoma in the elbow is indistinguishable from that in typical locations[2]. The lesion is usually smaller than 1.5 cm in diameter and is composed of a central core of vascular osteoid tissue (nidus) surrounded by a peripheral zone of reactive sclerotic bone. The nidus appears as a distinct oval or round reddish area that can be easily separated from its bed. Microscopically, the nidus consists of thin bone trabeculae uniformly distributed in loose stromal vascular connective tissue. The trabeculae are usually thin and their size varies from lesion to lesion and in different areas of the same nidus. The central portion of the nidus is heavily ossified and less cellular compared with the more cellular but less mineralized peripheral portion[3,5].

The diagnosis of osteoid osteoma in the described case was based on history, physical examination and radiology and was not confirmed by the pathology examination but by consensus of the national bone tumor committee. The complaints decreased and the range of motion improved after surgical excision of the tumor. In nearly 20% of patients surgical exploration fails to uncover the nidus, according to the Mayo clinic data[3]. Persistence of typical symptoms after surgery may mean that the nidus was not (completely) removed and that only surrounding reactive bone was excised. Some patients obtained complete postoperative relief of symptoms without histopathological confirmation of an osteoid osteoma nidus. This was possibly because the nidus may have been so small in relationship to the abundant surrounding sclerotic bone that it was removed but not recognized by the surgeon and thus not delivered for pathological examination; or the nidus may have been present in the specimens but was missed on histological survey; or the nidus may not have been found on pathological examination because of damage to the friable tissue or separation of the nidus[12].

A conservative treatment for osteoid osteoma described in the literature is management with anti-inflammatory drugs for 30 to 40 mo which can induce permanent relief of symptoms and regression of the nidus observed on radiographs[13]. However, given the tendency for synovitis and loss of motion with a prolonged period of symptoms from osteoid osteoma of the elbow, the indicated treatment is total excision of the nidus, either by open surgery or by radio-frequency percutaneous ablation[3,5,11].

Two issues were emphasized by reporting this case. Firstly, it is important to recognize the possibility of osteoid osteoma in a young adult patient with persistent chronic and nocturnal pain in the elbow which is alleviated with nonsteroidal anti-inflammatory drugs. Secondly, histopathological confirmation is not always possible and necessary to establish the diagnosis osteoid osteoma.

## ACKNOWLEDGMENTS

There are no financial or non-financial (political, personal, religious, ideological, academic, intellectual, commercial or any other) competing interests of the authors or a member of their immediate families to declare in relation to this manuscript. This case was also described in Dutch in the national orthopedic (non-indexed) journal.

## COMMENTS

### *Case characteristics*

A case of osteoid osteoma of the elbow in a patient with hemophilia A is described. This male patient presented with chronic and nocturnal pain of the left elbow which was alleviated with acetaminophen. Besides pain, he also complained of stiffness. Before these complaints he had recurrent bleedings in the elbow because of hemophilia.

### *Clinical diagnosis*

Physical examination of the left elbow revealed mild crepitus and no hydrops of the joint. Flexion of the elbow was possible until 110 degrees and there was an extension deficiency of 30 degrees. Pronation and supination was possible until 60 and 80 degrees respectively.

### *Differential diagnosis*

The possibility of osteoid osteoma must be considered in the presence of persistent pain with diminished range of movement of unknown etiology.

### *Imaging diagnosis*

A delayed diagnosis of osteoid osteoma in the proximal part of the left ulna was established by a bone scan and a multislice spiral computed tomography (CT) scan.

### *Treatment*

The lesion was surgically removed under CT-guidance. The histopathological analyses did not show specific features of osteoid osteoma.

### *Experiences and lessons*

Firstly, it is important to recognize the possibility of osteoid osteoma in a young adult patient with persistent chronic and nocturnal pain in the elbow which is alleviated with nonsteroidal anti-inflammatory drugs. Secondly, histopathological

confirmation is not always possible and necessary to establish the diagnosis osteoid osteoma.

### *Peer review*

This manuscript illustrates a unique case of osteoid osteoma of the elbow in a patient with hemophilia. The article is well-written and does not require modifications.

## Abstract

A 29-year-old gentleman underwent a transverse colostomy for intestinal obstruction caused by advanced rectal carcinoma. On the 5th postoperative day, the patient developed a painful swelling on the right side of the abdomen. The contrast enhanced computed tomography of the abdomen revealed a right sided hydronephrosis, a large rent in the renal pelvis, and a large retroperitoneal fluid collection on the right side. Percutaneous nephrostomy and pigtail catheter drainage of the urinoma led to resolution of abdominal swelling. Development of a urinoma as a consequence of rectal carcinoma is highly unusual. Prompt imaging for confirmation of diagnosis, decompression of the renal pelvicalyceal system, and drainage of the urinoma limits morbidity.

**Key words:** Colorectal cancer; Urinoma; Spontaneous rupture of the renal pelvis; Percutaneous nephrostomy; Pigtail catheter drainage

**Core tip:** A recent development of a loin swelling in a patient with a malignant pelvic tumor should alert the clinician to the possibility of a urinoma due to spontaneous rupture of the obstructed renal pelvis. Early imaging for confirmation of diagnosis and decompression of the renal pelvicalyceal system help to arrest a further downhill course of the patients.

## INTRODUCTION

A urinoma may be defined as a localized collection of urine within the retroperitoneum but outside the urinary system following a breach in the urothelium. Blunt abdominal trauma and iatrogenic injuries account for most urinomas. Pelvic malignancies have been less frequently implicated in the development of a urinoma. Infiltration of the lower ureter by the malignant pelvic growth causes persistent obstruction to urine flow and progressive dilatation of the upper urinary tract. The mounting pressure inside the pelvicalyceal system may lead to rupture of the renal pelvis and urinary extravasation[1]. We, herein, report a young patient suffering from locally advanced rectal adenocarcinoma who developed a urinoma following rupture of the obstructed right renal pelvis due to malignant infiltration of the lower ureter.

**Figure 1 Clinical photograph of the patient shows lump in right iliac fossa and diversion transverse colostomy.**

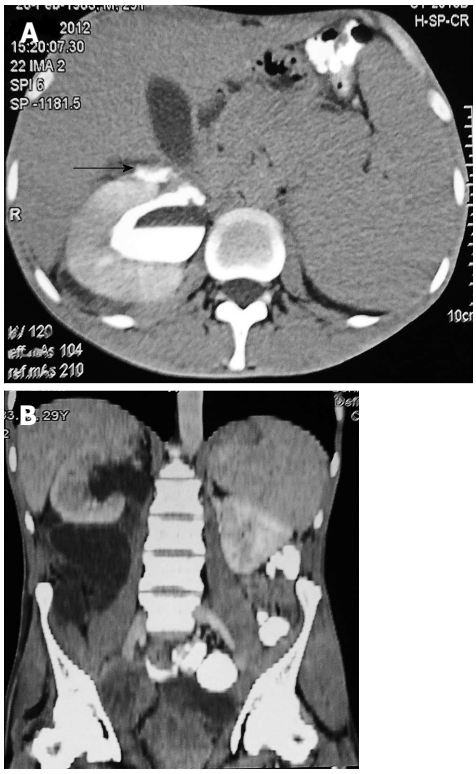

**Figure 2 Computed tomography imaging.** A: Axial contrast enhanced computed tomography (CT) of the abdomen shows a leak of contrast from the hydronephrotic right renal pelvis into the perinephric space (black arrow); B: CT coronal reconstruction shows a large retroperitoneal urinoma below the right kidney.

## CASE REPORT

A 29-year-old gentleman presented as a surgical emergency with features of intestinal obstruction. Abdominal examination revealed distention of the abdomen, palpable bowel loops and increased bowel sounds. Digital rectal examination coupled with proctoscopy revealed an encircling ulceroproliferative growth in the distal rectum, 5 cm proximal to the anal verge. The growth was fixed to the pelvis. A plain radiograph of the abdomen revealed dilated small and large bowel loops. Transverse colostomy was performed to relieve intestinal obstruction. Endoscopic biopsy of the rectal growth revealed adenocarcinoma. On the 5$^{th}$ postoperative day, the patient developed a painful swelling on the right side of the abdomen (Figure 1). He did not report any urinary and bowel symptoms. Ultrasonography of the abdomen showed a large hypoechoic collection along the right abdominal wall extending from the right kidney to the right iliac fossa. Contrast enhanced computed tomography (CECT) of the abdomen demonstrated right hydronephrosis, a large rent in the renal pelvis, perinephric stranding and a large retroperitoneal fluid collection on the right side (Figure 2). Ultrasound guided percutaneous nephrostomy and pigtail catheter drainage of the fluid collection was performed along with administration of intravenous antibiotics. Two liters of blood tinged urine was drained and the swelling subsided within the next two days. The pigtail catheter was removed after five days. The patient was advised to have definitive chemoradiation therapy for the rectal adenocarcinoma; however, he opted for alternative medicine and did not come for further treatment.

## DISCUSSION

Ureters can be easily obstructed by pelvic malignancies by virtue of their thin wall and narrow caliber lumen. Unrelieved progressive urinary obstruction in the presence of a functional kidney can disrupt the pelvicalyceal system, leading to formation of a urinoma[2]. The renal pelvis, least supported by the parenchymal mass of kidney, is vulnerable for rupture in such scenarios. Carcinoma of the rectum, cervix, ovary, urinary bladder, and metastatic pelvic lymphadenopathy have been implicated in causation of spontaneous urinary rupture and urinoma formation[3-5]. Carcinoma of the rectum in particular has an unrelenting course in young individuals, characterized by advanced stage and higher-grade tumors at diagnosis[6]. The incidence of extra-intestinal complications is also more frequent in these patients. Apart from malignancies, mechanical obstruction secondary to congenital anomalies, calculus, prostatomegaly and pregnancy can also lead to disruption of the pelvicalyceal integrity and formation of a urinoma.

Urinomas exhibit gradual enlargement in size until the whole retroperitoneum is filled with the cystic mass. Since the contained urine is sterile, pain is not an early and prominent symptom. The patients usually present with an asymptomatic loin lump that requires imaging to confirm the diagnosis. Development of pain suggests infection of the extravasated urine or compression on the adjacent structures by the expanding urinoma. Pain may also be related to the primary disease. Ipsilateral loin pain, ileus and low grade pyrexia constitute the characteristic manifestations of a symptomatic urinoma[7]. If treatment is delayed, blood urea nitrogen and serum creatinine may rise due to re-absorption of urine from the urinoma. The level of creatinine in the urinoma fluid is 10 times higher than the creatinine level in the patient's serum[8]. Ultrasonography, intravenous urogram and CECT have been used for confirmation of the diagnosis. CECT can

identify the underlying cause, the location of the breach in the urothelial lining, the dimension of the collection and its relationship with the adjacent structures.

Asymptomatic, small and non expanding urinomas can be managed with close observation. Active management of urinomas includes decompression of the kidneys by means of a double J ureteral stent or percutaneous nephrostomy tube and prophylactic broad spectrum antibiotics[9]. Endoscopic placement of a ureteral stent is difficult in patients with obstruction of the lower ureter due to malignant infiltration. Percutaneous drainage of the urinoma should be considered if it persists despite satisfactory diversion of urine flow or if the extravasated urine becomes infected. Percutaneous drainage of the urinoma alone is unhelpful as the urinoma rapidly refills unless the primary pathology is tackled expeditiously. Delay in the management predisposes to the development of complications like perinephric abscess, peritonitis, sepsis, urinary stricture and, rarely, obstructive nephropathy and secondary hypertension due to compression on the upper urinary tract[10]. Correction of the underlying pathology is of paramount importance for the improved survival of patients. Nephrostomy/a ureteric stent should be retained until the ureteric obstruction is relieved.

A recent development of a loin swelling in a patient with a malignant pelvic growth should alert the clinician regarding the possibility of spontaneous rupture of the renal pelvis. Early confirmation of diagnosis by imaging and decompression of the renal pelvicalyceal system helps to arrest a further downhill course of patients.

## COMMENTS

### *Case characteristics*

A 29-year-old gentleman underwent a transverse colostomy for intestinal obstruction caused by advanced rectal carcinoma. On the 5$^{th}$ postoperative day, the patient developed a painful swelling on the right side of the abdomen.

### *Clinical diagnosis*

Tender swelling in the right iliac fossa.

### *Differential diagnosis*

Clinical examination and imaging methods can help to arrive at the diagnosis.

### *Imaging diagnosis*

The contrast enhanced computed tomography of the abdomen revealed a right sided hydronephrosis, a large rent in the renal pelvis, and a large retroperitoneal fluid collection on the right side.

### *Treatment*

Ultrasound guided percutaneous nephrostomy and pigtail catheter drainage of the fluid collection was performed along with administration of intravenous antibiotics.

### *Experiences and lessons*

A recent development of a loin swelling in a patient with a malignant pelvic growth should alert the clinician regarding the possibility of spontaneous rupture of the renal pelvis.

### *Peer review*

This is a concise and clearly written case report which helps understanding of an unusual complication of malignant pelvic growth.

## Abstract

Reactive nodular fibrous pseudotumor (RNFP), which presents abdominal clinical manifestations and malignant radiographic results, usually requires radical resection as the treatment. However, RNFP has been recently described as an extremely rare benign post-inflammatory lesion of a reactive nature, which typically arises from the sub-serosal layer of the digestive tract or within the surrounding mesentery in association with local injury or inflammation. In addition, a postoperative diagnosis is necessary to differentiate it from the other reactive processes of the abdomen. Furthermore, RNFP shows a good prognosis without signs of recurrence or metastasis. A 16-year-old girl presented with a 3-mo history of epigastric discomfort, and auxiliary examinations suggested a malignant tumor originating from the stomach; postoperative pathology confirmed RNFP, and after a 2-year follow-up period, the patient did not display any signs of recurrence. This case highlights the importance of preoperative pathology for surgeons who may encounter similar cases.

**Key words:** Reactive nodular fibrous pseudotumor; Post-inflammatory lesion; Digestive tract; Mesentery; Good prognosis

**Core tip:** Our case report describes a rare benign tumor originating from the gastrointestinal tract. To date, this lesion has been reported in 20 cases worldwide. The most significant and important insights are that these diseases possess fairly good prognosis with opposite radiographic and clinical findings. Pathologically, reactive nodular fibrous pseudotumor (RNFP) was recently described arising from the sub-serosal layer or within the surrounding mesentery. However, the veracity of the pathological examination results and the etiology are still controversial. We will describe the complete diagnostic and therapeutic process of a young girl with RNFP and will retrospectively analyze the previously reported cases, particularly the microscopic and immunohistochemical characteristics.

Yi XJ, Chen CQ, Li Y, Ma JP, Li ZX, Cai SR, He YL. Rare case of an abdominal mass: Reactive nodular fibrous pseudotumor of the stomach encroaching on multiple abdominal organs. *World J Clin Cases* 2014; 2(4): 111-119 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i4/111.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i4.111

## INTRODUCTION

Reactive nodular fibrous pseudotumor (RNFP) is a recently reported lesion that may arise from the gastrointestinal tract or the mesentery. It was first described by Yantiss *et al*[1] in 2003. To date, 20 cases (8 cases in Czech Republic[2], 7 cases in the United States[1,3,4], 2 cases in France[5,6], and 1 case each in Australia[7], Turkey[8] and Italy[9]) have been reported in the literature. We described the first case in China. All the cases require surgical interventions with or without preoperative pathological examinations because of their typically malignant radiographic results. However, this lesion presents an encouraging prognosis during follow-up. Here we present a case in a young female patient.

## CASE REPORT

A 16-year-old girl from Jiangxi Province with no surgical history or abdominal injury history presented to a local medical institution with an approximately 3-mo history of progressive epigastric discomfort. Gastroscopy suggested a highly suspicious malignant tumor of the gastric cardia and fundus, chronic erythematosus exudative antral gastritis and a duodenal bulbar ulcer. For further treatment, the patient was admitted to our hospital. Her abdominal examination revealed light tenderness in the epigastric region. A computed tomography (CT) scan showed a mass (5.8 cm × 3.8 cm × 7.9 cm) in the lesser curvature of the fundus attached to the left adrenal gland with obscure boundaries, and gastrointestinal stromal tumor (GIST) was suspected (Figure 1). Gastroscopy revealed a protruding lesion on the back wall of the gastric cardia and fundus with a coarse surface, and an approximately 1.0 cm × 1.0 cm ulcer was located in the middle of the lesion (Figure 2). Gastroscopic pathological biopsy findings demonstrated an ulcer-forming chronic gastritis without evidence of carcinoma (Figure 3); immunohistochemically, the biopsy specimen was positive for CK and M-CEA in the glandular epithelium, positive for CD31 and CD34 in the vascular endothelium, and positive for CD3 and L26 in the small lymphocytes. Therefore, lymphoma and gastric cancer were excluded (Figure 4), and additional immunohistochemical diagnostic evidence was needed to differentiate GIST from other differential diagnoses (Figure 5). Further gastroscopic ultrasonography showed an immense mass (approximately 4.8 cm × 3.1 cm) that did not penetrate the serosa with an uneven hypoechoic appearance and blood flow on the back wall of the lesser curvature of the fundus. Approximately 6-7 lymph nodes were found next to the mass, and the largest one was 0.6 cm in size. Based on these findings, the patient was sent to the operating room with a presumptive diagnosis of malignant tumor of the fundus (GIST). Upon exploratory laparotomy, a small nodule (1.0 cm × 1.0 cm) in the lesser omentum was detected, and the main mass (approximately 8.0 cm × 6.0 cm × 5.0 cm) was located in the lesser curvature of the gastric cardia and fundus transmurally infiltrating the stomach and encroaching on the pancreatic body and tail, spleen, and left adrenal gland; several swollen perigastric lymph nodes were also visible. Based on the above findings, a total resection of the stomach, pancreatic body and tail, spleen, and left adrenal gland was performed. An esophagojejunal Roux-en-Y anastomosis was used to reconstruct the digestive tract. Postoperative pathologic evaluation revealed a mass (approximately 8.0 cm × 6.0 cm) with a coarse surface transmurally infiltrating the stomach. The gross gastric specimen (15.0 cm × 11.0 cm × 5.0 cm in size) revealed a small depressed region 2.0 cm in size below the main mass. Microscopically, ulcers were detected on the mucosa; the sub-mucosa was composed of mature spindle cells embedded in a dense collagenic hyalinized stroma containing abundant infiltrative lymphocytes, plasmocytes, and hyperplastic lymphoid follicles. No mitosis, necrosis, or nuclear atypia was identified. Other sections including the pancreatic body and tail, spleen, and left adrenal gland and lymph nodes did not reveal any carcinoma tissue, and the staple line also appeared to be microscopically free of tumor. The immunohistochemistry findings of the spindle cells were as follows: actin focally (+), CD34 focally (+), CD117 (-), S-100 (-), desmin (-), DOG-1 (-), PDGFR (-), Ki-67 approximately 2% (+); the immunohistochemistry findings of the lymphocytes were as follows: CD3 (+), L26 (+). Combining the Hematoxylin Eosin (HE) stain and immunohistochemistry, the lesion was diagnosed as RNFP (Figure 6). Postoperatively, the patient's laboratory evaluation revealed elevated white blood cells and platelets. Accordingly, antibiotics, dipyridamole, and bayaspirin were administered as symptomatic treatment. The patient did well after these interventions and was discharged from the hospital on postoperative day 11. Then, 10 mo later, a follow-up CT scan examination was clear of signs of recurrence and metastatic disease (Figure 7). After more than 2 years of follow-up, the patient did not complain of any discomfort and no signs of recurrence have been found.

HE stained 4-mm slides were cut from paraffin embedded tissue that was processed with 10% buffered formalin. A panel of antibodies (Table 1) was used to evaluate the tumors for the presence of smooth muscle,

fibroblasts, myofibroblasts, glandular epithelium, vascular endothelium and lymphocytic classification. Several pivotal markers expressed in GISTs (CD117, CD34, DOG-1, PDGFR) and inflammatory myofibroblastic tumors [anaplastic lymphoma kinase (ALK)] were used as well.

## DISCUSSION

The first 5 RNFP cases were reported in adults by Yantiss *et al*[1]. The original pathological description was consid-

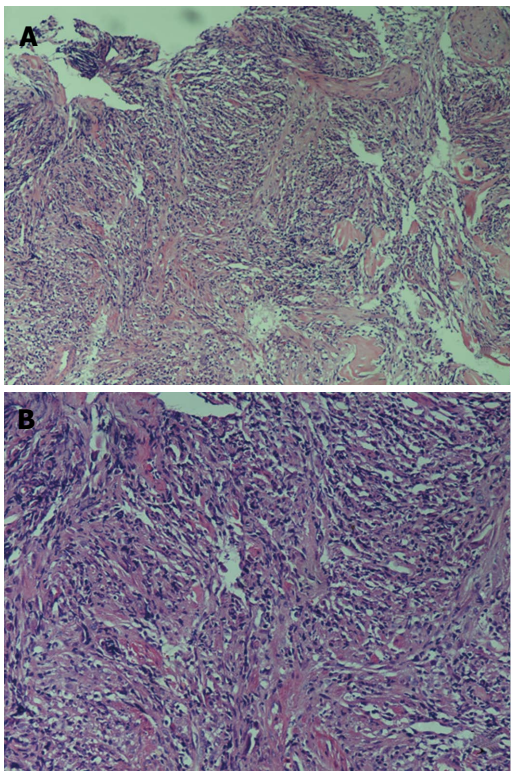

**Figure 3 Gastroscopic pathological biopsy findings (Hematoxylin eosin stain) demonstrating an ulcer-forming chronic gastritis without evidence of carcinoma.** [Magnification: A (10 × 10); B (10 × 20)].

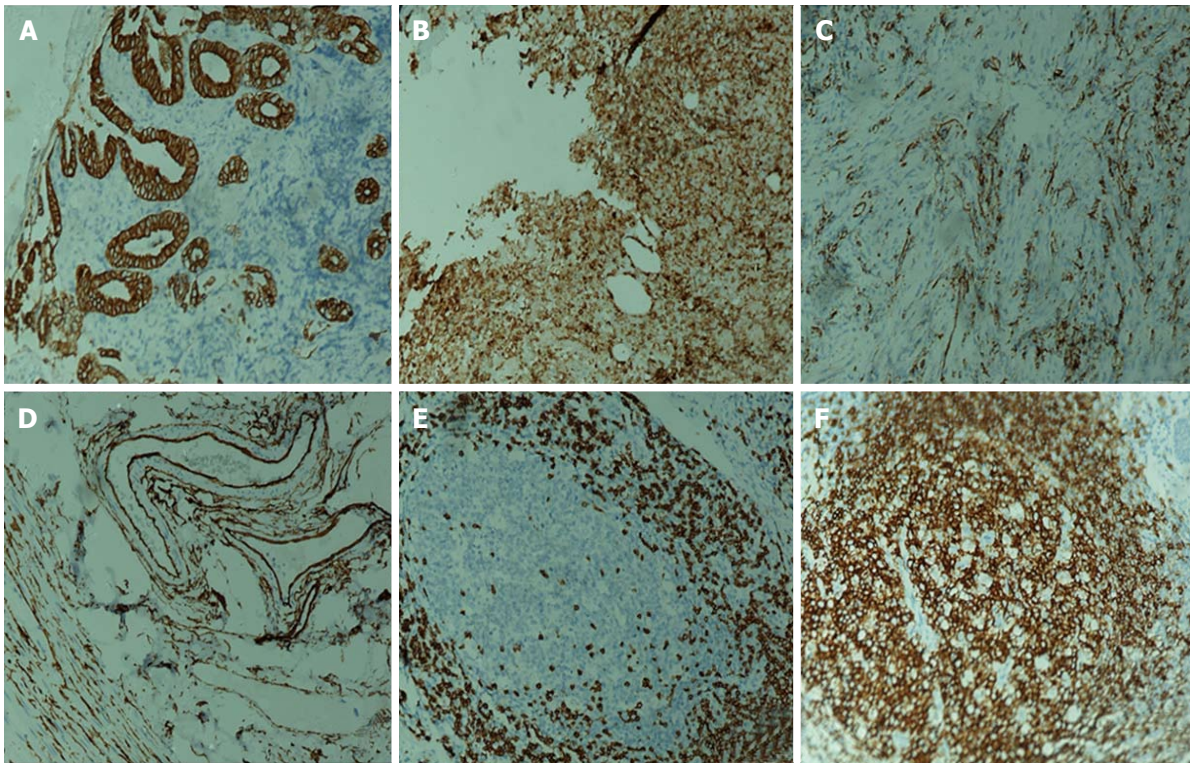

**Figure 4 Immunohistochemistry of gastroscopic pathological biopsy.** A: Glandular epithelium CK (+); B: Glandular epithelium M-CEA (+); C: Vascular endothelium CD31 (+); D: Vascular endothelium CD34 (+); E: Small lymphocyte CD3 (+); F: Small lymphocyte L26 (+). Magnification: 10 × 20.

ered a landmark in the short history of this disease. More recent cases have been reported, and our case represents the 21st report of this lesion worldwide in the English literature.

The adult population appears to be the main target in terms of the age distribution. A total of 18 adult cases (85.7%, age range, 22-72 years) have been reported compared to 1 case in a 1-year-old boy, 2 cases in a 13-year-old girl and our case of a 16-year-old girl. The average age is 46.1 years old (male: 49.6; female: 39.1). The sexual distribution ratio is 2:1 (male to female) consisting of 14 males (66.7%) and 7 females (33.3%). Unquestionably, males are more predisposed to this disease. The leading clinical characteristics can be summarized as follows: 11 patients including our case presented with abdominal symptoms, among which 4 patients had acute abdominal pain while 3 had chronic abdominal discomfort. Past medical history revealed that 5 patients (23.8%) had a history of abdominal surgery. One patient had undergone a left hemicolectomy 17 years previously for stage pT-3N0MO- II A colon cancer according to the 7th American Joint Committee on Cancer[9]. Yantiss *et al*[1] reported a patient with a history of alcoholism and recurrent pancreatitis, complicated by necrotizing pancreatitis, which required multiple surgical debridements. Another patient had a history of MEN-1 syndrome and multiple abdominal surgeries, including resections of an endocrine tumor of the pancreatic tail and an adrenal adenoma 23 and 21 years previously, respectively; one patient had a history of a laparoscopic cholecystectomy and resection of a duodenal gastrinoma 1 year before the development of this tumor-like mass. The fifth patient's surgical history included a cholecystectomy some years prior for cholecystitis and an operation in 2001 for a strangulated hernia[7]. A significant abdominal medical history was noted in 9 cases (42.9%), including the following: a peptic ulcer in 3 cases (containing our case); a perforated duodenal diverticulum in a 32-year-old man; endometriosis together with ergotamine use for migraine in a 28-year-old woman; chronic bowel obstruction complicated by an external fistula in a 30-year-old woman; ileus caused by a tumor of the ileum in a 22-year-old man; and ingestion of a foreign body in 2 cases (in one case, it was an iron pin, and in the other, it was a small abscess cavity containing foreign bodies). Hence, in 14 patients (66.7%), a medical or surgical abdominal history appears to play a vital role in the development of RNFP.

In 2004, Daum *et al*[2] first suggested that RFNP originated from multipotent subserosal progenitor cells rather than myofibroblasts; therefore, some scholars had addressed the importance of investigating a patient's past abdominal surgery and medical history because such conditions could more or less trigger the occurrence of these lesions' and illustrated its reactive nature. The general findings were that these lesions represented an exuberant inflammatory response rather than a true tumor. However, our case was similar to the minority of RNFPs without a previous abdominal surgery or injury.

RNFP presented with multiple masses or, a bit more frequently, as a single mass (13 cases, 61.9%). All of the

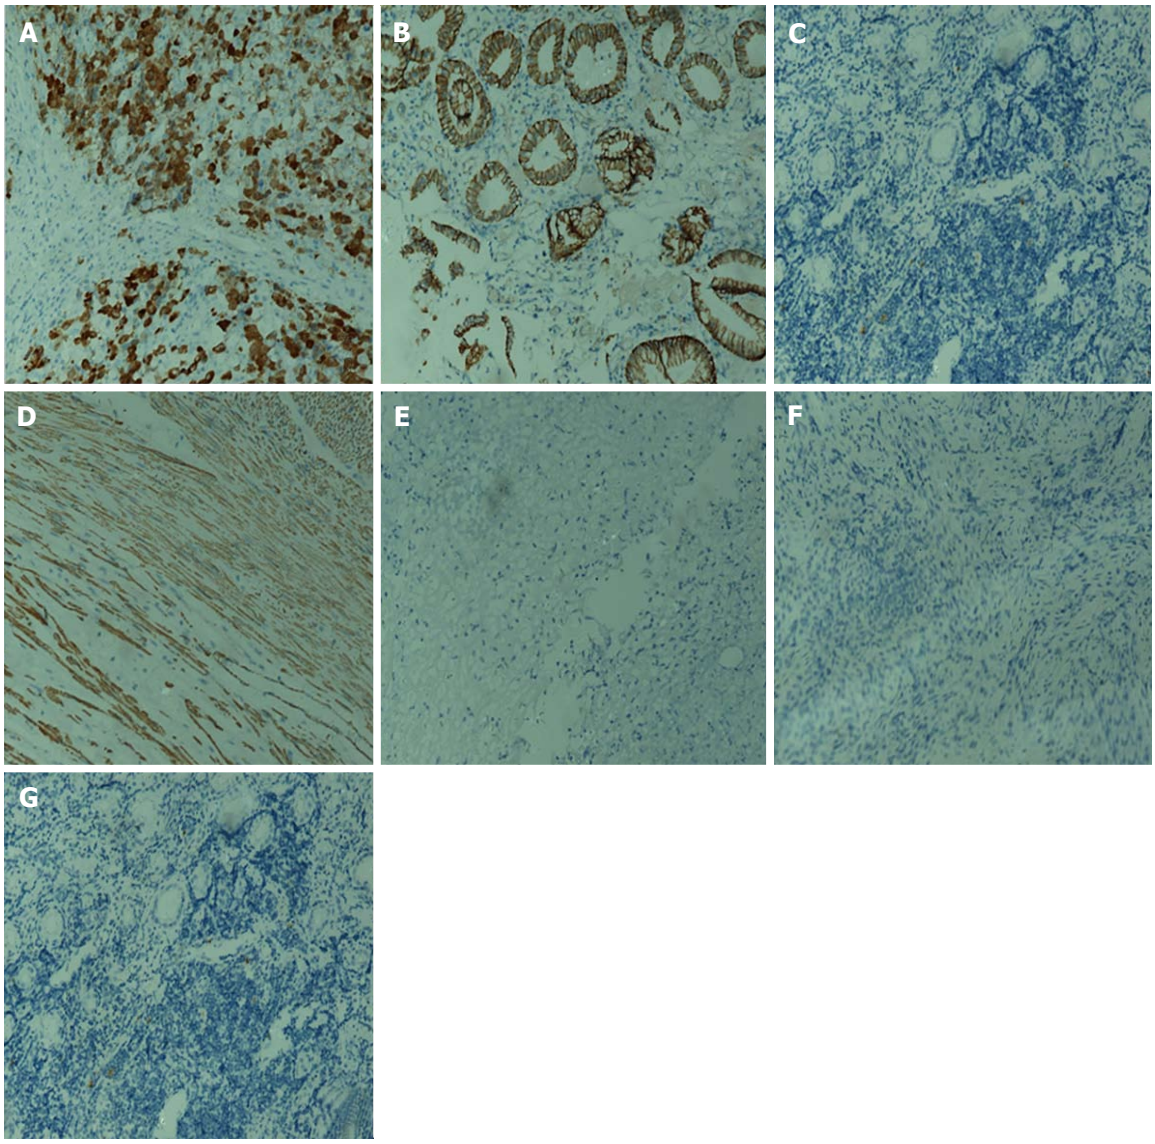

**Figure 5 More immunohistochemistry of endoscopic pathological biopsy.** A: Anaplastic lymphoma kinase (+); B: β-catenin (+); C: Desmin (-); D: Actin (+); E: CD117 (-); F: DOG-1 (-); G: S-100 (-). Magnification: 10 × 20.

cases underwent complete resections (18 cases, 85.7%) except 3 cases in which incomplete resections were performed because of too many masses or nodules. One patient was a 71-year-old man with multiple hepatic deposits[9], and in a 28-year-old woman, numerous nodules presenting on the surface of the ovaries, appendix, the bowel mesentery, the abdominal peritoneal wall, and the omentum were detected[8]. The anatomic site of the main lesions most commonly involved the colon with the appendix (7 patients) followed by the mesentery and the small bowel (especially the terminal ileum) (7 cases each), omentum (2 cases), the peritoneal wall (3 cases), the hepatic capsule, the gastric wall, and the peripancreas (1 case each). Our case was the first to be diagnosed as RNFP transmurally infiltrating the stomach, encroaching on the pancreatic body and tail, the spleen, and the left adrenal gland. Commonly, RNFP lesions are depicted as firm and of light colors from whitish to tan or gray; rarely, calcifications are present in the lesions (3 cases, 14.3%) (Table 2).

Microscopically, all of the lesions shared the same feature consisting of a paucicellular proliferation of spindle or stellate cells embedded in a hyalinized matrix and sometimes surrounded by inflammatory cells (mostly in the form of mononuclear lymphoid cells) or lymphoid aggregates. If a lesion contains foreign bodies, dispersed giant cell granulomas are observed. Characteristically, the lesions do not show mitosis, necrosis, or nuclear atypia.

Ultra-structural examination of 3 cases by Daum *et al*[2] revealed spindle or stellate-shaped cells with rare intercellular junctions and irregular nuclei, prominent rough endoplasmic reticulum, sparse pinocytic vesicles, bundles of microfilaments attached to dense bodies, and focal investment by external lamina. These features were typical of myofibroblastic differentiation. In addition, genetic investigations revealed no substitutions, deletions, or insertions occurring in exon 11 of the c-kit in 7 specimens. Likewise, no deletions or insertions in part of

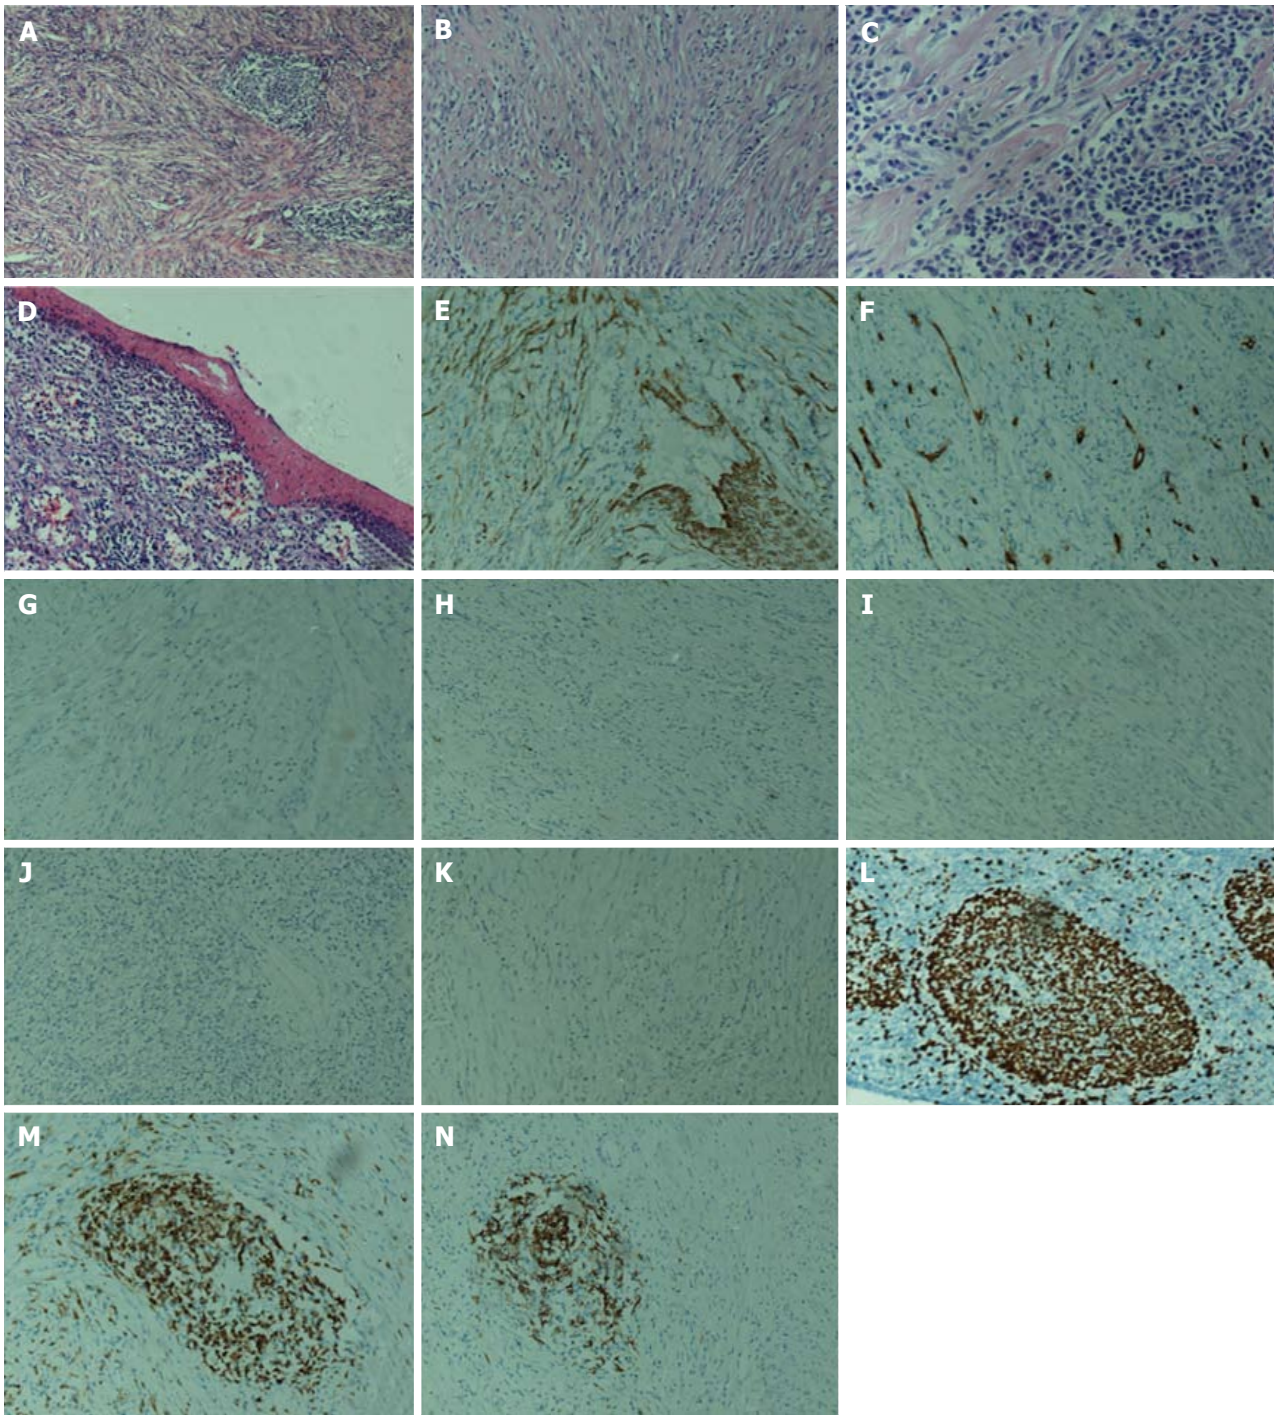

**Figure 6 Hematoxylin Eosin stain.** A-D: Microscopically, sub-mucosa composing of mature spindle cells embedded in a dense collagenic hyalinized stroma containing aboundant infiltrative lymphocytes, plasmocytes, and hyperplastic lymphoid follicles with incomplete capsule. No mitosis, necrosis, or nuclear atypia was identified; E-N: Immunohistochemistry, spindle cells: E: Actin focally (+); F: CD34 focally (+); G: CD117 (-); H: S-100 (-); I: desmin (-); J: DOG-1 (-); K: PDGFR (-); L: Ki-67 approximately 2% (+); lymphocytes: M: CD3 (+); N: L26 (+). Magnification: A (10 × 10); B, D-N (10 × 20); C (10 × 40).

exon 9 were observed. As above, ultra-structural analysis was performed by Yantiss *et al*[1] in 1 case, and the spindle or stellate-shaped cells were shown to contain abundant rough endoplasmic reticulum, aggregates of filaments associating with dense bodies, which are characteristic of fibroblastic and myofibroblastic differentiation.

Immunohistochemical staining demonstrated that all of the lesions stained positively for vimentin, (17/18) SMA, (8/15) CK, (10/13) MSA, except 4 cases that stained positively for CD117 reported by Yantiss *et al*[1] and 1 case reported by Chatelain *et al*[5]; most cases are negative for CD117. The vast majority of the lesions stained negatively for desmin, CD34, S-100 protein, and anaplastic lymphoma kinase-1. The immunohistochemical features of our case showed actin focally (+), CD34 focally (+), CD117 (-), S-100 (-), desmin (-), DOG-1 (-), PDGFR (-), Ki-67 approximately 2% (+). Thus, based on these observations, our case is consistent with a diagnosis

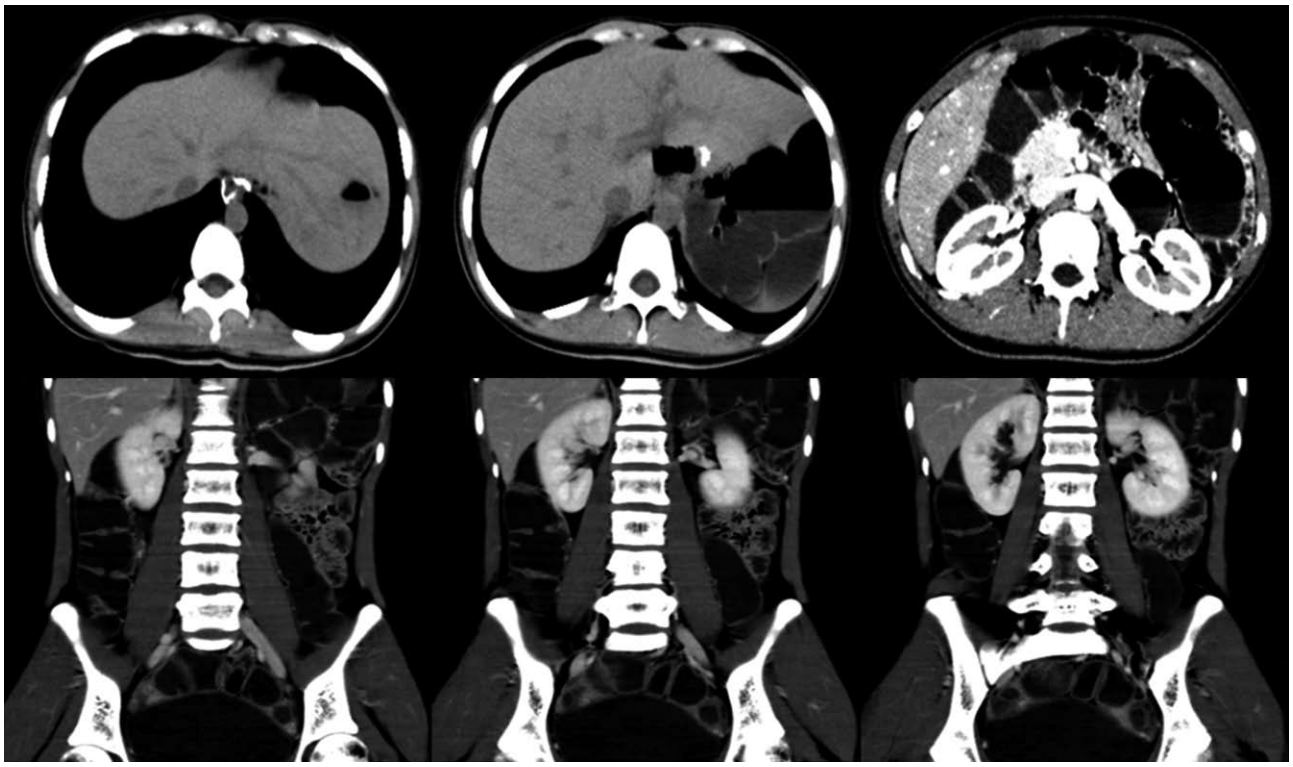

**Figure 7 Follow-up abdominal computed tomography scan after 10 mo showing no signs of recurrence and metastatic disease.**

| Virgilio *et al*[9] | Male | 71 | [1] | Abdominal surgical history | No signs of recurrent 4 yr later |
| Mcateer *et al*[4] | Female | 13 | Acute abdominal pain | No abdominal surgical history | [1] |

[1]No mention in the above articles.

of RNFP (Table 3).

Importantly, RNFP must be distinguished from the other reactive processes of the abdomen [such as calcifying fibrous pseudotumor, Vanek's tumor, retroperitoneal fibrosis, sclerosing mesenteritis, nodular fascitis, intra-abdominal fibromatosis] and more aggressive mesenchymal tumors, such as GIST, intraabdominal inflammatory myofibroblastic tumors, and inflammatory fibrosarcoma; such a differentiation may have strict requirement for pathologists.

Of the 21 patients, almost all cases underwent complete resections (18 cases, 85.7%); incomplete resections were performed in 3 cases because of too many masses or nodules. Surgical resection is currently the definitive method in these patients, and no chemotherapy treatment has been reported. Follow-up of 11 patients was available, without signs of recurrence and metastasis regardless of the modus operandi (Table 4).

## COMMENTS

### *Case characteristics*

A 16-year-old girl presented to the hospital with an approximately 3-mo history of progressive epigastric discomfort.

### *Clinical diagnosis*

Approximately 3-mo history of progressive epigastric discomfort.

### *Differential diagnosis*

Gastric cancer, colon cancer, acute pancreatitis.

### *Laboratory diagnosis*

Laboratory tests were within normal limits.

### *Imaging diagnosis*

A computed tomography scan showed a mass (5.8 cm × 3.8 cm × 7.9 cm) in the lesser curvature of the fundus attached to the left adrenal gland with obscure boundaries.

### *Pathological diagnosis*

Gastroscopic pathological biopsy demonstrated chronic ulcer-forming gastritis without evidence of carcinoma; immunohistochemically, the biopsy specimen was positive for CK and M-CEA in the glandular epithelium, positive for CD31 and CD34 in the vascular endothelium, and positive for CD3 and L26 in small lymphocytes, therefore, lymphoma and gastric cancer were excluded.

### *Treatment*

A total resection of the stomach, pancreatic body and tail, spleen, and left adrenal gland was performed, and an esophagojejunal Roux-en-Y anastomosis was performed to reconstruct the digestive tract.

### *Related reports*

The lesion is not very well understood and did not have predictive biomarkers to indicate reactive nodular fibrous pseudotumor.

### *Term explanation*

Actin, CD34, CD117, S-100, desmin, DOG-1, PDGFR, CD3 and L26 are immunohistochemical methods that are used for differentiating other tumors.

### *Experiences and lessons*

In the future, more microscopic and immunohistochemical methods should be developed, and more molecular level studies of these lesions to elucidate the etiology are needed.

### *Peer review*

This case presented in this article is well documented and interesting as it describes a rare pathology.

**Key words:** Nutrient deficiencies; Type 2 diabetes; Obesity; Israel

**Core tip:** In view of the wide nutritional deficiencies in Israel, we encourage local health, education and industrial ministries to expand efforts to study and document those deficiencies with the vision of fortifying basic commonly used foods in order to fight the deficiencies and prevent their occurrence in the future.

Haimi M, Lerner A. Nutritional deficiencies in the pediatric age group in a multicultural developed country, Israel. *World J Clin Cases* 2014; 2(5): 120-125 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i5/120.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i5.120

## Abstract

Nutrient deficiencies are prevalent worldwide. Diseases and morbid conditions have been described to result from nutritional deficiencies. It is essential to address nutrient deficiencies as these may lead to chronic long-term health problems such as rickets, iron deficiency anemia, goiter, obesity, coronary heart disease, type 2 diabetes, stroke, cancer and osteoporosis. In the present review we surveyed the extent and severity of nutritional deficiencies in Israel through a selective and comprehensive Medline review of previous reports and studies performed during the last 40 years. Israeli populations have multiple nutritional deficiencies, including iron, calcium, zinc, folic acid, and vitamins B12, C, D and E, spanning all age groups, several minorities, and specific regions. In Israel, some of the nutrients are mandatorily implemented and many of them are implemented voluntarily by local industries. We suggest ways to prevent and treat the nutritional deficiencies, as a step to promote food fortification in Israel.

## INTRODUCTION

Despite some reductions in world income-related poverty in recent years, malnutrition remains widespread. Nutrient deficiencies of iron, vitamin A, folic acid and zinc are prevalent worldwide, especially in children from low income areas[1].

The lack of sufficient amounts of micronutrients affects health, function, and physical and cognitive development throughout the life cycle[1-4]. Many diseases and morbid conditions have been described to result from nutritional deficiencies. These include developmental defects, such as birth defects, physical and cognitive development delays, increased risk of infectious diseases, as well as increased risk of poor health in adulthood. Almost two-thirds of deaths of young children around the world are related to nutritional deficiencies[5-7].

The discovery of essential nutrients and their roles in disease prevention has been instrumental in reducing

nutritional deficiency diseases such as goiter, rickets, pellagra and others in many places such as the United States, Canada, European countries and third world regions. In Israel, a state of massive immigration, where a substantial part of the population lives below the poverty line, there is a relatively high percentage of unemployment, and also aging of the population. These aspects contribute to the relatively high prevalence of essential nutrient deficiencies in various parts of the Israeli population, including iron-deficiency anemia, goiter and vitamin D deficiency[8-11]. Low vitamin B12 levels, low folic acid levels and consequently high homocysteine levels, and increased risk of coronary heart disease have also been observed in the Israeli population[12,13]. The regulatory authorities in Israel have been planning to implement food fortification for many years. Few of the nutrients are mandatorily implemented, and many are implemented voluntarily by local industries.

The goal of the present review was to survey the severity of nutritional deficiencies in Israel, and to suggest ways to prevent and treat this problem. Our hypothesis is that, in view of the special characteristics of Israel, despite being a developed country, with massive immigration, poverty and low social conditions, a high rate of nutritional deficiencies exist.

The present review is also aimed to summarize the subject, as a step to promote food fortification in Israel.

## RESEARCH

The extent and severity of nutritional deficiencies in Israel were reviewed through a selective and targeted Medline survey of previous reports and studies performed during the last 40 years.

The key words for the Medline search were combinations of the words: children, pediatrics, Israel, nutrients, nutrition, deficiency, fortification, as well as of specific nutrients such as iron, vitamins A, B, C, D, E, B12, Folic acid, calcium, phosphorus, magnesium, zinc and iodine.

## NUTRITIONAL DEFICIENCIES IN THE MODERN WORLD: CAUSES AND OUTCOME

The food consumption habits of the children changed during the last few decades, and they now consume too much fat, especially saturated fats, and sweetened beverages. They do not eat enough fruits or vegetables and consequently do not consume enough fiber. Most schoolchildren of low socioeconomic families consume less milk, cheese, meet, vegetables and fruits. Only a fifth of children consume the recommended daily amount of fruits and vegetables[5-8]. The calcium and iron intake among children is also low. One of the main reasons for the pediatric pandemia of obesity is the consumption of large amounts of soft drinks rich in sugar, accompanied by a lack of physical activity. It is essential to address nutrient and activity deficiencies as these may lead to chronic long-term health problems, such as obesity, coronary heart disease, type 2 diabetes, stroke, cancer, and osteoporosis. It is well documented that overweight children are more likely to become obese adults[1-3,5]. The most common nutrient deficiencies among school children are: calcium, fiber, folate, iron, magnesium, potassium and vitamin E. It has been reported that the 2 most common deficiencies seen in generally healthy children are iron and vitamin D deficiencies[3]. Classical nutrient deficiencies lead to stunting (energy, protein and zinc), rickets (vitamin D) and other bone abnormalities (copper, zinc, vitamin C)[7,8]. Iron deficiency anemia, as a public health problem, has been well recognized in recent years in developing countries and even in developed ones, and has received considerable attention by the World Health Organization (WHO)[2,8]. Vitamin D deficiency and osteoporosis are common in northern climates, but even in sunny countries such as Israel, Australia and southern Europe. It is especially common among the elderly, veiled, dark skinned, and other at-risk population groups, who are also regularly warned to avoid sunlight to prevent skin cancers[7-9,11].

The prevalence of endemic goiter and other iodine deficiencies has been reduced since the use of iodination of salt[8]. MacDonald[14] has reported that zinc deficiency in animals is characterized by growth inhibition and decreased food intake. Liu *et al*[15] indicated that malnutrition predisposes to neurocognitive deficits, which in turn predispose to persistent externalizing behavior problems throughout childhood and adolescence. Their findings suggest that reducing early malnutrition may help reduce later antisocial and aggressive behavior.

## NUTRITIONAL DEFICIENCIES IN ISRAEL

In Israel, nutritional deficiencies have been documented throughout the last years in many reports.

### *Deficiencies in special ethnic minorities*

In the Bedouin population[16-29], short stature, iron deficiency, vitamin A deficiency (15%-26% of infants), B12 deficiency, and vitamin E deficiency have been reported. In Ethiopians living in Israel, there are several reports of vitamin D deficiency and rickets[30,31].

### *Regional deficiencies*

There were several reports on nutritional deficiencies in specific regions in Israel, including iron deficiency in children from central regions such as Hadera[32]; iron deficiency in Jewish children from a new immigrant town[33]; anemia in Jewish and Arab children from Akko[34]; iron deficiency anemia in infants from southern Israel[35]; and iron and folate deficiencies in children from a city in the North of Israel (Kyriat-Shmona)[36].

### *Special populations have demonstrated specific nutritional deficiencies*

In adolescents, several deficiencies were reported, includ-

**Table 1 Summary of the main nutritional deficiencies in the Israeli population**

| Israeli sub-population | Nutritional deficiency | Ref. |
|---|---|---|
| Bedouins | Iron, vitamin A, vitamin B12, vitamin E | [16-29] |
| Ethiopians | Vitamin D | [30,31] |
| Specific regions | Iron, folic acid, vitamin B12 | [32,36,69] |
| Adolescents | Iron, vitamin D, calcium, phosphor, magnesium, zinc | [9,38-40] |
| Toddlers | Vitamin D, Iron, Calcium | [41,42] |
| Overweight children | Iron, vitamin B12, folic acid, phosphorus, calcium, vitamin D | [43-45] |
| Military recruits | Iron, magnesium | [46-48] |
| Infants | Iron | [32,49-53] |
| Vegetarians | Vitamin D, vitamin B12, vitamin B1, iron, zinc | [54-57] |
| Pregnant women | Iron | [58,59] |
| *Helicobacter pylori* gastritis | Iron | [60] |
| Celiac disease patients | Vitamin D | [10,61] |
| Gaucher patients | Vitamin B12 | [68] |
| Anorexia nervosa patients | Zinc | [70,71] |

ing iron deficiency (especially in athletes)[37], and deficiencies in vitamin D[9,38,39], calcium, phosphor, magnesium and zinc[40]. Toddlers and adolescents in Israel, as in other Western countries, are using "energy drinks", which can cause nutritional deficiencies such as vitamin D and iron[41]. A study of children from central Israel[42] revealed a lack of calcium in their food and decreased bone density. Children with overweight demonstrated iron deficiency[43] and vitamin B12 deficiency[44]. In bariatric surgery candidates, deficiencies in iron, folic acid, ferritin, B12, phosphor, calcium and vitamin D were reported[45].

In military recruits and in soldiers, iron deficiency[46,47], and low magnesium levels[48] were noted.

A high percentage of the infant population in Israel has iron deficiency anemia[32,49-52]. It can badly affect their learning achievements and behavior[53].

In the vegetarian population, there was a lack of calories and proteins, rickets, osteoporosis, B12 and B1 deficiencies, iron and zinc deficiencies, and increased risk of infections[54-57]. A high incidence of iron deficiency was noted in pregnant women[58,59]. Iron deficiency anemia was reported also in people with *Helicobacter pylori* (*H. Pylori*) gastritis[60]. Children with celiac disease had low bone mineral density. Their average serum vitamin D level was 25.6 ng/L, suggestive of osteopenia[10,61].

### *Specific deficiencies*

Iron deficiency anemia has been extensively documented in Israel, especially in infants[8,33,35,49-52], adolescents[47], pregnant women[58], adults and the elderly[8].

Vitamin D deficiency is common in the Israeli population. In 2009, 87% of the adult population and 52% of the pediatric population had low vitamin D levels[11,62-65]. Rickets in infants is attributable to inadequate vitamin D intake and decreased exposure to sunlight. It seems that vitamin D leading to osteoporosis is common in the elderly even in sunny countries such as Israel[63]. Vitamin D deficiency is also associated with autoimmune diseases[64]. Orthodox mothers after delivery had low levels of vitamin D[66].

Vitamin B12 and folate deficiencies has been noted in Israeli children, especially as a result of low intake of vegetables[44,67]; 22% of Ashkenazi Jews and 40% of Gaucher patients in Israel were reported to have B12 deficiency[68]. In Beer Sheva, a city in the south of Israel, 37% of the population had B12 deficiency[69]. Recent reports by Kark *et al*[12] have shown high homocysteine levels among Israelis, and despite vast reductions in mortality rates, the rates of coronary heart disease are still very high. Folic acid, as an antagonist to homocysteine, is increasingly accepted as a major preventive factor in coronary heart disease[13].

Zinc deficiency was noted, among other nutrient deficiencies, in anorexia nervosa patients in Israel[70,71]. Zinc deficiency was also reported in children[72], and in attention deficit hyperactivity disorder patients[73]. Table 1 summarizes the nutritional deficiencies in Israel described in our study.

In summary, Israeli populations have multiple nutritional deficiencies including iron, calcium, zinc, folic acid, and vitamins B12, C, D and E, spanning all age groups, several minorities, and specific regions. The most common nutritional deficiencies in the pediatric age group in Israel are iron and vitamin D. These deficiencies are mostly common in special populations, such as Bedouins, vegetarians, Ethiopians, obese children, pregnant women and their babies, gluten-sensitive populations, children with *H. Pylori*, children with behavioral problems and anorexia, diabetics, but deficiencies span the whole Israeli population.

## FOOD FORTIFICATION

Fortification of commonly eaten foods with micronutrients offers a cost-effective solution that can reach large populations[74].

It is the responsibility of public health authorities to ensure that the general population, and especially those under in poverty are assured of an adequate basic daily intake of minerals and vitamins. This can only be achieved through appropriate vitamin and mineral enrichment of basic foods. Food fortification can reach many people who either do not or cannot comply with the individual approach of health education and healthy diet, due to its higher cost, or due to a lack of knowledge or access[75,76]. The addition of micronutrients to food for health reasons has been known for many years[8,77,78].

Food fortification was adopted in the United States during the 1920s and the 1930s, by enriching flour in order to eliminate pellagra in the southern states. In 1942, a program to enrich flour with vitamins and iron was adopted by the United States government[76]. In the beginning it included enriching flour with vitamin B1 (thiamin) to prevent beriberi, niacin to prevent pellagra, riboflavin for efficient use of vitamin B6, and iron to prevent anemia. Later, it was decided to also add vitamin

D and calcium, and it was expanded to enrich corn flour in 1943, pasta in 1946, and rice in 1958. The success of this program led to additional fortification of breakfast cereals with B-vitamins and iron in 1969[75].

In Canada, food fortification has been mandatory since 1979, including iodine in salt, iron and vitamin B complex in flour, and vitamin A and D in milk products. In 1998, folic acid was additionally added to flour, with positive effects in reduction of neural tube defects within 2 years[79]. Fortification of flour and grains with folate was adopted also in the United States in 1998, and was followed by a decline in the total prevalence of neural tube defects[80].

In Europe, food fortification has encountered considerable opposition over the past 2 decades (especially in Scandinavian countries). Nevertheless, it has recently been put into practice, with most countries fortifying salt with iodine to prevent iodine deficiency[81].

In 1996, the WHO has renewed its call for the universal iodization of salt, since iodine deficiency was considered the greatest cause of preventable brain damage and mental retardation worldwide[82]. In addition, the WHO also promotes fortification and supplementation for reduction of iron deficiency anemia, vitamin A deficiency and others, although referring usually to developing countries.

Regarding vitamin D deficiency, it has been widely recognized, not only with reference to infants and children, but also for other age groups, including adolescents and older age groups. In 2003, the American Academy of Pediatrics emphasized the importance of milk fortification with vitamin D supplementation throughout childhood and adolescence, with consideration of subclinical vitamin D deficiency in many population groups[83].

Israel is working towards food fortification, but it is on a voluntary basis for some vitamins and minerals, while mandatory for others, such as fortification of salt, milk products and flour. Nevertheless, most salt sold to the Israeli population is still un-iodized[78]. As previously mentioned, although Israel is a sunny country, vitamin D deficiency is well recognized among the elderly[10,19,66], partly related to the advice to avoid sunlight exposure for fear of skin cancer. This fact makes vitamin D fortification of milk products a necessity.

The successful experience of food fortification in many countries emphasizes the safety and efficacy of this approach. Food fortification is vital in prevention of chronic diseases, and its implementation will bring long-term economic savings in health costs and will contribute to the health and nutritional habits of the population. In addition to fortification of breakfast cereals and some milk products, the recommendations of health ministries should include fortification of basic foods with iodine, iron, folic acid, vitamin A, vitamin B complexes (including B12), and vitamin D, in order to prevent birth defects as well as chronic diseases. National school feeding programs can be one of the means for nutritional education and food fortification as well as a means of alleviating food insecurity among children.

The limitations of our study are embedded in the methodology of the literature search, since some publications could have been missed or were unavailable in Medline. There is also a possibility of publication bias since negative or non-significant studies tend not to be published.

In summary, in view of the wide nutritional deficiencies in Israel, we encourage local health, education and industrial ministries to expand efforts to study and document these deficiencies with a view to fortifying basic commonly used foods in order to combat the deficiencies and prevent their occurrence in the future.

## Abstract

In this mini-review several commonly used animal models of atherosclerosis have been discussed. Among them, emphasis has been made on mice, rabbits, pigs and non-human primates. Although these animal models have played a significant role in our understanding of induction of atherosclerotic lesions, we still lack a reliable animal model for regression of the disease. Researchers have reported several genetically modified and transgenic animal models that replicate human atherosclerosis, however each of current animal models have some limitations. Among these animal models, the apolipoprotein (apo) E-knockout (KO) mice have been used extensively because they develop spontaneous atherosclerosis. Furthermore, atherosclerotic lesions developed in this model depending on experimental design may resemble humans' stable and unstable atherosclerotic lesions. This mouse model of hypercholesterolemia and atherosclerosis has been also used to investigate the impact of oxidative stress and inflammation on atherogenesis. Low density lipoprotein (LDL)-r-KO mice are a model of human familial hypercholesterolemia. However, unlike apo E-KO mice, the LDL-r-KO mice do not develop spontaneous atherosclerosis. Both apo E-KO and LDL-r-KO mice have been employed to generate other relevant mouse models of cardiovascular disease through breeding strategies. In addition to mice, rabbits have been used extensively particularly to understand the mechanisms of cholesterol-induced atherosclerosis. The present review paper details the characteristics of animal models that are used in atherosclerosis research.

**Key words:** Atherosclerosis; Dyslipidemia; Disease; Animal models

**Core tip:** This mini-review provides the essential information obtained from a number of animal models in the field of cardiovascular research. Such information can help researchers design their studies for understanding the pathophysiology of atherosclerosis.

## INTRODUCTION

Atherosclerosis is still a leading cause of mortality and

morbidity worldwide[1]. Several modifiable and non-modifiable risk factors have been identified for the disease. Many clinical and experimental attempts have been made to understand the pathophysiology of the disease. Among them, a number of animal models have been used for understanding the mechanisms involved in both induction and regression of atherosclerotic lesions. It was first in 1908 that Ignatowski reported atherogenesis in a rabbit model[2]. Subsequent studies documented a significant relationship between elevated levels of serum cholesterol and development of atherosclerotic lesions in experimental animals[3-6]. That was the basis of cholesterol-feeding trials in experimental models of atherosclerosis. However, later a naturally defective rabbit model namely Watanabe Heritable Hyperlipidemic (WHHL) rabbits was discovered and used in most of experimental settings[7-13]. Recent technology has allowed generation of a number of genetically-modified animal models in this field of research.

Overall, one may think that an ideal animal model for studying human disease should possess several features including availability, affordability and close resemblance to human conditions. In particular, an optimal animal model of atherosclerosis should develop various stages of the disease including fatty streaks, accumulation of foam cells, vulnerable and stable plaques as well as relevant complications such as calcification, ulceration, hemorrhage, plaque rapture, thrombosis and stenosis and the formation of aneurysms. Efforts are being made to develop animal models that replicate human atherosclerosis, however each of current animal models have some limitations. In this paper, attempts have been made to summarize the important features of the common animal models of atherosclerosis.

## MICE

The mouse has been used in medical research for decades. Well-known genetic background, easy to breed and low cost of maintenance are among advantages of this model. However, small size and some physiological characteristics may be considered as limiting factors. For example, the plasma lipoprotein profile in mice is very different from that in humans. The circulating cholesterol is mainly in high density lipoprotein (HDL) particles in the mouse, while it is in low density lipoprotein (LDL) particles in humans. This is probably the main reason that wild-type mice do not develop atherosclerosis, but humans do. One reason for this lipoprotein profile differences is the absence of cholesterol-ester transfer protein (CETP) in the mouse[14]. Another difference between the mouse and the man is their response to dietary cholesterol. The mouse does not absorb dietary cholesterol significantly[15], while the man absorbs approximately 50% of dietary cholesterol. This may also be seen as a limiting factor for cholesterol-induced atherogensis in wild-type mice (C57BL/6J).

To overcome these limitations, researchers have used DNA technology to generate a number of genetically modified mouse models. It was in 1992 that the very first line of such genetically modified mouse model was introduced to our research community. Zhang *et al*[3] reported a successful deletion of mouse apolipoprotein (apo) *E* gene. Further research led to generation of other genetically modified mouse models suitable for studying human dyslipidemia and atherosclerosis. Among them, LDL receptor-knockout (KO)[16], hepatic lipase-KO[17], human apo $B_{100}$ expression[18] and human CETP expression[19] can be named.

Of these genetically modified mouse models, apo E-KO mice develop spontaneous atherosclerosis. This is associated with elevated levels of circulating cholesterol-rich very LDL (VLDL) particles. This feature makes this animal model to be very robust for both induction and prevention of the disease. Several studies have reported that hypercholesterolemia and atherosclerosis can be prevented by dietary plant sterols in this animal model[20-22]. Unlike apo E-KO mice, LDL-r-KO mice need dietary cholesterol to develop hypercholesterolemia and atherosclerosis[16,23]. Morphological features of atherosclerotic lesions in apo E-KO and LDLr-KO mice are illustrated on Figure 1. Another mouse model which develops hypercholesterolemia and atherosclerosis on high fat/high cholesterol diets is apo E*3-Leiden transgenic mice[24-26]. Furthermore, a number of breeding experiments have been carried out to generate additional mouse models of human dyslipidemia and atherosclerosis. For example, cross breeding of human apo $B_{100}$ transgenic mice with LDL receptor deficient mice produced a highly susceptible strain ($HuBTg^{+/+}Ldlr^{-/-}$) with severe hypercholesterolemia and atherosclerosis[16]. Furthermore, Föger *et al*[19] reported that when human lecithin cholesterol acyl transferase (LCAT) transgenic mice were cross-bred with CETP transgenic mice they produce offspring with low total cholesterol levels and reduced atherosclerosis burden. Similarly, Lweis *et al*[27] generated apoE/GPx1 double KO ($ApoE^{-/-}$ $GPx1^{-/-}$), by cross breeding GPx1-deficient mice with apo E-deficient mice. This model features combined hyperlipidemia and hyperglycemia with increased oxidative stress. Chen *et al*[28] reported a mouse model that develops unstable/ruptured atherosclerotic plaques. They used surgical procedures to introduce a tandem stenosis in the carotid artery of apo $E^{-/-}$ mice fed a high fat diet, in order to develop unstable plaques in these mice. Atherosclerosis is known to be an inflammatory disease. We know that there are major differences in immune system between mice and humans[29]. This is another reason for questioning the mouse model for studying human atherosclerosis. Several inflammatory markers have been detected in both atherosclerotic plaques and in circulation of subjects or animals with atherosclerosis. Several strategies have been implemented to understand the role of inflammatory pathways in the progression of the disease and its complications. One of such experimental strategies was application of bone marrow transplant. Ishibashi and colleagues used bone marrow

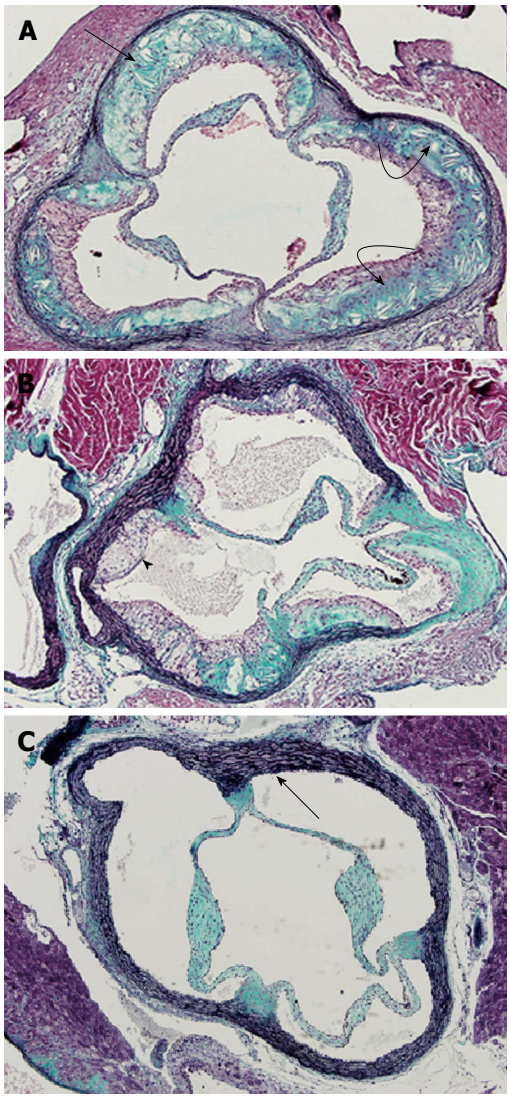

**Figure 1 Representative photomicrographs taken at aortic root from apolipoprotein E-knockout (A), low density lipoprotein-r-knockout (B) and their wild-type background C57BL/6J (C) mice.** A: Advanced atherosclerosis lesions in all 3 valves of the aortic root (arrow); these lesions are composed of numerous cholesterol clefts (curved arrows); B: Illustrating lipid-rich atherosclerotic lesions in the aortic root; the arrow head points to an atherosclerotic plaque primarily composed of apparent foam cells. No cholesterol cleft is visible in B; C: Demonstrating an atherosclerotic-lesion-free aortic root with normal-looking vascular wall (arrow) with apparent intact elastic lamina and endothelium. Trichrome staining; × 40.

transplant procedures to produce apo E-KO mice with and without deficiency of chemoattractant protein-1 receptor, CCR2[30]. Results from their studies suggest that CCR2 plays a crucial role in vascular inflammation and atherosclerosis. In another study, bone marrow transplant procedures were used to investigate the effects of macrophage-derived apo E on atherogenesis in apo E-KO mice[31]. Transplantation of bone marrow from wild-type mice to apo E-KO mice resulted in significant reductions in the formation of atherosclerotic lesions in apo E-KO mice.

Although we have significantly advanced our knowledge in understanding the process of induction of atherosclerotic lesions using various mouse model, our knowledge on regression of these lesions is still very limited. In an attempt to regress atherosclerotic lesions we used apo E-Ko mice. Over a 42-wk of low-fat diet and diets enriched phytosterols, we were unable to regress atherosclerotic lesions in this animal model[32]. Similarly, literature search did not show any significant evidence for a successful regression of advanced atherosclerotic lesions.

## RABBITS

The rabbit has been used in many research facilities as an animal model of diet induced atherosclerosis. This species shares several aspects of lipoprotein metabolism with humans. These include composition of apo B containing lipoproteins[33], production of apo $B_{100}$ containing VLDL by the liver[34] plasma CETP activity[35], and high absorption rate of dietary cholesterol[35]. However, the lack of hepatic lipase makes the rabbit to be different from man[36]. Dietary approach is a common method to induce atherogenesis in rabbits. Under these conditions, the animals develop atherosclerotic lesions in the aortic arch and thoracic aorta rather than abdominal aorta which is almost always affected in humans[36].

Two strains of rabbits, namely WHHL and St. Thomas' Hospital (STH) rabbits are naturally defective and relevant models for human hyperlipidemia[7-13,37-39]. The WHHL rabbits are deficient in LDL receptors and therefore resemble human familial hypercholesterolemia[7-13,37], while STH rabbits are used as a model for human hypertriglyceridemia and combined hyperlipidemia[38,39]. Recent advances in gene technology have allowed generation of transgenic rabbits. For example, New Zealand White rabbits have been used to produce human apo $B_{100}$ transgenic rabbits; these animals manifest combined hyperlipidemia with reduced HDL-cholesterol concentrations[33]. On the other hand, over expression of human apo AI or human LCAT in rabbits was associated with elevated HDL-cholesterol levels and reduced atherosclerosis[34,35].

## PIGS

Pigs have been used for induction of coronary atherosclerosis by several different laboratories[40-42]. However, induction of advanced atherosclerotic lesions required high levels of dietary cholesterol (up to 4% w/w)[41,43,44]. A strain of pigs has been discovered with three lipoprotein-associated mutations (designated Lpb5, Lpr1, and Lpu1) developing hypercholesterolemia and atherosclerosis without dietary cholesterol[43,44]. In addition to coronary arteries, iliac and femoral arties also develop atherosclerotic lesions which become complicated by 2 years of age[44].

## NON-HUMAN PRIMATES

Spontaneous atherosclerosis has been reported in squirrel monkeys, baboons, wooly and spider monkeys[45]. Similar to humans, monkeys can be divided into "hyper-

**Table 1 Animal models and their features**

| Model | Features | Ref. |
|---|---|---|
| Mice | | |
| Apo $E^{-/-}$ mice | Develops spontaneous atherosclerosis, associated with elevated levels of circulating cholesterol-rich VLDL particles | Zhang *et al*[3] |
| LDL receptor deficient KO mice | This model needs dietary cholesterol to develop hypercholesterolemia and atherosclerosis- associated with elevated levels of circulating cholesterol-rich LDL and VLDL particles | Sanan *et al*[16] |
| Apo E*3-Leiden transgenic mice | This model needs dietary cholesterol to develop hypercholesterolemia and atherosclerosis-associated with elevated levels of circulating cholesterol | Groot *et al*[24]<br>van Vlijmen *et al*[25] |
| Hepatic lipase-KO mice | This model lacks hepatic lipase and develops elevated levels of plasma cholesterol, phospholipids, and HDL cholesterol and can be used for the study of HDL metabolism. | Homanics *et al*[17] |
| Human apo $B_{100}$ transgenic mice | This mouse model, associated with substantial increased level of LDL cholesterol level and useful for studying various aspects of lipoprotein metabolism and for further delineating the role of LDL in atherogenesis. | Greeve *et al*[18] |
| Human CETP transgenic mice | This model has reported to have decreased HDL cholesterol levels with variable degree of atherosclerosis | Föger *et al*[19] |
| Cross breeding of human apo $B_{100}$ transgenic mice with LDL receptor deficient mice | This model develops severe hypercholesterolemia and atherosclerosis | Sanan *et al*[16] |
| Cross breeding of human LCAT transgenic mice with CETP transgenic mice. | A mouse model with low total cholesterol levels and reduced atherosclerosis burden. | Föger *et al*[19] |
| Apo E/GPx1 double knockout (apo $E^{-/-}$ $GPx1^{-/-}$) | This model features combined hyperlipidemia and hyperglycemia with increased oxidative stress | Lewis *et al*[27] |
| Surgical model of apo $E^{-/-}$ mice | A mouse model for studying unstable/ruptured atherosclerotic plaques | Chen *et al*[28] |
| Animal model developed using bone marrow technique | Apo E-KO mice model with and without deficiency of CCR2 | Ishibashi *et al*[30] |
| Rabbits | | |
| WHHL | Naturally deficient in LDL receptors resembling human familial hypercholesterolemia | Watanabe[10] |
| STH | Rabbit model for human hypertriglyceridemia and combined hyperlipidemia | Beaty *et al*[38] |
| NZW-human apo $B_{100}$ transgenic rabbits | Transgenic animal model manifesting combined hyperlipidemia with reduced HDL-cholesterol concentrations | Fan *et al*[33] |
| NZW-human apo AI or human LCAT transgenic rabbits | Rabbit model with elevated HDL-cholesterol levels and reduced atherosclerosis | Duverger *et al*[34] |
| Pigs | | |
| Lipoprotein-associated mutations (designated Lpb5, Lpr1, and Lpu1) | This pig model develops hypercholesterolemia and atherosclerosis without dietary cholesterol. In addition to coronary arteries, iliac and femoral arties also develop atherosclerotic lesions which become complicated by 2 year of age. | Prescott *et al*[44] |
| Non-human primates | | |
| Rhesus monkeys | Develops spontaneous atherosclerosis. This animal model develops majority of atherosclerotic lesions in the anterior descending and circumflex branches of the left coronary artery | Carey[45] |
| Cebus monkeys | Develops spontaneous atherosclerosis. This animal model develops atherosclerotic lesions in their carotid bifurcation and coronary arteries | Carey[45] |
| Cynomolgus monkeys and African green monkeys | These monkeys develop spontaneous atherosclerosis. Atherosclerotic lesions being developed in coronary arteries and abdominal aorta, respectively | Hollander *et al*[49] |
| Others | | |
| Dogs | These animal models have significant amount of limitations that have not extensively used | Geer *et al*[50] |
| Hamsters | | Nistor *et al*[52] |
| Guinea pigs | | Fernandez *et al*[54] |
| Birds | | Wagner *et al*[56] |

Apo $E^{-/-}$: Apolipoprotein E deficient; KO: Knockout; VLDL: Very low density lipoprotein; LDL: Low density lipoprotein; HDL: High density lipoprotein; CETP: Cholesterol-ester transfer protein; LCAT: Lecithin cholesterol acyl transferase; CCR2: Chemoattractant protein-1 receptor, CCR2; WHHL: Watanabe Heritable Hyperlipidemic; STH: St. Thomas' Hospital; NZW: New Zealand White.

responders" and "hypo-responders"[46,47]. Anatomical locations of atherosclerotic lesions vary among different strains of monkeys. For example, majority of atherosclerotic lesions are found in the anterior descending and circumflex branches of the left coronary artery in rhesus monkeys, while cebus monkeys develop such lesions in their carotid bifurcation and coronary arteries[45,48]. The cynomolgus monkeys and African green monkeys also vary from each other in the location of atherosclerotic lesions being developed in coronary arteries and abdominal aorta, respectively[49].

## OTHER ANIMAL MODELS

Dogs[50,51], hamsters[52,53], guinea pigs[54], and birds[55,56] have been also used in experimental atherosclerosis. However,

these animals have shown a significant amount of limitations that has not allowed popularity for the use of such animals extensively.

## CONCLUSION

This mini-review aims to summarize the features of the most commonly used animal models of atherosclerosis. Despite many advances in medical research, we still do not have specific animal models for specific human conditions. Every animal model has its own advantages and disadvantages. For example, while non-human-primates are the closest animals to humans, variability in lesion development, high cost, availability, possible hazard, ethical issues and handling matters are among major limitations in the use of these animals. Mice and rabbits also vary from humans in regard to lipoprotein metabolism and development of atherosclerotic lesions. However, these species have been the most common animal models used so far. Among these species, either naturally defective animals such as WHHL and STH rabbits[7-13,37-39,57-59], or genetically modified mice have been used extensively in atherosclerosis research. In particular, LDL-r-KO mice[23,60], apo E-KO mice[61-63], Cystathionine γ-lyase-KO mice[64] have contributed to our understanding of the disease pathophysiology. Furthermore, surgical procedures and infectious agents have been also used in a number of animal models to study the postoperative injuries such as neointimal hyperplasia[65], atherosclerotic plaque instability[28] or the role of Chlamydophila pneumoniae[66,67] in disease development. The use of these animal models has certainly advanced our knowledge of the induction of atherosclerotic lesions. However, there is no reliable animal model for regression of atherosclerotic lesions. Further research and development is needed to generate such animal models. The list of animal model and their characteristic are summarized in Table 1.

## Abstract

**AIM:** To evaluate endometrioma located at cesarean scatrix.

**METHODS:** Medical data of 6 patients who presented to our institution with abdominal wall endometrioma were evaluated retrospectively and reviewed literature in this case series. The diagnostic approaches and treatment is discussed.

**RESULTS:** All patients had a painful mass located at abdominal scars with history of cesarean section. The ages ranged from 31 to 34 and Doppler ultrasonography (US) detected hypoechoic mass with a mean diameter of 30 mm. Initial diagnosis was endometrioma in 4 and incisional hernia in 2 of 6 patients. Treatment was achieved with surgical excision in 5 patients, and one is followed by hormone suppression therapy with gonadotropin.

**CONCLUSION:** Malignant or benign tumors of abdominal wall and incisional hernias should be kept in mind for diagnosis of endometrioma. Imaging methods like doppler US, computed tomography and magnetic resonance imaging should be used for differential diagnosis. Definitive diagnosis can only be made histopathologically. The treatment should be complete surgical excision and take care against intraoperative auto-inoculation of endometrial tissue in order to prevent recurrences.

**Key words:** Scar endometrioma; Endometriosis; Cesarean

**Core tip:** This is a case series about endometrioma located at cesarean scatrix. We present 6 patients who have painful abdominal mass of endometrioma. Medical data of 6 patients who admitted to our institution with abdominal wall endometrioma were evaluated respectively in this study. The diagnostic approaches and treatment is discussed and recommended.

## INTRODUCTION

Endometriosis is defined as extrauterine localization of ectopic functional endometrial gland and stroma. Cystic or solid tumoral masses caused by endometriosis are named as endometrioma. Although this pathologic condition is mostly encountered in ligaments of uterus, ovaries, Douglas pouch and pelvic peritoneum; endometriosis has also been reported in nose, breast, lung, spleen, gastrointestinal tractus, kidney, abdominal wall, but scar endometrioma is extremely rare[1,2]. Endometriosis is seen in 8%-15% of young fertile women with regular menstrual cycles, and it's frequency varies between 0.03%-1.08% on incision scar following gynecologic operations and caesarean sections (C/S)[3-5]. Endometrioma is a disease with symptoms such as a cyclic painful mass. Endometrioma should be remembered in patients who have the history of C/S and a painful mass on scar tissue and in whom both pain and mass size differ during menstrual period and imaging methods like doppler ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI) and fine needle aspiration cytology should be benefited for diagnosis.

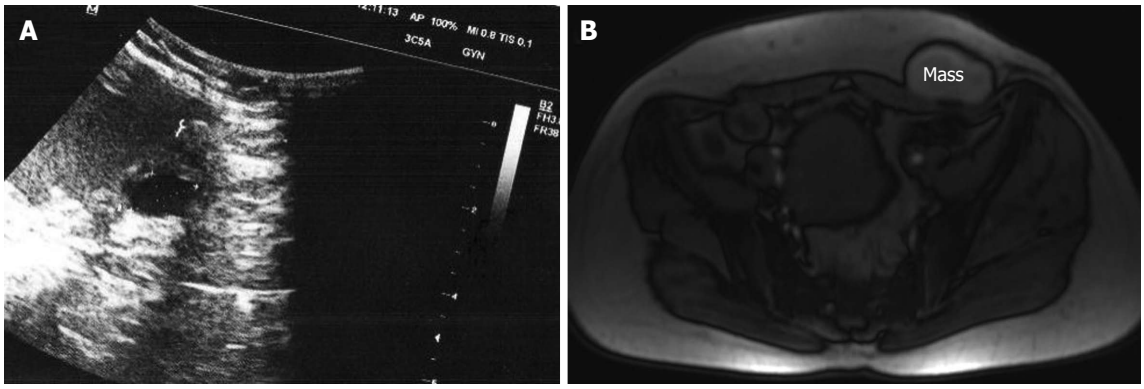

**Figure 1 Ultrasonographic view (A) and magnetic resonance imaging (B) of scar endometrioma.**

**Table 1 Medical data of patients who were diagnosed with scar endometrioma in caesarean sections site**

| Age, yr | C/S | Recurrent disease | Years after C/S | Interval to symptoms onset, yr | Pain type | Weight of lesion (g) | Size (cm) | Initial diagnosis |
|---|---|---|---|---|---|---|---|---|
| 34 | 1 | No | 3 | 1 | Cyclic | 54 | 3 × 2 | Incisional hernia |
| 32 | 2 | No | 7 | 4 | Non-cyclic | 60 | 3 × 3 | Incisional hernia |
| 32 | 1 | No | 3 | 1/2 | Cyclic | 58 | 3 × 3 | Incisional hernia |
| 31 | 2 | No | 3 | 1 | Cyclic | 48 | 2 × 2 | Incisional hernia |
| 33 | 2 | No | 4 | 1 | Cyclic | 70 | 4 × 4 | Endometrioma |
| 31 | 1 | No | 6 | 2 | Cyclic | 62 | 3 × 5 | Endometrioma |

## MATERIALS AND METHODS

This is a small case series and retrospective study on patients with abdominal wall C/S endometrioma. In this study, we presented clinical and laboratory findings of six consecutive patients with scar endometrioma (Figure 1) who admitted to our departement between 2009 and 2012 and reviewed the literature. There were 28 patients with incisional hernias and 36 benign abdominal wall tumors like lipomas, *etc*. in this period. Medical data of the patients were evaluated, and presented our experience with scar endometrioma consequently by this case series.

## RESULTS

Routine hematological and biochemical examinations were done following medical history and physical examination of patients who have a painful mass in their C/S site. Main complaint of our cases on admission was a palpable mass on incision site and cyclic pain. Abdominal pain was non-cyclic unusually in one patient. As you seen in Table 1, all patients were in third decade and aged between 31-34 years. Parity was 1 in three and 2 in other three patients and all deliveries were C/S's. While caesarean incision was Pfannenstiel in 5 patients and there was a subumbilical midline incision in one. Duration between the last C/S and hospital admission varied between 2-7 years and duration between emergence of a painful mass on scar site and hospital admission varied between 6 mo and 4 years. There were not abdominal endometriosis and scar endometrioma in previous history. There were 28 patients with incisional hernias and 36 benign abdominal wall tumors like lipomas, *etc*. during three years period. Initial diagnosis were incisional hernia in four and endometrioma in two of our six patients. Definite diagnosis was made by histopathological evaluation of excised materials. Prediagnosis was irreducible incisional hernia in 4 out of 6 patients (66.6%) and endometrioma in 2 patients (33.3%). There were four patients diagnosed in first five years after C/S, and two patients more than five years. Doppler US was done to make a definite diagnosis succesfully in five patients. Final diagnosis was made with USG and abdominal CT in one patient. The weight of resected materials were min 48 g, max 70 g and ultrasonographical size of the palpable mass in scar tissue varied between 2 to 5 cm (Table 1).

Treatment was achieved with complete surgical resection in 5 of six patients. One patient did not accept surgical intervention and she was followed up with medical treatment by using hormone suppressor drugs. Painful scar endometrioma were excised with undamaged borders and without making endometrial tissue implantation into the neighboring tissue in five patients who accepted surgical treatment. The glandular structure of endometrium and stroma were seen microscopically in fibrocollagenous tissue and that the mass belonged to endometrioma (Figure 2).

## DISCUSSION

Common use of laparoscopy has enabled more frequent detection of intraabdominal endometriosis. Dysmenorrhea, irregular menstrual cycles and infertility are the most common symptoms seen in endometriosis. A palpable mass on C/S incision site and a cyclic pain are pathognomonic in patients with endometrioma[2-6].

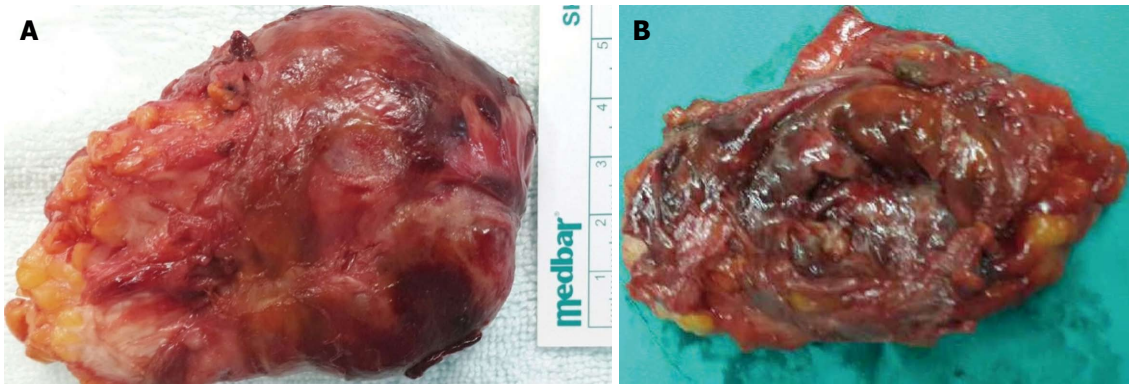

**Figure 2 External view of resected endometrioma (A), cut surface of specimen showed semi-solid and soft tumor (B).**

Two different theories are available to explain endometrioma development. According to the first hypothesis, multipotent mesenchymal cells differentiate to endometrial tissues in their site after puberty and show physiopathological changes, like proliferation, hemorrhage as response to hormonal functions. And second hypothesis; endometrial cells are transported to extrauterine areas in some instances and similarly endometrioma develops by being affected from hormonal changes[5]. Endometrioma development in C/S scar tissue on abdominal wall seems more consistent with the second hypothesis. An increase has been reported in endometrioma frequency in parallel with the increase in number of C/S in recent years[7,8]. Procedure responsible for endometrioma development on incision site is iatrogenic inoculation of endometrial tissue into incision site[9]. Three of our cases underwent one C/S, three cases twice C/S. Endometrioma usually emerges during a ten year period following C/S[10].

Scar endometrioma are not frequently met more than 5 years after C/S, but we have two patients with relatively late diagnosed scar endometrioma in our series. Basic and the most commonly detected complaints of the patients were a palpable mass in C/S scar tissue and cyclic pain[11]. These symptoms have begun within a 6 mo-4 year period following C/S operation. Abdominal pain or painfull mass were seen cyclic usually, but there were one patient with non-cyclic painfull endometrioma in our case series.

Definitive diagnosis of endometrioma is not possible without histopathological examination. They are some published parameters on clinical and ultrasonographic findings for differential diagnosis of abdominal wall endometrioma near cesarean section[12]. Lipomas , sebaceous cysts, hemangiomas and lymphangiomas, desmoid tumors among common benign tumors of abdominal wall[13,14]. It is recommended to keep in mind that these tumors may be a metastatic lesion arising from a malignant focus and to make diagnosis of endometrioma definite through US-guided fine needle aspiration cytology in patients who do not accept surgical treatment[5,12,13]. Imaging methods like doppler US, CT and MRI should absolutely be benefited for differential diagnosis of suspected masses. Definitive diagnosis can only be made histopathologically.

In a conclusion, the soft tissue tumors and endometrioma are probable diagnosis besides incisional hernia in patients who have a palpable mass on C/S scar following some obstetric and gynecologic interventions. A detailed medical history, physical examination findings and imaging methods in suspected cases are significant diagnostic tools to investigate the features of the pain and relationship with menstrual cycle. Radical treatment should be complete surgical excision for patients who receive prediagnosis of endometrioma and one should take care against intraoperative auto-inoculation of endometrial tissue in order to prevent recurrences. Combined oral contraceptives, progestagens and hormone suppression therapy with gonadotropin releasing hormone analogues should be used for medical treatment of patients who don't want surgery and whose diagnosis of endometrioma was verified through fine needle aspiration cytology.

## COMMENTS

### Background

Endometriosis and/or endometrioma is defined as ectopic occurrence of endometrium. Cystic or solid tumoral masses located at extrauterine organs caused by endometriosis are named as endometrioma.

### Innovations and breakthroughs

Abdominal endometriosis was seen often but cesarean scars endometrioma is rare and difficult to diagnose preoperatively.

### Peer review

This manuscript is worth to publish for increasing the awareness of incisional endometrioma possibility among patients with endometriosis.

## Abstract

**AIM:** To systematically review the literature on the efficacy of noninvasive methods of arresting the progression of non-cavitated occlusal carious lesions in dentin.

**METHODS:** The Medline/PubMed, LILACS, SciELO and Scopus databases were searched to identify relevant publications through to November 2013. Only clinical trials evaluating the ability of noninvasive methods to arrest the progression of occlusal non-cavitated carious lesions in dentin were included. Screening, data extraction and quality assessment were conducted independently and in duplicate.

**RESULTS:** Of 167 citations identified, nine full text articles were screened and five were included in the analysis. All papers reported on occlusal fissure sealing using a self-curing glass ionomer ($n$ = 1) or resin-based ($n$ = 4) sealant. Only the use of resin-based sealant to obliterate occlusal fissures arrested the progression of non-cavitated occlusal carious lesions in dentin.

**CONCLUSION:** Occlusal fissure sealing with a resin-based sealant may arrest the progression of non-cavitated occlusal dentinal caries. Further clinical trials with longer follow-up times should be performed to increase scientific evidence.

**Key words:** Dentin; Dental caries; Fissure sealants; Preventive therapy; Dental restoration

**Core tip:** Occlusal fissure sealing with a resin-based sealant may arrest the progression of non-cavitated occlusal dentinal caries.

## INTRODUCTION

Pit and fissure sealing is a noninvasive approach that has been used since the 1960s to prevent occlusal caries by providing a physical barrier that inhibits the accumulation of microorganisms and food particles. The efficacy and clinical safety of this preventive approach have been well established[1,2].

In restorative dentistry, the treatment of carious lesions has been reviewed many times. Minimally invasive dentistry, the goal of which is to preserve the greatest amount possible of tooth structure, is intended to replace conventional procedures[1]. When an open cavity is diagnosed, the option of restoration tends to be unquestionable. However, it should be noted that caries involving dentine may be present in non-cavitated lesions and that there may be a layer of intact enamel[2].

The use of pit and fissure sealant to seal fissures has

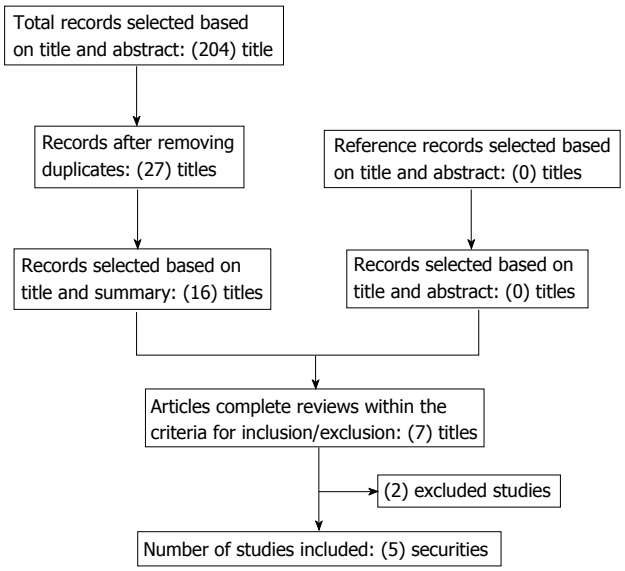

**Figure 1 Flow chart of studies through the review.**

been investigated as a secondary preventive approach to the management of non-cavitated occlusal carious lesions in dentin since it arrested their progression[3-7]. This noninvasive method may replace the traditional restorative approach as it can be performed with a shorter chair time in the absence of anesthesia. Moreover, it can conserve tooth structure by delaying intervention or minimizing the operative procedure[8]. Although several clinical trials have examined this use of pit and fissure sealants, a systematic analysis of their results is needed to provide scientific evidence for its effectiveness as a secondary preventive approach. Thus, we systematically reviewed the literature on the efficacy of noninvasive methods in arresting the progression of non-cavitated occlusal carious lesions in dentin.

## MATERIALS AND METHODS

### Focused question

The focused question addressed in this review was: "Can noninvasive treatments arrest the progression of non-cavitated occlusal carious lesions in dentin?".

### Search strategy

The Medline/PubMed, LILACS, SciELO and Scopus databases were searched to identify relevant studies published through to November 2013. The search strategy employed the following keywords related to the intervention method, type of carious lesion and outcome.

**Intervention:** "Sealing" or "fissure sealing" or "sealant" or "glass ionomer cement" or "nonoperative" or "non-operative" or "noninvasive" or "non-invasive" or "non-surgical" or "non-surgical".

**Type of caries lesion:** [("dentin" or "dentinal") and "caries"] and ("occlusal" or "pit and fissure" or "pits and fissures") and ("non-cavitated" or "noncavitated").

**Outcome:** "Progression" or "regression" or "arrest" or "arrested" or "arrestment" or "arresting".

### Inclusion and exclusion criteria

The selection was limited to clinical trials published in English that evaluated the efficacy of any noninvasive approach in treating non-cavitated occlusal carious lesions in dentin. Review articles, *in vitro* studies and those reporting only on proximal carious lesions or those in enamel were excluded. Studies that evaluated cavitated lesions were also excluded.

### Screening methods and data extraction

Two independent reviewers (Assunção IV and Costa GF) selected studies using a two stage screening process. In the first stage, titles and abstracts were screened to eliminate irrelevant articles and those that did not meet the inclusion criteria. In the second stage, the reviewers independently verified study eligibility after reading full texts and data extraction and quality assessment were performed for included studies. Disagreements about the inclusion or exclusion of a study were resolved by consensus and, when necessary, consultation with a third reviewer (Borges BCD). In the analysis of these included studies, the following questions were addressed: (1) Does pit and fissure sealing effectively arrest the progression of non-cavitated occlusal carious lesions in dentin?; (2) Is the noninvasive treatment of non-cavitated occlusal carious lesions in dentin effective in permanent and deciduous teeth?; and (3) Which materials should clinicians use to seal pits and fissures in the management of non-cavitated occlusal carious lesions in dentin? What are the perspectives on the use of alternative sealing materials and techniques?

## RESULTS

The initial search identified 204 articles (156 articles in Medline/PubMed, 22 articles in LILACS, 8 articles in SciELO and 18 articles in Scopus). Thirty-seven duplicate publications were excluded, leaving 167 potentially eligible articles. First stage screening of titles and abstracts identified nine articles that were qualified for full text screening. The second stage of screening identified five articles that met the inclusion criteria (two studies evaluating cavitated lesions, one article reporting on an invasive treatment and one review article were excluded) (Figure 1).

The content of selected studies is summarized in Table 1.

All five studies analyzed in this review were performed on similar samples of teeth with visually non-cavitated occlusal lesions between the dentin-enamel junction and middle third of dentin. The extent of carious lesions was confirmed by bite-wing radiographic analysis. The similar samples allow precise comparison of

**Table 1 Summary of studies included in the analysis**

| Author/yr | Study design | Sample characteristics | Analyzed variables and evaluation methods | Tested treatments | Follow up | Results/conclusions |
|---|---|---|---|---|---|---|
| Borges *et al*[3] (2010) | Randomized controlled clinical trial | Sixty permanent molars in 35 individuals (12–19.5 years old) with non-cavitated carious lesions radiographically located between the dentin-enamel junction and middle third of dentin | Caries progression and sealant loss; clinical and radiographic examinations | Experimental ($n$ = 30): oral hygiene instruction and fissure sealing (Fluorshield, Dentsply); control ($n$ = 30): oral hygiene instruction | 4-mo intervals for 1 year; control group was followed for only 8 mo due to signals of caries progression | Eight teeth (four per group) were lost at 1-year follow up. Clinical and radiographic caries progression was significantly more frequent in control than in experimental teeth. Sealant loss occurred in three cases and resulted in caries progression. Pit and fissure sealant effectively arrested caries progression, suggesting that this intervention may replace traditional invasive treatment of non-cavitated dentinal caries |
| Borges *et al*[4] (2012) | Randomized controlled clinical trial | Sixty permanent molars in 35 individuals (12-19.5 years old) with non-cavitated carious lesions radiographically located between the dentin-enamel junction and middle third of dentin | Caries progression and sealant loss; clinical and radiographic examinations | Experimental ($n$ = 30): oral hygiene instruction and fissure sealing (Fluorshield, Dentsply); control ($n$ = 30): oral hygiene instruction | 4-mo intervals for 1 year, then 12-mo intervals to 36 mo; control group was followed for only 8 mo due to signals of caries progression | Eight teeth (four per group) were lost at 1-year follow up; no tooth was lost subsequently. Clinical and radiographic caries progression was significantly more frequent in the control than in the experimental group. Three teeth lost sealant and showed caries progression at the 12-mo follow up. No sealant loss or caries progression was observed at 24 or 36 mo. Pit and fissure sealant effectively arrested carious lesions for a 36-mo period |
| Borges *et al*[5] (2012) | Randomized controlled split-mouth clinical trial | Sixty deciduous molars in 30 schoolchildren (5-9 years old) with non-cavitated carious lesions radiographically located between the dentin-enamel junction and middle third of dentin | Experimental group: caries progression and sealant loss; control group: secondary caries emergence and clinical failure of composite restorations | Experimental ($n$ = 30): fissure sealing (Fluorshield, Dentsply); control ($n$ = 30): composite restoration (Ice, SDI) | 4-mo intervals for 1 year | No tooth was lost to follow up. The treatment modalities were similarly effective in managing non-cavitated occlusal carious lesions in dentin of primary molars. Three teeth showed partial sealant retention and caries progression after 1 year. The invasive approach can be replaced with non-drilling fissure sealing techniques for the management of these lesions |
| da Silveira *et al*[6] (2012) | Randomized controlled clinical trial | Fifty-one permanent molars in 38 individuals (± 12.78 years old) with non-cavitated carious lesions radiographically located between the dentin-enamel junction and middle third of dentin | Caries progression and sealant loss; clinical and radiographic examinations | Experimental ($n$ = 27): oral hygiene instruction and sealing with self-curing glass ionomer cement (Vidrion-R, SS White) | 4-mo intervals for 1 year; control group was followed for only 8 mo due to signals of caries progression | No tooth was lost to follow up. Clinical examination showed no significant difference between groups, but radiographic examination showed less caries progression in sealed teeth |
| Bakhshandeh *et al*[7] (2012) | Clinical trial | Five premolars and 67 molars in 52 individuals (± 28 years old) lesions in need of restoration. The maximum depth of the lesions, radiographically assessed, was limited to the middle third of the dentin | Experimental group: caries progression and sealant loss; control group: secondary caries emergence and clinical failure of composite restorations | Control ($n$ = 24): oral hygiene instruction; experimental ($n$ = 60): resin-based fissure sealing (Delton, Dentsply) Control ($n$ = 12): composite restoration (Filtek Supreme XT, 3M ESPE) | 6-12-mo intervals for 25-38 (mean, 33) mo | Eleven sealed teeth were lost to follow up; no restored tooth was lost. All restorations and sealants functioned well; seven sealants were repaired/replaced due to failure and three sealed lesions were restored due to caries progression. Sealants arrested most (44/49) lesions; expansion of criteria for therapeutic sealing of occlusal carious lesions in adults will improve dental health |

study outcomes.

## DISCUSSION

### *Does pit and fissure sealing effectively arrest the progression of non-cavitated occlusal carious lesions in dentin?*

Four[3-5,7] of five studies analyzed reported that sealing arrested the progression of carious lesions when the sealant was intact and tight. These authors used only resin-based fissure sealants and analyzed caries progression by clinical and radiographic examinations. The blockade of the nutritional supply by the mechanical barrier created by the sealant

seems to be the most plausible explanation for the lack of caries progression observed in those studies. Because total retention is an integral requirement for sealant success, attempts should be made to increase the mechanical strength of sealing materials and their adhesion potential to enamel.

In contrast, de Silveira *et al*[6] reported that a self-curing glass ionomer fissure sealant did not arrest caries progression in molars with non-cavitated occlusal dentinal lesions. Although sealed teeth showed no sign of caries progression on radiographic examination, they exhibited visible cavitation after 12 mo of follow up. The rapid macroscopic loss of self-curing glass ionomer sealant may render fissures susceptible to biofilm adhesion and further acid attack, leading to the emergence of cavitations on occlusal enamel[6].

Some points reported by Borges *et al*[3,4] should be emphasized. The authors commented that possible limitations of their studies included the absence of power calculation, the sample size of 60 teeth and the loss of some of the sample at 12 mo, which may have reduced the internal and external validity of these investigations. However, they argued that the remarkable difference in caries progression observed between the sealed and unsealed groups at the 12 mo recall appointments indicated that the sample size was satisfactory for the analysis and that the observation period was appropriate to detect distinct differences in outcomes. The authors further emphasized that the lack of caries progression at 12, 24 and 36 mo recall appointments in teeth with intact sealant clearly confirmed that the sample size was satisfactory.

One should consider that only papers published in the English language were included in this systematic review. In fact, the most relevant papers are published in English language since it can be read worldwide. For this reason, we believe that data loss due to the exclusion of papers wrote in other languages could not generate a negative impact to the present results.

The minimally invasive approach to carious lesions in dentistry is based on the principle that nonsurgical treatments are preferable to invasive treatments as the former increase tooth longevity. Invasive interventions initiate a cycle of treatment and re-treatment, often leading to the need for crowns and implants, regardless of the quality of the initial filling preparation[11]. Data from studies included in this review demonstrate the great positive impact of a noninvasive approach to the management of non-cavitated occlusal carious lesions in dentin. Further studies with longer follow-up times should be performed to improve the evidence provided by the present systematic review.

### *Is the noninvasive treatment of non-cavitated occlusal carious lesions in dentin effective in permanent and deciduous teeth?*

Borges *et al*[5] compared the efficacy of pit and fissure sealing using a resin-based material with that of traditional tooth restoration in the treatment of non-cavitated occlusal carious lesions in the dentin of primary molars. They concluded that the invasive restorative approach can be replaced with the fissure sealing technique that does not require drilling. Borges *et al*[3,4] and Bakhshandeh *et al*[7] reported that the same noninvasive fissure sealing treatment arrested caries in permanent molars. Thus, this approach appears to be effective in deciduous and permanent molars.

### *Which materials should clinicians use to seal pits and fissures in the management of non-cavitated occlusal carious lesions in dentin? What are the perspectives on the use of alternative sealing materials and techniques?*

The clinical effectiveness of fissure sealing for the management of non-cavitated occlusal carious lesions in dentin depends on complete maintenance of the sealant in fissures[3-7]. The self-curing glass ionomer cement tested by de Silveira *et al*[6] showed high loss rates that prevented it from arresting caries progression, as determined by clinical examination. The authors observed the emergence of cavitations in enamel when the cement was lost. Resin-based fissure sealants showed higher complete retention rates, as reported by Borges *et al*[3-5] and Bakhshandeh *et al*[7]. These superior survival rates suggest that resin-based fissure sealant is preferable to self-curing glass ionomer cement.

Resin-based fissure sealants are adequate for the therapeutic sealing of non-cavitated occlusal carious lesions in dentin. However, the partial and total sealant losses observed by Borges *et al*[3-5] and Bakhshandeh *et al*[7] limit the effectiveness of this noninvasive therapeutic approach. Researchers have sought to improve sealant adhesion to enamel and/or the physical properties of polymeric networks as sealant adaptation and polymeric network strength may be related to the survival of sealants in tooth fissures[12]. Enamel conditioning with a casein phosphopeptide-amorphous calcium phosphate paste in association with adhesive system application improved the bond durability of a fissure sealant *in vitro*[13], suggesting that this protocol could increase sealant retention.

*In vitro* studies have demonstrated the superiority of flowable composites to traditional fissure sealants in terms of physical properties related to polymeric network strength, such as the degree of conversion, hardness and crosslink density[12,14-16]. Moreover, preheating of flowable composites before photoactivation has been found to increase softening resistance to acid challenge *in vitro*[17]. In this context, further clinical trials should be performed to evaluate the efficacy of the above described protocols *in vivo*.

In conclusion, noninvasive therapeutic fissure sealing is effective for the management of non-cavitated occlusal carious lesions in dentin if a resin-based fissure sealant is used. Since only relatively short-time follow-up clinical trials were found, further randomized controlled clinical trials with longer follow-up times should be performed to provide more scientific evidence for the efficacy of therapeutic sealing in the management of these lesions.

## COMMENTS

### Background

The use of pit and fissure sealant to seal fissures has been investigated as a secondary preventive approach to the management of non-cavitated occlusal carious lesions in dentin. Although several clinical trials have examined this use of pit and fissure sealants, a systematic analysis of their results is needed to provide scientific evidence for its effectiveness as a secondary preventive approach.

### Research frontiers

Cariology, restorative dentistry, preventive dentistry.

### Innovations and breakthroughs

Four of five studies analyzed in this systematic review reported that sealing occlusal fissures with a resin-based sealant arrested the progression of carious lesions when the sealant was intact and tight. Occlusal fissure sealing with a resin-based sealant may arrest the progression of non-cavitated occlusal dentinal caries.

### Applications

The actual restorative approach to treat non-cavitated caries lesion in dentin may be replaced with a noninvasive method. In turn, this will contribute to save sound dental tissues which are lost during cavity preparation, increasing tooth longevity.

### Terminology

Tooth demineralization refers to a process where an acidic environment leaches some of the mineral content (such as calcium) out of a tooth's calcified tissues (enamel and dentin). Non invasive treatment is when there is no cavity preparation involved and healthy tooth structure is preserved.

### Peer review

The present manuscript is a focused and well performed systematic review.

## Abstract

Dystrophic cardiac calcification is often associated with conditions causing systemic inflammation and when present, is usually extensive, often encompassing multiple cardiac chambers and valves. We present an unusual case of dystrophic left atrial calcification in the setting of end stage renal disease on hemodialysis diagnosed by echocardiography and computed tomography. Significant calcium deposition is confined within the walls of the left atrium with no involvement of the mitral valve, and no hemodynamic effects.

**Key words:** Left atrium calcification; Heart of stone; Atrial calcification; Dystrophic cardiac calcification; Renal failure

**Core tip:** Dystrophic cardiac calcification can often lead to complicated valvular stenosis, cardiac arrhythmias, cardiac block and abnormal cardiac hemodynamics by effecting systolic and diastolic cardiac function, thus awareness, early detection and treatment of the underlying cause, and resulting complications is key to patient outcome.

Jones C, Lodhi AM, Cao LB, Chagarlamudi AK, Movahed A. Atrium of stone: A case of confined left atrial calcification without hemodynamic compromise. *World J Clin Cases* 2014; 2(5): 142-145 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i5/142.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i5.142

## INTRODUCTION

Dystrophic cardiac calcification is often diffuse and occurs primarily in patients with chronic inflammatory diseases. Long term advancement of dystrophic calcification often lead to complicated valvular stenosis, cardiac arrhythmias, cardiac block and abnormal cardiac hemodynamic by effecting systolic and diastolic cardiac function, thus awareness, early detection and treatment of the underlying cause, and resulting complications is key to patient outcome.

## CASE REPORT

A 55-year-old African-American woman with past medical history of hypertension, endstage renal failure on dialysis with failure of previous renal transplant presented for cardiac risk stratification prior to renal transplant surgery. Previous work up for renal transplant had been unremarkable except for elevated intact parathyroid hormone of 1346 pg/mL. Electrocardiogram showed normal sinus rhythm. By Teichholtz equation, transthoracic echocardiography showed a left ventricular ejection fraction of 75%. In the parasternal long axis view, the interventricular septal diameter was 1 cm, the left ventricular

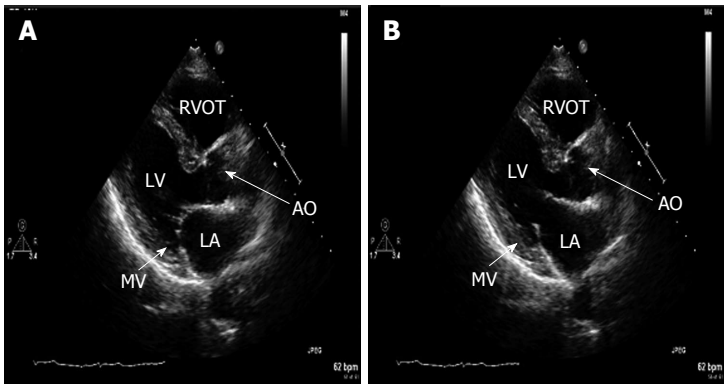

**Figure 1 Transthoracic 2D parasternal long axis.** A: Systole shows diffuse echo dense signal significantly confined to the walls of the left atrium indicated by arrow. No mitral valve (MV) or mitral annulus involvement. Valve closes normally during systole; B: Diastole shows adequate MV opening. LA: Left atrium; AO: Aortic root.

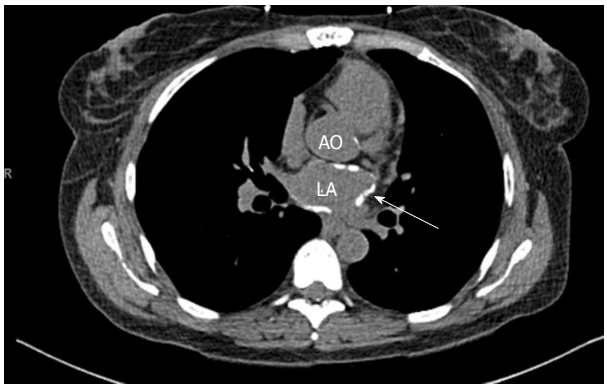

**Figure 2 Cardiac computed tomography indicating calcium within the walls of the left atrium and mild calcification of the aortic root.** LA: Left atrium; AO: Aortic root.

posterior wall diameter was 1.1 cm, the left ventricular end diastolic diameter was 4 cm, and the left ventricular mass index was greater than 86 g/m$^2$. There was concentric remodeling by relative wall thickness calculation. Grade 2 diastolic dysfunction with pseudonormalization mitral inflow pattern was observed. The E:A was 1.4, lateral e' of 8.68 cm/s, medial e' of 6.14 cm/s, and a deceleration time of 200 ms. The left atrial size and volume was in the upper limits of normal. (Normal left atrial size by index is < 29 cm/m$^2$)[1]. The left atrial wall, however, showed diffuse hyper-echogenicity not observed in the left ventricular walls. This hyper-echogenicity did not restrict the movement of the mitral valve leaflets (Figure 1). Tricuspid annular plane systolic excursion was 2.1 cm/s. A transesophageal echocardiogram was not performed in this case. However, in order to confirm our suspicion and diagnosis, the patient underwent a non-enhanced computed tomography (CT) of the chest which noted increased attenuation of the left atrial wall, consistent with calcification of majority of the left atrium and mild calcification of the ascending aorta (Figure 2). The CT unfortunately did not show the aorto-mitral continuity well. The Calcium-phosphorous product at time of evaluation was within normal limits, and patient had no history of tuberculosis or a positive Purified Protein Derivative.

## DISCUSSION

Calcification seen in patients is typically either a product of metastatic calcification or dystrophic calcification. Metastatic calcification is typically seen in patients with a disturbance of Calcium and Phosphorus metabolism, often due to renal dysfunction. In our patient, although the intact parathyroid hormone level was elevated on previous workup for renal transplant, the pattern of calcification was that of a dense, finely speckled pattern. This indicates that the calcification in the left atrium is a product of dystrophic calcification and not that of metastatic calcification.

Dystrophic myocardial calcification which is increased intracellular calcium deposition driven by high serum calcium, is a well described process associated with conditions that cause systemic inflammation such as renal failure, rheumatic disease or cardiac surgery[2-5]. Calcium deposition often involves the left atrial appendage, free wall and septal wall, and mitral valve as well. In severe cases the entire atrium is involved with significant mitral valve stenos is or malcoaptation[6]. In cases where an entire atrium is involved, it is often referred to as a "coconut"[7] or "porcelain atrium"[8]. Although calcification of parts or the whole left atrium have been well documented, calcium deposition confined to the left atrial walls without valvular involvement is a unique variant.

There are several genes that have been linked to dystrophic cardiac calcification, including but not limited to the ATP-binding cassette transporter subtype 6 gene which was recently found to mediate myocardial necrosis and calcification[9-11], the Adiponectin gene which was linked to calcification of the aortic median[12,13], the alpha2-HS-glycoprotein/fetuin gene which has been linked to calcification of coronary artery plaques in patients with type Ⅱ diabetes[14,15], the ectonucleotide pyrophosphatase/phosphodiesterase1 gene which has been linked to increased aortic arch calcifications in patients with type Ⅱ diabetes and higher coronary calcification scores in patients with End Stage Renal Disease[16-20], and the Osteoprotegerin gene which has been linked to increased risk for coronary artery disease[21-25].

Women in their fifth and sixth decades are most often affected[6] and can be classified into one of three types which are associated with prior mitral valve dysfunction[26]. Type A is caused by mitral stenos is with calcification confined to the left atrial appendage causing an increased occurrence of thrombi within the appendage. Type B is the result of advanced mitral stenos is with

**Figure 3 CXR shows a small amount of what appears to be pneumoperitoneum beneath the right hemidiaphragm that was present prior, otherwise, no change.**

calcification confined to the left atrial free wall and the mitral valve. Type C is the confined calcification of the posterior wall of the left atrium. This particular pattern of left atrial calcium deposition is known as MacCallum's patch and is often the result of a regurgitant mitral jet[26]. The structure that is most often spared is the interatrial septum. When the septal wall is calcified as well, the term coconut atrium is used to describe the hyperdense white appearance of the complete left atrial calcification on imaging[6]. Multiple imaging techniques can be used to diagnose and assess the extent of calcification. On anterior-posterior chest radiograph mural calcification presents as a thin C shaped curvilinear density outlining the left atrium partially or completely with the opening of the C anterior to mitral annulus. Hyper-echogenicity within the walls of the left atrium, Restriction in atrial wall motion and mitral valve abnormalities can be well visualized with transthoracic and transesophageal echocardiography, however, CT is superior to all other imaging modalities for determining extent of calcification[20,27].

Dystrophic calcification of the left atrium can cause significant complications which can lead to hemodynamic compromise or even collapse. A common complication is the occurrence of mitral stenos is as the mitral leaflets become restricted due to calcification[20]. In cases of significant calcium deposition Arrhythmias can present especially if calcification occurs outside the left atrium involving the SA node, AV node or other points along the cardiac conduction system. Over time increased left atrial pressure can develop due to decreased compliance of the left atrial walls and can be transmitted through pulmonary veins resulting in derangements in right heart hemodynamics (Figure 3)[7,28].

The accepted surgical treatment for left atrial calcification is endoatrioectomy with mitral valve replacement as the calcification usually does not extend beyond the endocardium[25]. Total endoatrioectomy of a calcified left atrium has been shown to be a technique with limited morbidity, however, not much follow up of atrial compliance has been done in patients who undergo this procedure in order to quantify improvement[29]. The two major contraindications to endoatrioectomy are calcification of the left atrial septal wall and mitral annulus. Septal calcification makes repair difficult and increases mortality due to the septum serving as a cleavage plane during surgery which helps prevent hemorrhage and embolization if thrombus is present. Caseous necrosis is known to cause mitral calcification, usually occurring along the posterior annulus[28,30].

Our case presentation is unique in that all of the walls of the left atrium are heavily calcified including the septal wall and left atrial appendage with minimal presence in the ascending aorta, however, there is no calcification of the mitral valve and no resultant mitral stenos is, mitral regurgitation, arrhythmias or hemodynamic compromise.

## COMMENTS

### *Case characteristics*

In a preoperative evaluation for renal transplant of an asymptomatic patient with a prior history of end stage renal disease (ESRD) and hypertension, there were no significant clinical or exam findings.

### *Clinical diagnosis*

However, upon routine echocardiogram and chest X-ray, findings of dystrophic calcification was seen in the heart.

### *Differential diagnosis*

Findings of dystrophic calcification lead to further concerns of tuberculosis, sarcoidosis, and other rare systemic inflammatory diseases.

### *Laboratory diagnosis*

Calcium-phosphorous product at time of evaluation was within normal limits, and patient had no history of tuberculosis or a positive Purified Protein Derivative.

### *Imaging diagnosis*

Further evaluation by computed tomography (CT) imaging confirmed a calcified left atrium and made sarcoidosis, and other more rare inflammatory disease less likely.

### *Pathological diagnosis*

No further pathological studies were done, but the additional imaging studies confirmed dystrophic calcification in an individual with ESRD, a systemic inflammatory disease equivalent.

### *Treatment*

The patient is at risk for complicated valvular stenosis, cardiac arrhythmias, cardiac block and abnormal cardiac hemodynamics due to this dystrophic calcification; thus close follow-up, and early treatment of these resulting complications are the key to the patient's outcome.

### *Term explanation*

An "atrium of stone", thus refers to this dystrophic calcification almost isolated to the left atrium.

### *Experiences and lessons*

ESRD patients often carry a higher mortality and morbidity than previous thought, which may not always be present on initial clinical and exam assessment.

### *Peer review*

The authors present an unusual case of dystrophic left atrial calcification in the setting of end stage renal disease on hemodialysis diagnosed by echocardiography and CT. Calcium deposition is significantly confined within the walls of the left atrium with no involvement of the mitral valve or untoward effects on hemodynamics. This is an interesting case report for the clinical practice.

## Abstract

We report a case of primary colonic lymphoma incidentally diagnosed in a patient presenting a gallbladder attack making particular attention on the diagnostic findings at ultrasound (US) and total body computed tomography (CT) exams that allowed us to make the correct final diagnosis. A 85-year-old Caucasian male patient was referred to our department due to acute pain at the upper right quadrant, spreaded to the right shoulder blade. Patient had nausea and mild fever and Murphy's maneuver was positive. At physical examination a large bulky mass was found in the right flank. Patient underwent to US exam that detected a big stone in the lumen of the gallbladder and in correspondence of the palpable mass, an extended concentric thickening of the colic wall. CT scan was performed and confirmed a widespread and concentric thickening of the wall of the ascending colon and cecum. In addition, revealed signs of microperforation of the colic wall. Numerous large lymphadenopathies were found in the abdominal, pelvic and thoracic cavity and there was a condition of splenomegaly, with some ischemic outcomes in the context of the spleen. No metastasis in the parenchimatous organs were found. These imaging findings suggest us the diagnosis of lymphoma. Patient underwent to surgery, and right hemicolectomy and cholecystectomy was performed. Histological examination confirmed our diagnosis, revealing a diffuse large B-cell lymphoma. The patient underwent to Cyclophosphamide, Hydroxydaunorubicin, Oncovin, Prednisone chemotherapy showing only a partial regression of the lymphadenopathies, being in advanced stage at the time of diagnosis.

**Key words:** Primary colonic lymphoma; Gastrointestinal lymphoma; Diffuse large B-cell lymphoma; Gallstone attack; Computed tomography

**Core tip:** The authors report their experience with a largely primary colonic lymphoma (PCL) incidentally detected in a patient presenting a gallbladder attack. PCL is a rare disease (less than 1% of all colorectal malignancies). Symptoms are unspecific and it is usually quite advanced by the time diagnosis is made. In this case, patient showed symptoms of gallbladder disease and presented a large bulky mass at physical exam. The authors pay particular attention in describing clinic and diagnostic findings which suggested the correct final diagnosis of PCL. The role of ultrasound and computed tomography exams with the respective radiological features are described.

## INTRODUCTION

Lymphomas are haematological malignancies which could have extranodal manifestations in approximately 40% of cases. The gastro-intestinal tract is the most common extranodal localization of non-Hodgkin lymphomas (NHLs) with a rare involvement of large bowel. The diagnostic criteria were firstly described by Barbaryan *et al*[1] in 1961.

Overall, primary colonic lymphoma (PCL) accounts for 1.4% of all cases of NHLs and represents only the 0.2%-0.6% of all large-bowel malignancies[2]. The most common histological types, in according with the Ann-Arbor classification, were: diffuse large B-cell lymphomas with frequency rate ranging from 47% to 81%, Mantle-cell lymphomas and Burkitt's lymphomas[3-5]. We report a case of PCL in a patient presenting with a gallbladder attack.

## CASE REPORT

A 85-year-old Caucasian male patient came to our Department of Radiological Sciences complaining of acute pain at the right flank, spreading to the back right shoulder blade area. The patient had nausea and mild fever. The pain arose during the night. At physical examination, the patient appeared pale. Murphy's maneuver was positive. Patient referred at least other two similar attacks of pain during the past 3 years.

Abdominal palpation revealed a voluminous bulky mass with a maximum diameter of about 8 cm in the right flank, fixed in the deep layers. Moreover, the patient referred weight loss in the last six months, persistent low-grade fever in the evening and loss of appetite.

The blood investigations revealed microcytic anemia (HB 8.8 mg/dL), slight increase of gamma-glutamyl transpeptidase and alkaline phosphatase (187 U/L). It was also observed an increase of erythrocyte sedimentation rate (30 mm/s) and of the C-reactive protein (128 mg/L). No further significant changes were found in the laboratory exams.

Therefore, it was performed an ultrasound (US) examination that detected a stone containing slightly thick walled gallbladder (maximum diameter of about 1.5 cm). Intra and extra-hepatic bile ducts were not dilated. The liver presented regular shape, normal size and no solid pathologic lesions were found. In the upper right quadrant, in correspondence of the palpable mass, there was a concentric thickening of the wall of the ascending colon, which assumed the appearance of a solid mass of 10 mm in maximum diameter (Figure 1).

We decided to perform a total body computed tomography (CT) scan which confirmed, close to the hepatic flexure, a widespread and concentric thickening of the wall of the ascending colon (maximum thickness 40 mm) extended in cranio-caudal direction for 10 cm.

In the submucosa, there were signs of microperforation with millimetric air bubbles in the context of the colic wall. The perivisceral and omental fatty tissue was inhomogeneous.

On the medial side of the lesion there was a great necrotic enlarged lymph node (dimensions: 45 mm of longitudinal diameter and 66 mm of transverse diameter).

Numerous lymphadenopathies were found in the abdominal and pelvic cavity, the most numerous of them lying in the inter-aorto-caval space and along the course of the splenic vein and the iliac vessels bilaterally. In addition, the spleen was enlarged (longitudinal diameter of 18 cm) with some parenchymal hypodense areas in the context that could be indicative of ischemic outcomes (Figures 2 and 3).

Not further significant alterations were found in the liver and in the other parenchymatous organs.

Some lymphadenopathies were found also in the thoracic cavity, located in the pretracheal and para-esophageal space (maximum diameter 14 mm).

In the cardio-phrenic space, bilaterally, there were other small pathologic lymph nodes.

Considering the morphology of the colonic thickening, which seemed to be expansive rather than infiltrative, the presence of multiple lymphadenopathies, the condition of splenomegaly and the absence of involvement of the liver and peritoneum, the diagnosis of lymphoma was suspected.

The patient was sent to surgery and a right hemicolectomy associated with loco-regional lymphadenectomy and cholecystectomy was performed.

Histological examination of the surgical specimen revealed a diffuse large B-cell lymphoma, CD19, CD20, CD22, CD79A, and BCL6 positive.

The patient underwent six cycles of chemotherapy [Cyclophosphamide, Hydroxydaunorubicin, Oncovin, Prednisone (CHOP) regimen] and showed only a partial regression of the lymphadenopathies.

## DISCUSSION

PCL is extremely rare, but may be increasing in frequency; it represents less than 1% of all colorectal malignancies[6,7]. There is a male predominance for these tumors, (twice as often in males compared with females) and the maximal incidence is found in the 50-65 year age group, with a mean age of 55 years[2].

There are not well-defined risk factors related with this disease and up to now the most common identified are: the immunosuppression (HIV or long-term corticosteroid therapy) and the inflammatory bowel diseases (IBD)[8].

Therefore, PCL can be present for a long period of time without causing symptoms and the diagnosis often

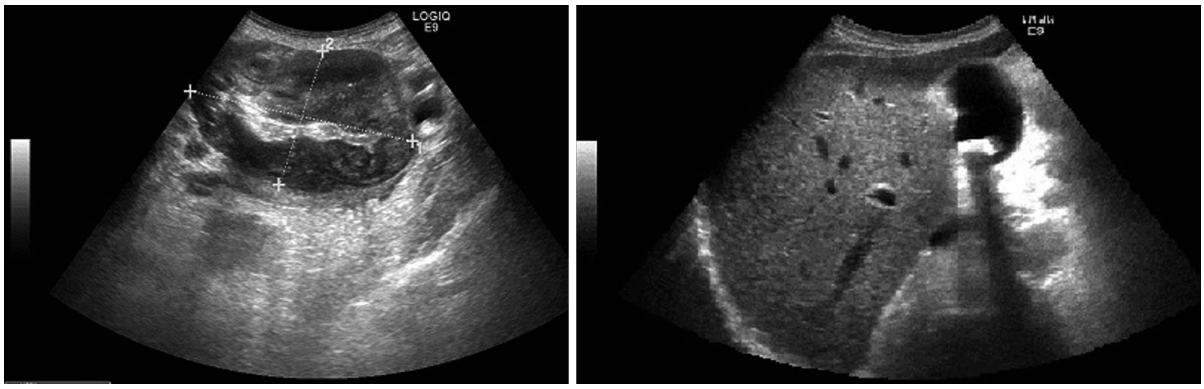

**Figure 1 Ultrasound exam findings.** The images show the concentric thickening of the wall of the ascending colon, which assumed the appearance of a solid mass. In addition the big gallstone in the lumen of the gallbladder is displayed.

**Figure 2 Computed tomography exam in the axial and coronal planes.** The images show the concentric thickening of the wall of the cecum and ascending colon. The millimetric air bubbles in the context of the colic wall are also depicted.

**Figure 3 Coronal computed tomography scan (portal venous phase).** The images show the large colic lesion at the level of the hepatic flexure (A), the large necrotic lymphadenopathy close to the lesion (B), the stone in the lumen of the gallbladder (C) and the hypodense area in the context of the spleen indicative of the ischemic outcomes (D).

is made in an advanced stage.

The most common signs and symptoms are unspecific, such as: abdominal pain (66.8%), anorexia and weight loss (43%) and an abdominal palpable mass (41.3%). Less common presentations are: bloody stool (23%), acute abdomen, microcytic anemia and rectal bleeding[2,5].

Our patient did not present any risk factors or specific symptoms for PCL, and diagnosis was incidental in occasion of a gallbladder attack.

Imaging methods were essential to perform a correct diagnosis, particularly US examination confirmed the presence of the large bulky mass found at physical exam and CT allowed us to suggest the diagnosis of lymphoma and to evaluate the disease extension.

Radiographic findings associated with PCL often could be nonspecific, sharing similarities with other types of colorectal disease, such as colorectal carcinoma and IBD[9].

In our case, CT gave us a high suspicion of PCL showing regional and systemic lymph nodes involvement, spleen enlargement, and absence of metastasis. The lesion was located in the cecum-ascending colon. These locations are the most common sites for colorectal lymphoma (respectively 57% and 18% of cases) probably because more lymphoid tissue is present in this region. Other sites involved are the transverse, recto-sigmoid colon (10%) and the descending colon (5%)[10].

The management of PCL is various, based on the extension of the disease and on clinical status of the patients at the time of diagnosis[11]. The treatment of PCL varies from chemotherapy alone to multimodal therapies combining surgery, chemotherapy, and even radiation therapy. The administration of chemotherapy and particularly the CHOP regimen remains the mainstay in the treatment management[12].

According to many authors the surgical treatment may provide important prognostic information, including histology, tumor extent and stage[13,14].

In the absence of disseminated disease, surgical resection is generally performed. The surgical approach may be used also as a therapy for local control in patients with aggressive lymphoma and to prevent complications like bleeding, perforation or intussusception. Diffuse large B cell lymphoma of the large bowel is generally treated with a uniform therapeutic approach: aggressive surgery followed by adjuvant chemotherapy[15].

Our patient directly underwent to a surgical approach, in consideration of the large size of the tumoral mass and in order to avoid complications and particularly the risk of perforation, in fact the rate of spontaneous perforation in patients with PCL is 5%-11.5% suggested by the presence of air bubbles. In addition, since the patient had recurrent attack of pain due to the gallstones, cholecystectomy was performed.

After surgery which confirmed the suspected diagnosis of lymphoma, he underwent CHOP scheme chemotherapy with a partial remission of disease. This outcome can be explained by the fact that, although resection plays an important role in the local control of the disease and in preventing bleeding and/or perforation, it rarely eradicates the lymphoma by itself.

Prognosis of PCL depends on numerous factors but the stage at diagnosis and the histological grade are the most important elements affecting survival rate[16]. Our patient showed advanced disease, in fact warning signs of lymphoma are so subtle that it may take some time before realizing that there is a serious problem. The age of the patient could have influenced the promptness of diagnosis, in fact ancient patients may underestimate symptoms for a long time[3,17].

The median survival in cases of advanced disease is generally low, ranging from 24 to 36 mo. Unfortunately, relapses are frequent (rates range from 33% to 75%), and most of them occur within the first 5 years after resection with diffuse disease[18,19].

In conclusion PCL is a rare disease. Often it is diagnosed in advanced state. Diagnostic imaging modalities, and particularly CT, have a fundamental role in the diagnosis of lymphomas. If CT reveals an infiltrative tumor with enlarged lymph nodes in the abdomen or pelvis, lymphoma should be highly taken into account in the differential diagnosis. The prediction of prognosis and the planning of a suitable therapeutic approach is essential for the patients and CT allows an accurate staging of the disease[20].

## COMMENTS

### Case characteristics

A 85-year-old male with acute pain at the right flank, presented a gallstone attack and a large bulky mass in the abdomen.

### Clinical diagnosis

Positivity to Murphy's maneuver, low-grade fever, weight loss and a palpable voluminous bulky mass in the right flank.

### Differential diagnosis

Colorectal carcinoma, Inflammatory bowel diseases.

### Laboratory diagnosis

HB 8.8 mg/dL, alkaline phosphatase 187 U/L, erythrocyte sedimentation rate 30 mm/s and C-reactive protein 128 mg/L.

### Imaging diagnosis

Ultrasound (US) examination detected a stone in the lumen of the gallbladder and a concentric thickening of the wall of the ascending colon; computed tomography (CT) confirmed the thickening of the wall of the cecum-ascending colon and revealed also signs of microperforation in the submucosa, numerous lymphadenopathies and a condition of splenomegaly.

### Pathological diagnosis

The histological examination of the surgical specimen revealed a diffuse large B cell lymphoma CD19, CD20, CD22, CD79A, and BCL6 positive.

### Treatment

The patient underwent to surgery (right hemicolectomy, loco-regional lymphadenectomy and cholecystectomy); in addition, underwent to six cycles of chemotherapy [Cyclophosphamide, Hydroxydaunorubicin, Oncovin, Prednisone (CHOP) regimen].

### Related reports

The latest studies confirmed that primary colonic lymphoma (PCL) is a very rare disease and that diagnosis is often incidental; in the authors' case report, diagnosis was made in advanced stage and we chose for a surgical approach before chemotherapy, according to some authors, for locoregional control of disease and to prevent complications.

### Term explanation

CHOP is the acronym of a chemotherapy scheme used in the treatment of non-Hodgkin lymphomas consisting of an alkylating agent (Cyclophosphamide), an intercalating agent (Hydroxydaunorubicin), a mitotic inhibitor (Oncovin) and a corticosteroid (Prednisone).

### Experiences and lessons

This case report describes the diagnostic features of PCL and the radiological findings of this rare colonic disease, that should be considered in order to make a correct differential diagnosis, particularly stressing the role of US and CT.

### Peer review

The strength of this article is that it well describes the radiological features of PCL and the case is really remarkable. The histological and immunochemical profile has been included.

## Abstract

A 24-year-old female patient with parathyroid carcinoma, the rarest endocrine malignancy, had two pregnancies. In the first pregnancy, she had severe nausea and fatigue. Hypercalcemia and hyperparathyroidism were diagnosed in the postpartum period. Hyperemesis gravidarum masked a diagnosis of hypercalcemia. Neck ultrasound and Tc-99m sestamibi found an enlarged lower right parathyroid gland. The gland was surgically removed, and an initial pathology report described atypical adenoma. Shortly afterward, she became pregnant again. During the second pregnancy, her calcium level was frequently controlled but was always in the normal range. Normocalcemia is explained by the specific physiology of pregnancy accompanied by hemodilution, hypoalbuminemia and maternal hypercalciuria (mediated by increased glomerular filtration). During lactation, calcium levels rose, and a new neck ultrasound showed a solitary mass in the area of prior surgery and an enlarged pretracheal lymph node. Fine needle aspiration of the solitary mass and node showed parathyroid carcinoma cells. The tumor mass was resected en bloc with the contiguous tissues and surrounding lymph nodes (pathology report; parathyroid carcinoma with metastases). Over the next five years, four consecutive surgeries were performed to remove malignant parathyroid tissue, lymph nodes and local metastases. Following the surgical procedures, no hypocalcemia was observed. More serious hypercalcemia recurred; the calcium level was difficult to control with a combination of pamidronate, cinacalcet and loop diuretic. No elements of multiple endocrine neoplasia were present.

**Key words:** Parathyroid carcinoma; Hypercalcemia; Hyperparathyroidism; Pregnancy; Hyperemesis gravidarum

**Core tip:** Parathyroid carcinoma is the rarest endocrine malignancy; it is extremely uncommon in pregnancy. Hyperemesis gravidarum can mask the symptoms of hypercalcemia. The calcium level can be lower during pregnancy due to its specific physiology. This is a case report of a 24-year-old female patient with parathyroid carcinoma and two consecutive pregnancies with good outcomes in the postnatal period despite poor prognosis due to malignant disease. In five years, four consecutive surgeries were performed to remove malignant parathyroid tissue, lymph nodes and local metastases. Hypercalcemia was difficult to control with a combination of pamidronate, cinacalcet and loop diuretic. There were no elements of multiple endocrine neoplasia.

## INTRODUCTION

Parathyroid carcinoma is a rare malignant disease in the general population. The United States National Cancer Database Report indicates that in the time period from 1985 to 1995, only 1% of patients with primary hyperparathyroidism had parathyroid cancers[1]. Some European countries, such as Italy, reported even higher prevalence (up to 5%)[2]. The etiology of parathyroid cancer remains unidentified; some authors mention neck irradiation as a risk factor, while others suggest long-standing secondary hyperparathyroidism[3,4]. Familial occurrences, such as hyperparathyroidism-jaw tumor syndrome, multiple endocrine neoplasia type 1 and 2A and familial isolated hyperparathyroidism[5], have been linked. It has been shown that mutations in the *HRPT2* gene (a tumor suppressor gene called parafibromin) are associated with the development of parathyroid carcinoma, both in sporadic types and in cases with some familial clustering[6]. Parathyroid adenomas occur rarely in pregnancy, with the risk to both the mother and child directly connected to the level of serum calcium[7,8]. Parathyroid carcinoma is even more rare[9]. A case report of a woman with two subsequent pregnancies and parathyroid carcinoma is presented in this paper.

## CASE REPORT

A 24-year-old woman had severe hyperemesis gravidarum during pregnancy, with constant nausea and vomiting 3-4 times daily. Symptoms started in the 10$^{th}$ week and persisted until the end of pregnancy, sometimes accompanied by fatigue and weakness. Vaginal delivery was at 37 wk of pregnancy. Shortly after the birth, her infant had neonatal convulsions; laboratory tests showed severe prolonged hypocalcemia of the child, and the mother' s calcium was checked. The mother's level of calcium was high, and she was referred to an endocrinologist. High parathyroid hormone (PTH) and low phosphorus pointed to hyperparathyroidism. Initial laboratory results confirmed that suspicion: calcium was 3.62 mmol/L (normal range, 2.14-2.53 nmol/L); ionized calcium, 1.87 mmol/L (normal range, 1.18-1.32); phosphorus, 0.53 mmol/L (normal range, 0.79-1.42 nmol/L); alkaline phosphatase, 187 U/L (normal range, 64-153 U/L); bone alkaline phosphatase, 133 U/L (normal range for premenopausal women, 14.2-42.7 U/L); and intact PTH, 36 pmol/L (normal range, 1-6.0 pmol/L). The patient had no previous history of familial hyperparathyroidism or other endocrine conditions, neck irradiation, chronic renal disease or kidney stones. There were no systemic manifestation of hypercalcemia, and later bone densitometry indicated osteoporosis (T score of the lumbar spine was -3.8) but without bone fractures. Neck Doppler ultrasound recognized an enlarged lower-right parathyroid gland, described as a well-defined mass hypoechoic to thyroid tissue with a homogenous echo pattern measuring 21 mm × 15 mm × 15 mm with few vascular structures (PTH in aspirate was higher than 150 pmol/L, Figure 1). Tc-99m sestamibi planar scan showed an area of increased uptake on the right side of the neck, additional evidence of hyperfunctioning parathyroid tissue. A pinhole collimator was used to increase the resolution of scintigraphy Fine needle aspiration showed epithelial cells with pronounced anisonucleosis (variation in the size of the cell nuclei). The cytoplasmic borders were not sharply defined; the described cells had many naked nuclei. Sliver reaction (Grimelius) stained weekly positive. Hypercalcemia was treated by hydration with isotonic sodium chloride solution, loop diuretics and pamidronate. Two months after delivery, the patient underwent surgical removal of the described parathyroid gland. The removed gland measured 2 cm × 3 cm, and the pathological report noted tissue made up of main and oxyphil cell types. There was no significant remodeling of the stroma cells or polymorphism; tumor cells were monotonous, small cells with focal cytological atypia. Mitotic figures were not observed (Figure 2A). The tumor was surrounded by a thick capsule, with cells infiltrating the capsule without breaking through it (Figure 2B). There was no invasion of tumor cells in blood vessels and no invasion of the surrounding fat tissue. However, malignant cells surrounded blood vessels in the tumor tissue, and the final pathological diagnosis was atypical adenoma of the parathyroid gland. The patient was repeatedly followed after surgery: she was normocalcemic and became pregnant again. The time interval between the two pregnancies was 15 mo. During the second pregnancy, calcium levels were normal, and the patient had no nausea or sickness, but in the third trimester her TSH level dropped significantly (TSH < 0.05 mIJ/L, normal range 0.4-4.5 mIJ/L). Free T3 and T4 remained in the normal range; thus, she was not treated with thyrostatic drugs. After the second delivery, while lactating, her calcium level rose again (3.48 mmol/L). Other lab results suggested a recurrence of hyperparathyroidism (high alkaline phosphatase 158 IU and PTH 12 pmol/L). The second baby had no convulsions or hypocalcemia after birth, unlike the first. A new neck ultrasound described a solitary mass measuring 5 mm × 3 mm × 5 mm in the area of the previous surgery (Figure 3). An enlarged lymph node was present in the pretracheal region (lower third of neck) (Figure 4A). Fine needle aspiration of the solitary mass described naked nuclei and malignant cells with pronounced macronucleosis and intranuclear inclusions, leading to a diagnosis of carcinoma of the parathyroid gland. The same cytological description was found in an aspirate of a pretracheal node, confirming metastasis of the parathyroid carcinoma. Single photon emission computed tomography (SPECT) of the neck and mediastinum showed no significant focal uptake of Tc-99m sestamibi in the region of the neck and mediastinum. Shortly after delivery, thyrostatic drugs were introduced in therapy. The patient underwent a second surgery: the tumor mass was resected en bloc, together with contiguous tissues to which the tumor adhered. Other parathyroid glands were not removed. Tracheoesophageal, paratracheal, and upper mediastinal lymph nodes were excised; due to hyperthyroidism total thyroidectomy

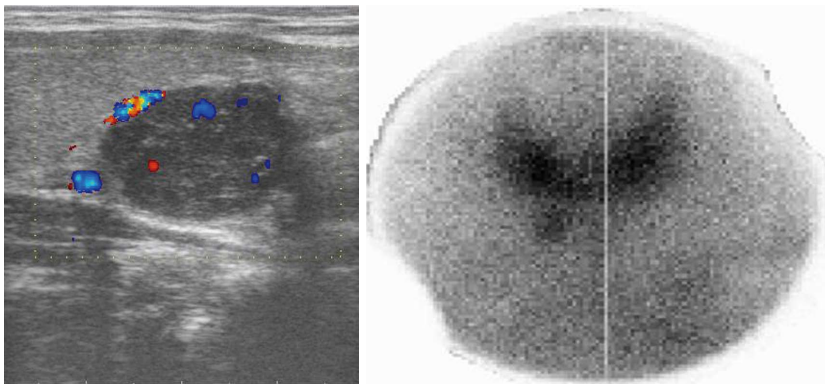

**Figure 1 Doppler ultrasound of parathyroid gland showing well-defined hypoechoic mass with color signals of few surrounding vascular structures and Tc-99m sestamibi planar scan with pinhole collimator, 10 min post injection.**

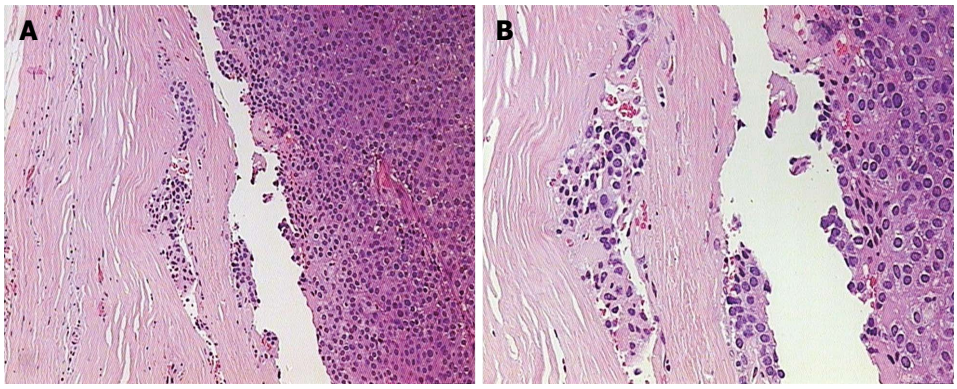

**Figure 2 Pathology image of atypical adenoma.** A: No significant remodeling of stroma cells or polymorphism, tumor cells are monotonous, small cells with focal cytological atypia without mitotic figures; B: Pathology image of atypical adenoma with tumour cells infiltrating thick fibrous capsule.

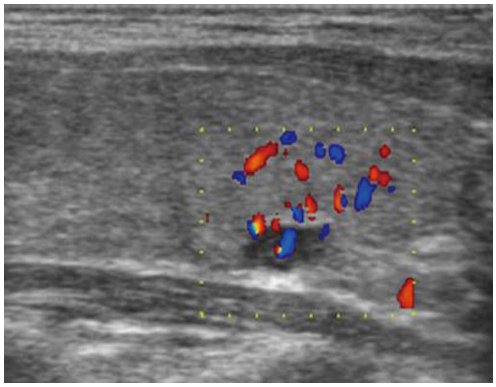

**Figure 3 Doppler ultrasound of parathyroid carcinoma: small solitary mass in the area of previous surgery.**

was performed as well. The pathology report described parathyroid carcinoma with mitotic figures, trabecular pattern and invasion of skeletal muscle (Figure 4). There were areas of tumor necrosis, and immunohistochemical results showed that the tissue was positive for PTH. Metastases of the parathyroid tumor were also found in the pretracheal lymph nodes. Postoperative hypocalcemia was prolonged but not severe. Patient received supplemental calcium and vitamin D, together with levothyroxine. In further evaluation, the levothyroxine dosage was modified according to the TSH level. Chromogranin A levels were normal (44 μg/L, normal levels < 100 μg/L), and there were no elements of multiple endocrine neoplasia.

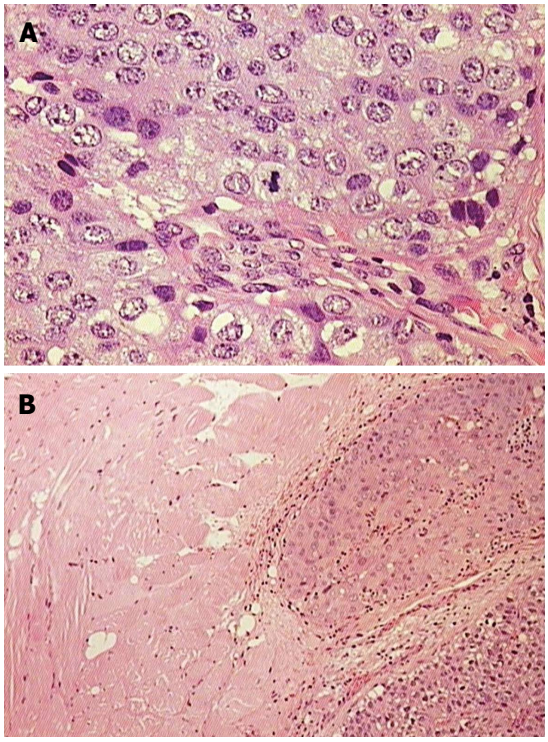

**Figure 4 Pathology image of parathyroid carcinoma.** A: Mitotic cells; B: Infiltrating skeletal muscle.

Gradually, the calcium level increased, and vitamin D and calcium supplementation were excluded from therapy. A

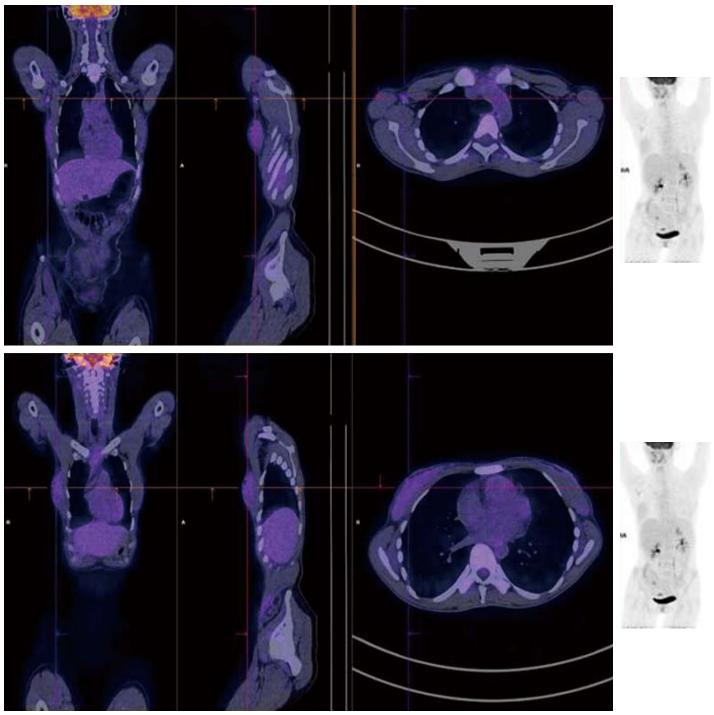

**Figure 5 Positron emission tomography/low-dose X-ray computed tomography (positron emission tomography/low-dose computed tomography) with F-18 FDG.** Focal accumulation is observed in enlarged lymph nodes of the right axillary region and diffuse uptake is observed in the right breast.

year later, magnetic resonance imaging of the neck and mediastinum showed a lymph node enlarged to 12 mm, located dorsally from the right subclavia. The consulted oncologist advised that surgical treatment was an option (disease was not disseminated at that point), and a third surgery was performed, removing all tissue surrounding the malignant parathyroid gland, lymph nodes and local metastases. Following the surgery, hypercalcemia persisted. Early SPECT images performed 15 min after Tc-99m sestamibi injection showed two foci of radiopharmaceutical uptake anterior to the lower third of the neck region. Delayed tomographic images obtained 2 h after Tc-99m sestamibi injection showed no significant focal uptake of radiopharmaceutical in the neck and mediastinum region. Focal accumulation of fluorodeoxyglucose (F-18 FDG) was observed in several enlarged lymph nodes of the right axillary region, and diffuse F-18 FDG uptake was observed in the right breast (Figure 5). Additional ultrasonography and fine needle aspiration cytology of one of the enlarged axillary lymph nodes were obtained (inflammatory changes). Breast ultrasonography found no suspicious-looking lesions. During the last neck exploration (fourth surgery), the surgeon described tumor formation on the left side of the neck, with subcutaneous location and muscle infiltration. A right paratracheal tumorous mass was located behind the right carotid bifurcation. The pathology report of the tissue was identical to that described in prior surgeries. Hypercalcemia persisted and was difficult to control, even with a combination of pamidronate, cinacalcet and loop diuretic. Calcium is a tumor marker that indicates a persistence of small, disseminated, hormonally active metastases. Further F-18 FDG positron emission tomography-computed tomography (PET/CT) evaluation is planned, in addition to a test for the *HRPT2* mutation.

## DISCUSSION

Parathyroid cancer is a rare condition, and only few cases have been reported during pregnancy in the literature[9-13]. This condition is associated with significant neonatal morbidity and mortality, as well as maternal morbidity, and it is very difficult to treat[12,13]. In this case report, the described patient had two consecutive pregnancies with good outcomes both for mother and children, despite later poor prognosis for the mother due to malignant disease. Hyperemesis gravidarum, *e.g.*, nausea, fatigue and weakness, are non-specific symptoms in pregnancy, but they are also symptoms of an elevated calcium level. The first pregnancy obscured the diagnosis of hypercalcemia. During the second pregnancy, the patient was normocalcemic. This result could be explained by the specific physiology of pregnancy, including hemodilution, hypoalbuminemia and maternal hypercalciuria, caused by an increase of the glomerular filtration rate. Sickness and vomiting in pregnancy usually start before the 9$^{th}$ week and, in most cases, resolve by 16 wk of pregnancy. Otherwise, hypercalcemia is one possible cause. Nausea and vomiting are not the only clinical manifestation described in similar cases. Some of those patients have had hypertension, abdominal pain, pancreatitis and pre-eclampsia. For all of these patients, parathyroid carcinoma was diagnosed during pregnancy, and most of them underwent surgery in the third trimester[9-13].

Tc-99m sestamibi scintigraphy has been used for the detection of hyperfunctioning parathyroid tissue, including parathyroid carcinoma[14]. Tc-99m sestamibi uptake correlates with parathyroid oxyphil cell content and the size of hyperfunctioning parathyroid tissue. False-negative sestamibi scans can occur with parathyroid glands that contain predominantly clear cells, small size of the

hyperfunctioning parathyroid tissue and rapid wash-out of the radiopharmaceutical from parathyroid cells[15]. A finding of focal accumulation of Tc-99m sestamibi in the lower third of the neck on early images and no significant uptake of radiopharmaceutical on delayed images is most likely due to rapid wash-out of Tc-99m sestamibi from the tumor cells.

Following the first surgery, the next scan was negative. F-18 FDG PET/CT is recognized as a powerful tool to detect tumors, especially malignant ones, due to the increased glucose metabolism of tumor cells[16]. FDG PET/CT is used in parathyroid carcinoma to detect recurrent disease. A negative finding on FDG PET/CT is most likely due to small tumor size.

There are no official guidelines for the treatment of hyperparathyroidism in pregnancy; even less is known about how to treat parathyroid carcinoma. The options are a conservative approach or surgery. Both approaches carry the risk of drug and procedure side effects, though the risk imposed by the elevated calcium level is sometimes greater. If surgery is an option, it should be performed in the third trimester of pregnancy. A literature analysis described 16 cases of primary hyperparathyroidism treated surgically after 27 wk of gestation, and carcinoma was found in a high percentage: 12.5% of cases. These patients had a low postoperative incidence of clinically significant complications for both the fetus and the mother[17]. When overt hyperparathyroidism is diagnosed in the postpartum period, surgery is the first choice of treatment. If parathyroid cancer is suspected (on the basis of the clinical picture and cytology, even before confirmation by pathology report), complete surgical resection with negative margins and removal of surrounding lymph nodes is the recommended course of action. In this case, the first pathological report was atypical adenoma. Atypical parathyroid adenomas have some histological findings that are suggestive of cancer but not enough to make the diagnosis. Atypical adenomas have a thick capsule, fibrous trabeculae, and a trabecular growth pattern with nuclear pleomorphism; they have no local or vascular invasion and no lymph node or distant metastasis[18].

This case suggests that any unusual parathyroid histology should be reviewed, and re-resection should be performed if there is suspicion of carcinoma. In such cases, pregnancy should not be a reason for withholding aggressive surgery, especially in very young patients.

## COMMENTS

### Case characteristics

A 24-year-old female patient with parathyroid carcinoma and two consecutive pregnancies.

### Clinical diagnosis

Hypercalcemia, hyperparathyroidism.

### Differential diagnosis

Adenoma of the parathyroid gland.

### Laboratory diagnosis

Calcium, 3.62 mmol/L (normal range, 2.14-2.53 nmol/L); ionized calcium, 1.87 mmol/L (normal range, 1.18-1.32); phosphorus, 0.53 mmol/L (normal range, 0.79-1.42 nmol/L); alkaline phosphatase, 187 U/L (normal range, 64-153 U/L); bone alkaline phosphatase, 133 U/L (normal range for premenopausal women, 14.2-42.7 U/L); intact parathyroid hormone (PTH), 36 pmol/L (normal range, 1-6.0 pmol/L). PTH in aspirate of right lower parathyroid gland higher than 150 pmol/L.

### Imaging diagnosis

Neck ultrasound; enlarged right lower parathyroid gland (well-defined mass hypoechoic to thyroid tissue with a homogenous echo pattern measuring 21 mm × 15 mm × 15 mm. Tc-99m sestamibi scan; an area of increased uptake on the right side of neck.

### Pathological diagnosis

Initial pathological diagnosis atypical adenoma of parathyroid gland; tissue made up of main and oxyphil cell-type, no significant remodeling of stroma cells or polymorphism, tumor cells monotonous, small cells with focal cytological atypia, mitotic figures not observed. Tumor is surrounded by thick capsule; cells infiltrate capsule, not breaking through. There is no invasion of tumor cells in blood vessels and no invasion of surrounding fat tissue. Next pathology report described a parathyroid carcinoma with mitotic figures, trabecular pattern and invasion of skeletal muscle.

### Treatment

In five years, four consecutive surgeries were performed to remove tissue surrounding the malignant parathyroid gland, lymph nodes and local metastases. Hypercalcemia was difficult to control with a combination of pamidronate, cinacalcet and loop diuretic.

### Term explanation

*HRPT2* gene or parafibromin is a tumor suppressor gene associated with the development of parathyroid carcinoma in both sporadic types and some familial clustering cases.

### Experiences and lessons

This case report represents a patient with parathyroid carcinoma and two pregnancies. Pregnancy itself can obscure proper diagnosis of the disease, as the unique physiology of pregnancy can alter clinical findings. It is necessary to be aggressive during the surgical treatment of parathyroid carcinoma.

### Peer review

This is an interesting case report clarifing the clinical findings of a 24-year-old female patient with parathyroid carcinoma and two consequent pregnancies with good outcome, despite poor prognosis due to malignant disease. Generally, the manuscript was straight-forward and well-written on this topic. This article is of potential interest to the readers.

## Abstract

The location of an ingested foreign object is often difficult to determine by X-ray if gastric air bubbles are not clear in the image. Methods that provide negative contrast can facilitate precise object localization, which is important for object retrieval and treatment of the patient. This case report describes a male child, 2 years and 2 mo of age, who accidentally swallowed a lithium battery while playing at home. A plain X-ray showed that the battery was in the abdomen, but it was unclear whether the object was still inside the stomach. A second X-ray examination performed after oral administration of a bloating agent to produce expansion of the stomach and provide negative contrast confirmed that the ingested battery was still in the stomach. The battery was then carefully removed using magnetic and balloon catheters under fluoroscopic guidance. This case report describes the successful use of an orally administered bloating agent without pain to the child in order to determine the precise location of a foreign object in the abdomen.

**Key words:** Accidental ingestion; Bloating agent; X-ray; Minimal invasion; Foreign object

**Core tip:** After ingestion of a foreign object, it is sometimes difficult to determine the object's exact location, which is important for successful retrieval and patient recovery. In the present case, an X-ray examination was performed after oral administration of a bloating agent to confirm that an ingested battery was still inside the stomach of a pediatric patient. This case demonstrates the successful and painless utilization of a bloating agent in a child for the diagnostic determination of an ingested foreign object location.

Tomishige H, Morise Z, Suzuki T, Hara F, Hibi M, Kato T, Hashimoto T. X-ray diagnosis with a bloating agent for foreign object ingestion. *World J Clin Cases* 2014; 2(5): 157-159 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i5/157.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i5.157

## INTRODUCTION

It is often difficult to determine the precise location of a foreign ingested object in a plain X-ray if gastric air bubbles are not clear in the image. We experienced a case in which a child who had accidentally swallowed a lithium battery was brought to our emergency department. An initial X-ray examination was performed, and failed to reveal the precise location of the battery within the abdomen. A second X-ray examination performed after oral administration of a bloating agent to produce gastric carbon dioxide air bubbles resulted in sufficient exten-

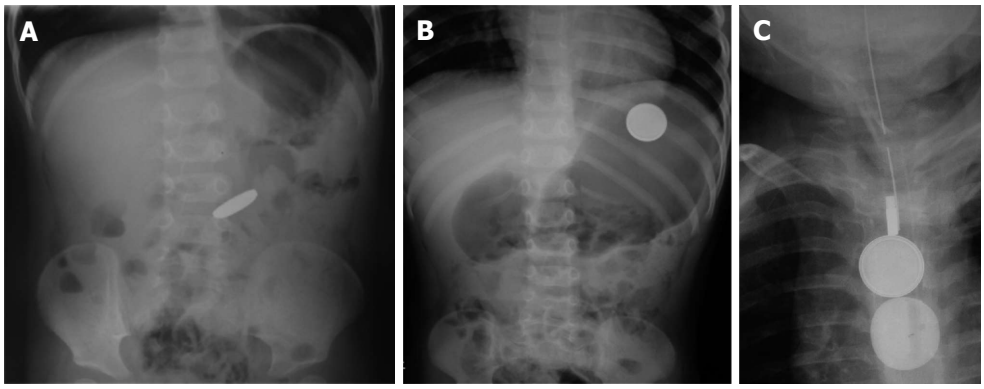

**Figure 1 X-ray image.** A: Initial X-ray image showing the presence of a foreign object in the patient's abdomen; B: Abdominal X-ray image taken after oral administration of a bloating agent. Gastric air bubbles produced after administration of the bloating agent provided sufficient distension and negative contrast to confirm that the battery was inside the stomach; C: Chest X-ray image during removal of the foreign object. A magnetic catheter was used in combination with a balloon catheter to attract and remove the battery under fluoroscopic guidance.

sion of the stomach to indicate that the battery was still inside the stomach. Thus, we describe the successful use of a bloating agent that can be administered orally and without pain to a child, which is useful for determining the location of a foreign object in the stomach.

## CASE REPORT

A male child, 2 years and 2 mo of age, accidentally swallowed a battery while playing at home. He was first taken to a nearby hospital and then brought to our hospital approximately 4 h after the accident. The general condition of the patient was good without any symptoms. The foreign object was identified in abdominal plain X-ray images, but it was unclear whether the object was inside the stomach (Figure 1A). Therefore, a bloating agent (Baros Effervescent Granules-S 3.5 g, Horii Pharmaceutical Ind., Osaka, Japan) was orally administered to provide a negative contrast agent for X-ray imaging. The patient was provided with approximately one-fifth of one packet of the agent with a small amount of water by his mother. This produced gastric air bubbles that expanded the stomach. An abdominal plain X-ray examination then showed that the battery was inside the stomach (Figure 1B). A magnetic catheter was inserted from the mouth into the stomach without anesthesia. The battery was removed using the attraction of the magnet, with concomitant use of a 14 Fr. balloon catheter under fluoroscopic guidance (Figure 1C). The foreign object was confirmed to be a lithium battery, which was partially darkened due to stomach fluid. After removal of the battery, the general condition of the patient was good.

## DISCUSSION

Due to the possibility for serious complications, foreign objects such as button-type batteries require an emergency removal from the esophagus[1], or the stomach. However, it is often difficult to determine whether the accidentally ingested foreign object is present in the stomach based on plain X-ray images. In such instances, the site of the object is usually confirmed by instilling air through a nasogastric tube to induce stomach expansion. A bloating agent for contrast X-ray can also be used to confirm the site of a foreign object, as the agent can extend the stomach and duodenum wall by immediately producing carbon dioxide, which at the same time enhances the image contrast by increasing the difference in X-ray transmittance. The foaming ingredient within such bloating agents consists of sodium hydrogen carbonate and tartaric acid. Carbon dioxide produced in the stomach is excreted from the oral cavity by eructation, or absorbed into the digestive tract and excreted out of the body by gas exchange in the pulmonary alveoli[2]. Some reports have recommended the use of carbonated drinks such as cola and soda for stomach expansion[3], however such drinks are not always appropriate for infants. Since the bloating agent used in our case was slightly sweet and sour, the child was able to take the agent without difficulty when given by his mother. Therefore, we suggest that a bloating agent for contrast X-ray is a suitable option to expand the stomach of a child who has swallowed a foreign object, since the approach is minimally invasive and does not require insertion of a nasogastric tube.

## COMMENTS

### *Case characteristics*

A two-year-old boy accidentally swallowed a lithium battery, which needed to be retrieved.

### *Clinical diagnosis*

The patient had swallowed a foreign object (a lithium battery), which was located in the stomach.

### *Differential diagnosis*

The foreign object (battery) may have been located in the intestine rather than the stomach.

### *Imaging diagnosis*

An X-ray performed after a bloating agent was administered allowed for stomach expansion and negative contrast to confirm that the foreign object (battery) was in the stomach and not the intestine.

### *Treatment*

A magnetic catheter and a 14 Fr. balloon catheter were used to remove the

magnet.

### *Experiences and lessons*

To treat a child who has swallowed a foreign object, we propose administration of boating agent prior to an X-ray, which expands the stomach and provides contrast while being minimally invasive and avoiding use of a nasogastric tube.

### *Peer review*

This paper describes a case in which an oral negative contrast media was used to localize a foreign body in the upper gastrointestinal tract. The diagnostic procedure presented in this case report is interesting and useful to other clinicians in need of a minimally invasive and painless technique to locate a swallowed foreign object.

## Abstract

The discovery of a strong association between hepatitis C virus (HCV) infection and mixed cryoglobulinemia (MC) has led to an increasingly rare diagnosis of idiopathic essential MC (EMC). The incidence of EMC is high in regions where there is a comparatively low HCV infection burden and low in areas of high infection prevalence, including HCV. The diagnosis of EMC requires an extensive laboratory investigation to exclude all possible causes of cryoglobulin formation. In addition, although cryoglobulin testing is simple, improper testing conditions will result in false negative results. Here, we present a 46-year-old female patient with a case of EMC with dermatological and renal manifestations, highlighting the importance of extensive investigation to reach a proper diagnosis. We review the need for appropriate laboratory testing, which is often neglected in clinical practice and which can result in false negative results. This review also emphasizes the significance of an extended testing repertoire necessary for better patient management. Despite a strong association of MC with HCV infection and other causes that lead to cryoglobulin formation, EMC remains a separate entity. Correct diagnosis requires proper temperature regulation during sample handling, as well as characterization and quantification of the cryoprecipitate. Inclusion of rheumatoid factor activity and complement levels in the cryoglobulin test-panel promotes better patient management and monitoring. Consensus guidelines should be developed and implemented for cryoglobulin detection and the diagnosis of cryoglobulinemic syndrome, which will reduce variability in inter-laboratory reporting.

**Key words:** Cryoglobulin characterization; Cryoglobulin detection; Essential mixed cryoglobulinemia; Cryoglobulinemic glomerulonephritis; Hepatitis C virus; Renal manifestations

**Core tip:** The diagnosis of essential mixed cryoglobulinemia (EMC) requires thorough laboratory investigation to exclude all possible causes of cryoglobulin formation. Although cryoglobulin testing is simple, it requires careful temperature regulation to avoid false negative results. The testing panel should also include cryoglobulin quantification and characterization, rheumatoid factor activity and complement levels, to better facilitate patient management. Furthermore, there is a need to develop and implement consensus guidelines for laboratory and clinical diagnoses of EMC.

## INTRODUCTION

Cryoglobulins (CGs) are abnormal proteins/immunoglobulins (Igs) that precipitate out of serum at temperatures below 37 ℃[1]. Initially identified by Winthrobe and Buell in 1933 and later named by Lerner *et al*[2], CGs are found in many disorders ranging from autoimmune and infectious diseases to malignancies[3-5]. Cryoglobulinemia, the presence of CGs in blood, is significant only when the associated symptoms are present[6,7]. Mixed cryoglobulinemia (MC) is strongly associated with hepatitis C virus (HCV) infection[8-11]. Other causes, including autoimmune disorders and other infections, can lead to MC[12]. When the cause for MC cannot be identified, the disease is termed as idiopathic or essential mixed cryoglobulinemia (EMC)[13-15]. An extensive laboratory investigation is required to rule out the known conditions associated with cryoglobulinemic vasculitis to impart a proper diagnosis of EMC[3,4,16]. Here, we present a 46-year-old female patient with EMC and briefly review the current laboratory methods for diagnosing this syndrome.

## CASE REPORT

A 46-year-old female patient presented to the Department of Nephrology after suffering from anuria and renal failure for ten days. Prior to admission at our institute, the patient had already undergone four sessions of dialysis in another hospital. The only significant medical history for the patient was a laparoscopic cholecystectomy she received two months prior. The patient had no history of hypertension, diabetes mellitus or other renal disease.

Upon routine examination, the patient was pale, icteric, apyrexial and normotensive, with facial and pedal edema. Palpable purpura was present on both hands. No other abnormalities were revealed during the remainder of the systemic examination. Laboratory investigations revealed normochromic and normocytic anemia, elevated total leukocyte counts with neutrophilia, and thrombocytopenia. Renal and liver functions were abnormal and proteinuria was present (+2 on a dipstick) (Table 1). A chest X-ray and an abdominal ultrasound were normal. There was no evidence of malignancy or infections upon bone marrow biopsy, and all requested cultures (blood, urine, and bone marrow) to rule out infections were negative. A provisional diagnosis of vasculitis was made.

In the absence of infections and malignancies, further examinations were carried out (Table 1). An immunological work-up showed low complement levels (C3 and C4) and a negative anti-nuclear antibody test, which remained negative at a 6-mo follow-up. Type Ⅱ CGs were detected, with a cryocrit of 6% (Figure 1A and B). Tests for anti-HCV antibodies and HCV RNA were negative. Other tests to evaluate vasculitis were also negative (Table 1). Renal biopsy showed evidence of cryoglobulinemic glomerulonephritis (Figure 1C and D).

Before vasculitis was suspected, the patient was empirically managed with antibiotics and hemodialysis, but did not show improvement. After the diagnosis of cryoglobulinemic glomerulonephritis was made, the patient was treated with intravenous solumedrol (15 mg/kg body weight) for three days, monthly intravenous injections of cyclophosphamide (15 mg/kg body weight) for five months, and plasmapheresis. After 14 plasmapheresis sessions, the patient's renal functions normalized (serum creatinine 1.2 mg/dL) and the cryocrit decreased to 1%. Cryocrit levels subsequently decreased to less than 1% over a

period of six months. Normal renal function was found to be maintained at the one-year follow-up examination.

## DISCUSSION

Brouet *et al*[17] immunochemically classified CGs into three types. Type I CGs are characterized by the presence of only a monoclonal component, mostly IgMκ, and are usually found in patients with lymphoid malignancies such as multiple myeloma. Mixed CGs are comprised of type Ⅱ, characterized by the presence of polyclonal Igs with a monoclonal component, and type Ⅲ, which contain only polyclonal Igs[17]. Mixed CGs are also associated with rheumatoid factor (RF) activity[7,18,19].

### *MC with or without HCV infection*

Before the discovery of HCV infection, most cases of MC were defined as EMC, without an underlying identifiable cause[20]. In the early 1990s, HCV became recognized as the major cause of CG formation, with approximately 90% of MC patients having the virus[3]. It has been reported that approximately 50% of HCV-infected patients develop CGs in their blood[6]. The viral particles have also been detected in cryoprecipitates[21,22]. Since this discovery, the diagnosis of EMC has become rare[10,16,23].

Autoimmune or connective tissue diseases[13,14,24,25], lymphoproliferative disorders[26] and other infections such as bacterial, viral and parasitic[27] infections, have been attributed to MC development. However, 5%-48% of cases with cryoglobulinemic syndrome have still been reported as EMC[28-30]. The incidence of EMC is higher in regions with a low prevalence of HCV infection, and lower in areas with high HCV prevalence[4]. In Pakistan, more than ten million people are infected with HCV[31,32] and there is a high burden of other infections, especially in immunocompromised populations[33], which makes the risk for EMC lower. Therefore, an extensive and thorough examination is required to rule out other causes of cryoglobulinemia and properly assign an EMC diagnosis[34,35].

### *Symptomatic MC*

Cryoglobulinemic syndrome was first described by Meltzer *et al*[18] in 1966 as a triad of symptoms including purpura, arthralgia and weakness. The syndrome may also involve the visceral organs, including hepatosplenomegaly[36], glomerulonephritis[37] and lymphadenopathy[30]. The presence of CGs is not always associated with clinical features[24], and low levels of CGs have been found in HCV-infected patients without associated symptoms[4,6,7]. During renal replacement therapy for end stage renal disease, low levels of CGs have been detected in a substantial number of non-infected and HCV-infected patients, with and without symptoms[33].

### *Renal manifestations in MC*

The incidence and presentation of renal manifestations

in HCV-associated cryoglobulinemia is well documented[10,11]. In non-HCV cryoglobulinemia, including EMC, the evidence of renal manifestations is predominantly confined to case reports[29,38-42]. It is important to note that most of the data on renal manifestations in EMC have come from studies on French populations[16,28,30,34]. In a multicenter French study comprised of 20 HCV-negative patients with renal manifestations, 50% of the patients had EMC[16]. In this study, microscopic hematuria and hypertension were the most common presenting clinical features, followed by nephrotic range proteinuria and renal insufficiency. In a separate French study, which contained 33 patients with type Ⅱ CGs, 13 (39%) of the patients had EMC. Of these patients, eight (62%) had renal involvement, with four of those suffering from renal insufficiency[34]. In a Dutch study of 22 non-HCV patients with type Ⅱ CGs, seven (32%) were found to have EMC, of which six patients had renal involvement[35].

### CG detection and testing repertoire

Detection of CGs requires stringent temperature control, a fact that cannot be stressed enough. It is imperative to maintain the sample temperature at 37 ℃ from the time the sample is collected until separation of the serum[43]. Failure to keep samples at 37 ℃ will result in false negative results[4,44,45]. In our own experience, centrifuges even those lacking a heater-with a wide temperature range (*e.g.*, 0 ℃-40 ℃) can be used to separate serum at 37 ℃. This can be achieved by preheating the instrument with an initial dry run at > 37 ℃ and then immediately transferring the samples from a 37 ℃ incubator to the centrifuge. Once centrifugation is complete, the samples should be immediately taken out of the centrifuge and placed in a 37 ℃ incubator until the supernatant can be separated. Adherence to this protocol helps to avoid red blood cell contamination, which can hinder the visibility of CGs.

Although cryoglobulinemic syndrome was first identified in 1933, the significance of a proper CG detection assay and awareness for the condition is still not fully recognized. A large European survey of 140 laboratories revealed that only 37 (26%) were following the appropriate standard procedure for CG detection[45]. The reporting of CG positive results should include quantification and characterization of these proteins, RF activity and complement (C3 and C4) levels[5,44,45]. Although CG concentration does not correlate well with disease activity, CG levels, along with RF activity and complement levels, are useful in monitoring the disease[5,19].

This case report highlights the importance for proper and thorough investigation of a patient in order to diagnose cryoglobulinemic syndrome in the absence of infections (including HCV) and other known causes of MC. Furthermore, the quantification and characterization of CGs is important, as the decrease in cryocrit level in the present case correlated well with clinical remission. Although repeated anti-nuclear antibody tests were negative, there was a weak positivity for anti-Ro52 antibodies, which can be found in various conditions, including cryoglobulinemia[46]. Similarly, a low C-reactive protein has also been observed in the serum of patients with MC, not related to systemic lupus erythematosus[19,47].

CG quantification can be done in various ways, including total protein or immunoglobulin content of cryoprecipitates, cryocrit determination[45], gel-based semi-quantitative tests[48] and other methods[49,50]. Determination of levels using a cryocrit is less cumbersome and more informative, though it should be noted that a cryocrit is less sensitive and specific than quantification of washed cryoproteins[44]. CG characterization provides valuable information that aids in long-term patient management[45,49]. Patients with type Ⅱ CGs should be closely monitored for B cell lymphoma development, especially in patients that are difficult to treat[6,15]. Lack of standardization and an incomplete testing repertoire inadvertently lead to distrust of laboratory results by the treating physicians and undermine the significance of CG detection in suspected cases, which may poorly affect patient management[4,45,49,50]. This is very important given that better treatment options are increasingly becoming available to manage this rare yet troublesome disorder[41,51,52].

### Diagnosis of cryoglobulinemic syndrome: Diagnostic versus classification criteria

Varied clinical presentation and insignificant correlation of CG concentration with clinical manifestations have made the diagnosis of cryoglobulinemic syndrome quite difficult. Thus, various diagnostic and classification criteria have been proposed to facilitate in the diagnosis of this condition[7,53,54]. Diagnostic criteria are based on major and minor laboratory and clinical features[54], and preliminary classification criteria have been proposed, including a questionnaire regarding symptoms, laboratory findings (including CG types, complement levels, RF activity and HCV presence) and organ involvement[7]. Diagnostic and classification criteria indicate that the presence of CGs in serum is the gold standard for a cryoglobulinemic vasculitis diagnosis. Moreover, the presence of clinical features consistent with this syndrome in the absence of CGs warrants repeat testing for these proteins given the possibility for false negative results[7,53].

In conclusion, despite a strong association of MC with HCV infection and other causes that can lead to CG formation, EMC remains a separate entity. Accurate diagnosis requires a thorough laboratory investigation to rule out the known causes of MC. Correct laboratory diagnosis not only requires proper handling of the samples for CG detection, but also quantification of the amount of cryoprecipitate and identification of the type of CGs present. Other tests, such as RF activity and complement levels (C3 and C4), should be included in the testing panel to ensure better patient management and monitoring. There is a need to develop and implement consensus guidelines for the detection of CGs and cryoglobulinemic syndrome to reduce variability in inter-laboratory reporting and to establish the diagnostic criteria for this clinical syndrome.

## COMMENTS

### Case characteristics

A 46-year-old female presented with anuria, acute renal failure and palpable purpura.

### Clinical diagnosis

The patient was diagnosed with essential mixed cryoglobulinemic syndrome.

### Differential diagnosis

Vasculitis causing acute renal failure was ruled out.

### Laboratory diagnosis

The following laboratory tests were acquired from the patient: negative cultures, anti-nuclear antibodies, anti-neutrophil cytoplasmic antibodies, anti-hepatitis C virus (HCV) and HCV RNA, and positive cryoglobulins (CGs) with low C3 and C4 levels and high rheumatoid factor (RF) activity.

### Imaging diagnosis

The patient had normal chest X-ray and abdominal ultrasound reports.

### Pathological diagnosis

Hematoxylin and eosin staining, in addition to periodic acid-Schiff stains from a renal biopsy, showed evidence of cryoglobulinemic glomerulonephritis.

### Treatment

The patient was treated with intravenous injections of solumedrol and cyclophosphamide, and plasmapheresis, which improved her condition.

### Related reports

Essential mixed cryoglobulinemia (EMC) is rare and requires a thorough examination to rule out other known causes. A complete work-up for cryoglobulinemic syndrome, including quantification and characterization of cryoprecipitates, complement levels and RF activity, is required for proper management and monitoring.

### Term explanation

Cryoglobulinemia is a disorder in which CGs precipitate out of the blood at temperatures lower than 37 ℃ and is often associated with hepatitis C viral infection.

### Experiences and lessons

Early recognition, extensive diagnostic work-up and proper patient management, including regular follow-ups and immunological monitoring, resulted in a favorable patient outcome in this study.

### Peer review

This case report with a mini-review highlights the importance of a thorough investigation for the rare and often neglected diagnosis of EMC. This article will be of great benefit to clinicians as it increases the awareness regarding the clinical utility and proper testing and interpretation of cryoglobulin detection assays.

## Abstract

Pancreatic tuberculosis (TB) is a rare condition, even in immunocompetent hosts. A case is presented of pancreatic TB that mimicked pancreatic head carcinoma in a 40-year-old immunocompetent male patient. The patient was admitted to our hospital after suffering for nine days from epigastralgia and obstructive jaundice. Computed tomography revealed a pancreatic mass that mimicked a pancreatic head carcinoma. The patient had undergone an operation four months prior for thoracic TB and was undergoing anti-TB therapy. A previous abdominal ultrasound was unremarkable with the exception of gallbladder steroid deposits. The patient underwent surgery due to the progressive discomfort of the upper abdomen and a mass that resembled a pancreatic malignancy. A biopsy of the pancreas and lymph nodes was performed, revealing TB infection. The patient received a cholecystostomy tube and recovered after being administered standard anti-TB therapy for 15 mo. This case is reported to emphasize the rare contribution of pancreatic TB to pancreatic masses and obstructive jaundice.

**Key words:** Anti-tuberculosis therapy; Pancreatic head carcinoma; Pancreatic tuberculosis; Pancreatic mass; Tube cholecystostomy

**Core tip:** Pancreatic tuberculosis (TB) is rare in immunocompetent or immunosuppressed hosts. We report a case of a 40-year-old immunocompetent host with pancreatic TB that mimicked pancreatic head carcinoma with obstructive jaundice. The patient had previously been operated on for thoracic TB and was receiving anti-TB therapy. We report this case to emphasize rare causes of pancreatic masses and obstructive jaundice, and to discuss alternate treatments for pancreatic TB.

Yang YJ, Li YX, Liu XQ, Yang M, Liu K. Pancreatic tuberculosis mimicking pancreatic carcinoma during anti-tuberculosis therapy: A case report. *World J Clin Cases* 2014; 2(5): 167-169 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i5/167.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i5.167

## INTRODUCTION

Pancreatic tuberculosis (TB) is a rare occurrence in either immunocompetent or immunosuppressed hosts; human immunodeficiency virus (HIV)-infected patients only have a 0.46% incidence[1]. Isolated pancreatic TB is predominantly observed in areas of widespread TB dissemination such as a military setting. Currently, there are few reports detailing pancreatic TB cases, and none of the patients were receiving anti-TB therapies at the time of diagnosis. Here, a case of pancreatic TB is presented in an immunocompetent host that was receiving anti-TB treatment. This article highlights the importance of understanding

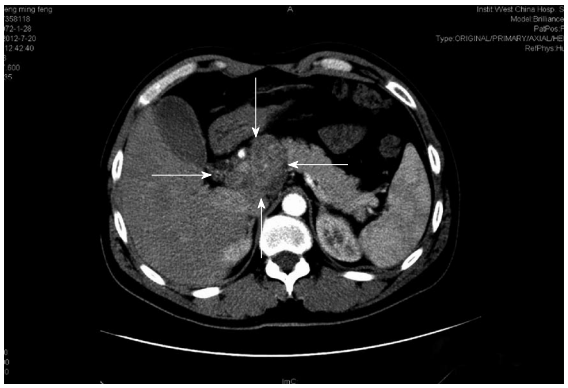

**Figure 1 Computed tomography of a pancreatic tuberculosis lesion.** Computed tomography revealed a necrotic and calcified cystic lesion (white arrows) with well-defined margins in the head of the pancreas; the lesion mimicked pancreatic head carcinoma.

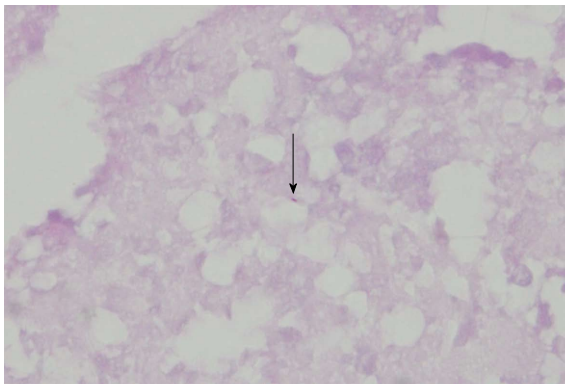

**Figure 2 Histopathology of lymph node biopsies.** Ziehl-Neelsen staining of a lymph node biopsy from the pancreatic region revealed granulomatous inflammation with necrosis and acid-fast bacilli (black arrow; magnification × 400).

this rare disease as a cause of pancreatic masses and obstructive jaundice.

## CASE REPORT

In July 2012, a 40-year-old male patient was admitted to our hospital after suffering from epigastralgia and jaundice for nine days. Upon eating, the patient complained of nausea and a worsening pain that radiated to his back. An abdominal examination revealed sensitivity in the upper abdomen without hepatosplenomegaly or ascites. The patient's medical history revealed that he had been previously diagnosed with thoracic TB and had undergone an operation for a thoracic abscess four months prior. Since his diagnosis, the patient was treated with a multi-drug anti-TB regimen that included 300 mg/d isoniazid, 600 mg/d rifampicin, and 750 mg/d ethambutol.

The patient did not present with signs of any immunosuppressive diseases and a serological test for HIV was negative. Laboratory tests revealed the following: 9.75 × $10^9$ white blood cells (WBC)/L [reference range (RR): 4.0 - 10.0 × $10^9$ WBC/L], 30.5 μmol/L total bilirubin (RR: 5.0 - 28.0 μmol/L), 24.5 μmol/L direct bilirubin (RR: < 8.8 μmol/L), 135 U/L alanine aminotransferase (RR: < 55 U/L), 64 U/L aspartate aminotransferase (RR: < 46 U/L), 715 U/L gamma glutamyl transpeptidase (RR: 6 - 46 U/L), 335 U/L alkaline phosphatase (RR: 47 - 138 U/L), and 66.84 U/mL carbohydrate antigen 199 (RR: < 22 U/mL).

Computed tomography (CT) revealed a soft tissue shadow in the head of the pancreas. The lesion, which was necrotic and calcified, measured 5.6 cm × 4.2 cm and mimicked a pancreatic head carcinoma. CT images also revealed upstream biliary dilatation and multiple lymphadenopathies surrounding the head of pancreas, the vena cava and the liver artery. The celiac trunk and descending part of duodenum could not be clearly identified in the lesion, suggesting that the above areas were involved. A pancreatic neoplasm with multiple lymph node metastases was suspected after CT (Figure 1). A chest CT revealed small nodes in the superior lobe of the left lung and in the lower lobes of both lungs. As the patient had a medical history of TB, the abdominal ultrasound taken four months prior was reexamined, but found to be unremarkable with the exception of steroid deposits in the gallbladder. Progressive discomfort in the patient's upper abdomen and the identification of a potential malignancy *via* CT led to the decision to operate and perform a biopsy.

Caseous necrosis and lymphadenectasis was observed during the biopsy procedure. Subsequently, a cholecystostomy tube was placed. Samples from the lymph nodes and biopsies of the mass were obtained for histopathologic examination. Ziehl-Neelsen staining revealed caseous granulomatous inflammation and necrosis with acid-fast bacilli (Figure 2). The presence of *Mycobacterium tuberculosis* DNA was confirmed within the biopsy samples by polymerase chain reaction (PCR). The patient was therefore administered the standard anti-TB therapy of 300 mg/d isoniazid, 600 mg/d rifampicin, 1.5 g/d pyrazinamide, and 750 mg/d ethambutol for nine months followed by six months of 300 mg/d isoniazid, 600 mg/d rifampicin, and 1.5 g/d pyrazinamide. The patient recovered quickly and was without abdominal pain during the 15 mo of treatment.

## DISCUSSION

Pancreatic TB is extremely rare, even in immunocompromised hosts, and this rarity is attributed to the resistance provided by the pancreatic enzymes[1,2]. Despite its rarity, pancreatic TB can occur even when patients are undergoing the standard anti-TB drug (ATD) regimen, as was demonstrated by the case reported here. A diverse spectrum of symptoms can arise during pancreatic TB, ranging from abdominal discomfort, obstructive jaundice, fever, loss of appetite or nausea, to night sweats and weight loss[3,4]. Imaging of the pancreas by ultrasound or CT has demonstrated that pancreatic TB can mimic a pancreatic neoplasm[4-6]. When this is the case, pancreatic head carcinoma must also be considered during the operation. We report the present case to emphasize alternate, though more rare, causes of pancreatic masses and obstructive

jaundice.

According to the literature, endoscopic ultrasound-guided fine needle aspiration biopsy (FNAB) and a PCR-based approach are recommended for pancreatic TB diagnosis[7-9]. However, FNAB is not always employed due to the increased risk for pancreatitis and tumor dissemination. Thus, an operation with an incisional biopsy represents a more specific diagnostic modality and an effective therapy for pancreatic abscesses. Current literature also promotes the use of standard ATD therapy for six to twelve months as an effective strategy to treat pancreatic TB in a majority of cases[1,2,7,10]. As pancreatic TB can occur during treatment, however, ATD may be an insufficient therapy for patients. In the present case, we feel that an operation accompanied by cholecystostomy tube placement aided in treating the patient.

In conclusion, the case report emphasizes a rare cause of pancreatic mass and obstructive jaundice, and shows that an operation and tube cholecystostomy in combination with ATD therapy are an effective treatment for pancreatic TB.

## COMMENTS

### Case characteristics

A 40-year-old male patient with a history of thoracic tuberculosis (TB) presented with epigastralgia and jaundice while receiving anti-TB therapy.

### Clinical diagnosis

An abdominal examination revealed sensitivity in the upper abdomen without hepatosplenomegaly or ascites.

### Differential diagnosis

Pancreatic carcinoma and pancreatitis.

### Laboratory diagnosis

The following laboratory results were obtained: 9.75 × $10^9$ white blood cells/L; 30.5 μmol/L total bilirubin; 24.5 μmol/L direct bilirubin; 135 U/L alanine aminotransferase; 64 U/L aspartate aminotransferase; 715 U/L gamma glutamyl transpeptidase; 335U/L alkaline phosphatase; 66.84 U/mL carbohydrate antigen 199.

### Imaging diagnosis

Computed tomography revealed a necrotic and calcified cystic lesion in the head of the pancreas that measured 5.6 cm × 4.2 cm and resembled a pancreatic malignancy.

### Pathological diagnosis

Biopsies of the lymph nodes and mass revealed caseous granulomatous inflammation and necrosis with acid-fast bacilli; a polymerase chain reaction-based approach confirmed the presence of *Mycobacterium tuberculosis* DNA.

### Treatment

After surgery, the patient was administered the standard anti-TB regimen of isoniazid, rifampicin, pyrazinamide, and ethambutol for nine months followed by a regimen of isoniazid, rifampicin, and pyrazinamide for an additional six months.

### Related reports

TB is most often observed as necrotic granulomas within the lungs. Extrapulmonary TB, however, accounts for approximately 10%-30% of all cases and more than 5% of patients have abdominal involvement. In the abdominal cavity, TB predominantly affects the peritoneum, gastrointestinal tract (especially the ileum and cecum), liver, spleen, and lymph nodes. Pancreatic TB is extremely rare, likely due to resistance provided by pancreatic enzymes, and may occur as a result of bacterial dissemination from lymph nodes in the area. Pancreatic TB is often confused with pancreatic malignancy in clinical and radiological examinations.

### Term explanation

TB is a disease caused by *Mycobacterium tuberculosis* bacteria. While the bacteria predominantly affect the lungs, they can also damage other parts of the body. Pancreatic TB occurs when these bacteria affect the pancreas. Pancreatic TB is extremely rare and can mimic a carcinoma, lymphoma or cystic neoplasia.

### Experiences and lessons

This case report highlights pancreatic TB as a rare cause of pancreatic masses and obstructive jaundice that can mimic pancreatic head carcinoma and be treated *via* tube cholecystostomy in combination with anti-TB therapy.

### Peer review

This article presented with the case report of a pancreatic TB which mimicking pancreatic head carcinoma in an immunocompetent host. After anti-tuberculin therapy, the patient recovered soon. This report is interesting and informative that provides useful information of rare disease as a cause of pancreatic masses and obstructive jaundice.

## Abstract

Pneumomediastinum, pneumorachis and subcutaneous emphysema are frequently benign and most commonly result from air escaping from the upper respiratory tract, intrathoracic airways, or gastrointestinal tract. Gas can also be generated by certain infections or reach the mediastinal space from outside air after trauma or surgery. In the article presented by Showkat *et al* a 14-year-old male patient with acute lymphoblastic leukemia (ALL) under chemotherapy developed pneumomediastinum, pneumorachis and subcutaneous emphysema. In the author's opinion, these complications were caused by ALL or chemotherapy that progressed to severe respiratory failure until the patient finally died in the intensive care unit. I would like to underline some important points, which have been raised following a paper published in the October issue of World Journal of Clinical Cases.

**Key words:** Acute lymphoblastic leukemia; Pneumomediastinum; Pneumorachis; Chemotherapy; Case report

**Core tip:** In the article presented by Showkat *et al*, the authors reported a 14-year-old male with acute lymphoblastic leukemia (ALL) under chemotherapy who developed pneumomediastinum, pneumorachis and subcutaneous emphysema, apparently caused by ALL or chemotherapy in the author's opinion, and eventually died.

Cruz-Portelles A. Pneumomediastinum after acute lymphoblastic leukemia and chemotherapy? *World J Clin Cases* 2014; 2(5): 170-171 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i5/170.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i5.170

## TO THE EDITOR

I read with interest the article presented by Showkat *et al*[1], where the authors reported a 14-year-old male under chemotherapy for acute lymphoblastic leukemia (ALL) who developed pneumomediastinum, pneumorachis and subcutaneous emphysema of apparently unknown origin. In this case, the doctors assumed that the cause was chemotherapy or ALL, but there are some points I would like to consider.

Pneumomediastinum or mediastinal emphysema is characterized by the entry of air or other gas into the mediastinum most commonly resulting from air escaping from the upper respiratory tract, intrathoracic airways, or gastrointestinal tract. Gas can also be generated by certain infections or reach the mediastinal space from outside air after trauma or surgery (Table 1)[2].

This particular patient could have been suffering from an idiopathic cause of pneumomediastinum (Hamman's syndrome)[3], and there are different processes that can explain this condition apart from ALL or chemotherapy: (1) patients who receive chemotherapy frequently vomit and this is a recognized cause of pneumomediastinum; and (2) pneumomediastinum *per se* is frequently benign but oxygenation in this patient was progressively deteriorating. What was the etiology of his respiratory arrest?

**Table 1 Etiology of pneumomediastinum**

| |
|---|
| Upper respiratory tract |
| Head and neck infections |
| Facial bone fractures |
| Dental procedures |
| Mucosal disruption |
| Tracheotomy |
| Lower respiratory airways |
| Chest trauma |
| Foreign body |
| Neoplasm |
| Alveolar rupture: trauma, biopsy, surgery, pleurotomy |
| Wind instrument playing |
| Scuba diving |
| Mechanical ventilation |
| Gastrointestinal tract |
| Pneumoperitoneum |
| Pneumoretroperitoneum |
| Esophageal perforation (*e.g.*, Boerhaave's syndrome) |
| Gas producing germs infection |
| Bacterial mediastinitis |
| Head and neck infections |
| Marijuana smoking and cocaine inhalation |
| Vomiting |
| Seizures |
| Coughing, sneezing, hiccupping |
| Heavy lifting |
| Air travel |
| Heimlich maneuver |

Did he develop a tension pneumothorax that could explain the respiratory arrest and the deteriorating respiratory condition? What happened while the patient was in the intensive care unit? What was the cause of death in this patient?

Pneumothorax in the supine patient may be difficult to diagnose and must be considered or it will be missed. Occasionally, tension pneumomediastinum may occur, although this is usually of greater clinical likelihood in pediatric patients. Concomitant pulmonary interstitial emphysema will result in further respiratory embarrassment secondary to compression of lung parenchyma by interstitial air, and decreases in both ventilation and perfusion, especially after mechanical ventilation. Tension pneumopericardium could complicate the presentation and impair venous return and cardiac function[4]. Air embolism or pneumocephalus are infrequent but could be ruled out[4,5]. No computed tomography scans or X-rays were mentioned later in the evaluation. Different investigations are not clear in this case that could help in the diagnosis.

In my opinion, chemotherapy or ALL *per se* does not explain the mechanism of production of pneumomediastinum, pneumorachis or subcutaneous emphysema. This association was possibly a coexisting condition instead of a complication of ALL or chemotherapy as the authors affirm. Unfortunately, there was no autopsy to establish the final diagnosis.

## Abstract

Human papillomavirus (HPV) has been implicated in the pathogenesis of a subset of oropharyngeal squamous cell carcinoma. As a result, traditional paradigms in relation to the management of head and neck squamous cell carcinoma have been changing. Research into HPV-related oropharyngeal squamous cell carcinoma is rapidly expanding, however many molecular pathological and clinical aspects of the role of HPV remain uncertain and are the subject of ongoing investigation. A detailed search of the literature pertaining to HPV-related oropharyngeal squamous cell carcinoma was performed and information on the topic was gathered. In this article, we present an extensive review of the current literature on the role of HPV in oropharyngeal squamous cell carcinoma, particularly in relation to epidemiology, risk factors, carcinogenesis, biomarkers and clinical implications. HPV has been established as a causative agent in oropharyngeal squamous cell carcinoma and biologically active HPV can act as a prognosticator with better overall survival than HPV-negative tumours. A distinct group of younger patients with limited tobacco and alcohol exposure have emerged as characteristic of this HPV-related subset of squamous cell carcinoma of the head and neck. However, the exact molecular mechanisms of carcinogenesis are not completely understood and further studies are needed to assist development of optimal prevention and treatment modalities.

**Key words:** Human papillomavirus; Human papillomavirus; Oropharynx; Oropharyngeal; Squamous cell carcinoma; Head and neck; Oncology

**Core tip:** Human papillomavirus has been accepted as a causative agent in a subset of head and neck squamous cell carcinoma (SCC), particularly of the tonsils and base of tongue. Importantly, there is an increasing incidence of this subset of patients, who demonstrate improved prognosis and may respond more favourably to treatment. Similarities and differences are evident between cervical and oropharyngeal human papillomavirus-related SCCs and the comparison between these tumours warrants further investigation to better understand the disease process.

Woods RSR, O'Regan EM, Kennedy S, Martin C, O'Leary JJ, Timon C. Role of human papillomavirus in oropharyngeal squamous cell carcinoma: A review. *World J Clin Cases* 2014; 2(6): 172-193 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/172.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.172

## INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) is

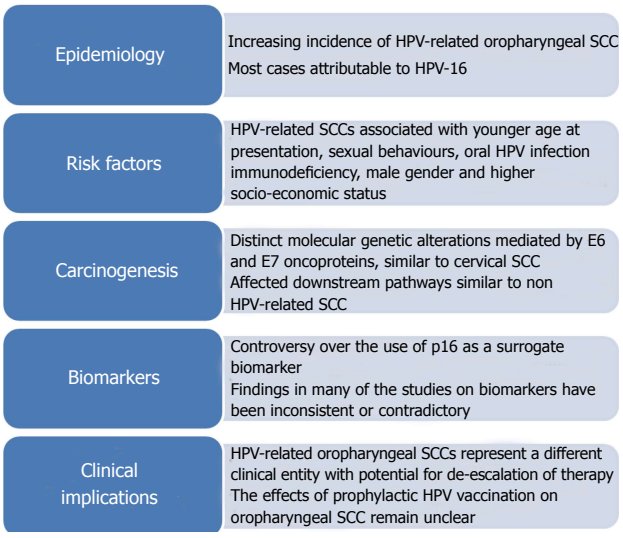

**Figure 1 Summary of key points.** HPV: Human papillomavirus; SCC: Squamous cell carcinoma.

the sixth most common type of cancer worldwide with approximately 633000 new cases diagnosed and 355000 deaths annually[1]. Over the past 10-15 years, the traditional paradigms of HNSCC have been changing significantly. It has emerged as a heterogeneous group of diseases, with distinct molecular genetic changes[2,3].

Human papillomavirus (HPV) has been linked to the pathogenesis of squamous cell carcinoma (SCC) since the 1970s[4] and, in 1995, it was recognised by the International Agency for Research on Cancer (IARC) that high risk HPV types 16 and 18 were carcinogenic in humans[5]. The role of HPV in cervical cancer is well described[6], however high risk HPV types are also linked with other ano-genital tumours and with SCCs of the head and neck[7,8], as well as potentially playing a role in cutaneous SCCs[9]. HPV accounts for roughly 4.8%-5.2% of the total global cancer burden, making it the highest among all viruses[10,11].

Since it was first suggested in 1983[12] and first identified in 1985[13], HPV infection has been increasingly recognized as a major aetiologic factor for HNSCCs, particularly a subset that arise from the oropharynx, mostly the base of tongue and palatine tonsils[14-16]. This subset is seen as a distinct clinicopathological entity in comparison to the traditional smoking and alcohol related HNSCCs[16-20]. Specific genetic changes induced through HPV E6 and E7 protein expression define this subset[21-23]. In contrast, tobacco associated HNSCCs are usually more genetically diverse[24]. HPV-related tumours of the oropharynx display specificity of HPV to the tumour cell nuclei[16], integration of HPV DNA into the host cell[16,25] and high viral copy numbers[26], giving evidence for the functional role of HPV in the pathogenesis of these tumours.

HPV-related SCC tends to display unique histology characterized by poorly differentiated, non-keratinising morphology with a basaloid appearance[17,27]. Nevertheless, even some true basaloid squamous cell carcinomas of the oropharynx have demonstrated HPV-positivity[28], and other variants such as papillary SCC, adenosquamous carcinoma, lymphoepithelial carcinoma-like tumours and small cell carcinoma have been associated with HPV infection[29-34].

It is estimated that the probability of a cancer of the oropharynx being attributable to HPV is five times higher than the oral cavity, larynx or hypopharynx[35], with HPV-related oropharyngeal SCC being described as an epidemic[36-40]. Current data from studies that assessed in situ hybridization or HPV E6/E7 mRNA suggest that HPV-related HNSCC is rare in the oral cavity, larynx, hypopharynx and other HNSCC sites[35], however the role of HPV in non-oropharyngeal sites remains unclear[41] and a causative relationship at these sites has not been established[42].

We review the current literature regarding HPV-related oropharyngeal tumours with regard to epidemiology, risk factors, carcinogenesis, biomarkers and clinical implications. A summary is shown in Figure 1.

## HUMAN PAPILLOMAVIRIDIAE

HPV is an epitheliotropic, non-enveloped DNA virus measuring approximately 55 nm in diameter, and carries a single molecule of circular double-stranded DNA, consisting of approximately 8000 base pairs[43]. The genome is broken down into three regions which consist of a long control region (LCR), an early (E) region and a late (L) region. There are eight genes in the E region and two in the L region. These genes in E and L encode viral proteins while LCR is an upstream non-coding regulatory region containing the origin of viral DNA replication and transcriptional regulatory elements.

At present, over 200 different genotypes of papillomaviridiae, characterized by at least 10% nucleotide divergence in capsid gene (*L1*)[44], have been identified by various techniques[45]. These can be classified according to similarities in their DNA sequences. They have also been grouped into mucosal (mostly of the alpha genus) or cutaneous (mostly of the beta genus) types based on their tropism for specific epithelia and they can be classified into low and high risk types based on their capacity to promote malignant transformation in host cells. Of these, HPV 16, 18, 31, 33, 34, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 73 and 82 are examples of those classified as high risk viruses, detectable in high grade squamous intraepithelial lesions in the cervix or in invasive cancer; while HPV 6, 11, 40, 42, 43, 44, 54, 61, 72, 81, and 89 can be considered as viruses with low oncogenic risk and can be isolated from low grade epithelial lesions of the cervix. There remain a number of HPV types that are potentially high risk with an unknown oncogenic potential. There exists some degree of intratypic variation[46,47], which may also relate to pathogenesis[48-50], as well as geographic variation in genotype prevalence[46,51].

HPV is one of the most powerful human carcinogens. The E6 and E7 genes produce E6 and E7 oncoproteins,

which confer the virus with oncogenic potential through their inhibitory effects on p53 and retinoblastoma (Rb) proteins, more of which is discussed later.

## EPIDEMIOLOGY

HNSCC includes tumours from a number of subsites, of which the oropharynx accounts for approximately 10%[52]. Worldwide, there were an estimated 85000 new cases of oropharyngeal SCC in 2008, of which 25.6% (22000) were estimated to be HPV-related[53]. Of the HPV-related cases, more than three quarters (17000) were estimated to be male.

Genotypes of oncogenic HPV found in cervical cancer in order of prevalence are 16, 18, 58, 33, 45, 31, 52, 35, 59, 39, 51 and 56[54]. However, the distribution of HPV types differs somewhat in oropharyngeal when compared to cervical cancers[55]. A systematic review found that HPV-16 was present in 95.7% of HPV-related oropharyngeal SCC, but only 73.9% of HPV-positive non-oropharyngeal HNSCCs[56], while only approximately 61% of cervical cancer display HPV-16[57]. While a significant number of other oncogenic HPV types are found in cervical cancer, only a small proportion of oropharyngeal cancers may be caused by additional HPV types such as 18, 31, 33, 35, 52 and 58[58,59]. HPV-16 is the commonest genotype found in oral cavity infection[60], while it constitutes over 90% of the genotype distribution in tonsil cancers[61].

Prevalence of oral high risk HPV infection in the general population is reported at 3.5%-3.7%[62,63], with higher rates for those also infected with HIV[64]. A systematic review of the literature in 2005 reported detection of HPV DNA in 35.6% of oropharyngeal tumours[65]. However, there exists a wide geographic variation, with a reported prevalence as high as 72%[59] in North America compared to 17% in southern Europe[53], 12.6% in Taiwan[66] and even as low as 4.4% reported in central Europe and Latin America[67]. Some of these figures are based on the assumption that detection of high-risk HPV DNA in tumour tissue signifies cancer attributable to HPV, however this does not delineate from the effects of tobacco exposure and alcohol in these cases. It has been recorded that HPV accounts for approximately 7.7% and 2.2% of all cancer cases in developing and developed countries, respectively[10]. The variations could partly be explained by geographic and temporal heterogeneity in sexual behaviours and tobacco exposure[41]. A more recent systematic review in 2012 reported a prevalence of HPV in oropharyngeal SCC of 59.9% in the United States, compared to 39.7% in Europe and 32.5% in the rest of the world[56]. There are limited data from less developed regions, but the incidence appears much lower.

Despite the variation in prevalence, case control studies conducted around the world show strong and consistent associations of markers of HPV exposure with risk of oropharyngeal cancers, even after adjustment for important HNSCC risk factors such as age, gender and tobacco and alcohol use[41].

While incidence of other HNSCCs has decreased over the past two decades, correlating with decreased tobacco use, the age-adjusted incidence of oropharyngeal SCC has been increasing in this same period[68,69], particularly of the base of tongue and tonsil region[70]. Meanwhile the population-level incidence of HPV positive oropharyngeal SCC increased by 225% between 1988 and 2004, with a concomitant decline by 50% for HPV-negative oropharyngeal SCC[59]. A particularly steep rise of over 70% has been reported for prevalence of HPV-related oropharyngeal SCC in the past decade, with prevalence in Europe increasing at a faster rate than North America[56]. This rise further emphasises the predilection of HPV for the oropharynx and suggests that it plays a less significant role in other HNSCCs.

With the rise in HPV-related oropharyngeal SCC coupled with the decline of HPV-related cervical SCC, it has been suggested that the annual numbers of HPV-related oropharyngeal cases could soon surpass that of cervical cancer[41].

## RISK FACTORS

HNSCCs, including those of the oropharynx, have traditionally been strongly associated with patients who have a long history of heavy smoking and alcohol consumption, with previous studies clearly showing a dose-response relationship with the frequency and duration of tobacco and alcohol exposure[71]. Age of onset is generally in an older age group (usually seventh decade) in these traditional HPV-negative oropharyngeal SCCs. Other risk factor associations with these tumours include poor oral hygiene[72,73], a diet low in fruit and vegetable consumption[74,75] and chronic inflammatory disease in the oral cavity[76-78].

### *Age*

The distinct subset of HPV-positive oropharyngeal SCCs generally present at a younger age, averaging a few years lower than HPV-negative tumours[39]. Although phenotypically similar to those in older patients, HNSSCs developing in younger patients are undoubtedly different at a genetic level with both germline and somatic differences seen[3,79-82]. One study showed that patients under 55 had a 3.4-fold higher risk of infection with carcinogenic HPV[83], while a strong association has been demonstrated with HPV-16 infection and tonsillar cancer in males under 40 years old[84]. Increasing incidence of oropharyngeal SCC is seen in those aged under 60[85], with a particularly steep rise seen between the ages of 50-59[86], although it is possible this may be due to other risk factor exposures in this birth cohort.

### *Sexual behaviours*

HPV-related oropharyngeal SCCs also show strong associations with sexual behaviours, correlating with disease[87]. In a large number of studies, both HPV-positive

HNSCCs and oropharyngeal SCCs have been strongly associated in comparison to other HNSCCs with number of lifetime sexual partners, number of vaginal, oral and anal sexual partners, young age at first intercourse/earlier sexual contact and history of sexually transmitted diseases, including genital warts[27,83,87-93]. After adjusting for HPV-16 serology, the associations in a case-control series were no longer significant, suggesting that sexual behaviours can be seen as a surrogate for HPV-16 exposure[27].

Data from a number of developed countries show that markers of high-risk sexual behaviours, such as earlier ages of sexual debut, practice of premarital sex, average number of lifetime partners, and practice of oral sex, have all increased among recent birth cohorts[94].

### Oral HPV infection

Oral HPV is predominantly acquired *via* sexual transmission and oral HPV prevalence has been associated with some of the above sexual behaviours. Studies have demonstrated increased HPV acquisition around sexual debut with oral HPV prevalence of 1.5% in 12-15 year olds, 3.3% in 16-20 year olds and 4.5%-6.9% in healthy adults[62,63,89,95]. Higher oral HPV prevalence has been reported in women with cervical HPV infection[96,97], and people infected with Human Immunodeficiency Virus (HIV)[96,98]. Several studies and some case reports have described concordant oral HPV infection between couples[99-102], however preliminary results from the HPV oral transmission study in partners over time (HOTSPOT) have not backed up these findings.

It has even been suggested that non-sexual HPV transmission through kissing may be possible[95,103], as well as intrapartum transmission[104] and transmission during laser surgery[105]. In itself, oral HPV-16 infection is a strong risk factor for oropharyngeal cancer, while the relationship is not necessarily clear for oral SCCs[106,107]. However, oral HPV prevalence is lower than cervical, perhaps explained by a lower proportion in oral-genital than genital-genital partners[55], but the natural history of HPV infection in the oral cavity appears similar to cervical infections[108]. Although type-specific concordance is low, HPV infection of the cervix and oral cavity are not independent[109] and so cervical HPV infection could be considered a risk factor for oral cavity HPV infection. Although the full natural history of HPV infection in the oral cavity and oropharynx is not entirely understood, there is an estimated incidence of 4.4% per year with most infections being cleared within one year[110]. However, changing sexual practices are potentially leading to higher rates of infection that could become recalcitrant to immune responses.

### Tobacco and alcohol exposure

Evidence of a role for tobacco exposure and alcohol use in HPV-related oropharyngeal SCCs and in oral HPV infection is equivocal, with some studies reporting positive association and suggesting smoking-induced immunosuppression or potentiation of carcinogenesis could play a role, while others report no association[41]. A role for tobacco smoking in cervical cancer, however, has been demonstrated, although this association becomes weak after adjustment for sexual and reproductive factors[111]. In comparison to traditional HNSCCs, these patients are less likely to have excessive tobacco exposure and alcohol use[16,88,112], however HPV-related oropharyngeal SCCs do occur in both in those with tobacco exposure and alcohol use and in those without. It is highly plausible that tobacco exposure potentiates the effects of HPV carcinogenesis[113] but a role in the causation of HPV-related oropharyngeal SCCs has not been definitively determined from available evidence[35]. Marijuana use has also been associated with oropharyngeal SCCs[87,114], however after adjustment for sexual behaviour variables in one study, this disappeared[62].

### Gender

Both HPV-related and non HPV-related HNSCC exhibit male predominance at a ratio of approximately 3:1. In tobacco and alcohol related HNSCC, this difference has decreased particularly as trends in smoking have changed, with 43% of men and 30% of women smoking in 1974 compared to 26% of men and 21% of women in 2000[115]. Nonetheless, the difference still remains for HPV-related HNSCC and the reason for this is uncertain. The male predominance exhibited cannot be fully explained by difference in sexual behaviours, which suggests potential biologic differences between men and women[41,116], or that some male characteristic preferentially predisposes to cancer of the oropharynx[117]. It has been suggested that hormonal differences[55,118] or the potential protective immunity from seroconversion in response to cervical HPV infections among women[119,120] may play a role. Although not all studies agree[63], the majority of studies report that oral HPV infection is more common in men than women[62,121,122]. It has also been suggested that transmissibility of oral HPV may be higher for men performing oral sex on women, possibly due to a higher HPV copy number in the vagina/cervix[94].

### Immunodeficiency

Immunodeficiency is a risk factor for a large number of tumours and HPV-related oropharyngeal SCC is included in that. For example, it is reported that patients infected with human immunodeficiency virus (HIV) have a 2-6 times increased risk of HPV-related HNSCC[123,124], although they are at greater risk of ano-genital SCCs than oropharyngeal[125]. It has been demonstrated in cervical cancer patients that immunosuppression leads to HPV persistence and disease progression[126-128]. The association of a deficient immune system with increased HPV-related HNSCC may partly explain any potential association with tobacco exposure due to the immunosuppressive effects of smoking[129], with one paper demonstrating a reduced antibody response in smokers[130].

### Socio-economic status

HNSCCs have been associated with patients from a low socio-economic group for many years[131]. However, HPV-

related oropharyngeal SCCs are associated with patients who are from a higher socio-economic group and who have a better performance status[132,133], although this has been refuted in one study[116]. Nonetheless, white males seem to be particularly at risk, with a rise in incidence reported in this group alone[59,85,116]. HPV positivity in oropharyngeal cancer is lower in African Americans than in other racial groups, with poorer survival in this racial group from oropharyngeal SCC, because a higher proportion is related to tobacco and alcohol exposure[134,135].

### *HPV serology*

There is a strong association between serologic evidence of HPV infection and HNSCC risk, even after adjustment for other HNSCC risk factors[106]. One study has even shown a temporal association, with pre-diagnostic serum samples from ten years prior that were positive for HPV-16 capsid antibodies conferring an increased risk of oropharyngeal SCC of 14.4[136], while patients with pre-diagnostic E6 seropositivity had a significantly higher risk of oropharyngeal cancer in another study[137].

It is evident that a number of factors can facilitate or increase the risk of HPV-related oropharyngeal SCCs. This includes oral HPV infection, male gender, younger age, white race, immunosuppression and a variety of sexual behaviours. Differences in sexual behaviours across age and gender and consequent HPV exposure risk could account for the rapidly increasing incidence of HPV-related oropharyngeal SCCs among younger patients. Interestingly a separate specific subgroup of younger females with non HPV-related oral cavity SCCs has also been identified[138].

## CARCINOGENESIS

The model for development of SCC involves exposure to carcinogens over time leading to progressive genetic and epigenetic changes that accumulate and lead to premalignant and eventually malignant lesions. However, HNSCC is a heterogeneous disease with a number of subtypes described, based on histological appearance, and supported by different gene expression profiles[139,140]. Squamous cell carcinomas from different sites in the body share a number of molecular characteristics but recent whole-exome sequencing[141-144] has helped to characterise the specific molecular pathogenesis of HNSCC with roles identified for tumour suppressor pathways including p53, Rb/INK4/ARF and NOTCH[145]. A role for cancer stem cells in HNSCC is likely, based on recent evidence[146-149], and further study of these progenitor cells will help to elucidate mechanisms of carcinogenesis.

Recent deep-sequencing studies on the HNSCC oncogenome have demonstrated a vast number of diverse genetic alterations, however most of these converge on four targetable molecular pathways[150]; mitogenic signalling and in particular amplification or up-regulation of epidermal growth factor receptor (EGFR) and the downstream pathway of phosphoinositide 3-kinase (PI3K)/mTOR as well as PTEN inactivation, each leading to pathways involving proliferation, DNA repair, survival and spread; defective differentiation involving NOTCH signalling alterations; cell cycle de-regulation involving inactivation of CDKN2A (encoding p16 INK4A ) tumour suppressor gene and CCND1 (encoding CYCLIN D1) amplification; genomic instability involving loss of TP53, which occurs in a large percentage of non HPV-related HNSCC and is the single most common mutational event, and other genes related to DNA damage recognition and repair. It is possible that smoking and alcohol affect distinct genes[151], giving further evidence for a synergistic effect of tobacco and alcohol exposure in relation to HNSCC carcinogenesis.

HNSCC usually displays field cancerisation, a term first coined in 1953[152], whereby specific genetic alterations can be widely distributed throughout the mucosa lining the aerodigestive tract even in the absence of overt histopathologic changes of malignancy[25]. Only a minority of precancerous fields in the oral cavity are recognised as leukoplakia or erythroplakia[153] and only 6%-36% of patients with leukoplakia or erythroplakia go on to develop oral SCC[154], particularly those demonstrating aneuploidy[155,156]. The accumulation of further genetic changes in precancerous fields leads to the development of SCC, with presence of field change leading to a higher risk of multiple synchronous or metachronous primary tumours. Exposure to carcinogens bring about these field changes, however evidence for a field effect is lacking for HPV-related SCC[157] and the risk of second primary malignancy in oropharyngeal SCC has markedly decreased over time[158], with the mutation rate of HPV-positive tumours only approximately half of that found in HPV-negative HNSCC[141,142].

Specific differences in chromosomal alteration and gene transcription have been identified between HPV and non HPV-related HNSCCs[21,22,159,160]. TP53 mutations, loss of 9p21, hypermethylation of 14-3-3σ and RASSF1A promoters and overexpression of cyclin D are all common in non HPV-related oropharyngeal SCCs, while pRb levels are normal and p16 is often decreased[161,162].

In the cervix, after initial infection at the transformation zone, viral genomes are maintained as episomes in the basal layer, with viral gene expression being tightly controlled as the infected cells move toward the epithelial surface[163]. Subsequent high-grade neoplasia represents an abortive infection in which viral gene expression becomes deregulated and the normal life cycle of the virus cannot be completed. The squamous epithelium in the cervix and the head and neck derive embryologically from endoderm and are susceptible to metaplasia[164]. In the head and neck, there is a predilection for HPV-positive tumours to occur in the reticular crypt epithelium of palatine and lingual tonsils and head and neck sites with mucosa associated lymphoid tissue[25,165,166]. It is possible that this occurs due to the particular microanatomy of the crypts, where there are breaks in the non-keratinising squamous epithelium that could allow viral entry, while a microabrasion theory of entry to basal cells at other head and neck sites has been proposed. Entry may be facilitat-

ed by M-cells lining the crypt epithelium[167], as with other viruses[168,169]. Another theory postulated is an influence on HPV carcinogenesis from increased cytokines related to nearby lymphoid tissue[170]. The recent observation of a distinct set of embryonic cells at the squamocolumnar junction of the cervix, which seem to confer a particularly high risk of malignancy, has led to a "top-down" theory of malignancy at this site, although it remains to be seen if this model translates to the oropharynx[171-173]. Despite being full of lymphatic tissue, the tonsils are known to harbour pathogenic viruses such as Epstein Barr virus, adenoviruses and herpes simplex virus[174], and it is the mechanisms of immune evasion that allow persistent infection and carcinogenic potential at these sites, hence immunosuppressed individuals are particularly at risk.

From cervical models, we understand that most HPV infections last no more than a few months and are eliminated by the immune response, with 90% of infections cleared within two years, although high risk HPV tends to persist longer than low risk[175,176]. Once immune evasion is established, integration of HPV DNA into the cellular genome likely represents a critical step for malignant transformation in those individuals who harbour HPV in their tonsils[25], with HPV integration representing a stochastic process resulting in clonal selection of aggressively expanding cells that display altered gene expression of integrated HPV genomes and potential perturbations of cellular genes at or near viral integration sites[177]. Viral integration can also lead to loss of E2-mediated inhibition of viral oncoprotein expression[178]. Furthermore, it has been shown that this HPV DNA integration is consistently centred on tonsil crypt epithelium[25], however the factors allowing transformation from episomal HPV infection, whether active or latent, to DNA integration remain poorly understood. It has also been noted that much of the HPV that is detected in oropharyngeal cancers seems to be episomal.

Based on cervical cancer models, high-risk HPV can induce genetic changes in a small number of those with persistent infection which leads to precancerous lesions, a fraction of whom will develop cancer many years after the original infection. While HPV-related precursor lesions in the oral cavity have been identified[179], there is an absence of detectable precancerous lesions in the oropharynx[41], perhaps related to the difficulty in assessing and sampling deep tonsillar crypts, the predominant location of HPV-related SCCs[180,181]. Nevertheless, HPV-related oropharyngeal SCCs present with distinct molecular profiles, more comparable to cervical SCC than to non HPV-related HNSCC[55]. Infection with HPV is likely an early oncogenic event in HNSCCs. The viral oncoproteins E6 (151 amino acids) and E7 (98 amino acids) of high risk HPV types, particularly HPV-16, are implicated as the drivers of transformation in HPV-related oropharyngeal SCCs[182]. These proteins help to re-program postmitotic terminally differentiated epithelial cells to re-enter the cell cycle and express proteins that are required for viral genome replication[183]. They also disrupt a number of cellular mechanisms through a wide variety of downstream effects.

The E5 oncoprotein co-operates with E6 and E7 to promote proliferation of infected cells and is likely to facilitate malignant progression[184], although this process is likely to take place in the early stages of carcinogenesis because viral integration frequently leads to loss of E5 gene expression[185]. Transcription of E6 and E7 viral oncogenes can occur when the virus is episomal however, in cervical SCC, alteration of E2 on integration may facilitate increased expression of E6 and E7 oncogenes, although this may not be the case in oropharyngeal SCC[186]. Viral integration is thought to play an important role in cervical SCC but the relevance of viral integration is not fully clear in oropharyngeal SCC[187]. Some studies suggest that viral integration in the tonsillar crypts plays an important role in carcinogenesis[165,188], which may explain the predilection of HPV-related HNSCCs at this site, while other studies suggest that episomal HPV alone contributes to the development of most oropharyngeal SCCs in contrast to SCCs of the cervix[186,187].

In cervical lesions, it is not possible to predict tumour progression based on HPV viral load[189]. It has been suggested that high HPV viral load (at least one HPV copy per tumour cell) in oropharyngeal SCC predicts active HPV infection[190-192]. The proportion of HPV-positive SCCs with high viral load varies between studies from 33%-77.5%[59,190]. It is possible that in cases of low viral load that HPV presence is coincidental and alternative mechanisms of carcinogenesis are implicated. However, gene expression varies widely and so a constitutive rather than a high expression of viral oncogenes may be all that is required for HPV-related oropharyngeal carcinogenesis[187].

The major role of E6 oncoprotein is induction of ubiquitin-mediated proteolysis, through E6 associated protein, leading to degradation of tumour suppressor p53. As p53 usually facilitates repair to damaged host DNA by arresting cells in the G1 phase (or else inducing apoptosis), E6 expressing cells face increased mitotic stress and genomic instability[193]. E6 aids cellular proliferation by up-regulating transcription of telomerase[194] and also, through the presence of the PDZ binding motif, high risk HPV E6 proteins bind to a number of PDZ domain containing proteins with presumed tumour suppressor activity that have diverse functions[183,195]. E6 also targets the Wnt and Notch signalling pathways[183].

The E7 oncoprotein causes cell cycle disruption by binding and inactivating tumour suppressor proteins of the retinoblastoma family (pRb) that regulate cellular senescence. E7 thereby causes cell proliferation through abnormal entry into the S-phase by the overexpression of released transcription factor E2F[196]. This functional inactivation of pRB also results in overexpression of p16 tumour suppressor protein, which is a CDK4A inhibitor, allowing the use of p16 as a surrogate marker for HPV-related oncogenesis[39,197-200], which will be discussed further below. E7 proteins also alter cell cycle control through interactions with histone deacetylases, cyclins

and cyclin-dependent kinase inhibitors[201].

Animal models suggest that E7 is the dominant HPV oncoprotein in HNSCC[202], but both E6 and E7 directly impact upon a number of apoptotic mechanisms; interaction with extracellular matrix adherence proteins to allow anchorage independent growth; interaction with cell surface receptors to resist cytokine induced extrinsic apoptosis; and interaction with proteins involved in interferon signalling and interleukin to allow immune evasion[201,203].

Genomic instability underpins the development of dysplasia, malignancy, invasion, and metastasis in cancers[204]. While aberrant proliferation induced by E7 is facilitated by suppression of apoptosis by E6 mechanisms, it is the additional functions of E6 and E7 to induce genomic instability by multiple mechanisms that lead to chromosomal mutations. These include centrosome abnormalities or spindle checkpoint failure leading to polyploidy, aneuploidy and chromosomal rearrangement[205,206], direct DNA damage[207] (which also occurs with viral integration[208]), variation in the Fanconi anaemia DNA repair pathway and induction of the ATM-ATR DNA damage repair pathway with concomitant disruption of checkpoint control mechanisms[201]. Tobacco exposure also causes genomic instability and so may help to induce malignancy on the background of E6 and E7 effects, allowing for a role of tobacco exposure in the potentiation of HPV-related HNSCC, which has been suggested from mouse models[209].

Different patterns of DNA methylation have been demonstrated between HPV and non HPV-related HNSCCs, with methylation patterns in HPV-related HNSCCs more analogous to cervical SCC patterns than non HPV-related HNSCCs[210]. Excess DNA methylation could be recruited by the integrated viral genome rendering it invisible to host immune responses or it could be an attempted defence mechanism by the host cell[210]. HPV-related HNSCCs also have a distinct miRNA profile, also more analogous to cervical SCCs, in comparison with non HPV-related HNSCCs[211]. Furthermore, differences in DNA methylation rate have been identified between HNSCCs in tobacco users versus nonusers as well as specific mRNA and microRNA clusters[212].

While distinct methods of carcinogenesis are evident between HPV-related and non HPV-related HNSCCs, the effects on downstream pathways are often the same, such as in the case of mTOR inhibition, either from TP53 mutations in tobacco related cases or from E6 induced degradation of p53 in HPV-related cases[150]. It is also important to note that E6 and E7 proteins expressed in low risk HPV types do not induce the same changes and that HPV present in some HNSCCs may exist as a latent passenger virus with no transcriptional activity[213,214]. New roles for HPV oncoproteins are continually being identified, offering many future potential therapeutic targets[215]. In any case, there is a distinct group of HPV-related tumours arising from the epithelium of lymphoid tissue characterised by viral oncoprotein expression, rather than SCCs that arise on a background of a long history of somatic mutations due to carcinogenic exposures. A proposed model of carcinogenesis in HPV-related oropharyngeal SCC is shown in Figure 2.

## BIOMARKERS

Studies have had difficulty identifying clinically useful biomarkers in HNSCC[216]. A high degree of heterogeneity is evident in HNSCC, with different prognosis described for different subsets of tumours. This includes a favourable prognosis for the growing cohort of HPV-related SCCs, particularly oropharyngeal[217], often despite a more advanced presentation. This is due to a number of factors including the sensitivity of this subset to chemoradiation[133], the lower likelihood of loco-regional recurrence[217] and a younger cohort of patients with fewer comorbidities as well as a possible decreased risk of second primary tumours.

HPV status and p16 status have each proven useful as biomarkers in HNSCC. The tumour suppressor p16 binds to the cyclin D1 CDK4/CDK6 complex, thereby helping to keep the Rb protein in its active hypophosphorylated form. With pRb functionally inactivated by the binding of HPV E7 oncoprotein, p16 expression is upregulated by its corresponding gene being released from transcriptional inhibition. In non HPV-related HNSCC, downregulation or loss of p16 protein expression is a common early event and is associated with a worse prognosis, consistent with the tumour-suppressor role it has[204], and oral cavity and hypopharyngeal SCC show lower levels of p16 positivity[218,219]. However, a strong correlation has been observed in numerous studies between integrated HPV detection and p16 protein overexpression. As such, p16 has been adopted as a surrogate biomarker for HPV-related HNSCC[39,197-200,220,221], with

immunohistochemistry for $p16^{INK4A}$ now routinely performed in many laboratories and guides for interpretation have been described[199].

Not only can p16 act as a surrogate biomarker for HPV status, with 46%-98% of HPV positive oropharyngeal SCCs demonstrating p16 positivity on pooled analysis[200], but, with 3%-51% of HNSCCs being p16 positive and HPV negative[200], p16 status can also act as an independent prognosticator, regardless of HPV status[222-225], although not all studies agree on the specific effect[214]. Overexpression of p16 has been found in normal tonsillar tissue[25,226] and HPV negative tumours, with dysregulation of epigenetic control or multiple transcription factors being other mechanisms that lead to aberrant expression of p16[227], some of which are associated with non HPV-related HNSCC carcinogenesis. The lack of clarity on p16 expression and discrepancies in interpretation of p16 IHC have led to controversy surrounding its use as a surrogate biomarker.

Overexpression of p16 is not evident in a subgroup of HNSCC with active HPV infection[228], 2%-54% in pooled analysis[200]. With overexpression of $p16^{INK4A}$ thought to represent activity of viral oncogenes, it is possible that HPV positive/p16 negative may represent latent HPV infection, which could explain why HPV positive/p16 negative HNSCCs have a slightly worse prognosis[229,230]. Therefore, by combining testing for HPV DNA positivity and p16 overexpression, one can eliminate cases related to inactive infection, improving specificity of p16 a surrogate biomarker for detection of biologically relevant HPV infection[200]. This has been shown to be as reliable as detection of HPV E6/E7 mRNA expression by polymerase chain reaction, which is considered the gold standard of testing for transcriptionally active virus because HPV-negative HNSCCs and HPV-positive/E6 and E7 mRNA-negative HNSCCs show similar survival curves[191]; however E6/E7 mRNA is only used in a small number of centres and is mostly restricted to the research laboratory[231]. Equivalent detection may also be possible with HPV mRNA ISH and this may be of more practical clinical use[232,233]. However, there is currently a great degree of heterogeneity of HPV assessment techniques used in clinical practice depending on location[234].

A large number of alternative prognostic or predictive biomarkers in HNSCC have been studied, such as EGFR, cyclin D1, Bcl-2, cyclin-dependent kinase inhibitor p27, MCM7, DSG3, vascular endothelial growth factor, p53, ERCC1, RRM1, β-catenin and MET[209,235-240]. Some examples of studies on biomarkers related to treatment response found MMP-7 and EGF to be predictive markers of, respectively, resistance to cisplatin and poor response to cetuximab[241-243], while survivin overexpression predicted improved response to radiotherapy[244]. However, findings in many of the studies on biomarkers have been either inconsistent or often even contradictory. Some biomarkers have not been studied in sufficient detail to draw a firm association[216]. However, EGFR positivity has been associated with poor survival in HNSCC in a number of studies[245-247], including in HPV-related HNSCCs[167,235] (although these tumours generally tend not to overexpress EGFR[248]), and an EGFR-targeting antibody, cetuximab, has shown benefit in combination with radiotherapy for patients with HNSCC[249] so is approved for clinical use alone or in combination with radiotherapy or chemotherapy. Evidence suggests p16 may be useful in the context of analysing treatment response to cetuximab[250]. Besides EGFR inhibition, new molecular targeted therapies that have an effect on other activated molecular signalling pathways such as mTOR, Src kinase and IGF-1R inhibitors are being developed[251].

In HPV-related oropharyngeal SCC, there is the potential for translation of cervical biomarkers given the similarities in carcinogenesis between these sites. New biomarkers are continually emerging from molecular biological research which are of as yet uncertain relevance, such as recently discovered distinct squamocolumnar junction-related biomarkers[171-173].

It has been suggested that the programmed death 1 (PD-1):PD-L1 pathway plays a role in HNSCC, particularly in HPV-related oropharyngeal cases[252], by facilitating HPV-related carcinogenesis in an immune-privileged site[253]. Furthermore, an investigation into a panel of serum cytokine and chemokine markers revealed significantly decreased IFN-γ in HNSCC patients[254], which may be caused by inhibition of T-cell regulation from increased expression of PD-1:PD-L1. Immune checkpoint blockade through a monoclonal antibody that inhibits the PD-1 receptor has the potential to play a big role in future therapy, because initiation of anti-tumour response is observed on PD-1 blockade in animal studies[255].

Personalised therapy may be possible with robust biomarker panels and it is detailed molecular analysis, such as DNA profiling[204], that may guide biomarker development. Limited success of individual markers to predict tumour behaviour has led to attempts to classify biomarker "signatures" such as panels of RNA or protein expression alterations[256]. It is possible that miRNA panels associated with HNSCC subsets may also act as biomarkers to improve diagnosis and management[257]. Some studies have investigated panels of predictive biomarkers in both HPV-related oropharyngeal SCC[258] and non-HPV related oropharyngeal SCC[259], however few of these are validated[239].

Research on biomarkers in HNSCC is a rapidly expanding field, with new potential markers that may provide valid therapeutic targets[260], however it is difficult to demonstrate clinical utility without well designed biomarkers or panels undergoing rigorous assessment in clinical trials. Hence many questions remain, with HPV infection as yet not formally validated as a predictive biomarker for any specific treatment modality or agent[256]. More practical diagnostics could be achieved through serum[137,239] or radiological[256] biomarkers, however clinical utility of these remains to be proven. There is no standardisation of detection and when p16 expression is used as a marker for HPV infection, approximately 10% of cases may be false positives[167], such that a combination of p16 overexpression with HPV DNA positivity may currently

represent the most practical investigation for biologically relevant HPV infection[200] and this has been shown to be the most relevant group in terms of prognosis[261]. The relevance of infection in head and neck cancer outside the oropharynx is unestablished and identification of robust fingerprints of HPV carcinogenesis will help to improve the estimate of HPV-related non-oropharyngeal HNSCC.

## CLINICAL IMPLICATIONS

HNSCC has a huge impact upon quality of life and longevity. Improvements in clinical outcome have been forthcoming through advancements in surgical technique, radiation oncology and emerging chemotherapeutic and biologic agents, however, despite a multidisciplinary team approach, treatments remain complex with an associated high morbidity and only two new treatments (EGFR antibodies and robotic surgery) have been approved in the past 30 years[262].

HPV-related oropharyngeal SCC, distinct from other HNSCC[39,263], generally presents with a more advanced clinical stage, with a higher nodal category[248,264], despite lower tumour extent[133,264] and have different tendencies for extracapsular spread and perineural invasion[265]. These HPV-related tumours may even be clinically occult, but often present with early lymph node metastases[14,266], which can be confused with branchial cleft cysts[267]. However, tonsil SCCs are long known to present with early lymph node metastases[268] and it may be that the characteristics of the affected site itself facilitate early spread or else potentially the depth of invasion[266].

As stated above, these patients tend to be younger and are less likely to have significant exposure to tobacco and alcohol. Despite more advanced presentation, improved survival, consistently higher than 30%[269], is evident in HPV-related oropharyngeal SCC[66,266,270,271], irrespective of treatment modality[133,220,272-276]. It has been suggested, therefore, that the current classification system for HNSCCs be altered to reflect the different status of HPV-related HNSCCs[273].

Detection of biologically relevant HPV infection is best accomplished using HPV E6 and E7 mRNA, however p16 in combination with HPV DNA correlates well and can be a practical alternative[277]. Studies have also shown an improved response to therapy from HPV-related HNSCCs[16,133,278-280]. As a result of this, it is possible that de-escalation of therapy would be appropriate for these tumours to improve associated morbidity and quality of life. Considering this, there are currently a number ongoing trials. A summary of some of these trials is shown in Table 1.

There have been conflicting reports on the benefit of cetuximab in HPV-related oropharyngeal SCC. While subset analysis in one study suggests improved survival for oropharyngeal SCCs in the cetuximab group (although not necessarily HPV-related)[281], others including the RTOG 0522 and SPECRUM trials disagree[269,282]. Preclinical investigation on treatment effects are limited by the sparse number of HPV-related HNSCC cell lines available.

While organ-preservation trials have led to primary chemoradiotherapy superseding surgical management in HNSCC, there has been renewed interest in transoral techniques for oropharyngeal SCC, particularly with the introduction of robotic surgery. Equivalent early oncologic outcomes to chemoradiotherapy and improved functional outcomes are promising[283]. Some trials involving transoral surgery are shown in Table 1.

Therapeutic vaccines are novel strategies aimed at improving the T-cell mediated immune response to HPV-related SCCs. Recent phase I and Ⅱ clinical trials, some in combination with chemotherapy to boost effectiveness, are investigating these[269,284].

There is currently no single standardized treatment for oropharyngeal SCCs, but before recommended management strategies are altered, results from randomized controlled trials are needed to assess the efficacy of the different treatment modalities available for both HPV-positive and HPV-negative oropharyngeal SCC[285], although recruitment of sufficient numbers remains difficult[265].

Induction of HPV-specific immune responses by prophylactic vaccination with recombinant HPV virus-like particles is likely the key to successful prevention of persistent HPV infection and the subsequent consequences. As such, bivalent and quadrivalent vaccines are now widely available and have shown efficacy in prevention of anal, cervical, vaginal, and vulvar pre-cancers in unexposed individuals[94,286,287]. Unfortunately, present vaccines are only proven to be effective if given before genotype-specific infection is established[288], duration of protection remains unclear and cost is high. Given the high specificity of oropharyngeal cases linked to HPV-16, it is unlikely that other genotypes would replace HPV-16, particularly in view of evidence for induction of cross-genotype immunity with genotype-specific immunisation[289].

In relation to the oropharynx, animal model investigation has revealed reduction in development of HPV-related oral lesions in immunised cases[290]. Recently, an IARC-led study established that a bivalent vaccine used for cervical cancer prevention also reduced oral infections with HPV 16 and 18 by 93.3%[291]. While oral HPV infection is a risk factor for development of HPV-related oropharyngeal SCC, pathogenesis is unclear and the lack of an obvious HPV-related precancerous stage does not facilitate screening and makes evaluation of vaccine effectiveness difficult. Accurate estimates of HPV-related oropharyngeal SCC will help determine the potential role of prophylactic vaccination. It is likely that the effects of vaccination on oropharyngeal SCC will only be revealed over time through longitudinal studies on incidence before and after vaccine introduction.

Treatment of HPV-related oropharyngeal SCC is currently varied geographically depending on tumour stage, patient status including age and co-morbidities, facilities available and HPV or p16 status. There remains uncertainty regarding vaccination, cetuximab and de-escalation

**Table 1 Ongoing clinical trials pertaining to treatment of human papillomavirus-related oropharyngeal squamous cell carcinoma**

| Trial | Phase | Inclusion | Arm 1 | Arm 2 | Outcomes |
|---|---|---|---|---|---|
| RTOG 1016 | Ⅲ | p16 positive locally advanced oropharyngeal SCC | Radiation and concurrent chemotherapy | Radiation and concurrent cetuximab | Survival, toxicity, locoregional recurrence and quality of life |
| ECOG E1308 | Ⅱ | Stage Ⅲ-Ⅳa HPV positive oropharyngeal SCC | Complete response to induction chemotherapy and reduced dose radiation with concurrent cetuximab | Incomplete response to induction chemotherapy and standard dose radiation with concurrent cetuximab | Survival, toxicity, response, quality of life and biomarker correlation |
| De-ESCALaTE HPV | Ⅲ | StageⅢ-Ⅳa HPV positive oropharyngeal SCC | Cetuximab and concurrent radiotherapy | standard concurrent cisplatin and chemoradiotherapy | Morbidity, quality of life, cost, survival and recurrence |
| QUARTERBACK | Ⅲ | Locally advanced HPV-16 positive oropharyngeal, unknown primary or nasopharyngeal SCC showing complete or partial response to induction therapy | Reduced dose radiation with cetuximab and chemotherapy | Standard dose radiation with chemotherapy | Survival, locoregional control, toxicity and biomarker correlation. |
| LCCC 1120 | Ⅱ | HPV positive and/or p16 positive low-risk oropharyngeal SCC | Decreased dose of radiation and chemotherapy | Standard radiation and chemotherapy | Pathological response rate, locoregional control, survival and quality of life |
| NCT01221753 | Ⅱ | Locally advanced HPV positive oropharyngeal SCC | Docetaxel/cisplatin/5-fluorouracil (TPF) induction chemotherapy followed by concurrent chemoradiation using a modified radiation dose | N/A | Locoregional control, survival and toxicity |
| SIRS | Ⅱ | Early to mid-stage HPV positive oropharyngeal SCC who receive transoral robotic surgery plus a neck dissection, where clinically indicated | Observation only | Low dose postoperative radiation only<br>Arm 3: Chemoradiation | Rates of locoregional control, overall survival and use of salvage chemoradiation in the observation group |
| TROG 12.01 | Ⅲ | HPV positive oropharyngeal SCC | Radiation and cetuximab | Radiation and cisplatin | Symptoms severity, swallowing, quality of life, toxicity, survival, locoregional recurrence |
| ADEPT | Ⅲ | p16 positive oropharyngeal SCC that has undergone transoral resection with negative margins | Postoperative radiation alone | Postoperative radiation with cisplatin | Survival, locoregional control, toxicity and quality of life |
| NCT01088802 | Ⅰ / Ⅱ | HPV positive T1-3 oropharyngeal SCC | De-escalated radiation from 70 Gy to 63 Gy with concurrent chemotherapy | De-escalated radiation from 58.1 Gy to 50.75 Gy with concurrent chemotherapy | Toxicity, quality of life and adverse events |
| ECOG E3311 | Ⅱ | Stage III-IVa HPV positive oropharyngeal SCC after transoral surgery and neck dissection with negative margins, no extracapsular spread and less than 4 lymph nodes involved | Transoral surgery with standard radiation | Transoral surgery with low-dose radiation | Survival, surgical complications, toxicity and swallowing |

SCC: Squamous cell carcinoma; HPV: Human papillomavirus.

of therapy, which will be made clearer through current prospective trials, leading to better delineation of therapy for HNSCC subsets. Accurate assessment for biologically relevant HPV will be critical to improvement in treatment approaches.

## CONCLUSION

HPV has been established beyond doubt as a causative agent in oropharyngeal SCC and biologically active HPV can act as a prognosticator with better overall survival than HPV-negative HNSCCs. A distinct group of younger patients with limited tobacco and alcohol exposure have emerged as characteristic of this HPV-related subset of HNSCC. However, the exact molecular mechanisms of carcinogenesis are not completely described and further studies are needed to assist development of optimal prevention and treatment modalities.

Despite the large pool of research on HPV in HNSCC, great variation exists in detection techniques. Detection of biologically relevant HPV infection will be important for clinical trial design. Also, biomarker discovery will be important not only to identify specific SCC subsets, including those that are HPV-related, to allow for individualised treatment strategies aimed at decreasing morbidity, but also to clarify the role of HPV in non-oropharyngeal sites.

With stored tissue available from the SEER database

in only 271 patients[265], there needs to be greater cooperation between institutions to improve research into understanding this disease. Nevertheless, it is likely that the key approach in future will be prevention and so further studies in prophylactic vaccination, specifically in relation to oropharyngeal SCC, are needed.

## Abstract

Epithelial ovarian cancer is the most lethal type of gynecologic malignancy. Sixty percent of women who are diagnosed with ovarian cancer present with advanced-stage disease that involves the peritoneal cavity and these patients have a 5-year survival rate of less than 30%. For more than two decades, tumor-debulking surgery followed by platinum-taxane combination chemotherapy has remained the conventional first-line treatment of ovarian cancer. Although the initial response rate is 70%-80%, most patients with advanced-stage ovarian cancer eventually relapse and succumb to recurrent chemoresistant disease. A number of molecular aberrations that drive tumor progression have been identified in ovarian cancer cells and intensive efforts have focused on developing therapeutic agents that target these aberrations. However, increasing evidence indicates that reciprocal interactions between tumor cells and various types of stromal cells also play important roles in driving ovarian tumor progression and that these stromal cells represent attractive therapeutic targets. Unlike tumor cells, stromal cells within the tumor microenvironment are in general genetically stable and are therefore less likely to become resistant to therapy. This concise review discusses the biological significance of the cross-talk between ovarian cancer cells and three major types of stromal cells (endothelial cells, fibroblasts, macrophages) and the development of new-generation therapies that target the ovarian tumor microenvironment.

**Key words:** Ovarian cancer; Tumor stroma; Endothelial cells; Fibroblasts; Macrophages; Targeted therapy

**Core tip:** Despite advances in clinical management, advanced-stage ovarian cancer is still rarely cured by conventional chemotherapy. Substantial efforts have been directed to developing new therapies that target ovarian cancer cells. However, recent studies have revealed important roles of a variety of stromal cells in driving the aggressive behavior of ovarian cancer. Here, we discuss: (1) the significance of three major types of stromal cells in the progression of ovarian cancer; (2) how receptor/ligand-mediated interactions between ovarian cancer cells and stromal cells serve as focal points for therapeutic intervention; and (3) key examples of new-generation agents that target stromal cells.

## INTRODUCTION

Epithelial ovarian cancer is the fifth leading cause of cancer death in women and the most lethal form of gynecologic malignancy[1]. The high morbidity and mortality caused by ovarian cancer primarily stems from late diagnosis. Sixty percent of women who are diagnosed with

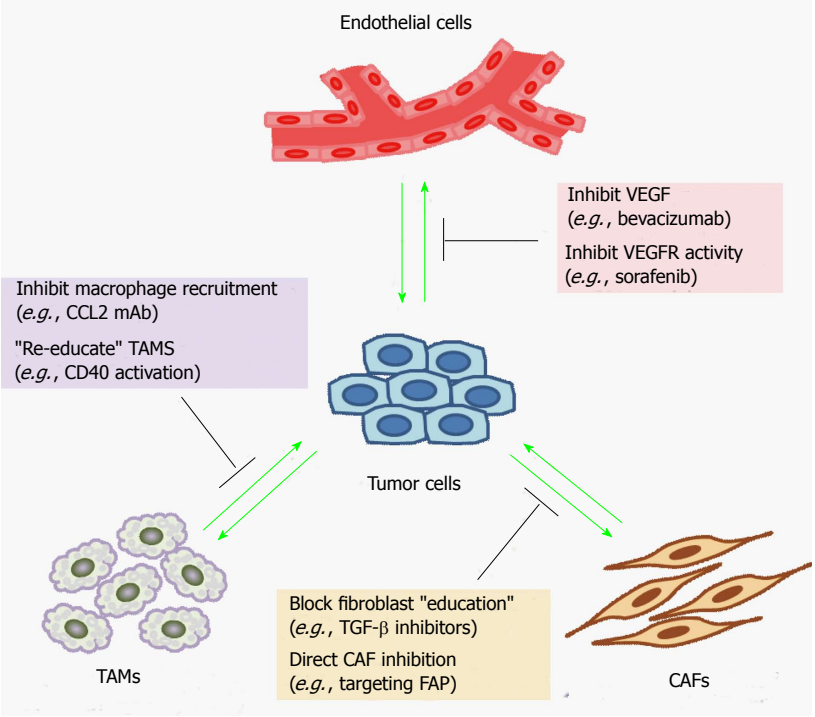

**Figure 1 Therapeutic strategies to target the tumor microenvironment.** Shown are examples of different strategies and agents that inhibit the regulation of a specific type of stromal cell or its functional properties. Several of these agents are in clinical use, whereas others are at different stages of clinical development. VEGF: Vascular endothelial growth factors; TAMs: Tumor-associated macrophages; CAFs: Cancer-associated fibroblasts; TGF-β: Transforming growth factor-β; FAP: Fibroblast activation protein; CCL2: chemokine (C-C motif) ligand 2; VEGFR: Vascular endothelial growth factor receptor.

ovarian cancer present with extensive peritoneal carcinomatosis and these patients have a 5-year survival rate of less than 30%[1]. For more than 20 years, tumor-debulking surgery followed by platinum-taxane combination chemotherapy has remained the standard first-line treatment[2]. Although the initial response rate is 70%-80%, most patients with advanced-stage ovarian cancer relapse within 18 mo and eventually die from the disease[2]. Substantial efforts have been directed to developing new-generation agents that target functionally relevant molecular aberrations in ovarian cancer cells[3]. Inhibitors of poly (ADP-ribose) polymerase, a DNA repair enzyme, have been undergoing clinical trials in patients with BRCA-deficient ovarian cancer and have attracted considerable attention[4]. In addition to agents that target pathways in ovarian cancer cells, agents that target the tumor vasculature have been the focus of intensive clinical investigation[5,6]. Increasing evidence indicates that ovarian tumor progression is driven not only by dynamic interplay between tumor cells and endothelial cells but also by other types of stromal cells that are "educated" by tumors to acquire properties that are permissive for tumor growth. In this article, we provide an overview of the cross-talk between ovarian cancer cells, endothelial cells and two other key constituents of the tumor microenvironment, specifically, fibroblasts and macrophages, and discuss examples of clinically used and emerging experimental agents that target these stromal cells.

## ENDOTHELIAL CELLS

Of the cell types that comprise the ovarian tumor microenvironment, the endothelial cell has been the most extensively studied in terms of its clinical significance. A number of independent studies have identified that increased tumor angiogenesis as manifested by high microvessel density is predictive of poor outcomes in ovarian cancer patients[7-9]. Angiogenesis is a dynamic process that involves the recruitment of endothelial progenitors, growth and maturation of endothelial cells and vessel formation, and is orchestrated by a repertoire of pro-angiogenic and anti-angiogenic factors[10,11]. Key pro-angiogenic factors include the vascular endothelial growth factors (VEGF), platelet-derived growth factor (PDGF), fibroblast growth factor-2 (FGF-2), angiopoietin, interleukin (IL)-6 and IL-8. Of these factors, VEGF-A has emerged as the predominant pro-angiogenic factor that is highly expressed in ovarian cancers[5,6]. VEGF-A has also been identified to be the causative factor of ascites formation by inducing vascular permeability[12].

Intensive clinical efforts have focused on evaluating agents that inhibit VEGF signaling. These agents fall into two categories: (1) those that inhibit the ligand; and (2) those that inhibit tyrosine kinase activity of the VEGF receptors (VEGFR) (Figure 1). Of the former group, bevacizumab has been the most extensively evaluated agent in ovarian cancer. Bevacizumab is a humanized monoclonal antibody (mAb) that neutralizes all forms of VEGF and was originally Food and Drug Administration-approved in 2004 for treatment of metastatic colorectal cancer. Bevacizumab has been evaluated as a single agent in the treatment of patients with recurrent ovarian cancer in two pivotal phase II trials. In one of these studies (AVF 2949g), the response rate was 15.9% and median overall survival (OS) was 10.7 mo[13]. This study was terminated early due to a high rate of gastrointestinal perforations (5 of 44 patients, 11.4%). In the other study [Gynecologic Oncology Group (GOG) 170D], the response rate was 21.0%, median OS was 16.9 mo, and no bowel perforations were observed[14]. One possible explanation for

the differences in results of these trials is that the GOG study was limited to patients who had received no more than two prior lines of therapy, whereas 21 of the 44 patients in the AVF 2949g study (including the five patients who developed bowel perforations) had received three prior regimens. Bevacizumab has also been evaluated in combination with carboplatin and paclitaxel. In the first-line setting, two phase III trials (GOG 218 and ICON7) reported that progression-free survival (PFS) was increased (by 3.8 and 1.7 mo, respectively) with the combination of bevacizumab and standard chemotherapy followed by bevacizumab maintenance, as compared to standard chemotherapy alone[15,16]. In the recurrent setting, two other phase III studies have found that PFS was increased by approximately 3.6 mo when bevacizumab was combined with standard chemotherapy[17,18]. Another ligand-inhibitory agent is aflibercept, a fusion protein that acts as a soluble VEGFR decoy. In a phase Ⅱ study of aflibercept in patients with recurrent ovarian cancer, the rate of gastrointestinal perforations was found to be low (1.4%) but the primary endpoint of a response rate of greater than 5% was not achieved[19].

Tyrosine kinase inhibitors (TKIs) represent another important class of anti-angiogenic agents. Sorafenib is an oral multi-kinase inhibitor that targets several receptor tyrosine kinases including VEGFR-2, VEGFR-3, platelet-derived growth factor receptor-β (PDGFR-β) and c-kit, and also the RAF family of serine/threonine kinases[20]. In a phase Ⅱ trial of sorafenib monotherapy in patients with recurrent ovarian cancer, two of the 59 evaluable patients had partial responses whereas 20 had stable disease and 30 had progressive disease[21]. Another phase Ⅱ study found that sorafenib did not improve efficacy of first-line carboplatin/paclitaxel treatment and resulted in additional toxicity[22]. Several TKIs that inhibit all three VEGFRs and both PDGFRs have been developed such as sunitinib, cediranib and pazopanib. Sunitinib has been found to have only modest activity as a single agent in patients with recurrent ovarian cancer[23,24]. Clinical trials are ongoing to evaluate cediranib[25] for treatment of recurrent ovarian cancer and pazopanib[26] as maintenance therapy for patients in remission following first-line platinum-taxane chemotherapy.

## CANCER-ASSOCIATED FIBROBLASTS

Cancer-associated fibroblasts (CAFs) constitute the cellular fibrotic component of the tumor stroma that is commonly described as "reactive" or desmoplastic stroma. CAFs are often distinguished from normal quiescent fibroblasts by their expression of markers of myofibroblasts and activated fibroblasts such as α-smooth muscle actin (αSMA) and fibroblast activation protein (FAP)[27,28]. CAFs derive from multiple cell types. Two important sources are mesenchymal stem cells (MSCs) and tissue-resident fibroblasts. MSCs are abundant in white adipose tissues such as the omentum[29], the most commonly involved site in ovarian cancer. It has been demonstrated that ovarian cancer cell-derived factors, such as transforming growth factor-β (TGF-β) and lysophosphatidic acid, induce normal omental fibroblasts and adipose MSCs to acquire features of CAFs[30,31]. Studies of other types of tumors have shown that CAFs can also derive from bone marrow MSCs that are recruited to tumors[32,33]. There is evidence in breast cancer that some CAFs derive from tumor cells that have undergone epithelial-to-mesenchymal transition[34]. However, a study of ovarian cancer xenograft models found that stromal $\alpha SMA^+$ cells did not derive from tumor cells, suggesting that ovarian cancer cells are not a major source of CAFs[31].

Substantial evidence indicates that CAFs contribute to poor survival of cancer patients by promoting tumor cell proliferation, angiogenesis and metastasis[27,28]. In a study of gene expression profiles of clinical specimens of ovarian cancer, Tothill *et al*[35] identified that the subset of cases with the poorest outcomes was characterized by a desmoplastic gene signature. As compared to normal omental fibroblasts, CAFs more highly express IL-6, chemokine (C-X-C motif) ligand 12 (CXCL12) and VEGF-A, and are more effective in stimulating growth of ovarian cancer cells and endothelial cells[31]. The abundance of CAFs in ovarian cancers has been found to correlate with microvessel density[36]. CAFs also highly express TGF-β, matrix metalloproteinases (MMPs) and numerous extracellular matrix proteins[27,28], and stimulate invasiveness of ovarian cancer cells[36]. Furthermore, McLean and colleagues identified that propagating ovarian cancer cells with MSCs derived from ovarian cancer specimens increased the number of cancer stem cells[37]. These findings suggest that another mechanism by which CAFs drive tumorigenesis is by expanding the sub-population of tumor-initiating cells.

Given the profound negative impact of CAFs on outcomes, there have been intensive efforts to develop strategies to target this cell population (Figure 1). Several approaches to inhibit CAFs have been directed to targeting FAP. A humanized mAb to FAP has been found to be well-tolerated, but failed to show efficacy in a clinical trial of patients with metastatic colorectal cancer[38]. In a preclinical study, a DNA vaccine against FAP inhibited tumor growth and increased survival in a mouse colon cancer model[39]. A study by Brennen and colleagues exploited both the expression of FAP on CAFs and its proteolytic activity. These authors generated a prodrug that consisted of a FAP-specific peptide coupled to a thapsigargin analog as the cytotoxic moiety, and demonstrated that the compound induced stromal cell death and inhibited growth of breast and prostate tumor xenografts[40]. Another potential approach to inhibit CAFs is to prevent normal MSCs and fibroblasts from transitioning into CAFs by blocking TGF-β signaling. A number of agents that inhibit TGF-β signaling have been developed including TGF-β-ligand traps, TGF-β antisense oligonucleotides and small molecule inhibitors of the TGF-β type I receptor kinase, and several of these agents have been evaluated in clinical trials[41,42]. The utility of TGF-β inhibitors has been little-explored in ovarian cancer. In one

study, treatment of mice with the TGF-β type I receptor inhibitor A83-01 reduced the fibrotic component of ovarian tumor xenografts but did not increase survival times[43]. Unlike TGF-β, PDGF does not induce myofibroblastic differentiation but instead stimulates fibroblasts to produce mitogenic factors for tumor cells and pro-angiogenic factors. Blockade of PDGFR signaling in a mouse model of cervical cancer has been found to inhibit tumor growth and angiogenesis in part by inhibiting FGF-2 production by CAFs[44]. As discussed earlier, several TKIs that block VEGFR signaling also inhibit the PDGFRs. The impact of these TKIs on the desmoplastic stroma warrants further study as the PDGFRs are often highly expressed in CAFs.

## TUMOR-ASSOCIATED MACROPHAGES

Macrophages are normally present in the peritoneal cavity of healthy women and are abundant in ascites of ovarian cancer patients[45]. Tumor-associated macrophages (TAMs) are the major immune component of the tumor stroma[46,47]. Macrophages exhibit polarized phenotypes in response to different microenvironmental cues. Macrophages that are stimulated with microbial agents and interferon-γ exhibit an immunostimulatory M1 phenotype. In contrast, TAMs exhibit an immunosuppressive M2 macrophage phenotype[46,47]. Polarization of macrophages towards an M2 phenotype is induced by stimulation with various cytokines such as IL-6, IL-10 and leukemia inhibitory factor (LIF) that are present at elevated levels in ascites of ovarian cancer patients[48,49]. Chemokine (C-C motif) ligand 2 (CCL2) and TGF-β2 are also expressed in ovarian cancer cells and in CAFs, and these ligands have been recently shown to induce normal peritoneal macrophages to acquire an M2 phenotype[50]. CCL2 is also a key chemotactic factor that is responsible for macrophage infiltration into tumors[47].

TAMS are strongly associated with poor outcomes in cancer patients[46]. A principal mechanism by which TAMs promote tumor progression is by suppressing adaptive immunity. The M2 macrophage phenotype is characterized by high expression of immunosuppressive cytokines and chemokines such as CCL17, CCL18, CCL22, IL-10 and TGF-β1[47]. IL-10 and TGF-β1 inhibit T cell proliferation and dendritic cell maturation[47]. CCL18 induces naïve T cell anergy and has been identified to be the most abundant chemokine present in ovarian cancer patient ascites[51]. CCL17 and CCL22 promote recruitment of T regulatory cells (Treg) cells[52,53]. Treg cells suppress activity of effector T cells and have been found to promote ovarian tumor growth and to be predictive of poor survival in ovarian cancer patients[52]. In addition to expressing factors that suppress adaptive immunity, TAMs express MMPs, VEGF-A and other growth factors that stimulate metastasis and angiogenesis[46,47]. Depletion of peritoneal macrophages has been found to inhibit ascites and peritoneal spread of ovarian cancer in xenograft models[54].

The recruitment of macrophages and their polarization towards a tumor-promoting M2 phenotype represent two candidate focal points for therapeutic intervention (Figure 1). Several approaches have been identified that "re-educate" TAMs towards a more tumoricidal M1 phenotype. Inhibition of the colony stimulating factor-1 receptor has been found to inhibit M2 macrophage polarization and to block glioma progression in animal models[55]. Inhibition of nuclear factor κB signaling in TAMs also induced an M2-to-M1 switch, increased tumoricidal activity of macrophages and led to regression of ovarian tumor xenografts[56]. Activation of CD40, a member of the tumor necrosis factor receptor superfamily, induced tumoricidal activity of macrophages in mouse models of pancreatic adenocarcinoma[57]. The combination of agonistic CD40 mAb and gemcitabine chemotherapy has been found to be well-tolerated and to have anti-tumor activity in a phase I study of patients with advanced pancreatic adenocarcinoma[58]. Zoledronic acid is clinically used to prevent bone fractures and also impairs M2 polarization of macrophages[59]. CCL2 is an attractive target because of its ability to stimulate monocyte chemotaxis as well as M2 polarization. Neutralization of CCL2 induced regression of prostate cancer xenografts[60]. A mAb to CCL2 has recently undergone clinical evaluation[61]. Bindarit, an anti-inflammatory compound that inhibits CCL2 synthesis, has been found to inhibit growth of breast and prostate tumor xenografts[62]. Trabectedin is an alkaloid that binds the minor groove of DNA and disrupts the cell cycle[63]. In a phase Ⅲ study of patients with recurrent ovarian cancer, the combination of Trabectedin and pegylated liposomal doxorubicin (PLD) was found to increase PFS by 1.5 mo as compared to PLD alone[64]. Trabectedin also inhibits production of CCL2 and IL-6 and inhibits the differentiation of monocytes into macrophages[65]. Germano *et al*[66] recently demonstrated the selective toxicity of Trabectedin for macrophages in xenograft models of ovarian cancer and several other solid tumors. In another recent study, Cieslewicz *et al*[67] identified a peptide (M2pep) that selectively binds to M2 macrophages. Administration of a fusion peptide comprising M2pep and a proapoptotic moiety improved survival rates of xenograft-bearing mice[67], raising the possibility that the M2pep peptide could be used as a vehicle for delivering cytotoxic agents to TAMs.

## CONCLUSION

Over the past decade, a wealth of insight has been gained into the biology of ovarian cancer, the fertile nature of the peritoneal cavity for carcinomatosis, and the complex networks of receptor/ligand-mediated interactions between tumor cells and stromal cells. Several of the key receptors and ligands serve as molecular targets against which new-generation therapeutic agents have been developed and evaluated. Although several studies have yielded promising results, the efficacy of most stromal-targeting drugs as single agents seems limited. Several challenges remain such as identifying the most effective combinations of these drugs with conventional chemo-

therapy or with other targeted therapies, minimizing toxicity, and determining the appropriate clinical setting for their use.

## Abstract

Atherosclerosis of cerebral vessels is a common cause of stroke. Racial differences in the distribution of cerebrovascular occlusive disease are well documented. Extracranial stenosis is more common in Caucasians, while intracranial stenosis is more common in Asians, Hispanics and African-Americans. Concurrent atherosclerosis of extracranial and intracranial vessels is common in Asians. The incidence of concurrent stenoses ranges from 10% to 48% in patients with symptomatic cerebrovascular disease. The long-term prognosis of these patients is poor and they are at high risk of further vascular events or death. The purpose of this review is to examine the epidemiology, risk factors, stroke mechanism and genetics of concurrent stenoses and to discuss strategies for treatment.

**Key words:** Atherosclerosis; Concurrent stenosis; Stroke; Asians

**Core tip:** Concurrent stenoses of extracranial and intracranial vessels are common in Asians, with an incidence that ranges from 10% to 48% in patients with symptomatic cerebrovascular disease. The long-term prognosis of these patients is poor and they are at high risk of further vascular events or death. The purpose of this review is to examine the epidemiology, risk factors, stroke mechanism and genetics of concurrent stenoses and to discuss strategies for treatment.

## INTRODUCTION

Cerebrovascular occlusive disease due to atherosclerosis is a common cause of stroke worldwide. However, there are marked racial differences in the distribution of vascular stenosis. Extracranial stenosis is the most common large vessel cause in Caucasians, while intracranial stenosis is more prevalent in Asians, Hispanics and African-Americans[1-4]. Moreover, recent studies suggested that concurrent stenoses of extracranial and intracranial vessels are common in Asians. The purpose of this review is to examine the epidemiology, risk factors, stroke mechanism and genetics of concurrent stenoses and to discuss strategies for investigations and treatment.

## EPIDEMIOLOGY

The incidence of concurrent stenoses ranges from 10% to 48% in patients with symptomatic cerebrovascular disease[2,5-8]. Wong *et al*[9] found that 21% of stroke patients had concurrent stenoses in Hong Kong. Yang *et al*[10] report 33% of stroke patients had concurrent stenoses in China. Liu *et al*[8] found that 18% of stroke patients in Taiwan had significant concurrent stenoses. Lee *et al*[6] reported that 48% of patients with more than 30% extracranial carotid stenosis had concurrent intracranial stenoses in South Korea.

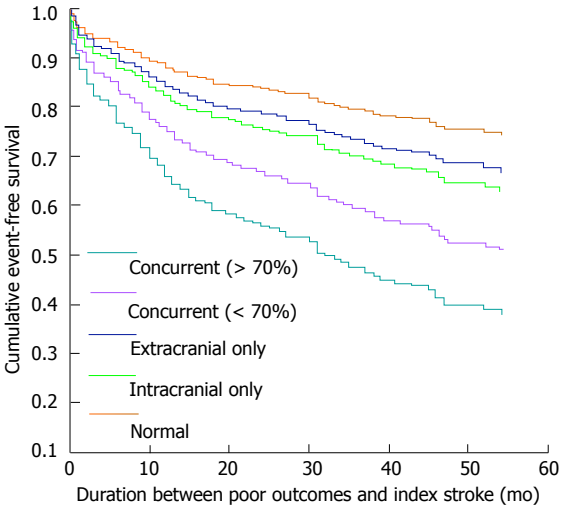

**Figure 1 Cumulative event-free survival in patients with different intracranial and extracranial lesions.** Concurrent (< 70%): Concurrent lesions with < 70% extracranial stenosis; Concurrent (> 70%): Concurrent lesions with > 70% extracranial stenosis; Extracranial only: Extracranial stenosis only; Intracranial only: Intracranial stenosis only; Normal: Normal craniocervical vasculature.

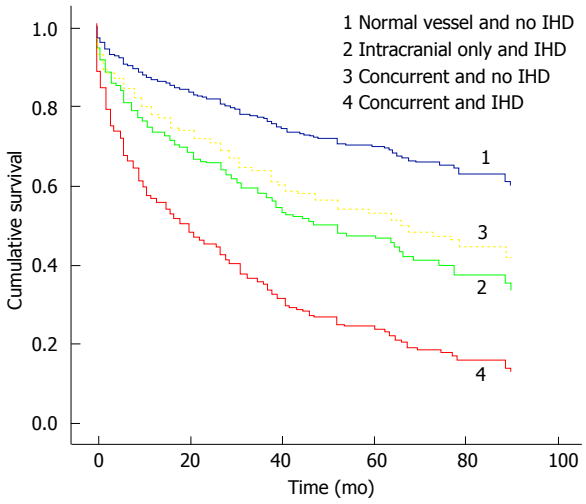

**Figure 2 Cumulative event-free survival of combined poor outcomes of different groups of patients.** Normal vessel: Normal craniocervical vasculature; Intracranial only: Intracranial stenosis only; Concurrent: Concurrent stenoses.

## NATURAL HISTORY OF CONCURRENT STENOSES

The long-term prognosis of ischemic stroke patients with concurrent atherosclerosis of intracranial and extracranial vessels is poor and they are at high risk of further vascular events or death. Our previous studies showed the 5-year cumulative rates of mortality, re-stroke and poor outcomes were 31%, 41% and 51%, respectively (Figure 1)[11]. Furthermore, ischemic stroke patients with concurrent stenoses and ischemic heart disease have an even worse prognosis. The 5-year cumulative rates of mortality, recurrent vascular events and combined poor outcomes were 40%, 50% and 83%, respectively (Figure 2)[12]. On the other hand, patients with concurrent stenoses and small vessel disease have poorer cognitive and functional outcomes[13]. This may be related to the burden of atherosclerosis and synergistic effect of multiple vascular lesions.

## RISK FACTORS ASSOCIATED WITH CONCURRENT STENOSES

Our previous studies showed that hypertension[14], diabetes mellitus[15], hyperlipidemia[15], recurrent stroke and poor pre-stroke modified Rankin scale[16] are associated with concurrent stenoses.

## ETIOLOGIES

The major cause of concurrent stenoses is atherosclerosis of the cerebrovascular circulation which typically affects large or medium sized arteries. These vessels range from 200-850 μm in diameter and are characterized by the accumulation of subintimal foam cells[16]. In the carotid artery, high risk plaques tend to be severely stenotic[17]. However, severe stenosis of the carotid artery is rare in Asian patients with concurrent stenosis[11]. Compared with extracranial vessels, the adventitia and the media of the intracranial arteries are thinner and their internal elastic lamina are fenestrated differently and thicker[18]. Luminal stenosis, lipid area, presence of neovasculature and inflammatory cells are all associated with ischemic stroke in the middle cerebral artery (MCA) territory[19].

## STROKE MECHANISMS

Patients with concurrent stenoses have more symptomatic stenoses, more concomitant perforating artery infarcts, pial infarcts, border zone infarcts and more multiple embolic infarcts in the territory of the leptomeningeal branches of MCA (Figure 3)[14]. The topographic patterns suggest that the combination of hemodynamic compromise attributable to concurrent stenoses and artery-to-artery embolization is a common stroke mechanism in these patients[14].

## GENETICS

Genetic factors may play a role in the development of concurrent stenoses on top of the other well established vascular risk factors. Our study showed that genetic polymorphisms of the pathways affecting lipid metabolism and homocysteine are associated with concurrent stenosis[15].

## TREATMENT OF CONCURRENT STENOSES

Patients with concurrent stenoses are at high risk of further vascular events or death. The optimal treatment for these groups of patients is still unknown. The American Heart Association/American Stroke Association recom-

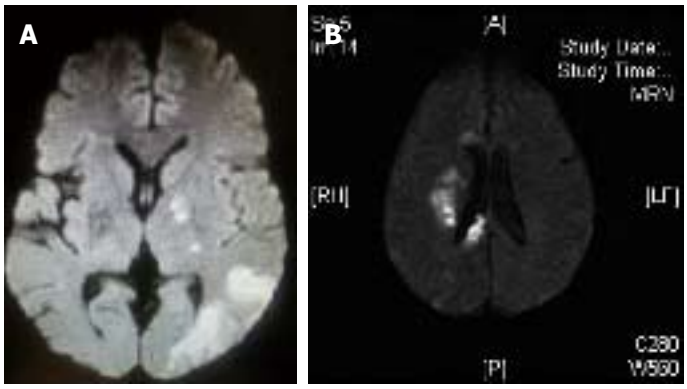

**Figure 3 Magnetic resonance imaging diffusion-weighted images of different lesion patterns.** A: Concomitant perforating artery infarct and pial infarcts; B: Border zone infarcts.

mend aspirin monotherapy, aspirin/extended-release dipyridamole combination and clopidogrel monotherapy as the acceptable options for all non-cardioembolic ischemic stroke patients[20]. A South Korean study[21] showed that the progression of intracranial stenosis was significantly less in patients taking cilostazol (a phosphodiesterase inhibitor).

However, medical treatment for patients with concurrent stenoses is often unsatisfactory[11,12] and surgical treatment may be indicated in these patients. Although severe carotid stenosis is rare in Asians, patients with severe carotid stenosis are recommended to have a carotid endarterectomy[17,22]. Carotid stenting is not recommended due to high perioperative risks and death associated with this procedure[23,24].

The Carotid Occlusion Surgery Study trial, which investigated the relationship between cerebral hemodynamics and cognitive function in stroke patients undergoing treatment for unilateral carotid artery occlusion with extracranial-intracranial arterial bypass (EC-IC bypass), was stopped prematurely in 2011 because of slow recruitment and a very low incidence of ipsilateral symptomatic ischemic events in patients assigned to the medical arm[25].

The increasing enthusiasm for intracranial stenting for significant intracranial stenosis was dampened by the significant periprocedural neurological complication rate, estimated at 5.3% to 28%[26-30]. The stenting *vs* aggressive medical management for prevention recurrent stroke in intracranial stenosis (SAMMPRIS) trial[31] has been halted due to the high perioperative risks of stroke and death in the treatment arm. However, the risks may be lower at centers with high volume and more experience in these stenting procedures. Jiang *et al*[32] reported on 100 consecutive patients from a single center with a 99% success rate of stent placement and 5% risk of 30 d perioperative stroke and death. Overall, the current evidence does not support the routine use of intracranial stenting in patients with intracranial stenosis.

## TRIALS IN PROGRESS

There are two ongoing randomized treatment trials using cilostazol in patients with intracranial stenosis. The first is the Trial of Cilostazol in Symptomatic Intracranial Arterial Stenosis Ⅱ in Asia, which is a double-blind, randomized trial comparing aspirin (75-150 mg per day) in combination with cilostazol (100 mg twice a day) with a combination of clopidogrel (75 mg per day) in patients with significant MCA or basilar artery stenosis[33]. The second is the open-label trial of Cilostazol-Aspirin Therapy Against Recurrent Stroke With Intracranial Artery Stenosis in Japan, comparing open-label aspirin and cilostazol with aspirin alone in patients with symptomatic 50%-99% stenosis of the supraclinoid internal carotid artery, MCA or basilar artery[34]. These trials may provide important information to optimize medical treatment in patients with intracranial stenosis.

Concerning the surgical treatment for intracranial stenosis, the Japanese EC-IC Bypass Trial (JET study) is in progress to determine the ability of STA-MCA bypass to prevent stroke caused specifically by intracranial stenosis, based on evaluations of hemodynamic ischemia[35,36]. The interim analyses of the JET study suggest that in patients with symptomatic intracranial stenosis and evidence of hemodynamic ischemia, surgical intervention with EC–IC bypass is superior to medical management in terms of stroke prevention. The final results of the trial are pending[36].

The Early Stent-assisted Angioplasty in Symptomatic Intracranial Stenosis (ESASIS) trial[37] aims to study the benefit of stenting in reducing the risk of ipsilateral stroke, similar to the SAMMPRIS trial. The Data Safety Monitoring Board of the ESASIS study reviewed the 30 d safety data (combined stroke and death) of 77 randomized patients and found that the safety data of the stenting arm is reassuring when compared with that of the medical arm and is better than the high event rate of 14% being reported in the stenting arm of the SAMMPRIS study. The ESASIS trial is therefore recommended to continue recruitment but with close monitoring of safety.

## CONCLUSION

Concurrent intracranial and extracranial stenoses are common in Asians. The patients have a high risk of death and recurrent vascular events. The risk factors include hypertension, diabetes mellitus, hyperlipidemia, previous history of stroke and poor pre-stroke modified Rankin scale. The combination of hemodynamic compromise

attributable to concurrent stenoses and artery-to-artery embolization is a common stroke mechanism in these patients. Optimal treatment for patients with concurrent stenoses is still unknown and more studies are needed on possible interventions which can improve the prognosis of these patients.

## Abstract

We report a case of a 77-year-old patient with complete atrioventricular block. She underwent permanent pacemaker implantation complicated by right ventricular lead perforation. This was suspected on transthoracic echocardiogram and confirmed by chest computed tomography. The lead was repositioned in the cardiac electrophysiology lab followed by an uneventful course thereafter.

**Key words:** Pacemaker; Lead; Perforation

**Core tip:** Cardiac perforation should be considered in cases of pacing lead malfunction. Chest computed tomography is helpful in diagnosing lead perforation and can be done without contrast and using a small field of view to diminish the effective radiation dose.

## INTRODUCTION

Cardiac perforation is a known complication of lead implantation and should be considered in cases of post operative lead malfunction. We present a case of early lead perforation diagnosed by chest computed tomography (CT).

## CASE REPORT

A 77-year-old Caucasian female with a past medical history of hypertension, hyperlipidemia and stage 3 chronic kidney disease was brought to the emergency department from home, after her family noticed her "passing out" while seated in a chair. She was noted to regain consciousness within a few seconds. On initial evaluation, her temperature was 36.6 degrees Celsius, blood pressure was 116/61 mmHg, pulse was 43 bpm and regular, respiratory rate was 12 breaths per minute, oxygen saturation on room air was 99%, physical exam was otherwise unremarkable. A sinus node rate of 88 bpm with 2:1 atrioventricular block (ventricular rate of 44 bpm), right bundle branch block and left anterior fasicular block was noted on a 12 lead electrocardiogram (ECG). Exercise myocardial scintigraphy performed one month prior to admission was normal. She was not taking any medications that could cause iatrogenic bradycardia. Ten seconds of ventricular asystole was noted on inpatient telemetry monitoring prompting insertion of a temporary transvenous pacemaker. Six hours later, a dual chamber permanent pacemaker was implanted in the cardiac electrophysiology lab with good post operative sensing and pacing thresholds in the atrium and ventricle. Twelve hours later she complained of left upper quadrant abdominal pain. Inpatient telemetry demonstrated 2:1 atrioventricular block with loss of ventricular capture at high

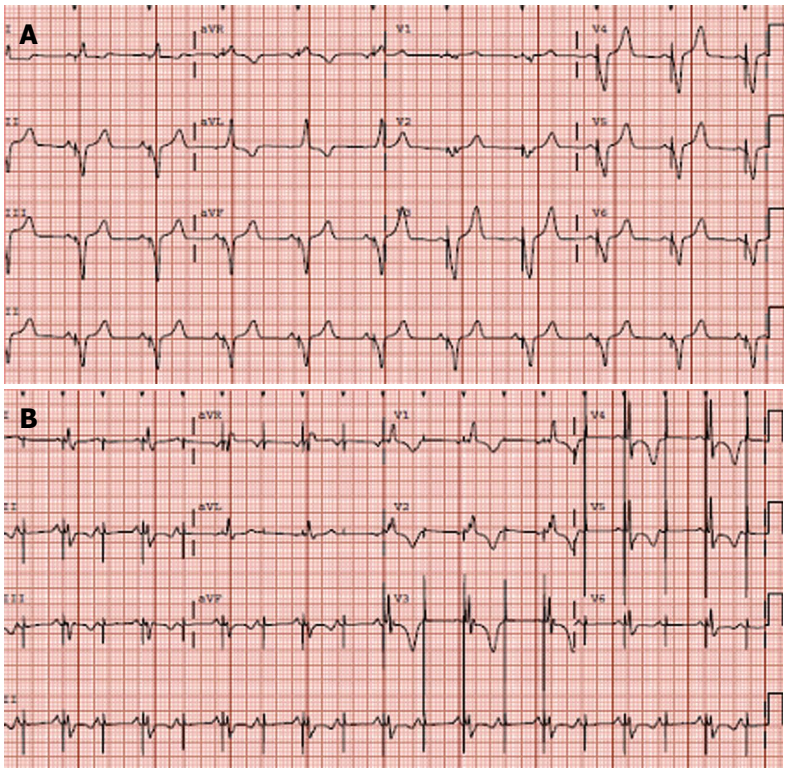

**Figure 1 Electrocardiogram.** Electrocardiogram on the top panel taken immediately after permanent pacemaker implantation demonstrates atrial sensing with ventricular pacing (A); The electrocardiogram on the bottom panel demonstrates failure to capture in the right ventricle with underlying 2:1 atrioventricular Block (B). The pacing configuration was bipolar with high outputs. Notice the prominent pacing spikes.

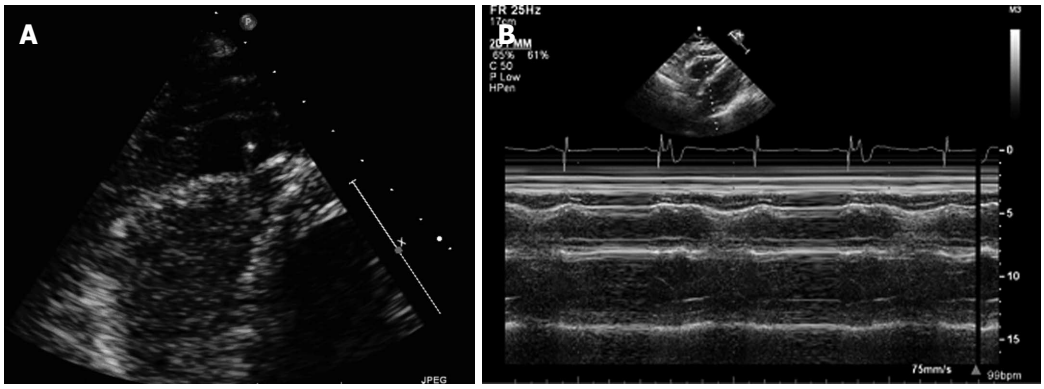

**Figure 2 Transthoracic echocardiogram.** A: Image is an apical 4 chamber view of a transthoracic echocardiogram showing a moderate sized localized pericardial effusion with an echo bright structure within the effusion suspicious for lead perforation; B: Image is taken in M-mode and demonstrates right ventricular diastolic collapse suggestive of increased pericardial pressures.

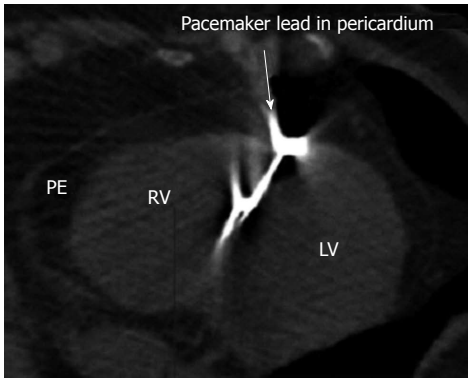

**Figure 3 This is an axial view of a non contrast chest computed tomography confirming diagnosis of right ventricular lead perforation.** The arrow points to the perforated lead. There is a pericardial effusion (PE). The right ventricle (RV) and left ventricle (LV) are also demonstrated.

pacing output (Figure 1). Chest X-ray did not show any shift in lead positions**.** A temporary transvenous pacemaker was reinserted. Ventricular lead perforation was suspected. A transthoracic echocardiogram demonstrated an echo bright structure protruding into the pericardial space. However, the images were suboptimal in quality and therefore technically limited to confirm lead perforation. A localized moderate sized pericardial effusion with right ventricular diastolic collapse best seen on M-mode imaging (Figure 2) was also noted. She demonstrated no clinical signs of cardiac tamponade. Non contrast chest CT confirmed lead perforation (Figure 3) with the tip of the right ventricular lead in the pericardial space. The lead was repositioned in the cardiac electrophysiology lab under fluoroscopic and echocardiographic guidance (Figure 4). Follow up echocardiogram revealed no change

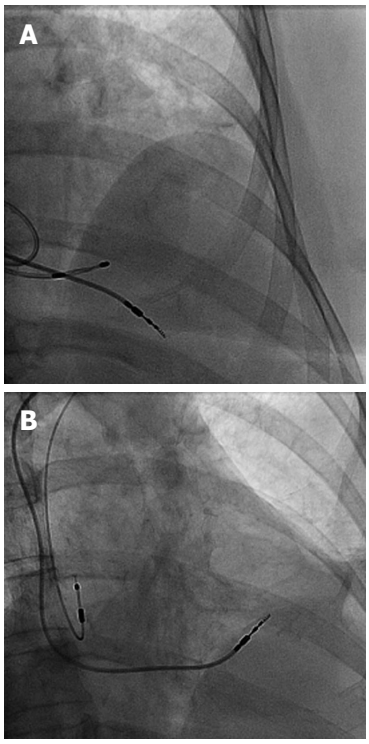

**Figure 4 Image.** Top image shows the right ventricular permanent pacemaker lead protruding well past the heart border, A temporary transvenous pacemaker lead can also be seen within the right ventricle (A); The bottom image shows the repositioned right ventricular lead higher up on the interventricular septum and absence of the temporary transvenous pacemaker lead. The right atrial lead can also be seen in this image (B).

in the size of the effusion. There was also resolution of right ventricular diastolic collapse. Device interrogation demonstrated stable pacing and sensing thresholds in the right ventricle. The leads remained in stable position on chest X-ray. On follow up 1 wk later the patient was doing well with complete resolution of the pericardial effusion on echocardiogram.

## DISCUSSION

Complications associated with permanent pacemaker implantation include pneumothorax, myocardial perforation, lead dislodgement or fracture, infection, hematoma, erosion and vein thrombosis[1]. The rates of cardiac perforation range from 0.1% to 0.8% for pacemaker leads[2]. One should be alerted to the possibility of cardiac perforation by a pacemaker lead if pacing or sensing malfunction is noted. Most cases of lead perforation happen during or shortly after implant, but cases of late perforation as long as 4.8 years after implant have been reported[3]. Chest X-ray has traditionally been used to evaluate lead positioning in cases of suspected pacemaker lead perforation. Echocardiogram can be used to provide additional information such as extent of pericardial effusion. Another option is a non-contrast chest CT utilizing a small field of view to reduce the effective radiation dose. In a small case series Henrikson *et al*[4] demonstrated that 64 slice Chest CT was able to make the diagnosis of cardiac perforation by a device lead in all suspected cases. Risk factors for lead perforation include patient characteristics such as female sex, age, small body habitus, thin heart walls; concomitant therapies such as steroids or anticoagulants; implant techniques; and the design characteristics of the lead[2]. Cardiac perforation by a lead can be corrected by repositioning it under fluoroscopic guidance in the cardiac electrophysiology lab, however surgery may be necessary.

## COMMENTS

### *Case characteristics*

This is a 77-year-old Caucasian female with a past medical history of hypertension, hyperlipidemia and stage 3 chronic kidney disease who presented with an episode of syncope.

### *Clinical diagnosis*

She had an episode of ventricular asystole while in the hospital and underwent permanent pacemaker implantation complicated by lead perforation.

### *Differential diagnosis*

Ischemic, infectious, iatrogenic and endocrine causes of atrioventricular block were ruled out.

### *Laboratory diagnosis*

The patient had normal electrolytes, thyroid stimulating hormone level and was not on any atrioventricular nodal blocking agents.

### *Imaging diagnosis*

A non-contrast chest computed tomography confirmed pacemaker lead perforation.

### *Pathological diagnosis*

There were no relevant pathological findings in this case.

### *Treatment*

The patient underwent permanent pacemaker implantation with subsequent lead revision after being diagnosed with cardiac perforation.

### *Related reports*

There are other case reports using various imaging modalities to diagnose cardiac perforation by a pacemaker lead.

### *Experiences and lessons*

Cardiac perforation by a pacemaker lead should be considered in cases of device malfunction regardless of the age of the device.

### *Peer review*

A well done case report. it find no ancillary comments that would aid the readership, continued success with this excellent writing.

## Abstract

Jejunal diverticula are rare and subsequent complications even more so. The usual small bowel diverticulum encountered by general surgeons is a Meckel's. These are embryological remnants of the vitello-intestinal duct and are on the anti-mesenteric surface of the terminal ileum. They may contain heterotopic gastric or pancreatic mucosa. Herein we explore the case of a young girl who presented with features of peritonitis secondary to a complication from a jejunal diverticulum. The case, pathology, complications and treatment of jejunal diverticulosis and heterotopic gastric mucosa in the jejunum are explored.

**Key words:** Jejunum; Perforation; Heterotopic gastric mucosa; Meckel's gastrointestinal diverticulum

**Core tip:** Herein we describe a rare but important cause of peritonitis in children. We feel it will be of interest to surgeons and pathologists alike and is an important reminder of the basic anatomy and pathology of surgical disease.

Bunni J, Barrett HL, Cook TA. Perforated jejunal ulcer associated with gastric mucosa in a jejunal diverticulum. *World J Clin Cases* 2014; 2(6): 209-210 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/209.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.209

## INTRODUCTION

Jejunal diverticula are rare and subsequent complications even more so[1]. The usual small bowel diverticulum encountered by general surgeons is a Meckel's. These are embryological remnants of the vitello-intestinal duct and are on the anti-mesenteric surface of the terminal ileum. They may contain heterotopic gastric or pancreatic mucosa.

Complications of true jejunal diverticula are rare particularly in young children. Herein we explore the case of a young girl who presented with features of peritonitis secondary to a complication from a jejunal diverticulum. Following surgery she made an excellent recovery. We explore the case, pathology, complications and treatment of jejunal diverticulosis and heterotopic gastric mucosa in the jejunum.

## CASE REPORT

A previously fit and well 5 years old girl presented to the pediatricians with a two day history of worsening abdominal pain, anorexia and vomiting.

Clinical findings were of pyrexia and generalised peritonitis. Bloods tests showed a lymphocytosis of 29.2 × $10^9$/L.

A working differential diagnosis was of acute perforated appendicitis or perforated Meckel's diverticulum and she was taken immediately to the operating theatre.

A 1 cm proximal jejunal perforation was identified on the antimesenteric border, directly opposite a mesenteric diverticulum, with a normal appendix. Small bowel re-

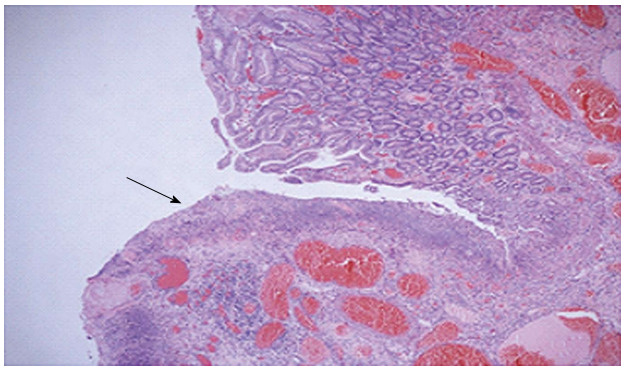

**Figure 1 Ulcerated small bowel mucosa (arrow) adjacent to area of perforation.**

section was performed with peritoneal toilet. She made a steady recovery and was discharged home on day four post-operatively.

## DISCUSSION

Histology of the small bowel showed features of a true diverticulum with gastric mucosa lining the diverticulum. Helicobacter-like organisms were not identified. The adjacent small bowel showed transmural inflammation and degeneration of the wall at the site of perforation with an adjacent serosal exudate (Figure 1). There was no evidence of malignancy. Sections of the appendix showed a mild serosal exudate but no evidence of mucosal acute inflammation.

Jejunal diverticula, like all diverticula can be true, involving all three layers of the bowel wall or false - a herniation of mucosa and submucosa through the muscularis propria. True diverticula are usually congenital and false are acquired. The latter are more common and are pulsion diverticula which arise at the weak point on the jejunal mesenteric surface (the point where the mural vessels penetrate the bowel wall). They are more common in middle aged males.

Rarer are the true diverticula which are congenital in nature. These can be on either the mesenteric or antimesenteric surface. The mesenteric diverticula are thought to be primarily related to the neurenteric remnants and duplications, and can be lined by gastric; intestinal or respiratory type epithelium or contain heterotopic pancreatic tissue.

Complications from jejunal diverticula are varied. Though the majority are silent, they can present with chronic abdominal pain, malabsorption, acute gastrointestinal haemorrhage, occult bleeding, diverticulitis, perforation, bacterial overgrowth or small bowel obstruction due to jejunal volvulus. Complications warranting surgical intervention occur in 8% to 30% of patients[2].

In the elective setting, if suspicious of jejunal diverticulosis there are different investigations that can be performed. These include small bowel follow through, small bowel enteroclysis, capsule endoscopy, computed tomography scanning as well as in the case of bleeding, radionuclide scans and mesenteric angiography.

Jejunal heterotopic gastric mucosa is a very rare entity, and literature review revealed the usual presenting age to be 14 years[3]. A common presentation is that of intermittent intussusception secondary to a small bowel (usually) polypoidal mass. This mass is predominantly located only a few centimetres distal to ligament of Treitz.

Management of jejunal diverticula depends on whether or not patients experience symptoms. Asymptomatic jejunal diverticula found incidentally rarely warrant treatment. In symptomatic cases small bowel resection and end-to-end anastomosis is advised.

Jejunal diverticula are rare and their complications even more so. There are subtle pathological differences and once responsible for complications the authors advise small bowel resection and end-to-end anastomosis so as to achieve a pathological diagnosis; cure the problem and ensure no remaining potential heterotopic mucosa of other organs remains.

## COMMENTS

### *Case characteristics*

This young patient presented with an acute abdomen and shock.

### *Clinical diagnosis*

Diagnose with peritonitis. Lab tests showed a lymphocytosis.

### *Differential diagnosis*

Acute appendicitis or perforated Meckel's diverticulum.

### *Laboratory diagnosis*

She was taken to the operating room whereby a small bowel perforation was identified and resected.

### *Pathological diagnosis*

Histopathological analysis revealed this to be a perforation secondary to heterotopic gastric mucosa.

### *Treatment*

Small bowel resection was performed with peritoneal toilet and making a steady recovery.

### *Experiences and lessons*

To rapidly identify the sick patient and not waste time on investigations that will not alter management. Awareness of the diversity of small bowel pathology.

### *Peer review*

This is a short case report showing a pediatric patient with perforating jejunal diverticulum. The case is rare and may be worth publication.

## Abstract

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder that almost exclusively involves motor neurons although autonomic dysfunction has also been reported. We present an 84-year-old female with no documented history of heart disease, who was admitted with negative T waves in the electrocardiogram precordial leads mimicking myocardial ischaemia. No other abnormalities were shown in the rest of the cardiologic evaluation, suggesting autonomic nervous system dysfunction. A neurophysiological study demonstrated acute and chronic denervation in multiple muscles with normal nerve conduction studies, confirming ALS diagnosis. Previous studies have shown that subclinical sympathetic hyperfunction and parasympathetic hypofunction might result in cardiovascular dysfunction in ALS patients. It is important to detect disturbances of autonomic cardiac control because this dysfunction may influence survival and quality of life, leading to a decrease in life expectancy in ALS patients. This Case Report may support the impairment of cardiac autonomic control in patients with ALS.

**Key words:** Amyotrophic lateral sclerosis; Autonomic nervous system diseases; Electrocardiography; Myocardial ischemia; Cardiac catheterization

**Core tip:** A few cases showing electrocardiogram (ECG) abnormalities in amyotrophic lateral sclerosis (ALS) patients have been previously reported suggesting an autonomic disturbance in ALS. We present an ALS patient with abnormal ECG mimicking myocardial ischaemia, in whom both coronary disease and cardiac anatomic damage were ruled out supporting the autonomic nervous system involvement in this mainly motor neuron disease.

Martínez J, Ramón C, Morís C, Pascual J, Morís G. Abnormal electrocardiogram in a patient with amyotrophic lateral sclerosis mimicking myocardial ischaemia. *World J Clin Cases* 2014; 2(6): 211-214 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/211.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.211

## INTRODUCTION

Amyotrophic lateral sclerosis (ALS) is an idiopathic, fatal neurodegenerative disease caused by degeneration of the first and second motoneurons. Recent advances indicate heterogeneity in phenotype, pathological substrate and genetic predisposition, suggesting that ALS should be considered a syndrome rather than a single disease entity. Therefore, the clinical presentation and progression of ALS may vary considerably. Cognitive and behavioural impairment is a frequent feature of ALS but other non-motor clinical features, such as autonomic nervous system (ANS) dysfunction, are underreported[1,2]. The

**Figure 1 Resting 12-lead electrocardiogram showing negative T waves in precordial leads Ⅰ, aVL, V2-V6.**

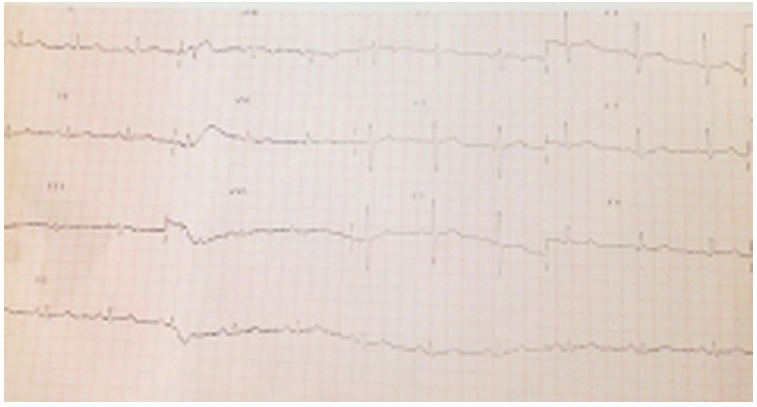

**Figure 2 Normal 12-lead electrocardiogram performed in 2002.**

affection of the ANS in ALS, as part of a complex degenerative process, has an increasing evidence and it is postulated that ALS patients develop dysautonomic dysfunction that may involve the heart[3].

Herein, we report an ALS patient with both negative T waves on the electrocardiogram (ECG) and no data of underlying coronary disease, supporting ANS dysfunction in ALS.

## CASE REPORT

An 84-year-old female with no history of heart disease was referred to our hospital because of chest pain, dyspnoea and abnormal ECG showing negative T waves in precordial leads V2-V6 and Ⅰ, aVL (Figure 1). Initially, the patient had been admitted to a different hospital due to chest pain and progressive dyspnoea. While performing an electromyogram, an episode of shortness of breath, rales on auscultation and desaturation was documented. A chest radiograph was performed suggesting cardiac failure and an ECG showed anterior and lateral subepicardial ischaemia. Diagnostic of acute coronary syndrome was done and the patient was transferred to our Hospital.

The patient had a diagnosis of hypertension made several years before, being under enalapril treatment since then. No other treatments had ever been prescribed. There was no history of myocardial infarction, myocarditis, cardiomyopathy, pericarditis, hyper- or hypothyroidism or calcium metabolism disturbances. An ECG performed 10 years ago showed no abnormalities (Figure 2); no other ECGs were performed before this episode. The patient was feeling well until six months ago, when she started experiencing painless and progressive weakness in her left hand. During the following weeks, weakness progressed to proximal and distal muscles in both upper limbs.

Neurological examination showed a normal mental status. Her speech was dysarthric, no facial paresis was noted but mild lingual weakness was observed. The visual fields were intact and ocular movements were full and smooth. Asymmetric muscle weakness and atrophy, involving the upper extremities, were present with severe atrophy of the left hand muscles. Mild proximal paresis was observed in both lower limbs. Fasciculations were noted in the tongue, upper, and lower extremities. Deep-tendon reflexes were brisk and there were bilateral ankle clonus. There was jaw hyperreflexia. Plantar responses were extensor. There were no sensory deficits. Bowel and bladder function remained normal. Complete blood cell count was normal, as were electrolyte, Troponin T, creatine kinase, creatinine, fasting plasma glucose and haemoglobin A1c concentrations. Liver function and thyroid function studies yielded normal results. A brain CT scan depicted no abnormalities and a cervical MRI showed no abnormal findings at the spinal cord or the nerve roots. A neurophysiological study demonstrated acute and ongoing chronic partial denervation in multiple muscles of bulbar region and both upper and lower extremities with normal nerve conduction studies. The diagnosis of definitive ALS was made according to the Awaji–Shima criteria[4]. Echocardiography showed 16 mm left ventricular

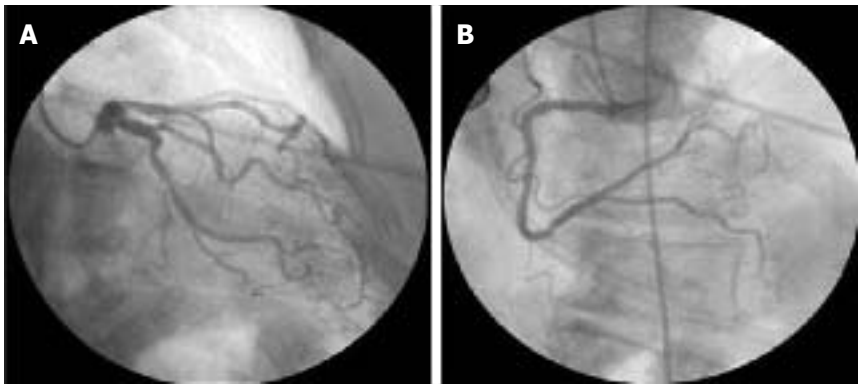

**Figure 3 Coronary angiogram showed normal coronary arteries.** A: left coronary arteries; B: right coronary artery.

symmetrical hypertrophy with normal wall motion and a coronary angiography showed no significant anomalies (Figure 3). The patient suffered a progressive respiratory failure and she died four days after hospital admission.

## DISCUSSION

There is well known that various central nervous system disorders can cause ECG abnormalities that mimic coronary syndromes including S-T elevation, T wave inversion and Q-T prolongation. These findings have been well described in relation with subarachnoid or subdural haematomas. Central o peripheral autonomic dysfunction has been also described in patient with Parkinson´s disease, multiple system atrophy or Guillain-Barré syndrome which increases the risk for arrhythmias, therefore, ECG monitoring is essential[5].

The impact of ALS on the cardiovascular system is well known. Several studies have shown that subclinical sympathetic hyperfunction and parasympathetic hypofunction might result in cardiovascular dysfunction in ALS patients[3,6-10]. There are very few reports describing the ECG characteristics in relation with this pathology. ECG alterations in ALS have been presented as a pseudo-ischaemic pattern, however a pseudo-myocardial infarction pattern has also been described[11-13]. Moreover, an elevated Troponin T levels in a patient with ALS without underlying ischaemic cardiopathy has been reported as a consequence of hypoxic respiratory failure or as immune-mediated myocardial injury secondary to ALS[14].

In ALS, involvement of sympathetic neurons has been associated with neuron degeneration in the intermediolateral nucleus of the upper thoracic spinal cord, causing subclinical findings such as reduction in nocturnal blood pressure and loss of correlation between blood pressure and heart rate. In a study analyzing changes in the corrected QT interval (QTc) and QTc dispersion, ECG showed that both the average QTc and QTc dispersion was significantly higher in patients with ALS supporting sympathetic disturbances in this motoneuron disease[6]. Furthermore, Pavlovic *et al*[3], studied the cardiovascular autonomic control in 55 patients with ALS and compared it with 30 healthy controls. They found that patients with ALS have a significantly higher degree of both sympathetic and parasympathetic dysfunction with relative sympathetic predominance compared with controls. Disturbances of autonomic cardiac control in ALS patients may influence survival and quality of life predisposing to hypertensive crisis, sudden cardiac death, and cardiovascular collapse, all leading to a decrease in life expectancy[3,10,15]. In addition, recent studies have established the contribution of neuronal ion channel dysfunction to the pathophysiology of ALS, mainly $Na^+$ and $K^+$ channels; moreover, the modulation of ion channel function has been proposed as the mechanism by which riluzole exerts the neuroprotective effects in ALS[16-18]. Based on ion channels dysfunction implicated in heart disease, it could also be argued that ECG changes in ALS patients may be related with ion channel dysfunction[19].

We present an ALS patient with an ECG showing negative T waves in precordial leads mimicking myocardial ischaemia. Complementary tests ruled out systemic and cardiologic causes that might have been associated with these ECG disturbances; therefore, an association between the pseudo-ischaemic ECG and ALS was suspected. The underlying mechanism of these abnormalities in the ECG must be addressed although ANS dysfunction has been proposed. Unfortunately, neither a baseline ECG nor a follow-up ECG after the acute episode were performed and the only previous ECG was done 10 years before. However, we cannot completely rule out that other underlying processes not covered by our investigations were the cause. In conclusion, it is important to detect disturbances of autonomic cardiac dysfunction in ALS patients to avoid sudden death or other conditions leading to a decrease in life expectancy.

## COMMENTS

### *Case characteristics*

An 84-year-old female with a diagnosis of amyotrophic lateral sclerosis (ALS) presented with negative T waves in the electrocardiogram (ECG) mimicking myocardial ischaemia.

### *Clinical diagnosis*

The patient exhibited classical clinical features of ALS and an ECG showed negative T waves in precordial leads I, aVL and V2-V6.

### *Differential diagnosis*

Differential diagnosis included myocardial infarction or ischaemia, myocarditis, cardiomyopathy, pericarditis, hyper- or hypothyroidism or calcium metabolism disturbances.

### *Laboratory diagnosis*

A neurophysiological study demonstrated acute and ongoing chronic partial denervation in multiple muscles of bulbar region and both upper and lower ex-

tremities with normal nerve conduction studies.

### *Imaging diagnosis*

The cardiologic studies including echocardiogram and coronary angiography were normal.

### *Treatment*

The patient did not receive any treatment and she died in a few days.

### *Related reports*

A literature search revealed only a few cases of abnormal ECG in patients with ALS mimicking myocardial ischaemia or infarct.

### *Term explanation*

The Awaji-Shima criteria in the diagnosis of ALS were proposed in 2008 to enable earlier diagnosis of ALS to obviate diagnostic delay and to promote earlier entry into clinical trials.

### *Experiences and lessons*

The affection of the autonomic nervous system in ALS has increasing evidence and it is postulated that ALS patients develop dysautonomic dysfunction that may involve the heart

### *Peer review*

This is a well-written, interesting case report with good images.

## Abstract

We report the case of an urgent nephrectomy because of a pyonephrosis and sepsis due to an unsuspected sarcomatoid transitional cell carcinoma, an infrequent subtype with a bad oncological prognosis. We present a 58-year-old man assessed by internal medicine for a general syndrome and weakness many months previously. A pyonephrotic kidney was observed at abdominal computed tomography in the context of septic shock, without suspecting the underlying cause. The pathology report described a sarcomatoid transitional cell carcinoma. Sarcomatoid transitional cell carcinoma is an invasive and infrequent subtype of urothelial tumors. The symptoms are often the same as other renal masses; however, in this case, sepsis and pyonephrosis were the rare initial symptoms.

**Key words:** Urothelial carcinoma; Renal pelvis; Sarcomatoid

**Core tip:** Sarcomatoid transitional cell carcinoma is an invasive and rare subtype of urothelial tumors. The symptoms are often the same as other renal masses; however, in this case, sepsis and pyonephrosis were the rare initial symptoms.

## INTRODUCTION

Primary tumors of the renal pelvis account for approximately 7% of all renal tumors[1]; most of them are urothelial carcinoma. Urothelium can display a wide range of metaplastic changes and neoplasms arising from this epithelium can show several types of differentiation, especially in high-grade neoplasms. Unlike bladder urothelial carcinomas, the majority of primary urothelial carcinomas of the renal pelvis present with a high histological grade and show a tendency to display unusual morphological features with a metaplastic phenomena and aggressive behavior. Due to their location inside the kidney, a delay in diagnosis may happen with advanced stages, metastatic disease or massive infiltration of the kidney[2,3]. The sarcomatoid subtype is a kind of high grade urothelial carcinoma, a histological variant defined by a biphasic differentiation, epithelial and mesenchymal. Few cases have been reported in the literature since 1961 when Fauci and collegues reported the first case[4].

## CASE REPORT

We present a 58-year-old man assessed for a general syndrome and isolated episode of hematuria a few months previously.

His medical history included being a heavy smoker and alcohol consumer, deep venous thrombosis and alcoholic chronic pancreatitis with partial pancreatectomy 10 years previously.

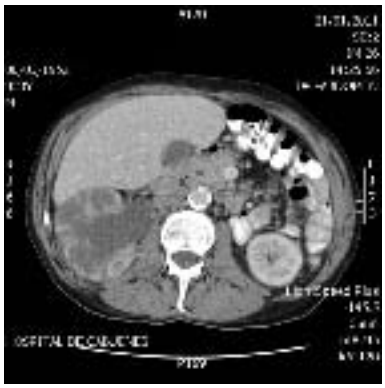

**Figure 1 Contrast enhanced abdominal computed tomography shows a dilated and unstructured right kidney.** No mass effect images.

**Figure 2 Macroscopic sagittal cut of the right kidney after nephrectomy, necrotic areas spread outside kidney and parenchyma is replaced by fibrotic tissue.**

From the urological point of view, an isolated episode of gross hematuria was described and was concomitant with a high dosage of oral anticoagulants. At this time, ultrasound and cystoscopy were within the normal limits.

In hospital, he was afebrile with low levels of blood pressure. His blood analysis showed anemia (hemoglobin 8.6 g/dL), discrete leukocytosis and serum creatinine within normal limits.

An abdominal computed tomography (CT) was requested which described a bizarre right kidney with intraparenchymatous levels of liquid with the renal pelvis and right ureter dilated up to the entrance of the bladder (Figure 1).

Initially, endovenous third generation cephalosporin treatment was administered and a ureteral stent was placed. After 12 h of observation, the clinical course worsened, with severe hypotension and elevated blood analysis parameters of lactic acid, C protein and procalcitonin. In this critical situation of septic shock, an emergency right nephrectomy was performed with an eleventh rib incision. The intraoperative description was of a dilated right kidney with plentiful purulent liquid linked with a pyonephrosis with no apparent cause. The patient had a normal postoperative course and was discharged on the seventh day.

The surgery specimen weighed 500 g and the volume was 15 cm × 9 cm × 7 cm, with thick parenchyma with pyelocalyceal dilation with purulent content at the sagittal section. Necrotic areas spread outside the renal tissue, the perinephric fatty tissue (Figure 2).

The pathology report described a sarcomatoid urothelial carcinoma with invasion into the parenchyma, renal sinus, perinephric fatty, lymphovascular and neural tissue. Carcinoma *in situ* was also associated with the upper calyceal system according to the American joint committee of cancer (AJCC), seventh edition, pT4NX. Immunochemistry studies revealed positivity to CK7, CD10 and vimentin. Moreover, the report described intense proliferative activity Ki67, 80% (Figure 3).

Chemotherapy was rejected due to the clinical situation of the patient and the patient refused a new surgical intervention in order to eliminate the ureteral remnant. The patient was followed up periodically and 18 mo after nephrectomy he was asymptomatic with no signs of relapse on imaging techniques.

## DISCUSSION

Transitional cell carcinoma of the renal pelvis and ureter are relatively rare and are less than 1% of all genitourinary cancers, likewise 5% and 7% of urinary tract tumors[5]. Tumors arising from the renal pelvis are morphologically similar to those from the bladder. Their incidence varies from 0.7 to 1.1 per 100000 with a male to female ratio of 1.7 to 1, but with an increasing trend in women. They more frequently appear in the elderly (mean age 70 years). Over 90% of tumors arising from the renal pelvis and ureter are urothelial carcinomas. Hematuria and back pain are the most common signs and symptoms[6]. Hematuria, either gross or microscopic, is present in 75%-90% of cases. Back pain occurs in 20%-40% of cases, usually secondary to obstruction by the tumor that can mimic a ureteral calculus. Urinary symptoms, such as dysuria, urinary frequency, nocturia or urinary retention, can be found in up to 25%-50% of patients. The physical examination is usually normal, with the exception of a lumbar palpable mass in less than 10% of patients[5].

Sarcomatoid transitional cell carcinoma (sarcomatoid carcinoma) of the renal pelvis should not be confused with sarcomatoid renal cell carcinoma, an undifferentiated high grade epithelial tumor whose origin is at the parenchyma. Another tumor with a bad prognosis is the collecting duct carcinoma (Bellini duct carcinoma) which is centered in the medulla, develops a tubulopapillary architecture and is surrounded by a desmoplastic reaction[7]. Radiologically, some researchers reported that sarcomatoid carcinomas and renal cell carcinomas are indistinguishable from each other.

The term "transitional cell carcinoma with sarcomatoid differentiation" should be used in solid tumors with biphasic epithelial and mesenchymal differentiation (with the presence or absence of heterologous components).

Another neoplasm considered at the differential diagnosis is carcinosarcoma. Carcinosarcomas and sarcoma-

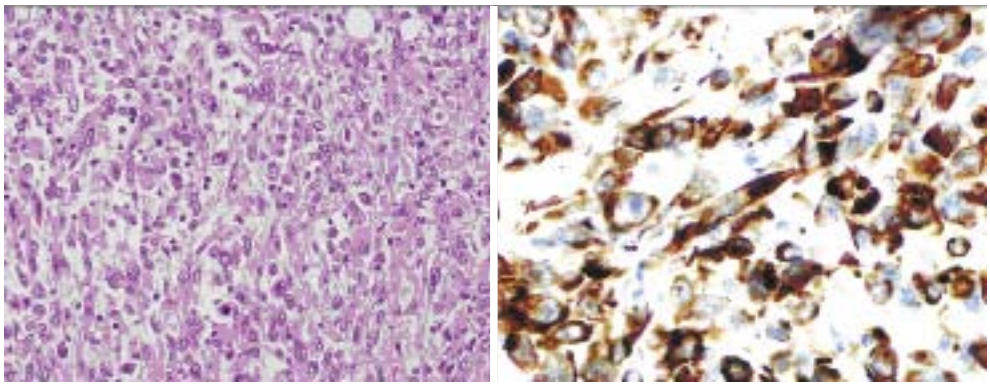

**Figure 3 On the left side the sample (x 20) shows the invasive sarcomatoid pattern and on the right side the immunochemistry (x 40) positivity for CK7.**

toid carcinomas are difficult to distinguish in hematoxylin-eosin samples. Carcinosarcomas are composed of two components, epithelial and sarcomatous, and sarcomatoid carcinomas are malignant epithelial tumors which show sarcomatoid changes[8]. There is too much confusion and disagreement in the literature regarding the nomenclature and histogenesis of these tumors. In some series, both terms, carcinosarcoma and sarcomatoid carcinoma, are included under the term "sarcomatoid carcinoma" and in others they are listed as two different entities[3,4,9,10].

In addition, the differential diagnosis should also include locally aggressive and benign conditions, such as postoperative spindle cell nodes and pseudotumors as inflammatory myofibroblastic tumors.

Histologically, sarcomatoid areas may be combined with foci of transitional cell carcinoma, squamous cell carcinoma, adenocarcinoma or small cell carcinoma. Heterologous differentiation may be present but has no prognostic significance. All sarcomatoid carcinomas are high-grade and have a poor prognosis. These tumors show no difference in survival when compared stage by stage with conventional urothelial carcinoma. In the absence of invasive urothelial carcinoma or obvious epithelial differentiation, a prior history of urothelial carcinoma, the coexistence of urothelial carcinoma *in situ*, or immunoreactivity for cytokeratin or epithelial membrane antigen (EMA) in the sarcomatous areas are useful for the diagnosis of sarcomatoid carcinoma. The immunohistochemistry is the key to the diagnosis.

The immunoreactivity for keratins and EMA are specific for epithelial cells and the presence of epithelial markers in mesenchymal areas and/or the presence in sarcomatoid elements of ultrastructural features of epithelial differentiation (desmosomes or tonofilaments) suggest the diagnoses of sarcomatoid carcinoma. Likewise, the mesenchymal elements in carcinosarcomas do not stain with epithelial markers and have no desmosomes or tonofilaments[3].

The gold standard treatment for urothelial carcinoma is surgery, in this case nephroureterectomy, but a nephrectomy was only performed because the presence of an aggressive tumour was unsuspected. Neoadjuvant chemotherapy was not an option for this patient. On the one hand, it was an emergency operation and on the other hand, contrary to what has been demonstrated for bladder cancer, there have been no reported effects of neoadjuvant therapy for upper urinary tract cancer[11].

Adjuvant chemotherapy can somehow achieve a recurrence free rate of up to 50% but clearly has no impact on survival and no data are currently available to provide any recommendations[12]. At our institution, chemotherapy is only considered as palliative in cases of metastatic evolution or with the presence of symptoms.

Adjuvant radiotherapy may improve local control of the disease and can be combined with a cisplatinum regimen[13] but they are no longer considered at our center as a standard care for this kind of tumors.

This pT4Nx tumor is included in the IV stage according to AJCC classification (remember IV stage includes all pT4 with N+ or N0 and M+ or M0), the fact of pT4 being directly included in IV prognostic stage in spite of no pathological node report and no signs of metastatic disease. The observed overall survival with this classification with data taken from National Cancer Data Base for the year 2000 to 2002 is: 43.3% in 1 year, 24% in 2 years, 16.4% in 3 years, 12.4% in 4 years and 10.2% in 5 years.

An interesting paper describes the local relapse rate during a mean follow-up of 58 mo in 14% of the patients, with the overall mortality of 14% and the mean survival of 109 mo. Stage T3 and T4 were significantly linked with survival[14].

We report the case of a 58-year-old man with the radiological finding of pyonephrosis and an emergency nephrectomy being performed with the worsening of the clinical condition. The pathology examination suggested a renal pelvis urothelial neoplasm with sarcomatoid differentiation. This neoplasm widely spread though perirenal fatty tissue and lymphatic vascular tissue.

Sarcomatoid subtype is a rare presentation of urothelial carcinoma and is linked with a bad prognosis. In the same sample, zones of epithelial carcinoma, adenocarcinoma and small cell carcinoma are usually described.

## COMMENTS

### *Case characteristics*

A 58-year-old man assessed for a general syndrome and isolated episode of hematuria.

### Clinical diagnosis
The radiological finding of pyonephrosis and worsening of the clinical condition, with an emergency nephrectomy being performed.

### Differential diagnosis
Ultrasound, cystoscopy, computed tomography (CT).

### Laboratory diagnosis
Blood analysis showed anemia (hemoglobin 8.6 g/dL). The surgery specimen weighed 500 g and volume was 15 cm × 9 cm × 7 cm, with thick parenchyma with pyelocalyceal dilation with purulent content at the sagittal section.

### Imaging diagnosis
An abdominal CT was requested and described a bizarre right kidney with intraparenchymatous levels of liquid, with the renal pelvis and right ureter dilated up to the entrance of the bladder.

### Pathological diagnosis
The pathology report described a sarcomatoid urothelial carcinoma with invasion into the parenchyma, renal sinus, perinephric fatty, lymphovascular and neural tissue.

### Treatment
The clinical evolution with an emergency nephrectomy.

### Experiences and lessons
Sarcomatoid subtype is a rare presentation of urothelial carcinoma and is linked with a bad prognosis. In the same sample, zones of epithelial carcinoma, adenocarcinoma and small cell carcinoma are usually described.

### Peer review
The authors describe a case of pyonephrosis as a sign of sarcomatoid carcinoma of the renal pelvis. This is an interesting paper.

## Abstract

Fractures of the lesser tuberosity of the humerus are typically met in combination with other injuries of the shoulder. Case reports of isolated lesser tuberosity fractures are particularly rare and, consequently, therapeutic protocols have not yet been completely clarified. Conservative as well as surgical treatment has been recommended, while several operative techniques have been applied. We present a case of a 39-year-old man with an isolated lesser tuberosity fracture who was treated surgically in our institution. Due to fracture comminution, a two-level reconstruction technique with headless screws and buttress plate was applied. As far as we know, this method of fixation of this type of fracture has not been previously described in the literature. The patient tolerated the procedure well and excellent results were obtained at the latest follow-up.

**Key words:** Shoulder; Humerus; Lesser tuberosity; Fixation; Technique; Two-level reconstruction

**Core tip:** Isolated fractures of the lesser tuberosity of the humerus in adults are extremely rare. Only a few cases have been reported so far in the literature. The optimal treatment method of these fractures is still a matter of debate. Herein, we present a case of a 39-year-old man with an isolated lesser tuberosity fracture who was treated surgically in our institution. Due to fracture comminution, a two-level reconstruction technique with headless screws and buttress plate was applied. As far as we know, this method of fixation of this type of fracture has not been previously described in the literature.

## INTRODUCTION

Five percent of all humeral fractures involve the proximal end alone[1,2]. Out of this, only 2% account for isolated lesser tuberosity fractures, making the incidence extremely rare. More often, they are seen as an isolated injury or with a combined posterior dislocation of the shoulder[3]. Moreover, these fractures may be difficult to identify because of the osseous overlapping in the standard x-ray examination or they are misdiagnosed as intra-articular loose bodies or calcifications of the rotator cuff[4].

The injury typically requires traumatic abduction and external rotation of the upper arm in relation to the shoulder. The forceful contraction of the subscapularis muscle leads to the avulsion fracture of the lesser tuberosity.

Epidemiologically, little is known but it has been described as an injury that involves male patients between the 2nd and 5th decades of life and youngsters with an open humeral physis. If not treated or missed, these injuries may lead to subscapularis weakness and/or impinge-

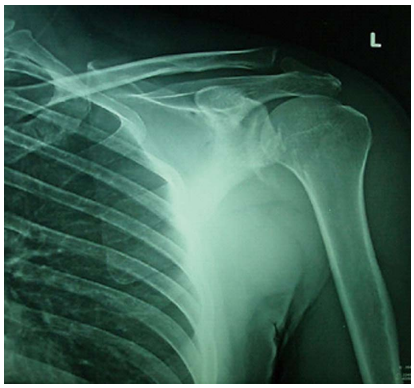

**Figure 1 Anteroposterior radiograph of left shoulder showing a crescent-shaped fragment near the inferior part of the glenoid rim.**

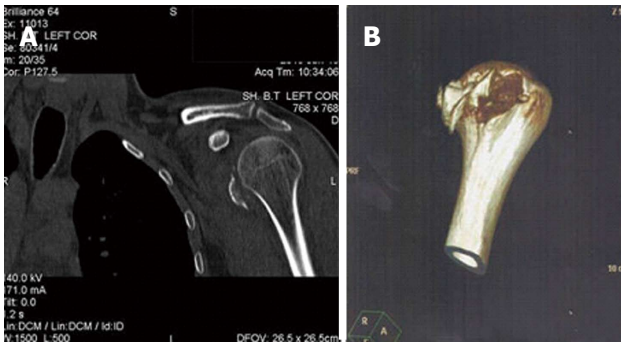

**Figure 2 Further examination with computed tomography scan (A) and 3D computed tomography reconstruction (B) confirmed the diagnosis and revealed the comminution of the lesser tuberosity avulsion fracture.**

ment of the malunited part[5,6].

Generally, open reduction and internal fixation is the treatment of choice in otherwise medically fit patients but some authors suggest conservative treatment for minimally displaced fractures and report clinically successful results[7,8].

Operative procedures can be challenging in cases of comminuted fractures of the lesser tuberosity. We present a case of a comminuted isolated avulsion fracture of the lesser tuberosity of the humerus in a young male patient. A two-level reconstruction technique is described.

## CASE REPORT

A 39-year-old male presented to our emergency department with a history of a fall from a height of about 2 m on to his outstretched left arm. On clinical examination, there was tenderness on palpation on the frontal aspect of the proximal humerus and restriction of movements of the joint, energetically and passively. No neurovascular damage was noted.

Standard anteroposterior radiograph revealed a crescent-shaped fragment near the inferior part of the glenoid rim. At that point, lateral X-ray was not possible due to patient's pain (Figure 1).

The patient was admitted to our orthopedic department and a computed tomography (CT) scan was performed to describe the damage in greater detail (Figure 2). A magnetic resonance imaging (MRI) scan was also performed to exclude possible intra-articular damage and/or tendon pathology (Figure 3).

**Figure 3 Magnetic resonance imaging exam of the left shoulder excluded intra-articular extension of the fracture or other tendon ruptures.**

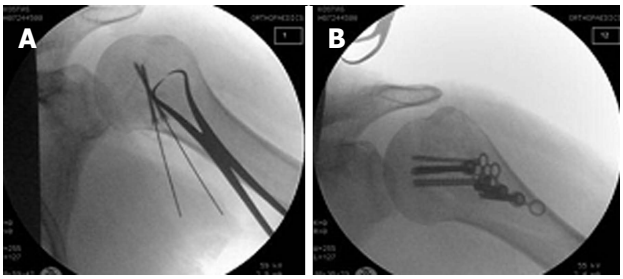

**Figure 4 Intra-operative fluoroscopic images.** Initially, the bigger fragments of the lesser tuberosity were reduced using reduction forceps and fixed using cannulated headless Hebert screws (A). The smaller fragments were then reduced and stabilized under a low profile, bendable neutralization buttress plate (B).

The isolated comminuted avulsion fracture of the lesser tuberosity was confirmed, with no other intra-articular pathology of the shoulder joint. It was decided to operate and the patient was transferred to the operating room 48 h after the injury.

Under general anesthesia and with the patient supine in the so-called beach chair position, with the image intensifier placed on the opposite side of the operating table, a standard deltopectoral approach was used. Fragments of the avulsed lesser tuberosity with the subscapularis tendon were identified. The fracture did not extend to the articular surface or the bicipital groove. Initially, the larger fragment of the avulsed lesser tuberosity was reduced using reduction forceps. Two cannulated Herbert screws were used to stabilize the fragment (Figure 4). The smaller fragments were then reduced and stabilized using a low profile, bendable neutralization buttress plate (T-plate, NCB proximal humerus, Zimmer Company, Winterthur, Switzerland) (Figure 5). The long head of the biceps tendon was identified and found to be stable (Figure 6). Excellent fracture reduction was confirmed with intraoperative fluoroscopy (Figure 4). A drain was positioned and the wound was closed in the usual fashion. Figure 7 shows the immediate post-operative X-ray.

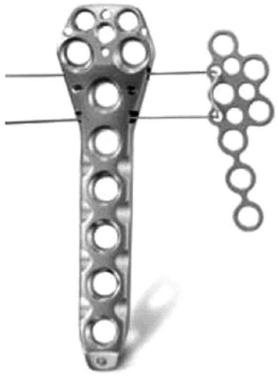

**Figure 5 The 7-holes T-minus plate (right) that was used as a buttress plate is part of the Non-Contact Bridging proximal humerus, polyaxial locking plate system (Zimmer Company, Winterthur, Switzerland).**

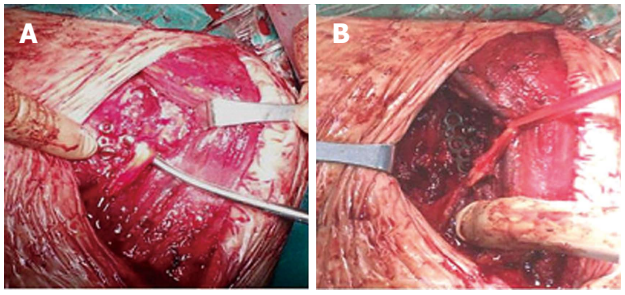

**Figure 6 Intraoperative photos.** A: The headless Herbert screw is inserted and the larger fragments have been stabilized; B: The T-minus plate has been positioned acting as a buttress plate. The biceps tendon was found to be stable and was protected during the procedure.

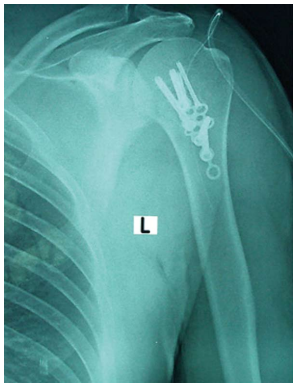

**Figure 7 Immediate post-op X-ray of the left shoulder, showing excellent fracture reduction.**

The arm was placed in a sling in a neutral position and the elbow flexed 90 degrees. The patient was released from the hospital 2 d post-operatively. Immediately after stitches removal, the patient initiated his rehabilitation program, with passive assisted exercises to regain full range of motion. Six weeks post-operatively, active exercises were implicated.

On follow-up, the patient had achieved painless full range of motion and regained his normal activities. X-ray examination at the latest follow-up, 18 mo after surgery, revealed full union of the fracture and no hardware failure (Figures 8 and 9).

**Figure 8 At the latest follow-up, the patient demonstrated pain-free, full range of movement of the left shoulder.**

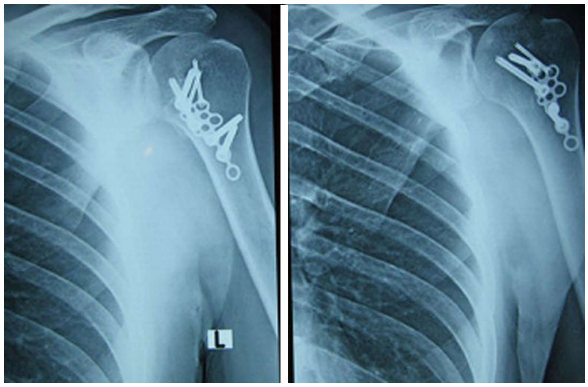

**Figure 9 Eighteen months after surgery, X-ray examination of the left shoulder shows full union of fracture without hardware movement or failure.**

## DISCUSSION

Approximately 2% of proximal humeral fractures are isolated fractures of the lesser tuberosity[9]. This demonstrates how rarely those injuries are met. Until now, the lack of an extensive published case series does not allow the determination of a standard therapeutic protocol for this type of fracture. The small sized lesser tuberosity, which is adequately protected in the medial aspect of the proximal humerus, is not frequently fractured and, when this happens, sudden contraction of the subscapularis muscle, which is attached to the tuberosity and prevents the abduction and external rotation of the shoulder, is the most common mechanism of injury[6]. The clinical presentation of the patient, characterized by pain particularly in the frontal aspect of the shoulder and restricted motion, is not typical and requires proper radiographic control, which generally includes at least two views of the shoulder. Although in our case the fracture can be noted in the anteroposterior view of the shoulder, often the diagnosis is missed or delayed due to the lack of a complete imaging. An axillary view especially generally demonstrates lesser tuberosity fractures most clearly and possibly displaced fragments[10]. However, on plain radiographs, these fractures may be misdiagnosed as calcific tendonitis

of the rotator cuff or osseous Bankart lesions[8].

Thus, the usefulness of a CT scan in the diagnosis and treatment of this type of fracture, including the surgical technique for its fixation, is particularly important[2]. More specifically, a CT scan is a valuable tool in the hands of the surgeon for the estimation of specific characteristics of the fracture, such as displacement, comminution and possible involvement of the articular surface[2]. Further investigation with MRI can also help in determining possible severe soft tissue damage, including rotator cuff tendon injury, or severe trauma of the articular surface.

Once the diagnosis is made, several therapeutic options have been proposed. Conservative treatment, although not frequently indicated, has its own remarkable position in the therapeutic "arsenal", particularly in minimally displaced fractures[10] and in children[11,12]. However, controversy exists about the displacement of fracture as an indication of surgery; some authors recommend open reduction and internal fixation of even minimally displaced fractures in order to avoid late displacement and involvement of the bicipital groove[7]. Generally, operative treatment is recommended in cases of displacement more than 5 mm, angulation more than 45 degrees, persistent pain, blockage to motion and significant clinical weakness[5].

Regardless of the size or displacement of the fractured fragments, a review of the literature demonstrates that open reduction and internal fixation is the gold standard of the management of isolated lesser tuberosity fractures. Apart from open reduction and internal fixation, other methods of surgical treatment do exist and have generally given satisfactory results; surgical excision of the fractured fragment[13-15] and arthroscopically assisted reduction[16] have been proposed by several authors and have been proven efficient.

The common technique of open reduction and internal fixation of isolated lesser tuberosity fractures described in the literature includes the use of screws, cerclage wire[6] and, particularly in skeletally immature patients, the use of heavy sutures and suture anchors[5].

In conclusion, as far as we know, a two-level reconstruction of this type of fracture with headless screws and a buttress plate has not been previously described. The fact that led us to this surgical option was the comminution of the fracture and subsequent inability of adequate fixation with screws only. The larger fragments of the fracture were successfully fixed with headless Herbert screws. The smaller fragments were buttressed using a low profile, multi-hole plate. This plate also provided a more secure fixation of the larger fragments. As was proven, the clinical outcome was satisfactory and comparable with other cases in which different surgical methods were applied.

## COMMENTS

### Case characteristics

Isolated fracture of the lesser tuberosity of the humerus in a young adult male.

### Clinical diagnosis

There was tenderness on palpation on the frontal aspect of the proximal humerus and restriction of movements of the joint, energetically and passively. No neurovascular damage was noted.

### Differential diagnosis

Shoulder fracture dislocation, rotator cuff pathology and/or osseous Bankart lesion were considered in the differential diagnosis based on patient's symptoms. X-ray examination, computed tomography (CT) scan with 3D reconstruction and magnetic resonance imaging (MRI) of the injured shoulder were carried out.

### Imaging diagnosis

Standard anteroposterior radiograph revealed a crescent-shaped fragment near the inferior part of the glenoid rim. Further examination with CT scan and 3D CT reconstruction confirmed the diagnosis and revealed the comminution of the lesser tuberosity avulsion fracture. MRI exam of the left shoulder excluded intra-articular extension of the fracture or other tendon ruptures.

### Treatment

Due to fracture comminution, a two-level reconstruction technique with headless screws and buttress plate was applied.

### Experiences and lessons

Isolated fractures of the lesser tuberosity of the humerus are extremely rare in adults. Open reduction and internal fixation is usually the treatment of choice. In the setting of severe fragment comminution, adequate stabilization of the fractured lesser tuberosity can be challenging. Using the proposed operative technique, with two-level reconstruction of the lesser tuberosity, resulted in excellent fracture healing and the clinical outcome was satisfactory and comparable with other cases in which different surgical methods were applied.

### Peer review

This is a well written case report describing a new surgical approach. It will be of general interest to orthopedic surgeons.

## Abstract

We report our first simultaneous bilateral robot assisted partial nephrectomy (RAPN) in order to show and critically discuss the feasibility of this procedure. Materials and methods A 69-year-old male patient visited our department due to incidental finding of bilateral mesorenal small masses (2.5 cm on the right and 3.5 cm on the left) suspicious for malignancy. We started from the right side with patient in flank position. Port placement: 12-mm periumbilical camera port, two 8-mm robotic ports in wide "V"configuration, additional 12 mm assistant port on the midline between the umbilicus and symphysis pubis. A right unclamping RAPN with sliding clip renorrhaphy was performed. The trocars were removed and the robot undocked. Without interrupting the anesthesiological procedures, the patient was reported in supine position and, after 180 degrees rotation of the surgical bed, was newly placed in contralateral flank position. Using both the previous periumbilical and midline ports, two other 8-mm robotic trocars were placed. The robot was then redocked and RAPN was also performed on the left side using the same previously reported technique. Results Total time: 285 min. Estimated blood losses: 150 cc. Postoperative period: uneventful. Pathological examination: bilateral renal cell carcinoma, negative surgical margins. Conclusions Our experience was encouraging and confirmed the feasibility and safety of this procedure. The planning of our technique was time and cost effective with cosmetic benefit for the patient. However, we think that an appropriate selection of the patients and a skill in robotic renal surgery are advisable before approaching this type of surgery.

**Key words:** Robotics; Nephrectomy; Renal cell carcinoma; Remote operation robotics

**Core tip:** Very few papers have been reported concerning simultaneous bilateral robot assisted partial nephrectomy. We think that our technique was noteworthy for some important aspects: the number of the ports was minimized, the disposition of the operatory room allows the quick rotation of the patient's bed and the redocking of the robot, the operative time was acceptable, the unclamping technique decreased the risk of renal insufficiency, the cost for two nephrectomies was decreased. In conclusion, our technique was safe, feasible, time and cost effective with a cosmetic benefit for the patient.

Simultaneous bilateral robotic partial nephrectomy: Case report and critical evaluation of the technique. *World J Clin Cases* 2014; 2(6): 224-227 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/224.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.224

## INTRODUCTION

In the last few years, robot-assisted partial nephrectomy (RAPN) has become a promising procedure able to

bridge the technical difficulties of laparoscopic partial nephrectomy (LPN), permitting a broader diffusion of laparoscopic treatment of renal masses[1-3].

In fact, the 3D vision, the optical magnification and the robotic instruments allow surgeons to realize very precise tumor resection and to simplify the reconstructive steps of the procedure, minimizing the potential risks due to the ischemia time.

More recently, the expanded role of robot-assisted surgery has also included the simultaneous treatment of bilateral renal tumors[4,5].

This type of procedure, which is certainly fascinating, still needs to be well defined regarding the indications and the technique. We report our first case of simultaneous bilateral robotic partial nephrectomy in order to show the feasibility of our technique and critically discuss both the advantages and the disadvantages of this procedure.

## CASE REPORT

### Patient

A 69-year-old male patient visited our department due to the incidental finding of bilateral small renal masses. Magnetic resonance scans showed a 2.5 cm mass in the middle portion of the right kidney and a 3.5 cm mass in the middle portion of the left kidney with no involvement of the collecting systems. The two masses were suspicious for malignancy (Figure 1). The differential diagnosis was made with benign tumors and complicated cysts. There was no past surgical history. General physical examination and the preoperative exams were normal. The body mass index (BMI) was 23.51.

### Surgical technique

The operating theatre was set up as shown in Figure 2. The procedure was performed using a three-arm Da Vinci Robot, standard version, starting from the right side. The patient was secured in a flank position with the table slightly bent. Regarding the port placement, a 12-mm periumbilical port was placed for the camera. Two 8-mm robotic instrument ports were placed approximately 8 cm from the camera in a wide "V" configuration centered on the renal tumor. An additional 12 mm assistant trocar was placed on the midline between the umbilicus and symphysis pubis (Figure 3). A 30° angle lens was used. The robotic instruments included bipolar fenestrated forceps, monopolar cautery scissors, and two needle drivers. The peritoneum was incised sharply along the line of Toldt and the bowel was mobilized medially exposing the Gerota's fascia. The renal artery and vein were isolated and vessel loops were placed around them. The Gerota's fascia was dissected off the surface of the kidney and the kidney was extensively mobilized until easy access to the tumor was achieved from all sides. The RAPN was then performed without hilar clamping. The renal specimen was retrieved using an endobag. The inner defect was closed with a running outside-in Monocryl 4-0 suture preloaded with a Hem-o-lok clip, taking care to include retracted vessels or calyces into the suture. The borders

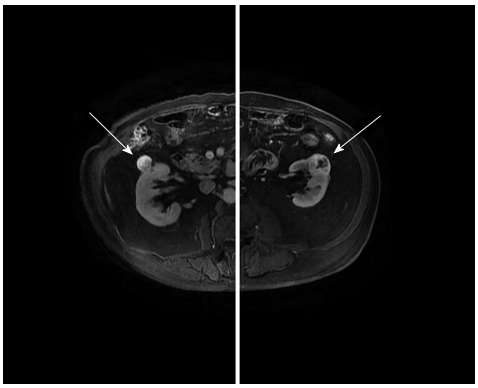

**Figure 1 Magnetic resonance scans.** The right and left small renal masses are indicated.

of the defect were closed with another running outside to inside Monocryl 2-0 suture including a haemostatic agent and secured with Hem-o-lok clips at each bite. Through the sliding clip technique, the right tension was brought on these sutures[6].

The Gerota's fascia and the peritoneum were closed. A wound drain was introduced through the inferior 8-mm port. All the trocars were removed and the robot was undocked.

Without interrupting the anesthesia, the patient was repositioned in the supine position and, after a 180 degree rotation of the surgical bed, he was placed in the contralateral flank position. Using both the previous periumbilical and midline ports for the camera and the additional 12-mm assistant trocar, respectively, the other 8-mm robotic trocars were placed in a wide "V"configuration centered on the left renal tumor (Figure 3). The robot was then redocked without changing any disposition of the instruments, the furniture or the staff inside the operating theatre.

A second RAPN without hilar clamping was also performed on the left side following the previously reported technique. Intraoperative ultrasonography was used on this side in order to score the margins of the lesion.

The total operation time was 285 min and total console time was 240 min. The estimated blood loss was 150 cc. The postoperative period was uneventful. The patient was mobilized on day 2. The urethral catheter was removed on day 2. The right and left drains were removed on days 2 and 3, respectively. The patient was discharged on day 4. The pathological examination reported bilateral renal cell carcinoma, Fuhrman grade 1, with negative surgical margins. Six months after surgery, computed tomography scan did not show tumor local recurrences.

## DISCUSSION

The robotic approach for conservative renal surgery is becoming increasingly common due to the reported encouraging outcomes in terms of safety, feasibility and efficacy of this procedure[1-3,7]. Very few papers have been reported in literature concerning simultaneous bilateral RAPNs probably due to the low incidence of bilateral re-

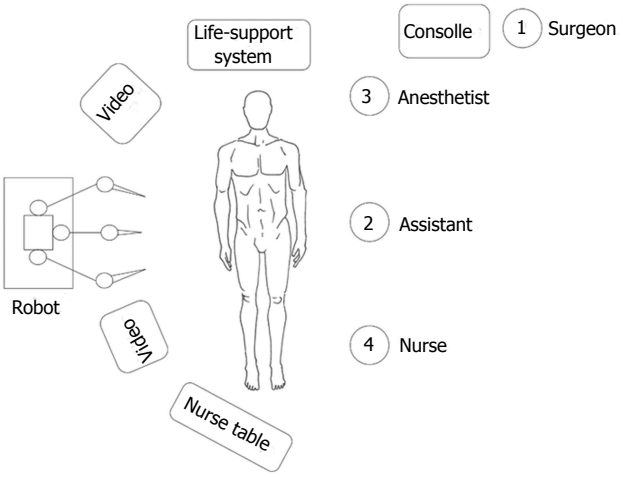

**Figure 2 Disposition of the operating theatre.**

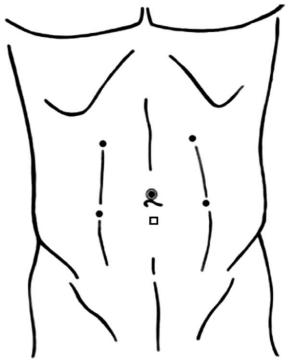

**Figure 3 Port placements.** Four 8-mm robotic ports (black circles), one 12-mm periumbilical camera port (double circle) and one 12-mm midline port (square).

nal tumors but also due to the difficulties of this type of surgery[4-5]. The potential benefits of simultaneous bilateral surgery could be related to the advantages of a unique surgical procedure with single anesthesia, shorter overall hospitalization, faster overall recovery and lower costs than two separate procedures. Furthermore, a cosmetic benefit due to the reuse of some ports for both sides could be considered. However, these advantages could be balanced by the risks of longer total anesthesia time, higher blood loss and postoperative renal insufficiency. In this setting, the procedure should be planned appropriately in order to maximize the benefits and minimize the risks. We think that our technique was noteworthy for some aspects.

The positioning of the ports was planned accurately in order to minimize the number of the abdominal incisions. In particular, the camera and the assistant ports were positioned on the xifopubic line and used for both sides. In the end, the bilateral RAPN was performed using only six ports.

The disposition of the operating theatre was studied in order to allow the rotation of the patient's bed without changing the positions of the robot, the instruments and the operators. This detail allowed us to undock and redock the robot very quickly between the two nephrectomies, avoiding the waste of precious minutes.

Overall, the entire operation lasted less than 5 h including anesthesiological procedures, patient positioning and trocar placement. We think that this is an acceptable anesthesia time for a bilateral procedure as confirmed by the regular observations made in the postoperative period.

The surgical technique with no arterial clamping decreased the risk of postoperative renal insufficiency which can be more frequent after a bilateral procedure, especially when bilateral clamping is performed, as already reported in literature[4].

This procedure was really cost effective. In fact, the two nephrectomies were performed without shutting the robot down and using the same surgical instruments. These aspects helped strongly to decrease the costs of a robotic operation.

Some limitations of our technique should be mentioned. In fact, an appropriate selection of the patients (mainly regarding the size, the location of the tumors or the preexisting condition of chronic renal insufficiency) and a very good skill in renal robotic surgery are really advisable before approaching this type of surgery.

In conclusion, our experience was encouraging and confirmed the feasibility and the safety of this procedure. Furthermore, the planning of our technique was time and cost effective with a cosmetic benefit for the patient. However, we think that an appropriate selection of the patients and skill in robotic renal surgery are really advisable before approaching this type of surgery.

We thank Dr. Jennifer McDermott for the language revision.

## COMMENTS

### *Case characteristics*

A 69-year-old male patient visited our department due to the incidental finding of bilateral small renal masses.

### *Clinical diagnosis*

The general physical examination was normal, the renal masses were not palpable. The body mass index was 23.51.

### *Differential diagnosis*

Benign tumors, complicated cysts.

### *Laboratory diagnosis*

The preoperative exams were normal.

### *Imaging diagnosis*

Magnetic resonance scans showed a 2.5 cm mass in the middle portion of the right kidney and a 3.5 cm mass in the middle portion of the left kidney with no involvement of the collecting systems.

### *Pathological diagnosis*

The pathological examination reported bilateral renal cell carcinoma, Fuhrman grade 1, with negative surgical margins.

### *Treatment*

A simultaneous bilateral robotic partial nephrectomy was performed.

### *Related reports*

The surgical treatment of small renal masses is well known using different approaches (mainly open surgery, laparoscopy and cryotherapy). However, very few papers have been reported in literature concerning simultaneous bilateral

robot assisted partial nephrectomy probably due to the low incidence of bilateral renal tumors but also due to the difficulties of this type of surgery.

### *Experiences and lessons*

This case report showed the feasibility, the safety, the time and cost effectiveness of this procedure with a cosmetic benefit for the patient.

### *Peer review*

This is a well written and interesting case.

## Abstract

Prostate cancer is the most common non-cutaneous malignancy for men. The skeleton is the most common metastatic site but, following an improvement in survival, metastases in uncommon sites are being found more frequently in clinical practice, especially brain metastases. Despite the new drugs now available for metastatic castration resistant prostate cancer, no clinical evidence exists about their effectiveness on brain metastases. We describe the clinical history of 3 patients treated with cabazitaxel plus whole brain radiotherapy. These case reports demonstrate that cabazitaxel is highly active and well tolerated in brain metastases.

**Key words:** Cabazitaxel; Brain metastases; Prostate cancer

**Core tip:** Due to the improvement in terms of survival, the incidence of brain metastases (BMs) has increased in patients with metastatic castration resistant prostatic cancer (mCRPC). Despite the large number of treatments now available, the prognosis of patients with BMs is still poor. First, we demonstrate the efficacy of cabazitaxel on brain mestastases in three CRPC patients and then show its profile of tolerability in combination with whole brain radiotherapy.

Cabazitaxel in castration resistant prostate cancer with brain metastases: 3 case reports. *World J Clin Cases* 2014; 2(6): 228-231 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/228.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.228

## INTRODUCTION

Prostate cancer (PC) is the most common non-cutaneous malignancy for men, with an estimated number of new cases of 241740 in 2013 in the United States[1]. Nevertheless, PC is not the leading cause of death in the male population due to its ability to rarely metastasize to organs other than bones[2].

Although the skeleton remains the most common metastatic site, the availability of new active drugs for metastatic castration resistant prostatic cancer (mCRPC) has changed the natural history of this disease, leading to a considerable improvement in survival so that metastases in previously considered uncommon sites are now found more frequently[3].

Brain is the site of metastases in almost 12% of cases with a poor prognosis at their appearance[4].

Despite an increased incidence of BMs, the impact of new drugs for mCRPC on this metastatic site remains poorly understood. First of all, patients with BMs are not routinely enrolled in phase Ⅲ clinical trials and there are

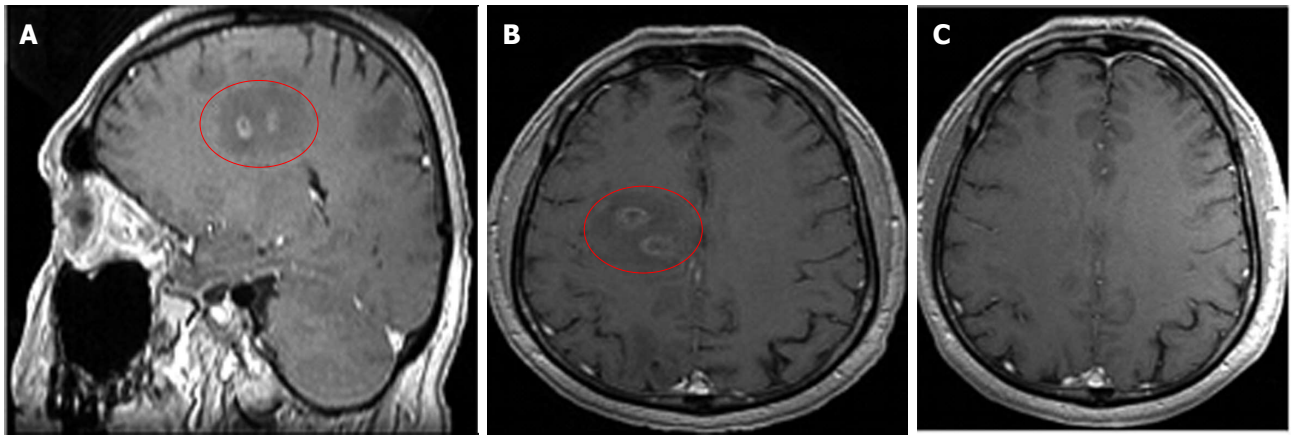

**Figure 1 Show a complete response in the brain lesions before and after 6 cycles of cabazitaxel.** A, B: Brain metastases before cabazitaxel; C: Complete response after 6 cycles of cabazitaxel.

no prospective and ad-hoc studies in this particular setting. Actually, there is only preclinical data showing that cabazitaxel is able to pass the brain-blood barrier (BBB)[5] but no evidence about its efficacy in humans.

Otherwise, there is also little data concerning the role of radiation therapy on the treatment of BMs from PC which seems to have only a palliative intent[6]. Here, we describe three case reports of brain metastases in CRPC patients who were treated with cabazitaxel plus whole brain radiotherapy.

## CASE REPORT

The patients were 70, 70 and 72 years old. All patients presented at diagnosis with a high risk disease (Table 1). Patients 1 and 2 did not receive primary treatment because bone metastases and lymph node metastases were detected with bone and computed tomography scans. These 2 patients began hormonal therapy with luteinizing hormone releasing hormone analogue (aLHRH) first and then with complete androgen blockage (CAB), adding bicalutamide 50 mg.

Patient 3 underwent prostatectomy and radiotherapy for locally advanced disease. The disease progressed after 5 mo due to the appearance of bone metastases and aLHRH was started. All patients had a long androgen deprivation therapy (ADT) history (36-50 mo). Docetaxel was first line chemotherapy with a progression free survival (PFS) of 7, 7 and 11 mo respectively (Table 1). Patient 3 was treated with abiraterone as second line treatment and progressed after 6 mo.

The patients presented with multiple BMs (in number, 2, 3 and 3 respectively) confirmed with a magnetic resonance imagining (MRI) before starting cabazitaxel and the liver and lung were the other metastatic sites (Table 1). A total of 30 cycles of cabazitaxel were administered at standard dose without reductions (Table 1). Contemporaneous whole brain radiotherapy was performed at the dose of 30 Gy.

Patient 3 obtained a complete response on brain and liver metastases with a PSA reduction of 90% after 6 cycles (Figure 1), while two partial responses in brain (the lesions were halved) and lung were observed, with a PSA decrease of 40% after 6 cycles for patient 1 and 2.

No grade 3-4 toxicities were experienced; all patients received pegylated granulocyte colony stimulating factor (PEG-G-CSF) to prevent febrile neutropenia. The most important non-hematological toxicities were grade 2 nausea and asthenia.

The PFS of patients 1 and 2 was 7 and 13 mo while patient 3 is still progression-free. Patients 1 and 2 received further therapy after cabazitaxel (abiraterone and platinum regimen) and died after 3 mo.

## DISCUSSION

BM appearance is a rare and terminal event in the natural history of PC due to greater aggressiveness and poor response to common therapies. BMs are often essentially single, supratentorial and occur with nonfocal neurological symptoms related to intracranial hypertension. A retrospective study of 103 patients with BMs showed that radiotherapy alone is an effective treatment with a median survival of 3.5 mo[7].

Further improvement in survival was noted in five patients who underwent stereotactic radiosurgery (SRS). Although no complete responses were obtained, symptoms improved[8].

BMs are more frequent in the CRPC setting than in the past due to the availability of new drugs and longer survival of metastatic patients. In the docetaxel era, the prognosis of patients with BMs was still poor and median survival was only 8 weeks after BM diagnosis, demonstrating the clinical ineffectiveness of docetaxel[3].

Among the new approved drugs for mCRPC, such as cabazitaxel, abiraterone, enzalutamide and sipuleucel-T, only cabazitaxel has been shown to be able to pass the BBB. Cisternino and colleagues observed a non-linear accumulation of cabazitaxel in the brains of rats, occurring by saturation of the P-glycoprotein in the BBB[5].

**Table 1 Patient characteristics**

| | Patient 1 | Patient 2 | Patient 3 |
|---|---|---|---|
| Age (yr) | 70 | 70 | 72 |
| Comorbidities | Hypertension | Hypertension | Diabetes |
| Primary treatment | Hormonal therapy | Hormonal therapy | Surgery and radiation therapy |
| Gleason score | 8 (4 + 4) | 8 (4 + 4) | 8 (5 + 3) |
| PSA at baseline[1] (ng/mL) | 158 | 82 | 17 |
| ADT time (mo) | 38 | 36 | 50 |
| Docetaxel cycles | 12 | 8 | 8 |
| PSA pre-cabazitaxel (ng/mL) | 95 | 292 | 140 |
| Sites of metastases | Bone, lung, brain | Bone, lung, brain | Bone, liver, brain |
| Cabazitaxel cycles | 12 | 8 | 10 |
| Best response | PR on brain and lung | PR on brain and lung | CR on liver and brain |
| Toxicities | Anemia grade 1, asthenia grade 2 | Nausea grade 2; neutropenia grade 2 | Asthenia grade 2 |

[1]Before primary treatment. ADT: androgen deprivation therapy; PR: Partial response; CR: Complete response.

These 3 case reports describe the role of cabazitaxel in patients with BMs for the first time and the results are encouraging for 3 reasons.

Firstly, it shows the definite efficacy of cabazitaxel in BMs with an amazing PFS compared with the Tropic trial PFS[9]. Secondly, the association of whole brain radiotherapy and chemotherapy with cabazitaxel gives better results in terms of radiological response and survival than the data presented above.

Thirdly, the combination does not seem to be particularly toxic, especially in terms of hematological toxicities. We administered preventive PEG-G-CSF and, as previously shown in an Italian study, it reduced the grade 3 and 4 neutropenia reported with cabazitaxel[10]. Of note, all three patients had a gleason 8 at diagnosis, which is consistent with our previosly reported findings suggesting improved PFS in patients with high gleason score receiving cabazitaxel[11].

Our case reports demonstrate that cabazitaxel improved PFS and overall survival in our patients with BMs and is well tolerated in combination with we decided to report these cases in a full paper without presenting them as a meeting abstract, considering that only 50% of abstracts are subsequently published as full papers[12]. The lack of ad-hoc studies and the exclusion of men with brain metastases from phase Ⅲ trials make our data the first evidence in this field. Prospective trials are needed to confirm our preliminary results.

## COMMENTS

### *Case characteristics*

All patients presented at diagnosis with a high risk disease.

### *Treatment*

The authors demonstrate the efficacy of cabazitaxel on brain metastases in three castration resistant prostatic cancer patients and show its profile of tolerability in combination with whole brain radiotherapy.

### *Experiences and lessons*

These case reports demonstrate that cabazitaxel is highly active and well tolerated in brain metastases.

### *Peer review*

Nice, well written paper with interesting data potentially useful in the clinical setting.

## Abstract

Meckel's diverticulum is a very common congenital anomaly of the gastrointestinal tract but many cases remain asymptomatic and are diagnosed incidentally during laparoscopic or other surgical procedures. Cases of femoral hernia involving Meckel's diverticulum are rare, with less than 50 cases reported in the literature since Littre published the first description of this coincident condition over 300 years ago. While all true "Littre's hernias" contain a Meckel's diverticulum, the involved anatomical sites are various, the most common being the inner groin (inguinal), the outer groin (femoral), and the belly button (umbilical). Complications of Littre's hernias include incarceration, strangulation, necrosis, and perforation. Herein, we describe a case of Littre's hernia that involved an incarcerated Meckel's diverticulum in a femoral hernia that was diagnosed upon investigation of symptomology manifesting from perforation and was successfully managed by surgical resection with stapler devices.

**Key words:** Meckel's diverticulum; Incarceration; Littre Hernia; Gastrointestinal perforation

**Core tip:** Meckel's diverticulum is most commonly diagnosed congenital anomaly of the gastrointestinal tract. Any hernia containing a Meckel's diverticulum is designated as a Littre's hernia. Although rare in overall incidence, the most common complications of Littre's hernias are perforation, bowel obstruction secondary to strangulation, and incarceration within the hernial sac. In this case study, we present and share the diagnosis and successfully management of a case of incarcerated Meckel's diverticulum in a femoral hernia (Littre's hernia) with perforation.

Yagmur Y, Akbulut S, Can MA. Gastrointestinal perforation due to incarcerated Meckel's diverticulum in right femoral canal. *World J Clin Cases* 2014; 2(6): 232-234 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/232.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.232

## INTRODUCTION

The most commonly diagnosed congenital abnormality of the small intestine, Meckel's diverticulum, occurs when a portion of the vitelline duct fails to properly regress into the antimesenteric border of the terminal ileum at the end of the seventh week of gestation. As such, a Meckel's diverticulum contains all layers of the intestinal wall and is classified as a true diverticulum[1-6]. Estimates of the incidence of this condition have ranged from 0.3% to 3%, but its frequent asymptomatic nature may belie its true rates among the general population. Meckel's diverticula can be diagnosed as incident findings in laparoscopic or laparotomic examinations for unexplained symptoms or other conditions that have manifested clinical symptoms. Any hernia containing a Meckel's diverticulum is designated as a Littre's hernia. The most common sites of these coincident anatomical abnormalities are the inner groin (inguinal hernia, approximately 50%), the outer groin (femoral hernia, approximately 20%), and the belly button (umbilical hernia, approximately 20%).

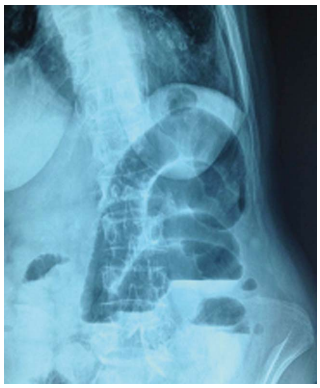

**Figure 1 Air-fluid levels detected by abdominal radiography.** The findings were compatible with intestinal obstruction.

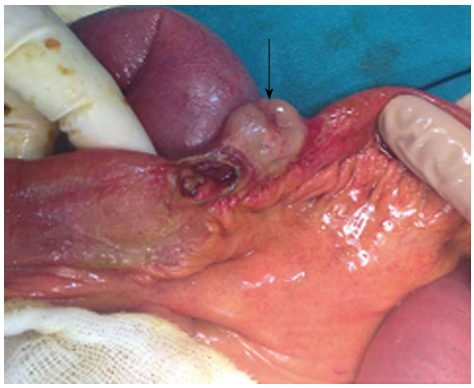

**Figure 2 Perforation area proximal to the Meckel's diverticulum.** The Meckel's diverticulum is indicated by a black arrow.

Although rare in overall incidence, the most common complications of Littre's hernias are perforation, bowel obstruction secondary to strangulation, and incarceration within the hernial sac[1]. Herein, we report the diagnosis and successfully management of a case of incarcerated Meckel's diverticulum in a femoral hernia (Littre's hernia) with ileal perforation.

## CASE REPORT

A 73-year-old female presented to our Emergency Department with severe abdominal pain, nausea, and vomiting; the symptoms had begun one week previous, but had increased in severity over the last two days. The patient also reported the last instances of flatulence and defecation being three days previous. Results of standard laboratory blood tests were normal, hemoglobin: 13.2 g/dL (normal range, NR: 12.5-16.0), blood urea nitrogen: 22 mg/dL (NR: 10-50 mg/dL), and creatinine: 0.5 mg/dL (NR: 0.4-1.2 mg/dL), with the exception of a high white blood cell count [16000/μL (NR: 4100-11200/μL)] and neutrophil ratio [89% (NR: 50%-78%)]. In physical examination, auscultation revealed obstructive and hyperactive bowel sounds and palpation revealed serious tenderness with rebound pain that was particularly robust in the right lower quadrant. Abdominal radiographic examination showed air-fluid levels (Figure 1). Nasogastric decompression was performed in the Emergency Department. The collected clinical symptoms and findings from biochemical analysis and radiological examination suggested acute mechanical small bowel obstruction possibly related to internal herniation or perforation. The patient was prepared for exploration. Laparotomy with a midline incision revealed a Meckel's diverticulum with an ileal segment incarcerated in the right femoral canal and which had perforated the antimesenteric border of the ileum (Figure 2). The abnormality was managed by first removing the diverticulum through the femoral canal, suturing the femoral canal closed, resecting the partial ileal segment that included the perforated ileal segment and Meckel's diverticulum (15 cm in length), and creating a side-to-side anastomosis with stapler devices (Endo-GIA Stapling System; Covidian, Dublin, Ireland). Postoperative recovery was uncomplicated and the patient was discharged to home. Pathological analysis of the resected tissues showed no signs of gastric or pancreatic metaplasia.

## DISCUSSION

In the first five weeks of normal gestational development, the Meckel's diverticulum is the intestinal portion of the omphaloenteric duct through which the midgut communicates with the umbilical vesicle. Located at the antimesenteric border of the ileum, about 30 to 90 cm from the ileocecal valve, it can measure between 3 and 6 cm in length and is usually approximately 2 cm in diameter[2]. Failure of the tissue to regress by gestational week 7 is not fatal, and the congenital abnormality may remain asymptomatic (and undetected) throughout life. The lifetime complication rate estimated to be approximately 4%, with a higher incidence in males[4], and the most common complications are bleeding, inflammation, and obstruction[5].

Cases of femoral hernia involving Meckel's diverticulum are rare, with less than 50 cases reported in the literature since Littre published the first description of this coincident condition over 300 years ago[2]. A true Littre's hernia contains a Meckel's diverticulum alone, but cases of mixed Littre's hernia containing ileum or other abdominal viscera have been reported[3]. Perforation of the Meckel's diverticulum may occur due to peptic ulceration or compromised circulation and luminal patency at the narrow neck of the hernia[3].

Preoperative diagnosis of a strangulated Littre's hernia is unlikely, as the presenting signs and symptoms are subtler and evolve more slowly than those of strangulated small intestine. Fever, pain, and signs of intestinal obstruction occur late or not at all. Moreover, there may be no specific sign of bowel involvement, other than local inflammation surrounding the hernia until an enterocutaneous fistula develops[5]. The *septuagenarian* case described herein presented with signs of obstruction (*i.e.*, serious abdominal tenderness, rebound pain, and air-fluid levels).

In Littre's hernia, obstruction can occur if the base of the diverticulum is broad enough to cause narrowing of the intestinal lumen. Presenting symptoms are tender

mass proximal to a hernial orifice with nausea, vomiting, abdominal pain, local groin pain and swelling. Pyrexia is normally associated with strangulation[5]. Repair of the Littre's hernia consists of local diverticulum resection and herniorrhaphy. In cases of perforation, care must be taken to not contaminate the hernia field[2], and resection of the diverticulum ileal loop with end-to-end or side-to-side anastomosis is the recommended treatment.

## COMMENTS

### Case characteristics

A 73-year-old female presented to our Emergency Department with severe abdominal pain, nausea, and vomiting; the symptoms had begun one week previous, but had increased in severity over the last two days.

### Clinical diagnosis

Auscultation revealed obstructive and hyperactive bowel sounds and palpation revealed serious tenderness with rebound pain that was particularly robust in the right lower quadrant.

### Imaging diagnosis

Abdominal radiographic examination showed air-fluid levels. Laparotomy with a midline incision revealed a Meckel's diverticulum with an ileal segment incarcerated in the right femoral canal and which had perforated the antimesenteric border of the ileum

### Pathological diagnosis

Pathological analysis of the resected tissues showed no signs of gastric or pancreatic metaplasia.

### Treatment

Care must be taken to not contaminate the hernia field, and resection of the diverticulum ileal loop with end-to-end or side-to-side anastomosis is the recommended treatment.

### Peer review

The authors described the case of gastrointestinal perforation due to incarcerated Meckel's diverticulum in right femoral canal. The authors also demonstrated the figure of air-fluid levels detected by abdominal radiography.

## Abstract

We present a case of an elderly man, who initially presented with right facial nerve palsy, ipsilateral headache, elevated erythrocyte sedimentation rate (ESR) and no fever. A presumptive diagnosis of giant cell arteritis was made and the patient was treated with high-dose steroids. A temporal artery biopsy was negative. Several months later, while on 16 mg of methylprednisolone daily, he presented with severe sensorimotor peripheral symmetric neuropathy, muscle wasting and inability to walk, uncontrolled blood sugar and psychosis. A work-up for malignancy was initiated with the suspicion of a paraneoplastic process. At the same time a biopsy of the macular skin lesions that had appeared on the skin of the left elbow and right knee almost simultaneously was inconclusive, whereas a repeat biopsy from the same area of the lesions that had become nodular, a month later, was indicative of Kaposi's sarcoma. Finally, a third biopsy of a similar lesion, after spreading of the skin process, confirmed the diagnosis of Kaposi's sarcoma. He was treated with interferon α and later was seen in very satisfactory condition, with no clinical evidence of neuropathy, normal muscle strength, no headache, normal electrophysiologic nerve studies, involution of Kaposi's lesions and a normal ESR.

**Key words:** Facial nerve palsy; Peripheral neuropathy; Vasculitis; Paraneoplastic syndrome; Kaposi's sarcoma

**Core tip:** We present a case of an elderly man, who initially presented with right facial nerve palsy, ipsilateral headache, elevated erythrocyte sedimentation rate and no fever. A presumptive diagnosis of giant cell arteritis was made and the patient was started on high-dose steroids. Several months later, he presented with severe sensorimotor peripheral symmetric neuropathy. A biopsy of the macular skin lesions that had appeared almost simultaneously, was suggestive of Kaposi's sarcoma. Although peripheral and cranial nerve involvement has not been reported in Kaposi's sarcoma, we postulate that the patient's condition could be attributed to that, within the context of a paraneoplastic process.

Facial nerve palsy, headache, peripheral neuropathy and Kaposi's sarcoma in an elderly man. *World J Clin Cases* 2014; 2(6): 235-239 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i6/235.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i6.235

## INTRODUCTION

We present herein an interesting case of an elderly patient with right facial nerve palsy, ipsilateral headache, elevated erythrocyte sedimentation rate (ESR), sensorimotor neu-

ropathy and Kaposi's sarcoma.

## CASE REPORT

### *History report*

**Dimitrios Daoussis, MD:** The patient was a 72-year-old white man, who was initially admitted on September 16, 2009 to the department of neurology, with chief complaint of severe persistent right sided headache. Twenty days prior to admission, he experienced acutely right facial nerve palsy of peripheral type. Ten days later he developed severe right temporal headache, and was started on prednisolone 25 mg/d by oral administration (*po*) advised by a neurologist. He had noticed gradual impairment of hearing acuity since four months ago. Glaucoma had been present for the last three years, and right eye blindness for ten years, due to an accident. There was no fever, and except for right peripheral facial nerve palsy, physical examination was unremarkable. Laboratory examination revealed a hematocrit of 35.1% with mean corpuscular volume 93.4, a white blood cell (WBC) count of 12700/μL, a platelet count of 372 000/μL and a markedly elevated ESR of 105 mm/h. All biochemical parameters and his serologic profile, including rheumatoid factor, antinuclear antibodies, complement (C3 and C4) and antineutrophil cytoplasmic antibodies (ANCA) were within the normal range. Computed tomography (CT) and magnetic resonance imaging (MRI) brain scans were normal. Otolaryngologic evaluation suggested bilateral adhesive otitis, whereas ophthalmologic examination confirmed the presence of glaucoma and the right side blindness. The patient was started on methylprednisolone 48 mg/d *po*, with the presumptive diagnosis of giant cell arteritis (GCA). He was discharged on this regimen on September 24, 2009, pending the result of a right temporal artery biopsy, performed on the day of discharge.

He was first seen at the rheumatology outpatient clinic three months later, on December 20, 2009, again complaining of right temporal headache, despite of having been taking methylprednisolone 40 mg/d. The report of the temporal artery biopsy was negative for GCA and steroid tapering was started.

On February 23, 2010, he reported deterioration of his headaches, whereas his ESR was 58 mm/h. Methylprednisolone dose was increased back to 32 mg/d, and on March 22, 2010, his ESR had dropped to 6 mm/h and headaches had improved. Gradual tapering of steroids was again undertaken and an appointment after two months was given.

The patient was admitted to the department of medicine on June 26, 2010 with fatigue, profound muscle weakness, inability to walk and psychosis. While on methylprednisolone 16 mg/d, his admission glucose was 665 mg/dL, whereas it had been always normal before. He was afebrile without headache. He was profoundly wasted, with severe proximal muscle weakness and decreased deep tendon reflexes. The right facial nerve palsy had improved. Two bluish-red macules, about 1.5 cm in diameter, were noticed over the skin of the right knee and left elbow, respectively. Laboratory tests revealed a hematocrit of 29.8%, mild leukocytosis, normal platelet count, an ESR of 28 mm/h, potassium of 3.73 mg%, sodium of 136 mg%, calcium of 8.64 mg%, magnesium of 1.5 mg%, creatinine of 0.6 mg%, total serum protein of 5 g% with albumin 2 g%, and normal creatine phosphokinase, transaminases, alkaline phosphatase and normal urinalysis. Serologic profile for rheumatic diseases and A, B and C hepatitis was unrevealing. Serum angiotensin converting enzyme (SACE) level was normal. A chest X-ray was also normal. An electrophysiologic evaluation was compatible with mixed sensorimotor neuropathy, worse on the lower extremities, but no myositis was found, except for changes due to chronic steroid administration. Cerebrospinal fluid examination was normal. Proximal muscle biopsy did not disclose myositis, vasculitis or granuloma. A purified protein derivative skin test was negative. Thyroid function was also normal.

With the suspicion of an underlying occult malignancy, an extensive work- up towards that direction was initiated; gastroscopy, barium enema, brain, thoracic and abdominal CT scans, thyroid ultrasound and cancer indices including alpha fetoprotein, carcinoembryonic antigen (CEA), CA 19-9, prostatic specific antigen, beta horionic gonadotrophin were all normal. A biopsy of the left elbow skin lesion displayed atypical changes (see pathological description below).

With the patient's condition deteriorating, both clinically and in laboratory test results (Ht = 20.3%, ESR = 70 mm/h), with uncontrolled blood sugar levels, and cushingoid features, including psychosis and severe muscle wasting, in an attempt to spare steroids, we treated the patient with methotrexate 7.5 mg/wk. His condition improved and on July 24, 2000, one month after his admission, he was discharged on the above methotrexate dose, methylprednisolone 16 mg/d and insulin, to be followed closely.

On the August 23 appointment, the patient's general condition was relatively satisfactory, with significant improvement of his muscle strength, and a hematocrit of 36.6% and ESR 15 mm/h. However, the previously noted macules on the skin of the left elbow and right knee had become nodular and a biopsy of the lesion of the elbow was taken. This biopsy was indicative of Kaposi's sarcoma, although not typical. One month later, on September 27, the patient returned with similar bluish-red nodules all over his body, typical of Kaposi's sarcoma, and a third biopsy confirmed the diagnosis. The methotrexate was discontinued and the patient was admitted on October 5, 2000 to the dermatology service and started on interferon α (IFNα-2α) treatment. At that time, his hematocrit was 35% and ESR 25 mm/h, whereas serology for HIV was negative. An electrophysiologic nerve study showed definite improvement of the neuropathy. He was discharged on November 18, 2000, on IFNα and methylprednisolone 16 mg/d.

On January 9, 2011 at his outpatient visit, he was found in very good condition, with normal muscle strength and gait, very mild right temporal headache, no

**Table 1 Findings of nerve conduction serial studies in this patient**

| Nerve | Parameter | 1st study | 2nd study | 3rd study | Normal limits |
|---|---|---|---|---|---|
| Motor conduction | | | | | |
| Median | CV (ms) | 46 | 60 | 60 | ⩾ 50 |
| | CMAP (mV) | 4 | 6 | 6 | ⩾ 5 |
| | Min F-wave (ms) | 32 | 28 | 27 | ⩽ 30 |
| Peroneal | CV (ms) | 35 | 40 | 43 | ⩾ 41 |
| | CMAP (mV) | 0.4 | 1 | 2 | ⩾ 2 |
| | Min F-wave (ms) | - | - | 54 | ⩽ 52 |
| Sensory conduction | | | | | |
| Sural | CV (ms) | - | - | 32 | ⩾ 40 |
| | SAP (μV) | - | - | 4 | ⩾ 8 |

CV: Conduction velocity; CMAP: Compound muscle action potential; SAP: Sensory action potential.

psychotic features, with normal deep tendon reflexes, and with only pale-brownish skin macules, remnants of involuted previous nodular lesions. A third electrophysiologic study showed further improvement of the neuropathy, and the patient was put to regular follow-up.

### *Electrophysiologic nerve studies*

**Elisabeth Chroni, MD, PhD:** The findings were consistent with distal sensorimotor neuropathy of mixed-axonal and demylinating-type. On follow-up studies 5 and 7 mo later, a gradual improvement was observed.

Electromyography of facial muscles showed denervation potentials (fibrillations and positive waves) at rest and poor recruitment of motor units indicating axonal damage of facial nerve. All the above are depicted in Table 1.

### *Pathological description*

**Athanassios C Tsamandas, MD**: The first biopsy revealed areas with proliferation of fibroblasts and capillaries, in the dermis (Figure 1A-D). The vessels of medium size displayed fibrosis of the wall, luminal narrowing and elastic lamina disruption without any fibrin deposition.

The second biopsy (Figure 1E-G) was consistent with early changes of Kaposi's sarcoma (macular-patch stage).

The third biopsy (Figure 1H-M) showed a well-defined nodule composed of vascular spaces and spindle cells that replaced the dermal collagen. Spindle cells and endothelial cells lining the vascular clefts were CD34 (+). A diagnosis of Kaposi's sarcoma was made.

Retrospectively, the slides were reviewed and the features in the first biopsy were suggestive of a very early Kaposi's sarcoma lesion.

## DISCUSSION

**Andrew P Andonopoulos, MD, FACP**: It would be simplistic to guess that our patient had a Bell's palsy, independent of the neuropathy he later developed, and the malignancy which appeared almost concomitantly with the latter. The facial nerve palsy and the headache, along with the impressively elevated ESR, speak against the possibility of idiopathic Bell's palsy. Furthermore, the patient had no hypertension or diabetes. The psychotic episode that our patient suffered was probably associated with the iatrogenic Cushing.

Similarly, the whole picture and its evolution are against the possibility of a metabolic or toxic cause of the neurologic syndrome in our patient. Instead, it would be very suggestive of a vasculitic process, if not related to a paraneoplastic syndrome, due to the malignancy, which appeared almost simultaneously with the peripheral neuropathy.

At a first glance, there was a very strong diagnostic possibility of GCA at the time of the initial presentation of this elderly gentleman, with temporal headache and an impressively elevated ESR. The negative biopsy, despite the fact that the specimen was meticulously examined and even recut later, does not rule out this possibility, because the procedure is not 100% sensitive[1]. However, one could argue that the response of the headache to the treatment was not the one typically expected in GCA, as it was mentioned. The apparent response of the ESR to steroid administration, does not necessarily mean that the elevated ESR was secondary to GCA, because similar responses may be encountered in several vasculitic or even other different processes. Furthermore, the development of neuropathy secondary to GCA, on steroid treatment, would be unusual. Peripheral neuropathy has been described in GCA as a rather rare manifestation, coincident with clinically active disease. In a study by Caselli *et al*[2] out of 166 consecutive patients with GCA, 23 had clinical evidence of peripheral neuropathic disease, of whom 11 had a generalized peripheral neuropathy, nine had mononeuritis multiplex and three had a mononeuropathy. Only a few reports of facial nerve palsy in the context of GCA appear in the literature[3-7].

Wegener's granulomatosis is, among the vasculitides, the one that can involve most commonly cranial nerves, besides causing peripheral neuropathy[8]. Our patient had no features of Wegener's granulomatosis, without upper airway, lung or kidney involvement, and negative ANCA.

Polyarteritis nodosa would be another remote possibility, but the absence of fever, hypertension and kidney involvement, along with the negative, for vasculitis, muscle biopsy argue against this possibility[9]. Churg-Strauss syndrome could not account for our patient's picture, because the hallmarks of this entity were absent[10].

Isolated granulomatous vasculitis of the central nervous system could have been another possibility. The advanced age of our patient, the impressively high ESR, and especially the normal brain MRI and cerebrospinal fluid argue strongly against this diagnosis[11]. Finally, our patient had no evidence of sarcoidosis, with normal chest X-ray, normal SACE and negative for non-caseating granuloma muscle biopsy.

Keeping all the above considerations in mind, one then should try to correlate the patient's manifestations with the malignant disease which he was found to have.

Axonal peripheral neuropathy, such as this patient had, can be a feature of a paraneoplastic syndrome,

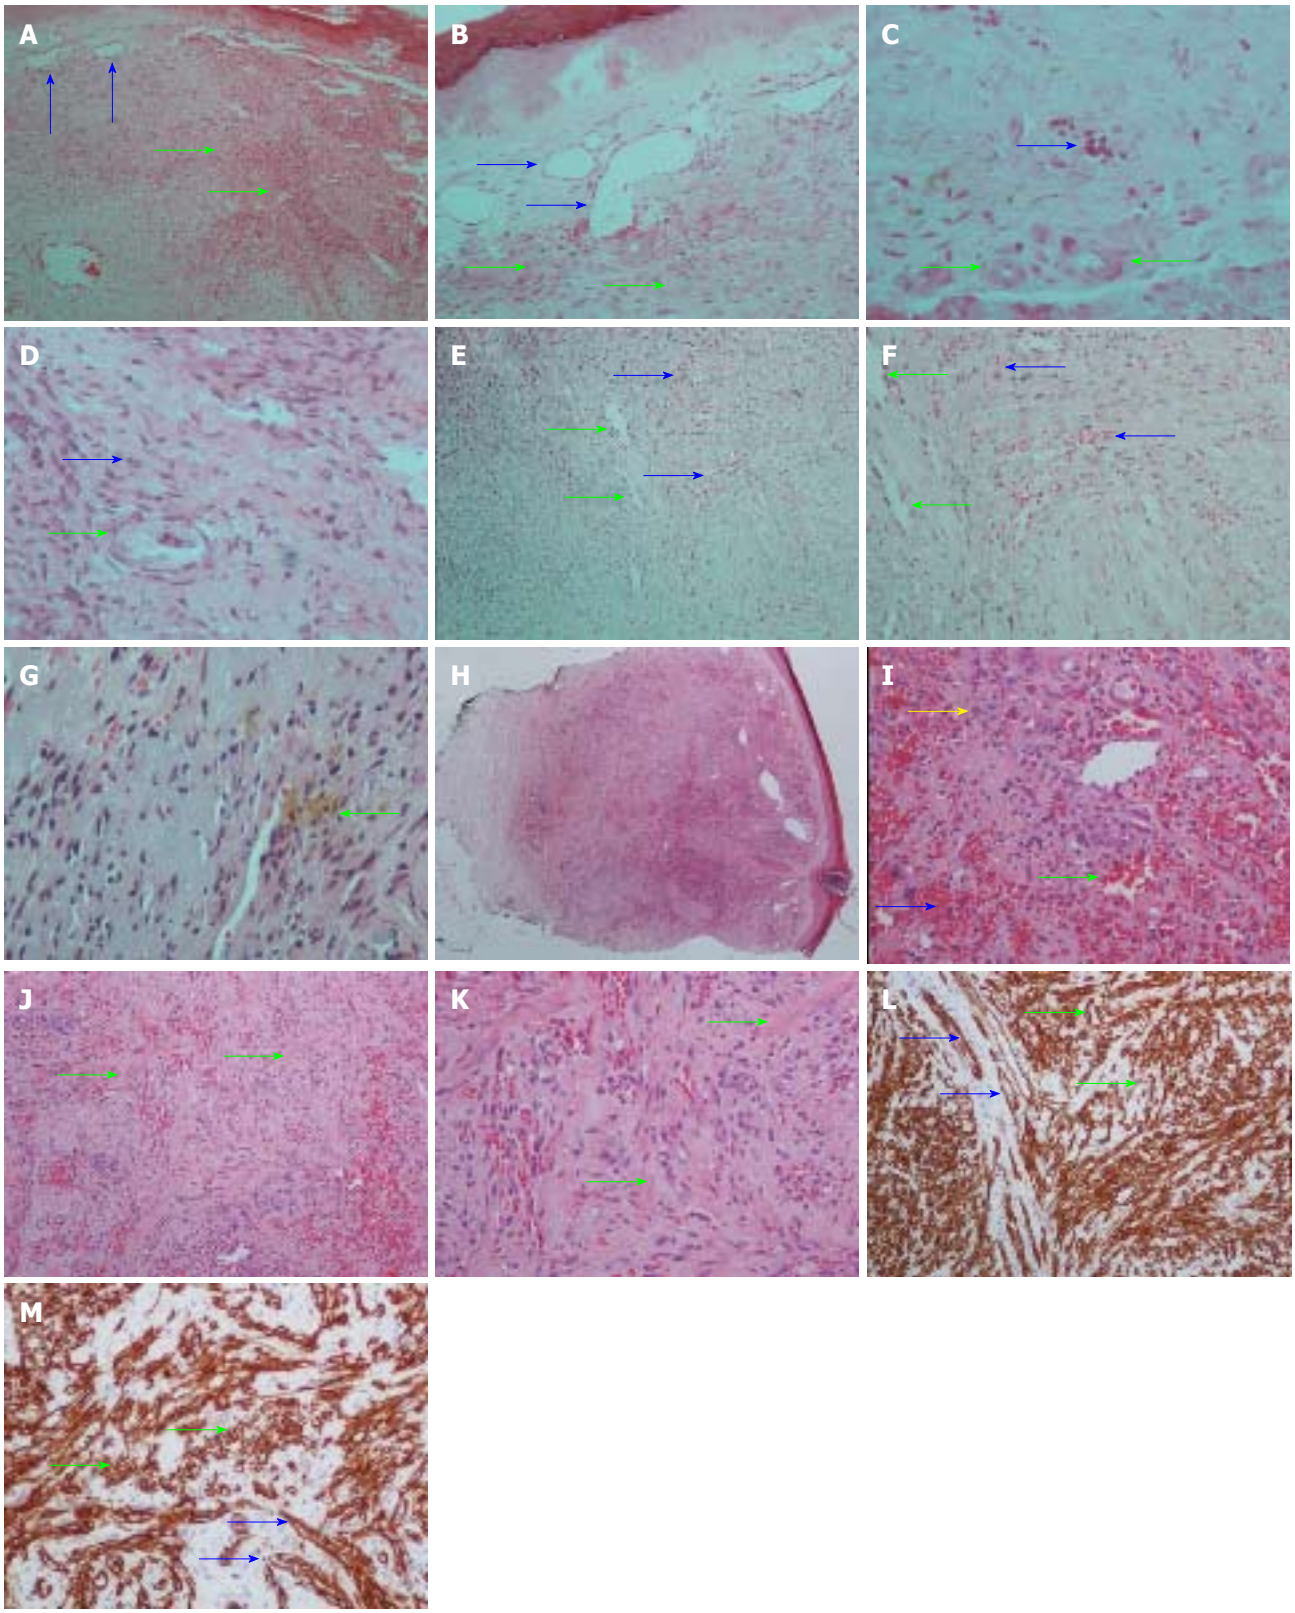

**Figure 1 Microphotographs.** A, B: The first skin biopsy showing proliferation of fibroblasts (green arrows) and capillaries (blue arrows) in the dermis (H and E, A, × 100; B, × 200); C: The same biopsy showing narrowing of the lumen of medium size vessels (green arrow) and blood cell extravasation (blue arrow) (H and E, × 200); D: The same biopsy showing lumen narrowing of a medium size vessel (green arrows) and fibroblast proliferation (blue arrow) (H and E, × 400); E, F: The second skin biopsy showing dilated and irregular vessels (green arrows) and blood extravasation (blue arrows). (H and E, E, × 100; F, × 200); G: The same biopsy showing the presence of siderophages (green arrow) (H and E, × 400); H: The third skin biopsy showing a well-defined nodule composed of vascular spaces and spindle cells that has replaced the dermal collagen (H and E, × 20); I: At a higher magnification, there are blood-filled vessels (green arrow), spindle cells (yellow arrow) and blood cell extravasation (blue arrow) (H and E, × 200); J, K: The same biopsy showing compartmentalization of the nodule by bands of fibrocollagen tissue (green arrows); L, M: The same biopsy showing that spindle cells (green arrows) and endothelial vascular cells (blue arrows) expressed CD34. shared by several malignancies, mainly of the lung, but of other organs as well. A meticulous search of the literature did not result in the finding of any report of Kaposi's sarcoma associated with a paraneoplastic picture from the nervous system, nor with any related to direct peripheral nerve invasion by this particular malignancy. However, this possibility cannot be excluded in our patient, and in view of our inability to find another cause responsible for his symptoms, if we wanted to put everything under one basic pathogenetic process, it would be very tempting to attribute the whole picture to the underlying malignancy.

On the other hand, it would be very difficult to accept that Kaposi's sarcoma in our patient developed iatrogenically, following immunosuppression. Kaposi's sarcoma may be caused by iatrogenic immunosuppression, but this has been mainly reported in transplant patients, receiving heavy immunosuppressive treatment with cyclosporin A and steroids with azathioprine. In addition, our patient must have Kaposi's lesions, although not diagnosed, as it could be documented from the presentation, before methotrexate was started.

In conclusion, although peripheral and cranial nerve involvement has not been reported in Kaposi's sarcoma, we postulate that the patient's condition could be attributed to this within the context of a paraneoplastic process.

## COMMENTS

### *Case characteristics*

A 72-year-old man with ipsilateral headache, skin lesions and neuropathy.

### *Clinical diagnosis*

Facial nerve pulsy and peripheral neuropathy.

### *Differential diagnosis*

Giant cell arteritis (GCA) or other systemic vasculitis *vs* paraneoplastic manifestations in the context of Kaposi's sarcoma.

### *Laboratory diagnosis*

Raised inflammatory markers and anemia.

### *Imaging diagnosis*

Negative computed tomography (CT) scan of thorax-abdomen, negative brain CT and magnetic resonance imaging.

### *Pathological diagnosis*

Biopsies of skin lesions diagnostic of Kaposi's sarcoma.

### *Treatment*

Initial treatment with high-dose steroids with the diagnosis of GCA. Following diagnosis of Kaposi's sarcoma, the patient was successfully treated with interferon.

### *Experiences and lessons*

A paraneoplastic process may present with atypical manifestations.

### *Peer review*

Although peripheral and cranial nerve involvement has not been reported in Kaposi's sarcoma, authors postulate that the patient's picture could be attributed to this within the context of a paraneoplastic process. This is a very interesting case.

## Abstract

Atherosclerotic cardiovascular diseases, chronic inflammatory diseases of multifactorial etiology, are the leading cause of death worldwide. In the last decade, more infectious agents, labeled as "infectious burden", rather than any single pathogen, have been showed to contribute to the development of atherosclerosis through different mechanisms. Some microorganisms, such as *Chlamydia pneumoniae* (*C. pneumoniae*), human cytomegalovirus, *etc.* may act directly on the arterial wall contributing to endothelial dysfunction, foam cell formation, smooth muscle cell proliferation, platelet aggregation as well as cytokine, reactive oxygen specie, growth factor, and cellular adhesion molecule production. Others, such as *Helicobacter pylori* (*H. pylori*), influenza virus, *etc.* may induce a systemic inflammation which in turn may damage the vascular wall (*e.g.*, by cytokines and proteases). Moreover, another indirect mechanism by which some infectious agents (such as *H. pylori*, *C. pneumoniae*, periodontal pathogens, *etc.*) may play a role in the pathogenesis of atherosclerosis is molecular mimicry. Given the complexity of the mechanisms by which each microorganism may contribute to atherosclerosis, defining the interplay of more infectious agents is far more difficult because the pro-atherogenic effect of each pathogen might be amplified. Clearly, continued research and a greater awareness will be helpful to improve our knowledge on the complex interaction between the infectious burden and atherosclerosis.

**Key words:** Infectious burden; Atherosclerosis; Bacteria; Virus; Pathogenetic mechanisms

**Core tip:** Several studies support the hypothesis that the infectious burden (IB) may be more involved in the pathogenesis of atherosclerosis than any single pathogen. However, because of the complexity of the interplay of more infectious agents in the host and the limitations of the methods available for the assessment of IB, the role of IB in the pathogenesis of atherosclerosis may have been underestimated.

Sessa R, Di Pietro M, Filardo S, Turriziani O. Infectious burden and atherosclerosis: A clinical issue. *World J Clin Cases* 2014; 2(7): 240-249 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/240.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.240

## INTRODUCTION

Atherosclerosis, a chronic inflammatory disease of multifactorial etiology, may be considered as a multistage process, starting from the endothelial injury to the fibrous cap and thrombus formation in the advanced plaque. Key process in the development of atherosclerosis is low density lipoprotein (LDL) oxidation and accumulation in vascular cells, promoting foam cell formation as well as increased secretion of mediators of inflammation, such as interleukin (IL)-1, IL-6 and tumor necrosis factor (TNF)-α[1]. The inflammatory state, in turn, can induce oxidative stress by enhancing the production of reactive

oxygen species (ROS) in the vascular wall[1], contributing to the progression and destabilization of atherosclerotic plaque and consequently to cardiovascular diseases (CVDs). It is well known that CVDs are the leading cause of death worldwide, accounting for approximately 17.3 million deaths per year[2].

Current opinion is that increased incidence of CVDs is probably the result of a high prevalence of both traditional risk factors such as hypertension, dyslipidemia, etc. and nontraditional risk factors including inflammation, oxidative stress, and infectious agents[3]. In the last decade, infectious agents have acquired a growing importance, since they are able to induce inflammation and/or oxidative stress[4].

More recently, several studies have provided evidence that more infectious agents, for example, *Chlamydia pneumonia* (*C. pneumoniae*), *Helicobacter pylori* (*H. pylori*), human cytomegalovirus (HCMV), Herpes simplex virus (HSV), labeled as "infectious burden" (IB), rather than any single pathogen, may be involved in the development of atherosclerosis and the subsequent cardiovascular events.

## EVIDENCE LINKING INFECTIOUS BURDEN WITH ATHEROSCLEROSIS

Zhu *et al*[5] were the first to show the association between increasing risk of coronary artery disease (CAD) and increasing number of infectious agents including *C. pneumoniae*, *H. pylori*, HCMV, HSV-1 and 2, and hepatitis A virus (HAV). Indeed, the prevalence of CAD was 48%, 69% and 85% in individuals with seropositivity to $\leqslant$ 2 pathogens, to 3 or 4 pathogens and to 5 pathogens respectively. Since then, several serological studies found a prospective relation between increasing number of infectious agents (HSV-1 and 2, HCMV, Epstein Barr virus, EBV, *Haemophilus influenzae*, *C. pneumoniae*, *Mycoplasma pneumoniae*, and *H. pylori*) and CVD outcomes[6-8]. At the same time, serological assessments demonstrated the association between increasing number of infectious agents (*C. pneumoniae*, *H. pylori*, *M. pneumoniae*, *H. influenzae*, HCMV, EBV, HSV-1 and 2) and progression of atherosclerosis[9,10]. Again, cross-sectional and case-control studies confirmed the relationship between the seropositivity to *C. pneumoniae*, *H. pylori*, HAV, HCMV, HSV-1 and 2, and atherosclerosis[11,12].

The evidence for a direct contribution of IB in the pathogenesis of atherosclerosis is based on the simultaneous detection of two pathogens in the atherosclerotic plaque (*C. pneumoniae* and *H. pylori* or *M. pneumoniae* and *C. pneumoniae* or *C. pneumoniae* and HCMV)[13-15]. Better yet is the evidence for a synergistic effect of *C. pneumoniae* and *H. pylori*, *M. pneumoniae* and *C. pneumoniae*, HCMV and *C. pneumoniae* in initiating or aggravating atherosclerosis in several animal models[16-18]. Similarly, there are some data showing the synergistic effect of the co-infection with *C. pneumoniae* and HCMV on the expression of atherogenic factors including IL-6, IL-8 and basic fibroblast growth factor in vascular smooth muscle cells (VSMCs) involved in advanced plaque formation[19]. Also seropositivity for both *C. pneumoniae* and HCMV infections was found to be associated with premature myocardial infarction even after adjustment for coronary risk factors and socioeconomic status[20].

Interestingly, the significant association between the increasing number of infectious agents together with elevated IL-6, C-reactive protein (CRP), and fibrinogen levels, and CAD prevalence**,** supports the hypothesis that inflammation may be one pathway by which more infectious agents and CVDs are linked[5,8,12].

The involvement of IB in the pathogenesis of atherosclerosis is expected since numerous infectious agents have been shown to play a role in the development and progression of atherosclerosis[4].

*C. pneumoniae*, an obligate intracellular bacterium, is responsible for respiratory infections such as sinusitis, pharyngitis and pneumonia. Exposure to *C. pneumoniae* is extremely common and epidemiological studies indicate that anti-*C. pneumoniae* antibody prevalence is 50% by the age of 20 and increases with increasing age[21]. *C. pneumoniae* is characterized by the ability to systematically disseminate from the lungs through peripheral blood mononuclear cells and to localize in several extrapulmonary tissues[22-25]. In recent years, it has been demonstrated that *C. pneumoniae*, in response to several stress conditions (iron or essential amino acid starvation, interferon (IFN)-γ or antibiotic treatment), can generate a persistent form during its developmental cycle[26-29]. Chlamydial persistent form may endure for a long time inside host cells since it is more suited to evade the host immune response and is more difficult to eradicate with antibiotics, leading to a chronic inflammatory state[26].

Cumulative evidence on the involvement of *C. pneumoniae* and atherosclerosis has been provided by seroepidemiological studies[30-32], *C. pneumoniae* DNA detection in the atherosclerotic plaque[31-33], the isolation of viable bacteria from the atheroma[4,32] and *in vivo* studies, demonstrating that *C. pneumoniae* infection may accelerate the progression of atherosclerotic lesion in animal models[4,31,34]. Lastly, *in vitro* studies have evidenced that *C. pneumoniae* is able to multiply within vascular cells, such as macrophages, endothelial cells, SMCs and platelets, and to induce chronic inflammation through the elicitation of inflammatory cytokines (*e.g.*, IL-6, IL-1β and TNF-α)[31,32,35]. Furthermore, once inside the vascular tissue, *C. pneumoniae* has been shown to induce the production of ROS leading to oxidative stress, which contributes to LDL oxidation and accumulation within vascular cells and to foam cell formation[36].

Periodontal pathogens, such as *Porphyromonas gingivalis* (*P. gingivalis*), *Aggregatibacter actinomycetemcomitans* (*A. actinomycetemcomitans*), *Tannerella forsythia* (*T. forsythia*), *Prevotella intermedia*, *Fusobacterium nucleatum* (*F. nucleatum*), *Treponema denticola*, *Campylobacter rectus*, *Streptococcus sanguis*, and *Streptococcus mutans*, are responsible of a complex group of chronic oral inflammatory diseases like periodontitis or gingivitis. Over the last years, different lines of evidence have supported the role of periodontal bacteria in cardio-

vascular diseases. First of all, it has been demonstrated that oral bacteria can disseminate in the blood stream causing bacteriemia[37] and localize in vascular wall. Indeed, DNA, RNA and antigens of a variety of oral bacterial species (*e.g.*, *P. gingivalis*, *A. actinomycetemcomitans*, *T. forsythia* and *F. nucleatum*) have been detected in atherosclerotic plaques[4]. More importantly, evidence of live *P. gingivalis* and *A. actinomycetemcomitans* in the atheroma[38], supports the direct involvement of these pathogens in the pathogenesis of atherosclerosis. Moreover, *in vivo* studies have shown the ability of *P. gingivalis* to accelerate atherosclerosis in murine models[4,39] and to induce aortic and coronary lesions in both normocholesterolemic and hypercholesterolemic pigs[40]. *In vitro* studies have demonstrated that periodontal pathogens are able to infect endothelial cells, SMCs and macrophages, eliciting the production of proinflammatory cytokines and chemokines (*e.g.*, IL-6 and monocyte chemoattractant protein (MCP)-1) and the formation of foam cells, hence contributing to atherosclerosis[41,42].

*H. pylori*, a common cause of chronic gastritis as well as a risk factor for gastric cancer, is widespread in the general population. In the last decade, it has been considered as a possible risk factor for atherosclerosis, since *H. pylori* DNA has been found in the atherosclerotic plaque[4,14]. Several seroepidemiological studies have confirmed a relationship between *H. pylori* and atherosclerosis although others have failed to demonstrate such an association[43-46]. Controversial are data showing the ability of *H. pylori* to accelerate the atherosclerotic lesion development in mouse models[4]. However, *H. pylori* may also contribute to the systemic inflammation underlying atherosclerosis through the elicitation of acute-phase reactants (*e.g.*, CRP) and inflammatory cytokines (*e.g.*, IL-6)[47].

Other bacteria, such as *M. pneumoniae*, have been proposed as possible pathogens in atherosclerosis with controversial results. Several seroepidemiological studies have found the association between CVDs and *M. pneumoniae*[48,49]. Furthermore, an *in vivo* study has demonstrated that *M. pneumoniae* infection aggravated atherosclerosis in hypercholesterolemic mice[18]. However, pathological studies have not supported the association between this microorganism and atherosclerosis, since *M. pneumoniae* DNA has been detected in atherosclerotic tissues as well as in healthy vessels[4].

Lifelong persistent infection with HCMV has been also associated with atherosclerosis. HCMV was first detected in human atheromatous tissue by Benditt *et al*[50] in 1983. Experimental data have shown the ability of HCMV to infect the human vascular wall, resulting in altered function of the endothelium[51]. Furthermore, both antigen and nucleic acid sequence of HCMV have been detected in SMCs from carotid artery plaques[52-54].

In addition, HCMV DNA has been more often detected in arterial samples from patients with atherosclerosis than in control subjects[55]. Similarly, higher prevalence as well as higher titer of HCMV antibody have been observed in patients undergoing vascular surgery for atherosclerosis than in control subjects[56]. In addition, a meta-analysis study has reported a significant increased coronary heart disease risk for patients infected with HCMV[57].

Recently it has been suggested that HSV-2, but not HSV-1, was associated with premature CVD[58]. Consistent with a potential relationship between HSV-2 and CVD, Raza-Ahmad *et al*[59] previously examined coronary artery specimens of patients undergoing coronary artery bypass grafting and found 45% of them positive for HSV-2 and only 1% positive for HSV-1. Likewise, a large cross sectional study linked HSV-2 to hypertension, but it did not find any association with HSV-1. The reasons of the association with HSV-2 and not with HSV-1 are unclear.

There is also evidence supporting the role of influenza as a trigger for cardiovascular events[60]. However, data are debated. Some authors think that influenza (A and B) seropositivity is not a predictor of risk for CAD. Others propose that influenza virus might play a role in atherogenesis or atherothrombosis and that influenza vaccination might reduce the risk of recurrent myocardial infarction[60,61]. Recently, a correlation between influenza B virus infection and acute myocardial infarction has been reported[62].

Although there have been positive associations of antibody titers or viral antigens of the hepatitis viruses with CVD[63-65], many recent studies have reported no association. Zhu *et al*[63] has suggested a causal role for HAV infection in atherogenesis, on the basis of a significantly higher prevalence of CAD among subjects living in the Washington, DC, area who had serum IgG antibodies to HAV. The same research group has reported a high relative hazard for myocardial infarction or death among individuals positive for IgG antibodies to HAV. However, some authors believe that epidemiological evidence argues against a significant role for HAV infection in atherogenesis, since in countries where HAV infection is far less frequent, such as northern European countries and Australia, the incidence of cardiovascular diseases is remarkably higher than that detected in countries showing an high HAV infection prevalence[66].

Several studies have also investigated the association of atherosclerosis with hepatitis C virus (HCV) infection, with conflicting results. Some studies have reported that the presence of antibody against HCV was associated with an increased risk of carotid artery plaque in the general population[65]. In addition, positive-strand HCV RNA has been detected in carotid plaque tissues from anti-HCV antibody-positive patients but it was not detected in anti-HCV antibody-negative patients[67,68]. Furthermore, multivariate logistic regression analysis has showed that HCV core protein positivity was an independent predictor of carotid plaque, supporting the possible link between persistent HCV infection and carotid atherosclerosis in subjects without severe liver dysfunction[69]. Patients with chronic HCV infection are known to develop not only hepatitis, but also various metabolic disorders[70,71]. Indeed, HCV affects both glucose and

lipid metabolism. Recent population-based studies have demonstrated hypolipidemia in subjects with chronic HCV infection[72,73]. Although altered lipid metabolism is linked to atherosclerosis, the effect of HCV on atherosclerosis remains controversial[73-75]. A systematic review published by Roed *et al*[76] has suggested an increased risk of CAD in HCV infected individuals. Recently, a study has revealed that chronic HCV infection was associated with increased insulin resistance and with mild atherosclerosis, thus underlining the complexity of this association[77].

A growing body of literature reports that human immunodeficiency virus (HIV) infected patients suffer from an elevated risk for both subclinical atherosclerotic disease and CVD events than uninfected individuals[78-81]. However, the results of a meta-analysis as well as a number of independent studies have questioned this association[82,83]. Furthermore, antiretroviral therapy (ART) has been shown to have independent effects on lesion development in several experimental studies, and some compounds, such as protease inhibitors, are associated with lipodystrophy, central adiposity, hyperlipidaemia, and endothelial dysfunction, all recognized risk factors for CVD[84-86]. However, the risk of CVD associated with HIV infection is not fully accounted for by the effects of antiretrovirals in these studies. Indeed, other papers have suggested that direct HIV infection of endothelial cells could contribute to atherosclerosis by causing endothelial dysfunction[87]. Furthermore, Hsue *et al*[88] have shown that increased atherosclerosis can occur in the absence of ART in HIV-infected patients. Recently, Desvarieux *et al*[89] have further emphasized the role of HIV in atherosclerosis, reporting the preponderant association of HIV infection (rather than ART) with increased atherosclerosis in never smokers, thus also determining the validity of the relationship independent of this important confounder.

## POSSIBLE MECHANISMS UNDERLYING INFECTIOUS BURDEN RELATED TO ATHEROSCLEROSIS

A substantial body of evidence supports the hypothesis that more infectious agents rather than a single pathogen may contribute to atherosclerosis through different mechanisms (Figure 1). Some microorganisms, such as *A. actinomycetemcomitans*, may act directly on the arterial wall contributing to endothelial dysfunction, foam cell formation, SMC proliferation, platelet aggregation and cytokine production[4,41]. Otherwise, microorganisms, such as *H. pylori*, may induce a systemic inflammation which in turn may damage the vascular wall (*e.g.*, by cytokines and proteases). Indeed, many observational studies have reported the association of the seropositivity to *H. pylori* with a sensitive marker of systemic inflammation and even predictor of acute cardiovascular events such as CRP[90,91].

Furthermore, there are also infectious agents, such as *C. pneumoniae* and *P. gingivalis*, that may contribute to atherosclerosis by both direct and indirect mechanisms. As a direct effect, these microorganisms have been shown to infect macrophages, SMCs and endothelial cells inducing the production of ROS, cytokines (IL-6, IL-1β and TNF-α, *etc.*), growth factors (basic fibroblast growth factor, bFGF, tumor growth factor (TGF)-β, *etc.*) and cellular adhesion molecules (vascular cell adhesion molecule-1, VCAM-1, intercellular adhesion molecule-1, ICAM-1, endothelial-leukocyte adhesion molecule-1, ELAM-1, *etc.*), all responsible for the typical pathological changes of the atherosclerotic plaque[36,41,42]. On the other hand, *C. pneumoniae* and *P. gingivalis* can contribute to atherosclerosis indirectly by inducing systemic inflammation[92,93]. Indeed, circulating cytokines (IL-6) and acute phase proteins (serum amyloid A), produced in response to systemic infection of animal models with *C. pneumoniae* or *P. gingivalis*, have been associated with the progression and destabilization of atherosclerotic lesions[94,95]. Also, in human, increases in circulating CRP levels and *P. gingivalis* or *C. pneumoniae* antibody levels have been associated with an increased risk of CAD[4,96].

Another indirect mechanism by which infectious agents play a role in the pathogenesis of atherosclerosis is molecular mimicry. There is evidence that the humoral immune response against the heat shock proteins (HSPs) found in *C. pneumoniae*, *H. pylori* and *P. gingivalis*, may cross-react with human HSPs in vascular cells, initiating an autoimmune process, responsible for vascular endothelial injury[97-99]. In fact, antibody levels against HSPs have been associated with early and advanced atherosclerosis[100]. In addition, *in vivo* studies have also confirmed that the T-cell immune response against HSP, derived from *H. pylori*, *C. pneumoniae* and *P. gingivalis*, could promote atherogenesis[101-103].

As far as concern viral agents, data supporting a direct effect of these agents on the pathogenesis of atherosclerosis are usually weak; infections with viruses are more likely to have an indirect effect on the initiation and progression of atherosclerosis.

Relative to HCMV, it has been observed that SMCs isolated from atherosclerotic coronary lesions, harbor HCMV DNA sequences and express immediate early proteins, such as IE84, one of the immediate early proteins of the virus that binds and inhibits p53[104]. Inhibition of p53 by the virus is held responsible for the enhanced proliferation of SMCs and impaired apoptosis, either of which may contribute to restenosis[104]. Furthermore, persistent infection of HCMV in endothelial cells leads to dysfunction of these cells and activates proinflammatory signaling pathways, which promote enhanced proliferation and migration of monocytes and SMCs into *intima* of the vascular wall as well as lipid accumulation and expansion of the atherosclerotic lesion[105,106].

The precise mechanism by which influenza virus infection contributes to atherosclerosis is unclear, however inflammation and coagulopathy seem to be key factors. Specifically, the potential mechanisms may include: (1) antigenic cross-reactivity; (2) an increase in pro-inflammatory and prothrombotic cytokines, such as IL-2, IL-6, IL-10 and IL-18; (3) pronounced expression of inflammatory cytokines by infected monocytes and reduced

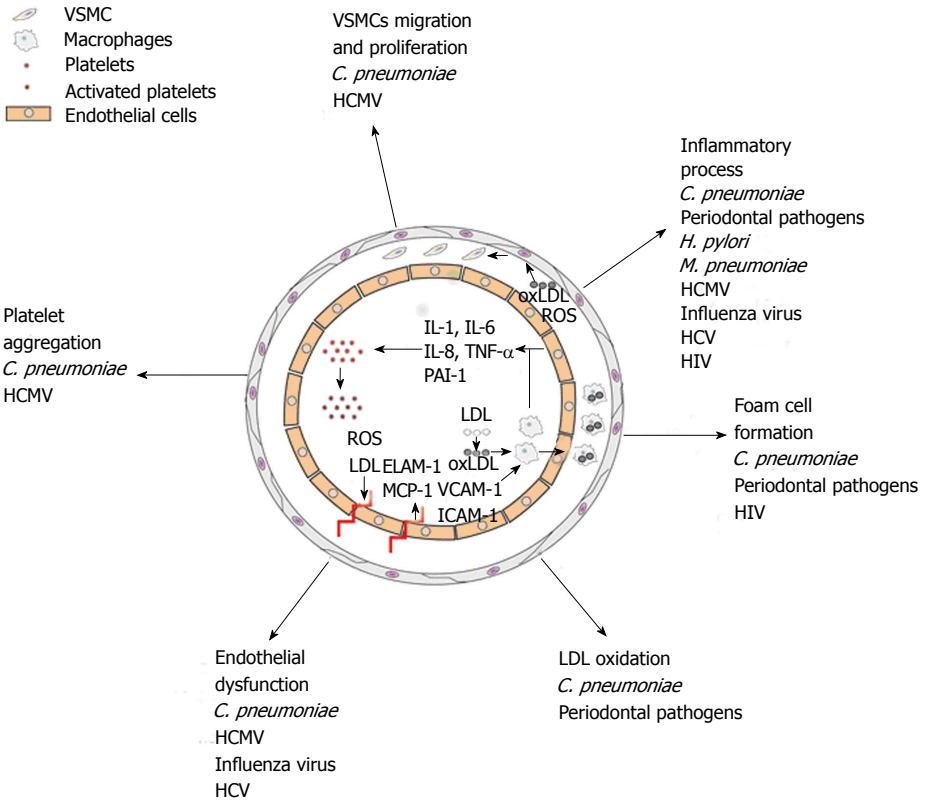

**Figure 1 Schematic representation of transversal artery section.** Possible etiopathogenetic mechanisms of the infectious agents in atherosclerotic plaque development. *C. pneumoniae*: *Chlamydia pneumoniae*; HCMV: Human cytomegalovirus; *H. pylori*: *Helicobacter pylori*; *M. pneumoniae*: *Mycoplasma pneumoniae*; HCV: Hepatitis C virus; HIV: Human immunodeficiency virus; SMC; Smooth muscle cell; ROS; Reactive oxygen species; LDL; Low-density lipoprotein; Ox-LDL: Oxidized low-density lipoprotein; IL: Interleukin; TNF-α: Tumor necrosis factor; PAI: Plasminogen activator inhibitor-1; ELAM-1: Endothelial-leukocyte adhesion molecule-1; VCAM-1: Vascular cell adhesion molecule-1; ICAM-1: Intercellular adhesion molecule-1; MCP-1: Monocyte chemoattractant protein-1.

clotting time; (4) increased trafficking of macrophages into the arterial wall; and (5) induction of procoagulant activity in infected endothelial cells, reduced clotting time, and increased expression of tissue factor[60,62]. Repeated influenza virus infection may injure vascular endothelial cells and initiate the inflammatory response that is required to accelerate and enhance the development of atherosclerosis.

It has been suggested that influenza virus may trigger the destabilization of already present vulnerable plaques. Naghavi *et al*[107] have showed that inoculation of influenza virus A in atherosclerotic apolipoprotein E-deficient mice led to a marked increase in inflammation and thrombosis in plaques but not in normal area. Influenza virus infection may cause the production of IL-2, IL-6, IL-10, IL-18, IFN-γ and TNF-α, which induces endothelial cells to release endothelin (ET)-1, sICAM-1 and sVCAM-1. These inflammatory cytokines may trigger the destabilization of existing vulnerable plaques and lead to an acute myocardial infarction without being involved in the development or progression of atherosclerosis[108].

As stated before, the role of HCV in atherosclerosis is widely debated. A role of chronic inflammation in atherogenesis has been suggested[109] because chronic HCV infection has been associated with vasculitis and mixed cryoglobulinemia, which may cause vascular injury as well as cerebrovascular damage[110]. Concentrations of sICAM-1 have been reported to be higher in HCV patients than in control subjects[111], and Cacoub *et al*[112] have reported a possible association of anti-endothelial cell autoantibodies, commonly observed in HCV patients but not in other viral diseases, with vasculitis. However, a recent paper has demonstrated a favorable effect of HCV on atherosclerosis[77] probably due to the alteration in lipid parameters of the subjects with chronic HCV infection caused by the progression of liver disease and partly by a metabolic process associated with HCV replication.

Several papers have reported that atherosclerosis is consistently higher among the HIV positive patients, with or without treatment. Recently Shrestha *et al*[113] have postulated three key sequential biological processes that lead to accelerate progression of atherosclerosis: (1) inflammation leads to the recruitment of monocytes; (2) monocytes migrate to the endothelium and differentiate to macrophages and foam cells; and (3) apoptosis of foam cells leads to plaque development through calcium-dependent endoplasmic reticulum stress. The HIV itself, or together with treatment, affects this progression by increasing inflammation, promoting the transformation of monocytes, and increasing apoptosis through ER stress and an imbalance of calcium.

Given the complexity of the mechanisms by which each microorganism may play a role in the pathogenesis of atherosclerosis, defining the interplay of more infectious agents is far more difficult because the pro-atherogenic effect of each pathogen might be amplified.

## ASSESSMENT OF INFECTIOUS BURDEN RELATED TO ATHEROSCLEROSIS

The main unanswered question is the definition of IB. Several infectious agents, such as *C. pneumoniae*, *H. influenzae*, *H. pylori*, *M. pneumoniae*, HCMV, HSV, EBV and HAV, *etc.* have been proposed as constituting the IB related to

atherosclerosis, but, to date, there is no consensus both on the number and on which microorganisms should be considered.

The majority of the infectious agents involved in the IB are widespread, as evidenced from the high prevalence of antibodies in the general population; more than half of the world population is seropositive, for example, to *C. pneumoniae, H. pylori*, HCMV and HSV. Again, HSV, HCMV, *C. pneumoniae* and *H. pylori* infections could be acquired early in life, and persist over time. The situation is further complicated by the fact that the infectious agents involved in IB are responsible for persistent infection (*e.g.*, HIV and *C. pneumoniae*), repeated infection (*e.g.*, influenza virus), latent infection followed by life-long reactivation (*e.g.*, HSV and HCMV) or chronic infection (*e.g.*, HBV, HCV and, *H. pylori*).

Nowadays, the assessment of the IB related to atherosclerosis is based mainly on serological methods. The main limitations of serology are to define whether the antibody response reflects a past or chronic infection and to identify the differences in seropositivity between patients and general population, especially if seropositivity is common. In addition, serological diagnostic methods are not appropriate for the detection of novel or rare pathogens. Lastly, most serological assays are designed for diagnostic testing in clinical settings, and not for the assessment of the burden of infections acquired through life. Notably, most of the infectious agents involved in the IB, such as *C. pneumoniae*, *H. pylori*, HSV, and HCMV, can cause asymptomatic infections that are not routinely investigated. As a result, these undiagnosed infections, if left untreated, can contribute to the development of severe complications, including CVDs.

Other technical obstacles in the assessment of the IB related to atherosclerosis include difficulties in obtaining atherosclerotic plaques and in isolating and culturing certain infectious agents. Indeed, atherosclerotic plaques are obtained too late during the course of the disease to be of clinical use.

Another intriguing issue is the interaction of more infectious agents with host factors, such as age, gender, ethnicity, and other concomitant infections or clinical conditions that may impair the host immune system, thus potentially modifying the establishment, progression and outcome of the infection. Moreover, genome-wide association studies have now convincingly shown that the susceptibility to an infection as well as the diverse outcomes (for example the resolution of infection, the clinical deterioration to severe disease, or the progression from acute infection to persistent infection) can be, at least, partly explained by genetic variation[114]. In this regard, a recent study has showed that *IL-6* gene polymorphisms appear to influence the susceptibility to the atherogenic effect of more infectious agents including *C. pneumoniae*, CMV, *H. pylori* and HSV-1[115].

## CONCLUSION

Based on the extent of the issues previously described, the role of the IB in the pathogenesis of atherosclerosis may have been substantially underestimated, so that the true impact of IB is likely to be much greater than it is currently recognized.

Different approaches could be taken to address the problem; one possibility may be to conceive a well-designed protocol that includes the number and the type of infectious agents, the antibody response (IgG and/or IgA) as well as the monitoring of antibody titer, atherosclerotic biological markers and cytokines. The latter are particularly critical in chronic viral infections, such as HIV infection, in which two monocytes surface markers (CD11b and chemokine (C-X-C motif) receptor (CXCR)-1) have been proposed as predictors of CVD[116].

Clearly, continued research and a better awareness of this problem will be helpful to improve our knowledge on the complex interaction between IB and atherosclerosis.

## Abstract

A number of animal and human studies suggest omega 3-fatty acids are anti-inflammatory. As a result they may have a therapeutic role in inflammatory bowel disease (IBD). The aim of this review is to briefly assess the literature about the utility of poly-unsaturated fatty acids (PUFAs) in the management of IBD. Taken together, almost all studies suggest some beneficial effects of n-3 PUFAs in IBD but the mechanism remains controversial. In addition, clinical benefit seems to be largely confined to ulcerative colitis. However all studies have concluded that these compounds have no potential for a steroid/aminosalicylic acid sparing effect or to maintain remission. Now the question arises as to whether this treatment is of real value to IBD patients? Clearly they have some therapeutic potential but further work is needed.

**Key words:** Fish oil; Ulcerative colitis; Crohn's disease; Treatment; n-3 poly-unsaturated fatty acids

**Core tip:** Fish oil supplements are probably of benefit to patients with ulcerative colitis. They have a much less certain role in Crohn's disease.

Farrukh A, Mayberry JF. Is there a role for fish oil in inflammatory bowel disease? *World J Clin Cases* 2014; 2(7): 250-252 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/250.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.250

## INTRODUCTION

Both animal and clinical work suggest that omega 3-fatty acids are anti-inflammatory in their action and so have the potential to be of use in the treatment of inflammatory bowel disease (IBD). In particular, they appeal to patients who see them as both safe and natural. The purpose of this review is to survey the literature and assess the utility of poly-unsaturated fatty acids (PUFAs) in the management of IBD.

## THE UTILITY OF PUFAS IN THE MANAGEMENT OF IBD

The aetiology of IBD remains unclear but local mediators including arachidonic acid metabolites, cytokines and altered cell mediated immunity are likely to contribute to the disease. The rationale for the prescription of n-3 PUFA to promote a healthy gastrointestinal tract has been linked to their suggested anti-inflammatory properties. Different strategies have been adopted in various clinical trials to evaluate n-3 PUFA in patients with IBD. Inhibition of natural cytotoxicity, changes in interleukin 2 (IL-2) and arachidonic acid metabolites, *e.g.*, $LTB_4$ are the main chemotactic signals seen in the mucosa during a relapse. All are known to mediate the natural killer activity. A second hypothesis is based on the possible deficiency of essential fatty acids (EFAs) in IBD and its effect on cell membranes[1]. A further possibility is that fish oil ameliorates oxidative stress in IBD.

In a randomised crossover trial from four units which

involved 18 patients with ulcerative colitis (UC) fish oil supplements reduced $LTB_4$ levels in a rectal dialysate. Histology improved and patients' weight increased[2].

Conversely, a small Canadian trial of 11 patients found that addition of fish oil was of clinical benefit in UC but did not reduce mucosal $LTB_4$[3]. However, over a six month period serum $LTB_4$ was insignificant while there was a simultaneous fall in NK cell cytotoxicity[4].

An American study of 47 patients with long-standing bowel problems looked at the frequency of essential fatty acid deficiency. The majority had Crohn's disease. Compared to 56 control subjects, patients' metabolism was comparable to that seen in essential fatty acid deficiency (EFAD). Patients had: (1) 7% lower PUFA levels; (2) Lower concentrations of saturated and monounsaturated fatty acids.

The authors suggested patients with IBD should be assessed for EFAD and receive significant quantities of supplements with a high EFA content[5]. In contrast, a Japanese study found that EFAD rarely occurs in Crohn's disease[6]. A United Kingdom prospective study based on 26000 recruits living in Norfolk showed that total dietary n-3PUFAs, eicosapentaenoic acid and docosahexaenoic acid were associated with a reduced risk of ulcerative colitis[7]. This was not found in a small cross-sectional study of 51 patients with inflammatory bowel disease from Hungary[8].

To gauge whether fish oil can reduce oxidative stress in ulcerative colitis a Brazilian crossover study of nine patients on conventional treatment with sulfasalazine also received omega-3 fatty acids or placebo for two months separated by two months. They were compared with nine healthy people. Disease activity was examined through a range of standard serological measures as well as endoscopy and histology. The results showed that fish oil can act as a free radical scavenger and so protect patients[9]. The influence of monounsaturated, n-3, and n-3 + n-6 polyunsaturated fatty acids on histology, mucosal defence, mucosal prostaglandin E2 and $LTB_4$ in a rat model was investigated in Spain. It concluded that n-3 PUFAs can prevent inflammation but cause a decrease in the colon's defence system leading to oxidative injury[10]. Therefore, although it seems likely that these compounds have anti-inflammatory effects, the mechanism by which they achieve this needs further exploration.

There are some important considerations which should be borne in mind before promoting their use in the clinical care of patients with IBD: (1) Do they decrease disease activity? (2) Do they maintain remission? (3) Can they be used as an alternative to steroids or aminosalicylic acid (ASA) compounds?

There are studies which demonstrated a reduction in disease activity with these compounds, *e.g.*, a pilot study in United Kingdom evaluated their effectiveness both in terms of disease activity and histological scores when compared with pre-treatment measures[11,12]. In a German trial 5-ASA compounds were stopped in 64 patients who had ulcerative colitis and had been in remission for three months. They received a fish oil supplement and their clinical course was followed for 24 mo with colonoscopies at the beginning and end of the study. Freedom from disease activity was only seen in two of the 24 mo and the overall relapse rate was similar for active treatment and placebo groups. It seems that n-3 PUFAs can temporarily retard but not prevent relapse in UC[12]. Another randomised blinded control study of 87 patients from United Kingdom found fish oil had some benefit. Corticosteroid requirements were reduced for those 53 patients who had active disease on trial entry. Fish oil induced faster remission, although this trend did not reach significance. In contrast there was no difference in relapse rates if patients were in remission. So, it appears fish oil supplementation has a modest benefit in active disease allowing use of smaller doses of corticosteroids. In contrast they seem to have no role in maintenance[13]. A randomised controlled multicentre trial of 204 patients with Crohn's disease in Germany confirmed that omega-3 fatty acids had no role in prolonging remission[14,15]. Confirmation of the limited benefit in ulcerative colitis and absence of effect in Crohn's disease was first suggested in 1989 in a study of 39 patients[16]. The multicentre EPIC study from North America and Europe which included 738 patients with Crohn's disease again confirmed that omega 3 free fatty acids had no role in maintenance[17]. Support for such an interpretation comes from 3 systematic reviews[18-20]. However, this might not be the case in children and young people. In a study of 38 patients addition of enteric coated omega-3 fatty acids to 5-ASA treatment appeared of benefit[21]. Support for their role in Crohn's disease also came from a rigorous trial in 78 patients[22].

Ten patients with moderately active colitis were assessed in a study which used a randomized cross-over methodology. The treatments were either sulfasalazine or omega-3 fatty acids for 2 mo. Response was measured by endoscopic assessment, histological review and whole-body protein turnover. Treatment with omega-3 fatty acids alone led to a less objective improvement than conventional treatment. This shows that for active ulcerative colitis sulfasalazine is better than omega-3 fatty acids[23].

## CONCLUSION

Taken together, almost all studies suggest some beneficial effects of n-3 PUFAs in IBD but the mechanism remains controversial. In addition, clinical benefit seem largely confined to UC. However all studies have concluded that these compounds have no potential for a Steroid/ASA sparing effect or to maintain remission. Now the question arises as to whether this treatment is of real value to IBD patients? Clearly they have some therapeutic potential but further work is needed with larger numbers and more highly powered trials.

## Abstract

Oral hairy leukoplakia (OHL) is a disease associated with Epstein-Barr virus and human immunodeficiency virus infections. OHL is usually an asymptomatic lesion, but in some cases treatment is recommended to reestablish the normal characteristics of the tongue, to eliminate pathogenic microorganisms, to improve patient comfort and for cosmetic reasons. Proposed treatments for this condition include surgery, systemic antiviral treatment and topical management. Topical treatment is an inexpensive and safe therapy that is easy to apply, noninvasive, free of systemic adverse effects and effective over a long period of time. The aim of this study was to present a review of the literature for topical therapy for OHL. Gentian violet, retinoids, podophyllin, acyclovir and podophyllin associated with topical antiviral drugs were used to treat OHL. Reports with this focus are limited, and since 2010, no new studies have been published that discuss the efficacy of topical treatments for OHL. Podophyllin with acyclovir cream was found to be effective, causing regression of lesions with no recurrences. Additional searches are necessary to provide clinical evidence of topical management effectiveness.

**Key words:** Oral hairy leukoplakia; Human immunodeficiency virus infection; Topical treatment; Topical agents; Recurrence rate

**Core tip:** This literature review was performed to assess the evidence for topical treatments for oral hairy leukoplakia (OHL). Although highly active antiretroviral therapy has reduced oral lesions associated with human immunodeficiency virus, prevalence studies revealed that OHL is still observed in patients with HIV infections. Knowledge about appropriate management of this condition is relevant, specifically regarding topical treatments that are less invasive, low-cost, easy to apply and free of systemic adverse effects.

Brasileiro CB, Abreu MHNG, Mesquita RA. Critical review of topical management of oral hairy leukoplakia. *World J Clin Cases* 2014; 2(7): 253-256 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/253.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.253

## INTRODUCTION

Oral hairy leukoplakia (OHL) was first described in 1984 by Greenspan *et al*[1] and is described as a white plaque generally on the lateral borders of the tongue in patients with human immunodeficiency virus (HIV) that later developed acquired immunodeficiency syndrome (AIDS). Later, other studies confirmed OHL as an early indicator of HIV infection and revealed that this disease may be related to the progression to AIDS. However, OHL

**Table 1 Topical agents used in the treatment of oral hairy leukoplakia and study types**

is not exclusive to HIV infection and may be associated with other cases of immunosuppressed patients[1-3]. OHL appears clinically as an asymptomatic white lesion on the lateral border of the tongue, unilaterally or bilaterally, with imprecise boundaries, a flat, corrugated or hairy surface, that is not removed by scraping[4]. Some patients may present with symptoms including mild pain and alteration of taste[5].

The pathogenesis of OHL is related to the infection of oral squamous epithelial cells with the Epstein-Barr virus (EBV)[3,4]. The absence of or high reduction of Langerhans cells in OHL has been demonstrated[6]. Langerhans cells are the antigen-presenting immune cells that are required for an immune system response to a viral infection. This deficiency of Langerhans cells may permit EBV to replicate[5-7].

Topical therapy is the most highly recommended treatment for OHL because it has a low cost, is easy to use, has few side effects and is effective for a long period of time[4]. However, there are few studies that evaluate the effects of topical treatment in patients with OHL. This can be explained by the significant reduction in the prevalence of the oral lesions in HIV patients after the introduction of highly active antiretroviral therapy[4,8]. The purpose of this article is to present a review of topical therapies for OHL. The methodology was a search of the literature, from 1966 through December 2013, related to the topical treatment of OHL and listed on PubMed. The search was conducted in both English and Portuguese, and the keywords used were "oral hairy leukoplakia", "oral hairy leukoplakia and topical management" and "oral hairy leukoplakia and topical treatment". Additional studies were found in the reference lists of the selected articles. Randomized clinical trials, case reports and review articles were included in the current paper (Table 1).

## REVIEW

Usually, OHL does not require specific therapy, and when indicated, therapy is intended to restore the patient's comfort, eliminate the hairiness, reestablish the normal appearance of the tongue for aesthetic reasons and remove niches for bacteria, viruses (EBV) and fungi to prevent the establishment of other oral diseases[2]. Proposed treatments include surgery, systemic antiviral therapy and topical management. A search of the literature found 16 articles related to topical treatments for OHL. All forms of topical management of OHL identified in published studies will be presented herein.

### Gentian violet

Gentian violet is a triphenylmethane dye that was synthesized by Charles Lauth, in 1861, under the name of "Violet de Paris". Churchman, in 1912, demonstrated the bacteriostatic action of gentian violet against Gram-positive microorganisms *in vitro* and in animal models, as well as the antimycotic effects of this agent against multiple species of Candida[9]. Since then, several studies have evaluated the antibacterial and antifungal actions of gentian violet.

The antiviral properties of gentian violet were investigated based on evidence that EBV viral products induce the generation of reactive oxygen, and gentian violet is a potent inhibitor of reactive oxygen species[10]. Given that gentian violet is well-tolerated, approved for human use and is an inexpensive agent, Bhandarkar *et al*[3] performed a study using gentian violet (2%) as a topical treatment for OHL in one HIV-infected man. Gentian violet was applied topically to the lesion three times in a one-month period. Complete regression of OHL was observed at a one-month follow-up, and there was no recurrence of the OHL one year after treatment.

### Retinoids

Retin-A is a dekeratinizing agent responsible for the modulation of the presence of Langerhans cells in OHL. Local application of 0.1% vitamin A twice daily was performed in twelve cases of OHL and regression of the lesions was observed after 10 d[11]. Daily application of a tretinoin solution (Retin-A) for 15 to 20 d was performed in 22 patients, and 37 patients received no treatment. Lesion healing was observed in 69% of treated patients and spontaneous regression was detected in 10.8% of untreated patients[12]. Retin-A is a costly drug and causes a burning sensation after prolonged use[13,14].

### Podophyllin

Podophyllin is a dry, alcoholic extract of rhizomes and roots of *Podophyllum peltatum*. It is a lipid-soluble substance that crosses cell membranes and interferes with cell replication; this substance is commonly used as a topical chemotherapy agent[14]. It is inexpensive, simple to apply, and effective over a long period of time. Although podophyllin has a very bitter and unpleasant taste, the palate returns to normal two hours after of application[2].

The results of a 25% alcoholic solution of podophyllin as topical therapy for OHL are significant, especially in the first week after application. In a case series, nine patients were treated with podophyllin resin 25% sol in a benzoin compound tincture. The results showed complete regression of all lesions: five patients within one

week and four after a second application a week later. Those four patients had presented with more extensive lesions[13]. In another study, six men with OHL were treated with a once-daily application of podophyllin 25%, and healing of all lesions was verified in three to 5 d[15]. Gowdey *et al*[14] assessed ten HIV-infected patients with OHL on the tongue and treated one side with a single application of topical podophyllin resin 25% solution. The other side was used as a control. The patients were evaluated at days two, seven, and thirty of the study. They described a slight change of taste, burning sensation and pain with a short duration. There was regression of lesions, especially on the second day after application.

The dose usually applied in topical therapy for OHL varied from 10 mg to 20 mg of podophyllin[2,14]. This dose has not been associated with adverse or systemic effects; these effects are observed after ingestion or when more than 100 mg of podophyllin is topically applied and not removed within 4 to 6 h[14].

### Acyclovir

Acyclovir is a chemotherapeutic antiviral agent that is highly effective against herpes simplex virus types I and II, EBV, Varicella zoster virus, and cytomegalovirus[2]. The only previous study performed using acyclovir cream for topical treatment was performed by Ficarra *et al*[16]. The authors observed OHL in 23 out of 120 HIV-positive patients (19%), and found a complete resolution of OHL in two patients and partial regression in one patient after topical application of acyclovir cream.

### Combined topical therapy

Topical antiviral drugs may be used in combination with podophyllin, increasing the efficiency of OHL treatment. After the dekeratinization of superficial epithelial cells by podophyllin, the topical antiviral drug acts on exposed and infected cells located below the surface[4]. A clinical trial study, performed randomly, proposed a combined topical therapy of 25% podophyllin and 5% acyclovir cream and compared the results with 25% podophyllin[2]. In both protocols, applications were performed weekly. All lesions treated with podophyllin and acyclovir showed total clinical regression, and in the podophyllin group, four lesions did not display total clinical resolution after 25 applications. Furthermore, in the 25% podophyllin group, smaller lesions showed clinical regression with fewer applications than larger lesions. In the 25% podophyllin and 5% acyclovir cream group, there was no significant difference in the number of applications.

Based on their previous study, a new topical treatment for OHL employing 25% podophyllin resin with 1% penciclovir cream was tested and the results were compared to 25% podophyllin resin and 25% podophyllin resin with 5% acyclovir cream applied topically[4]. Fourteen patients were treated in each protocol. The authors concluded that about half of the patients (55%) had clinical healing of OHL within 7-8 wk of each topical treatment, but the 25% podophyllin resin with 5% acyclovir cream resulted in a faster clinical healing rate of OHL after the sixth week; moreover, no recurrent lesions were observed in this treatment group twelve months after clinical healing of OHL.

### Recurrence rate

Some studies evaluated the recurrence rate of OHL after topical treatment. Bhandarkar *et al*[3] and Ficarra *et al*[16] showed no recurrence of the lesion one year after 2% gentian violet treatment and six months after acyclovir cream topical therapy, respectively, in patients with total clinical regression. For topical retinoid, recurrence is observed a few days following discontinuation of treatment[11]. Sanchez *et al*[15] observed a recurrence rate of 33.3% of OHL treated with 25% podophyllin. Two of the six cases evaluated presented with regression of the lesion four and nine months after treatment. Moura *et al*[2] showed a recurrence of 11.2% twelve months post-therapy with 25% podophyllin. No recurrence was observed in the 25% podophyllin resin with 5% acyclovir cream group. These data suggest that synergism of podophyllin and acyclovir decreases recurrence of OHL after topical therapy.

Systemic antiviral drugs such as desciclovir, valacyclovir, acyclovir and ganciclovir have been used for OHL treatment with recurrence observed after discontinuation[17,18]. The possibility of the occurrence of side effects and drug resistance must be carefully evaluated so that the potential harm of treatment does not exceed the expected benefits[18]. Surgical excision as a treatment for OHL has been performed, and no recurrence was observed within three months. However, most patients presented with new foci of OHL after this time[19]. Considering this, and comparing it to systemic therapy and surgery, topical treatment is recommended because it does not produce systemic adverse effects, is less invasive and is effective over a long period of time[4].

## CONCLUSION

A combined topical therapy of 25% podophyllin and 5% acyclovir cream is effective, demonstrating fast healing without recurrence. In this case, additional multicenter studies are necessary. As for other agents, gentian violet (2%) was also used successfully in the treatment of OHL, with no recurrences in a year, although only one previous study has evaluated the effectiveness of this therapy. Future double-blind and placebo-controlled trials are needed to provide clinical evidence for the efficacy of topical management of OHL.

## Abstract

**AIM:** To investigate the complex relationships between resting energy expenditure (REE), eating psychopathology, and Hypothalamus Pituitary Adrenal axis functioning in patients with eating disorders.

**METHODS:** The study was designed as a cross-sectional survey, and it was planned by the Clinic for Eating Disorders of the University of Florence (Italy). The protocol was approved by the Ethics Committee of the Institution. Twenty two anorexia nervosa and twenty one Bulimia Nervosa patients were assessed by means of a clinical interview and the structured clinical interview for diagnostic and statistical manual of mental disorders, fourth edition. Eating attitudes and behaviour were specifically investigated by means of the eating disorder examination questionnaire (EDE-Q). Patients were also evaluated by means of the symptom checklist (SCL 90-R), REE was measured by means of indirect calorimetry, and blood cortisol morning levels were evaluated.

**RESULTS:** Both anorexia nervosa and bulimia nervosa patients showed a reduced REE as compared with predicted REE. Body mass index (BMI) was positively associated with resting energy expenditure in Bulimics, whereas a strong, negative association between BMI and REE was observed in Anorectics. The pattern of associations between variables supported a mediation model, where shape concern accounted for variations in REE and cortisol levels (mediator), and variations in the mediator significantly accounted for variations in REE. When these associations where taken into account together, the relationship between shape concern and REE was no longer significant, whereas the association between cortisol levels and REE retained its significance, showing strong evidence for a single, dominant mediator. Anorectics and Bulimics showed an opposite pattern of association between BMI and REE. In Anorectics only, a higher REE was associated with a more severe eating disorder specific psychopathology, and cortisol levels represent a possible mediating factor for this relationship.

**CONCLUSION:** The data supported a mediation model where cortisol levels mediated the relationship between eating psychopathology (concern about body shape) and REE.

**Key words:** Anorexia nervosa; Bulimia nervosa; Cortisol; Psychopathology; Resting energy expenditure

**Core tip:** We have investigated the relationship between resting energy expenditure (REE), eating psychopathology, and hypothalamus adrenal axis in EDs. Twenty two anorexia nervosa (AN) and 21 bulimia nervosa (BN) patients were assessed. Both AN and BN showed a reduced REE as compared with predicted REE. AN and BN showed an opposite pattern of association between REE and Body Mass Index (BMI) which was positively associated with REE in BN, whereas a strong, negative association between BMI and REE was observed in AN. In AN only, a higher REE was associated with a more severe eating disorder psychopathology, and higher cortisol levels. The data supported a mediation model where cortisol levels mediated the relationship between eating psychopathology and REE.

Association between resting energy expenditure, psychopathology and HPA-axis in eating disorders. *World J Clin Cases* 2014; 2(7): 257-264 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/257.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.257

## INTRODUCTION

Chronic underfeeding and binge-purging behaviours can lead to alterations in metabolism and body composition. Several studies investigated energy metabolism in patients with anorexia nervosa (AN)[1-6], and the observed reduction of resting energy expenditure (REE) has been associated to the smaller volume of metabolically active tissues and to an adaptation to underfeeding[6-8]. Measured REE is significantly lower than predicted REE in AN subjects[9]. As far as bulimic normal weight patients are concerned, most of the published studies found that the resting metabolic rate of these patients was significantly lower than that of controls[10,11], whereas Detzer *et al*[12] did not find significant differences between patients with bulimia nervosa (BN) and controls.

REE is one component of the total energy expenditure. It includes basal metabolic rate, which refers to the minimum part of energy required to maintain the organisms' basic functions, and it is related to the amount of energy utilized when the body is at complete rest. It can be measured by means of indirect calorimetry, and it is often used in clinical settings. REE alterations found in eating disorders could be partly explained with the quantitative changes in cell mass[1,13]. Similarly, Vaisman *et al*[14] attributed the lowered resting metabolic rate to the reduction in lean body mass.

Alternatively, previous findings supported the relationship between stress induced cortisol levels and metabolic rate. In eating disorders, increased hypothalamus adrenal axis (HPA) arousal with abnormalities in its regulation is well proven[15,16]; HPA axis hyperactivity is well documented in AN and BN especially during the acute phase of the illness, even if the abnormalities showed by the BN patients are milder[17]. The HPA axis alterations can influence other biological systems involved in eating behaviour, such as leptin, endogenous opioids, thyroid, reproductive, immune and sympathetic nervous systems and the abnormalities in these systems could be considered to be involved in the onset and the maintenance of eating disorders[17]. HPA axis abnormalities seem to be associated with an history of stressful life events and an excess of traumatic life events, such as sexual and physical abuse are reported in patients with eating disorders. As the relationship between life events and HPA axis is well known[17-19], it is not unexpected that the HPA axis may also be functioning abnormally in eating disorders. Moreover cortisol is considered a catabolic hormone[20,21], and it has been found that weight gain in AN was associated with normalization of plasmatic and urinary cortisol levels[22], HPA functioning and the reduction of cortisol secretory burst[23].

Finally, few studies considered the relationship between eating disorder psychopathology and REE in eating disorders patients, with conflicting results[13,23,24].

The aims of the present study were as follows: (1) to evaluate the pattern of association between body mass index (BMI) and REE in AN and BN; (2) to investigate the possible mechanisms of REE alterations in AN and BN, analyzing the interaction between eating disorder psychopathology, HPA functioning and metabolic status.

## MATERIALS AND METHODS

### Sample and measures

The study was designed as a cross-sectional survey, and it was planned by the Clinic for Eating Disorders of the University of Florence (Italy). The protocol was approved by the Ethics Committee of the Institution. A written informed consent was obtained from each patient after the procedures of the study were fully explained. The study was performed on a series of 61 eating disorders patients attending the Clinic for Eating Disorders between January 2010 and July 2013, provided they met the following inclusion criteria: female, age between 18 and 60 years, diagnosis of AN restricting type and BN Binge/Purging type, assessed by means of the Structured Clinical Interview for Diagnostic and statistical manual of mental disorders, fourth edition (DSM-IV)[25,26]. Patients were included if they reported at least 1 year of a stable Eating Disorder diagnosis (at least 1 year with full diagnostic criteria for anorexia nervosa or bulimia nervosa according the DSM-IV criteria and without diagnostic crossover in the same year), at least 6 wk of a stable body weight, no intense physical exercise in the past six months (both assessed by means of a face-to face clinical interview). None of the patients were in a remission or recovery phase of disease. The exclusion criteria were as follows: comorbid schizophrenia or bipolar disorder, illiteracy, mental retardation, severe medical conditions, current use of psychoactive medications that can interfere with HPA Axis response (*i.e.*, antidepressants use could increase human hippocampal neurogenesis by activating

the glucocorticoid receptor[27].

Six patients refused to participate in the study, and 12 patients were excluded because of the following reasons: bipolar disorder (2 patient), illiteracy (1 patient), mental retardation (1 patient), severe medical conditions (3 patients with heart failure, 1 with renal failure), pharmacological treatments (4 patients taking SSRI). The final sample was composed of 43 female subjects, 22 with AN Restricting Type, and 21 with BN Binge/Purging type. The Structured clinical interview for DSM-IV[26] axis was used to confirm psychiatric diagnoses.

### Psychological assessment

Psychopathological, behavioural and sociodemographic data were collected through a face-to-face interview on the first day of admission, by two expert psychiatrists (L.L., C.I.S.). The structured clinical interview for DSM IV[26] was applied to evaluate diagnoses according to DSM-IV. Anthropometric measurements were made using standard calibrated instruments. Height (m) was measured using a wall-mounted stadiometer, weight (kg) using electronic scales. BMI was calculated. Eating attitudes and behaviour were specifically investigated by means of the eating disorder examination questionnaire (EDE-Q)[28]. The self-reported EDE-Q consists of 38 items, assessing the core psychopathological features of eating disorders, and contains 4 subscales: dietary restraint, eating concern, weight concern, and shape concern. Finally, patients were evaluated by means of the symptom checklist (SCL 90-R)[29], a psychometric instrument devoted to the identification of psychopathological distress.

### Blood samples

Blood samples were drawn in the morning (8 am), after an overnight fast, for the determination of cortisol levels (mcg/L), TSH, and thyroid hormones levels.

### Indirect calorimetry

REE was measured by means of indirect calorimetry using a canopy system (MMC Horizon, Sensor Medics, Anaheim, United States in a quiet environment, with the patients in the supine position for 20 min before measurement, because activities of daily living increase REE, but a short rest (20 min) before testing is sufficient for the effect to dissipate) and after a 12 h overnight fast. Measurement duration of 10 min with the first 5 min deleted and the remaining 5 min having a coefficient of variation < 10% gave accurate readings of REE[30]. Energy expenditure was derived from $CO_2$ production and $O_2$ consumption, with the appropriate Weir's formula, neglecting protein oxidation[31]. The inter-day coefficient of variation of such measurements (as determined in six patients on subsequent days) was always less than 3%, without any sequence effect. Basal energy expenditure can be measured a number of different ways, but perhaps the most convenient way is by indirect calorimetry. This method is based on the assumption that metabolism is a reflection of energy expenditure. Since the oxidation of nutrients requires oxygen, by measuring oxygen consumption and carbon dioxide production, an estimate of energy production in kilocalories can be made. However, if indirect calorimetry is unavailable, the Harris-Benedict equations (multiple linear regression equations derived from a sample of normal individuals), based on height, weight, age, and sex, can be used clinically to estimate basal energy expenditure[8]. For females, the equation is: basal energy expenditure = 655.1 + (9.56 × body weight in kg) + (1.84 × height in cm) - (4.67 × age in years)[32,33]. REE was measured prior to start psychological and pharmacological interventions.

### Statistical analysis

For between-group comparisons (AN *vs* BN), $\chi^2$ and Independent-Samples *t* test were applied, while Paired Sample *t* test was adopted to compare REE with predicted REE within each group. Correlation analyses (Pearson's correlation), and subsequently linear regression analyses were performed in the whole sample, and within each group, to assess the associations between BMI, cortisol levels, eating specific and general psychopathology, and REE.

Subsequently, moderator and mediator effect analyses were performed. Whereas moderator variables specify when certain effects will hold, mediators consider how or why such effects occur (Baron and Kenny)[34]. The moderator function of third variables partitions a focal independent variable into subgroups, that establish its domains of maximal effectiveness in regard to a given dependent variable. Therefore, in order to evaluate whether the relationship between REE and BMI was different within Eating Disorders subgroups (first aim of the study), general linear model (GLM) was used to examine the moderating effect of diagnosis (AN *vs* BN) on the interaction between REE and BMI.

In order to evaluate the possible mechanisms that could explain the associations between REE and BMI (second aim of the study), mediators effect analyses were performed. The mediator function of a third variable represents the generative mechanism through which the focal independent variable is able to influence the dependent variable of interest.

## RESULTS

Table 1 reported demographic, clinical and psychopathological variables for AN and BN patients. No significant difference was detected between AN and BN, with the exception of BMI and FT3, which were higher in BN as compared with AN patients. No significant difference was found between AN and BN, in terms of REE while predicted REE was significant lower in AN. REE was lower than predicted REE, in both AN ($t$ = 2.27; $P$ = 0.034) and BN ($t$ = 5.82; $P$ < 0.001) groups. These comparisons retained their significance even when adjusting for FT3 hormones.

GLM analysis (Figure 1; part A) was adopted to evaluate whether the relationship between REE and BMI was different according to EDs subgroups (AN and BN).

| Purging behaviours (month frequency) | | 8.4 ± 5.9 | |

[a]Calculated by means of Harris-Benedict equation. Data are expressed as mean ± SD deviation; for between groups comparisons: Independent-Sample *t* test; [a]$P < 0.05$; [b]$P < 0.01$. REE: Resting energy expenditure; BMI: Body mass index; SCL-90 GSI: Symptom checklist (SCL 90-R) global severity index; EDE-Q: Eating disorder examination questionnaire.

GLM (age adjusted) showed a significant effect of REE by diagnosis on BMI ($\beta = 0.32$; $P < 0.001$). The significant interaction was confirmed even when adjusting for body surface area. Therefore, when the interaction was broken down (Figure 1; part B), an opposite pattern of association was found in AN and BN: the increased BMI was associated with higher REE in the BN group (age adjusted $\beta = 0.64$, $P = 0.001$), while in AN patients the reduced BMI was associated with higher REE (age adjusted $\beta = 0.63$, $P = 0.003$).

To evaluate the possible underlying mechanisms for maintenance of REE in AN and BN, Person's correlations were performed, considering psychopathological variables, cortisol levels, BMI and REE, within AN and BN patients (Table 2). No significant association was found in BN patients between REE and binge eating or purging behaviours, TSH or thyroid hormones levels. Considering AN patients, a strong positive association was found between REE and EDE-Q shape concern. Moreover, in the same group, significant positive correlations between EDE-Q shape concern and cortisol levels were also observed, as well as between cortisol levels and REE. Conversely, in BN group these associations were lacking or less significant than in AN.

In order to explain the relationship between a more severe eating disorder psychopathology and a higher REE in AN, we hypothesized a possible mediating role of cortisol levels. According to Baron *et al*[34], we assumed a three variable system represented by a path diagram, where the dependent variable was REE (Figure 2). It included a direct impact (Path c) of the independent variable (EDE-Q shape concern), the impact of the mediator (cortisol levels; Path b), and the impact of the independent variable on the mediator (Path a). To test for mediation, we regressed the mediator on the independent variable, the dependent variable on the independent variable, the independent variable on the dependent variable (direct impact), and the dependent variable on both the independent variable and on the mediator. Separate coefficients were estimated and reported. According to this model, the following conditions supported mediation hypothesis: (1) variations in levels of the independent variable (EDE-Q shape concern) significantly accounted for variations in the mediator (cortisol levels; $\beta = 0.47$; $P = 0.01$); (2) variations in the mediator significantly accounted for variations in the dependent variable (REE; $\beta = 0.80$; $P < 0.01$); (3) variations in the independent variable significantly accounted for variations in the dependent variable (REE; $\beta = 0.63$; $P < 0.01$); (4) finally, when Paths a and b were controlled, this previously significant relation between EDE-Q shape concern and REE was no longer significant ($\beta = 0.12$; $P = 0.53$), while the relation between cortisol levels and REE retained its significance ($\beta = 0.75$; $P = 0.002$), showing strong evidence for a single, dominant mediator.

In order to calculate the indirect effect of EDE-Q shape concern on REE *via* the mediator (cortisol levels) we performed the Sobel test[35], which resulted to be significant ($Z = 2.51$; $P = 0.005$). The model described above was tested also for EDE-Q total and subscale scores (data not shown). The best fit for the data was represented by the model including EDE-Q shape concern scores.

## DISCUSSION

To the best of our knowledge, this is the first study which evaluated REE in AN and BN, considering eating disorder specific psychopathology and HPA functioning as possible factors involved in the metabolic alterations.

According to our main results: (1) AN and BN patients showed an opposite pattern of association between BMI and REE. In AN patients, a higher REE was negatively associated with BMI, whereas BN patients showed a positive association between these two variables; (2) in AN patients only, a higher REE was associated with a more severe eating disorder specific psychopathology, and cortisol levels represented a possible mediating factor for this relationship.

According to previous findings[2,9,11,13], both AN and BN showed a reduced REE, which was significantly lower than the predicted REE. It has been suggested that dietary restraint places both AN and BN patients in a state of semi-starvation which is responsible for REE reduction, and it is partially compensated by binge eating behaviours in BN[7]. However, in the present study, AN patients did not show a reduced REE compared with BN, despite their lower BMI. In AN patients, we found

**Table 2 Pearson's correlations**

**B**

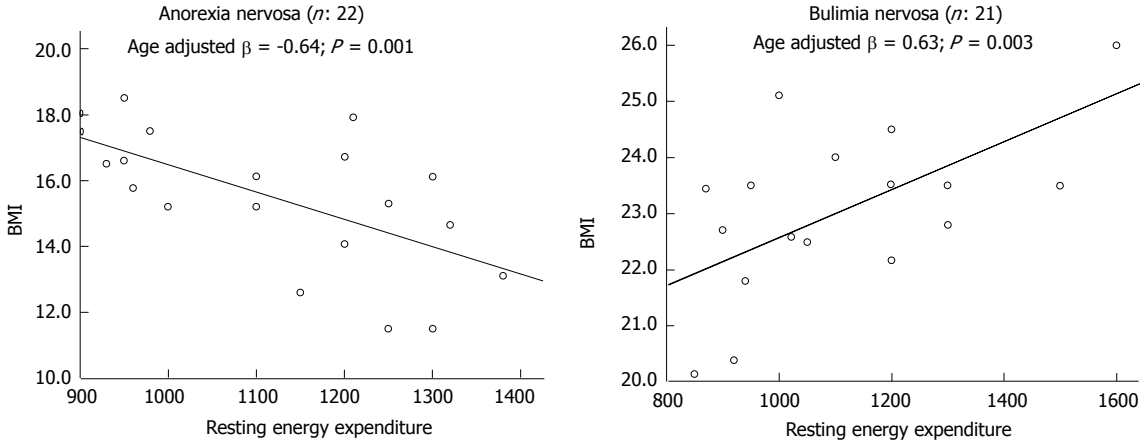

**Figure 1 Moderators of the relationship between resting energy expenditure and body mass index.** A: General linear model analysis (age adjusted) showed the effect of resting energy expenditure (REE) by diagnosis. Diagnosis was coded as dummy variables: 0 = Anorexia nervosa, 1 = Bulimia nervosa; B: The interaction showed in part A was broken down within diagnoses. Graphs reports results from linear regression analyses (age adjusted) of the opposite pattern of association between REE and body mass index (BMI) in anorexia nervosa and bulimia nervosa subjects.

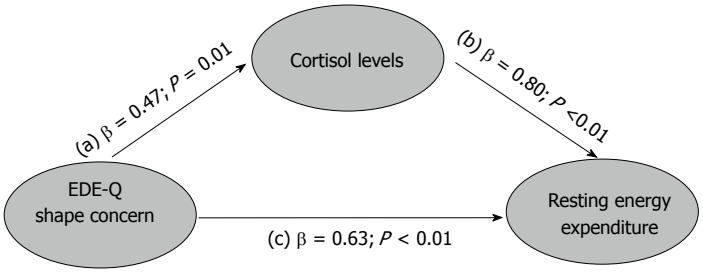

(d)

Dependent variable: Resting energy expenditure

| | β | *P* |
|---|---|---|
| EDE-Q Shape Concern | 0.12 | 0.53 |
| Cortisol Levels | 0.75 | 0.002 |

Sobel test statistic: $Z = 2.51$; $P = 0.005$

**Figure 2 Mediator Model for the relationship between shape concern, cortisol levels and resting energy expenditure.** The model included a direct impact (Path c) of the independent variable [eating disorder examination questionnaire (EDE-Q) shape concern]on the dependent variable (REE), the impact of the mediator (cortisol levels; Path b), and the impact of the independent variable on the mediator (Path a). The β values of separate regression analyses are reported in the graph. Table (d section of the figure) reported the regression analysis of the combined effect of EDE-Q shape concern, and cortisol levels on REE. The bottom part of the graph reports the results of the Sobel test, in order to calculate the indirect effect of shape concern on REE *via* the mediator (cortisol levels).

that a higher REE was associated with a worse clinical condition, including lower BMI and higher eating disorder psychopathology.

It is generally assumed that AN patients maintain their low weight by severely restricting food intake, purging, and engaging in physical activity[36]. However, clinical observations consistently suggest that these patients gain weight with great difficulty, and they usually maintain their low body weight for a long time, as well. The physiological maintenance of their low body weight has been inferred from some clinical observations suggesting that AN patients apparently require high energy intake to gain weight[37]. This relative increase in energy expenditure could also account for the difficulties of AN subjects to gain weight when desired.

This pilot study provided evidences for possible explaining mechanisms of this phenomenon. We found that a severe underweight status in AN was associated with relative higher REE, and that these two conditions were both associated with an over concern about body shape, which represents the "core psychopathology" of AN.

In order to explain such a relationship, we hypothesized a mediating role of the HPA axis. According to mediation model by Baron *et al*[34], a given variable may be said to function as a mediator to the extent that it accounts for the relationship between the predictor and the criterion. In this study, the cortisol levels (mediator) explained how eating specific psychopathology accounted for REE variability in AN patients.

As a possible causal mechanisms, it has been supposed that increased plasma cortisol in AN is due to the higher corticotropin releasing hormone (CRH) production in the central nervous system. As already described, stress-which in this study was specifically related with eating psychopathology- may lead to the hypersecretion of CRH, which is known to be a potent anorexic agent[21].

Furthermore, previous findings supported the relationship between stress induced cortisol levels and REE. It has been suggested that, when in excess, cortisol is an overall catabolic hormone, which decreases lean body mass and muscle mass and increase energy expenditure[20,21]. Moreover, it increases availability of all fuel substrates by mobilization of glucose[38], free fatty acids[39], and amino acids from endogenous stores[40]. Given the cross-sectional design of the study, we are not able to derive final conclusion on causal relationship psychopathology and REE. The present mediation model support a strong mediator role of cortisol, suggesting a possible underlying mechanism. However, it does not explain all the variance of the mentioned association, which could be caused by other metabolic factors related to underweight in AN patients.

Some limitations of this pilot study should be considered. First of all we do not analyze the body composition of the patients, one of the determinant of the REE. Then, the cross- sectional design of the study does not allow any firm conclusion about causal relationships. Temperament and personality disorders information were not available. Finally the sample size is small, and it did not allow the generalization of the main findings. Moreover, it is possible that other psychopathological measures (*e.g.*, EDE-Q weight concern) could reach significant associations with larger samples. Therefore, our results should be considered as preliminary, and larger, prospective researches are warranted in order to confirm or not these findings. The results of the present study supported the hypothesis that Cortisol levels in AN, through changes in REE, could represent a biological substrate for the capacity to maintain low body weight, and for the inefficiency at gaining weight. Safe and effective re-feeding strategies in Eating Disorders should carefully consider the complex mechanisms which can determine the energy balance impairment observed in AN and BN patients.

## COMMENTS

### Background

Metabolic changes in eating disorders patients may partially explain the obstacles of weight regain interventions. One of the reasons can be the resting energy expenditure alteration which appears to be correlated with the disorder severity in terms of both weight loss and eating disorder psychopathology. Cortisol levels, a measure of response to stress appear to be a putative biological mechanism underlying the association between eating psychopathology and resting energy expenditure.

### Research frontiers

The present paper is in line with the recent advanced neurobiological and psychosomatic models based on the complex interaction between psychiatric conditions, stress response and subjective perception of symptoms.

### Innovations and breakthroughs

Resting energy expenditure abnormalities have already been described in Anorexia Nervosa patients, but generally they do not consider the role of psychopathology, as a marker of severity of the disorder. The present study is original and innovative, since it proposes a model which includes resting expenditure, cortisol levels as a marker of stress, as well as eating disorder specific psychopathology.

### Applications

The present study demonstrated that the severity of psychopathology represents not just an indicator of subjective perception of the eating disorder, but also of more compromised metabolic condition which could interfere with treatment process.

### Terminology

Resting Energy Expenditure: it is based on the assumption that metabolism is a reflection of energy expenditure. Since the oxidation of nutrients requires oxygen, by measuring oxygen consumption and carbon dioxide production, an estimate of energy production in kilocalories can be made. Shape concern: it includes all the concerns and behaviors associated with once own body. It is the core psychopathological feature of eating disorders.

### Peer review

This is, in summary, an interesting cross-sectional survey aimed to investigate the relationship between resting energy expenditure, eating psychopathology, and hypothalamus pituitary adrenal-axis functioning in twenty-two patients with eating disorders. The manuscript is interesting and well-written.

## Abstract

**AIM:** To investigate the influence of ethnicity in social anxiety disorder (SAD), and the relationship with symptom severity, depression and substance use or abuse, in health sciences' students .

**METHODS:** This was a cross-sectional survey of 112 1st, 2nd and 3rd year students from the Faculty of Medicine and Health Sciences at Stellenbosch University, Cape Town, South Africa. The self-reported Social Anxiety Spectrum questionnaire was used to assess for SAD. The Social Phobia Inventory (SPIN) was adapted to a version called the E-SPIN (Ethnic-SPIN) in order to evaluate the effects of ethnicity. Two sub-questions per stem question were included to assess whether SAD symptoms in social interactions were ethnicity dependent. Substance use was assessed with the Alcohol Use Disorders Identification Test and Drug Use Disorders Identification Test, and depression with the Centre for Epidemiological Studies Depression Scale.

**RESULTS:** Of 112 students who completed the E-SPIN questionnaire, 54.4% ($n$ = 61) met criteria for SAD, with significantly more females than males meeting criteria. Ethnicity had a significant effect on SAD symptomatology, but there was no effect of ethnicity on the rates of drug and alcohol abuse in students with and without SAD. Overall significantly more students with SAD met criteria for depression compared with students without the disorder.

**CONCLUSION:** Among university students, SAD is prevalent regardless of whether interactions are with individuals of the same or different ethnic group. However, ethnicity may be an important determinant of social anxiety for some ethnic groups. SAD was significantly associated with major depression but not significantly associated with drug or alcohol abuse.

**Key words:** Social anxiety; Social phobia; Ethnicity; Students; South Africa

**Core tip:** We investigated the relationship between social anxiety disorder (SAD) and ethnicity, as well as its association with depression and alcohol and drug abuse, among South African students. High levels of social anxiety were present and were significantly associated with major depression but not with drug or alcohol abuse. Ethnicity was found to independently influence social anxiety symptomatology, suggesting that it is an important factor in student interactions in this context. These results contribute to the extant literature by demonstrating that different risk factors may be uniquely associated with SAD for different ethnic/racial groups, and require further exploration given South Africa's historical context.

## INTRODUCTION

Social anxiety disorder (SAD), which is characterized by a persistent fear of social or performance situations (such as public speaking) where embarrassment might occur, is a common, psychiatric condition, with a lifetime prevalence ranging from 7% to 13% in the general population[1]. Age of onset is generally early; by age 11 in about 50% individuals and by age 20 in approximately 80% of individuals[2]. SAD is also highly comorbid with major depression, substance use disorders and other anxiety disorders, and the lifetime prevalence of any two of the aforementioned conditions ranges from 69% to 81%[3]. A nationally representative household survey conducted in South Africa between 2002 and 2004 found the most prevalent group of disorders to be anxiety disorders (15.8%). After agoraphobia without panic, SAD was the second most common anxiety disorder. In addition, high lifetime rates of substance abuse (13.5%) and major depression (9.8%) with an early age at onset were documented[2,4].

Psychological treatments and medication have been shown to be effective in the treatment of SAD, with a combination of the two seeming to be most beneficial[5-7]. Despite this, the condition remains underdiagnosed and only a small proportion of those in need receive treatment[8], possibly due to factors such as fear of stigmatization, inability to access care due to financial issues, and lack of awareness of the disorder by both patients and service providers.

The student population is diverse and provides many opportunities for social contact and support. Academic activities require social interaction and performance as part of students' learning and assessment, while interpersonal skills are key attributes of student academic success[9]. University or college students fall in the age range of increased risk for the onset of SAD. As well as struggling with fundamental issues related to identity and self-management, students are particularly vulnerable to experiences of social anxiety[10,11]. Fears of confirming negative stereotypes may also play a significant role in the symptoms of SAD. A related phenomenon is the occurrence of intergroup anxiety, where interracial relations or exchanges carry the potential for intense social anxiety[12]. Stephan *et al*[13] term intergroup anxiety as an emotion that involves feelings of uneasiness and awkwardness in the presence of out-group members (people from different ethnic groups than oneself). Recent literature has shown that ethnicity and culture both have a big impact on how anxiety is experienced and how individuals deal with it. In a review by Hofmann *et al*[14], the authors concluded that an individual's social concerns need to be examined in the context of cultural, racial, and ethnic background to adequately assess the degree and expression of social anxiety and SAD. South Africa is a multicultural and multi-ethnic society and, given the particular circumstances of the country's colonial and apartheid past, it is important to understand the role of ethnicity in social interactions.

This study investigated the influence of ethnicity on social interactions and SAD, and the association of SAD with symptom severity, depression and substance use in a student sample. We hypothesised higher rates of social anxiety and distress in interactions between different ethnic groups compared with same-ethnicity interactions. We further hypothesised that ethnicity would independently predict social anxiety symptomatology and that social anxiety and distress in different-ethnicity interactions would be positively correlated with depression, alcohol and drug abuse symptomatology.

## MATERIALS AND METHODS

We conducted a cross-sectional survey among health science students (medical and allied health science students) at the Stellenbosch University Faculty of Medicine and Health Sciences, Cape Town (South Africa). We sampled 1$^{st}$, 2$^{nd}$ and 3$^{rd}$ year students. The faculty is representative of all the main ethnic groupings in the country (Black, Coloured, Indian, White). The study was approved by the Health Research Ethics Committee of Stellenbosch University and was conducted in accordance with The Declaration of Helsinki and Medical Research Ethical Guidelines on Human Research. After obtaining permission from the respective student departments, an invitation was sent out *via* email to all students inviting them to complete an online questionnaire on a secure online site, SurveyMonkey.com. Carlbring *et al*[15] have demonstrated that anxiety measures completed *via* online questionnaires show similar psychometric properties when compared with questionnaires administered through conventional methods. Survey monkey is a secure service that stores all data in an encrypted, anonymous form. In total three email invitations were sent out. We also made use of other recruitment methods, such as handing out flyers to students after lectures and advertising the survey on the local student website and on television (LCD) screens at the faculty. Students were required to provide informed consent prior to completing the survey. The informed consent form was available online and in the e-mails sent to students, and provided study information (*i.e.*, aims), as well as contact details of investigators and the ethics committee.

We developed a socio-demographic data form that was used to elicit socio-economic status (SES) and socio-demographic profiles. The SES variable was based on questions pertaining to household access to basic needs, number of inhabitants and their educational level, as well as total income. A total score out of 44 was then calculated. Three SES categories were created by dividing the

SES scores into thirds: low: 6-19, medium 20-33, high 34-44. This indicator is similar to that currently used by Statistics South Africa and has been used by others in the South African context[16].

The social phobia inventory (SPIN) is a brief 17-item self-report instrument for measuring SAD severity. A cut off score of 19 distinguishes those with SAD from those without[17,18]. The SPIN consists of questions that evaluate fear, avoidance and physiological discomfort. Each of the 17 items is rated on a scale from 0 to 4: not at all, a little bit, somewhat, very much, and extremely (higher scores correspond to greater distress). Scores range from 0-68. The SPIN has proved to be a useful and valid self-rated scale to assess fear, avoidance and physiological aspects of SAD. It validly measures severity of illness, is sensitive to reduction in symptoms over time, and discriminates between treatments[18]. The internal consistency (Cronbach's alpha) for individuals with SAD was 0.92 and for combined clinical and non-clinical samples the Cronbach's alpha has been shown to be 0.95[18]. For the current study, we adapted the SPIN to evaluate the effects of ethnicity. The E-SPIN or Ethnicity-SPIN includes two sub-questions for each stem question to determine whether respondents experience an exacerbation of SAD symptoms and greater distress when interacting with individuals from a different ethnic group compared to interactions with their own ethnic group.

The Social Anxiety Spectrum Self-Report (SHY-SR) questionnaire is a self-report inventory, used to measure the spectrum of social anxiety. It was derived from the Structured Clinical Interview for Social Anxiety Spectrum, the SCI-SHY, an interview which has previously been validated in psychiatric samples and in control groups in a large Italian multi-center study[19,20]. The version of the SHY-SR used in the current study was the "last month" questionnaire. This version includes an appendix on substances and three domains: (1) the interpersonal sensitivity domain, which assesses hypersensitivity to criticism, judgment and refusal, discomfort when the centre of attention, low self-confidence, feeling of inferiority, poor assertiveness, and interpersonal difficulties; (2) the behavioral inhibition and somatic symptoms (BI) domain which explores social behaviour and somatic symptoms associated with social anxiety; and (3) the specific phobias (SP) domain, which assesses situations that may trigger anticipatory anxiety and avoidance behaviours. The items of the SP domain are grouped into 14 subsections, ranging from talking on the phone to dating. These questions are dichotomous (yes/no) and refer to experiences that have occurred in the last month. The instrument is designed for administration in both adults and adolescents. A variety of cut-off scores have been determined using the receiver operating characteristic curve on data used to investigate the validity and reliability of the SCI-SHY. The diagnostic cut-off score of 68, which has a sensitivity and specificity of 84.8% and 85.6%, respectively, was used here[21].

The Center for Epidemiological Studies Depression Scale (CES-D) is a short 20-item questionnaire[22]. Each item is rated on a four-point scale during the last seven-day period. The scales range from "rarely or none of the time" to "most or all of the time". Scores range from 0 to 60, with higher scores indicating more symptoms of depression. CES-D scores of 16 to 26 are considered indicative of mild depression and scores of 27 or more indicative of severe depression[23]. The CES-D has been validated in a number of studies in community and primary care populations and has good test-retest reliability[20]. The scale has very good internal reliability, with a Cronbach's alpha value of 0.85 in the general population and 0.90 in a psychiatric population[22].

Alcohol Use Disorders Identification Test (AUDIT) detects hazardous and harmful alcohol use[24]. The AUDIT contains 10 items referring to alcohol consumption and alcohol-related problems in the past 12-mo period with a cut off score of 8. Responses to each question are scored from 0 to 4, giving a maximum possible score of 40. The AUDIT was designed to measure three domains; consumption (3 items), dependence (3 items) and alcohol-related consequences (4 items). In its original psychometric evaluation, 92% of those diagnosed with alcohol abuse had a score of 8 or more, while 94% of those with non-hazardous consumption had a score of less than 8[24]. In a study that assessed the psychometric performance of three alcohol use disorder tools including the AUDIT, the AUDIT had a Cronbach alpha of 0.75[25].

The Drug Use Disorders Identification (DUDIT) (Berman *et al*[26], 2005) is a self-report screening instrument that focuses on current drug-related problems. The eleven items of the DUDIT were chosen to yield information on the level of drug intake and fulfillment of selected criteria for substance abuse/harmful use and dependence according to the International Classification of Diseases, 10$^{th}$ edition (ICD-10) and Diagnostic and Statistical Manual of Mental Disorders, 4$^{th}$ edition (DSM-IV) diagnostic systems. Responses to each question are scored from 0 to 4 with a maximum score of 44. In the general population, the DUDIT can screen for drug-related problems at a cut-off score of 6 (for men) and 2 (for women). The DUDIT predicts drug dependence with a sensitivity of 90% for both DSM-IV and ICD-10 with a respective specificity of 78% and 88%, and has an internal reliability of 0.80.

### *Statistical analysis*

Only completed questionnaires were included in the data analysis. Demographic variables were compared between those with SAD and those without SAD on the E-SPIN using cross-tabulations with $\chi^2$ statistics. The SHY-SR means and standard deviations of the sample were reported using the subscale cut-off scores of the instrument. Owing to missing data, 7 items were omitted from the SH-SR questionnaire. Domain scores were transformed to a 0-100 scale which facilitated comparison of domain scores with other studies. ANOVAs (analysis of variance tests) were conducted to determine differences between groups. Furthermore, we also compared AUDIT, DUDIT and CES-D cut off scores between

N's vary from 89 to 112 due to missing data. The diagnostic cut-off score for the SHY-SR is 68, the cut-off score of 59 identifies subjects who score high on the social anxiety spectrum but do not meet the diagnostic criteria for the social anxiety disorder (SAD). SHY-SR: Sub-scale domains includes; IPS: Interpersonal sensitivity; BI: Behavioral inhibition; SP: Specific phobia. E-SPIN: Ethnicity-Social Phobia Inventory; DUDIT: Drug Use Disorders Identification Test; AUDIT: Alcohol Use Disorders Identification test; CES-D: Center for Epidemiological Studies Depression Scale; SHY-SR: Social Anxiety Spectrum Self-Report.

students with SAD and those without SAD using $\chi^2$ tests. Multiple regression analysis was conducted with E-SPIN scores as the dependent variable and ethnicity as the independent variable. Variables such as age, gender, SES were used as covariates in the model. We used a linear regression model to determine if ethnicity predicts E-SPIN scores (*i.e.*, whether ethnicity provides additional explanatory power to explain social anxiety symptom severity). We selected a 5% increase in overall R-squared as our effect size. All statistical analyses were performed using the SPSS 19.0 software package (SPSS Inc., Chicago, IL)[27].

## RESULTS

Of the 958 students invited to participate, responses were received from 120 students (12.5%). Respondents had a mean age of 19.68 years (SD = 2.48) and comprised of 40 (33.3%) males and 80 (66.6%) females. Given that the gender distribution of students at the university is roughly 50/50 this shows that females were more likely to complete the survey. The ethnicity of respondents was similar to that in the general undergraduate student population for Black and Coloured students (16% each), but there were significantly more Indian/Asian respondents (15% *vs* under 3% in the student population), and fewer White respondents (48% *vs* 65% in the student population).

The majority were studying for a Bachelor of Medicine and Surgery degree 101 (84.2%), with the remainder (15.8%) being Bachelor students in Dietetics, Physiotherapy, Occupational Therapy, and Speech Language and Hearing Therapy. Of this sample, 112 finished the E-SPIN questionnaire (same and different ethnicity interactions), 90 finished the SHY-SR and DUDIT, whereas the AUDIT and CES-D were completed by 89 students. The mean SES score was 33 (range: 19-44) with all ethnic groups falling into the "high" SES category. Despite this, the difference in SES between ethnic groups approached significance, with white and black participants endorsing a higher SES than Coloured and Indian participants, based on our scale [F (3,43) = 2.804; $P = 0.051$].

Table 1 differentiates students in the sample based on clinical cut-offs on the various measures of psychopathology, and presents the means and standard deviations of the original and transformed (0-100) scores of the SHY-SR. Of the 90 students who completed the SHY-SR, 28 (31.1%) scored above the diagnostic cut-off score of 68 and had a mean score of 51.77 (SD = 32.12). High scorers (5.6%) had a mean score of 87.79 (SD = 22.15) while low scorers (63.3%) students had a mean score of 31.48 (SD = 15.01). Ethnic groups did not differ significantly on total SHY-SR scores, but there was a significant difference in the SP domain F (3,86) = 2.867, $P = 0.041$, with Coloured students scoring significantly higher than White students.

Table 2 shows the association of SAD with sociodemographic and psychopathology variables. 54.5% ($n$ = 61) of students met criteria for SAD, with significantly more females 63.2% ($n$ = 48), than males 36.1% ($n$ = 13). More students met criteria for SAD in the context of different ethnic interactions (59.8%, $n$ = 67) than in the context of same ethnicity interactions (53.6%, $n$ = 60). Gender differences were present with significantly more females than males meeting criteria for SAD, both in same ethnicity [60.5% females ($n$ = 46) *vs* 38.9% males ($n$ = 14) ($\chi^2 = 4.598$, df = 1, $P < 0.05$)], and different ethnicity [67.1 % females ($n$ = 51) *vs* 44.4% males ($n$ = 16) ($\chi^2 = 5.222$, df = 3, $P < 0.05$)] interactions. Further, there was an association between ethnic group and SAD in the context of same ethnic interactions; Black students experienced significantly more anxiety in interactions with others of ($\chi^2 = 8.530$, df = 3, $P < 0.05$).

There was no effect of ethnicity on the rates of drug and alcohol abuse in students with and without SAD. Overall significantly more students with SAD met criteria for depression (73.8%) compared with students without the disorder (26.2%), ($\chi^2 = 7.512$, df = 1, $P < 0.01$). This was true both for same ethnicity (73.8% *vs* 26.2%, $\chi^2 = 10.041$, df = 1, $P < 0.01$) and different ethnicity (73.8% *vs* 26.2%, $\chi^2 = 5.751$, df = 1, $P < 0.01$) interactions (Table 2).

We conducted a multiple linear regression with the E-SPIN total score as the independent variable, ethnicity as the dependent variable, and SES, age and gender as covariates. The adjusted $R^2$ was 0.074. In subsequent

[a]$P < 0.05$, 60.5% females ($n = 46$) *vs* 38.9% males ($n = 14$); different ethnicity 67.1 % females ($n = 51$) *vs* 44.4% males; and anxiety in ethnic group and SAD in the context of same-ethnic interactions-Black students *vs* others of their own ethnicity; [b]$P < 0.01$, students with SAD met criteria for depression (73.8%) *vs* students without the disorder (26.2%); same ethnicity 73.8.% *vs* 26.2%; and different ethnicity 73.8% *vs* 26.2%. SES Categories Low: 6-19; Medium: 20-33; High: 34-44; E-SPIN: Ethnicity-Social Phobia Inventory; DUDIT: Drug Use Disorders Identification Test; AUDIT: Alcohol Use Disorders Identification Test; CES-D: Center for Epidemiological Studies Depression Scale; SES: Social economic status; SHY-SR: Social Anxiety Spectrum Self-Report Scale.

multiple linear regression with ethnicity excluded, the adjusted $R^2$ was 0.068, (a decrease of 6%). We had selected a 5% change in overall R-squared as the effect size, thus ethnicity had sufficient explanatory power in predicting E-SPIN scores, when controlling for age, gender and SES.

## DISCUSSION

We investigated the relationship between SAD and ethnicity in a student sample, as well as its association with depression and alcohol and drug abuse. This is, to our knowledge, the first study of this nature among South African students. South Africa is a multicultural and multi-ethnic society and, given the country's colonial and apartheid past, it is important to understand the role of ethnicity in social interactions. University or college students fall in the age group of increased risk for the onset of SAD. As well as struggling with fundamental issues related to identity and self-management, students are particularly vulnerable to experiences of social anxiety[10,11].

First, more than half of the sample (54.4%) met criteria for SAD. This rate increased to 60.8% in response to questions regarding interactions with different ethnic groups. Although these rates are significantly higher than in the general population, our sample, as a whole, does not appear to suffer more from SAD than other student samples, as former studies have tended to report higher rates using the SPIN in student populations[1,10,28]. Stewart *et al*[29] also found a high prevalence of SAD in college students and suggested that normative developmental and contextual issues in the lives of college students may be contributory.

Second, SHY-SR sub-scale domain scores were relatively high, and higher than in an Italian study of 520 high school students (mean age of 18.4 years) in their last year of school[21]. Transition from high school to a tertiary setting with the additional academic and social adaptational pressures may partially explain the higher social anxiety symptomatology in the current study.

Third, SAD was more prevalent among females which is consistent with community samples internationally[3,30]. However, findings from student samples indicate that gender differences are not common For instance, there was no significant main effect for gender in a study by Stewart *et al*[11]. Further, in a study that compared a clinical sample with a non-clinical undergraduate sample, although women in the clinical sample reported relatively higher fears of criticism/embarrassment and authority than a semi-colon men, suggesting that women with SAD may be more fearful of criticism/embarrassment and more fearful of authority than men, this was not shown in the non-clinical undergraduate sample[31].

Fourth, we found that ethnicity independently influenced severity of social anxiety symptomatology, suggesting that it is an important factor in student interactions in the South African context. Previous research in the area of intercultural communication has suggested that

uncertainty as well as anxiety are important predictors of avoidance behaviour in intercultural encounters[32,33]. Given that the expressions of racial bias are no longer socially acceptable[9], research on intergroup prejudice, in particular, indicates that the idea of appearing prejudiced in front of others may elicit strong social anxiety, which may emerge in interracial interactions, as well as in same-race interactions in which an individual fears social sanctions from in-group members for expressing prejudice toward an out-group[34].

Of interest was that Black students appear to fear social disapproval from others of their own ethnicity more than from those of other ethnicities. A possible explanation for this may be that this group of students experienced greater stereotype confirmation concern, a construct described as "a chronic experience of uncertainty and apprehension about appearing to confirm as self-characteristic, a stereotype about ones' group"[35], among their own ethnic group. Furthermore, Coloured students were found to experience significantly more anxiety in situations that triggered anticipatory anxiety and avoidance behaviours, such as talking on the phone (the SHY-SR specific phobias domain). These results, on the contribution of ethnicity in SAD, are not strongly significant but require further exploration given the historical context, and contribute to the extant literature by demonstrating that different risk factors may be uniquely associated with SAD for different ethnic/racial groups.

SAD was significantly associated with major depression but not significantly associated with drug or alcohol abuse. These findings are consistent with a study on the prevalence of SAD and comorbidities among Nigerian undergraduates, which found that both lifetime and 12 mo depression were significantly associated with lifetime and 12 mo SAD but that there was no significant relationship between SAD and alcohol abuse[36]. This suggests that in the student population depression is more likely to be co-morbid with SAD than substance abuse. These findings are further supported by a study of 228 American college students which found that alcohol problems were more directly related to peer influence and social networks than to social anxiety[37]. High rates of co-morbidity with depression among university students contribute to further disability (*e.g.*, academic achievement) and quality of life impairments.

Results of this study must be considered preliminary given the small sample size and the fact that self-report measures were used. Participant bias is also an important consideration, as this was a convenience sample and only 112 of a total of 958 first, second and third year students who were invited actually participated. It is therefore plausible that the sample is skewed toward students who were more symptomatic and who chose to participate. This survey could be extended to include health science students at other universities, especially those institutions characterised by greater ethnic diversity. Furthermore, it would be advantageous to explore ways to increase student participation while keeping anonymity intact. It would also be useful to conduct a comparative analysis of first, second and third year students to elucidate whether SAD prevalence and symptom severity intensifies or is alleviated through the undergraduate student years, particularly with regards to in- and out-group interactions.

## COMMENTS

### Background

Social anxiety disorder (SAD) is a common psychiatric condition that is often comorbid with major depression, substance use disorders and other anxiety disorders. University students fall in the age range of increased risk for the onset of SAD. Recent literature has shown that ethnicity and culture both impact on the experience of anxiety and how individuals deal with it, and indicate that an individual's social concerns need to be examined in the context of cultural, racial, and ethnic background to adequately assess the degree and expression of social anxiety and SAD.

### Research frontiers

South Africa is a multicultural and multi-ethnic society and, given the particular circumstances of the country's colonial and apartheid past, it is important to understand the role of ethnicity in social interactions.

### Innovations and breakthroughs

Although the results on the contribution of ethnicity in SAD are not strongly significant, they do require further exploration given the historical context. This study contributes to the extant literature demonstrating that different risk factors may be uniquely associated with SAD for different ethnic/racial groups.

### Applications

This study indicates that ethnicity has the potential to independently influence severity of social anxiety symptomatology, suggesting that it is an important factor in student interactions, particularly in the South African context, and as such should be considered when assessing for SAD.

### Terminology

SAD or social anxiety disorder is a fairly prevalent anxiety disorder that causes extreme discomfort or fear regarding being judged or evaluated by others in social interactions.

### Peer review

The manuscript aims to investigate the role of ethnic factors in SAD among South African medical students. The topic is interesting and of high scientific and social significance.

## Abstract

**AIM:** To determine the cut-off values of body mass index (BMI) and waist circumference to predict hypertension in adults in north India.

**METHODS:** A community based cross-sectional study was conducted in 801 subjects in Kanpur, aged 20 years and above, using multistage stratified random sampling technique. A pre-tested structured questionnaire was used to elicit the required information from the study participants and the diagnostic criteria for hypertension were taken according to the Seventh Joint National Committee Report on Hypertension (JNC-7). Receiver operating characteristic (ROC) analysis was used to estimate the cut-off values of BMI and waist circumference to predict hypertension.

**RESULTS:** The ROC analysis revealed that BMI is a good predictor of hypertension for both men (area under the ROC curve 0.714) and women (area under the ROC curve 0.821). The cut-off values of BMI for predicting hypertension were identified as $\geqslant$ 24.5 kg/m$^2$ in men and $\geqslant$ 24.9 kg/m$^2$ in women. Similarly, the ROC analysis for waist circumference showed that it is a good predictor of hypertension both for men (area under the ROC curve 0.784) and women (area under the ROC curve 0.815). The cut-offs for waist circumference for predicting hypertension were estimated as $\geqslant$ 83 cm for men and $\geqslant$ 78 cm for women. Adults with high BMI or high waist circumference had a higher prevalence of hypertension, respectively.

**CONCLUSION:** Simple anthropometric measurements such as BMI and waist circumference can be used for screening people at increased risk of hypertension in order to refer them for more careful and early diagnostic evaluation. Policies and programs are required for primary and secondary prevention of hypertension.

**Key words:** Anthropometric indices; Body mass index; Waist circumference; Obesity, Hypertension; Adults

**Core tip:** The Receiver operating characteristic analysis for body mass index (BMI) and waist circumference, respectively, showed good discriminatory power for hypertension in both men and women. The cut-off for BMI was identified as $\geqslant$ 24.5 kg/m$^2$ in men and $\geqslant$ 24.9

kg/m$^2$ in women. The cut-off for waist circumference for screening of hypertension was estimated as ⩾ 83 cm in men and ⩾ 78 cm in women. BMI and waist circumference, being simple tools in identifying hypertension, can be used for primordial and primary prevention and can thereby bring about a substantial reduction in cardiovascular morbidity and mortality which occurs as a consequence of hypertension.

Midha T, Krishna V, Nath B, Kumari R, Rao YK, Pandey U, Kaur S. Cut-off of body mass index and waist circumference to predict hypertension in Indian adults. *World J Clin Cases* 2014; 2(7): 272-278 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/272.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.272

## INTRODUCTION

According to World Health Organization (WHO), cardiovascular diseases (CVDs) are the number one cause of death globally: more people die annually from CVDs than from any other cause[1]. An estimated 17.3 million people died from CVDs in 2008, representing 30% of all global deaths. The prevalence of hypertension in adults aged 25 years and above, worldwide, was around 40% in 2008[1]. Globally, raised blood pressure is estimated to cause 7.5 million deaths, about 12.8% of the total mortality. This, accounts for 57 million disability adjusted life years (DALYS) or 3.7% of total DALYS[1]. WHO has estimated that hypertension is directly responsible for about 62% of CVDs and 49% of ischemic heart disease (IHD) worldwide[2].

A meta-analysis of prevalence studies on hypertension in India, from January 2000 to June 2012, revealed a high prevalence of hypertension in the urban (40.8%) as well as rural population (17.9%)[3]. India accounts for 17% of the world's population, second largest in the world, thereby contributing largely to the statistics of any disease in the world[4].

Hypertension is a controllable disease and it has been reported that targeted reductions in blood pressure in hypertensives as well as modest population-wide blood pressure reductions are expected to produce large reductions in the burden of cardiovascular disease[5]. Miall suggested that genetic influences contribute not more than a third to the variance in blood pressure levels[6]. If the remaining two-thirds are environmental in origin, then an understanding of these environmental factors and appropriate preventive measures could help to bring down the burden of hypertension in the world. According to the Seventh Report of the Joint National Committee (JNC-7) on prevention, detection, evaluation, and treatment of high blood pressure, modification of risk factors plays an important role in the prevention and control of high blood pressure[7].

Recent studies show that for every known person with hypertension there are two persons with either undiagnosed hypertension or prehypertension[8]. Screening the population for hypertension can go a long way in identifying individuals with undiagnosed hypertension and prevent a significant proportion of cardiovascular morbidity and mortality due to inapparent hypertension.

Being overweight in adulthood is well known to increase the risk of CVD especially hypertension[9]. It has also been seen that having a body mass index (BMI) outside the normal range significantly worsens risk parameters for CVD in school aged children[10]. Recognizing obesity using BMI and waist circumference as a marker, and thereby screening for cardiovascular risk can be a simple and inexpensive method of combating CVDs at the primary health care level. Given the magnitude of the problem of hypertension in India and its grave cardiovascular consequences, accurate estimates of cut-offs of BMI and waist circumference in predicting hypertension in the Indian population are necessary to plan effective control measures.

## MATERIALS AND METHODS

### Study population

The study population consisted of the total population of Kanpur district aged more than 20 years.

### Study design and sample size

This was a population based cross-sectional study. The sample size required (N = 372) was calculated taking a prevalence of obesity of 6.2%, as reported in the "Five City study" from Moradabad, with a precision of 2.5% and a confidence level of 95%[11]. The formula used was, $n = Z_{(1-\alpha/2)}{}^2 pq/d^2$ (where $Z_{(1-\alpha/2)}$ was taken at 95% confidence; p = prevalence of obesity, q = 100-p; d = absolute precision). For this study, p = 6.2%; q = 93.8%; d = 2.5%. Adding a 10% for incomplete answers, the total number came out to be 409. Since it was a multistage stratified random sampling, a design effect of 2 was included to minimize any error due to inherent variation in the population. The calculated sample size was multiplied by 2 to obtain the sample size of 818. The data was analyzed for 801 subjects only who had provided complete answers.

### Sampling technique

Urban Kanpur has 110 wards and a total population of 2797511 according to 2001 census, and rural Kanpur has 10 blocks and a population of 1370488 which implies a ratio of 2:1 respectively[12]. Therefore, applying Probability Proportional to Size (PPS), out of 818 subjects, two-thirds (545) were selected from the urban population and one- third (273) were selected from the rural population. Multistage stratified random sampling technique was used to select representative subjects of Kanpur district. At the first stage, 8 wards were randomly selected to study the urban population[13]. Similarly, to study the rural population, 4 blocks were randomly selected[14]. At the second stage, 1 urban locality from each ward was randomly selected. Similarly, 1 village from each block was randomly selected. A total of 68 subjects from each

**Table 1 Characteristics of the study population**

| Parameters | Men ($n$ =356) | Women ($n$ =445) | Total ($n$ = 801) |
|---|---|---|---|
| Age (yr) | 36.4 ± 13.8 | 34.8 ± 11.6 | 35.5 ± 12.6 |
| Weight (kg) | 58.6 ± 11.5 | 51.7 ± 11.7 | 54.8 ± 12.1 |
| Height (cm) | 165.3 ± 7.1 | 151.7 ± 5.9 | 157.7 ± 9.3 |
| BMI (kg/m$^2$) | 21.4 ± 3.9 | 22.4 ± 4.6 | 21.9 ± 4.3 |
| Waist circumference (cm) | 78.9 ± 11.0 | 74.4 ± 11.1 | 76.5 ± 11.3 |
| SBP (mmHg) | 127 ± 16 | 122 ± 18 | 124 ± 17 |
| DBP (mmHg) | 82 ± 9 | 78 ± 10 | 80 ± 9 |

Values are written as mean ± SD. SBP: Systolic blood pressure; DBP: Diastolic blood pressure; BMI: Body mass index.

urban locality/village were interviewed to complete the required sample size.

### Selection of subjects

The households in every urban area/village were selected for the study by systematic sampling. Depending upon the population of the particular urban locality/village, a random number was chosen and every n$^{th}$ household was selected for the study. This process was continued till the required sample size was completed. In every household, only one member, aged more than 20 years was randomly selected. Out of the 545 respondents interviewed in the urban area, 10 were excluded owing to incomplete answers, whereas of the 273 respondents interviewed in the rural area 7 were excluded. Therefore, the final analysis included the responses from a total of 801 study subjects. Data collection was done from December 2006 to February 2007.

### Data collection

A pre-tested structured questionnaire was used to elicit the required information from the study participants. A standard mercury sphygmomanometer was used for recording blood pressure. Before the measurement was taken, the patient was seated comfortably for at least 5 min. Care was taken that the arm muscles were relaxed and the arm was supported at heart level. The cuff was applied to the right upper arm and was inflated until the manometer reading was 30 mm Hg above the level at which the radial pulse disappears, and then slowly deflated at a rate of approximately 2 mmHg/s. During this time, the Korotkoff sounds were monitored using a stethoscope placed over the brachial artery. The first (appearance) and the fifth (disappearance) Korotkoff sounds were recorded as the systolic and diastolic blood pressure, respectively. Blood pressures were measured twice and their mean was recorded. According to JNC-7[15], normal blood pressure was defined as a systolic blood pressure (SBP) < 120 mmHg and a diastolic blood pressure (DBP) < 80 mmHg; pre-hypertension as SBP 120-139 mmHg and/or DBP 80-89 mmHg; Stage I hypertension as SBP 140-159 mmHg and/or DBP 90-99 mmHg and stage Ⅱ hypertension as ⩾ 160 mmHg and/or DBP ⩾ 100 mmHg. In the present study, subjects in stage I and Stage Ⅱ were considered as hypertensive. Waist circumference was measured to the nearest 0.1 cm using a non-extensible tape. Measurement was made at the level of the umbilicus, with the subject in the erect position, breathing silently.

### Statistical analysis

Data was compiled in Microsoft Excel and analysed using MedCalc12.7.5 software. Receiver operating characteristic (ROC) analysis was used to compare the predictive validity, and to determine the optimal cut-off values of anthropometric indices. Area under the curve was also measured to determine the diagnostic power of the test, and to describe the probability that the anthropometric indices would correctly identify subjects with hypertension. Optimal cut-off values were measured by calculating the sensitivity and specificity of the anthropometric measurements at various cut-off points. Youden index was calculated to find out the associated criterion with maximum sensitivity and specificity for predicting hypertension.

## RESULTS

In the present study, the mean age of the study subjects was 35.5 ± 12.6 years, while that of men and women respectively was 36.4 ± 13.8 years and 34.8 ± 11.6 years (Table 1). Average BMI of the study population was 21.9 ± 4.3 kg/m$^2$. The mean waist circumference of men was 78.9 ± 11.0 cm and that of women was 74.4 ± 11.1 cm. Average systolic and diastolic blood pressure of the study population was 124 ± 17 mmHg and 80 ± 9 mmHg respectively. The mean systolic blood pressure among men was 127 ± 16 mmHg and that among women was 122 ± 18 mmHg. The mean diastolic blood pressure among men and women was 82 ± 9 mmHg and 78 ± 10 mmHg respectively.

The ROC analysis for BMI showed good discriminatory power for hypertension for both men and women. Area under the ROC curve was 0.714 for men and 0.821 for women respectively (Figure 1 A and B). The cut-off for BMI with better properties for screening of hypertension was identified as ⩾ 24.5 kg/m$^2$ in men and ⩾ 24.9 kg/m$^2$ in women (Table 2). The sensitivity and specificity of cut-off for BMI in men was 48.1% and 87.2% respectively, and that for women was 71.9% and 80.7% respectively.

Similarly, the ROC analysis for waist circumference revealed that it is a predictor of hypertension for both men and women. Area under the ROC curve was 0.784 for men and 0.815 for women respectively (Figure 1C and D). The cut-offs for waist circumference for screening of hypertension was estimated as ⩾ 83 cm for men and ⩾ 78 cm for women (Table 2). The sensitivity and specificity of cut-off of waist circumference in men was 67.9% and 80.4% respectively while that for women was 81.7% and 71.3% respectively. Adults with high BMI or high waist circumference had a higher prevalence of hypertension, respectively.

ROC analysis was also done after combining the pre-hypertensive and hypertensive subjects as non-normoten-

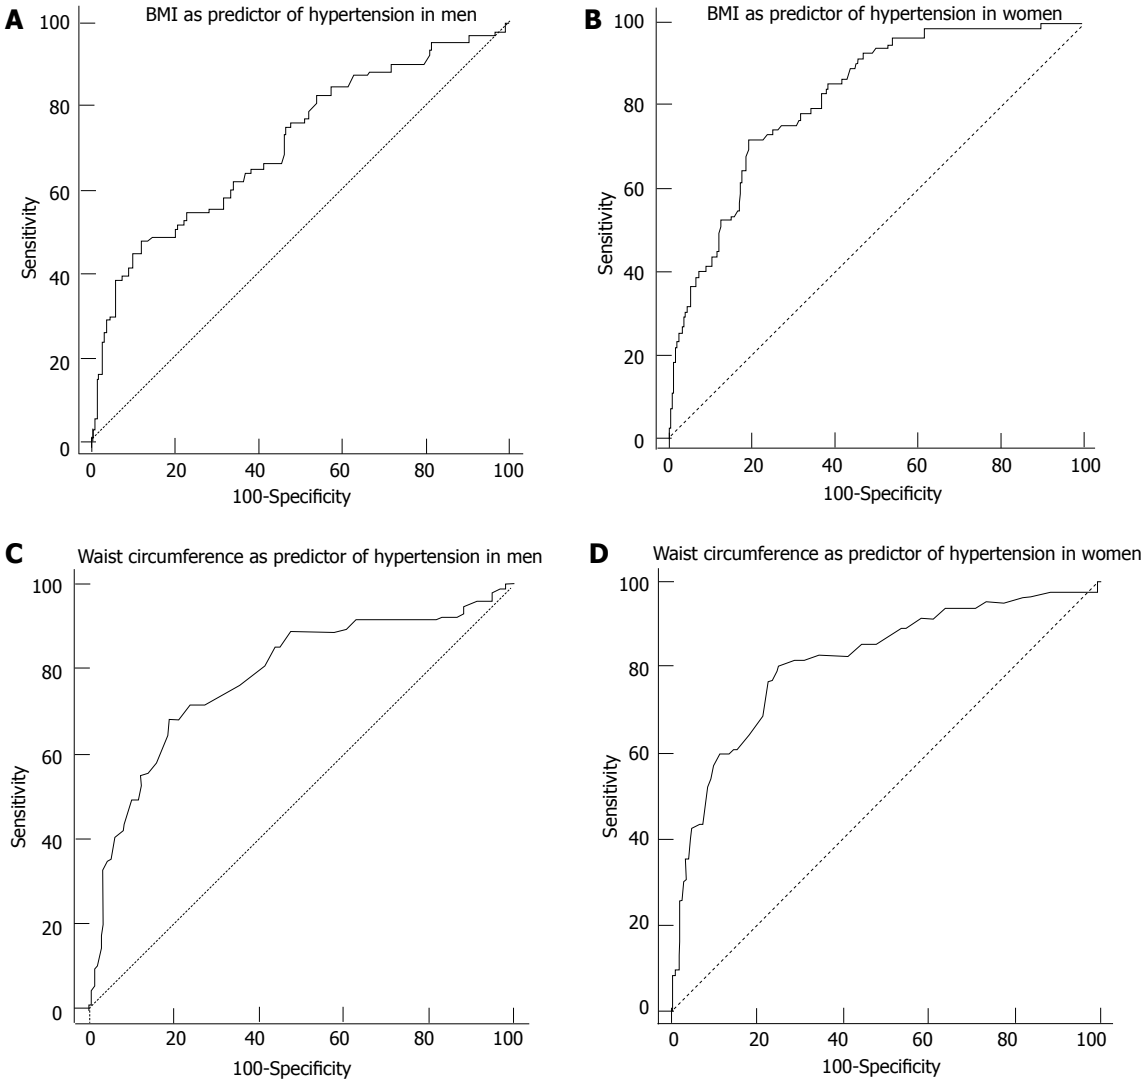

**Figure 1 Criterion values and coordinates of the receiver operating characteristic curve.** A: Receiver operating characteristic (ROC) analysis for body mass index (BMI) as a predictor of hypertension among men revealed area under the curve = 0.714. The optimal cut-off for maximum sensitivity and specificity was 24.5; B: ROC analysis for BMI as a predictor of hypertension among women revealed area under the curve = 0.821. The optimal cut-off for maximum sensitivity and specificity was 24.9; C: ROC analysis for waist circumference as a predictor of hypertension among men revealed area under the curve = 0.784. The optimal cut-off for maximum sensitivity and specificity was 83; D: ROC analysis for waist circumference as a predictor of hypertension among women revealed area under the curve = 0.815. The optimal cut-off for maximum sensitivity and specificity was 78.

sive and the remaining normal subjects as normotensive. It was observed that BMI was not a good predictor of non-normotensive status both in men and women. Area under the curve was 0.452 for BMI among men and 0.540 among women respectively. Similarly it was found that waist circumference did have good discriminatory power for non-normotensive status both in men and women. Area under the curve was 0.429 among men and 0.552 among women respectively. These results were not statistically significant.

Therefore, BMI and waist circumference can be considered good predictors of hypertension but not of pre-hypertension.

## DISCUSSION

In the present study, cut-off for BMI for predicting hypertension was identified as $\geqslant$ 24.5 kg/m$^2$ in men and $\geqslant$ 24.9 kg/m$^2$ in women. In a study from Malaysia, the mean age of the study subjects was 44 $\pm$ 14 years and the cut-off for BMI as predictor of hypertension was 25.5 kg/m$^2$ in men and 24.9 kg/m$^2$ in women, which was very similar to our study. Areas under the curves of BMI as a predictor of hypertension were 0.59 and 0.61 in men and women, respectively[16]. Area under the curves of 0.6-0.7 are considered to be poor while 0.7-0.8 are considered fair, as seen in our study. Increased CVD risks related to obesity at lower BMIs have been found in Asians[17,18]. In addition, Asians are also predisposed to visceral or abdominal obesity[19]. Therefore, WHO recently proposed lower BMI values to define overweight and obesity in people of the Asia-Pacific region[20]. According to the World Heart Federation, if a person's BMI is more than 30, he/she is obese and at serious risk of cardiovascular disease, whereas in our study, optimal cut-off for BMI for predicting hypertension was identified as $\geqslant$ 24.5 kg/m$^2$ in

BMI: Body mass index; ROC: Receiver operating characteristic.

men and ⩾ 24.9 kg/m$^2$ in women[21].

However, some studies have also revealed that BMI follows a J-shaped curve to predict all case mortality. BMI is a strong predictor of overall mortality both above and below the apparent optimum of about 22.5-25 kg/m$^2$[22]. The progressive excess mortality above this range is mainly due to vascular diseases and is probably causal at large. At 30-35 kg/m$^2$, median survival is reduced by 2-4 years; at 40-45 kg/m$^2$, it is reduced by 8-10 years (which is comparable with the effects of smoking). The definite excess mortality below 22.5 kg/m$^2$ is mainly due to smoking-related diseases, and is not fully explained.

In the present study, the optimal cut-offs of waist circumference for screening of hypertension was estimated as ⩾ 83 cm for men and ⩾ 78 cm for women. The waist circumference cut-offs for risk of hypertension obtained in this study are comparable to those reported by Snehalatha *et al*[23] for South Indians, which was reported as 85 cm for men and 80 cm for women wherein the mean age of the study population was 40.4 ± 14.2 years. These were also similar to the cut-offs observed by Rao *et al*[24] in Maharashtra as 86 cm in the male population averaging 42.9 ± 7.9 years and 79 cm in the female population averaging 42.2 ± 7.8 years[23,24]. The cut-offs in the present study were slightly lower for men when compared to those reported by Misra *et al*[25] for North Indians (90 cm for men averaging 40.5 ± 14.7 years) and slightly higher for women (80 cm for women having mean age of 38.8 ± 14.8 years). In other Asian populations, cut-offs reported by Wildman *et al*[26] for Chinese adults (86 cm for both sexes) and those observed by Lin *et al*[27] for adults from Taiwan as 80.5 cm for men and 71.5 cm for women with mean age 37.3 ± 10.9 years in men and 37.0 ± 11.1 years in women, were on the lower side. Ethnicity plays an important role in determining the predictive power of waist circumference for hypertension. Also, nutrition habits vary among different populations which may be the reason for the difference in waist circumference cut-offs.

According to the World Heart Federation, if the waist circumference is more than 102 cm among men, the person is at serious risk of CVDs, but for Asian men the cut-off has been set at 90 cm[21]. Similarly for women the high risk cut-off is 88 cm whereas in Asian women, it is 80 cm. In our study, the optimal cut-offs for waist circumference for predicting hypertension were ⩾ 83 cm for men and ⩾ 78 cm for women, which approximate the Asian cut-offs. In Asians, more than in the Western population, there is a strong association between blood pressure and stroke. It has been estimated that reduction of 3 mmHg in DBP would reduce the number of strokes in Asia by one third. Identification of indicators predicting risk of hypertension therefore has an important implication towards prevention of morbidity and mortality due to CVDs[28].

A major limitation of the study was that the classification of hypertension was based on a single measurement of blood pressure. Secondly, the number of female study subjects was greater than males which might act as a source of bias in studying the difference in the cut-offs for predicting hypertension in men and women, respectively. Although this is not a meta-analysis, it is a useful study with practical application for the prevention and control of hypertension.

The present study reveals that BMI and waist circumference are simple tools in identifying hypertension. Although it is not easy to determine how low the cut-off should be, the findings in this study provide sufficient evidence that BMI and waist circumference can be used as a screening tool for hypertension. Since high blood pressure itself is the entry point to other non-communicable diseases, this emphasizes the need for further research to identify cut-offs of simple anthropometric measurements, which can be calculated by people themselves, for screening of hypertension. Given the risk of CVD associated with high blood pressure, hypertension screening and health education programs regarding weight reduction may be considered as a cost-effective public health approach in dealing with the morbidity attributed to CVDs. This study is only a prelude to the upcoming research in the field of non-communicable diseases especially in the Asian population which is more vulnerable to adverse effects of obesity.

## COMMENTS

### Background

Cardiovascular diseases (CVDs) are the most common cause of mortality in the world; around 30% of all global deaths in 2008 were attributed CVDs. High blood pressure is the entry point to CVDs and other non-communicable diseases. The magnitude of hypertension in adults aged 25 and over was around 40% in the world in 2008. A meta-analysis in 2013 estimated the prevalence of hypertension as 40.8% in the urban and 17.9% in the rural Indian population. Body mass index (BMI) and waist circumference are simple tools in predicting hypertension, which can be calculated by the people themselves. The findings in this study provide cut-off levels of BMI and waist circumference for screening of hypertension in the Indian population. Given the risk of CVDs associated with high blood pressure, hypertension screening and health education programs regarding weight reduction may be considered as a cost-effective public health approach in dealing with the morbidity attributed to CVDs. Therefore, a precise estimate of the cut-offs of BMI and waist circumference specific to the indigenous population of the country is required to assess the magnitude of

the problem that has to be addressed and to design programs and policies for prevention and control.

### Research frontiers

In India, very few studies are available on the cut-offs of BMI and waist circumference for predicting hypertension. Given the variation in anthropometry due to ethnic differences and discrepancies in the nutritional status of different populations, an estimate of the cut-offs for screening of hypertension in the Indian population is required which can help in the development of preventive strategies.

### Innovations and breakthroughs

BMI and waist circumference have good discriminatory power for predicting hypertension in the Indian population and this knowledge will help in shaping primordial and primary level preventive programs for the country.

### Applications

Very few studies on cut-off levels of BMI and waist circumference for screening of hypertension are available in India; therefore, the main application of this study is to provide cut-offs levels for our indigenous population to help develop a strategy for control and prevention of hypertension appropriate for the country.

### Terminology

The ROC curve is a fundamental tool for diagnostic test evaluation using a graphical plot. In a ROC curve the true positive rate (Sensitivity) is plotted as a function of the false positive rate (100-Specificity) for different cut-off points of a parameter. Each point on the ROC curve represents a sensitivity/specificity pair corresponding to a particular decision threshold. The ROC curve estimates and reports all of the combinations of sensitivity and specificity that a diagnostic test is able to provide.The area under the ROC curve (AUC) is a measure of how well a parameter can distinguish between two diagnostic groups (diseased/normal). Accuracy of a diagnostic test is measured by the area under the ROC curve. An area of 1 represents a perfect test; an area of 0.5 represents a worthless test. The associated criterion value corresponding with the Youden index J is the optimal criterion value when disease prevalence is 50% and equal weight is given to sensitivity and specificity.

### Peer review

The study titled "Optimal Cut-off values of BMI and waist circumference to predict hypertension in adults: A cross-sectional study in a north Indian population" has been well thought out. It may be an incremental contribution of the manuscript to the field. Design of the manuscript is also good. It is well-marked that this paper would have a few literature errors formally.

## Abstract

Myelolipomas are rare tumors consisting of both adipose and hematopoietic tissue and are typically found within the adrenal gland. Extra-adrenal involvement is rare, especially those tumors involving the perirenal space and collecting system. We report a case of a patient with an incidentally discovered perirenal mass that was initially concerning for a retroperitoneal liposarcoma. Following surgical resection and pathological analysis, the lesion was found to be an extra-adrenal myelolipoma. This case report and review of the literature demonstrates the importance of the proper work-up and management of perirenal lipoma variants while addressing the issues of tissue biopsy, surgical intervention, and pre- and post-operative surveillance.

**Key words:** Myelolipoma; Lipoma; Perirenal mass; Nephrectomy; Oncology

## INTRODUCTION

Myelolipomas are mesenchymal tumors which consist of a mixture of mature adipose tissue with hematopoietic cells. This intriguing tumor most commonly occurs within the adrenal gland; however, it has been occasionally found within the pelvis, thorax, retroperitoneal space, and various other sites throughout the body[1-7]. There have been less than 60 reported cases of extra-adrenal myelolipomas to this date, with the majority of the literature describing neoplasms found within the pre-sacral space[2,8-10]. Perirenal extra-adrenal myelolipomas are especially rare, with only 9 cases previously reported[11]. We present a case of a patient with an incidentally discovered perirenal mass which, after having shown interval growth on longitudinal surveillance imaging studies, was surgically resected along with a left nephrectomy for presumed retroperitoneal liposarcoma. On final pathological analysis the lesion was found to be an extra-adrenal myelolipoma.

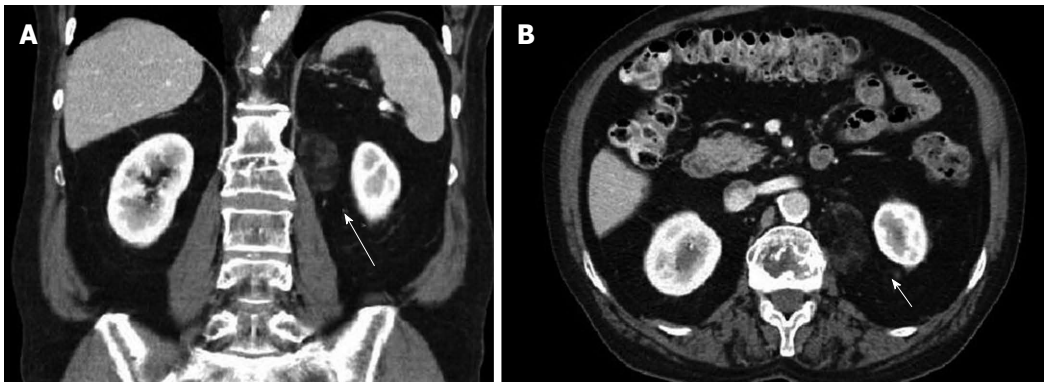

**Figure 1 Initial computed tomography scan.** Shows incidentally found non-enhancing heterogeneous mass measuring approximately 3.8 cm × 2.3 cm in longitudinal (A) and anterior-posterior dimensions (B), just inferior to the left renal vein (long arrow) and medial to the left kidney (arrow).

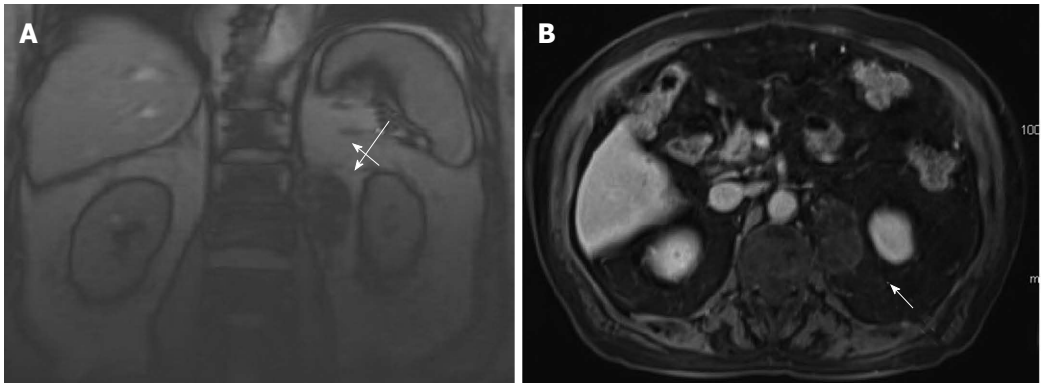

**Figure 2 Surveillance magnetic resonance imaging.** Imaging obtained 17 mo after the initial diagnostic computed tomography scan shows that the mass, located just inferior to the left renal vein (long arrow) and medial to the left kidney (arrow), increased in size to 5.0 cm × 3.4 cm in longitudinal (A) and anterior-posterior dimensions (B).

## CASE REPORT

A 78-year-old gentleman presented to the surgical oncology clinic to be evaluated for a left-sided retroperitoneal mass that was incidentally discovered on a computed tomography (CT) scan for a suspected case of acute pancreatitis. His prior medical history included hypertension, hyperlipidemia, acalculous cholecystitis, atrial fibrillation, and coronary artery disease. Initial radiographic findings revealed a non-enhancing heterogeneous mass measuring approximately 3.8 cm × 2.3 cm in longitudinal and anterior-posterior (AP) dimensions, just inferior to the left renal vein and medial to the left kidney (Figure 1). As the lesion appeared to contain mostly adipose with a small amount of soft tissue density, a well differentiated liposarcoma was suspected. The patient was initially offered surgical resection of the lesion, which he refused. Given the small size of the mass and patient's age and health status, the decision was made to closely monitor the lesion with routine cross-sectional surveillance imaging and regular follow-up at 4 to 6 mo.

Throughout the surveillance period, the patient did not complain of any new symptoms. Physical examination repeatedly revealed a soft, non-tender abdomen with no palpable masses or hernias. Repeat cross-sectional imaging studies, however, did reveal a slowly enlarging left-sided heterogeneous perirenal mass. A magnetic resonance imaging (MRI) obtained 17 mo after initial diagnosis showed that the mass had increased in size to 5.0 cm × 3.4 cm (Figure 2). Four months prior the tumor had remained unchanged. The concern for a progressing malignant lesion prompted the decision to proceed with surgical intervention. Due to its proximity to the renal vessels, as well as the fact that the preoperative diagnosis was liposarcoma, the mass was excised en bloc with the left kidney in an attempt to gain wide surgical margins. The patient tolerated the procedure well and his postoperative course was uneventful. He was discharged home in stable condition on the ninth day following the procedure.

Gross pathology revealed an encapsulated, well-defined, focally hemorrhagic mass measuring 7.2 cm × 4.1 cm × 3.3 cm in size. The tumor did not extend into the renal capsule or adrenal gland. Histology revealed that the mass was composed of mostly mature adipocytes mixed with islands of hematopoietic cells. Trilineage hematopoiesis was present, including nucleated red blood cells and megakaryocytes (Figure 3). Tumor resection margins were free. The above mentioned morphological features were consistent with the diagnosis of "perirenal (extra-

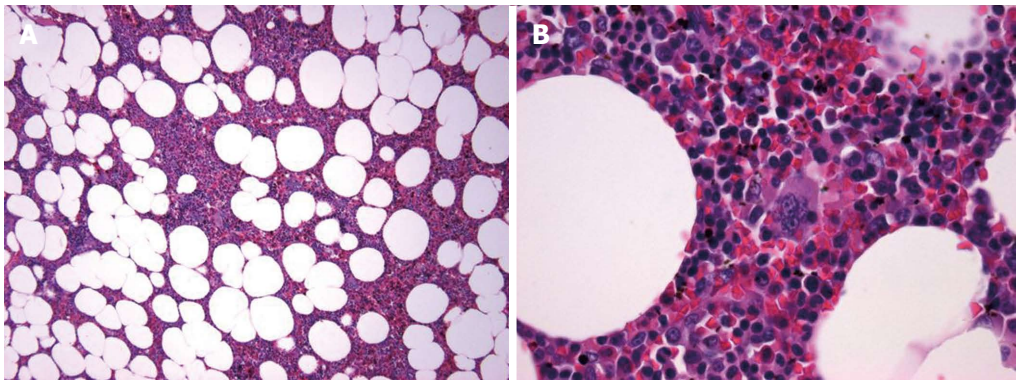

**Figure 3 Hematoxylin and eosin stain at 10 × (A) and 60 × (B) magnification.** Shows mature adipose cells with hematopoietic cells including erythroid precursors, granulocytic precursors, and megakaryocytes.

adrenal) myelolipoma".

## DISCUSSION

Myelolipoma is a unique mesenchymal tumor that is composed of a mixture of adipose and hematopoietic cells. The first case of an adrenal lesion containing both fat and myeloid elements was described by Gierke[12] in 1905. The reported incidence of myelolipoma on autopsy ranges from 0.08% to 0.4%[13]. This type of tumor is most commonly localized to the adrenal gland; however, there are rare but well-documented cases of extra-adrenal involvement[1]. To our knowledge, less than 60 cases of extra-adrenal myelolipomas have been reported[2,8-10], most of them involving the pre-sacral space. Tumors involving the mediastinum, lung, spleen, mandible, and nasal cavity have also been described[2-7]. Perirenal extra-adrenal myelolipomas are especially rare, with only 9 cases described so far[11].

A review of the literature shows that extra-adrenal myelolipomas exhibit a slight female predominance and are typically discovered between the ages of 50 to 70 years old[4,7,11]. Most tumors are unilateral and have been found to range from 2 to 26 cm in size at the time of diagnosis[14,15]. The etiology of extra-adrenal myelolipomas is still to be established. Several theories exist regarding their embryologic origin and pathogenesis. Amin *et al*[16] suggest that there may be a relationship between the reactivation of primitive peritoneal foci of extramedullary hematopoiesis under pathological stresses (*i.e.*, severe anemia, sepsis, myeloproliferative disease) and the origin and progression of extra-adrenal myelolipomas. Another theory postulates that myelolipomas originate from metaplasia of previously uncommitted adrenal cortical mesenchymal cells or hematopoietic stem cells that normally migrate to the adrenal gland during intrauterine development[16].

The widespread application of modern imaging techniques has led to a dramatic increase in the detection of extra-adrenal myelolipomas. The majority of patients are asymptomatic at the time of diagnosis, and lesions are discovered incidentally on imaging for alternative medical problems. Typically, physical examination and routine blood tests fail to yield any conclusive diagnostic findings. Depending on the size and location of the lesion, some patients may present with vague flank or abdominal pain due to hemorrhage, mechanical compression, or tumor infarction[17]. CT and MRI have been used to diagnose extra-adrenal myelolipomas. When a myelolipoma is contained within the adrenal gland, the diagnosis is straightforward because it is the only known entity composed of adipose tissue occurring in this location[18]. A fatty mass within the retroperitoneal space represents a diagnostic challenge because the differential diagnosis includes an angiomyolipoma, a retroperitoneal teratoma, or a well-differentiated liposarcoma. A study that reviewed the MRI results of 126 consecutively imaged grossly fatty masses found that the sensitivity of MRI in diagnosing well-differentiated liposarcomas is 100%; however, its specificity is merely 83% due to the inability to differentiate between liposarcomas and other lipoma variants[19].

Fine needle biopsy under ultrasound or CT guidance may be useful for the diagnosis of extra-adrenal myelolipoma. Well-differentiated liposarcoma differs from myelolipoma in that the former contains atypical stromal cells, variable-sized adipocytes, some of them with nuclear atypia, and lipoblast which, however, are not diagnostic, being absent in some cases. By contrast, extra-adrenal myelolipomas are composed of mature adipocytes with scattered hematopoietic cells, including megakaryocytes[20]. Although these histological differences between the two tumors, in many cases the final diagnosis is difficult, if not impossible, based on tissue biopsy[11]. Furthermore, the risks of hemorrhage, rupture, or infection that are associated with biopsy must factor into a clinician's decision to proceed with this invasive diagnostic procedure[11]. In our patient, tissue biopsy was deferred due to the patient's preference to forego the procedure.

There is currently no standard treatment for patients with this disease. Daneshmand *et al*[21] suggest that small asymptomatic tumors (< 4 cm) should be monitored with routine cross-sectional surveillance imaging, while large symptomatic tumors (> 7 cm) should be surgically removed. Extra-adrenal myelolipomas have been removed using a thoracoabdominal incision, but recently a laparoscopic approach has proven to be just as effective[10].

**Table 1 Review of reported cases of perirenal extra-adrenal myelolipomas**

| Age at time of diagnosis (yr) | Sex | Presentation | Diagnostic imaging | Biopsy | Gross pathology | Treatment | Ref. |
|---|---|---|---|---|---|---|---|
| 45 | Male | Asymptomatic | CT (5 cm × 5 cm) | No | 6.0 cm × 3.5 cm × 2.5 cm | Partial nephrectomy | Wagner *et al*[23], 1997 |
| 45 | Female | Flank pain Dysuria Frequency Urgency | CT (10 cm × 7 cm) | Yes | 9.0 cm × 6.4 cm × 5.5 cm | Laparoscopic mass resection | Beiko *et al*[10], 2010 |
| 60 | Male | Abdominal pain | CT (4.2 cm × 3.7 cm) | No | Not reported | Radical nephrectomy | Pascual García *et al*[24], 2007 |
| 63 | Male | Asymptomatic | CT (6.5 cm × 5.5 cm) | No | Not reported | Open mass resection | Dan *et al*[15], 2012 |
| 65 | Male | Flank pain, Weight loss Hematuria | CT (5.5 cm × 4.5 cm) | No | 7.0 cm × 5.0 cm × 1.5 cm | Radical nephrectomy | Talwalkar *et al*[9], 2006 |
| 66 | Female | Abdominal distention | CT (20 cm × 20 cm) | No | 20 cm × 15 cm × 15 cm | Open mass resection | Brietta *et al*[25], 1994 |
| 67 | Male | Asymptomatic | CT (7 cm × 5 cm) | No | Not reported | Radical nephrectomy | Sneiders *et al*[26], 1993 |
| 70 | Male | Flank pain Fever | Ultrasound (12 cm × 8.5 cm) | No | 17.0 cm × 10.0 cm × 5.0 cm | Open mass resection | Kilinc[27], 2007 |
| 77 | Male | Abdominal distension Hypertension | CT (Bilateral fat-containing masses) | Yes | Not reported | Follow-up CT 3 mo showed no change | Temizoz *et al*[20], 2010 |

CT: Computed tomography.

Early detection and proper management of myelolipomas is important due to the potential for tumor growth and hemorrhage. A study of 86 myelolipomas found that hemorrhage is more common in larger lesions with a diameter measuring greater than 10 cm[22].

A review of 9 reported cases perirenal extra-adrenal myelolipomas, shows that the average age at diagnosis is 62 years of age (Table 1). Perirenal lesions exhibited a male-to-female ratio of 7:2. At the time of diagnosis, patients were either asymptomatic or complained of various symptoms including flank pain, dysuria, frequency, urgency, weight loss, hematuria, or abdominal distention. CT and ultrasound were the imaging modalities used to characterize the masses. Biopsy was used in only 2 of the 9 cases prior to surgical intervention. The average size on imaging is 8.7 cm × 7.4 cm, while the size of the resected masses on gross pathological evaluation is 11.8 cm × 8.0 cm × 5.9 cm. Treatment included open and laparoscopic mass excision with or without nephrectomy or partial nephrectomy depending on concern for adequate surgical margins. Upon reviewing the literature, we felt it was reasonable to monitor the lesion with routine surveillance imaging until the tumor increased in size and to perform a mass resection with a nephrectomy to ensure adequate surgical margins.

Since an extra-adrenal myelolipoma is such a rare entity, a retroperitoneal mass that has imaging characteristics of a well-differentiated liposarcoma should ultimately end up being approached and treated as such. However, this report demonstrates that extra-adrenal myelolipoma should be considered as part of the list of differential diagnoses. In cases in which surgical extirpation of an extra-adrenal myelolipoma is performed, there are no clear recommendations for post-operative surveillance. Our review did not reveal a case of local recurrence of a retroperitoneal myelolipoma, however, routine radiographic surveillance would certainly be helpful to detect potential locally recurrent disease.

In summary, perirenal extra-adrenal myelolipoma is extremely rare. This neoplasm is typically discovered incidentally on cross-sectional imaging and commonly thought to be a liposarcoma. It can be managed conservatively or surgically depending on the patient's symptoms or level of concern for a malignant lesion. Early detection and proper management of myelolipomas are important due to the potential for tumor growth and hemorrhage.

## COMMENTS

### *Case characteristics*

This case features a left-sided retroperitoneal mass that was incidentally discovered on a computed tomography (CT) scan for a suspected case of acute pancreatitis.

### *Clinical diagnosis*

Imaging revealed a non-enhancing heterogeneous mass measuring approximately 3.8 cm x 2.3 cm in longitudinal and anterior-posterior dimensions, just inferior to the left renal vein and medial to the left kidney, and histological evaluation revealed that the mass was composed of mostly mature adipocytes mixed with islands of hematopoietic cells.

### *Differential diagnosis*

Differential diagnosis was most concerning for liposarcoma, lipoma, malignant fibrous histiocytoma, or a fibrosarcoma.

### *Laboratory diagnosis*

Laboratory findings were non-contributory to arriving at the final diagnosis.

### *Imaging diagnosis*

CT and MRI were used to initially detect and follow the progression of the mass.

### *Pathological diagnosis*

Hematoxylin and eosin (H and E) stain at 10 x and 60 x magnification revealed

mature adipose cells with hematopoietic cells including erythroid precursors, granulocytic precursors, and megakaryocytes.

### Treatment

The mass was excised en bloc with the left kidney in an attempt to gain wide surgical margins.

### Related reports

The list of references to this article contains several related reports to aid readers to further understand this topic.

### Term explanation

*Myelolipoma* is a unique mesenchymal tumor that is composed of a mixture of adipose and hematopoietic cells.

### Experiences and lessons

Perirenal extra-adrenal myelolipomas are neoplasms that are typically discovered incidentally on cross-sectional imaging, they can be managed conservatively or surgically depending on the patient's symptoms or level of concern for a malignant lesion, and early detection and proper management of myelolipomas are critical due to the potential for tumor growth and hemorrhage.

### Peer review

This study describes a lesion which is not a unique phenomenon. Nevertheless, it is well writen with a good review of the literature.

## Abstract

Verrucous carcinoma of the esophagus is a variant of a squamous cell cancer. Our case is a 78-year-old male patient comes in with the dysphagia and weight loss, and on endoscopy (EGD) he is found to have an irregular intraluminal mass at the distal esophagus. With the deep EGD assisted biopsy, diagnosis of the verrucous carcinoma is made. Due to multiple co morbidities and possible infiltration to the pericardium, patient is taken for the esophageal stent placement and is being referred for the chemo-radiation treatment. The diagnosis can be very difficult to make with the superficial biopsies due to very non specific histological changes and requires very high clinical suspicion and deep mucosal biopsies are required for accurate diagnosis of the tumor. Chronic and local disease process is the main risk factor for the development of the verrucous carcinoma of the esophagus. Surgery is the treatment of the choice for the early stage tumor and advanced cases are treated with the palliation and possibly chemo-radiation. The prognosis is usually guarded and needs long term follow up.

**Key words:** Verrucous carcinoma; Hyperkeratosis; Esophageal stent placement; Esophageal carcinoma; Endoscopic Ultrasound

**Core tip:** A verrucous carcinoma is a slow growing, well differentiated, rare form of squamous carcinoma variant. It is associated with chronic, local disease process and it invades locally. On endoscopy (EGD), it appears as an exophytic irregular warty projecting mass, and it is very difficult to diagnose by superficial biopsy due to non specific superficial histological findings. So it requires high index of suspicion and deep biopsy with EGD or endoscopic ultrasonography (EUS). It projects as hypoechoic mucosal thickening on EUS. Early stages of cancers are treated surgically. Advanced cases can be referred for esophageal stent placement for palliation and chemo radiation. It has high morbidity and mortality and requires long term follow up for accurate numbers regarding to the treatment and the follow up.

## INTRODUCTION

Verrucous carcinoma of the esophagus is a rare form of carcinoma of squamous cell origin[1-9]. Majority of the cases are associated with the smoking, reflux esophagitis, alcohol use, human papilloma virus (HPV), achalasia and few other chronic inflammatory conditions[1-9]. An incidence rate of such cancer has been shown to be higher in males than females with a ratio of 2:1 and seen in the group from 35 to 80 years[1-3,6]. Superficial biopsies of the lesion often show merely chronic inflammation with no

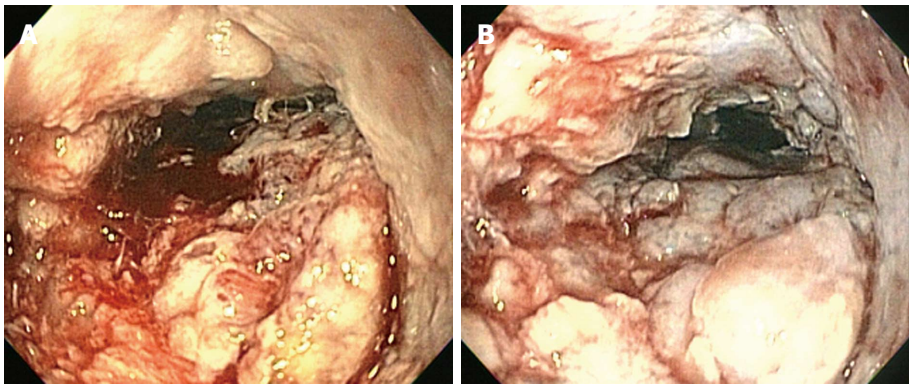

**Figure 1 Upper endoscopy showing an irregular velvety appearing intraluminal mass in the esophagus (A and B).**

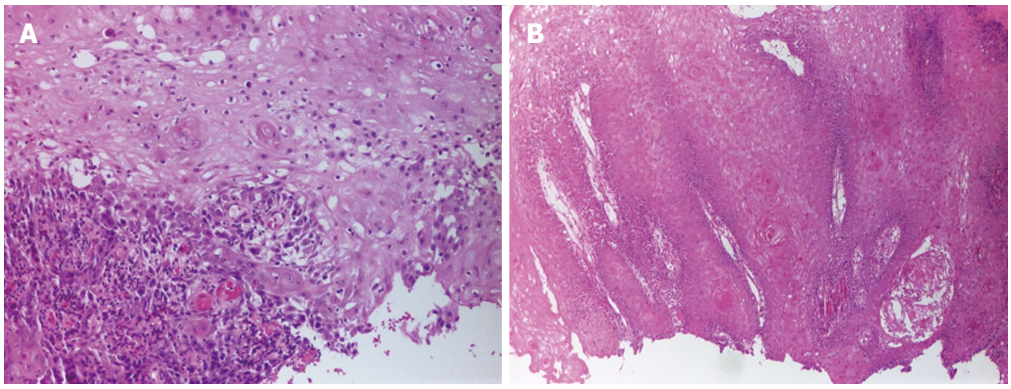

**Figure 2 Superficial biopsy of the lesion showing Mild cytological atypia and chronic inflammation and reactive appearing basal layer of sq cell epithelium (A); deep biopsy of the lesion with a jumbo forceps showing Florid proliferation of sq epithelium with verrucous pattern (B).**

high grade dysplasia, which makes it difficult to diagnose.

So far, less than 30 cases of such carcinomas are reported in the English literature. We are presenting a case of the verrucous carcinoma of the esophagus with no documented risk factors associated with the carcinoma and a diagnosis is made by deep biopsies of the lesions.

## CASE REPORT

We have recently seen a 78-year-old African American man, presenting with dysphagia, weight loss of 15 Lbs over 4-5 wk and right lower quadrant dull, and non radiating abdominal pain. His past medical history included coronary artery disease status post angioplasty with stent placement, hypertension, dyslipidemia, and diabetes mellitus with complications including diabetic retinopathy and nephropathy. He was non-smoker and non-drinker and denied any history of GERD. And symptoms were gradual in onset over last couple of months. His physical exam showed no abnormality. On lab evaluation, His BUN and serum creatinine were 42 and 2.4 respectively, normal liver function tests; Hemoglobin was 12.4 g/dL with MCV 84.4 fl. All other labs were within normal limits. ultrasonography of the abdomen and computed tomography (CT) scan of the abdomen and pelvis were unremarkable for any hepatobilliary, pancreatic or intestinal pathology. He underwent barium esophagogram, and was found to have a long, irregular stricture involving the mid and distal esophagus with an apparent intraluminal mass at its proximal end. The endoscopic examination showed a luminal warty appearing mass occupying distal 8 cm of the esophagus (Figure 1). Endoscopic ultrasonography (EUS) examination was performed which showed solid tumor measuring approx 5 cm in greatest dimension, possibly infiltrating into the pericardium (Figure 2). It also showed hypoechoic concentric wall thickening that appeared to be either an inflammatory process or lymphoma.

Initial biopsies were remarkable for squamous epithelial cells with parakeratosis and marked acute and chronic inflammation, ulceration and focal squamous cell with atypia. The repeat endoscopic examination and extensive biopsies with jumbo forceps revealed the diagnosis of verrucous carcinoma of the esophagus. In situ hybridization for both high and low risk HPV was negative.

A CT scan of the chest showed some mediastinal lymph nodes. Bone scan showed no any bone metastasis. In view of the dysphagia, patient underwent endoscopy (EGD) and placement of an esophageal Wallflex stent (Boston scientific partially covered 23 mm wide and 125 mm long).

Due to extensive medical history and fairly advanced stage, surgery was contraindicated and the patient was referred for chemotherapy and radiation.

## DISCUSSION

Verrucous carcinomas are a variant of squamous carcinoma. They are slow growing and seen in the oropharynx, larynx, glans penis, scrotum, vulva, vagina, cervix, endometrium, urinary bladder, anorectal region and the sole of the feet[2-4]. The Verrucous carcinomas are believed to be associated with the chronic mucosal irritation or inflammation or a long-term disease process[2,4].

Amongst all different sites for verrucous carcinoma, it is rarely seen in the esophagus[1-9]. First ever case of such cancer in esophagus was reported by Minelly in 1967[2,3,4,7] and thereafter so far less than 30 cases are reported in the English literature[8].

The etiological factors are not clearly delineated in the literature but it seems to be associated with the chronic inflammatory conditions or long term local disease process[1-9]. Risk factors may include smoking; alcohol abuse; hiatal hernia; achalasia; esophagitis; caustic injury from lye, battery or kerosene ingestion; esophageal diverticulum or nutcracker esophagus. In the recent years, few reported cases have shown the association with the HPV virus, although the clear association is very unclear[5,6,8,9]. Our case was not clearly associated with the any of these documented risk factors. Devlin *et al*[3] mentions that the acid inhibition decreases the tumor length and also changes the appearance from polypoid to sessile and warty. This hypothesizes that the long term acid damage could be a contributory for the development of the verrucous carcinoma.

The incidence rate is higher in male as compared to female with a ratio of approx 2:1[1-3]. An age distribution of this type of carcinoma ranges from 36 to 79 with a mean age of 61[1-3]. Most common presenting sign and symptoms in the verrucous carcinoma of the esophagus are dysphagia and weight loss, seen in our case as well[1-3,5,6]. Other symptoms would be hematemesis, coughing and odynophagia[2,6]. Endoscopic appearance of such lesions includes, shaggy, white, exophytic, wart-like, velvety, papillary, spiked, cauliflower like mass[1-3,7-9]. The tumor is located mostly in the lower esophagus (70%) with no clear reason but it can involve the upper (23%) or the mid part of the esophagus (7%) as well[2-9].

A diagnosis is usually made by either endoscopy guided deep mucosal biopsy or EUS guided tunnel biopsy or post surgery specimen evaluation. Verrucous carcinoma of the esophagus usually evolves in the sequential fashion from acanthosis, hyperkeratosis, parakeratosis, leukoplakia, verrucous lesions, and papillary hyperplasia to verrucous carcinoma[2]. Superficial biopsies of such lesions show only non specific acanthosis, parakeratosis, or hyperkeratosis, with associated acute or chronic inflammation[2,3,6,8]. which makes these types of carcinomas are difficult to diagnose and requires high index of suspicion and repeat endoscopic deep biopsies as in our case (Figure 3). Endoscopic biopsies have revealed 46% cases of the verrucous carcinoma, remaining of them have been diagnosed either after surgery or with the use of EUS[2-9]. EUS is highly accurate imaging modalities for the diagnosis and staging as well as follow up of esophageal tumors. It also estimates the depth of invasion as well as any lymphadenopathy which is helpful in staging. EUS guided tunnel biopsy of such lesions can be useful as seen in few case reports[2-4,8]. A Verrucous carcinoma of the esophagus commonly projects as a diffuse hypoechoic mucosal thickening with varying degree of depth with varying degree of lymphadenopathy in EUS exam[2-4,7,8]. It invades as a column of neoplastic

cells in a pushing manner instead of invasion in discreet cells[3], with the 80% invades through and beyond superficial epithelium, 8% limited to the superficial epithelium only and 12% unclear[2-9]. More than 50% cases are found have inflammatory infiltrates surrounding the tumor[3,6], and the lymphnode biopsy mostly shows hyperplastic nodes secondary to local inflammation which can prove that the chronic inflammation predisposes to the verrucous carcinoma of the esophagus[2,7]. Overall, histologically, it is similar to benign squamous papilloma and the tumor infiltration beyond the superficial mucosa fairly differentiates it from the benign squamous cell papilloma[2].

Despite of its slow growth and high degree of differentiation, it has very poor prognosis. As per literature, there is a delay between the onset of the symptoms and the diagnosis. And at the time of the diagnosis, majority of the cases are locally advanced[1-9]. Morbidity and mortality associated with such tumors are mainly due to local invasion or due to surgical complications. There is no any reported case of distant metastasis in the literature. It can spread locally to the lungs, bronchi, pleura and can form fistulas[1,2,8]. Our case is the first reported instance of pericardial invasion confirmed with EUS study. With regards to therapy, early stages of the cancer can be treated surgically with esophageal resection or polypectomy/mucosal resection[1-9]. More advanced cases, or non surgical candidates can be treated with esophageal stent placement, as done in our case. Due to rarity of such tumors, no clear data are available for any effective chemo- radiation therapy. However, most recent post operative follow up case series have shown better prognosis with cancer free survival ranges from 9 mo to 3 years[2,3]. We need a long term follow up with such patients and that can improve the outcome.

A verrucous carcinoma is a slow growing, well differentiated, rare form of squamous carcinoma variant. It is associated with chronic, local disease process and it invades locally. On EGD, it appears as an exophytic irregular warty projecting mass, and it is very difficult to diagnose by superficial biopsy due to non specific superficial histological findings. So it requires high index of suspicion and deep biopsy with EGD or EUS. It projects as hypoechoic mucosal thickening on EUS. Early stages of cancers are treated surgically. Advanced cases can be referred for esophageal stent placement for palliation and chemo radiation. It has high morbidity and mortality and requires long term follow up for accurate numbers regarding to the treatment and the follow up.

## COMMENTS

### Case characteristics

A 78-year-old African American man presented with dysphagia, weight loss of 15 Lbs over 4-5 wk and right lower quadrant dull, and non radiating abdominal pain.

### Clinical Diagnosis

Physical examination was unremarkable.

### Differential diagnosis

Benign squamous papilloma, adenocarcinoma of the esophagus

### Laboratory diagnosis

BUN and serum creatinine were 42 and 2.4 respectively, normal liver function tests; Hemoglobin was 12.4 with MCV 84.4.

### Imaging diagnosis

A barium esophagogram showed a long, irregular stricture involving the mid and distal esophagus with an apparent intraluminal mass at its proximal end. A computed tomography scan of the chest showed some mediastinal lymph nodes. Bone scan showed no any bone metastasis.

### Pathological diagnosis

The endoscopic examination and extensive biopsies with jumbo forceps revealed the diagnosis of verrucous carcinoma of the esophagus. In situ hybridization for both high and low risk HPV was negative.

### Treatment

Due to extensive medical history and fairly advanced stage, surgery was contraindicated and the patient Patient underwent EGD and placement of an esophageal Wallflex stent and was referred to chemotherapy and radiation.

### Related reports

The etiological factors are not clearly delineated in the literature. It has high morbidity and mortality and requires long term follow up for accurate numbers regarding to the treatment and the follow up.

### Experiences and lessons

This report presents a case of rare variant of squamous cell cancer of esophagus, and difficulties associated with the diagnosis and treatment. It is very beneficial for the patients, if it is diagnosed in the early stages. But nonspecific superficial biopsies make it difficult to diagnose and it requires high index of suspicion even without any associated risk factors.

### Peer review

It is indeed a rare form of squamous cell carcinoma. Due to the same reasons, there are not enough studies available in terms of management that can be applied to general population.

## Abstract

Surgical treatment for cervical kyphotic deformity is still controversial. Circumferential approach has been well described in the literature but long terms outcomes are not well reported. Important to decide the correct treatment option is the preoperative radiological exams to value the type of deformity (flexible or fixed). We report the case of a 67-year-old woman affected by a severe cervical kyphotic deformity who underwent combined anterior/posterior surgical approach, getting a good reduction of the deformity and an optimal stability in a long term follow up.

**Key words:** Cervical deformity; High grade kyphosis; Circumferential fusion; Surgical technique; Degenerative cervical spine

**Core tip:** The choice of the treatment for cervical kyphotic deformity takes into account preoperative radiological exams which allow the classification of the deformity in flexible or fixed.

Landi A, Marotta N, Mancarella C, Dugoni DE, Tarantino R, Delfini R. 360° fusion for realignment of high grade cervical kyphosis by one step surgery: Case report. *World J Clin Cases* 2014; 2(7): 289-292 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/289.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.289

## INTRODUCTION

The treatment option for correcting a cervical kyphotic deformity is currently controversial. Lots of studies examined the one/stage combined anterior-posterior treatment, although the rate of fusion and the long term follow up controls are rarely mentioned in the literature[1-7]. We present the case of a 67-year-old woman affected by a severe cervical kyphosis. We performed a one-step combined anterior/posterior approach to correct the deformity, getting a good reduction of kyphosis and good stability in a long term follow up. We enclosed that the evidence of motility by dynamic X-rays permits a good anterior decompression and reduction only by discectomy, fusion and plating, without need of multiple corpectomy. Treatment must be completed with posterior fixation and fusion. These strategies could be performed in one step, and shows a good reduction and optimal stability in a long term follow-up. Immobilizing with hard collar and neurophysiological monitoring remains fundamental for the safe and efficacy of this treatment.

## CASE REPORT

A 67-year-old woman affected by a severe cervical kyphotic deformity, came to our attention complaining 4 mohistory of bilateral cervicobrachialgia. She didn't have any significant medical diseases; she denied to have ever suffered of ankylosing spondylitis, osteogenesis imperfecta, rheumatoid arthritis or Larsen syndrome.

Neurological examination showed moderate upper limbs weakness, confirmed by signs of radicular suffering

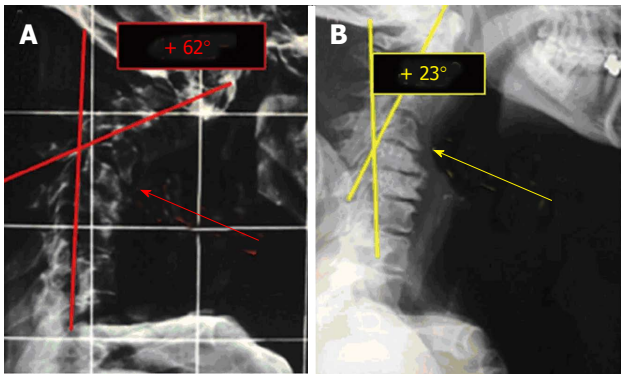

**Figure 1 X-ray pictures.** A: Standard X-ray demonstrating a severe cervical kyphosis (preop. Angle of Jackson + 62°); B: A cervical spine X-ray on the bed with a pillow under the shoulders showing a good reduction of kyphosis (+ 23° according to Jackson) due to the motor unit C4-C5 mobility.

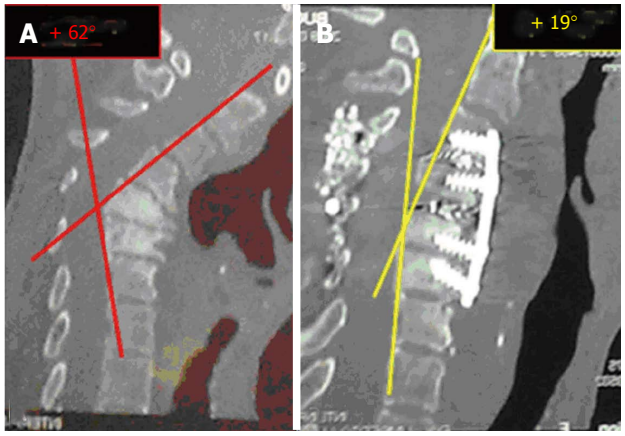

**Figure 2 The preoperative computed tomography.** A: Scan control (preop. Angle of Jackson + 62°); B: Showing a good reduction of kyphosis (postop angle of Jackson + 19°).

on the ElectroMioGraphy (EMG). The patient performed standard and flexion/extension cervical spine X-ray demonstrating a severe cervical kyphosis [preop. Ishihara index 64.18% and (8) preop. Angle of Jackson +62°] apparently fixed on the dynamic X-ray. Performed, then, cervical spine computed tomography (CT) and Magnetic Resonance Imaging showing important myeloradicular compression at C5-C6 and C4-C5.

The immediate preoperative exam that the patient had to perform was a cervical spine X-ray on the bed with a pillow under the shoulders in prevision to apply a traction system. This exam showed a good reduction of kyphosis (+23° according to Jackson) due to the motor unit C4-C5 mobility (Figure 1). It was therefore decided not to apply traction and to proceed with combined anterior/posterior surgical approach using neurophysiological monitoring SomatoSensory evoked potentials (SSEP), EMG and motor evoked potentials (MEP).

The first surgical step was the anterior approach, with hyperextension of the neck of the patient. The reduction status of the kyphosis was assessed under fluoroscopic visualization; patient underwent left anterior presternocleidomastoid-precarotid approach, anterior

**Figure 3 A postoperative X-ray control after 6 mo showing a good anterior and posterolateral arthrodesis.**

decompression through microdiscectomy C3-C4 and C4-C5, followed by interbody fusion using a carbon fiber cage in lordosis and anterior plate fixed on C3-C4-C5-C6. The second step was represented by the posterior approach, so the patient was placed in prone position. A C3/C6 posterior stabilization according to magerl was performed followed by posterolateral fusion at all levels. At the end of the procedure a Philadelphia brace was applied. The postoperative CT and X-ray control (Figure 2) and after 3 and 6 mo showed a good reduction of kyphosis (postop. Ishihara index 32.38 % and postop angle of Jackson + 19° with reduction of kyphosis of 31.8% according to Ishihara and 43° according to Jackson ), and a good anterior and posterolateral arthrodesis (Figure 3). The patient presented a complete regression of the upper limbs deficit and of the cervicobrachialgia. Six months later the patient is symptoms free.

## DISCUSSION

Cervical kyphosis can be classified into two different groups: type 1 (flexible cervical kyphosis) and type 2 (fixed cervical kyphosis). The treatment for flexible cervical kyphosis (type 1) posturally reducible is usually a posterior stabilization with fusion to guarantee the stability of the cervical spine[6,7]. Alternatively, some authors have reported the use of anterior only surgery for flexible cervical kyphosis as discectomy and corporectomy. This approach is useful for anterior column load sharing however it is not required for deformity correction. Fixed cervical kyphosis characterized by postural rigidity needs circumferential approach[8-10]. The circumferential approach for the correction of cervical kyphotic deformity is well described in the literature although the long term controls are not always diriment on the real fusion of the correction[11,12]. The debate is not whether or not to perform circumferential correction, but if it is more useful to perform a multiple anterior discectomy or multiple corpectomy. In the literature it is described as the execution of multiple discectomies has a greater potential for correction of kyphosis in relation to: (1) a greater kyphosis correction due to the possibility of including more lordotic cages at multiple levels, so to restore a greater

degree of lordosis; and (2) a greater possibility of fusion because of a larger cage-bone interface compared with the use of a Harms mesh or an expansion cage.

In cases of multilevel cervical stenosis, the choice of surgical technique (discectomy *vs* corpectomy) mainly depends on the location of the stenosis. In the case of a kyphotic deformity however, the choice depends on the mobility or less of the bodies involved in the deformity[10-16]. It is also important to note that such deformities occur slowly over the time and are frequently the product of a degenerative process that affects the patient for many years: this include a wrong postural attitude that causes a compensatory hypertrophy of the supporting muscles of the neck, which may hide a metameric mobility of kyphosis. In our case, in fact, the dynamic exam in the upright position showed that the kyphosis appeared fixed and cannot be reduced[10].

The X-ray performed in the bed with a pillow under the shoulder, allowed us to appreciate how such kyphosis was actually not fixed on two vertebrae. This made us choose a multiple discectomy and not corpectomy with consequent greater angular correction of kyphosis. Another important aspect in the evaluation of the motor unit motility is the reactive ankylosis of the articular processes. In the severe kyphosis the fusion occurs both at the level of the disc and of the articular masses, thus preventing a good correction of kyphosis after performing the anterior approach. When the articular masses are ankylotic it is necessary a 3-step surgery. The first step is represented by a posterior approach to release the ankylotic articular masses in order to allow the reduction of kyphosis. The second step is the anterior approach with discectomy, and the third step is represented by the posterior approach again to fix and to make arthrodesis[17-20].

To this end, it is crucial to recognize accurately the real motility of the vertebral body, and to do that it is important to perform a dynamic exam without load, to eliminate the reactive contracture of the muscles supporting the neck. Useful for this purpose is to perform radiographic examinations in supine position with supports placed at the base of the neck which put the cervical spine in hyperextension eliminating the analgesic muscle contracture. Another aspect to highlight is the use of intraoperative neurophysiological monitoring, in particular SEPP and MEP; these allow a direct observation of the function of the spinal cord during the entire procedure. The neurophysiological monitoring is important especially during the correction of the spinal deformities because, as these constituted and organized by time, may have led to spinal cord adaptations that may break with the correction maneuvers, resulting in severe neurological deficits. Their use avoid for such eventuality.

In a conclusion, we enclosed that the evidence of motility by dynamic X-rays permits a good anterior decompression and reduction only by discectomy, fusion and plating, without need of multiple corpectomy. Treatment have to be completed with posterior fixation and fusion. These strategies could be performed in one step, and shows a good reduction and optimal stability in a long term follow-up. Immobilizing with hard collar and neurophysiological monitoring remains fundamental for the safe and efficacy of these treatment.

## COMMENTS

### Case characteristics

The patient complained a 4-mo history of bilateral cervicobrachialgia.

### Clinical diagnosis

At the neurological examination the patient presented moderate upper limb weakness and severe cervical kyphotic deformity.

### Differential diagnosis

Through radiological exams we put cervical kyphotic deformity due to degenerative process in differential diagnosis with neoplastic and infective pathologies.

### Imaging diagnosis

The patient underwent computed tomography scan, magnetic resonance imaging and dynamic X-ray. The most important preoperative exam was X-ray performed in supine position with a pillow under the shoulder.

### Pathological diagnosis

The patient suffered severe cervical kyphotic deformity.

### Treatment

The authors performed combined anterior\posterior surgical approach using neurophysiological monitoring SomatoSensory Evoked Potentials, ElectroMioGraphy and Motor Evoked Potentials.

### Related reports

The choice of surgical treatment depends on the mobility or less of the bodies involved in the deformity.

### Term explanation

Cervical kyphosis is a progressive deformity; circumferential approach means one step combined anterior/posterior approach.

### Experiences and lessons

It is important to recognize the real motility of the vertebral body, and to do that it is necessary to perform a dynamic exam without load, to eliminate the reactive contracture of the muscles supporting the neck.

### Peer review

The author introduces an efficient surgical treatment for severe cervical spine deformity, and to improve the quality of life.

## Abstract

Focal epithelial hyperplasia (FEH), or Heck's disease, is a rare disease of the oral mucosa; it is mostly found in children or young adults who are immunosuppressed and who live in regions with low socioeconomic status. It is characterized by asymptomatic papules on the oral mucosa, gingiva, tongue, and lips. Healing can be spontaneous, and treatment is indicated if there are aesthetic or functional complications. Human papillomavirus, especially genotypes 13 and 32, has been associated with FEH and is detected in the majority of lesions. Histopathologically, FEH is characterized by parakeratosis, epithelial hyperplasia, focal acanthosis, and fusion and horizontal outgrowth of epithelial ridges. A 37-year-old male patient was referred to the Department of Oral and Maxillofacial Sciences at the Sapienza University of Rome, complaining of numerous exophytic lesions in his mouth. He stated that the lesions were not painful but he had experienced occasional bleeding after incidental masticatory trauma. He had received no previous treatment for the oral lesions. His medical history revealed that he was human immuno-deficiency virus positive and was a smoker with numerous, asymptomatic oral papules clinically and histologically corresponding to FEH. The labial and buccal mucosa were especially affected by lesions. Surgical treatment was performed using a 532-nm potassium titanyl phosphate laser (SmartLite, Deka, Florence, Italy) in continuous mode with a 300 μm fiber and power of 1.4 W (power density 1980.22 W/cm$^2$). After anesthesia without vasoconstrictors, the lesions were tractioned with sutures or an Allis clamp and then completely excised. The lesions were preserved in 10% formalin for histological examination, which confirmed the clinical diagnosis of FEH. In this case, the laser allowed excellent control of bleeding, without postoperative sutures, and optimal wound healing.

## INTRODUCTION

Focal epithelial hyperplasia (FEH), or Heck's disease, is an uncommon, benign disease of the oral mucosa; it is mostly found in children and young adults. It has also been described in some Native American communities in North and South America, as well as in Eskimos of Greenland[1,2]. FEH is characterized by numerous nodules or papules, usually painless, with sizes that vary from 1 mm to 1 cm, that are mainly found on the lips, buccal mucosa, tongue and palate[3]. Human papillomavirus (HPV) has been detected in the lesions with both electron microscopy and DNA testing[4,5]. The most frequently involved viruses are HPV 13 and HPV 32[5]. The case of a young HIV-positive adult affected by FEH is reported below.

## CASE REPORT

An African male patient, 37-year-old, was referred to the Department of Oral and Maxillofacial Sciences at the Sapienza University of Rome, complaining about numerous exophytic lesions in his mouth. He stated that the lesions were not painful but that he had experienced occasional bleeding after incidental masticatory trauma. He had not received previous treatment for the oral lesions. His medical history revealed that he was human immunodeficiency virus (HIV)-positive. The diagnosis of HIV was made 2 years previously. He was, at the time of the visit, in treatment with lopinavir and ritonavir (Kaletra, Abbott Italy, Campoverde di Aprilia, Italy), emtricitabine and tenofovir (Truvada, Gilead, Foster City, CA, United States), and in prophylaxis with sulfamethoxazole and trimetoprim (Bactrim, Roche, Milan, Italy). He also smoked 10 cigarettes per day, but he did not make use of alcoholic drinks.

According to the classification of the Centers for Disease Control, he was classified as stage A3.

Extraoral examination did not reveal any signs of other diseases. Intraoral examination showed the presence of 17 sessile, soft, normochromic lesions in the oral cavity. The lesions were localized on the lower lip and the buccal mucosa, on both sides (Figure 1). After the examination, a diagnostic hypothesis of FEH was assumed. Excisional biopsy was performed on one of the lesions to confirm the diagnostic hypothesis. The biopsy was performed using a potassium-titanyl-phosphate (KTP) laser with a wavelength of 532 nm (SmartLite, Deka, Florence, Italy) in continuous mode with a 300 μm fiber, power 1.4 W (power density 1980.22 W/cm$^2$). After anesthesia without vasoconstrictors (Mepivacaina Pierrel 30 mg/mL, Pierrel, Milan, Italy) the lesions were tractioned with sutures or an Allis clamp and then completely excised (Figure 2).

**Figure 1 Clinical aspect of the focal epithelial hyperplasia lesions on the lower lip mucosa.**

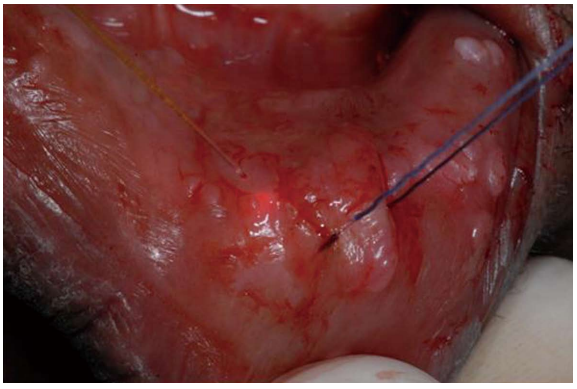

**Figure 2 Laser excisional biopsy of one of the lesions on the lower lip.**

The specimens were preserved in 10% buffered formalin for histological examination, which confirmed the clinical diagnosis of FEH.

In this case, the laser allowed excellent control of bleeding, without postoperative sutures, and optimal wound healing. After the first excisional biopsy, all of the lesions were surgically removed, in several steps, using the same operative approach. The patient was monitored with follow-up visits for one year, during which no recurrence of the pathology was observed (Figure 3), and he was asked to return if any lesions reappeared in the future.

## DISCUSSION

FEH is a rare condition in Italy and Europe. Here, we describe the case of an immunosuppressed African man with FEH. This pathology has been extensively described among native South and North American populations[1,6-8]. It seems that there could be a genetic predilection for FEH, as cases seem to be limited to specific ethnic groups in certain geographic regions[1,6]. Ledesma-Montes *et al*[7] suggested a series of factors that could contribute to the development of FEH: poverty, genetic predisposition (ethnic factors), and a deficient hygienic lifestyle. FEH lesions are most frequently localized on the buccal mucosa, lip, tongue, and commissures; the retromolar area, palate, and mouth floor are rarer local-

**Figure 3 Clinical aspect of the healing after excision of the lesions on the lower lip, 1 yr after treatment.**

izations[7]. FEH must be included in differential diagnosis with several pathological conditions that can be observed in the oral cavity[8], namely, condylomata acuminata, verrucous carcinoma, inflammatory fibrous hyperplasia, inflammatory papillary hyperplasia, and verruciform xanthoma[3]. Condyloma may appear similarly because it is caused by the same virus, but FEH lesions are more numerous and flatter, with typical localizations (buccal mucosa, lip and tongue)[9]. Verrucous carcinoma is a malign neoplasm that usually occurs in a different age group, usually in the sixth decade of life, with epidemiological characteristics that are similar to other oral carcinomas[10].

The last three pathologies are reactive lesions that usually occur with an irritating stimulus[9]. The diagnosis of FEH can be performed on the basis of clinical observation and can be confirmed by histological examination[11-13].

The histological features of this disease are parakeratosis, acanthosis, elongation of rete ridges, some of which may be anastomosed (the so-called "bronze age battle-axe" appearance[14], and usually koilocytes, as well as other cellular modifications that can indicate viral infection[5,14]. Cells with nuclear degeneration, called mitosoid cells, can also appear[15]. FEH can be associated with HIV infection, although the relationship between these conditions has not yet been completely clarified[12]. Suppression of the immune system leaves the patient vulnerable to opportunistic infections, including HPV infections[12].

There is no agreement in the literature on the potential malignant transformation of FEH lesions in immunocompromised patients. Moerman *et al*[12] stated that FEH lesions may have a high risk of malignant transformation in immunocompromised patients. Durso *et al*[13] tended to consider FEH a benign condition and stated that to date, no research has demonstrated the potential for malignant transformation of FEH lesions with HPV 13 and 32 subtypes. Only one case of malignant transformation of FEH caused by HPV type 24 has been reported[16]. Further studies are required to clarify this point.

Several therapeutic approaches have been proposed throughout the years. Some authors advise against removing the lesions because spontaneous regression can be observed[17], especially in children. Steinhoff *et al*[18] successfully treated FEH with topical applications of interferon beta. Other described methods include scalpel surgery, electrocoagulation, electrodessication, cryosurgery, and laser surgery[19,20]. In this case, laser surgery allowed excellent control of bleeding, without postoperative sutures, and optimal wound healing. Moreover, histological analysis is always possible with laser surgery when the proper parameters and correct surgical technique are used[21].

## COMMENTS

### Case characteristics

A 37-year-old male with a history of human immuno-deficiency virus (HIV) infection presented with numerous asymptomatic lesions in the oral cavity.

### Clinical diagnosis

Seventeen sessile, soft, normochromic lesions on the lower lip and the buccal mucosa, on both sides.

### Differential diagnosis

Condylomata acuminata, verrucous carcinoma, inflammatory fibrous hyperplasia, inflammatory papillary hyperplasia, verruciform xanthoma.

### Laboratory diagnosis

Cluster of differentiation 4 receptors (CD4) 129/μL; HIV RNA < 37 copies/mL; metabolic panel and coagulation within normal limits.

### Pathological diagnosis

Histological examination revealed parakeratosis, acanthosis, presence of koilocytes and mitosoid cells.

### Treatment

Excisional biopsy with a 532-nm potassium titanyl phosphate (KTP) laser.

### Related reports

Focal epithelial hyperplasia (FEH) can be associated with HIV infection, although the relationship between these two conditions has not yet been completely clarified; most likely, suppression of the immune system leaves the patient vulnerable to opportunistic infections, including HPV infections.

### Term explanation

KTP lasers are powerful tools for oral surgery and oral pathology, as are other types of lasers.

### Experiences and lessons

Oral lesions can be a manifestation of more complex systemic diseases; advanced surgical techniques can be useful tools in the management of multiple oral viral lesions.

### Peer review

This paper is worthy of publication as an interesting case report of uncommon oral mucosa disease in HIV infected patient. Particularly, an information of efficiency of KTP laser surgery in treatment of Heck's disease will be useful for clinicians.

## Abstract

Nasopharyngeal carcinoma is rare in western countries, accounting for less than 1% of all malignancies. Despite prognosis is satisfactory for newly diagnosed, non-metastatic disease, management of recurrent disease is challenging, with a survival expectancy of approximately 6 mo with the use of chemotherapy as the sole salvage treatment. We report a case of recurrent nasopharyngeal carcinoma treated with a combination of chemotherapy, radiotherapy and surgery in the context of a multidisciplinary approach. A durable complete response was achieved.

**Key words:** Cetuximab; Nasopharyngeal carcinoma; Re-irradiation; Surgery of metastases; Undifferentiated

**Core tip:** Recurrent nasopharyngeal carcinoma requires multi-modality therapy based on radiotherapy, surgery and chemotherapy, with a careful evaluation of expected toxicity and patient's quality of life.

## INTRODUCTION

Nasopharyngeal carcinoma (NPC) accounts for less than 1% of all malignancies and is rare in western countries[1]. NPC is usually poorly differentiated and is diagnosed in young patients. The prognosis of loco-regional disease is satisfactory, with a 5-year overall survival exceeding 80%. Radiation alone is employed for stage I - II disease, while for locally advanced NPC the combination of chemotherapy and radiotherapy is the standard approach[1]. The advent of new radiotherapy techniques, like intensity modulated radiotherapy (IMRT), has further improved prognosis of newly diagnosed NPC patients and contributed to allow re-irradiation of recurrent disease. On the other hand, management of recurrent/metastatic disease remains challenging for medical and radiation oncologists. In addition to cisplatin-based chemotherapy, which is the standard systemic treatment for NPC[2], cetuximab may be in patients with NPC and squamous histology according to guidelines. Importantly, in undifferentiated

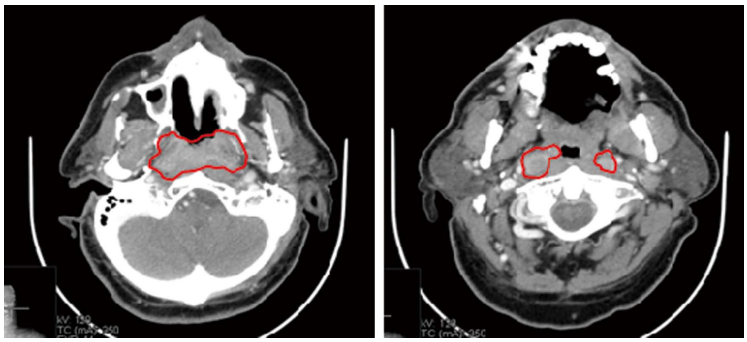

**Figure 1 A large lesion arising from the posterior wall of the nasopharynx and bilateral lymphnode metastasis were detected in the parapharyngeal space (October 2009).**

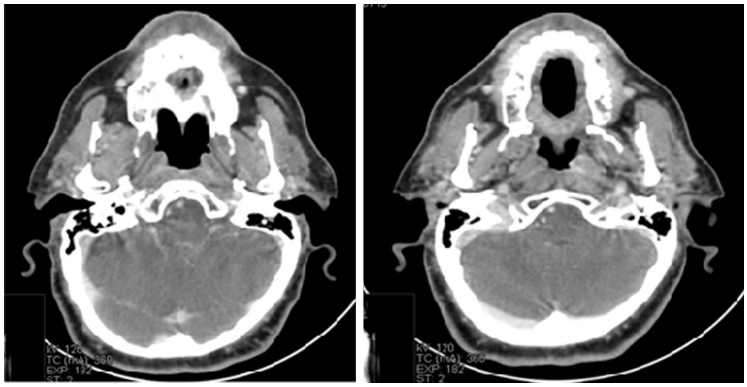

**Figure 2 After neoadjuvant TPF followed by cetuximab-radiotherapy, a complete response was obtained (March 2010).**

NPC, epithelial growth factor receptor is often overexpressed and k-RAS is never mutated, so cetuximab may provide benefit also in these patients[3]. We here report how multidisciplinary management coupled with recent advances in the field allowed us the obtain a durable complete response in a patient with relapsing undifferentiated nasopharyngeal carcinoma.

## CASE REPORT

In September 2009, a 59-year-old male patient was referred to our office for undifferentiated nasopharyngeal carcinoma. Histological diagnosis was made on fiberoscopy-guided biopsy. A computed tomography (CT) scan showed a large lesion arising from the posterior wall of the nasopharynx and extending into the paranasal sinuses. The lesion infiltrated the clivus and the oropharynx, and bilateral laterocervical lymphnode metastases were detected. Magnetic resonance imaging (MRI) confirmed CT findings (clinical stage, T4N3M0, IVa AJCC).

A therapeutic strategy based on 3 cycles of neoadjuvant docetaxel, cisplatin and 5-fluorouracil followed by radiotherapy was pursed after written informed consent was obtained. Docetaxel and cisplatin were given at doses of 75 mg/m$^2$ on day one and 5-Fluorouracil was administered at 750 mg/m$^2$ daily *via* continuous infusion for four consecutive days every three weeks. In November 2009, CT scan (Figure 1) showed partial response according to RECIST criteria 1.1 (reduction greater than 50% in the sum of the longest diameters of target lesions). From December 2009 until February 2010, a combined cetuximab-RT treatment was delivered. Cetuximab was given at standard doses. A total dose of 70 Gy (2 Gy dose fractions) on clinical target volume was delivered *via* 3D conformational radiotherapy. Toxicity mainly consisted of grade 2 cutaneous rash and grade 2 xerostomia, and did not lead to treatment interruption. Forty-five days after completion of chemo-radiotherapy, a complete response was shown on CT scan (Figure 2) and on PET scan after 60 d.

The patient remained free of disease recurrence until May 2012, when CT scan showed loco-regional recurrence involving the nasopharynx, the left orbitary cavity and intraparotid lymph nodes on the left side of the head. Patient presented with visual disturbances and moderate pain. PET scan and cytology confirmed the nature and extension of the recurrence. After multidisciplinary consultation involving the medical oncologist, the radiation oncologist, the pathologist and the surgeon, we decided to use a combined strategy based on an neoadjuvant chemotherapy, followed by re-irradiation and a surgical evaluation of residual disease.

Given the prolonged time to relapse, we deemed the disease to have preserved its sensitivity to taxanes and platinum compounds, so we delivered carboplatin (CBDCA) AUC 5 (area under curve) on day one every 3 wk, paclitaxel at the dose of 175 mg/m$^2$ on day one every three weeks and standard doses of weekly cetuximab. Radiological and symptomatic improvement was obtained after three cycles. A CT scan showed disappearance of the nasopharyngeal lesion, shrinkage of the lymphnode mass but no change of the orbital lesion. Toxicity was low, with grade 1 skin rash the most relevant side effect. Re-irradiation was performed from the end of August to the beginning of October 2012 *via* helical IMRT, 18 FDG PET/CT based planning. A total dose of 66 Gy, deliv-

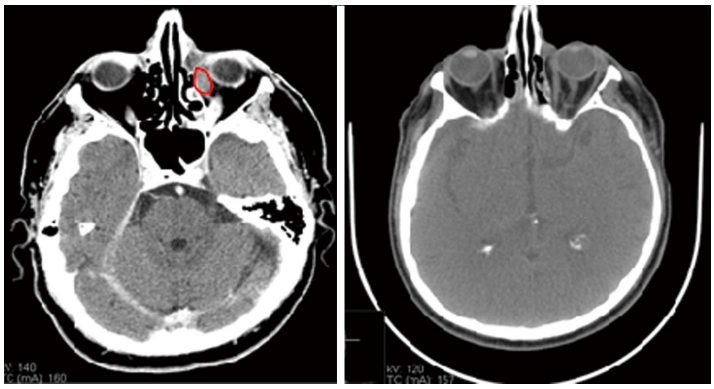

**Figure 3 Computed tomography scan showed an intraorbital lesion (May 2012).**

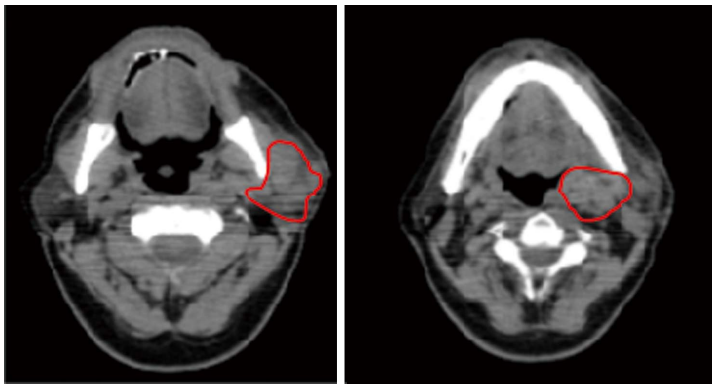

**Figure 4 Computed tomography scan showed that the only site of persistent disease was the lymph node mass in the neck (December 2012).**

ered in 30 daily fractions of 2.2 Gy, were administered to the site of disease, with the exclusion of the lymphnode mass in the neck, with disappearance (Figure 3) of both the orbital lesion and the nasopharynx. After subsequent chemotherapy (three cycles of CBDCA-Pac and cetuximab) CT scan showed that the only site of persistent disease was the lymph node mass in the neck (Figure 4). Patient was scheduled for surgical removal of parothyd and laterocervical Ⅱ, Ⅲ and Ⅳ neck levels. In June 2013, CT scan showed no sign of residual disease. As of January 2014, the patient is free of disease. He complains of grade 2 chronic xerostomia due to radiotherapy, and a facial nerve paralysis due to the surgical intervention.

## DISCUSSION

Locally advanced nasopharyngeal carcinoma can be successfully managed by combination platinum-based chemotherapy and radiotherapy[4]. Neo-adjuvant chemotherapy is also a valuable option and is especially indicated in patients with large lesions and locally advance disease, in order to decrease the gross tumor volume[5]. Comibination of taxanes and platinum compounds is highly active, not only in nasopharyngeal carcinomas but also in other clinical situations, such as head-neck carcinomas of unknown primary[6].

On the other hand, current management of recurrent/metastatic disease is far from yielding satisfactory results, and the prognosis is grim. In addition to cisplatin-based chemotherapy, cetuximab may also be employed in patients with NPC, as shown in some preliminary experiences[7]. Our case appears of great interest not only because cetuximab appeared to improve the outcome at first presentation, but it appeared to have preserved its effectiveness at disease relapse. Cetuximab was well tolerated both at initial presentation and at recurrence. Randomized controlled trials are required to assess efficacy of cetuximab in nasopharyngeal carcinoma before it can be recommended in this setting.

Our case also highlights the importance of a multidisciplinary approach in all patients and especially in those with recurrent disease. The multidisciplinary approach is able to balance toxicity and efficacy associated to combined use of diversified treatments. In recurrent patients, the use of chemotherapy as the sole salvage treatment is associated to a 6-mo prognosis[8-10]. With a multidisciplinary approach, we obtained a complete response, and our patient is free of disease recurrence after more than 6 mo and has an acceptable quality of life. Doctor-doctor and patient-doctor communication was of utmost importance for the management of this case, which should set an example of optimal integrated strategy of recurrent nasopharyngeal carcinoma.

## COMMENTS

### *Case characteristics*

Patient presented with recurrent nasopharyngeal carcinoma treated with chemotherapy, biological therapy, radiation therapy and surgery.

### *Clinical diagnosis*

Patient was affected by a locally advanced nasopharyngeal tumor, which was shown to be undifferentiated carcinoma on biopsy

### *Differential diagnosis*

Differential diagnosis included lymphoma and squamous carcinoma.

### Laboratory diagnosis
Patient had normal liver, bone marrow and kidney function at diagnosis and throughout treatment.

### Imaging diagnosis
Patient had locally advanced disease at diagnosis, with a large lesion arising from the posterior wall of the nasopharynx and infiltrating the clivus and bilateral laterocervical lymphnode metastases.

### Pathological diagnosis
Patient was affected by undifferentiated nasopharyngeal carcinoma.

### Treatment
After patient underwent treatment with docetaxel, cisplatin and 5-Fluorouracil and combined cetuximab-radiotherapy, he was treated with carboplatin, paclitaxel and cetuximab, followed by re-irradiation and surgery.

### Term explanation
Clinical target volume.

### Experiences and lessons
Irradiation with cetuximab is advantageous when chemotherapy cannot be delivered.

### Peer review
This paper is a useful clinical case in head and neck diseas.

## Abstract

Intravesical bacillus Calmette-Guerin (BCG) instillation has been adopted for the treatment of patients with superficial bladder cancer. Severe adverse events due to local instillation of BCG are uncommon, with an overall rate of serious complications of less than 5%. We report the case of an immunocompetent adult patient with multi-system effects, namely pneumonitis, granulomatous hepatitis and meningitis, who responded well to standard treatment for *Mycobacterium bovis.* This case highlights the importance of a thorough assessment of this type of patient.

**Key words:** Tuberculosis; *Mycobacterium bovis*; Bladder cancer; Bacillus Calmette-Guerin

**Core tip:** Intravesical instillation of bacillus Calmette-Guerin (BCG) is a therapeutic option in bladder cancer. Multi-system effects are a rare complication of this procedure, and certain aspects concerning its diagnosis and treatment are unclear. We report the case of a patient who developed effects on multiple organs after intravesical BCG instillations, and we review current knowledge concerning the diagnosis and management of BCG infection.

Marquez-Batalla S, Fraile-Villarejo E, Belhassen-García M, Gutierrez-Zubiaurre N, Cordero-Sánchez M. Disseminated infection due to *Mycobacterium bovis* after intravesical BCG instillation. *World J Clin Cases* 2014; 2(7): 301-303 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i7/301.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i7.301

## INTRODUCTION

Intravesical administration of bacillus Calmette-Guerin (BCG) is an essential tool in the treatment of superficial bladder carcinoma in situ[1]. This approach is generally well tolerated, although it occasionally leads to severe local and/or systemic complications[2]. The most serious complications of intravesical BCG instillation are related to disseminated infection. When disseminated BCG infection occurs, antituberculous therapy with or without glucocorticoids should be administered. We report a case of disseminated infection due to intravesical BCG instillations, resulting in pneumonitis, granulomatous hepatitis and meningitis.

## CASE REPORT

We present the case of a 64-year-old male patient with a

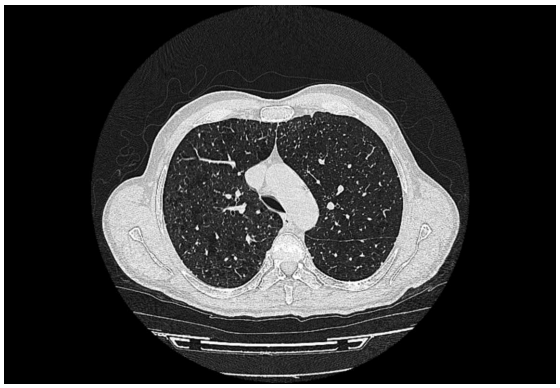

**Figure 1 A thoracic computed tomography scan revealed a pulmonary micronodular pattern.**

**Figure 2 An abdominal computed tomography scan revealed hepatic granulomas and hepatosplenomegaly.**

history of urothelial vesical neoplasm, benign prostatic hyperplasia and chronic obstructive pulmonary disease. He was being treated with tamsulosin, tiotropium bromide and salbutamol. Six months before, he had received six weekly doses of intravesical BCG instillation as an induction treatment, and one month before, he had started maintenance therapy with three doses per week. At the time of presentation, he reported weakness, weight loss and a slight fever with three weeks of evolution. Physical examination revealed hepatosplenomegaly. An analysis showed hepatic cholestasis (alkaline phosphatase 358 U/L, gamma-glutamyl transpeptidase 306 U/L), lactate dehydrogenase (LDH) 547 U/L and C-reactive protein 1.27 mg/dL. A complete blood count and urine sediment were normal. A thoracic X-ray showed multiple micronodular opacities. A thoraco-abdominal CT scan revealed a pulmonary micronodular pattern, hepatic granulomas and hepatosplenomegaly (Figures 1 and 2). Blood and urine cultures for bacteria were negative, as was a serological analysis (for HIV, HBV, HCV and *Treponema pallidum*). The urinalysis was positive for the species *Mycobacterium tuberculosis*, and *Mycobacterium bovis* (*M. bovis*) BCG grew with resistance to cycloserine and pyrazinamide. A genetic study detected the pnc A C169G (H57D) mutation, and we identified the species as *M. bovis*. The patient started treatment with isoniazid, rifampicin and ethambutol. After one week of treatment, the patient showed dizziness and instability while standing still and walking. The cerebrospinal fluid (CSF) showed red blood cells 4500/μL, leukocytes 16 μL (polymorphonuclear 25%, mononuclear 75%), proteins 82 mg/mL, glucose 67 mg/mL (capillary glycemia 144 mg/dL), LDH: 35 IU/L and adenosine deaminase 5.6 U/L (0-5). Magnetic resonance imaging of the brain (Figure 3) showed thickening and linear meningeal enhancement. Microbiological analysis of the CSF was negative. Given the meningeal involvement, anti-tuberculosis treatment was administered for one year, with good clinical and radiological responses.

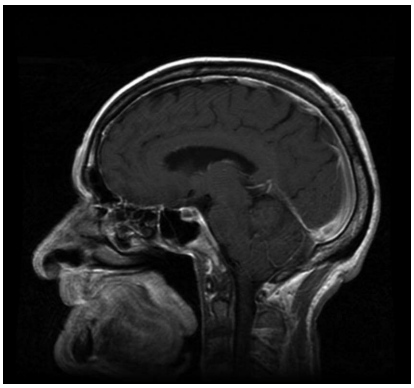

**Figure 3 Magnetic resonance imaging showed thickening and linear meningeal enhancement.**

## DISCUSSION

The adverse effects of intravesical BCG instillations can appear early or several years after the treatment. Although there are certain common local effects, such as cystitis (91%)[3] (this condition can be difficult to differentiate from other urinary tract infections), systemic complications are rare. The frequency of appearance ranges from 2.9% in cases with fever to 0.3% in cases with skin exanthema[4]. The most severe symptoms are pneumonitis, hepatitis, sepsis and pancytopenia. No differences in the incidence of complications were observed when comparing different BCG preparations or doses[5]. The spreading mechanism is not exhaustively known. Certain authors think that hematogenous spread occurs from the bladder[3], whereas others believe that the spread is due to a type IV hypersensitivity-related mechanism[6]. The response to glucocorticoids administered along with antituberculous drugs has also supported the notion of a hypersensitivity response. There are no established effective measures to prevent a disseminated infection with BCG[7], although the risk increases when instillations are temporally close to surgery or to traumatic catheterization[8]. The genetic study of the urine sample of our patient allowed us to identify *M. bovis* and to confirm its classic resistance profile. Given the meningeal involvement in the patient in our case, the treatment was extended for one year, with combination with corticoids in the first weeks.

In conclusion, intravesical BCG instillation can induce disseminated infection. Molecular techniques can help in early diagnosis because a delay in management can be lethal. In our patient, standard triple therapy with steroids led to complete recovery.

## COMMENTS

### *Case characteristics*

A 64-year-old male patient with an urothelial-vesical neoplasm treated by intravesical bacillus Calmette-Guerin (BCG) instillations.

### *Clinical diagnosis*

Hepatosplenomegaly and later dizziness and instability.

### *Differential diagnosis*

Neoplasm and central nervous system infection.

### *Laboratory diagnosis*

Alkaline phosphatase 358 U/L, gamma-glutamyl transpeptidase 306 U/L, lactate dehydrogenase 547 U/L and C-reactive protein 1.27 mg/dL. A complete blood count and urine sediment were normal.

### *Imaging diagnosis*

A thoracic X-ray showed multiple micronodular opacities. A thoraco-abdominal computed tomography scan revealed a pulmonary micronodular pattern, hepatic granulomas and hepatosplenomegaly. Magnetic resonance imaging of the brain showed thickening and linear meningeal enhancement.

### *Pathological diagnosis*

A urinalysis was positive for *Mycobacterium bovis*.

### *Treatment*

Anti-tuberculosis treatment was administered for one year.

### *Related reports*

Severe adverse events due to local instillation of BCG are uncommon, and disseminated BCG infection can simulate several diseases.

### *Term explanation*

BGG is a low-virulence mycobacterium that originates from successive cultures of *Mycobacterium bovis*. Pnc A is a gene encoding the mycobacterial enzyme pyrazinamidase.

### *Experiences and lessons*

BCG can induce disseminated disease with multi-system failure.

### *Peer review*

This paper reports the case of serious complications in a variety of organs after intravesical BCG instillation. The manuscript is basically well written.

## Abstract

We describe two cases of prosthetic joint infection (PJI) of the hip due to *Salmonella*. The first patient presented with an early infection 5 d after being discharged following a total hip replacement and the second patient presented at the emergency ward with a late infection, thirteen years following a total hip replacement. Both cases occurred within one month of each other at our institution and both were successfully treated with a one-stage revision. PJI caused by *Salmonella* species is very rare: so far only 20 *Salmonella* PJIs of the hip have been described. Therefore, full consensus on the best treatment approach has not yet been reached. An aggressive two-stage approach is advised because of the virulence of *Salmonella*, although a limited number of successful one-stage approaches have been described as well. According to the latest guidelines, one-stage revision has comparable success rates and less morbidity compared to two-stage treatment, when selecting the right patients. In our opinion, PJI caused by *Salmonella* should be treated just as PJI caused by other bacteria, with consideration of the selection criteria as mentioned in several treatment guidelines. As illustrated by these two cases, one-stage revision can be successful in both early and late *Salmonella* PJI of the hip.

**Key words:** *Salmonella*; Prosthetic joint infection; One-stage revision; Two-stage revision; Treatment

**Core tip:** Prosthetic joint infection (PJI) of the hip by *Salmonella* species is rare. There is an ongoing debate whether treatment of prosthetic joint infection should consist of a one- or two-stage approach and also whether or not PJI caused by *Salmonella* should be treated similarly to PJI caused by other bacteria. We report two cases of *Salmonella* PJI, one early and one late infection, successfully treated by one-stage revision.

## INTRODUCTION

*Salmonella* infections are usually associated with food consumption, specifically raw egg and related products, which account for at least one third of all outbreaks in the United States[1]. In the Netherlands, a Salmonellosis incidence of around 300/100000 is seen, mostly manifesting as gastroenteritis[2]. Although a general decline in human Salmonellosis has occurred in the last two

decades[1,2], because of demographic changes, the excess mortality due to *Salmonella* infections was predicted to double in the next 50 years[3].

The same demographic changes, i.e. the relatively and absolutely growing elderly population, will account for an increase in the number of total hip arthroplasties (THAs), and subsequently prosthetic joint infections (PJIs) of these hips[4]. PJI occurs in around 1%-2% of all THAs[5], and is one of the most severe and costly complications, usually requiring additional surgery, a prolonged hospital stay and administration of antibiotic agents, and (temporary) decreased function and quality of life[6,7].

PJI caused by *Salmonella* is nevertheless rare: only 28 patients (30 joints) have been described in the literature, of which 20 were prosthetic hip infections[8]. In the case of *Salmonella typhi*, the most common serotype, the prevalence of involvement of the bones or joints is only 1% or even less[9]. A higher frequency of *Salmonella* infections is seen in patients with sickle cell disease, systemic lupus erythematosus (SLE) and other immunocompromised states[5,10], and in children aged under five[3,11,12]. Most cases of *Salmonella* joint infections are caused by hematogenous spread[5,13].

An aggressive approach with two-stage revision is advised in cases of *Salmonella* PJI, because of the bacterial virulence[8].

We describe two cases of *Salmonella* prosthetic hip infection, both occurring within one month of each other, treated with one-stage revision.

## CASE REPORT

### *Case 1*

A 68-year-old female patient visited our outpatient clinic for severe osteoarthritis of the right hip. Her medical history further included clubfoot correction in her early youth, pneumonectomy for carcinoid tumor, hypophysectomy after pituitary adenoma, hypertension, renal failure grade 3, heart failure grade 3, atrial flutter and a stroke. She was using anticoagulants (acenocoumarol) and steroids (hydrocortisone) among other medication. She also mentioned an allergy for cephalosporins. In accord with the patient THA was planned.

Four days prior to surgery, her anticoagulants were replaced by therapeutic low molecular weight heparins (LMWH, nadroparin 5700 IE two times daily). Perioperatively, prophylactic clindamycin was administered. A non-cemented Trident cup with polyethylene insert (Trident system, Stryker Orthopaedics, Mahwah, New Jersey, United States) and a cemented Exeter stem (Exeter Total Hip system, Stryker Orthopaedics, Mahwah, New Jersey, United States) using Simplex P bone cement with Tobramycin (1 g tobramycin, Stryker Orthopaedics, Mahwah, New Jersey, United States) were implanted.

After an uncomplicated rehabilitation course of 5 d the patient was discharged. However, she was readmitted at her local hospital just 2 d later, with anemia (hemoglobin of 4.1 mmol/L, reference value 7.5-10.0 mmol/L). She was given 2 units of packed red blood cells (PRBC) and was transferred to our center.

Due to a sudden onset of right flank pain and elevated liver enzymes, an abdominal computed tomography was performed, which revealed a retroperitoneal hematoma, possibly with ongoing bleeding. Administration of nadroparin was discontinued, the patient received another 4 units of PRBC and after fluid resuscitation her hemodynamic status remained stable.

Gram staining of joint aspirate and superficial wound cultures revealed gram negative rods, while blood parameters showed a C-reactive protein (CRP of 334 mg/L (reference value < 8 mg/L). DAIR (debridement, antibiotics, irrigation and retention) was performed soon after. Intra-operatively 5 cultures were gathered, the insert and prosthetic head were exchanged, and 3 resorbable gentamicin sponges (130 mg gentamicin per sponge; Garacol, EUSA Pharma, Oxford, United Kingdom) were left in the surgical area. Afterwards, intravenous ciprofloxacin was started at 400 mg 3 times daily combined with intravenous vancomycin 1000 mg once daily.

After one week the cultures taken intra-operatively yielded Group E *Salmonella* species. At that moment the vancomycine was stopped while intravenous ciprofloxacine was continued for another week. This was followed by 4 wk of 750 mg ciprofloxacine orally twice a day. Then, due to her existing renal failure, the dosage of ciprofloxacine was lowered to 500 mg twice a day for one week and 500mg once a day for yet another week.

Due to sanguinous wound drainage, the dosage of nadroparin was changed to the prophylactic dosage (0.3 mL = 2850 IE, once a day). Because of the continuing wound drainage and increasing CRP from 119 to 147 mg/L, it was decided to proceed with a one-stage revision, nearly two months after the initial arthroplasty.

Intra-operatively, all components and cement were removed and the wound was thoroughly debrided and irrigated. Subsequently the medullary canal was reamed and an uncemented Restoration Modular stem (Restoration Modular System, Stryker Orthopaedics, Mahwah, New Jersey, United States) and Trident cup were inserted. Antibiotic treatment was continued with ciprofloxacin, according to the antibiogram from the cultures taken previously.

A subsequent debridement, antibiotics and implant retention (DAIR) procedure was performed because of persistent leakage, which appeared to be due to a fracture of the proximal femur around the stable stem. After wiring of this fracture and after exchanging the insert and prosthetic head of THA again, the patient recovered quickly and wound leakage cessated.

The 5 cultures taken during the one-stage revision, as well as the 2 cultures from the second DAIR procedure, all taken during antibiotic treatment, turned out negative. After the second DAIR procedure oral ciprofloxacin dose was administered at 750 mg 2 times daily again. After 5 wk this was lowered back to 500 mg once a day (because of the renal failure).

At the first follow up, two months since the one-stage revision, the patient was walking with a walker. The wound still showed a little redness, but CRP had declined

to 26 mg/L and erythrocyte sedimentation rate (ESR) was 43 mm/h (reference value < 20 mm/h).

At 5 mo follow-up, antibiotic treatment was stopped, the wound showed no signs of infection and ESR had normalized.

### Case 2

A 59-year-old man presented at the emergency department with pain in the right groin since four days, along with a progressive fever and nausea. At the age 16 he underwent screw osteosynthesis, because of epiphysiolysis capitis femoris, which was followed by THA in 1999 at the age of 46. No other comorbidities were present.

On physical examination of the hip the patient showed a painless function of 100 degrees flexion, 0 degrees extension, 20 degrees endorotation, and 30 degrees exorotation. Pressure in the groin was painful, however. The psoas sign was negative.

Additional blood tests showed a C-reactive protein of 193 mg/L and ESR 23 mm/h. On X-ray the prosthetic head appeared not to be centered (sign of polyethylene wear), though there were no signs of loosening of the prosthesis. Ultrasound of the groin revealed a 5.5 cm × 7.5 cm abscess. Aspiration produced some drops of pus, along with serosanguinous synovial fluid. After culturing the aspirated fluid revealed *Salmonella enteritidis*.

Antibiotic treatment was postponed until after intra-operative cultures could be taken, as the patient was not septic.

Six days after admission the patient underwent a one-stage revision. The decision to proceed with a one-stage revision rather than performing a DAIR procedure, was made intra-operatively, when osteolytic lesions were found around the femoral stem. A Trident cup and Omnifit stem (Omnifit system, Stryker Orthopaedics, Mahwah, New Jersey, United States) were inserted. Ciprofloxacin was started at 400 mg intravenously three times daily.

After the operation, CRP declined to 49 mg/L (from 245 mg/L at the day of operation) and the incision showed no redness or wound drainage. All 5 cultures obtained intra-operatively showed *Salmonella enteridis*. The patient was discharged with a regimen of oral ciprofloxacin (750 mg twice a day) after having received ciprofloxacin intravenously for 8 d.

At follow up, two weeks after discontinuing the antibiotic treatment (3 mo regime in total) and a total of 3 mo after discharge, the patient had no infectious signs or symptoms. Blood results showed a CRP of 5 mg/L, and an ESR of 9 mm/h. At 6 mo follow up the clinical and radiological findings were normal.

## DISCUSSION

PJIs are a severe complication seen in 1%-2% of cases after arthroplasty, causing additional costs and morbidity, including serious impairment in quality of life for the patient[7]. PJI due to *Salmonella* is especially uncommon.

Although most patients having a *Salmonella* infection are suffering from gastro-intestinal complaints, in the presented cases no overt gastro-intestinal symptoms were present (one patient presented only with mild nausea), indicating that PJI by *Salmonella* can occur without general gastro-intestinal complaints as has been previously stated[12].

Even though our cases presented within the same month, the course of infection was different. In the first case, symptoms occurred only 2 wk after initial THA, classifying this as an early infection[14,15] suggesting intra-operative contamination, although *Salmonella* usually spreads *via* the hematogenous route[16]. Another possibility is a carrier state of *Salmonella* species, however, we did not take fecal cultures to rule this out. Hematogenous spread in the early postoperative phase, although unlikely, is of course also possible.

The second PJI would be classified as a late infection[14,15] occurring 13 years after initial surgery.

When comparing this with other case-reports, there seems to be no outspoken trend in time since THA before infection: out of the 20 cases of *Salmonella* PJI in THA, 9 were late (> 24 mo) [11,14,17-22], 5 were delayed (3-24 mo)[23-26] and 5 were early infections (< 3 mo)[10,15,17,27]. In one case time until infection was not specified[28].

In bone infections the most encountered serotypes of *Salmonella* are *S. typhimurium* (group D) and S. *enteritidis* (group B)[15]. In the first case PJI was caused by group E *Salmonella*, which has not been reported before. The other patient's culture turned out to be the more common *Salmonella enteritidis*, reported previously in 5 PJIs of the hip[8,11,20,23,28] and in 6 PJIs of the knee[8,10,23,29-31].

For both our patients, the original treatment plan was to perform a DAIR procedure. In the first patient however, DAIR treatment failed, and a one-stage revision was performed.

During surgery in the second patient we proceeded with a one-stage revision rather than a DAIR procedure because of the encountered osteolysis. Because of good previous experiences by the surgeon, we opted for a one-stage revision rather than a two-stage revision. Only one case treated with a one-stage revision has been described before. In that case it was performed instead of the preferred two-stage procedure, because of the patient's co-morbidity[11].

In 2004, Zimmerli *et al*[15] already set ground rules for choosing between retention or resection of the prosthesis. This choice is based on duration of symptoms, (absence of) prosthetic loosening, tissue status and bacterial susceptibility.

In a recent systematic review by Leonard *et al*[32], functional outcome and reinfection rates were compared between one- and two-stage revision for PJI of the hip. There seems to be a trend toward better functional outcome in single-stage surgery, whereas reinfection rates turn out to be comparable between the two approaches. Besides this, a two-stage revision is associated with a significantly higher morbidity and mortality, and tissue changes associated with a period without a hip implant can lead to important functional deficits after reimplantation[32].

Furthermore, if the selection criteria, mentioned by Zimmerli *et al*[15] and by multiple other articles as summarized in the infectious diseases society of America (IDSA) guidelines[14], are strictly followed, retention and debridement and one-stage revision have high success rates, with less morbidity, in selected patients.

Nevertheless, despite commonly accepted directives and reported good results of one-stage revision in general PJI, both Tóth *et al*[11] and De la Torre *et al*[8] advocate a two-stage approach in patients with a *Salmonella* PJI.

De la Torre *et al*[8] propagate the aggressive treatment approach, because the virulence of *Salmonella* infections, difficulty in re-revision, and results of debridement procedures (based on a meta-analysis of studies published between 1977 and 1999)[8,33]. The virulence of *Salmonella* infections will generally cause a quick onset of symptoms. This means patients will present with symptoms quickly, and treatment can be started early (surgically and medically). If the bacterium has good susceptibility, a high cure rate can be expected, just like the guidelines propagate (Osmon 2013)[14].

In a recent study by Papavasileiou *et al*[34], the antimicrobial resistance of *Salmonella enteritidis* was compared between the planktonic form and the biofilm form in multiple antibiotics[34]. It appeared that the best results were obtained with ciprofloxacin and moxifloxacin[34]. None of the previously described case-reports in which ciprofloxacin was used reported recurrence of PJI[11,23,29,30,35]. This includes the one case treated with a one-stage revision[11].

So far neither of our patients, both treated with a one-stage approach and ciprofloxacin, show signs of reinfection. However, the first patient had undergone a DAIR procedure prior to, and after the one-stage approach, which might have influenced the outcome in a positive way: the IDSA guidelines describe that the thoroughness of debridement positively affects the success rate of a single stage surgery[14], and in our opinion, this might be true for multiple debridements as well.

In conclusion, good results can be achieved with one-stage revision, taking into consideration the guidelines for selecting the right patients[14,15], in combination with the use of appropriate antibiotics with a good activity against the causative micro-organism. One-stage revision is, in selected cases, a better alternative than the two-stage approach, causing less morbidity, less mortality and a much smaller burden of disease for the patient. In our opinion, *Salmonella* PJI could and should be treated as other bacterial PJIs, depending on the factors mentioned in the guidelines, and therefore one-stage revision could also be performed more often in these particular cases.

## COMMENTS

### Case characteristics

Case 1: A 68-year-old female with a history of severe osteoarthritis of the right hip was readmitted with anemia 5 d after right total hip arthroplasty; Case 2: A 59-year-old male with a history of total hip arthroplasty presented at the emergency department with pain in the right groin.

### Clinical diagnosis

Case 1: Anemia and sudden onset of right flank pain shortly after right total hip arthroplasty; Case 2: Mildly declined function of the hip, painful pressure in the groin, along with fever and nausea.

### Differential diagnosis

Case 1: Post-operative bleeding, periprosthetic joint infection, loosening of the prosthesis, periprosthetic fissure or fracture, total hip arthroplasty (THA) dislocation, intraabdominal pathology; Case 2: Periprosthetic joint infection, loosening of the prosthesis, THA dislocation, heterotopic ossification, hernia inguinalis

### Laboratory diagnosis

Case 1: Hemoglobin 4.1 mmol/L; C-reactive protein (CRP) 334 mg/L; elevated liver enzymes; Case 2: CRP 193 mg/L; erythrocyte sedimentation rate 23 mm/h.

### Imaging diagnosis

Case 1: Computed tomography revealed a retroperitoneal hematoma; Case 2: On X-ray the prosthetic head appeared not to be centered, without signs of loosening of the prosthesis, while an ultrasound of the groin revealed a 5.5 cm × 7.5 cm abscess.

### Pathological diagnosis

Case 1: Intraoperatively taken cultures yielded group E *Salmonella* species; Case 2: Joint aspiration fluid revealed *Salmonella enteritidis*.

### Treatment

Case 1: After one failed debridement, antibiotics and implant retention-procedure, one-stage revision was performed followed by ciprofloxacin; Case 2: Because of encountered osteolysis the patient was treated with a one-stage revision, followed by ciprofolxacin.

### Related reports

There is an ongoing debate whether prosthetic joint infection of the hip is best treated by one- or two-stage revision surgery, but also whether Salmonella infections should be treated similarly to periprosthetic joint infections due to other bacteria.

### Experiences and lessons

This case report illustrates that one-stage revision of periprosthetic joint infections of the hip can be a successful treatment even when infection is due to *Salmonella* species.

### Peer review

This is a report of two case with a prosthetic joint infection cause by Salmonella treated with one-stage revision. The paper is very well presented with a clear message.

## Abstract

Esophageal atresia with tracheo-oesophageal fistula (TEF) occurs in 1 in 3500 live births. Anorectal malformation is found to be associated with 14% of TEF. Esophageal atresia with TEF is a congenital anomaly which classically presents as excessive frothing from the mouth and respiratory distress. Rarely gastric position of the feeding tube in a case of TEF can be obtained delaying the diagnosis of TEF. We had an uncommon situation where a nasogastric tube reached the stomach through the trachea and tracheo-esophageal fistula, leading to misdiagnosis in a case of esophageal atresia with tracheoesophageal fistula. By using a stiff rubber catheter instead of a soft feeding tube for the diagnosis of esophageal atresia and TEF, such situation can be avoided.

**Key words:** Esophageal atresia; Tracheoesophageal fistula; Nasogastric tube; Red rubber catheter; Misdiagnosis

**Core tip:** Esophageal atresia with tracheoesophageal fistula is congenital anomaly which presents as excessive froathing from mouth and respiratory distress. It can be suspected when a nasogastric tube difficult to insert into stomach or radiographically presence coiled nasogastric tube in pharynx. We had an uncommon situation where a nasogastric tube reached the stomach through the trachea and tracheo-esophageal fistula, leading to misdiagnosis in a case of esophageal atresia with tracheoesophageal fistula. Similar clinical situations can be avoided by using a stiff rubber catheter instead of a soft feeding tube for the diagnosis of esophageal atresia and tracheo-oesophageal fistula.

## INTRODUCTION

Esophageal atresia with tracheooesophageal fistula (TEF) is a congenital anomaly which classically presents as excessive frothing from the mouth and respiratory distress. It is diagnosed by inability to pass a catheter into the stomach which usually gets stuck at 10 to 12 cm from the mouth. We had an uncommon situation where a nasogastric tube reached the stomach through the trachea and tracheo-esophageal fistula, leading to misdiagnosis in a case of esophageal atresia with tracheooesophageal fistula.

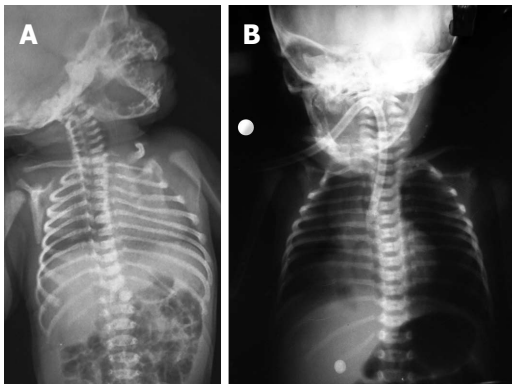

**Figure 1 Radiograph.** A: Showing tip of nasogastric tube in stomach; B: Showing red rubber catheter in upper esophageal pouch.

## CASE REPORT

A one day old, full term, male child (2.7 kg) was referred from a peripheral Hospital as a case of imperforate anus with cleft lip and palate. At the peripheral hospital a 7 Fr nasogastric tube was inserted which had bilious aspirate. A chest X-ray showed the nasogastric tube in the stomach (Figure 1A). The baby had excessive oral secretions and bilateral chest crepitations along with cleft lip and palate. Prone crosstable X-ray was suggestive of high anorectal malformation. The patient was taken for diverting colostomy.

During intubation the anesthetist noticed that the nasogastric tube was passing through the trachea. Findings were reconfirmed by laryngoscopy and laryngotracheoesophagial cleft was ruled out. We tried to pass a number 10 stiff red rubber catheter through esophagus but were unable to pass beyond 10 cm. A diagnosis of esophageal atresia (EA) with tracheooesophageal fistula (TEF) was suspected and X-ray chest was repeated with the red rubber catheter *in situ* which confirmed the diagnosis (Figure 1B). Right posterolateral thoracotomy was done. The patient had tracheoesophageal fistula type Ⅲ with a Wide fistula, short upper pouch and a long gap. The fistula was ligated and a Left sided cervical oseophagostomy with feeding gastrostomy was done. Transverse colostomy was done for imperforate anus.

The baby was shifted on ventilator and was successfully weaned off at post operative day 5. The baby is now 4 mo old and is doing well on follow up. He is awaiting definitive management for anorectal malformation, esophageal replacement, cleft lip and cleft palate repair.

## DISCUSSION

Esophageal atresia with TEF occurs in 1 in 3500 live births[1]. Anorectal malformation is found to be associated with 14% of TEF[1]. TEF classically presents as excessive frothing from the mouth and regurgitation, choking and coughing after feed. There is a routine practice of passing a 5Fr or 6Fr infant feeding tube through the nose in patients of imperforate anus to decompress the obstructed intestinal tract and also to rule out associated esophageal atresia. If the radiograph shows a coiled catheter in the upper esophageal pouch one can suspect esophageal atresia.

Rarely gastric position of the feeding tube in a case of TEF can be obtained delaying the diagnosis of TEF[2,3]. In this case we did not suspect an esophageal atresia as the patient came with the IFT in the stomach with bilious aspirate and this had been confirmed radio graphically. The feeding tube could reach the stomach from the upper pouch then into the tracheal route and then through the TEF. A peculiar pathological anatomy and a weak cough reflex made this occurrence possible. Only three such cases have been reported so far in literature[2,3]. If an esophageal atresia is suspected on clinical grounds the ideal test would be to pass a stiff red rubber catheter through the mouth and note the resistance. Radiographs should be taken with a red rubber catheter *in situ* which will show the position of the catheter tip. Barium esophagography is not usually advised due to the risk of aspiration pneumonitis. Instead a small amount of air can be used as contrast[1].

In a conclusion, all neonates with excessive frothing and respiratory distress should be evaluated for TEF. Similar clinical situations can be avoided by using a stiff rubber catheter instead of a soft feeding tube for the diagnosis of EA and TEF.

## COMMENTS

### *Case characteristics*

Authors' came across a uncommon situation, a neonate refered from peripheral hospital with nasogastric tube passed through tracheo-esophageal fistula into the stomach.

### *Clinical diagnosis*

The baby had excessive oral secretions and bilateral chest crepitations along with cleft lip and palate.

### *Differential diagnosis*

Prone crosstable X-ray was suggestive of high anorectal malformation.

### *Peer review*

The case report is interesting and well written, the field of the report is focused on pediatric.

## Abstract

We investigated the sebaceous gland metaplasia (SGM) of the esophagus and clarified the evidence of misdiagnosis and its diagnosis pitfall. Cases of pathologically proven SGM were enrolled in the clinical analysis and reviewed description of endoscope. In the current study, we demonstrated that SGM is very rare esophageal condition with an incidence around 0.00465% and an occurrence rate of 0.41 per year. There were 57.1% of senior endoscopists identified 8 episodes of SGM. In contrast, 7.7% of junior endoscopists identified SGM in only 2 episodes. Moreover, we investigated the difference in endoscopic biopsy attempt rate between the senior and junior endoscopist ($P$ = 0.0001). The senior endoscopists had more motivation to look for SGM than did junior endoscopists ($P$ = 0.01). We concluded that SGM of the esophagus is rare condition that is easily and not recognized in endoscopy studies omitting pathological review.

**Key words:** Esophagus; Sebaceous gland; Metaplasia; Endoscopy; Endoscopist

## INTRODUCTION

Sebaceous gland metaplasia (SGM) tends to be found incidentally during autopsy or esophageal resection[1,2]. From the point of differential diagnosis of esophageal lesions, SGM becomes of scientific interest during endoscopic studies. Endoscopists should take the first look at unusual lesions[3]. Although several reports have attempted to determine whether SGM is the result of a metaplastic process or a congenital anomaly, histological examination of endoscopic biopsies is traditionally used to make a pathological diagnosis in clinical practice[2]. Biopsied tis-

sues can be taken for histological and marker studies of SGM[4,5]. Due to the benign nature of SGM-containing endoscopic readings[6], the diagnosis is commonly missed when tissue biopsies are not reviewed. Therefore, the aim of this study was to clarify the incidence of SGM and identify the hallmarks of SGM in endoscopic review.

## CASE REPORT

### Method

From January 1, 1998 to June 30, 2012, a total of 215046 patients underwent endoscopic procedures with 35302 tissue biopsies taken by 33 endoscopists in the endoscopy unit of Kaohsiung Chang Memorial Hospital. The endoscopic procedures included 864 esophagoscopiesand 214182 gastroscopies (include 650 nasoendoscopies). Cases of endoscopic ultrasound of the upper gastrointestinal tract, endoscopic retrograde cholangiopancreatography, and double-balloon enteroscopy *via* an oral route were excluded from this study. The cases of pathologically proven SGM were enrolled in the clinical analysis and the endoscopic characteristics were reviewed.

By definition, an endoscopist with more than 20 years of experience was defined as a senior endoscopist, while an endoscopist with less than 20 years of experience was defined as a junior endoscopist. Accordingly, 7 senior and 26 junior endoscopists were identified. The senior endoscopists performed 110022 (51.2%) endoscopic studies and 16012 (14.5%) endoscopic biopsies, and the junior endoscopists performed 105046 (48.8%) endoscopic studies and 19290 (18.4%) endoscopic biopsies. Histological examinations of the endoscopic biopsies were performed by an experienced pathologist.

Statistical analyses were performed using SPSS software (version 12.0; SPSS, Chicago, IL, United States). Comparisons of the endoscopic biopsy parameters and SGM frequency between the senior and junior endoscopists were performed using the $\chi^2$ test and Fisher's exact test. *P* values less than 0.05 were considered statistically significant.

### Results

Among the 215046 endoscopic studies performed during the study period, there were 6 cases of pathologically documented SGM in 10 endoscopic studies (Table 1). The incidence and occurrence rates were 0.00465% was 0.41 per year, respectively. The male to female ratio was 3:1, and the mean age was 57.6 years (range 46-71 years). Four of the 6 cases with SGM came from a health screening center, and the other 2 came from outpatient clinics. All of the cases had numerous tiny yellowish lesions with histopathological examination identified heterotopic sebaceous gland located in the middle-lower esophagus (Figure 1).

The primary endoscopic impression was xanthoma (by senior 1, 2 and 3) in 3 cases, candidiasis (by junior 2 and senior 3) in 2 cases, papilloma (by senior 2 and senior 4) in 2 cases, and a negative description (by junior 1) in 1 case (Table 1). No cases of SGM were recognized by the senior endoscopists 1, 2, 3 and 4 or junior endoscopists 1 and 2 in the primary endoscopic study, and no cases (0/3) of SGM were recognized by senior endoscopists 2 or 4 or junior endoscopist 1 in the secondary endoscopic impression without tissue pathology review (Table 1). The rate improved after pathological review, there was a 100% (2/2) positive diagnosis experienced in the case 2 and case 3 in the primary endoscopic impression by senior 1, and only 3.03% (1/33) of our endoscopists did it.

Among the 6 pathologically confirmed cases of SGM, 5 were diagnosed in the first endoscopic study by tissue biopsy, while the sixth case was diagnosed in the second endoscopic study by tissue biopsy (Table 1). Among the 7 senior endoscopists who performed 110022 (51.2%) endoscopies, 16012 (14.5%) endoscopic biopsies were performed, an average of 2287 biopsies per senior en-

[1]$P$ = 0.0001 using the $\chi^2$ test; [2]$P$ = 0.01 using Fisher's exact test; [3]senior 1 in 3, senior 2 in 2, senior 3 in 2, and senior 4 in 1 meet; [4]junior 1 in 1 and junior 2 in 1 case of identified SG. SGM: Sebaceous gland metaplasia; ESP: Endoscopist; End: Endoscopic.

doscopist and 4 (57.1%) cases diagnosed of SGM in 8 episodes by senior 1 of 3 times, senior 2 of 2 times, senior 3 of 2 times, and senior 4 in 1 time. In contrast, of the 105024 (48.8%) endoscopies performed by 26 junior endoscopists, 19290 (18.4%) endoscopic biopsies were performed, an average of 741.9 biopsies per junior endoscopists, and identified-2 (7.7%)cases SGM in only 2 episodes by junior 1 and junior 2 respectively. Significantly fewer endoscopic biopsies were performed by the senior endoscopists than by the junior endoscopists ($P$ = 0.0001), and significantly more cases of HSGM were identified by senior endoscopists than by junior endoscopists ($P$ = 0.01) (Table 2).

Endoscopic biopsy showed multiple light yellow plaques 2-5 mm in diameter with clustering distribution that embedded the surface of the esophagus (Figure 1). In 100% (6/6) of cases, sebaceous glands were located at the lower to middle esophagus. Pathological analysis revealed stratified squamous epithelium with lobules of sebaceous glands abutting the lower epithelium. No associated polymorphic nuclear or cellular infiltration was noted (Figure 2).

## DISCUSSION

The present study demonstrated that SGM is a very rare esophageal condition with an incidence around 0.00465% and an occurrence rate of 0.41 per year. There was no doubt of the pathological diagnosis of SGM[7,8], but endoscopic biopsy should make an important impact on the incidence of SGM. In the real world, endoscopic biopsy is performed by endoscopists for 2 possible reasons: a suspected malignant lesion, or a lesion that is difficult to identify under endoscopic study. Such lesions look benign, especially in narrow band imaging[9,10], we believed that endoscopists does not perform biopsy, if they macroscopically diagnosed the lesion for benign. It may be a reason for the incidence of SGM is likely underestimated.

In the current study, senior endoscopist 1 encountered SGM 3 times (cases 1, 2 and 3) in 1998, 1999 and 2002. After the endoscopic biopsy and pathological review in the first case, a 100% (2/2) endoscopic diagnosis rate of senior endoscopist 1 was noted in cases 2 and 3. In contrast, senior endoscopist 2 missed an endoscopic diagnosis in a xanthoma due to a lack of pathological review despite the first case being proven. Senior endoscopist 2 also missed an endoscopic diagnosis in a papilloma that was biopsied but not pathologically reviewed.

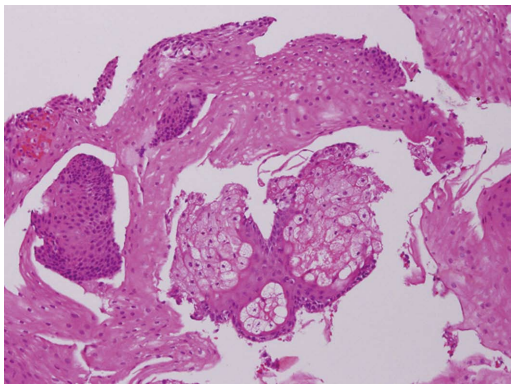

**Figure 2 Esophageal squamous epithelial with sebaceous glands (HE stained × 400).**

In the meantime, senior endoscopist 4 also missed an endoscopic diagnosis in a papilloma in case 4 due to lack of pathological review. In SGM cases 5 and 6, the primary endoscopic diagnosis of candida esophagitis was made by junior endoscopist 2 and senior endoscopist 3. Junior endoscopist 2 had performed an endoscopic biopsy in case 5, but senior endoscopist 3 did not in case 6.

Due to the lack of a pathological review, junior endoscopist 1 made a negative endoscopic diagnosis in case 5 during a scheduled health screen. In contrast, senior endoscopist 2 also missed the endoscopic diagnosis in SGM case 6 due to the lack of a response to candida infection treatment in the follow-up clinic. Because endoscopic biopsy and pathological review were both performed, 6 cases of SGM were documented in our series.

Our series showed that 66.7% of the cases of SGM came from health screening centers, and for these cases the pathology reports were not returned to the ordering endoscopist. In addition, the interpreting doctor at the health screening center was not the original endoscopist, and the patients did not return to the outpatient clinic due to there being no evidence of malignancy. To overcome the diagnostic underestimation demonstrated here, endoscopists need to actively follow up each pathological report after an endoscopic biopsy, or a computer management system should send the final pathological report to the original endoscopist on a weekly basis. Therefore, the accurate diagnosis of SGM requires both endoscopic biopsy and pathological review[11].

Studies have reported that candida infection (Figure 3A) is the most common endoscopic diagnosis to appear as SGM[7,8]. In the present study (Table 1), 10 episodes of SGM were found at a rate of 3 in xanthomas, 2 in candida infections, and 2 in papillomas (Figure 3B). The same situation was the first impression as candida infection of the esophagus but no medication response to it in our case 6[12]. SGM case 6 was determined by a subsequent pathological review. For most endoscopists, the first impression would be glycogenic acanthosis (Figure 3C), potentially with minor atypical features. All of the

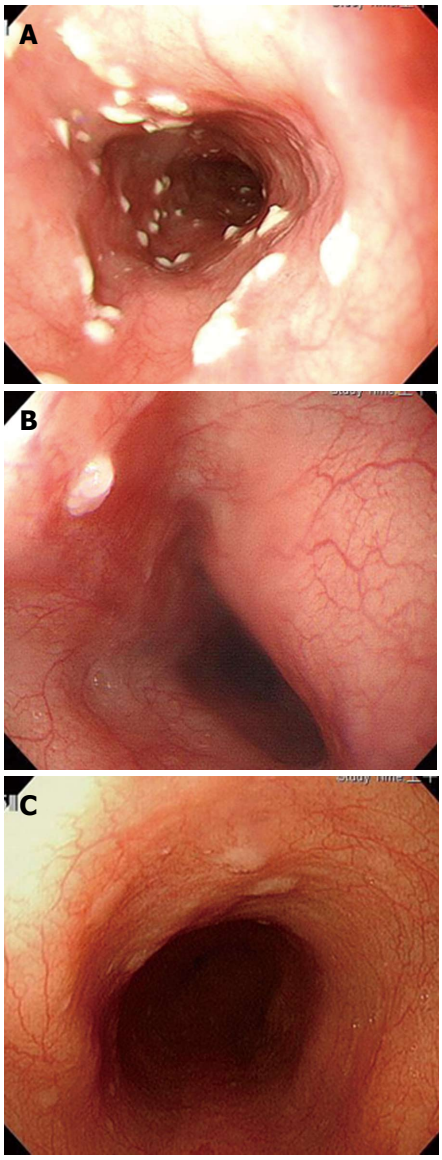

**Figure 3 Photograph.** A: Candida infection of the esophagus. Multiple small brightly whitish elevated patches at the upper and middle esophagus; B: Papilloma of the esophagus. A single round whitish elevated nodule at the middle esophagus; C: Glycogenic acanthosis of the esophagus. Some small round lucent to lightly whitish nodules at the upper and middle esophagus.

above situations belong to the benign nature of the etiology of SGM, and the symptoms of SGM are not alarming enough to warrant an endoscopic biopsy. Therefore, missing endoscopic diagnosis occurs easily in situations in which both endoscopic biopsy and pathological review are not both performed.

An interesting finding in the current study was the difference in endoscopic biopsy attempts between the senior and junior endoscopists. More cases were examined by the senior endoscopists than by the junior endoscopists (51.2% *vs* 48.8%), in contrast to the endoscopic biopsy rate (14.5% *vs* 18.4%). The large difference in the number of biopsies taken by senior (21.2%) *vs* junior endoscopists (78.8%) might give a false impression in statistical analysis. Senior endoscopists had a 3-fold higher number of endoscopic biopsies compared to the junior endoscopists (2287.4 *vs* 741.9 endoscopic biopsies per endoscopist). Senior endoscopists had more motivation to look for SGM than the junior endoscopists. Anyway, SGM is a very rare endoscopically indistinct benign finding in the esophagus. The histogenesis of ectopic sebaceous glands in the esophagus is unknown; whilst it could be a congenital abnormality, a majority of authors defined it like an acquired metaplastic process. No malignant transformation has yet been reported. From the pathologists' point of view an inflammatory or neoplastic process has to be excluded as the cause of the non-distinctive endoscopic findings[8,13]. In our recent study found that senior endoscopists are more interested than junior endoscopist, in look for the esophagus SGM cells as well as the attempt for endoscopic biopsy[14].

In conclusion, asymptomatic esophageal SGM is a rare condition that occurs in old age (> 50 years) and is male dominant. A differential diagnosis of a benign non-inflammatory nature should be kept in mind in daily practice with endoscopic biopsies and pathological review but may be never seen clinically.

## COMMENTS

### *Case characteristics*

Sebaceous gland metaplasia of esophagus tends to be found incidentally because of the usually no symptoms.

### *Clinical diagnosis*

It is hard to make a clinical diagnosis due to the silent disease.

### *Differential diagnosis*

Endoscopic biopsy with pathological review is very important for the differential diagnosis from the other esophageal pathologies.

### *Laboratory diagnosis*

Histological examination with HE stained showed characteristic sebaceous differentiation.

### *Imaging diagnosis*

Endoscopy demonstrated numerous tiny rounded, elevated, white-yellowish lesions distributed at the middle and lower esophagus.

### *Pathological diagnosis*

Histopathological examination identified numerous sebaceous glands were located in the lamina propria, revealed lobules of cells that showed characteristic sebaceous differentiation.

### *Treatment*

Because there were no esophageal symptoms or/and eating problems, the patient did not require endoscopic surgery or other treatment.

### *Term explanation*

A sebaceous cell of presumed ectodermal origin, in the esophageal mucosa, which is of endodermal origin, is of scientific interest. Different theories may explain the existence of this peculiarity by sebaceous gland metaplasia is the most plausible.

### *Experiences and lessons*

Sebaceous gland metaplasia tends to be found incidentally during autopsy or esophageal resection.

### *Peer review*

This is a well designed and well written case report which may be interesting for gastroenterologists and other clinicians.

## Abstract

Impaired motor and functional activity following stroke often has negative impacts on the patient, the family and society. The available rehabilitation programs for stroke patients are reviewed. Conventional rehabilitation strategies (Bobath, Brunnstrom, proprioception neuromuscular facilitation, motor relearning and function-based principles) are the mainstream tactics in clinical practices. Numerous advanced strategies for sensory-motor functional enhancement, including electrical stimulation, electromyographic biofeedback, constraint-induced movement therapy, robotics-aided systems, virtual reality, intermittent compression, partial body weight supported treadmill training and thermal stimulation, are being developed and incorporated into conventional rehabilitation programs. The concept of combining valuable rehabilitative procedures into "a training package", based on the patient's functional status during different recovery phases after stroke is proposed. Integrated sensorimotor rehabilitation programs with appropriate temporal arrangements might provide great functional benefits for stroke patients.

**Key words:** Stroke; Rehabilitation; Sensory stimulation; Thermal stimulation

**Core tip:** Rehabilitation strategies, including conventional interventions with an empirical basis and advanced interventions based on scientific evidence, are reviewed. The concept of a training package that is related to the severity of impairment and the phase of recovery from stroke is proposed to maximize the recovery of motor function after a stroke. The training package for therapists provides valuable suggestions for selecting from the available and suitable advanced rehabilitation methods as well as from the conventional rehabilitation methods.

## INTRODUCTION

Following stroke, more than half of the patients have moderate to severe deficits at admission, and their functional activities are often confined to the bedside or wheelchair[1,2]. The most commonly occurring deficits are hemiparesis, resulting in an immediate impairment to upper limb function[2-4], or the ability to stand, balance and walk[2,3,5]. These deficits not only limit the person's activities in the family and participation in society but pose a heavy physical burden on their relatives or caregivers[6]. Stroke patients recover their walking function to a certain degree after discharge from hospital. However, 50% or more of stroke patients are still frustrated by mild or severe deficits of their upper limb functions 6 mo post-

stroke[2-5]. Thus, facilitating the restoration of upper limb motor function and maximizing walking ability as early as possible after a stroke are generally priorities for stroke patients, their families and clinicians.

In the clinic, numerous rehabilitative approaches have been shown to promote functional motor recovery after stroke[7-14]. In general, repetitive sensory stimulation and mass motor or task practice facilitate neuroplasticity and brain reorganization in stroke patients, resulting in enhanced motor and functional recovery after stroke[13-17]. In this scenario, physical therapy that emphasizes sensory stimulation has gained increased prominence among modern rehabilitation strategies[13-16]. However, there has been no systematic review of sensorimotor rehabilitation programs according to the patient's status during different stroke rehabilitation phases (the acute, subacute and chronic phases). Due to the dynamic and complex process of stroke recovery (the patient's status and recovery phase)[10,11] and the methodological heterogeneity in various studies[7-10], it is difficult to draw a conclusion as to which programs are superior to others or which ones could be adopted for the entire rehabilitation process. In this article, we attempt to summarize all of the possible programs and introduce a schematic program that combines valuable treatments[9,11] into "a training package" to maximize the functional outcomes of stroke patients.

## CATEGORIZATION OF STROKE REHABILITATION PROGRAMS

Regarding physical therapy for stroke patients, the rehabilitative programs can be categorized into two main groups according to the theoretical backgrounds of the clinical trials[7-14]: conventional and advanced rehabilitation programs.

Conventional rehabilitation programs address the effectiveness of treatment approaches based on neurophysiological, motor control and learning, or strengthening and functional principles. These programs are often called traditional physiotherapeutic "schools"[7-9,13,14]. The present study considered conventional rehabilitation programs to be the regular or standard therapies applied in clinical stroke rehabilitation. Conventional rehabilitation strategies are mostly based on clinical experiences and observations[18-24]. They were developed early and are usually applied for routine rehabilitation in the clinic.

Advanced rehabilitation programs emphasize the effectiveness of specific interventions based on neuroscientific evidence[7-14]. Because stroke patients must receive a reasonable level of rehabilitation in the hospital, conventional rehabilitation strategies are generally employed in the clinic. There is concern over incorporating advanced rehabilitation strategies with conventional rehabilitation strategies in the hospital due to ethical issues. In particular, in the case of acute and subacute stroke patients, the assessment for advanced rehabilitation yields two groups: a conventional + advanced rehabilitation group *vs* a conventional rehabilitation group. Only a few studies in chronic stroke patients have directly compared the advanced treatment with "dose-matched" conventional rehabilitation.

## CONVENTIONAL REHABILITATION STRATEGIES

The conventional rehabilitation strategies for stroke include the Bobath (also called Neurodevelopmental Treatment)[14,18,19], Brunnstrom[20], proprioceptive neuromuscular facilitation (PNF)[21], motor relearning[22] and the functional or strengthening[7-9,13,14,23,24] approaches. Although these approaches are mostly based on empirical results rather than scientific evidence, they or their concepts are commonly adopted in clinical settings in the standard or routine rehabilitation programs for stroke patients to regain their motor functions[7-9,11-14].

In recent decades, several studies have shown the positive effects of these interventions on the recovery of motor functions after strokes[23-33]. Among these approaches, the Bobath treatment is widely used in Western countries[30-33]. Abnormal muscle tone and movement patterns, which generally lead to impaired postural control, are deemed the two major problems experienced by people with hemiplegia. Therefore, a major goal of the Bobath treatment[18,19] is to normalize the movement pattern and postural control (or tone) by handling the major joints of each body part of the patient, such as the neck, shoulder, hand, hip, knee and ankle. Recently, the Bobath treatment was re-defined as a problem-solving approach for the assessment and treatment of individuals with deficits in function, movement, and postural control caused by a central nervous system lesion. The goals in a given task are successfully met by identifying and analyzing problems in the movement components and the underlying impairments during functional activities and participation[19]. Incorporating appropriate inputs (visual, verbal, or tactile) also plays a vital role in Bobath training because the afferent inputs affect the motor performance[19]. The Bobath treatment should improve the efficiency of movement and generally facilitate the activities of everyday life.

The Brunnstrom approach[20] considers six hierarchical movement developmental stages, from flaccidity to normal movement-pattern control. The Brunnstrom treatment involves a reflex or limb synergistic movement, initially with cutaneous stimulation. Later, the appropriate inhibition of the synergy pattern and facilitation of the anti-synergy pattern are required to attain normal movement control and functional performance. Visual and somatic modalities are considered in the motor training using the Brunnstrom approach, which facilitates volitional movement and motor recovery for patients with moderate to severe strokes.

The PNF approach stresses stimulating proprioceptors in the muscles/joints of the affected limbs following stroke. The PNF procedures are often accompanied by verbal/visual and tactile feedback to facilitate muscle

**Table 1 Summary of conventional rehabilitation therapies with an emphasis on sensory inputs and outcomes**

| Treatment | Sensory inputs | Rationale | Sensory outcome | Result[1] |
|---|---|---|---|---|
| Bobath | Visual, verbal and tactile | Neurophysiology concept (emphasis on selective movement and postural control by key points of the body, with problem-solving training) | None | UL (-), LL (-) |
| Brunnstrom | Visual and cutaneous | Neurophysiology (an ordered, predictable, stepwise progression from initial flaccidity to stereotypical synergy and then to normal patterns of voluntary movements) | None | NA |
| PNF | Visual, tactile, verbal and proprioceptive | Neurophysiology concept (through the stimulation or relaxation of muscle groups combined with various sensory inputs in response to specific movement patterns to promote functional movement) | None | NA |
| Motor relearning | Visual, tactile and auditory | Neuropsychology (Active practice of context-specific motor task with well-designed motor and sensory components ) | None | NA [UL (-) and LL (-) motor control with 3 RCTs] |

[1]Obtained from meta-analyses or systematic reviews. PNF: Proprioceptive neuromuscular facilitation; -: Not better than the control group; LL: Lower limb; UL: Upper limb; NA: Not available; RCT: Randomized clinical trial.

contraction and motor control in terms of many techniques, such as joint approximation, traction, irradiation or overflow. Therapists rebuild the movement and function of the limbs rendered paretic due to strokes by guiding a specific movement pattern (diagonal or spiral direction) for concomitant muscle contractions with reversal, stabilization, repetition or combination techniques. The motor control or movement pattern facilitated by the therapist follows a sequence of static/dynamic and assistive-active-resistant progressions for regaining motor control and enhancing the muscle strength of the paretic limbs of stroke patients. Verbal and vision inputs are also basic facilitative procedures used in this approach[21]. The facilitated progression due to the PNF procedures follows a hierarchical process from mobility to stability, then controlled mobility to skillful movement.

The motor relearning technique[22] emphasizes the active practice of context-specific motor tasks in a structured environment with appropriate feedback, manual guiding or verbal commands. Through this well-designed learning program, stroke patients progressively learn to perform the task-oriented functional activities well. In general, the motor relearning technique consists of the following four steps: (1) analysis of the task; (2) practicing the missing components of the task; (3) practicing the entire task; and (4) transferring the training to perform the task. This technique requires the patient to first understand the kinematics and kinetics of normal movement and then the patients can use the kinetic knowledge to practice various dynamic characteristics of the movements necessary to complete a task. The motor relearning technique recruits a single or several inputs (visual, verbal, or auditory) within a training program.

The functional and strengthening approaches, which are based on theories regarding motor control and learning, consist of bed mobility, sitting, transfers, sit-to-stand and gait[7-9,13]. Clinically, the therapists target the impairments in the neuromuscular or musculoskeletal system following stroke and provide practice or an experience leading to changes in the capability of producing skilled action. To reduce impairments and facilitate functioning, the therapists encourage the patients to practice purposeful or functional movement and postural adjustment by selective allocation of muscle tension across joint segments[7-9,13].

The aforementioned rehabilitation strategies are often used in a clinical setting for stroke patients, but the scientific evidence regarding these conventional rehabilitation methods remains limited. The functional outcomes of the Bobath and motor relearning approaches[25-27] were not significantly different throughout a 4-year follow-up[27], but the motor relearning treatment is seemly preferred for shortening the length of hospitalization of stroke patients during the acute phase. No significant difference was found in the functional outcomes of stroke patients given the Bobath, PNF, Brunnstrom and/or strengthening treatments[24,28,29]. Although the Bobath technique is more popular in Western countries[30,31], recent reviews indicated that the Bobath technique is not superior to the other approaches in general, including the outcomes regarding the sensorimotor control of upper and lower limbs, dexterity, mobility, the activities of daily living or the health-related quality of life[31-33]. Interestingly, a mixture of treatments combining different approaches may be more beneficial than receiving no treatment or a placebo control for lower limb functionality and postural control after strokes[8].

Table 1 summarizes the characteristics of the sensory inputs and outcomes, theoretical basis, and the results of the four conventional rehabilitative strategies. Due to the methodological heterogeneity in previous studies and the lack of well-designed larger investigations, the ideal and favorable training strategies among these conventional treatments for stroke rehabilitation are yet to be determined[19-23].

## ADVANCED REHABILITATION STRATEGIES

Numerous advanced and novel rehabilitation treatments have been developed for patients in the acute, subacute or chronic phase of stroke, to facilitate and maximize their functional recovery[7-14]. Most of these techniques are

based on neuroscientific evidence rather than pragmatism. For instance, neuroplasticity and brain reorganization in patients with good functional recovery from strokes have been demonstrated using functional brain imaging or other advanced neuro-technologies[8-11,15,16]. Compared to conventional rehabilitation treatments, more high-quality clinical trials concerning the advanced rehabilitation strategies have been reported in recent decades. In this study, several advanced rehabilitation techniques and their enhanced results compared with those of conventional rehabilitation treatment are summarized below.

## ELECTRICAL STIMULATION

Electrical stimulation (ES) is a technique that was developed early and is widely applied to stroke rehabilitation as an adjunctive treatment[7-10,17,34-44]. Many aspects of ES, including transcutaneous electrical nerve stimulation (TENS)[34-38], functional electrical stimulation (FES) or neuromuscular electrical stimulation (NMES)[14-17,34,37-40,44], and electromyographic (EMG) biofeedback[41-43], have been used for different clinical purposes. TENS is generally applied for sensory stimulation (sensory threshold) or for selective muscle contraction (motor threshold) based on the patient's status[35-38]. In contrast, the intensities of the other three modalities are largely above the motor threshold[34,37-44]. ES primarily stimulates cutaneous receptors and proprioceptors and/or activates muscle contractions and joint movements, which can increase the cortical excitability of the somatosensory and/or motor areas. Long-lasting cortical plasticity occurs, accompanied by motor recovery, in stroke patients treated by ES[13-17,36]. ES is popularly used as an adjunct in clinical rehabilitations and has a positive effect on the range of motion, motor control, and muscle strength of the affected limbs and the gait speed of stroke patients[13-16,34-43]. The ES intensity with sensory threshold shows effects on motor outcomes[16,37]. In particular, ES combined with active training significantly improved the performance of both sensory and motor functions[34,36]. In addition, ES may also be beneficial in preventing secondary complications of stroke[39], such as shoulder pain, subluxation, spasticity and upper limb contracture.

The EMG biofeedback technique, another type of ES involving minimally active muscle contraction at the targeted joint, is also beneficial for the control of motor function or the muscle strength of the upper limb following stroke[41-43]. However, the EMG-triggered feedback causes little improvement in upper limb functionality[43]. The effect of the NMES with three periods of stimulation on the upper extremities of 66 stroke survivors with severe motor deficits was investigated[44]. However, the optimal effective parameters of ES are inconclusive[36,37]. The ES treatments used in all of the previous studies have been added to conventional rehabilitation programs to enhance motor-function recovery after a stroke[34-38,40-44].

## ROBOTIC-AIDED SYSTEMS

The most advantageous feature of robotic-aided system is that it reduces the physical effort of handling patients using computer-assisted devices. Because the system can automatically set the duration and intensity of the paretic limb movement using either passive or active assistance, robotic-aided therapy allows patients to train independently with no therapist or with a supervising therapist[45,46]. The device may provide different optimized movement patterns to help moderate to severe stroke patients regain their motor functions. However, a robotic-aided system requires that the distal part of the limb (hand or foot) be fixed on the handle bar or footplate of the device during training.

At least five types of robotic-aided systems have been developed for upper limb rehabilitation after a stroke, including the MIT-MANUS, the InMotion shoulder-elbow robot, the ARM Guide, the mirror-image motion enabler, and the bi-manu-track[45-50]. Generally, the exercise protocols of a robotic therapy system for upper limb rehabilitation after a stroke focus on shoulder and elbow movement patterns and fixing the hand (or fingers) in the robotic handle bar[44-48]. The system guides a patient's paretic hand on a support board in front of the patient and tracks the movement of the robotic handle to the target on the computer screen to attain a goal-directed movement through simultaneous visual, auditory, and proprioceptive feedback. Robotic-aided therapy has demonstrated advantages for motor recovery but did not affect the daily functions of stroke patients[46]. However, when directly compared with matched intensive conventional rehabilitative techniques, the robot-assisted therapy showed no additional benefit for moderate to severe arm impairment in subacute stroke patients[47].

The Lokomat and Gait Trainer were recently developed as robotic-gait machines for lower limb rehabilitation following stroke and are intended to relieve the strenuous efforts of the therapists[51-53]. Although their effects were not significantly different compared with those of a similar dosage of treadmill training[51] or conventional therapy[52], using the robotic-gait machine is a feasible treatment for lower limb and gait rehabilitation[51-53]. Robotic-gait therapy combined with conventional therapy is more effective for gait performance than conventional therapy alone in patients with subacute stroke who have greater motor impairment[53]. A similar phenomenon regarding better improvement has been reported for using robotic-gait therapy combined with FES treatment[54].

The use of a robotic-aided system for stroke rehabilitation is rapidly growing. Recently, robotic-aided therapy combined with individual arm therapy (IAT) using a motor relearning approach was as effective as double sessions of IAT in terms of the restoration of upper limb motor functions[47]. Robot-assisted therapy during the training phase is more convenient than conventional rehabilitation therapy. However, the cost of the devices is still prohibitive for the average clinic[52].

## PARTIAL BODY WEIGHT SUPPORTED TREADMILL TRAINING

Partial body weight supported treadmill training (PBWSTT)

involves using a treadmill with body-weight support provided by a harness that is connected to an overhead support system, with coincidental proprioceptive stimulation and visual inflow during stepping. PBWSTT is a method used to treat walking impairments post-stroke. PBWSTT has been used for more than 20 years and is beneficial for the walking function of stroke patients[55-60]. Initially, the stroke subjects in most of the previous PBWSTT studies were independent or partially independent walkers and many of the studies were conducted using chronic stroke patients[55-57]. These studies reported a good outcome after the application of the PBWSTT. In contrast, the outcomes of early severe stroke patients or even patients after a 6-mo follow-up compared with those given conventional rehabilitation training are controversial[57,58]. In a large long-term follow-up study, the effects of PBWSTT were not superior to progressive exercise at home that was managed by a physical therapist[59]. The use of PBWSTT for walking rehabilitation of stroke patients slightly improved the walking velocity and walking endurance but not significantly compared with the effects of conventional rehabilitation[60]. Moreover, two (or even three) therapists and a strenuous effort are generally required during PBWSTT therapy. Thus, these factors could limit clinical therapists from initiating walking training on the treadmill to moderate to severe stroke patients in the acute phase.

## VIRTUAL REALITY

Computerized virtual reality (VR), a type of human-computer interface technology, allows patients to interact with a multisensory simulated environment and to receive "real-time" feedback on their performance[61,62]. Visual and auditory feedback is crucial for instantaneous reactions to stimulation from the environment or the exercises. The feedback training incorporated with conventional rehabilitation treatment led to significant improvement of the upper arm functions of stroke patients[61,62].

VR applications can range from nonimmersive to fully immersive. Recently, a variety of nonimmersive video game systems developed by the entertainment industry have become available for home use. The home-based VR system is inexpensive and more accessible to clinicians and individuals. Among patients with acute strokes who were receiving conventional rehabilitation, the group receiving VR therapy using Wii games demonstrated better recovery of motor function than the recreational group[63]. Furthermore, VR therapy in conjunction with PBWSTT treatment is feasible and effective in improving patients' walking and balancing abilities post-stroke[64].

Although VR can enhance patients' motivation and compliance regarding rehabilitation and reduce their perception of exertion during activities, it is unable to replace actual sensory experiences, such as manipulating objects during normal daily activities. Sometimes, the VR system may cause symptoms of motion sickness, such as nausea, disorientation, dizziness, and headache, in a few patients during training[61]. A recent review[62] summarized the results of five randomized clinical trials (RCTs) and seven observational studies, concluding that large multicenter, well-designed randomized trials of VR therapy are required. However, the subjects enrolled in most VR studies have a moderate to mild status, which limits the apparatus to a selected group of stroke patients. The cost and complexity of VR devices and the supporting software may not be acceptable for all clinical centers.

## INTERMITTENT COMPRESSION

The intermittent compression technique is a neurophysiological treatment. This treatment involves the stimulation of cutaneous and proprioceptive receptors by repeated movements. Previous randomized control trials have shown its beneficial effects on the sensory and motor functions of stroke patients in the acute[65] or chronic[66] phase. A significant enhancement was observed in subjects even at the 5-year follow-up[67]. However, heretofore, no further investigations have been conducted.

## CONSTRAINT-INDUCED MOVEMENT THERAPY

Constraint-induced movement therapy (CIMT) is a revolutionary rehabilitation technique based on the "learned non-use" theory[68-73]. The concept of CIMT involves constraining the movements of the non-affected arm with a sling or mitten and forcing the paretic hand to practice using a task-orientated approach for most of the waking hours. Highly intensive and mass-repetitive practice using the affected arm is the major requirement for at least 2 wk of training. Two mechanisms underlying CIMT were proposed[71,73]: the "learned non-use" of the affected limb, which is often behaviorally reinforced, is reversed and the contralateral cortical area responsible for the movement of the affected limb is expanded due to repetitive forced use[69]. Although CIMT therapy has been proven to have a significant effect on the upper limb mobility following strokes[68-73], a minimal voluntary movement (wrist extension of at least 20 degrees and finger flexion of 10 degrees) at the beginning of treatment and during long-duration daily treatment is required for the application of this therapy. Thus, it is uncertain whether the CIMT approach is appropriate for patients with flaccidity or little volitional movement of their upper limbs during either the early or chronic phase of stroke and those with insufficient tolerance of the method. In the case of mild motor function in chronic stroke patients[71,73], CIMT therapy could act as a routine rehabilitation technique.

## THERMAL STIMULATION

Thermal stimulation (TS) was first developed using alternative hot and cold stimulation. TS combined with conventional rehabilitation methods has been demonstrated to facilitate upper-limb motor function in acute stroke patients[74]. TS causes greater activation of the brain areas

**Table 2 Comparison of the characteristics of sensory stimulation modalities and the rationales for recent advanced rehabilitation strategies and their outcomes**

| Treatment | Sensory modality | Rationale | Sensory outcome | Result[1] |
|---|---|---|---|---|
| Electrical stimulation | Proprioceptive and tactile | Neurophysiology/neuropsychology | Yes (+) | UL (+) for motor control, LL (+) for gait ability |
| Robotic therapy | Visual, auditory and proprioceptive | Neurophysiology/neuropsychology | None | UL (+) for motor control |
| Virtual reality | Visual and auditory | Neuropsychology | None | NA [UL (+/-) motor control with RCTs] |
| Intermittent compression | Tactile and proprioceptive | Neurophysiology | Yes (+) | NA [UL (+) motor control with RCTs] |
| CIMT | Visual and verbal | Neuropsychology | None | UL (+) |
| PBWSTT | Visual and proprioceptive | Neurophysiology/neuropsychology | None | LL (+) motor and gait function |
| Thermal stimulation | Hot and cold agent | Neurophysiology/neuropsychology | Yes (+) | NA [UL/LE (+) motor control with 5 RCTs] |

[1]Obtained from meta-analyses or systematic reviews. CIMT: Constraint-induced movement therapy; PBWSTT: Partial body weight-supported treadmill training; +: Positive effect; -: No better than the control group; LL: Lower limb; UL: Upper limb; NA: Not available; RCT: Randomized clinical trial.

involved in tactile or mechanical stimulation, as shown in functional brain imaging studies of healthy subjects[75,76]. In RCTs, TS significantly improved several aspects of the upper- and lower-limb outcomes of acute and subacute stroke patients[74,77-80] when combined with standard rehabilitation therapy. Comparable enhancement was also observed and maintained in the lower-limb outcomes at the 3-mo follow-up but disappeared at the 6-mo follow-up[79]. The use of TS in rehabilitation not only provides sensory stimulation but also deploys the forced-use strategy to provoke volitional/reflexive motor activity. Neural plasticity may be a reason for the effect of TS in stroke patients. TS can be a low-cost, practicable intervention using home-made materials, such as a water pack. Thus, TS can easily be established as a generally popular home-care therapy. Table 2 summarizes the characteristics of the stimulation modalities used in recent rehabilitation programs.

## A "TRAINING PACKAGE" CONCEPT FOR REAHBILITATION

Both conventional rehabilitation strategies and the recently developed advanced treatments mostly emphasized the motor functional outcomes and viewed various types of sensory stimulation (inputs) or feedback as crucial components in stroke rehabilitation[7,13-17,34-38,41-43,46,63,74]. A large number of robust large-scale studies of evidence-based treatments for stroke rehabilitation have been published in recent decades[7-11]. These studies provide evidence that advanced rehabilitation methods significantly enhance functional outcomes during particular phases of recovery from stroke. In addition to the significance of the advanced rehabilitation therapies, knowing the ideal and most powerful training strategies for recovery during the acute, subacute to chronic phases is very helpful to stroke patients and therapists. Before we describe the concept of an ideal training program (a training package), several perspectives need to be considered.

First, no clear evidence indicates that the recently developed rehabilitation therapy can replace any of the treatments based on physiotherapeutic "schools" that are generally viewed as the standard rehabilitation treatments for stroke. In general, most of the specific rehabilitation strategies have been adopted or added as supplementary methods by therapists to reinforce functional recovery after stroke. The significance of the advanced therapies, such as ES[37,38,42], robotic therapy[46], virtual reality therapy[62], PBWSTT[59,60], and CIMT[71,73], has been derived through meta-analysis of stroke patients in a particular phase. However, no large longitudinal study that integrated these advanced therapies to treat stroke patients throughout the entire rehabilitation process has been conducted.

Second, previous studies focused mostly on comparing the effect of specific treatments within a particular period following stroke, either in the acute/subacute or chronic phase. However, the progress of stroke recovery is dynamic and individualized, dependent on the nature of the injury, the patient's characteristics and other intrinsic or extrinsic factors[10,11]. Faced with the dynamic alteration of motor function, there is no evidence to support that any single intervention plays an important role in achieving the maximum benefit throughout an entire rehabilitation process, from acute to subacute to chronic status. Due to the diversity of the advanced treatments and the heterogeneous methodologies applied, previous meta-analyses or systematic review articles generally focused on the effect of a single specific treatment[9,14,36-38,42,46,60,62,71,73]. Thus, it is difficult to compare their performance in a time-related progression.

Third, very few studies have systematically evaluated the optimal intensity and/or duration of a specific intervention. Thus, it is unclear what the threshold of an effective "dose" of an intervention might be or how long an effective intervention should be applied. As a result, the intervention may cease before rehabilitation reaches a peak. Lastly, therapy in clinical practice is often provided for only a few weeks, generally 4 to 8 wk[9,14,31,36-38,42,46,60,62,73]. A therapy may fail to provide comprehensive progression in the intensity and task complexity because the optimal frequency and duration of treatment sessions are undetermined. Moreover, therapists often use the treatments either single or combined with other treatments in clinical practice according

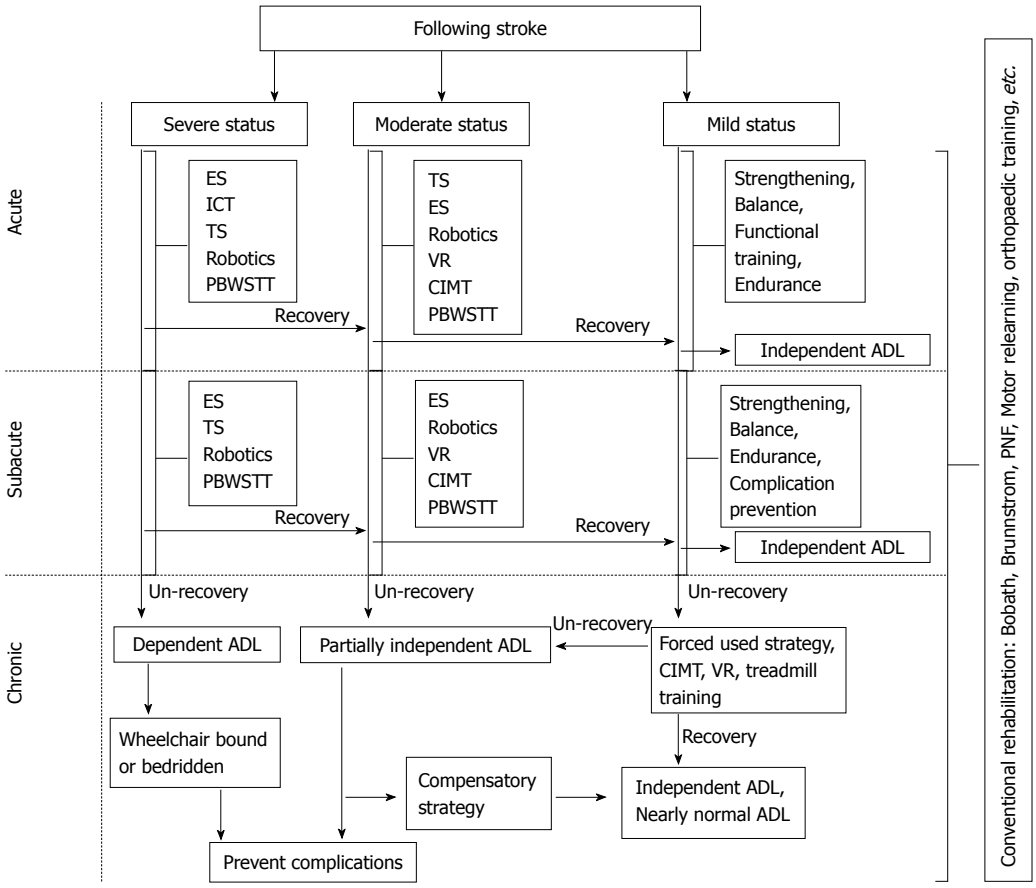

**Figure 1 Schematic flowchart for selecting from the available rehabilitation strategies for stroke patients with impairments of various severity levels during different stroke phases.** Functional recovery from a severe to moderate and mild condition after stroke is indicated by arrows with indications of the progression of recovery and unrecovery. Appropriate advanced rehabilitation technique(s) combined with conventional rehabilitation are selected to maximize the patient's functional recovery according to his/her initial motor function (mild, moderate or severe) in the clinic. ADLs: Activities of daily living; CIMT: Constraint induced movement therapy; ES: Electrical stimulation; PBWSTT: Partial body weight supported treadmill training; PNF: Proprioceptive neuromuscular facilitation; TS: Thermal stimulation.

to the patient's status and progress during the recovery phase. Therefore, customizing the available interventions during different recovery phases after stroke to meet the needs of the patient's current status to optimize the outcomes will be a major challenge for therapists.

A single or two rehabilitation approaches can be easily used in the clinic and home, and these strategies must be based on the individual's progression throughout the rehabilitation period. Combining valuable treatments is believed to be a good tactic for facilitating the restoration of functional mobility. It is generally believed that treatments could be given in a parallel or sequential way depending on the patient's recovery process and her/his functional status. Figure 1 shows a schematic diagram of the available techniques that are suggested for patients with different functional status during the three stroke phases. Based on the available evidence described above, the appropriate advanced intervention combined with a conventional rehabilitation treatment has been summarized for stroke patients with impairments of different severities. Functional progression is indicated by arrows in terms of the outcome, *i.e.*, recovery or unrecovery. The therapist can easily select the appropriate strategies to maximize the functional outcome of stroke patients.

For instance, if a patient shows little or no voluntary movement of the paretic limb (severe status) during the early poststroke stage, rehabilitation through task-oriented training is often difficult to apply[50-57]. Most of newly developed therapies, which require a minimal motor ability, cannot be utilized during the early phase of recovery of stroke patients[40,49-50,53-58]. ES[35-37], TS[74,78-79] and robotics-aided treatments[44,46,48] provide significant improvement in several aspects of motor or functional activities, particularly for those in the initial phase of recovery from moderate to severe strokes who show little or no voluntary movement. Thus, these techniques could be chosen to treat or activate motor activity in the paretic limbs. Until the patient' condition has progressed to a moderate or mild status, alternative interventions, such as VR, CIMT or PBWSTT, which combine strengthening and functional training strategies, can improve the outcome. From a practical perspective, the training package schematic shown in Figure 1 provides selective strategies for the initial phase of recovery to the subsequent recovery process for stroke patients with a different severity status. Although the various interventions are categorized according to the severity status, an optimal rehabilitation program (the ideal training package) can be individualized

and needs to be further investigated.

An appropriate protocol for a selected group of patients plays an important role in terms of cost-effectiveness, limiting the period of hospitalization and minimizing the labor of the therapist during the early phase of stroke recovery. For example, in terms of a "training package", when therapists need to decide the clinical plan for the upper limb rehabilitation of acute stroke patients with a moderate to severe status during the initial stage, the TS technique would be the choice that facilitates active movement cost-effectively as early as possible. When a certain degree of voluntary movement is elicited in the stroke patient, the therapist can apply other suitable techniques, such as CIMT or forced use with a task-oriented approach. Ideally, a protocol combining several rehabilitation strategies at the right time, as "a training package", could maximize the patient's progress during recovery. Although we propose a reasonable strategy for planning a rehabilitation roadmap based on the available evidence for a particular status of stroke, the ideal training package for the progression of a stroke patient remains to be determined.

## CONCLUSION

Rehabilitation is a long process for a stroke patient. How to choose the appropriate route(s) in a complex roadmap for stroke patients whose status differs during the phases of their recovery is always a great challenge to the clinician, patient and family. Conventional rehabilitation therapies (including the Bobath, PNF, motor relearning and Brunnstrom techniques, either singly or combined) are the regular or routine treatments applied in stroke rehabilitation units. Several advanced rehabilitation strategies with a strong evidence basis have been developed and are summarized here. According to the patient's mobility status and recovery phase, the appropriate advanced rehabilitation therapy combined with conventional rehabilitation treatment comprise a training package. This training package may provide suggestion for therapists to maximize the improvement of stroke patients in the right timeframe. To further validate the usefulness of the training package approach, longitudinal or serial studies of the outcomes of selected and combined therapies are important.

## Abstract

Borderline personality disorder, conversion disorder and obsessive compulsive disorder frequently have dissociative symptoms. The literature has demonstrated that the level of dissociation might be correlated with the severity of obsessive compulsive disorder (OCD) and that those not responding to treatment had high dissociative symptoms. The structured clinical interview for DSM-IV dissociative disorders, dissociation questionnaire, somatoform dissociation questionnaire and dissociative experiences scale can be used for screening dissociative symptoms and detecting dissociative disorders in patients with OCD. However, a history of neglect and abuse during childhood is linked to a risk factor in the pathogenesis of dissociative psychopathology in adults. The childhood trauma questionnaire-53 and childhood trauma questionnaire-40 can be used for this purpose. Clinicians should not fail to notice the hidden dissociative symptoms and childhood traumatic experiences in OCD cases with severe symptoms that are resistant to treatment. Symptom screening and diagnostic tools used for this purpose should be known. Knowing how to treat these pathologies in patients who are diagnosed with OCD can be crucial.

**Key words:** Dissociation; Obsessive compulsive disorder; Screening and diagnostic tools

**Core tip:** The literature has demonstrated that the level of dissociation might be correlated with the severity of obsessive compulsive disorder (OCD) and that those not responding to treatment had high dissociative symptoms. The structured clinical interview for DSM-IV dissociative disorders, dissociation questionnaire, somatoform dissociation questionnaire and dissociative experiences scale can be used for screening dissociative symptoms and detecting dissociative disorders in patients with OCD. However, a history of neglect and abuse during childhood is linked to a risk factor in the pathogenesis of dissociative psychopathology in adults. The childhood trauma questionnaire-53 and childhood trauma questionnaire-40 can be used for this purpose.

## INTRODUCTION

The term dissociation was used by James in 1890 from the translation of the French term *désagrégation* after it was described by Pierre Janet in 1889. Pierre Janet described dissociation as the deterioration in the unification of experiences at the mental level. These experiences consisted of perception, memory, cognition and emotions. Normally, these experiences all together constituted wholeness in the stream of mind[1,2]. Patients perceive dissociation as dispersion in the wholeness of sense of self. This

dispersion emerges as the deterioration in the unity of chronological, biographic and perceptive identity[2,3].

Dissociative disorders were first described as categorical independent nasographical cases in the Diagnostic and Statistical Manual of Mental Disorders (DMS-Ⅲ) which was published in 1980. Before that, they were among the phenomena associated with dissociative symptomatology hysteria[1,2].

According to DSM-IV-TR, dissociation is described as the deterioration in the integrative functions of consciousness, like the perception of memory, identity and environment. On the other hand, in the etiology of dissociation, traumatic experiences, especially like childhood abuse, take an important place[4,5]. Dissociation functions as the autohypnotic defense mechanism that provides the psychological wholeness of the individual against these traumas[6]. Dissociative disorders contain a group of clinical syndromes associated with the deterioration of one or more of these features described. Dissociation may have a sudden or gradual, temporary or chronic stream. Among the dissociative disorders, the type that has the most chronic and complex features and that contains all the other dissociative phenomena is the dissociative identity disorder. Other dissociative disorders are depersonalization disorder, dissociative amnesia and dissociative fugue disorder. On the other hand, the category that does not meet the specific diagnostic criteria is described as the dissociative disorder that cannot be named otherwise. According to some writers, in cases when the prevalence of dissociative disorders is used as a base for the DSM-Ⅳ diagnosis criteria in clinical practice, it cannot be estimated. These disorders may go unnoticed in clinical practice and it is thought that they are more widespread than estimated. Besides, there is no research based on large populations[2,3]. However, according to recent research, the frequency is estimated to be 5.6% to 10% in the general population[1]. Despite the fact that they are a separate diagnostic category on their own, dissociative symptoms can be observed together with almost all the psychiatric disorders. They can affect the clinical stream of the psychiatric disorders that they are found with[7]. Dissociative symptoms are frequently found with borderline personality disorder[8,9], conversion disorder[10] and obsessive compulsive disorder[11].

Obsessive compulsive disorder (OCD) is a disorder frequently encountered and its lifelong prevalence is between 1% and 3%[4]. OCD is an illness that generally has a chronic stream. This disorder is characterized by obsessions or compulsions, takes very much of the person's time and causes intense stress or affects the individual's personal life[12].

## DISSOCIATIVE PROCESSES AMONG PATIENTS WITH OBSESSIVE COMPULSIVE DISORDER

OCD is phenotypically very heterogeneous. This disease has several manifestations, with various dimensions regarding symptoms. In this study, 50 patients who had been diagnosed with OCD were investigated in terms of dissociative symptoms and the relationship of these with symptom dimensions of OCD. In general, dissociative scores were correlated with the level of severity of OCD. However, the controlling dimension was the parameter that was most closely correlated with dissociation. Amnesic dissociative symptoms were found to be correlated with controlling compulsive scores[11].

Rufer *et al*[13] evaluated 52 patients with the diagnosis of OCD. In this study, Cognitive Behavioral Therapy (CBT) was administered to patients for 9.5 wk on average and patients received exposure therapy. In this study group, a high level of dissociative symptoms was detected in patients who ceased treatment because of non compliance. In 43 patients who continued the treatment, however, those with severe OCD symptoms and not responding to the treatment had high dissociative symptoms. In this study, it was reported that high dissociative symptoms can be an indicator for poor response to CBT.

In a study where Belli *et al*[14] included 78 OCD cases, a significant relationship between severity of obsessive compulsive symptoms and dissociative symptom levels was detected. Dissociative disorder dual diagnoses were also investigated using SCID-D. The rate of having at least one dissociative disorder in study group was 14%. In this study, the most common dissociative disorder was depersonalization disorder, followed by dissociative amnesia and dissociative identity disorder. These diagnoses indicated that complicated dissociative disorders accompanied OCD considerably. In another study, Belli *et al*[15] found high levels of dissociative symptoms and a significant correlation between these symptoms and obsessive compulsive symptoms was noted. However, no significant relationship between dissociative symptoms and childhood traumatic experiences was detected.

Semiz *et al*[16] divided the patients into two groups in a study which included 120 OCD patients. Fifty-eight of these patients constituted the treatment-resistant group, whereas the treatment-responding group included 62 patients. The groups were compared to each other. The treatment-resistant group had a higher level of disease severity, dissociative symptoms and childhood traumas. The results of this study suggested that dissociative symptoms and childhood traumatic experiences can precede poor response to treatment.

In another study, Selvi *et al*[17] investigated 95 OCD patients from a different aspect. In this study, the relationship between possible dissociation, childhood trauma and cognitive processes in patients with OCD was investigated. It was found that dissociative symptomatology was strongly related to pathological processes that constituted OCD symptoms.

One of the most important methods for the treatment of OCD is Cognitive Behavioral Therapy (CBT). Pathological cognitive processes are looked for in the

formulation of treatment in OCD. However, no adequate response to CBT was reported in 30%-60% of cases. This also requires consideration of multifactorial intrapsychic structures that constitute OCD. The hypnotherapeutic approach that focuses on dissociative phenomena is one of the most important of these factors. Hypnotherapeutic approaches can also be used in the treatment of OCD[18]. It was reported that dissociative symptomatology can be a very important factor in not responding to treatment. This condition can involve not only treatment resistance to CBT, but also cases who do not adequately respond to medication[19]. However, the relationship between dissociative symptomatology with childhood traumatic experiences was well established. Hypnotherapeutic approaches can also be used in repairing the traumatic memory[20]. It is apparent that systematic studies are needed to measure the efficiency of hypnotherapeutic approaches in treatment resistant cases in regards to relevant dissociative pathology. Ego state therapy, a systematic approach in which hypnotic phenomena are used[21], can be beneficial in the treatment of complex conditions, such as the dissociative amnesia or dissociative identity disorder that accompany OCD.

## ASSESSMENT OF DISSOCIATION SYMPTOMS AND CHILDHOOD TRAUMATIC EXPERIENCES IN PATIENTS USING THE TOOLS AND SCALES

### *The structured clinical interview for DSM-IV dissociative disorders*

SCID-D is a semi-structured interview tool developed by Steinberg. It is used to explore and determine the dissociative disorders according to DSM-IV. By using this interview tool, dissociative identity disorder, depersonalization disorder, dissociative amnesia, dissociative fugue and the dissociative disorder diagnoses that cannot be named otherwise can be established. Because of the fact that the dissociative identity disorder diagnosis can meet the symptoms of all the other diagnosis categories, it is generally established on its own. If this diagnosis is established, then generally no other diagnoses are established[22].

### *Dissociation questionnaire*

This scale was developed by Svedin *et al*[23]. By using this scale, dissociative experiences are explored and the severity of these symptoms is evaluated. This scale can be used to explore the traumatic experiences of psychiatry patients and consists of 63 questions. Individuals mark the choices appropriate to them. Every heading is evaluated by a point between 1 and 5 and the average score is obtained by dividing the total points by 63[23].

### *The somatoform dissociation questionnaire*

This scale is a self-rating instrument that consists of 20 articles that patients themselves fill out, used in the exploration of somatoform symptoms of patients who have had traumatic experiences. Every heading is evaluated by a point between 1 and 5 and the average score is obtained by dividing the total points by 20. This scale was developed by Nijenhuis *et al*[24].

### *The dissociative experiences scale*

This scale is a psychological self-rating instrument that evaluates dissociative symptoms. The scale contains 28 questions, a general score and four sub scales. Every heading is evaluated by a point between 0 and 100 and the average score is obtained by dividing the total points by 28[25].

A history of neglect and abuse during childhood is linked to a risk factor in the pathogenesis of dissociative psychopathology in adults[5,26-29]. Dissociation is also linked to traumatic life events, especially childhood traumas[30]. Therefore, childhood traumas must be investigated when dissociative symptoms are found in patients with an OCD diagnosis. This could be very important in planning treatment and the following scales can be used for this purpose.

### *Childhood trauma questionnaire (CTQ-53)*

This is a self-rating scale developed by Bernstein *et al*[31] consisting of 53 questions. With this scale, childhood emotional, physical and sexual abuse and childhood physical and emotional neglect situations are evaluated. Points between 1 and 5 are given for all types of possible childhood traumas and the total of the points are derived from the total points of every childhood trauma between 5 and 25. The measurement also contains the minimization/denial scale that has three headings and is potentially out of the rating[31]. The 3 items comprising the minimization/denial scale are dichotomized (never = 0, all other responses = 1) and summed; a total of one (1) or greater "suggests the possible underreporting of maltreatment" false negatives.

### *Childhood trauma questionnaire (CTQ-40)*

This scale was developed by Bernstein *et al*[31]. It consists of 40 questions and every question has five choices. It is a self-rating scale that explores childhood traumatic experiences before the age of 18. The answers are composed of five choices. These answers are: never (1); rarely (2); sometimes (3); often (4); and very often (5). High scores reveal that abuse in adolescence and childhood took place very often. The total points are between 40 and 200[31].

## CONCLUSION

OCD is a disorder with high lifelong prevalence that can severely deteriorate the quality of life. Therefore, every aspect influencing the development and treatment of this disorder should be addressed seriously.

The individuals diagnosed with OCD can be evaluated in three categories in an etiological context. These dimensions can be classified as cognitive, biological and

emotional[32,33]. Some writers emphasize the importance of traumatic dissociative, existential and acquired developmental factors in the etiology of OCD of some patients in the emotional dimension. For many years, various treatments have been suggested for the treatment of OCD. It is frequently emphasized that cognitive behavioral therapy is one of the most effective treatment methods[34]. Some authors[20,35,36] indicated that the therapist should target the stress eugenic factors that are acquired in intrapsychic and developmental ways and that contain conflicts, existential traumas and dissociated pieces of personality in order for the OCD symptoms to be treated successfully. However, the relationship between dissociative symptomatology and childhood traumas has not been clearly defined. To a large extent, dissociation is especially related to childhood abuse[26,37]. Dissociation functions as the autohypnotic defense mechanism that provides the psychological wholeness of the individual against these traumas[4,5]. In addition to the cognitive behavioral model, different methods can also be used in the treatment of dissociative symptoms and chronic dissociative disorders. Some writers stated that ego state therapy and hypnotherapy can be effective on dissociative processes. In the ego state therapy, hypnotic phenomena are used as the basic technique. In this therapy method, it is thought that the self develops in a fragmented way and functions by becoming integrated. Childhood trauma and stresses can disrupt this integrity. During the therapy, these childhood experiences are concentrated on again in order to fix the disrupted integrity. It is apparent that systematic studies are needed to measure efficiency of hypnotherapeutic approaches in treatment resistant cases in regard to relevant dissociative pathology. Ego state therapy is a systematic approach in which hypnotic phenomena are used[20,21].

Investigating the dissociative symptoms, complex dissociative disorders and childhood traumas is very important in patients who are diagnosed with OCD. Clinicians should not fail to notice the hidden dissociative symptoms and childhood traumatic experiences in OCD cases with severe symptoms and resistant to treatment. Symptom screening scales and diagnostic tools used for this purpose should be known. To know how to treat these pathologies in patients who are diagnosed with OCD, particularly in cases with resistance to treatment, can be crucial.

OCD is a disease with high lifelong prevalence that can severely deteriorate the quality of life. The literature has demonstrated that the level of dissociation might be correlated with the severity of OCD and that those not responding to treatment had high dissociative symptoms.

It is important to know the scales that explore the dissociative symptoms and childhood experiences for patients diagnosed with OCD. Apart from that, the tools that serve to diagnose complex and chronic dissociative disorders can also help. More research that investigates the relationship between OCD and dissociative processes are needed. These studies need to have a large sample size that comprises both genders. As these studies increase, serious developments will take place in treatment plans.

## Abstract

Studies for prevalence and causal relationship established that addressing comorbidities of mental illnesses with medical disease will be another revolution in psychiatry. Increasing number of evidence shows that there is a bidirectional connection between mood disorders and some medical diseases. Glucocorticoid/insulin signal mechanisms and immunoenflammatory effector systems are junction points that show pathophysiology between bipolar disorder and general medical situations susceptible to stress. A subgroup of mood disorder patients are under risk of developing obesity and diabetes. Their habits and life styles, genetic predisposition and treatment options are parameters that define this subgroup. Medical disease in adults had a significant relationship to adverse life experiences in childhood. This illustrates that adverse experiences in childhood are related to adult disease by two basic etiologic mechanisms: (1) conventional risk factors that actually are compensatory behaviors, attempts at self-help through the use of agents and foods; and (2) the effects of chronic stress.

**Key words:** Obesity; Dyslipidemia; Hypertension; Diabetes; Childhood trauma; Mood disorder

**Core tip:** Psychiatric and medical diseases have a two-way relationship, and may have some effects on each other's clinical appearance and clinical course, treatment options and choices as they affect the possibility of keeping links to carry the etiologic causes. The lifespan of people with serious and chronic disorders, such as mood disorder, decrease by 30% because of untreated medical diseases.

## INTRODUCTION

Studies for prevalence and causal relationship established that addressing comorbidities of mental illnesses with medical disease will be another revolution in psychiatry[1]. There is a bidirectional relationship between psyche and soma, each influencing the other. Plausible biological explanations are appearing at an astonishing rate. Psychiatric comorbidity with many chronic physical disorders has remained neglected. Evidence base of prevalence and causal relationship of psychiatric comorbidities in these disorders has been highlighted and strategies to meet the challenge of comorbidity have been indicated.

In our study on 2000 outpatient population, prevalence of medical diseases in mental illnesses, temporal relationship between appearance of medical diseases and mental illnesses and, whether treatment of mental illness is suitable for medical condition were cross-sectionally analysed, the rate of calculated of third axis co-diagnosis were as follows; 56% for mood disorders (MD), 42.3% for anxiety disorders (AD), and 38.3% for schizophrenia (S)[2]. The rate of calculated of third axis co-diagnosis

were different between MD, AD and S as follows; hypertension 34.4%, diabetes 23.6%, thyroid disease 18.5%, coronary arteria disease 13% in MD, hypertension 42.4%, respiratory disease 30.7%, gastrointestinal disease 25%, autoimmune disease 7% in AD, hypertension 65.3%, diabetes 14%, respiratory disease 12%, gastrointestinal disease 8% in S. The time interval between the beginning of disease to from now was detected as follows 6.19 ± 7.55/7.12 ± 8.15, similar in mood disorders ($r$ = 0.912). Coefficient of correlation (r) were 0.265 and 0.425 for AD and S respectively (3.21 ± 3.15/8.34 ± 5.71 and 13.82 ± 11.36/8.21 ± 8.55). Our results revealed that MD and medical disease appeared simultaneously. The pharmacologically treatment of MD, AD and, S insuitable to the Ⅲ. Axis diagnosis and, found as high valuable mean in.

In bipolar disorder (BD), metabolic syndrome is more prevalent than general population. A subgroup of bipolar patients have higher risk of developing metabolic syndrome. Their habits, life styles, genetic susceptibility and choices of treatment are variables determining this subgroup, childhood trauma may be another variable. Metabolic syndrome has been reported at the rate of 35%-40% in bipolar patients. Metabolic syndrome encompasses obesity, diabetes, hypertension and dyslipidemia as cardiovascular risk factors. Although they are not among diagnostic criteria of metabolic syndrome, proinflammatory and prothrombotic state are considered in the framework of metabolic syndrome[3]. In our study, ICAM and VCAM levels measured at first manic episode were found to be higher than those found in subsequent remission period and healthy individuals. As our study group included only patients at first manic episode, there was no chronic effect of psychotropics use on these results. According to these results, probable cardiovascular disease (CVD) risk, reflected by increased ICAM and VCAM levels, is already present at the onset of the disease in bipolar patients[4].

Exploring the biological pathways that could account for the observed link show that dysregulated inflammatory background could be a common factor underlying metabolic syndrome and MD. Comorbid medical illnesses in bipolar disorder might be viewed not only as the consequence of health behaviors and of psychotropic medications, but rather as an early manifestation of a multi-systemic disorder[5]. It is also necessary to look for subgroups of MD based on their rates of comorbid disorders.

Psychiatric and medical diseases have a two-way relationship, and may have some effects on each other's clinical appearance and clinical course, treatment options and choices as they affect the possibility of keeping links to carry the etiologic causes. The lifespan of people with serious and chronic disorders, such as mood disorder, decrease by 30% because of untreated medical diseases[6]. Obesity and diabetes are most common metabolic disease, related hypertension, dyslipidemia and cardiovascular disease.

## OBESITY

Obesity is a leading cause of preventable death and the prevalence of overweight and obesity is increasing. A survey of 4.115 adult conducted in 1999 and 2000 as part of the National Health and Nutrition Examination Survey found that 64.5% of the population is overweight and 30.5% is obese[7]. A separate, smaller study of 50 bipolar patients, found an obesity rate that was only slightly higher (32%)[8]. In this study, most of the weight gain occurred during acute rather than maintenance treatment, and the increase in body mass index (BMI) was related to severity of depressive episode. Although several studies have found significant obesity in bipolar patients[9]. It is difficult to ascertain the degree to which the obesity is secondary to medications used to treat bipolar disorder or to the illness perse[10]. In our study rate of overweight was 62% and obesity 8% of the first episode manic patients[11]. Longitudinal studies of children and adolescents have found a positive association of major depressive disorder with adult BMI. This association persisted even after controlling for age, gender, substance abuse, socioeconomic level and medication exposure[12].

Atypical antipsychotic medications are associated specifically with central obesity, which occurs when the main deposits of body fat are localized around abdomen. Accumulating evidence suggests that central deposition of body fat is a risk factor independent of overall obesity for mortality due to cardiovascular disease and type Ⅱ diabetes[13]. In our study BMI was predictive variable of the diabetes in first episode mania[11]. Other medications used the treatment affective disorders, including lithium, valproate, and some antidepressants, have also associated with weight gain. Thus far, there has been less concern regarding the development of metabolic syndrome with this drugs than with the atypical antipsychotics.

Beyond weight gain caused medications, symptoms of depressive episode itself can lead to obesity. Depressed mood leads to lower levels of activity. Depressive episodes with atypical features such as hyperphagia, hypersomnia, leaden paralysis and carbohydrate craving are more liable to lead to weight gain. In the majority of bipolar patients, however, depressive symptoms are far more frequent than manic symptoms[14]. Depression is often accompanied by hypercortisolemia, which is also associated with central obesity. Even in the context of normal body weight, hypercortisolemia has been associated with excess visceral fat deposition as measured by computed tomography scan[15]. A national survey of 40.086 adults examined the relationship between body weight was associated with major depression and suicidal ideation and suicide attempts[16].

## DIABETES

Because overweight and obesity are associated with diabetes, many risk factors that have been linked to weight gain apply also to the development of diabetes. The prevalence of reported diabetes mellitus was found to be approximately three times higher in a sample of 345 hospitalized bipolar patients than in the general population (3.4%)[17]. Patients in this sample also had a more severe

course of their mood disorders such as rapid cycling and chronic course[18]. In a recent work which takes its sampling from the society, the ratio of present diabetes diagnosis among bipolar diagnosed cases is found to be higher than healthy individuals (10.8%)[19].

A subgroup of bipolar disorder patients are under risk of developing diabetes[9]. Their habits and life styles, genetic predisposition and treatment options are parameters that define this sub-group[12]. Metabolic syndrome and glucose abnormalities are reported between 18% and 30% in bipolar cases[18]. Among these, 7% are diabetes, while 23 % are pre-diabetes abnormalities.

Besides, the level of HbA1c in nonmedicated bipolar cases was found to be higher than the healthy controls[20]. In another similar study, hyperglycemia was found to be 43.5% in bipolar patients evaluated at the beginning of acute episode treatment[21]. According to the same study, 4.3% of the patients are under antidiabetic treatment. In a study of cases that exhibit violent (homicidal) behavior conducted by Langevin *et al*[22], it was reported that diabetes prevalence was found higher in the sampling group, and more importantly, diabetes diagnosis was missed out in more than 25% of the cases[22]. In the same group it was stated that manic and psychotic findings were found often and especially among the younger cases, injury crime was not rare.

In our study, DM diagnosis was determined as 18% among first manic episode bipolar cases. When evaluated with glucose metabolism abnormalities, this ratio becomes 64%[11]. In late onset bipolar cases evaluating cases aged over 50, 42% of cases have manic episode diagnosis related to general medical condition. In general medical conditions, the ratio of diabetes is 50%[12].

Dysregulation of the hypothalamic-pituitary-adrenocortical axis occurs frequently in patients with mood disorders. Hypercortisolemia associated with depressive states can lead to insulin resistance. Elevated levels of cortisol can lead to decreased insulin receptor sensitivity through currently unknown mechanisms[14].

A more hypothetical link between bipolar disorder and diabetes relates to intracellular signal transduction involving the enzyme glycogen synthase kinase-3-beta (GSK-3β). Glycogen synthetase kinase (GSK3) is a serine/threonine kinase that is a responsible enzyme from the cyclic mechanisms of the cell, gene expression, oncogenesis and neuronal protection[23]. Hippocampal volume and BDNF level decrease in diabetes[7]. Animal studies show that in diabetes-related depression, neurogenesis is inhibited in dentate gyrus[24].

Alterations in GSK-3β functioning play role in insulin resistance. Insulin inhibits GSK-3β which result enhanced glucose transport into skeletal muscle. Insulin mediated inhibition of GSK-3β leads as well to increased glucose utilization and the production of glycogen[25]. GSK-3β is also one of targets for lithium action. Lithium significantly inhibits brain GSK-3β at concentrations relevant fort he treatment bipolar disorder. Disturbances in the GSK-3β signal transduction pathway associated with diabetes may affect the viability of neurons that play a role in mood stabilisation. Diminished insulin mediated inhibition of GSK-3β may have an effect opposite to that of lithium and may ultimately lead to an accentuation of psychiatric symptoms related to bipolar disorder. Besides, in a clinical study intranasal insulin was found to be more effective than placebo on cognitive distortion in unipolar and bipolar euthymic cases[26].

When patients with diabetes are being treated, lithium should be used with care. Patients with juvenil onset insulin dependent diabetes are susceptible to diabetic nephropathy, and the risk is increased by the presence of hypertension. On the other hand, there is evidence that when lithium is combined with an oral antidiabetics or insulin, it has an assisting hypoglycemic effect in diabetic patients[27]. Lithium increases the sensitivity of glucose transport and metabolism in skeletal muscle and adiposytes. This effects similar to the effects of exercise.

In our study, free T4 levels have been found higher in diabetic first episode manic patients than nondiabetic first episode manic patients[11]. Thyroid Releasing Hormone (TRH -which is an endogen like antidepressant neuropeptide-) decreases the expression of GSK3-β[28]. GSK3-β activity, which increases in the manic phase of bipolar disorder, may be causing the reactive increase of free T4 by suppressing TRH.

In diabetic bipolar cases, triglyceride and cholesterol levels and BMI are determined as higher[11]. Triglyceride level and BMI are predictors in third and fourth order in regression analysis. When diabetes is in question, these findings are not a surprise, such that diabetes development is together with lipid metabolism abnormalities[10]. Also in our study, there is a correlation between triglyceride levels with fasting blood glucose and blood glucose level at the first hour of oral glucose tolerance test[11]. There is a stronger correlation between BMI with fasting blood glucose and HbA1c. In a recent work, the prevalence of obesity among bipolar cases was reported as 39.1%[29]. In the same study, high BMI, chronic course, longer disease period, lower functionality scores are shown to be comorbid with prevalent anxiety disorder, hypertension, diabetes and other diseases frequently. Additionally, in cases that show remission with lithium, BMI was found lower. In bipolar cases evaluated by Kim *et al*[21] at the beginning of acute period treatment, the ratio of hyperglycemia was determined as 43.5%. In the same study, 4.3% of the cases are under antidiabetic treatment, while 1.1 % of the cases are under anticholesterolemic treatment. There is hypercholesterolemia in 20.7% of the cases and obesity in 30.4% of the cases. All these findings should be considered as to question if the bipolar disorder itself acts like metabolic syndrome.

Increasing number of evidence shows that there is a bidirectional connection between mood disorders and some medical diseases[30]. Glucocorticoid/insulin signal mechanisms and immunoinflammatory effector systems are junction points that show pathophysiology between bipolar disorder and general medical situations

susceptible to stress[7]. In BD, the changes in brain energy metabolism and brain glucose metabolism may be important in BD pathophysiology[31]. Noradrenalin (NA), a signal molecule in the central nervous system, which has etiologic importance for many diseases is an important neurotransmitter in BD etiology[32]. High noradrenergic tonus, which is determined mostly genetically, may develop susceptibility for more than one medical and mental diseases in a wide spectrum for many people. So that, hypertension, progressive weight gaining, diabetes and mania are all conditions in which noradrenergic tonus increases. Since 1987, the prevalence of hypertension has been reported to be elevated (14%) in bipolar patients, compared to normal population (5.6%) and to unipolar depression (5%)[5]. This was replicated in several studies in USA and in Europe. While the largest study involving 25339 bipolar patients and 113698 controls found an increased rate of new-onset cases of hypertension among bipolar patients compared to general population and to schizophrenic cases.

Impaired fatty acid and phospholipid metabolism may be a primary cause of depression in many patients and may explain the interactions with other diseases. Postmortem analysis of brains of bipolar patients revealed that in orbitofrontal cortex of those subjects reduced DHC levels were detected due to elevated saturated fatty acids and arachydonic acid metabolism[31]. In manic patients both DHA and arachydonic acids levels were increased[33]. The same fatty acids and phospholipid mediated disruption of secondary messaging systems in BD is also operative in diabetes and vascular disease[34].

Hepatic steatosis, is more frequent among people with diabetes and obesity, and is almost universally present amongst morbidly obese diabetic patients. the links between hypercortisolism and obesity/metabolic syndrome, they hypothesize that this low prevalence of fat accumulation in the liver of patients with Cushing' s syndrome could result from the inhibition of the so-called low-grade chronic-inflammation, mainly mediated by interleukin 6, due to an excess of cortisol, a hormone characterized by an anti-inflammatory effect[35]. Moreover, insulin resistance is associated with lower serotonin levels. Visceral obesity, strictly linked to hepatic steatosis is specifically associated with mild to severe somatic affective-depressive symptom clusters. Previous data support the view that depression involves serotonergic systems, reflecting low levels of urinary 5- hydroxy-3-indoleacetic acid (5-HIAA). In Tarantino *et al*'s study[36], among metabolic indices, cholesterol, HDL-cholesterol, triglycerides and uric acid were not able to predict urinary concentrations of 5-HIAA, which were not associated with hepatic steatosis; vice versa, ferritin levels, and mainly HOMA values, were independent predictors of the urinary excretion of 5-HIAA. Dystimia/depression severity was negatively predicted by urinary 5-HIAA levels in the sense that the highest BDI values were forecast by the lowest values of urinary 5-HIAA. The importance of measuring the 24-h urinary excretion of 5-HIAA in follow-ups could rely on a method simultaneously mirroring the well-being status, the adherence to physical activity, which leads to improved insulin sensitivity, and the eating habits acquired by dystimic/depressed overweight/obese patients. In contrast, the significance of the urinary 5-HIAA is reduced in evaluating the severity of hepatic steatosis, likely because it is a structured process.

Recently, an increasing number of susceptibility variants have been identified for complex diseases. Somatic gene conversion and deletion were shown for BD, coronary arterial disease, rheumatoid arthritis, Chron's disease, hypertension and diabetes[37]. In a study of Lehne *et al*[38], comorbidity is mentioned between BD, Chron's disease and diabetes. At the same time, the concern of "missing heritability" has also emerged. There is however no unified way to assess the heritability explained by individual genetic variants for binary outcomes. A systemic and quantitative assessment of the degree of "missing heritability" for complex diseases is lacking. The diseases under evaluation included Alzheimer's disease, bipolar disorder, breast cancer, coronary artery disease, Crohn's disease, prostate cancer, schizophrenia, systemic lupus erythematosus (SLE), type 1 diabetes and type 2 diabetes[39]. The median total variance explained across the 10 diseases was 9.81%, while the median variance explained per associated SNP was around 0.25%. These results evaluated according to environmental impact assessment. This is because methylations and demethylations of DNA continue in primordial germ cells during of development within the terms of epigenetic principles. In fact, a substantial proportion of heritability remains unexplained for the diseases.

## CONCLUSION

Medical disease in adults had a significant relationship to adverse life experiences in childhood (ACE). Examples of the links between childhood experience and adult biomedical disease are the relationship of ACE score to obesity, diabetes, coronary artery disease chronic obstructive pulmonary disease and autoimmune disease[40]. This illustrates that adverse experiences in childhood are related to adult disease by two basic etiologic mechanisms: (1) conventional risk factors that actually are compensatory behaviors, attempts at self-help through the use of agents and foods; (2) the effects of chronic stress as mediated through the mechanisms of chronic hypercortisolemia, proinflammatory cytokines and other stress responses on the developing brain and body systems, dysregulation of the stress response and pathophysiological mechanisms yet to be discovered. There is some biological correlates for adverse life experiences of childhood in bipolar patients. Early menarche and EEG abnormalities are some of them[41-43].

Individuals reporting a history of any childhood adversity had higher systolic and diastolic blood pressure[44]. Among subjects with a history of sexual abuse, a significant proportion met criteria for obesity, a trend

toward overweight was found for subjects with a history of physical abuse, although this relationship did not remain significant after adjusting for potential confounders. There was no statistically significant difference in the overall rate of dyslipidemia and/or metabolic syndrome between subjects with and without childhood adversity. The results herein provide preliminary evidence suggesting that childhood adversity is associated with metabolic syndrome components in individuals with mood disorders. An association between stressful events and episode recurrences has repeatedly been found in bipolar patients[45].

Psychological stress also may activate inflammatory responses in the brain[46]. The theoretical model frames the depressive episode as being a repair response to stress induced neuronal microdamage that can grade into a chronic neuroinflammatory condition. Cardiovascular damage and atherogenic changes could be a by-product of this process. One of the mechanisms whereby psychosocial stress influences both peripheral and central inflammatory cascade, is coordinated by autonomic nervous system. Thus, the release of noradrenaline and adrenaline follows the activation of the sympathetic system and induces the activation of both alpha and beta adrenoreceptors on immune cells thereby initiating the release of pro-inflammatory cytokines *via* the nuclear factor-kappa-beta cascade[47]. The brain is now known to be directly influenced by peripherally derived cytokines and gluco-corticoids as well as immune cells, which can access the brain through leaky blood-brain barrier and/or by activation of endothelial cells that line the cerebral vasculature, or bind to cytokine receptors[48].

A public health paradox is implicit in these observations. One sees that certain common public health problems, while being often also unconscious attempted solutions to major life problems, harken back to the developmental years. The idea of the problem being a solution, while understandably disturbing to many, is certainly in keeping with the fact that opposing forces routinely coexist in biological systems. Clinical evidence suggests that metabolism and emotion homeostasis might share common mechanisms.

## Abstract

Both pseudocyesis and delusional pregnancy are said to be rare syndromes, but are reported frequently in developing countries. A distinction has been made between the two syndromes, but the line of demarcation is blurred. The aim of this paper is to review recent cases of pseudocyesis/delusional pregnancy in order to learn more about biopsychosocial antecedents. The recent world literature (2000-2014) on this subject (women only) was reviewed, making no distinction between pseudocyesis and delusional pregnancy. Eighty case histories were found, most of them originating in developing countries. Fifty patients had been given a diagnosis of psychosis, although criteria for making the diagnosis were not always clear. The psychological antecedents included ambivalence about pregnancy, relationship issues, and loss. Very frequently, pseudocyesis/delusional pregnancy occurred when a married couple was infertile and living in a pronatalist society. The infertility was attributed to the woman, which resulted in her experiencing substantial distress and discrimination. When antipsychotic medication was used to treat psychotic symptoms in these women, it led to high prolactin levels and apparent manifestations of pregnancy, such as amenorrhea and galactorrhea, thus reinforcing a false conviction of pregnancy. Developing the erroneous belief that one is pregnant is an understandable process, making the delusion of pregnancy a useful template against which to study the evolution of other, less explicable delusions.

**Key words:** Pseudocyesis; Delusional pregnancy; Infertility; Prolactin; Delusion

**Core tip:** It is usually impossible to distinguish between pseudocyesis and delusional pregnancy. Both occur primarily in developing countries, and especially where there is strong familial and cultural pressure on women to be fertile. The delusion starts in a climate of apprehension and develops when sensory perceptions are interpreted as signifying pregnancy, despite evidence to the contrary. Understanding this delusion can help to understand other, more unusual false beliefs.

Seeman MV. Pseudocyesis, delusional pregnancy, and psychosis: The birth of a delusion. *World J Clin Cases* 2014; 2(8): 338-344 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/338.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.338

## INTRODUCTION

It is not uncommon for women to believe that they are pregnant when they are not. In jest this has been called "jestation". But it ceases being a jest when the preoccupation with pregnancy becomes an over-valued idea or a delusion. In women suffering from psychosis, delusional pregnancy is not uncommon, especially since the advent of antipsychotic medications, which, by virtue of inhibiting dopamine secretion, raise prolactin levels to produce amenorrhea, breast swelling/tenderness, and ga-

lactorrhea-akin to the somatic experience of pregnancy[1]. Moreover, antipsychotic drugs are associated with considerable weight gain, distending the abdomen and adding to a misperception of pregnancy. Even when there has been no prior sexual activity, fantasy-prone women can find ways of convincing themselves that they are pregnant. They imagine the implantation occurring by magic or through the wizardry of advanced reproductive technology. Such was the case of a 17-year-old girl reported by Manoj[2], who believed she was carrying a "test tube baby". Cruzado describes a further case where the imagined pregnancy was a product of "artificial insemination" and two more cases where impregnation was believed to have occurred *via* telepathy[3].

Another example was a patient (now deceased) who attended the Women's Clinic for Psychosis in Toronto, Canada[4].

## CASE ILLUSTRATION

AC, a single 60-year-old woman, suffered from schizophrenia since age 16. After several inpatient admissions, she was being treated with depot antipsychotic medication, and was living independently, never completely free, however, of auditory, olfactory, and somatic hallucinations, nor of delusional thinking. At different times in her life AC developed romantic fantasies about men she met, her latest fantasy involving her psychiatrist, Dr. J. She knew Dr. J. was a married man but allusions to him on TV convinced her that he reciprocated her interest. After she watched a wedding on TV, she was persuaded that she and Dr. J. were secretly married. She began wearing a wedding ring and to believe that she was pregnant.

When asked how she could be pregnant since she had never had sexual relations, she stated that the depot injection she received monthly (prescribed by Dr. J.) had successfully implanted Dr. J.'s seed in her body and that she would soon be giving birth to his child.

A distinction has been drawn between pseudocyesis, where signs of pregnancy are demonstrably present (abdominal swelling, menstrual disturbance, spotting, the report of quickening, breast tenderness and engorgement, weight gain, galactorrhea) and delusions of pregnancy, where there may be cessation of menstrual periods and abdominal distension, but no other outward signs[5]. The first is said to be a somatoform disorder while the second is a symptom of psychosis[6]. More recently, however, with the growing recognition that elevated prolactin levels can lead to many of the signs of pregnancy, the two conditions (pseudocyesis and delusional pregnancy) are conceptualized as occurring on a continuum, sometimes in women with no prior or subsequent psychiatric history, sometimes in the midst of a depressive or related illness, sometimes in women suffering from ongoing psychotic illness[3,7]. What has been written about pseudocyesis applies equally well to the psychodynamics of delusional pregnancy. It may also apply to a range of related delusions centering around procreation[8,9], from the conviction of having an intimate partner (when none in fact exists), of being pregnant (when one is demonstrably not), of not being pregnant when one indeed is[10], of wrongly insisting, when in pain for other reasons, that one is undergoing labor and delivery[11], to the false idea of being a parent, a potentially dangerous delusion that has been known to lead to the kidnapping of other people's children[12].

In an effort to better understand the birth of delusions in general, the aim of this review is to focus on psychological, biological, and sociocultural antecedents as described in modern case reports of pseudocyesis.

The pertinent literature (Google Scholar, Pub Med databases) after the year 2000 was searched with the following terms: pseudocyesis, delusion of pregnancy, false/imaginary/phantom/pseudo/spurious pregnancy. All languages were included. Delusional pregnancy occurring in men or in species other than human was excluded. All the papers consisted of case reports except two[7,13], which used case control study designs.

## EPIDEMIOLOGY

The case of AC described above from the Women with Psychosis Clinic is the 80$^{th}$ instance of delusional pregnancy/pseudocyesis reported since 2000, the 50$^{th}$ in whom the delusion emerged in the context of a prior psychotic illness. Although diagnosis is not always clear in the published reports, this suggests that, in most cases described in recent years, the affected women suffer from a concomitant psychotic illness. In the past, pseudocyesis has been reported as rare but, in developing countries, India[14] or sub-Saharan Africa[15], it is considered fairly common. It has a reported occurrence rate in Africa of 1 in every 344 pregnancies[16]. Over a period of 5 years, of 486 women with abdominal distension in Ghana who came for sonography thinking they might be pregnant, three were diagnosed with pseudocyesis (of the others, almost half had fibroids, 10% had a benign ovarian tumor, 10% had cancer of the cervix with ascites; about 7% suffered only from obesity)[17]. In Nigeria[18], five out of 242 women who came for sonography for gynecological complaints referable to the lower abdomen were diagnosed with pseudocyesis. Out of 3200 women presenting for infertility treatment in a teaching hospital in Sudan over a five-year period, 20 were diagnosed with pseudocyesis[19].

Though once said to occur only 1-6 times per 22000 births in the West[20], Moselhy *et al*[21] reported in 2000 that they ascertained three cases in a six month period on an acute psychiatric ward in Birmingham, United Kingdom.

The majority of cases of pseudocyesis are described in reproductive age women and 80% of the affected women are said to be married.

## PHENOMENOLOGY

Delusional pregnancy can present as a monothematic de-

lusion[22,23] or, more commonly, in association with other delusions (polythematic delusions). Delusional pregnancy has presented in conjunction with Clerambeault's syndrome, as in the case of AC, or with Capgras syndrome[24]. It can present as a form of couvade syndrome, a "copy cat pregnancy" when a loved (and/or envied) intimate becomes pregnant[25-27]. It can be transient or long lasting, corrigible (or not) by demonstrated evidence, education, cognitive behavioral therapy, or psychopharmaceutical agents. It can be primary or appear in the context of medical conditions that cause abdominal distension such as fibroids[28], urinary retention[29], polydipsia[30], metabolic syndrome[31], tubal cyst[32] or abdominal pain such as cholecystitis[11]. Sonographs have picked up a number of additional potential causes of abdominal distension that can accompany pseudocyesis[33], such as abdominal neoplasm or enlarged liver. Neurological conditions can be associated with this delusion as, for instance, frontotemporal lobar degeneration[34,35]. Endocrine disturbance such as hypothyroidism can present as pseudocyesis[27]. It has been associated with the postpartum state[36], with premature menopause[37] and with high progesterone levels[38]. Most especially, pseudocyesis has been tied to hyperprolactinemia because elevated prolactin levels lead to many of the symptoms of pregnancy[1]. Hyperprolactinemia can result from psychological stress, especially the stress that accompanies a psychotic episode, independent of antipsychotic medication[39]. Prolactin levels can be raised by many organic conditions and by nipple stimulation as well as by drugs such as estrogens, antidepressants, antihypertensives, protease inhibitors, opiates, benzodiazepines, cimetidine, and dopamine blockers[40].

Antipsychotic drugs are all dopamine blockers and all raise prolactin level to some degree, some more than others, in a dose dependent fashion[41]. This means that women suffering from psychosis who are being treated with these agents often perceive body changes that they may associate with pregnancy[1]. This has been reported in several of the cases published since 2000[42-47]. Ahuja and Moorehead[13] describe six cases of pseudocyesis. Four of the six had been pregnant before and likened their current experience of high prolactin levels to the feeling they had during past pregnancies. In all six of these patients, the ideas/delusions of pregnancy disappeared soon after a change to a relatively prolactin-sparing antipsychotic.

Patient attributions-reasons given when confronted with the fact that blood tests and sonography were negative despite their own certainty that they were pregnant-vary according to cultural tradition and degree of patient education or sophistication. Absence of a fetus on sonography was explained by one patient by the probability that the fetus had migrated from her uterus to her back where he/she was hidden from view by bone and muscle[32]. A patient described by El Ouazzani[30] who had had six separate episodes of delusional pregnancy explained the pregnancies and the failure to confirm on possession by the devil. One of Dalfallah's patients[19], one of three wives in a polygamous marriage, attributed both her original infertility and her current "invisible" pregnancy to the envy of her husband's other wives and the witchcraft they exerted. Ruzanna and Marhani's patient[48] explained the apparent "loss" of her pregnancy by calling upon the Malay tradition of orang bunian, evil spirits taking possession of developing fetuses.

## PSYCHOLOGICAL ANTECEDENTS

According to both Koic[49] and Ibekwe[15], pseudopregnancy always occurs in the context of a simultaneous wish and fear of pregnancy, *e.g.*, emotional conflict, stress, and ambivalence. It should be noted, as an aside, that anticipation and fear will substantially raise prolactin levels in many women, thus mimicking signs of pregnancy[50]. When there is pressure to conceive and simultaneous fear of pregnancy, the ground is laid for this form of delusion. Ambivalence may arise when a pregnancy, though unwanted, is seen as a possible means of recapturing a wayward lover, as illustrated in the case of the 15-year-old girl reported by Skrabic[51]. For women who live in societies where womanhood is defined by motherhood, as described in Dafallah[19], pregnancy, however problematic the circumstances, may still be wished for. In societies where women are rated by the number of their sons[14], a woman with only daughters will zealously pursue pregnancy, but ambivalently, fearing the birth of another girl. Simon[36] describe pseudocyesis among the Roma in rural Hungary where there is strong social pressure to become pregnant as soon as possible after marriage. At the same time, there is a high rate of maternal death during labor and delivery, making women ambivalent about pregnancy.

It was impossible to ascertain, in most of the case histories, whether the women described were infertile. Infertility, whether due to lack of a partner, menopause, gynecologic problems, prior sterilization, or concomitant illness, heightens the wish for pregnancy, while its very impossibility can fuel magical fantasies[15]. The timing of emergence of the delusion often coincides with the early stages of menopause[5,30,49,52,53], inferring that infertility plays a triggering role. Sometimes the timing suggests that the delusional pregnancy serves to compensate not only for the loss of fertility, but for loss in general. In the report by Marusic, the patient came to hospital a year after the death of her father, delusionally convinced that she was about to deliver a baby[46]. In Grover[44] a 46-year-old woman developed a psychosis two months after the death of an only son. The psychosis was treated with antipsychotic drugs, resulting in hyperprolactinemia and weight gain. Still on her medication, on the first anniversary of her son's death, the patient became convinced (falsely) that she was pregnant, that she felt fetal movements, and that the new baby was a male.

Some authors have suggested other related antecedents to the delusion of pregnancy such as social isolation, so that a baby becomes a hoped-for companion[54]. Ibekwe[15] has suggested that women's perception of their inherent powerlessness in a patriarchal society leads to

the development of pseudocyesis. Women in many developing countries, cannot compensate for lack of children, as can women in the West, by succeeding in a career, or making money in business or going out to war. Being pregnant (and gaining status thereby) is their one source of power.

In fact, because pregnancy is a highly respected state and women are treated especially well during this time by their spouses, in-laws, and society in general, giving up the pregnant state may be psychologically difficult. Simon *et al*[36] describe two cases where a delusional pregnancy occurred shortly after delivery, during the postpartum period, and seemed to be motivated by the wish to continue to be treated as if pregnant. Pregnancy confers advantages. In Muslim cultures, a husband cannot divorce his wife while she is pregnant[55]. In some religious traditions, pregnancy and breast-feeding absolve women from unwanted sexual activity[56].

From the results of their series of cases, Rosch *et al*[7] conclude that false pregnancy can be an unconscious adaptive strategy to guard against loss of a relationship. This view is seconded by Ibekwe[15] whose case describes an imagined pregnancy that brought the patient personal fulfillment, stability to her marriage and newfound acceptance from her in-laws. Ibekwe suggests that the delusion solved the dilemma faced by this infertile woman in a culture (Nigeria) that places immense value on children not only because procreation is religiously mandated, but also because it is economically necessary for survival and generational continuity. In sub-Saharan Africa, infertility is said to affect one third of all couples[57], is always blamed on the woman, and leads to discrimination and abuse[58]. In developing countries, violence against infertile women is reported to occur in 10 to 60 percent of instances[59,60].

## EFFECTS OF CULTURE

Although perceived infertility is not always at the heart of delusional pregnancy[61], it contributes, more so in some social contexts than in others[62]. Infertility can cause extreme levels of distress[63,64], especially in developing countries where childlessness is never an acceptable option for married women, and where infertility treatments are often not available. Even where they are financially available, Islamic law forbids sperm and ova donations, as well as surrogacy[65]. Adoptions are also forbidden in most interpretations of Islamic law[66] because preservation of hereditary lineage is important. Infertility, though often caused by the male partner, is attributed, almost always in developing countries, to the woman[61]. A childless woman is viewed as a failure and is rejected by her husband and his family, as described in ethnographic studies carried out in the countries where pseudocyesis appears to be relatively commonplace[67-70].

Pronatalism, the belief that a woman's social value is linked to her production of children is strong in developing countries[71]. Only the presence of children gives a woman the right to share in her husband's property in sub-Saharan Africa. Infertility can be just cause for divorce or, in polygamous societies, justification for the husband taking another, more fertile wife[55,61]. The paradox is that infertility is relatively common in these same countries because of the prevalence of genital infection spread by unprotected sexual contact and because of unsanitary obstetric practices. To make matters worse, infant mortality is also high in many of these regions, partly because of the popularity of consanguineous marriages[72]. This translates into pressure on couples to give birth to as many children as possible, to insure against loss. In some traditional societies, the pressure to produce children is experienced as coming not only from family members but also, importantly, from dead ancestors who may feel wronged by the lack of descendants, and take revenge[73].

The role of cultural factors is evident in the identifications that women sometimes make when they develop a delusional pregnancy. The best illustration of this is in Battacharyya and Chaturvedi[6] who describe a woman from Bangalore India who believed that, in a previous birth, she had been the wife of the Hindu god Lord Rama and was now pregnant by him. In Hindu legend, Rama and his wife Sita are the personifications of ideal love, but are destined to be separated from each other. Furthermore, Sita (like the woman in question) gives birth to her twin sons when she is alone.

Where it is commonplace to believe that magic and evil spirits can cause disease, the distinction between a belief and a delusion can be easily blurred, as in Saudi Arabia, for instance, where many believe that pregnancy does not require sexual contact, but can be induced by spirits[55].

## BIRTH OF A DELUSION

The delusion of pregnancy, as exemplified by the 80 cases reported since 2000, illustrates the circumstances of birth and development of a delusion. According to Conrad[74], the first stage, which he called "das trema" is a general feeling of non-specific apprehension. This can be a result of familial and societal pressures or personal aspirations to become pregnant despite obstacles such as infertility, old age, spinsterhood, ill health, poor marital relationship, or inadequate socioeconomic conditions. The general apprehension during this first stage may follow the loss of a child, or loss of status, or loss of a love relationship. The second stage of delusion formation is a sensory perception, such as weight gain, or vaginal spotting, or abdominal movement, or frequency of urination. The same sensory perception may have occurred many times before but, this time around, as the person searches for what it might mean, it suddenly acquires extraordinary significance. This is the third stage, where meaning is attached to an otherwise neutral sensation. The meaning, seemingly of surreal importance so urgent is its message, appears "out of the blue" ("Ah, I must be pregnant!")[75]. It feels convincingly true because, in one fell swoop, it resolves the difficult dilemmas with which the woman has

been struggling ("How can I live without my son?" "How can I be a woman if I'm infertile?" "How can I hold on to a man who is no longer interested?" "How can I avoid sex and still be a wife?")[76]. How a person then deals with this momentous information depends on personal factors (health, education, reasoning ability, cognitive biases) and on situational factors (family, socioeconomics, culture, religion). Such factors may serve to dispel the delusion for want of evidence and plausibility or they may serve to reinforce it by recalling traditional beliefs and fictional accounts[77].

## FUTURE DIRECTIONS

A better understanding of pseudocyesis/delusional pregnancy requires experimental study designs. Antecedents, onsets, and diagnoses could be compared in (1) women and men with this condition[78]; (2) fertile[61] and infertile women; and (3) pseudocyesis and other monothematic delusions such as Capgras syndrome or Cotard syndrome[79]. It may also prove interesting to compare, on the same variables, women who delusionally deny pregnancy[10] with those who delusionally insist, against all evidence, that they are pregnant. Such careful comparisons will shed more light on this and other delusional conditions.

## Abstract

**AIM:** To characterize and compare our current series of patients to prior reports in order to identify any changes in the incidence of neurological injury related to hunting accidents in Rochester, New York.

**METHODS:** All tree stand-related injuries referred to our regional trauma center from September 2003 through November 2011 were reviewed. Information was obtained from the hospital's trauma registry and medical records were retrospectively reviewed for data pertaining to the injuries.

**RESULTS:** Fifty-four patients were identified. Ninety-six percent of patients were male with a mean age of 47.9 years (range 15-69). The mean Injury Severity Score was 12.53 ± 1.17 (range 2-34). The average height of fall was 18.2 feet (range 4-40 feet). All patients fell to the ground with the exception of one who landed on rocks, and many hit the tree or branches on the way down. A reason for the fall was documented in only 13 patients, and included tree stand construction (3), loss of balance (3), falling asleep (3), structural failure (2), safety harness breakage (3) or lightheadedness (1). The most common injuries were spinal fractures (54%), most commonly in the cervical spine (69%), followed by the thoracic (38%) and lumbar (21%) spine. Eight patients required operative repair. Head injuries occurred in 22%. Other systemic injuries include rib/clavicular fractures (47%), pelvic fractures (11%), solid organ injury (23%), and pneumothorax or hemothorax (19%). No patient deaths were reported. The average hospital length of stay was 6.56 ± 1.07 d. Most patients were discharged home without (72%) or with (11%) services and 17% required rehabilitation.

**CONCLUSION:** Falls from hunting tree stands are still common, with a high rate of neurological injury. Compared to a decade ago we have made no progress in preventing these neurological injuries, despite an increase in safety advances. Neurosurgeons must continue to advocate for increased safety awareness and participate in leadership roles to improve outcomes for hunters.

**Key words:** Neurological sports medicine; Hunting; Tree stand falls; Spine injury; Traumatic brain injury

**Core tip:** Hunting is a popular sport and hunters have devised numerous ways to increase their advantage against their quarry. Tree stands have been developed to allow hunters better sight and increased protection. However, improper use, faulty construction, and other factors can increase the risk of injury, specifically to the

central nervous system. We present the data obtained at our institution over an eight-year period cataloging the injuries obtained while using tree stands. We have begun outreach to the community with our findings, with the goal of increasing awareness and education to reduce risks and increase hunter safety.

## INTRODUCTION

Hunting is a popular sport and recreational activity nationwide, with nearly 15 million licensed hunters in the United States and approximately 680000 in New York State according to the Fish and Wildlife Service[1]. Hunting is a favorite pastime for those in the Rochester, NY area that spans all age ranges. Hunters age 12 and above may obtain a hunting license in New York and most use bows or firearms to hunt a variety of wildlife animals. Over time, hunters have developed various methods to improve the leisure of the sport. One such method is the elevated tree stand.

Tree stands, also referred to as deer stands, are elevated platforms or seats that can be built in, nailed, locked, or rested up against a tree. Stands give hunters an advantage of wider visibility, while decreasing the chances of being detected by sight or scent[2-4]. Hunting tree stands can be commercial or homemade, and are usually installed 15 to 30 feet above ground. Commercial tree stands typically have a two-by-two feet platform seat, and may or may not be attached to the tree by safety belts, a harness, or straps. These safety straps are designed to help prevent the hunter from falling from the tree or stand.

Hunting related accidents and injuries have been largely attributed to falls from tree stands[2]. This is the most common way hunters are injured, debunking the popular misconception of intoxicated hunters sustaining self-inflected ballistic injuries[5]. Estimates reveal that nearly 10% of hunters who use tree stands are injured annually, and more than 75% of tree stand injuries occur while using fixed position or climbing stands[6]. As much as 75% of the time spent during a hunt is spent on tree stands, and tree stands are considered an essential component of large game hunting[6]. In North America, nearly 85% of hunters pursue large game (*e.g.*, deer, elk, bear, turkey, *etc.*), suggesting that the overwhelming majority of hunters have or will at some point use a tree stand[6]. When hunters fall from tree stands, they can reach a velocity of up to 30 mph. Yet these common hunting-related accidents often go unreported as victims only present to hospitals with serious injuries[3,4,7].

Falls from tree stands can lead to high impact injuries. One study demonstrated that 80% of fall victims required operative interventions, and nearly 10% of falls resulted in permanent neurological deficits or death[5]. The series of common injuries were fractures to the spinal cord, lower extremities, and traumatic brain injuries. The high morbidity of falls from tree stands have led to a small series of interventions to prevent devastating spinal cord injury through promoting the use of safety harnesses publicly[8]. It appears these interventions were successful as the incidence of tree-stand associated accidents was significantly reduced.

A previous study conducted nearly a decade ago at a Level I trauma center and Medical Examiner's offices in Western New York and central Maryland previously identified 51 cases of tree-stand associated injuries over a 5-year period[2]. The majority of injuries were spinal and extremity fractures. The most frequent reported reasons for falls were related to errors in placement of the stand with subsequent structural failure, and errors climbing in or out of the tree stand[2]. The need for hunter education was emphasized and the implementation of trauma prevention programs was suggested.

Our objective was to compile the current series of patients and the frequency and types of injuries they sustained. Additionally we wanted to compare our results to prior reports to identify any changes in the incidence of neurological injury related to tree stand hunting accidents.

## MATERIALS AND METHODS

All tree stand-related injuries evaluated at the University of Rochester Medical Center's Emergency Department between September 2003 and November 2011 were reviewed. Information was obtained from hospital's trauma registry, and medical records were retrospectively reviewed for data pertaining to the injuries, with particular emphasis on neurological injuries and any associated details. The patients were identified based ICD-9 codes (*e.g.*, E884.9: fall from one level to another) and further review of the charts allowed us to select only falls that were sustained while hunting from a tree stand. Further data collected from the trauma registry included age, gender, Injury Severity Score (ISS), Glasgow Coma Score at the time of patient arrival, vital signs, intensive care unit (ICU) and hospital lengths of stay (LOS), procedures, and discharge disposition. The study was approved by the University of Rochester Medical Center institutional review board, and all investigators completed training in protection of human subjects.

## RESULTS

A total of 54 patients were identified with tree stand related injuries during the study period. Ninety-six percent of tree-stand associated falls occurred in men. The mean age was 47.9 years (range, 15-69). The mean Injury Severity Score was 12.53 ± 1.17 (range, 2-34). The aver-

**Table 1 Demographics and categorization of injuries**

| Metric | If not specified ($n$ = 54) |
|---|---|
| Age (years with range) | 47.9 (15–69) |
| Male gender | (96) |
| Average fall (ft with range) | 18.2 (4–40) |
| Average length of stay | 6.56 ± 1.07 |
| Disposition | |
| Home | (72) |
| Home with services | (11) |
| Rehabilitation | (17) |

**Table 2 Reasons reported cause of falls $n$ (%)**

| Reported reason | Falls ($n$ = 13) |
|---|---|
| Tree stand construction | 3 (23) |
| Loss of balance | 3 (23) |
| Falling asleep | 3 (23) |
| Structural failure | 2 (15) |
| Lightheadedness | 1 (8) |
| Other | 1 (8) |

age height of fall was 18.2 feet (range, 4-40 feet) (Table 1). No correlation could be drawn from records between height of the fall and the severity of the injuries. All patients fell to the ground with exception of one patient falling onto rocks, and many hit the tree or branches on the way down. There were no patient deaths related to tree stand falls. The direct mechanism contributing to the fall were documented in only 13 patients, and included tree stand construction (3 patients), loss of balance (3 patients), falling asleep (3 patients), structural failure (2 patients), safety harness breaking (3 patients) or "lightheadedness" (1 patient) (Table 2).

The most common injuries sustained were spinal fractures (54%). In these patients, fractures to the cervical spine were the most common (69%), followed by the thoracic (38%) and lumbar (21%) spine. These injuries included burst fractures, compression fractures, dislocations, and spinal cord transections. One patient sustained injuries resulting in immediate C5 quadriplegia, while another was paraplegic. Eight patients went to the operating room for fusion (Table 3). The remaining patients were treated nonoperatively with bracing and pain control.

The tree stand falls resulted in head injuries in 22% of patients (Table 3). Five patients suffered from facial lacerations. In addition, seven patients experienced loss of consciousness throughout the course of injury.

Thoracic injury was a common injury in many of the patients in this group. Pulmonary contusion was noted in four patients (7%). In 10 cases, patients developed a pneumothorax or hemothorax (19%), and eight of these patients were treated with a chest tube (Table 4). The other associated non-neurological injuries include injuries to the thorax such as rib/clavicle fractures (47%), pelvic fractures (11%), and abdominal solid organ injury involving lacerations to the liver, spleen, or kidney (23%) (Table 4).

**Table 3 Neurological injuries resulting from tree stand falls**

| Injury | Patients ($n$ = 54) |
|---|---|
| Spinal column | (54) |
| Cervical spine | (69) |
| Thoracic spine | (38) |
| Lumbar spine | (21) |
| Requiring surgery | (15) |
| Cranial vault/brain | (22) |

**Table 4 Non-neurological injuries resulting from tree stand falls $n$ (%)**

| Injury | Patients ($n$ = 54) |
|---|---|
| Orthopedic | |
| Upper extremity | 10 (19) |
| Lower extremity | 13 (24) |
| Hip/pelvis | 6 (11) |
| Abdominal | |
| Liver | 2 (4) |
| Kidney | 3 (6) |
| Spleen | 5 (9) |
| Other | 2 (4) |
| Thoracic | |
| Pulmonary contusion | 4 (7) |
| Pneumo-/hemothorax | 10 (19) |
| Rib fractures | 22 (41) |
| Clavicle fracture | 3 (6) |
| Scapula fracture | 1 (2) |
| Sternal fracture | 3 (6) |

Patients endured extremity fractures in 54% of the cases. The common injuries included fractures of the lower extremity affecting the tibia, fibula, foot, and ankle (24%), upper extremity affecting the humerus, radius, and ulna (19%), and hip and pelvis (11%) (Table 4). Fourteen patients went to the operating room for repair of extremity fractures.

The average hospital LOS was 6.56 ± 1.07. One patient required ICU care for 3 d. The discharge plans were home (72%), home with services (11%), and rehabilitation placement (17%) (Table 1).

## DISCUSSION

Hunting in the American outdoors remains a unique and popular recreational activity for all ages during various times of the year. A myriad of game animals (*e.g.*, rabbit, pheasants, deer, *etc.*) are hunted with a variety of weapons from bows to shotguns or rifles[9]. Hunters have become increasingly savvier in their techniques to evade detection from their prey; one tool has been the use of tree stands or elevated platforms. Tree stands have given hunters an advantage of wider visibility without revealing their position by sight or scent[2,3]. However, with this advantage comes the increased risk of injury associated with falls during the use of these stands. The tree stands may be difficult to carry, offer minimal room for movement, and do not protect against poor weather[10]. Tree stands are typically located 15 to 30 feet above ground and can be

attached to the tree by nails, locks, or straps. The patients in our study fell from a similar height (mean fall height of 18.2 feet). As these individuals fall, the impact surface of their landing can be on hard surfaces, logs, and parts of hunting equipment adding another factor to the injury[5].

One particular study outlines that the duration of the impact force from the nature of the surface is the most important predictor of injury severity[3]. Several other studies in the literature report serious injuries related to tree stand fall[2-8]. By and large, the incidence of tree stand falls and related injuries has become one of the leading causes of hunting-related incidents. This information debunks the popular misconception that intoxicated hunters sustain self-inflected ballistic injuries as a leading cause of hunting-related incidents. In 2010, Crockett *et al*[5] discovered that 50% of the patients in their series sustained falls from tree stands compared to 29% that endured gunshot wounds in central Ohio. In our study we sought to characterize a current series of patients and compare them to prior reports in order to identify any changes in the incidence of neurological injury related to such hunting accidents. These efforts would help highlight areas to prevent the dangerous injuries from tree stand falls and improve patient safety measures through education.

There are several types of tree stands available. Some are made by commercial manufacturers using metal materials and others are homemade by hunters using wood. Only stands approved by the Tree Stand Manufacturers Association should be used, as many of the homemade types are discouraged due to deterioration of wood over time[11]. The Tree Stand Manufacturers Association (TMA), a group of corporations organized for the promotion of safe hunting practices, estimates millions of tree stand units are sold each year in the United States. One limitation of our study is that the type of tree stand used by our patients was not information available to us.

We identified 54 cases of tree stand related injuries over an 8-year period at the University of Rochester Medical Center. Our result remains consistent with the previous study done at this trauma center that detected 27 cases over a 5-year period[2]. Our current study observed that tree stand falls continues to make up a significant portion of hunting related accidents. Consequently, prior efforts to reduce the morbidity and mortality associated with tree stand falls have not been successful. This evidence suggests that tree stand safety must remain a priority for hunters and health care providers. The most common mechanisms of the injury pattern noted in our study were due to tree stand construction, structural failure, loss of balance, falling asleep, structural failure, and the safety harness breaking. In some cases patients were unsure of how they had fallen as some were amnestic to the incident. All of these contributing factors of injury indicated that further instruction is required in New York State to ensure the safety of licensed hunters. New York requires a mandatory hunter education course for a minimum 10 h in length[12]. While hunters are mandated to take a course, we recommend stronger measures to ensure hunters acquire the information needed to safely operate tree stands (*e.g.*, periodic testing of proper use by Safety Course instructors).

Due to the large number of patients injured as a result of preventable causes, an educational safety course is warranted and further instruction to hunters is necessary to ensure more compliance with these guidelines. During these Hunter's Safety Courses offered by the state or county governments the quantity and severity of these neurological injury patterns, extended hospitalizations, and permanent disability needs to be addressed in more length to provide greater awareness. Additional instruction on adherence to the regulations while hunting should be emphasized; for example, the need to exercise extreme precaution when entering or exiting the tree stand, and the need to wear a safety harness at all times. Emphasis on proper techniques need to be made to ensure hunters pay more attention when they hoist or lower items from the tree stand in a safe manner. Hunters should avoid hunting when fatigued, use communication devices, restrict alcohol or drug while hunting, hunt in groups, and only hunt during times specified by local or state regulations.

Active awareness to hunters has been proven to reduce the incidence of tree stand related trauma. In Louisiana, letters were sent to licensed hunters, hunting clubs, sporting goods stores, and hunting supply retailers across the state that detailed the risks associated with tree stand use without a safety device[3,8,13]. In the 3 years following this active awareness campaign, there were no spinal cord injuries from tree stand related incidents. Rochester, NY and other areas with active tree stand hunters will greatly benefit from similar campaign efforts.

Tree stand manufacturers add specific guidelines to the products they produce and encourage the strict use of wearing a full body safety harnesses[14]. Review of the medical records at Strong Memorial Hospital did not include information regarding safety harnesses. This may be due to recall bias from post-concussive amnesia, or insufficient information surrounding the circumstances of the injury. However prior studies have specifically documented the lack of a safety harness as a contributing mechanism[2,3], and we speculate that the absence of this information may suggest these safety devices were not used.

Injuries sustained from tree stand falls often require operative or other interventions that can increase the total cost to the healthcare system[7]. In an era where healthcare costs are carefully monitored, any preventive efforts that can reduce the overall cost of care and diminish the long-term costs for permanently disabled patients should be investigated and pursued. Additionally early identification of injured patients and a thorough assessment of their injuries are critical to improving outcomes[3]. Though it is tempting to focus on the intracranial and spinal pathologies, non-neurological injuries must not be minimized in the evaluation of these types of patients as tree stand falls do result in significant thoracic, abdomi-

nal, and pelvic trauma. A complete trauma assessment must be performed for each patient and all injuries thoroughly documented and treated in a timely fashion.

While we attempted to catalogue and describe the incidence of all tree-stand related injuries, our work is not without limitations. First, while all injuries that were deemed by the injured party or their associates were brought for hospital evaluation, it is reasonable to assume that hunters who sustained injuries may have declined to seek medical attention. The lack of any obvious trauma following a fall also may have prevented hunters from evaluation. Our series also does not capture those patients who sustained injuries at regional, community hospitals but whose injuries were not severe enough to warrant transfer to our facility. Lastly, while a thorough search for all patients was attempted, using ICD-9 codes as an initial filter may have missed patients whose diagnoses were not accurately documented at the time of their presentation.

From an international standpoint, hunting, as both a source of food and recreation, has been enjoyed by civilizations for thousands of years. Indian emperors would routinely employ elephants to hunt for wild game, and European monarchs often enjoyed fox and boar hunting as a sport while on horseback. However, from our search, tree stands appear to be a more modern invention that are primarily used in North America. Literature searches yielded no published data on hunting accidents outside of North America, and most international hunting and safety organizations focus their attention to this area as well.

In light of this data, more awareness and education are sorely needed. To this end, the authors have utilized the findings from this paper in local print and television media to educate the local community on the continued prevalence of tree stand injuries. A campaign has been initiated in New York to better educate hunters, with the aim of formally incorporating this study's findings in novel educational material for the New York State hunter safety educational curriculum.

Hunting remains an attractive recreational activity and the methodical use of tree stands have made hunters more effective at game hunting. This study reveals that nearly 10 years later, tree stand falls remain a significant cause of life-threatening neurological injury and subsequent disability. Increased awareness by healthcare providers and implementation of prevention strategies is critical to reducing the incidence of injuries sustained while hunting with tree stands. These prevention strategies can be taught during hunter safety education courses. All hunters should be made aware of the preventable risk factors that contribute to injury (structural failure, fatigue, lack of sleep, and drug and alcohol use). Additionally, hunters should be licensed and properly educated on the safe and proper use of tree stand and associated equipment (*e.g.*, safety harness), and ensure that equipment is in proper working condition on a routine basis. Tree stand manufacturers can aid in these hunter education prevention programs by giving more support to efforts for the hunter's safety. Health care providers can also aid safety and education efforts, as physicians who treat these hunters may advocate for these prevention efforts to reduce incidence of neurologic injury during hunting.

## ACKNOWLEDGMENTS

The authors thank Gina Ryan, RN, BSN and Krista Sokolowski, RN, MS, at the University of Rochester Regional Trauma Center at Strong Memorial Hospital who accumulated the data from the hospital trauma registry.

## COMMENTS

### *Background*

The role of tree stands in hunting accidents has been investigated to determine the incidence of injuries involving these devices. This study also compared current data with data obtained nearly a decade ago to identify any trends that have changed.

### *Research frontiers*

Neurotrauma, public health.

### *Innovations and breakthroughs*

Despite improvements in medical care, tree stand injuries continue to occur with no real abatement in incidence. Other states have instituted public health campaigns to educate hunters of the risks and these efforts have reduced rates of injury.

### *Terminology*

Tree stands are devices used by hunters to give them a seat at an elevated position in a tree to observe wild game.

### *Peer review*

This is a well-written study on hunting related injuries due to tree stand falls. The topic is interesting, important, and not sufficiently researched and the findings will hopefully raise awareness on safety issues. The study is well-designed and the findings are adequately presented. The discussion is balanced and informative.

## Abstract

**AIM:** To study the risks and benefits of intracerebroventricular (ICV) opiate pumps for the management of benign head and face pain.

**METHODS:** SSix patients with refractory trigeminal neuralgia and/or cluster headaches were evaluated for implantation of an ICV opiate infusion pump using either ICV injections through an Ommaya reservoir or external ventricular drain. Four patients received morphine ICV pumps and two patientS received a hydromorphone pump. Of the Four patients with morphine ICV pumps, one patient had the medication changed to hydromorphone. Preoperative and post-operative visual analog scores (VAS) were obtained. Patients were evaluated post-operatively for a minimum of 3 mo and the pump dosage was adjusted at each outpatient clinic visit according to the patient's pain level.

**RESULTS:** All 6 patients had an intracerebroventricular opiate injection trial period, using either an Ommaya reservoir or an external ventricular drain. There was an average VAS improvement of 75.8%. During the trial period, no complications were observed. Pump implantation was performed an average of 3.7 wk (range 1-7) after the trial injections. After implantation, an average of 20.7 ± 8.3 dose adjustments were made over 3-56 mo after surgery to achieve maximal pain relief. At the most recent follow-up (26.2 mo, range 3-56), VAS scores significantly improved from an average of 7.8 ± 0.5 (range 6-10) to 2.8 ± 0.7 (range 0-5) at the final dose (mean improvement 5.0 ± 1.0, $P < 0.001$). All patients required a stepwise increase in opiate infusion rates to achieve maximal benefit. The most common complications were nausea and drowsiness, both of which resolved with pump adjustments. On average, infusion pumps were replaced every 4-5 years.

**CONCLUSION:** These results suggest that ICV delivery of opiates may potentially be a viable treatment option for patients with intractable pain from trigeminal neuralgia or cluster headache.

**Key words:** Intracerebroventricular; Opiate; Trigeminal neuralgia; Cluster headache; Pain

**Core tip:** Chronic head and face pain remains a debilitating condition, and patients may often be refractory to traditional medical therapies or surgical intervention (*i.e.*, stereotactic radiosurgery or microvascular decompression). Alternatively, the use of intracerebroventricular (ICV) pain pumps has been used for refractory nociceptive pain from head and neck cancer; however, its use in non-cancer head and face pain has not been well described. Here, we report the potential risks and benefits of ICV opiate pain pumps for cluster headaches and trigeminal neuralgia refractory to medical and surgical treatment.

Intracerebroventricular opiate infusion for refractory head and facial pain. *World J Clin Cases* 2014; 2(8): 351-356 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/351.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.351

## INTRODUCTION

Chronic head and face pain is a debilitating condition that affects over 3%-5% of people worldwide[1], dramatically impacting emotional, psychological, and economic well-being. Two common etiologies of severe head and face pain are cluster headache and trigeminal neuralgia, which affect 300000 and 100000 people in the United States, respectively. Cluster headache is typically managed with medical therapies or botox injections[2,3], and most cases of trigeminal neuralgia are successfully treated with oral medications, stereotactic radiosurgery, or microvascular decompression[4]. However, 5% of patients with cluster headache[5] and 11%-25% of patients with trigeminal neuralgia[6-10] do not achieve adequate pain relief with these therapies and may require other treatment options.

Neurosurgical treatment options for pain syndromes have generally focused on modulation of specific pain pathways by lesioning, electrical stimulation, or spinal intrathecal delivery of pharmacological agents[11,12]. Targets for electrical neuromodulation include the dorsal columns of the spinal cord, the sensory nuclei of the thalamus, the precentral motor cortex for neurogenic/neuropathic pain, and the periventricular/periaqueductal gray area for somatic or nociceptive pain[13]. Chemical neuromodulation *via* central delivery of pharmacological agents is primarily accomplished *via* spinal intrathecal delivery strategies[14].

Intracerebroventricular (ICV) administration of opioids represents a chemical, rather than electrical, neuromodulation treatment strategy. This allows for drug delivery directly at its anatomical site of action, achieving high tissue concentrations of drug that would not be achievable with systemic drug delivery. ICV delivery of opiate medications has been previously described for management of refractory nociceptive pain from head and neck cancer[15-19]. This is typically accomplished *via* intermittent injection of opiates into an Ommaya reservoir[17,20-22], although use of an implanted infusion pump has also been reported[19,23]. In this study, we present our institutional experience treating six patients with ICV opiate pain pumps for treatment of severe, refractory head and face pain due to cluster headache and/or trigeminal neuralgia.

## MATERIALS AND METHODS

### Patient population

Six adult patients (4 women, 2 men) underwent implantation of an ICV opiate pump into the right lateral ventricle for treatment of severe, refractory head and/or face pain at the University of California, Davis Medical Center. The average age of symptom onset was 44.3 years (range 17-75), the average duration of symptoms was 14.8 years (range 4-31), and the average age at ICV implantation was 59.0 years (range 35-79). Four patients had facial pain, 1 patient had cluster headaches, and 1 patient had cluster headache and atypical facial pain. Patients had trialed an average of 4 (range 1-9) oral pain medications prior to ICV implantation; 2 patients trialed opiate injection therapy, 2 patients had failed microvascular decompression for facial pain, and none of the patients in this series had undergone previous radiosurgery for pain (Table 1). The University of California, Davis Institutional Review Board approved this retrospective study.

### Treatment protocol

Prior to ICV opiate pump implantation, all patients demonstrated significant clinical benefit with trial injection of opiates through an Ommaya reservoir ($n$ = 5) or an external ventricular drain (EVD, $n$ = 1). Trial injections were performed in the neurosurgical intensive care unit for close monitoring of known complications of ICV opiate delivery, including mental clouding, visual hallucinations, seizures, somnolence, respiratory depression, and coma[24]. Initially, patients underwent a trial injection phase (3-15 d) at which time the dose of morphine or hydromorphone was titrated to determine an optimal dose for each individual. A Medtronic (Minnesota, United States) pain pump was implanted into a subcutaneous fat space in the abdomen within one month of the trial injections by one of two neurosurgeons (J.E.B, K.S.). In one patient (patient 6), intraoperative computed tomography was used to confirm placement of the intraventricular catheter (Figure 1). Adjustment of dose rates and/or refilling of pumps occurred monthly.

### Outcome assessment

Visual analogue scale (VAS) scores were obtained before and after intraventricular trial injections, and before and after the ICV opiate pump infusion began. VAS scores were collected on an intermittent basis during outpatient clinic visits, before and after infusion rate adjustments.

## RESULTS

There were no complications associated with placement of an Ommaya reservoir or EVD to perform trial injections. During trial injection therapy, one patient experienced a transient side effect of nausea but there were no permanent complications. An average of 9.2 doses (range 2-27) was necessary during the trial phase to provide maximum VAS improvement with trial injections (average VAS improvement 75.8%, range 50%-100%).

Pump implantation was performed an average of 3.7 wk (range 1-7) after ICU trial injections had been completed, and patients required an average of 20.7 (range 2-51) outpatient adjustments to the dose. At the most recent follow-up (26.2 mo, range 2-56, one patient transferred care to a different institution), VAS pain scores significantly im-

**Table 1 Patient characteristics and outcomes**

| Patient | Age (at pump placement, yr) | Gender | Primary diagnosis | Prior surgeries | Pre-implantation trial | ICV pump medication | Initial dose (mg/d) | Final dose (mg/d) | Pre-op VAS | Post-op day 1 VAS | Last VAS | Last post-op visit (mo) |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 67 | Male | Trigeminal neuralgia (left) | | Ommaya reservoir-morphine | Morphine then dilaudid | 0.1 morphine | 3.27 dilaudid | 6 | 3.5 | 4 | 145 |
| 2 | 35 | Female | Cluster headaches | | Ommaya reservoir-morphine | Morphine | 0.65 morphine | 19.0 morphine | 8 | 4 | 0 | 166 |
| 3 | 37 | Female | Trigeminal neuralgia (right), Cluster headaches | | Ommaya reservoir-morphine, dilaudid | Dilaudid | 0.1 dilaudid | 0.2 dilaudid | 8 | 2.5 | 3 | 9 |

VAS: Visual analogue scale; ICV: Intracerebroventricular.

**Figure 1 Intraoperative computed tomography of the head demonstrates intraventricular placement of the pump catheter (Patient 6).**

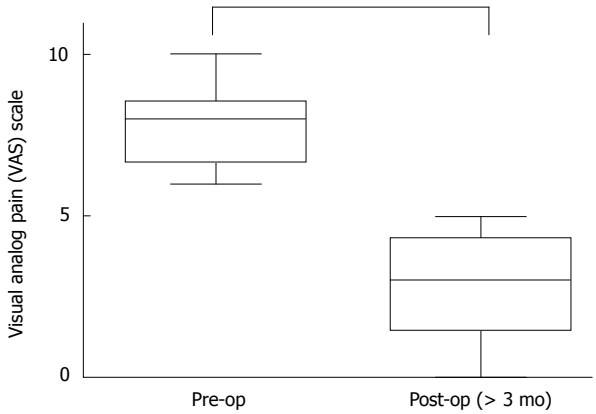

**Figure 2 Preoperative visual analogue scale pain scores ranged from 6-10 out of 10 (average 7.8 ± 0.5).** Post-operative visual analogue scale (VAS) scores at > 3 mo following opioid pain pump placement were significantly lower ($P < 0.001$ *vs* Post-op), ranging 0-5 out of 10 (average 2.7 ± 0.4).

proved from an average of 7.8 ± 0.5 (range 6-10) to 2.8 ± 0.7 (range 0-5) once reaching final dose (mean improvement 5.0 ± 1.0, $P < 0.001$, Table 1, Figure 2).

All patients required stepwise increases in infusion rates to achieve maximal benefit. The average initial morphine dose was 1.4 mg/d (range 0.1-4.0 mg/d) and the average final dose was 11.7 mg/d (range 2-21.5, $n = 4$). The average initial hydromorphone dose was 0.08 mg/d (range 0.01-0.2 mg/d) and the average final dose was 1.2 mg/d (range 0.1-3.3). In one patient (Patient 1), the medication was changed from morphine to hydromorphone to achieve maximal benefit; in this patient, 12 morphine dosage adjustments were made prior to converting to hydromorphone 15 mo after implantation. The final morphine dosage was 21.5 mg/d and the initial hydromorphone dosage was 2.1 mg/d. Following medication adjustment, an additional 12 adjustments with hydromorphone were made. On average, infusion pumps were replaced every 4-5 years.

The most common complications in this series were nausea ($n = 2$) and drowsiness ($n = 2$), both of which resolved with adjustments in pump settings (Table 2). One patient experienced withdrawal symptoms due to pump failure, and underwent a distal catheter revision (to clear an obstruction) with subsequent resolution of her symptoms. One patient experienced psychiatric irritability after 10 years of good pain relief and had the ICV pain pump removed.

**Table 2 Dose ranges and complications**

| Patient | Dose range (mg/d) | Complications |
|---|---|---|
| 1 | 0.10-21.5 (morphine) | Nausea/Emesis (transient-decreased dosage) |
| | 2.10-3.27 (dilaudid) | Changed medication due to inadequate pain control/nausea |
| 2 | 0.65-19.0 (morphine) | Replacement of pump × 2 (q5 yr) |
| | | Withdrawal symptoms (transient) |
| 3 | 0.20 (dilaudid) | Psychiatric disturbances leading to removal of pain pump after 11 yr |
| 4 | 0.75-2.0 (morphine) | Nausea/ Emesis (transient- decreased dosage) |
| 5 | 4.00-4.25 (morphine) | Lost to follow-up after 1 yr |
| 6 | 0.01–0.10 (dilaudid) | |

## DISCUSSION

ICV opiate infusion using an implanted pump provides significant pain relief in patients with severe, refractory head and/or face pain that have failed other medical and surgical therapies. This study adds to the existing literature on successful use of ICV opiates for management of head and neck cancer pain[25], and suggests that ICV opiate infusion may be a prudent treatment option for select patients with severe cluster headache or trigeminal neuralgia.

While the mechanism and site of action of opioids in the brain for head and neck pain is not completely understood, it is known that morphine and its derivatives bind to receptors that are found in the periventricular and periaqueductal gray regions, medulla spinalis, substantia gelatinosa, and the hypothalamus[13,26-30]. Therefore, it is possible that ICV delivery of opioids selectively modulates activity in these brain regions, resulting in a level of analgesia that may be superior to that achieved with systemic therapies.

The efficacy of deep brain stimulation (DBS) of the periventricular/periaqueductal gray region for management of cluster headache and other central pain syndromes[11,13,26] supports the hypothesis that targeted delivery is effective for refractory cases. Due to its proximity to pain pathways in the brainstem, hypothalamus, and thalamus, ICV delivery may potentially be more prudent than intraspinal intrathecal delivery for severe, refractory head and face pain syndromes. Prospective comparative studies are needed to further explore this possibility.

Because the pathophysiology of refractory trigeminal neuralgia and cluster headaches are poorly understood, ICV infusion therapy may be more effective than DBS since its effects are more regional and affect a larger volume of tissue. Different brain areas have been implicated in refractory cluster headache[31,32], and the anatomical basis of trigeminal neuralgia that fails medical therapy and microvascular decompression is often elusive and has been attributed to demyelination or other unknown processes. Various lesioning therapies have been proposed for failed microvascular decompression, including therapies that target the facial nerve (chemical, mechanical decompression, radiosurgery, and nerve cutting) or its brainstem pathways (nucleus caudalis dorsal root entry zone lesioning). Since these procedures are irreversible and can carry significant risks, ICV opioid infusion may be a preferable alternative since it allows for delivery of a regional targeted therapy that can be titrated to effect and, if necessary, discontinued.

It is important to note that cluster headache and trigeminal neuralgia are very different disorders with unique clinical and pathological characteristics. For example, cluster headaches are far more common in men (8:3 ratio)[33] whereas trigeminal neuralgia affects more women than men (3:2 ratio)[34]. Since morphine is generally more potent in men than women, it is possible that different opioid infusion strategies are needed to achieve adequate analgesia in these conditions. Such differences were not evident in the current series, but larger clinical studies are needed to determine if gender-specific and/or disease-specific opioid infusion strategies will yield better clinical outcomes.

The risks associated with ICV opiate infusion therapy include neurological injury from ventricular catheter placement, implant infection, and opioid toxicity (including allergy, intolerance or significant clinical side effects). We recommend a trial therapy in an ICU setting prior to pump implantation to confirm clinical efficacy and evaluate for any signs of opioid toxicity. After implantation, a slow, step-wise titration of opioid infusion is recommended to achieve maximum clinical efficacy with minimal side effects and complications. In this series, the average number of dose adjustments was 20.7 (range 2-51). The high number of adjustments demonstrates that opioid tolerance can develop over time. Special consideration should be given to the development of opioid tolerance and the risks associated with abrupt disruption or withdrawal of therapy (in the setting of pump failure, for example). There is some evidence that co-administration of drugs may enhance analgesia and reduce the likelihood of tolerance. For example, pre-clinical animal studies suggest that co-administration of drugs like calmodulin inhibitors[35,36] or inhibitors of protein kinases[37] may reduce or prevent morphine tolerance from developing. Also, there is evidence that certain non-opioid medications, such as the voltage-gated calcium channel blocker ziconotide, are extremely effective when delivered as an intrathecal infusion[38,39] and may be appropriate alternatives to opioids or effective in a co-administration strategy.

In conclusion, severe head and facial pain syndromes that are refractory to conventional medical and surgical

therapies can be extremely debilitating and very difficult to manage. ICV opioid infusion has the potential to enhance analgesia through regional delivery of drug to brain centers that are directly responsible for processing pain signals. Using a careful clinical protocol to screen for efficacy and reduce risks, ICV opioid infusion therapy may be an effective treatment option for patients with severe head and facial pain due to cluster headache and trigeminal neuralgia.

## COMMENTS

### Background

Intracerebroventricular (ICV) opiate pumps are used for management of chronic pain due to head and neck cancers, but their use for neurological etiologies of benign head and face pain has not been well studied. This study aims to evaluate the risks and benefits of intracerebroventricular opiate pumps for management of benign head and face pain.

### Research frontiers

Here, the authors describe the use of intracerebroventricular pain pumps for benign head and face pain refractory to medical and/or surgical treatment. While neurosurgical options for pain include lesioning, electrical stimulation, or spinal intrathecal delivery of pharmacological agents, the use of intracerebroventricular opiates has not been well described.

### Innovations and breakthroughs

While intracerebroventricular pain pumps have been used for head and neck cancer pain, its use for benign head and face pain, such as trigeminal neuralgia or cluster headaches, has not been well described. This study suggests that ICV pain pumps may be a potential treatment option for patients suffering from benign head and face pain refractory to medical and/or surgical treatments.

### Applications

This study suggests that intracerebroventricular pain pumps may be a viable option for patients with benign head and face pain that are refractory to previous medical or surgical treatments. Randomized controlled trials would need to be performed to further evaluate the efficacy and safety of this modality.

### Terminology

Intracerebroventricular pain pump: Opiates can be administered into the ventricles directly *via* this modality. This can be distinguished from spinal catheter pain pumps. Visual analog score: 10-point pain scale used to evaluate severity of pain (0: no pain, 10 most severe pain).

### Peer review

Interesting clinical article on intracerebroventricular opiate infusion for refractory head and facial pain. The authors report on a cohort of 6 patients with refractory trigeminal neuralgia and/or cluster headaches which underwent implantation of an intracerebroventricular opiate infusion pump as a means to control intractable pain. The article is well written, the patient population is presented in detail and the same applies to treatment protocol and outcome assessment. The results are equally presented with clarity and the discussion includes up to date references that correlate with the authors clinical results.

## Abstract

**AIM:** To evaluate the clinical and functional results after repair of distal biceps tendon tears, following the Morrey's modified double-incision approach.

**METHODS:** We retrospectively reviewed 47 patients with distal rupture of biceps brachii treated between 2003 and 2012 in our Orthopedic Department with muscle-splitting double-incision technique. Outcome measures included the Mayo elbow performance, the DASH questionnaire, patient's satisfaction, elbow and forearm motion, grip strength and complications occurrence.

**RESULTS:** At an average 18 mo follow-up (range, 7 mo-10 years) the average Mayo elbow performance and DASH score were respectively 97.2 and 4.8. The elbow flexion range was 94%, extension was -2°, supination was 93% and pronation 96% compared with the uninjured limb. The mean grip strength, expressed as percentage of respective contralateral limb, was 83%. The average patient satisfaction rating on a Likert scale (from 0 to 10) was 9.4. The following complications were observed: 3 cases of heterotopic ossification (6.4%), one (2.1%) re-rupture of the tendon at the site of reattachment and 2 cases (4.3%) of posterior interosseous nerve palsy. No complication required further surgical treatment.

**CONCLUSION:** This technique allows an anatomic reattachment of distal biceps tendon at the radial tuberosity providing full functional recovery with low complication rate.

**Key words:** Distal biceps tendon; Rupture; Double incision; Complications; Clinical outcome; Trans-osseous tunnels; Morrey

**Core tip:** Both single and double-incision approaches have been successfully used for distal biceps tendon lesions. At present there is no solid scientific evidence to support preference of one technique over the other. However, recently, it has been demonstrated that the 2-incision technique recreates more closely footprint position compared with that of the 1-incision approach. In the present research the Morrey's modified double-incision repair provided excellent outcome (including functional outcome, satisfaction, elbow and forearm motion, and grip strength) with few post-operative complications, mainly represented by heterotopic ossification and posterior interosseous nerve injuries.

Distal biceps tendon rupture reconstruction using muscle-splitting double-incision approach. *World J Clin Cases* 2014; 2(8): 357-361 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/357.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.357

## INTRODUCTION

The incidence of distal biceps ruptures is estimated between 0.9 and 1.8 per 100000 population per year, and accounts for 3% of biceps brachii tendon injuries[1]. This injury is very common in men who are in their fifth or sixth decade of life, but can also occur at any age[2-4].

Many studies demonstrated that surgical approaches allow better clinical results than conservative treatments[5,6]. In literature, various surgical methods have been described, dating back to the first report by Acquaviva in 1898[7,8].

In 1956 Fischer *et al*[9] used the volar Henry approach to reattach the distal biceps tendon to the radial tuberosity. This allowed a good recovery of flexion and supination strength, but radial nerve palsy occurred in several cases consequently to the extensive exposure needed using this approach[10,11].

To decrease the risk of neurologic complications limiting the exposure needed Boyd *et al*[12] in 1961 described a two-incision technique to access the tuberosity more easily. They felt that a second dorsal incision was necessary in order to limit the volar surgical dissection required near the radial nerve as it passes through the supinator muscle[13-15]. However, complications with special respect to heterotopic ossifications including loss of forearm rotation, radioulnar synostosis, and posterior interosseous nerve injury were described using the double-incision technique[16,17].

In an effort to overcome any complications connected with each approach, more modern techniques have been developed in the last decades. The two-incision approach was updated by Morrey *et al*[18], who used a posterior muscle-splitting approach that avoids subperiosteal exposure of the ulna, and therefore reduces the possibility of radioulnar synostosis. With this adjustment, the tendon can be reattached to the radial tuberosity through transosseous drill holes.

More recently approaches that use suture anchors and a limited single anterior incision have been described[11,19,20]. Currently there is no consensus with respect to the best surgical approach and favorable results with both techniques[21-23].

The aim of our study is to evaluate the clinical and functional outcomes after surgical repair of distal tendons tears, using a muscle-splitting double incision approach modified by Morrey[18].

## MATERIALS AND METHODS

This study has been authorized by the local ethical committee and was carried out in accordance with the Ethical standards of the 1964 Declaration of Helsinki as updated in 2004. We retrospectively reviewed 47 patients operated by two different surgeons of distal rupture of biceps brachii, treated in our Orthopedic Department between March 2003 and September 2012 using the muscle-splitting double-incision technique. Every patient undergoing distal biceps tendon acute rupture repair, was included in our review and informed consent was obtained. Exclusion criteria included the presence of an associated fracture, and dislocation about the elbow as etiology of biceps injury. All patients included in our cohort were treated within 15 d from trauma. We analyzed the rate of major and minor complications. Major complications included posterior interosseous nerve (PIN) palsy, heterotopic ossification and re-rupture. Minor complications included superficial infection, lateral antebrachial cutaneous nerve paresthesia and radial sensory nerve paresthesia. All 47 cases are men, with an average age of 45 (range, 28-66 years) at the time of injury. The dominant arm was involved in 43 patients, 91% of all cases. The injury mechanism was the same in every case: an eccentric load applied to a flexed elbow during daily or sport activity. Subjective outcomes included the Disability of Arm, Shoulder and Hand (DASH) questionnaire and the Mayo elbow performance score. In addition, levels of overall patient satisfaction were determined using a 10-point scale: in which 10 points denoting very satisfied and 1 point denoting very unsatisfied. All measurements were performed at an average 18 mo follow-up (range, 7 mo-10 years) by an independent assessor who measured elbow and forearm motion using a goniometer.

All patients underwent the same surgical method: the double incision technique uses a transverse incision in the antecubital fossa. After identification of the distal portion of the biceps tendon, the degenerated part is resected. Two locking Krackow sutures with N.2 fiber-wire (Arthrex, Naples, FL) are passed through the distal part of the tendon. After bicipital tuberosity identification, a curved clamp is lead through the interosseous space, forceps are then palped on the dorsal aspect of the proximal part of the forearm, and second longitudinal incision is made over it. With the forearm in maximal pronation, the tuberosity is exposed with a muscle-splitting technique. Three drill holes are placed approximately at 1 cm intervals through the dorsal cortical margin of the tuberosity. The tendon sutures are then passed through the holes. With the elbow at 90° of flexion and the forearm pronated, the biceps tendon is pulled into the bicipital tuberosity and sutures are pulled tight and tied (Figure 1). The elbow is then splinted for 4 wk. Early active-assistive and ROM activities into elbow flexion and extension are advised 3-4 times per day. All patients were treated with indomethacin 75 mg for 3 wk as a standard protocol to prevent heterotopic ossifications.

## RESULTS

The average elbow flexion range was 94% of the uninjured limb (125° *vs* 135°). Average extension was -2°. Supination was 93 % and pronation 96% compared with the uninjuried limb (supination 80° *vs* 84°; pronation 86° *vs* 82°) (Figure 2). The average Mayo elbow performance and DASH score were respectively 97.2 and 4.8. The satisfaction rating score was 9.4 points (Table 1).

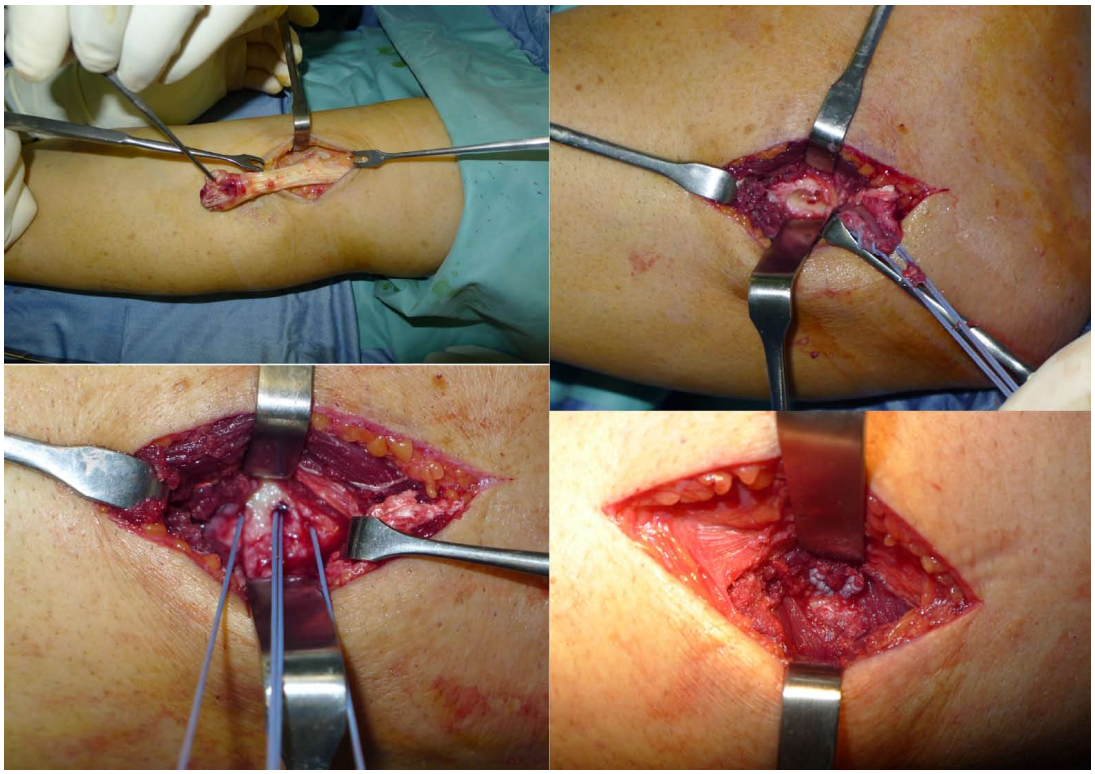

**Figure 1 Intraoperative view showing the double access and the surgical procedure.**

**Figure 2 Clinical evaluation at 40 d after surgery showing complete recovery of the range of motion.**

The reported complications included nerve dysfunction, heterotopic ossification and failure at repair site. We had 3 cases of heterotopic ossification with limited range of movement near to complete loss of forearm rotation. Resection of heterotopic bone was associated with restoration of near-normal motion. One re-rupture of the

tendon at the site of reattachment was found. Two cases of posterior interosseous nerve (PIN) palsy were found but both were resolved without intervention (Table 1).

## DISCUSSION

Distal biceps tendon ruptures usually arise in the dominant elbow of middle-aged male patients[24]. The clinical presentation is characteristic and radiographs, MRI or ultrasound are not necessary to diagnose an acute rupture of the distal biceps. In recent decades surgical repair of this type of lesions have shown improved functional outcomes compared with conservative treatment. Baker *et al*[2] compared operative and nonoperative treatment showing decreased supination strength of 55% and supination endurance of 86% with nonoperative approach compared with controls. Several surgical options have been described in literature: the one incision-approach, using suture anchor, endobuttons, biotenodesis screw for fixation and a two incision approach using bone tunnels[25]. The recreation of an anatomic reattachment of the distal biceps tendon to its osseous insertion at the radial tuberosity has to be the main objective of operative treatment. The modified two-incision approach has demonstrated excellent clinical results with regards to postoperative range of motion, strength, and endurance[26]. Distal biceps tendon repair sometimes lacks elbow motion, due to heterotopic ossification or radioulnar exostosis as well as neurological complications such as PIN injury[27]. Heterotopic bone formation is common following distal biceps tendon surgery and has been reported in both single and double-incision repairs. Higher rates of heterotopic ossification have been described in double-incision treatments performed using the Boyd-Anderson method, where the posterior soft tissues are elevated off the ulna to expose the radial tuberosity[16,17]. Radioulnar synostosis, although rare, is more common with the Boyd-Anderson method rather than with muscle-splitting double-incision approach, in which the periosteal surface of the ulna is not exposed. With this technique, the incidence of synostosis and heterotopic bone has substantially decreased[28,29]. In our cohort complications were reported in 12.8% of cases: 3 cases of heterotopic ossification (6.4%), one (2.1%) re-rupture of the tendon at the site of reattachment and 2 cases (4.3%) of PIN palsy, all of them resolved without intervention. Our rate of complications appears similar to the 10% of cases reported by El-Hawary *et al*[21] using the 2-incision technique, associated with 6-wk prophylaxis with indomethacin 25 mg 3 times a day for 6 wk. In particular they didn't observed any case of heterotopic ossification, and the only type of complication reported was a transient superficial radial nerve paresthesia, supporting a longer lasting profilaxis against heterotopic ossification.

In our research tendon fixation was performed by 3 trans-osseous tunnels placed at the apex of radial tuberosity. In the last years, new fixation equipment like suture anchors, interference screws, and fixation buttons have been brought in and biomechanically tested[30-34], demonstrating encouraging results[35-37].

Clinical studies have found little difference between 1- and 2-incision approaches in terms of complications, re-ruptures, flexion and supination strength as well as endurance[21,23,26,38]. However, recently, it has been demonstrated that the 2-incision approach recreates more closely footprint position compared with the 1-incision approach[39].

In conclusion, the Morrey's modified double-incision repair provided excellent outcome (including functional outcome, satisfaction, elbow and forearm motion, and grip strength) with few post-operative complications, mainly represented by heterotopic ossification and PIN injuries.

## COMMENTS

### *Background*

Biceps tendon ruptures occur at the distal aspect in 3% of all lesions. Both single-incision and 2-incision techniques, using various fixation methods, have been described to accomplish tendon reattachment to the bicipital tuberosity; however there is no consensus with respect to the best surgical approach.

### *Research frontiers*

Authors retrospectively reviewed 47 patients with distal rupture of biceps brachii treated between 2003 and 2012 in authors' Orthopedic Department with muscle-splitting double-incision technique.

### *Innovations and breakthroughs*

In the present research the Morrey's modified double-incision repair provided excellent outcome (including functional outcome, satisfaction, elbow and forearm motion, and grip strength) with few post-operative complications, mainly represented by heterotopic ossification and posterior interosseous nerve injuries.

### *Peer review*

The article is interesting, well written, documented and analyzed with tests valid and internationally recognized. Good and clear figures. The discussion and conclusions interesting and valid. The author think it can be published with high priority.

## Abstract

**AIM:** To investigate the outcomes of trauma patients with traumatic brain injury (TBI) on Dabigatran Etexilate (DE).

**METHODS:** Following IRB approval, all patients taking DE who were admitted to our level 1 trauma service were enrolled in the study. Injury complexity, length of stay (LOS), intensive care length of stay, operative intervention, therapeutic interventions and outcomes were analyzed retrospectively.

**RESULTS:** Twenty-eight of 4310 admissions were taking DE. Eleven patients were excluded on concurrent antiplatelet therapy. Average age was 77.14 years (64-94 years), and average LOS was 4.7 d (1-35 d). Thirty-two percent were admitted with intracranial hemorrhage. Eighteen percent received factor Ⅶ, and 22% received dialysis in attempts to correct coagulopathy. Mortality was 21%.

**CONCLUSION:** The low incidence, absence of reversal agents, and lack of practice guidelines makes managing patients with TBI taking DE frustrating and provider specific. Local practice guidelines may be helpful in managing such patients.

**Key words:** Dabigatran; Brain injury; Anticoagulation; Dabigatran reversal

**Core tip:** Dabigatran Etexilate (DE) and other novel anticoagulants that lack reversal agents complicate the care of trauma patients. Current practice guidelines should be available to aid in managing patients with traumatic brain injury on DE.

## INTRODUCTION

Arterial and venous thromboembolism (VTE) is a significant cause of mortality and morbidity. Direct and indirect inhibitors of coagulation are being increasingly utilized for prophylaxis and treatment of myocardial infarction, valvular disease, deep venous thrombosis, pulmonary embolism, atrial fibrillation, and stroke[1]. Compliance rates for VTE prophylaxis are being used in pay for performance by third party payors and have been included as an independent new core measure by the Center for Medicare and Medicaid Services[2].

Many anticoagulants are available to the clinician: an-

tiplatelet agents, thromboxane A2 receptor antagonists, Adenosine Diphosphate (ADP) receptor antagonists, Protease Activated Receptor (PAR)-1 antagonists, inhibitors of initiation or propagation of coagulation, Factor Ⅸ-directed antibodies, direct and indirect Factor Xa inhibitors, factor Va and Ⅷa inhibitors, inhibitors of fibrin formation, and medications than enhance fibrinolysis[3]. Due to the complication rate, volume of distribution, delayed onset, prolonged effect, unpredictable pharmacokinetics, food and medication interactions, and frequent monitoring associated with warfarin usage, industry has focused on developing oral thrombin and Factor Xa inhibitors for patients who require long-term anticoagulation.

Dabigatran Etexilate (DE) (Pradaxa®) 150 mg twice daily is the first orally available FDA approved direct thrombin inhibitor (DTI) in the United States. Due to predictable pharmacokinetics and pharmacodynamics, limited drug-drug interaction or effect of food, and no need for coagulation monitoring, DE was introduced enthusiastically and approved for treatment of non-vavlular atrial fibrillation (AF) with a class 1 recommendation[4]. Head to head trials with warfarin showed that DE reduced the risk of stroke by more than one-half and that mortality from intracranial hemorrhage was not increased (1B)[5]. Patients on DE had a significantly higher rate of gastrointestinal bleeding and trended toward an increased number of adjudicated coronary events[5]. As no reversal agent or accurate method of measuring the clinical effect of DE exists, recommendations for patients undergoing elective surgery currently taking DE are to stop the DE 1-5 d prior to the procedure, depending on the complexity of the surgery and the patient's creatinine clearance (CrCL)[3,6,7].

Trauma patients and those with acute surgical issues frequently do not have the luxury of waiting 1-5 d for the pharmacologic effects of DE to subside. After several frustrating patient interactions that essentially involved supportive care, we hypothesized that patients taking DE admitted with traumatic injuries would have poor outcomes due to the lack of a reversal agent. We herein report our series of patients admitted to our trauma and acute care surgery service on DE, focusing on patients with traumatic brain injury (TBI), and comment on potential treatment strategies available.

## MATERIALS AND METHODS

After receiving institutional board approval, all patients between October 2011 and September 2012 admitted through the emergency room to one health system's two Level 1 trauma centers were prospectively evaluated to include all patients who were actively taking DE on admission. Only patients over the age of 18 with vital signs on arrival were included in the study.

Patient management was directed by the trauma and acute care surgeon in conjunction with subspecialized physicians. Presence of traumatic brain injury on computed tomography (CT) was verified by a board certified radiologist, and demographic data, admission laboratory data including hemoglobin, prothrombin time (PT/INR), and partial thromboplastin time (PTT), patient acuity, therapeutic interventions, transfusion requirements, and patient outcomes were evaluated retrospectively.

### *Statistical analysis*

Statistical analysis was performed using Microsoft Excel Analysis ToolPak (Student *t*-Test, $\chi^2$ Test, Anova).

## RESULTS

Of the 4310 admissions to the trauma and acute care surgery service over the twelve month period, 31 (0.7%) patients taking DE were identified. Nine of the 1259 admissions with CT evidence of TBI were taking DE. Three of the 31 patients on DE were excluded because no significant surgical pathology was present. Of the remaining 28, the average age (SD) was 77.14 (10.5), median admission INR/PTT was 1.45/50.3, 11 were on concurrent anti-platelet medications. 6 received DE directed dialysis and 6 received factor Ⅶa. Mortality was 21% (6/28). Results for the subgroups of patients with TBI, injury without TBI, and acute care surgery are displayed in Table 1.

The individual data for the nine TBI injured patients on DE are listed in Table 2. Eight patients (89%) were taking DE for stroke prophylaxis and one for treatment of a prior pulmonary embolism. Recorded dosage was 150mg BID for all 9 subjects. Eight of nine patients had an elevated INR (mean = 1.68) and PTT (mean = 54). Four patients were taking antiplatelet medications concomitantly. Types of intracranial hemorrhage observed in these patients were sub-arachnoid (4), sub-dural (2), combined (2), and intraparenchymal (1). Two of the three patients who received no intervention died: one presented with a non-survivable injury and the second initially appeared to have a minor injury that within hours progressed clinically and radiographically (Figure 1).

## DISCUSSION

Coagulopathy and associated bleeding remain significant issues in the trauma population. Coagulopathy due to blood loss is addressed by controlling the ongoing bleed-

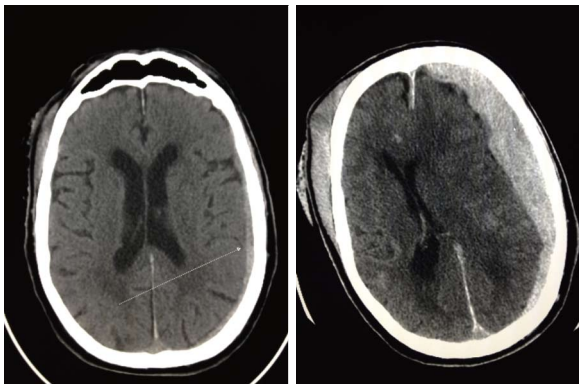

**Figure 1 Rapid progression of intracerebral hemorrhage on patient on Dabigatran Etexilate.**

ing, keeping the patient warm and perfused, and using accepted protocols to replace blood and blood products. Pharmacologically induced coagulopathy poses a similar risk and is becoming more prevalent, with approximately 1.5 million Americans taking a vitamin K antagonist daily[8]. Treatment of these patients is fairly straightforward as the effect of vitamin K is easily measured and the deficient clotting factors can be replaced.

With the introduction of DE, and subsequent FDA approval of direct factor Xa inhibitors rivaroxaban (Xarelto®) and apixaban (Eliquis®), the trauma surgeon faces a unique challenge in patients with ongoing bleeding who may or may not require surgery. DE is an orally available direct thrombin inhibitor that is rapidly converted to dabigatran and binds to free and clot bound thrombin. Time to maximum concentration is 2 h, half-life is 12-17 h, limited protein binding suggest DE may be dialyzed, and over 80% of the drug is excreted by the kidneys[3,7,9]. The FDA-approved indication is to reduce the risk of stroke and systemic embolism in patients with non-valvular atrial fibrillation[10].

Advantages of DE include the significant risk reduction of stroke and systemic embolization, predictable pharmacokinetics requiring no coagulation monitoring, a fast onset and offset of action, a relatively short half-life, and limited drug-drug interaction[3,7,11]. Drug cost compared to monitoring with warfarin is revenue neutral. Worldwide there have been at least 260 episodes of post-marketing bleeds resulting in death in patients on DE[12,13]. Our study documents the institutional complication rates of patients on DE and not the effectiveness of DE *vs* oral vitamin K antagonist. The dilemma facing the trauma surgeon is that there is no accepted laboratory test to measure the effect of DE nor are there recommended reversal agents[3,6,7,14]. Both of these factors are especially relevant in the patient with a TBI. The anticoagulant effects have attempted to be quantified in normal human subjects, laboratory animals, and *in vitro* by adding DE to human serum. Assays evaluated include PT, aPTT, factors Ⅱ, Ⅷ, Ⅸ, Ⅹ, and Ⅺ, quantitative D-dimer, reptilase time, von Willebrand factor antigen , antithrombin, plasminogen, thrombin clotting time, protein C activity, ecarin clotting time, and activated protein C resistance[1,11]. Although analytes may be elevated with various concentrations of DE, most notably the aPTT and thrombin clotting time, reported levels frequently are factitiously elevated or low, display incomplete correction, do not correlate with serum levels leading to misdiagnosis and mismanagement, or are insensitive or oversensitive, making virtually any result unreliable[11]. The best determinate of DE effect is knowing the timing of administration, as peak effect is usually two hours after ingestion, the dosage and the patient's renal function (CrCl > 50 provides normal excretion)[9].

Treatment can be simplistic and futile as no known DE counteracting agent exists, so any form of intervention in patients with life-threatening bleeding is empirical. What makes this even more frustrating is the individual trauma surgeon most likely treats a patient taking DE once every several months, has no recommended guidelines, and may be unfamiliar with the intricacies and pharmacokinetics of the most recently approved oral anticoagulant. Considering that not intervening when a patient is actively bleeding is difficult for the treating surgeon, we will discuss the rationale behind several available treatment strategies although all lack even level 3 evidence.

Excluding direct compression, topical thrombin, and simple surgical procedures to obtain hemostasis, viable options to treat extensively injured, TBI, and complex surgical patients taking DE include oral charcoal, activated prothrombin complex concentrates (aPCC), recombinant factor Ⅶa, concentrates of coagulation factors Ⅱ,

IX, and X, and dialysis.

Oral charcoal can be used within two hours of ingestion as charcoal significantly inhibits absorption of DE[6,7]. Kcentra (CSL Behring LLC) is the only four factor prothrombin complex concentrate available in the United States, has not been shown to correct the aPTT in healthy volunteers taking DE, but high doses have been shown to limit intracranial bleeding in rats[3,14]. In a patient with life-threatening bleeding with limited therapeutic options, an INR based dose of 25-50 IU/kg may be justified[6]. Recombinant VIIa has not demonstrated any alteration in the coagulation profile or outcomes in healthy volunteers or laboratory animals taking DE and has documented higher arterial thromboembolic events[15]. Subsequently, salvage therapy with rVIIa should be used cautiously, although a case report suggests high dose therapy (7.2 mg × 2) may be beneficial[16]. Activated PCC has been shown to correct the anticoagulant effect of DE in animal models and reduces clot initiation time in humans *in vitro*. Siegal suggests using aPCC (80 U/kg) over PCC in patients taking DE, but reverses the recommendation for patients taking rivaroxaban (XareltoR) or apixaban (Eliquis), acknowledging that any such recommendation is based on limited data[17]. Kcentra has been shown to partially reverse the effects of factor Xa inhibitors[14].

Dialysis is an attractive option as DE is not plasma bound and excreted renally, but this is the most invasive option and use may be limited due to injury severity. In patients with end-stage renal disease, dialysis removed 62% of circulating DE within two hours, although due to the volume of distribution serum levels rebounded quickly upon cessation of dialysis[9]. Selective case reports suggest that prolonged dialysis (6 h) with flow rates of 700 mL/min improve outcome[16].

Maintaining adequate diuresis is important for all patients, but should not be overlooked as DE is excreted renally. Currently no role exists for desmopressin, protamine sulfate, tranexamic acid, or vitamin K, or fresh frozen plasma[3,6,7]. Platelet concentrates should only be used in cases with thrombocytopenia or concurrent antiplatelet therapies. Although not yet available, a monoclonal antibody directed against DE is under development[17].

In our experience, less than one percent of trauma and acute surgical admissions were taking DE and each surgeon averaged fewer than two patients per year. The percentage of patients with TBI is remarkably similar. With such limited numbers, and reviewing the largest industry sponsored trial (18113 patients) reporting outcomes of 22 patients with TBI, level 1 management recommendations are unlikely[18].

Subsequently, we developed an in-house protocol for patients admitted taking DE, where we obtain baseline clotting studies, a stat hematology consult for major or life-threatening hemorrhage, a nephrology consult for initiation of hemodialysis, and the option of giving a 40 mcg/kg IV dose of rfactor VIIa or Kcentra.

Our study is limited by the small sample size and retrospective collection of the data. Additionally, recommendations extrapolated from the literature combine data from multiple laboratories and include human, animal, and *in-vitro* studies. Finally, treatment is individualized and up to the discretion of the surgeon.

In a conclusion, DE is a cost-neutral highly effective oral direct thrombin inhibitor approved recently along with two factor Xa inhibitors, rivaroxaban and apixaban. Management of the traumatic brain injury patient taking DE poses unique and confounding issues as the effect of DE is not measurable and no reversal agents are currently recommended. Trauma surgeons manage patients on DE infrequently and such encounters may be frustrating. For patients taking DE, strategies for non-operative management of bleeding are discretionary and institution dependent and include oral charcoal, maintaining adequate diuresis, PCC, aPCC, and dialysis.

## COMMENTS

### Background

Seventy million Americans will be over the age of 65 by 2030 and five percent of these patients have atrial fibrillation and are candidates for anticoagulation. In 2010, the ACC Foundation and the AHA added Dabigatran Etexilate (DE) to their treatment guidelines with a class 1 recommendation for non-valvular atrial fibrillation. DE is an attractive alternative to warfarin (WF) due to improved outcomes and the lack of need for serial monitoring. However, it poses a risk to the trauma population because of an extended half-life and the lack of a reversal agent. Therefore it was our aim to review the outcomes of patients with TBI on DE.

### Research frontiers

DE and other novel anticoagulants that lack a true reversal agent post a unique dilemma for trauma surgeons. Local care plans should be initiated until dose specific reversal agents are commercial available.

### Applications

Current practice guidelines should be available to aid in managing patients with traumatic brain injury on DE. Therapeutic options include: oral charcoal, maintaining adequate diuresis, prothrombin complex concentrates, activated prothrombin complex concentrates, and dialysis.

### Terminology

Dabigatran Etexilate is a new oral anticoagulant that works by directly inhibiting thrombin in the clotting cascade.

### Peer review

This is a single institution observation study and it is limited as such. Future research goals will be multi institution collaborations on not just DE but other novel agents in the hopes of developing nationwide guidelines for treatment of novel agents until industry specific antidotes are commercially available.

## Abstract

Desmoplastic small round cell tumor (DSRCT) is a rare, aggressive malignant neoplasm of unknown origin, and is comprised of small round cells with a characteristic desmoplastic stroma. DSRCT typically expresses epithelial, mesenchymal and neural markers simultaneously. We describe a case of DSRCT with an atypical immunohistochemical profile and rhabdoid-like tumor cells on electron microscopy. In the present case, the neoplastic cells were positive only for vimentin, desmin (cytoplasmic membranous pattern) and CD56, and negative for smooth muscle actin, synaptophysin, CD117, CD45, myogenin, CAM5.2, pancytokeratin, WT1, EMA, CD99, neurofilament, CD34 and p53. Ki67 showed a low proliferative activity. Electron microscopy showed focal rhabdoid differentiation. However, INI-1 (SNF-5/BAF47) demonstrated preservation of nuclear positivity in the neoplastic cells. Cytogenetic studies showed translocation t(11;22)(p13;q12) confirming an EWSR1-WT1 translocation characteristic for DSRCT, and t(1;15)(q11;p11.2) of unknown significance. This case is a diagnostic challenge because of atypical immunohistochemical profile and cytogenetic study is crucial in rendering the correct diagnosis.

**Key words:** Desmoplastic small round cell tumor; Ultrastructure; Cytogenetics; Rhabdoid cells; EWSR1-WT1

**Core tip:** We describe a case of desmoplastic small round cell tumor (DSRCT) with an atypical immunohistochemical profile and rhabdoid-like tumor cells on electron microscopy (EM). DSRCT typically expresses epithelial, mesenchymal and neural markers simultaneously. In this case, the neoplastic cells were positive only for vimentin, desmin and CD56 and negative for epithelial and other muscle markers. EM showed focal rhabdoid differentiation, but INI-1 (SNF-5/BAF47) demonstrated preservation of nuclear positivity in the neoplastic cells. Cytogenetic studies showed translocation t(11;22)(p13;q12) confirming an EWSR1-WT1 translocation characteristic for DSRCT, and t(1;15)(q11;p11.2) of unknown significance.

Desmoplastic small round cell tumor with atypical immunohistochemical profile and rhabdoid-like differentiation. *World J Clin Cases* 2014; 2(8): 367-372 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/367.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.367

## INTRODUCTION

Desmoplastic small round cell tumor (DSRCT) was first

described in 1989[1,2]. DSRCT is a rare, aggressive malignant neoplasm of unknown origin, and is comprised of small round cells with a characteristic desmoplastic stroma. DSRCT is most common in children and young adults (mean age 22 years), with a male predominance (male to female ratio 4:1)[3]. The most common location is the abdominal and/or pelvic cavity, but it has been described in many organ systems, including ovary, paratesticular region, kidney, lung, pleura, parotid gland and central nervous system[4-11]. Typically, DSRCT has a distinctive immunohistochemical profile and expresses polyphenotypic markers simultaneously. The tumor cells usually express epithelial (cytokeratin, epithelial membrane antigen), mesenchymal (desmin, vimentin) and neural (neuron-specific enolase, chromogranin, synaptophysin) markers. Desmin immunoreactive displays in a perinuclear *dot-like* Golgi *pattern*. DSRCTs with atypical morphology or immunohistochemical features have been reported[12,13]. Cytogenetics, FISH, RT-PCR and molecular testing are crucial in rendering the correct diagnosis[14].

DSRCT is associated with a unique chromosomal *translocation* t(11:22)(p13;q12) which involves the Ewing sarcoma gene breakpoint region 1 (*EWSR1*) on 22q13 and the Wilms tumor gene (*WT1*) on chromosome 11p13[15]. *EWSR1* gene encodes EWS protein, which is a multifunctional protein associated with gene expression, cell signaling, and RNA processing and transport. *WT1* is a tumor suppressor gene that encodes a zinc finger protein which regulates several growth factors, including platelet-derived growth factor-A (PDGFA)[16]. The most common breakpoints involve the intron between *EWSR1* exon 7 and 8 and the intron between *WT1* exons 7 and 8, although breakpoint variations have been described[17-19].

## CASE REPORT

An 8 years old male with no known significant past medical history presented with 1 wk history of vague abdominal pain. The child was afebrile, had regular bowel movements, tolerated a regular diet, and denied nausea and vomiting. Physical examination showed a mildly distended abdomen without a readily palpable mass. CT of the abdomen and pelvis revealed a 17-cm heterogeneously enhancing complex cystic lesion, which displaced the colon and small intestine laterally and superiorly. On exploratory laparotomy, the mass was adherent to the omentum. The mass was tossed, with large dilated blood vessels on the external surface of the tumor. The patient tolerated the surgical procedure well.

### Gross pathology

Upon gross examination, the mass was encapsulated, lobulated and measured 17.0 cm × 11.0 cm × 5.0 cm, with attached omental tissue (Figure 1A, B). Cross sections of the mass showed variegated cut appearance ranging from tan to red to black in color. Focal areas of hemorrhage and necrosis were noted.

### Microscopic and immunohistochemical features

Microscopic examination showed small round cell aggregates embedded in a fibromyxoid stroma (Figure 1C-F). The tumor cells were round to oval with scant cytoplasm, hyperchromatic nuclei and inconspicuous nucleoli. However, certain tumor cells have a different histomorphologic appearance with enlarged nuclei, open chromatin and prominent nucleoli. Focal tumor necrosis and hemorrhage were present, corresponding to these features seen upon gross examination. Prominent vascular proliferation was associated with the tumor. An atypical immunophenotype (Figure 2A-D) was demonstrated. The tumor cells were positive only for vimentin, desmin (cytoplasmic membranous pattern) and CD56, while being negative for smooth muscle actin, synaptophysin, CD117, CD45, myogenin, CAM5.2, pancytokeratin, WT1, EMA, CD99, neurofilament, CD34 and p53. Ki67 showed a low proliferative activity.

### Ultrastructural features

Electronic microscopy (Figure 2E, F) showed closely apposed tumor cells with rudimentary intercellular junctions and without myofilaments, dense core neurosecretory granules, cytokeratin-like intermediate filaments and no glycogen aggregates. The tumor cells had irregular nuclear outlines, prominent heterochromatin and moderate cytoplasm. There was readily identified rhabdoid differentiation within a certain population of tumor cells. These tumor cells had large aggregates of cytoplasmic filaments that displaced the nuclei to the periphery of the cell, with some tumor cells having indented nuclear profiles. There were also entrapped organelles within cytoplasmic filament whirls. Upon discovery of these rhabdoid cells on ultrastructural examination, immunohistochemical staining for INI-1 (SNF-5/BAF47) was performed. Surprisingly, all tumor cells demonstrated preservation of nuclear positivity, eliminating rhabdoid tumor from the differential diagnosis.

### Cytogenetics

Upon cytogenetic analysis, the karyotype of the cultured tumor cells was shown to be 46,XY, t(11;22)(p13;q12)[12]/92, idemx2[4] with t(1;15)(q11;p11.2). The t(11;22) translocation harbored the *EWSR1-WT1* translocation, a tumor-defining feature of DSRCT. A diagnosis of DSRCT with rhabdoid-like cell component was rendered.

## DISCUSSION

The differential diagnosis of a "small round cell tumor" includes Ewing sarcoma, Wilms tumor, neuroblastoma, medulloblastoma, rhabdomyosarcoma, small cell osteosarcoma, small cell synovial sarcoma, small cell carcinoma, lymphoma, and rhabdoid tumor. DSRCT has characteristic immunohistochemical features, with expression of epithelial, mesenchymal and neural markers simultaneously, which is helpful in differentiating DSRCT from other "small round cell tumors". However

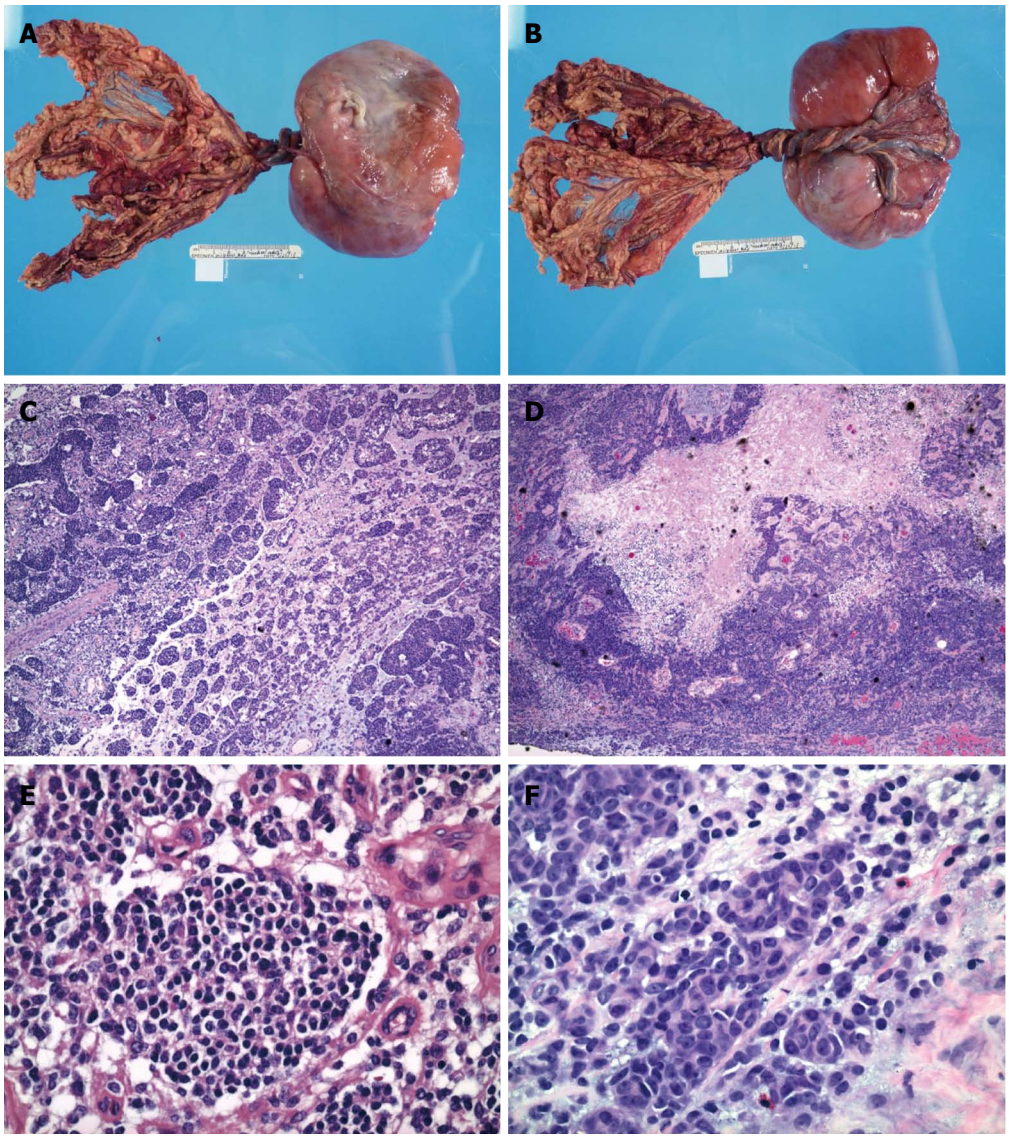

**Figure 1 Gross and microscopic feature of abdominal mass.** A, B: Gross examination showed an encapsulated and lobulated soft tissue mass with attached omental tissue; C-F: The small round cell tumor possessed round to oval hyperchromatic nuclei with inconspicuous nucleoli and scant cytoplasm. Focal tumor cells with enlarged nuclei, open chromatin and prominent nucleoli, as well as rhabdoid differentiation were noted. Focal tumor necrosis and hemorrhages were present (HE staining).

in the present case, the tumor cells were negative for many epithelial, myogenic and neural markers and positive only for vimentin, CD56 and desmin. CD56 is a nonspecific marker, and expressed in many "small round cell tumors", including alveolar rhabdomyosarcoma, embryonal rhabdomyosarcoma, neuroblastoma, Wilms tumor, neuroendocrine neoplasms and undifferentiated sarcoma[20]. Desmin showed a cytoplasmic membranous pattern, instead of the typical perinuclear dot-like Golgi pattern characteristic for DSRCT. The atypical immunohistochemical features made it difficult to make a correct diagnosis by morphologic and immunohistochemical features alone. DSRCT lacking epithelial markers and/or divergent immunophenotype has been described in several reports[12,13,21]. Cytogenetic and molecular studies are crucial in these cases in rendering an accurate diagnosis.

DSRCT can have many morphologic variations[22-24]. In our case, focal rhabdoid differentiation was identified on EM. However, the nuclear expression of SNF-5(INI1/BAF47) was preserved in the tumor cells, which did not support a diagnosis of rhabdoid tumor. The ultrastructural features of DSRCT include intracellular whirls and packets of intermediate filaments that usually fill the cytoplasm and displace the nucleus, while entrapping cytoplasmic organelles within the filaments[25-27]. Rhabdoid differentiation, as well as focal areas with increased nuclear atypia, has been previously described in DSRCT[28]. Although DSRCT usually has a desmoplastic stroma, this was not present in our case. Prominent vascular proliferation can be seen in DSRCT, as in our case, and the differential diagnosis of infiltrating glomus tumor may be entertained. However, infiltrating glomus tumor typically expresses smooth muscle actin and variably desmin. Other morphologic variations previously described

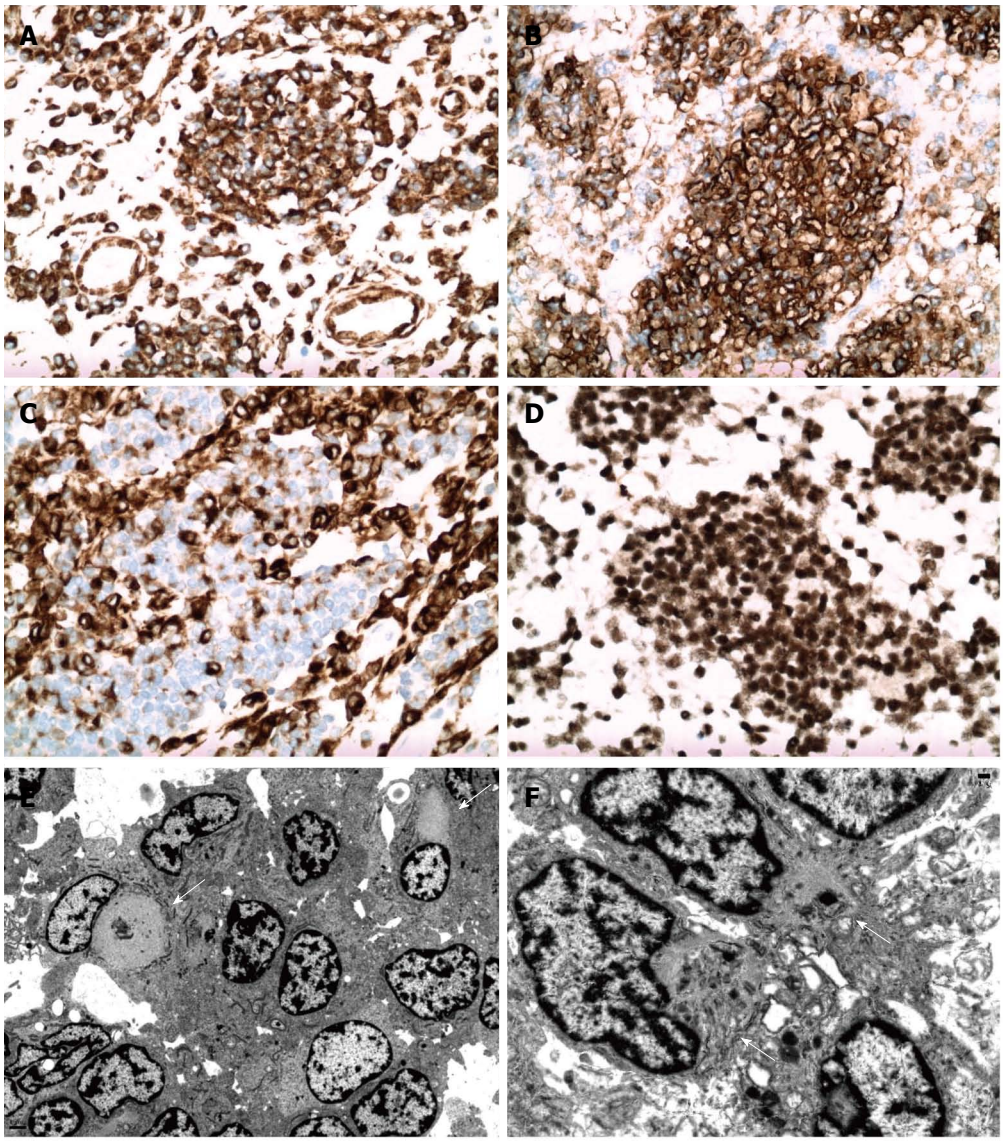

**Figure 2 Immunohistochemical and ultrastructural features of abdominal mass.** Tumor cells exhibited strong diffuse cytoplasmic vimentin expression (A), diffuse membranous CD56 expression (B), cytoplasmic and membranous desmin expression (C), and nuclear INI-1 reactivity (SNF-5/BAF47) with tumor cells and non-neoplastic cells. Electron microscopy (E, F) showed closely apposed tumor cells with irregular nuclear outlines and heterochromatin. There were intermixed tumor cells with aggregates and whirls of intermediate filaments (arrows) that displaced the nuclei and entrapped organelles.

in DSRCT, such as signet ring-like appearance, "zellballen" pattern, tubular-like structure or papillary areas were not identified in our case[23,29].

Interestingly, our case not only had an unusual immunohistochemical profile, but also a unique karyotype. Cytogenetic study showed translocation t(11;22)(p13;q12), which is characteristic of DSRCT, and an additional translocation t(1;15)(q11;p11.2). Even though the characteristic *EWSR1/WT1* translocation can be detected by reverse transcription polymerase chain reaction (RT-PCR), cytogenetic testing is necessary to detect tumor-defining translocations, novel translocations and complex karyotypic aberrations. Of note, the INI-1 (hSNF5) gene is located at 22q11.2 in close proximity to EWSR1. This close proximity may have led to dysregulation of the IN1-1 gene function without loss of INI-1 gene protein expression. Rhabdoid tumors without INI-1 gene loss or mutation and expression of INI-1 gene protein have been reported[30]. These rhabdoid tumors have loss or mutation of *SMARCA4* (19p13.2) which dysregulates a signaling pathway downstream from INI-1 gene protein function. In an extensive search of the English language literature, the t(1;15)(q11;p11.2) has not been previously reported in pediatric neoplasia. Of interest, translocations involving 1q11 have been reported in myelodysplastic syndromes. The pericentromeric region of chromosome 1 is an unstable region involved in several chromosomal rearrangements. A possibility is that the heterochromatin of chromosome 1 may have a silencing effect, or otherwise interfering effect, with genes present in the region involved in the translocation. Few myelodysplastic syndrome cases with a der(1;15) translocation have been reported[31].

In the present case, infrequent tumor cells also showed

tetraploid clonal evolution, which is common in many tumors and has been previous reported in DSRCT[32]. Our hypothesis is that the unusual immunohistochemical profile in our case was due to the complex karyotype. It is debatable if the tumors with complex karyotype should still be called DSRCT or a new category of "gray zone small blue cell tumor" should be created in the future. Currently, no standard oncologic therapy is available for DSRCT and the prognosis is dismal even with multimodality oncologic therapy[33-35]. The 5-year survival rate is approximately 15%[35]. The prognosis significance of DSRCT with complex karyotype is currently unclear.

## COMMENTS

### Case characteristics

An 8 years old male with no known significant past medical history presented with 1 wk history of vague abdominal pain.

### Clinical diagnosis

The child was afebrile, had regular bowel movements, tolerated a regular diet, and denied nausea and vomiting. Physical examination showed a mildly distended abdomen without a readily palpable mass.

### Differential diagnosis

Electronic computer X-ray tomography technique of the abdomen and pelvis revealed a 17-cm heterogeneously enhancing complex cystic lesion, which displaced the colon and small intestine laterally and superiorly.

### Treatment

The authors describe a case of desmoplastic small round cell tumor with an atypical immunohistochemical profile and rhabdoid-like tumor cells on electron microscopy.

### Experiences and lessons

This case is a diagnostic challenge because of atypical immunohistochemical profile and cytogenetic study is crucial in rendering the correct diagnosis.

### Peer review

The authors report an atypical small round cell tumor case. The manuscript is clearly written and the case is of interest.

## Abstract

A 50-year-old male who underwent a HeartMate Ⅱ left ventricular assist device placement for ischemic cardiomyopathy presented with discolored urine and hemolysis 3 mo after the operation. His hemolysis was thought to be due to thrombosis within the pump. Imaging studies were not able to visualize a left ventricular thrombus. Medical management with anticoagulation failed and he underwent surgery for a pump exchange. Intraoperatively, a firm thrombus was found within the pump of the HeartMate Ⅱ, and the color of the urine changed dramatically from cola-colored to yellow which enabled us to confirm the diagnosis.

**Key words:** Cardiac surgery; Hemolysis; Left ventricular assist device; Thrombosis

**Core tip:** Diagnosis of pump thrombosis is difficult, but the intraoperative change of the color of urine may be seen almost immediately after pump exchange. This report also highlights the technical aspect of replacing the HeartMate Ⅱ pump, and we believe the images are educational for the readers.

## INTRODUCTION

HeartMate Ⅱ (Thoratec, Pleasanton, CA) is a continuous flow left ventricular assist device (LVAD), which has improved the quality of life and survival of patients who have end-stage heart failure refractory to medical therapy. The device is consisted of an inflow cannula in the left ventricle, axial flow pump, and an outflow graft to the ascending aorta. It is designed for long-term usage, either bridge to transplant or destination therapy. Since 2006, more than 10000 HeartMate Ⅱ LVADs have been implanted, and 2500 LVADs have been implanted in 2013, according to the INTERMACS registry[1]. Consequently, the incidence of device-related complications, such as pump thrombosis, infection, bleeding, has increased, which often require re-admission and/or surgery[2]. Pump thrombosis is one of the common causes of hemolysis in patients with LVAD. Hemolysis related to the LVAD could be due to kinking of the outflow graft, malposition of the inflow cannula, or malfunction of the pump. We present a case of an LVAD thrombosis that presented with hemolysis and discolored urine 3 mo after the LVAD placement. The patient failed conservative medical management and underwent surgery for pump exchange. Thrombus was seen in the pump and the color of the urine changed dramatically after the pump was exchanged which enabled us to confirm the diagnosis of pump thrombosis.

## CASE REPORT

A 50-year-old male with a history of axillo-bifemoral

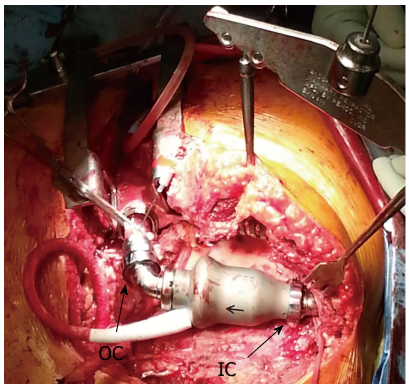

**Figure 1 Intraoperative photo after the replacement of the pump.** IC: Inflow connection; OC: Outflow connection.

**Figure 2 Inspection of the pump revealed a firm thrombus along the inlet stator.**

bypass for bilateral chronic iliac artery occlusive disease, ischemic cardiomyopathy with an ejection fraction of 20%, underwent placement of a HeartMate Ⅱ LVAD as a bridge to cardiac transplantation. Preoperative hematology work-up disclosed no evidence of hypercoagulability. Heparin infusion was started on postoperative day 1 and warfarin was started on postoperative day 3. Heparin drip was maintained with a goal PTT level of 60 to 70 s until the INR reached 1.8. He was discharged on postoperative day 15 on aspirin 325 mg and warfarin with a target INR of 1.8 to 2.5. Upon discharge, the LVAD was set at 9200 rpm, giving a flow of 5.7 L/min, with a pulsatility index (the pulsatility of the flow through the pump) of 5.5 and pump power (a direct measurement of motor voltage and current) of 6.7 watts.

Three months later on his scheduled office visit, his lactate dehydrogenase (LDH) was found to be elevated to 1352 IU/L (Table 1). His baseline LDH level was between 400 and 500 IU/L. Interrogation of the pump parameters revealed several episodes of elevation in the pump power a few days before the office visit that had since resolved. It was thought to be due to a small pump thrombus that resolved spontaneously. Ten days later, he was admitted to the hospital due to discolored urine. Urine analysis showed strongly positive hemoglobin, very few red blood cells, and white blood cells. He denied any chest pain, shortness of breath, or edema. There were no signs of infection. Hemoglobin was 7.6 g/dL, plasma free hemoglobin was 52.0 mg/dL. The LDH, haptoglobin, AST were unable to be measured due to severe hemolysis. Other lab values included INR 1.7, serum creatinine 1.9 mg/dL (baseline 1.2 mg/dL), total bilirubin 1.1 mg/dL. Echocardiography showed severe biventricular dysfunction and opening of the aortic valve with every heartbeat. The velocity through the inflow cannula was 1.1 m/s. The LVAD parameters showed occasional pump power elevation over 9 watts. Heparin was initiated but there was no resolution of the discolored urine over three days. Although echocardiography and chest CT scan failed to demonstrate a thrombus, he was clinically diagnosed with pump thrombosis. Due to the persistently elevated creatinine and requirement of multiple blood transfusions for hemolytic anemia despite optimum medical therapy, the decision was made to proceed with pump exchange.

After resternotomy, cardiopulmonary bypass (CPB) was established with ascending aorta and right femoral vein cannulation, as the femoral arteries were not able to be cannulated due to iliac artery occlusions. To gain access to the inflow portion of the LVAD, a left subcostal incision was added and the body of the HeartMate Ⅱ pump was removed by unscrewing the inflow- and outflow- connections. It was replaced with a new HeartMate Ⅱ pump (Figure 1). There was no thrombus in the inflow cannula or outflow conduit. Intraoperative inspection of the original LVAD interior demonstrated a firm thrombus along the inlet stator (Figure 2). The urine color was tea-colored before CPB (Figure 3A). It changed to reddish upon cessation of flow from the original LVAD and institution of CPB (Figure 3B). Following initiation of the new LVAD flow and discontinuation of CPB, it changed to a yellow color (Figure 3C). Postoperative recovery was steady and his renal function recovered with clear urine (Table 1). Anticoagulation therapy consisted of intravenous heparin with overlapping warfarin (INR 2.5 to 3.5), aspirin 325 mg, and clopidogrel 75 mg. He was discharged home on postoperative day 8. The patient was symptom free afterwards, and underwent heart transplant 2 mo later.

## DISCUSSION

LVAD therapy requires a balance between anticoagulation and hemostasis to prevent the complications of bleeding and thrombosis. There are many anticoagulation regimens to achieve this goal, and most combine inhibition of the clotting cascade with warfarin and at least one antiplatelet agent. The optimal anticoagulation/antiplatelet strategy remains elusive because of the heterogeneity in the reaction between the biological components (*i.e.*, blood) and artificial surfaces (*i.e.*, LVAD) as well as the variability in the responsiveness to anticoagulants and anti-platelet medications[3]. As a result of this imperfect coexistence between "man" and "machine", the lead-

ing causes of LVAD readmissions include bleeding and thrombosis. Thrombosis of the LVAD is a potentially lethal complication which occurs in 2% to 3% of the patients who receive the HeartMate Ⅱ LVAD and the incidence is reported to be increasing[4-6]. Patients typically present with elevated pump power, heat over the pump, heart failure and signs of hemolysis. Echocardiography may show opening of the aortic valve due to inadequate decompression of the left ventricle (LV) and increased LV end-diastolic diameter. Serial recording of LV end-diastolic diameter while increasing the pump speeds may diagnose pump thrombus or other flow obstructions[7]. However, there have been reports of pump thrombosis with normal echo and pump parameters as well[8,9]. Hemolysis may be the only sign of thrombosis, although hemolysis may be due to various reasons, such as kinking of the outflow graft, malposition of the inflow cannula or the pump itself (high shear stress, *etc.*)[8,9]. The diagnostic challenge is that pump thrombus may not be visualized with contrast CT scan or echocardiography, due to artifacts caused by the metallic housing of the LVAD[8]. In our case, we were able to confirm that the hemolysis was due to pump thrombosis by intraoperative inspection of the removed pump and the resolution of the urine after pump exchange.

Change of urine color is easily noticeable to patients and should be promptly addressed as a sign of possible pump thrombosis. In the current era of non-pulsatile LVAD therapy, it is likely that the risk of pump thrombosis and hemolysis will remain, and LVAD exchange may be necessary in cases that are refractory to medical management. Fortunately, the modular nature of LVAD technology allows for pump exchange with a reasonable degree of safety; the mortality is reported to be 6% to 7%[10,11]. In contrast, medical management; adding anti-platelet agents such as dipyridamole or clopidogrel, increasing the dose of aspirin and/or increasing the target PT-INR for anticoagulation, resulted in a 48.2% mortality in the following six months after the diagnosis of pump thrombosis[6].

In conclusion, thrombosis during LVAD therapy is a potentially life-threatening complication requiring prompt diagnosis and management. We presented a report of LVAD thrombosis causing hemolysis and discoloration of the urine that resolved promptly after the pump exchange. The diagnosis is challenging, but we were able to confirm the diagnosis by intraoperative inspection of the pump and the prompt resolution of the discolored urine.

## COMMENTS

### *Case characteristics*

A 50-year-old-male with a history of HeartMate II implantation presented with

discolored urine.

### *Clinical diagnosis*

He denied any chest pain, shortness of breath, or edema.

### *Differential diagnosis*

Discolored urine and the lab values suggesting hemolysis, occasional pump power spikes were thought to be due to pump thrombosis.

### *Laboratory diagnosis*

Hemoglobin 7.6 g/dL; plasma free hemoglobin 52.0 mg/dL; PT-INR 1.7; serum creatinine 1.9 mg/dL; total bilirubin 1.1 mg/dL. The lactate dehydrogenase, haptoglobin, AST were not able to be measured due to severe hemolysis.

### *Imaging diagnosis*

Echocardiography showed severe biventricular dysfunction and opening of the aortic valve with every heartbeat.

### *Treatment*

The patient underwent pump exchange.

### *Related reports*

Medical management resulted in a 48.2% mortality in the following six months after the diagnosis of pump thrombosis.

### *Experiences and lessons*

The diagnosis of pump thrombosis is challenging, but the authors were able to confirm the diagnosis by intraoperative inspection of the pump and the prompt resolution of the discolored urine.

### *Peer review*

The manuscript describes frequent complication of left ventricular assist device. The manuscript is well written and has a good structure with excellent images.

## Abstract

Renal cell carcinoma is a common urological malignancy with the unique ability to invade the inferior vena cava (IVC) and to extend into the right atrium of the heart. Of those with Renal cell carcinoma only 4%-25% are found to have IVC invasion and of those only 2%-10% extend into the right atrium. If treated surgically, extension of tumor thrombus is not a determinant of survival; therefore it is imperative to determine the presence and extent of tumor thrombus in order to determine surgical approach and tumor resection. To date this has been primarily accomplished by magnetic resonance imaging and computed tomography. We present a case of 61 years old African American woman in which transthoracic echocardiography provided a more accurate determination/characterization of the presence and degree of tumor thrombus and extension.

**Key words:** Renal cell carcinoma; Tumor thrombus; Cardiac extension; Right atrial mass

## INTRODUCTION

Renal cell carcinoma is a common urological malignancy with the unique ability to invade the inferior vena cava (IVC) and to extend into the right atrium of the heart. Of those with Renal cell carcinoma (RCC) only 4%-25% are found to have IVC invasion and of those only 2%-10% extend into the right atrium. If treated surgically, extension of tumor thrombus is not a determinant of survival; therefore it is imperative to determine the presence and extent of tumor thrombus in order to determine surgical approach and tumor resection. To date this has been primarily accomplished by magnetic resonance imaging (MRI) and computed tomography (CT).

## CASE REPORT

A 61 years old African-American female with past medi-

**Figure 1 Computed tomography scan (coronal view) revealing inferior vena cava thrombus with no evidence of extension into the right atrium.**

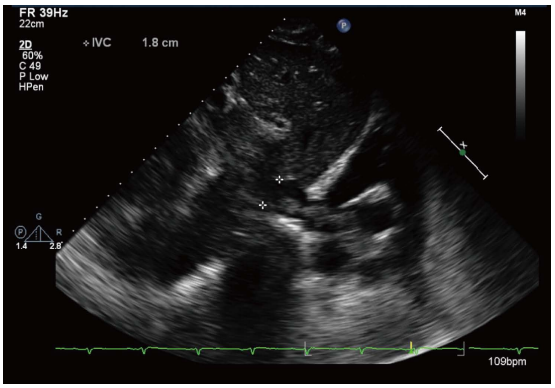

**Figure 3 Subcostal view showing the tumor thrombus extending from the inferior vena cava into the right atrium.**

cal history of hypertension, hyperlipidemia, and diabetes mellitus initially presented to her primary care physician for progressively worsening fatigue, anorexia, and weight loss. As part of her work-up, she underwent an abdominal and pelvis CT scan, which revealed a large right sided renal mass with possible invasion of the right renal vein and inferior vena cava. A follow up abdominal MRI confirmed the presence of a very large right-sided renal mass consistent with renal cell carcinoma and subsequent invasion of the right renal vein and adjacent inferior vena cava. Further assessment revealed a tumor thrombus extending beyond the renal veins into the intrahepatic inferior vena cava and toward the right atrium. In order to fully characterize the extent of tumor thrombus extension, a CT angiogram (CTA) of the chest and transthoracic echocardiogram (TTE) was done. The chest CTA revealed a filling defect in the IVC in the intrahepatic and subhepatic regions consistent with known tumor thrombus, but showed no evidence of right atrium invasion (Figure 1). On the other hand, the TTE showed a large right atrial mass (Figure 2) with diastolic prolapse into the right ventricle and extension into the IVC (Figure 3). In the setting of her known history of RCC with migration and the fact that this mass was also seen to extend into the IVC, it was felt that this was indeed right atrial invasion of the tumor thrombus and less likely to be a hematological thrombus. A preoperative left heart catheterization was also performed revealing significant mid right coronary artery disease.

After completing the aforementioned preoperative assessment and evaluation by Urology, Vascular Surgery and Cardiothoracic Surgery, the patient underwent a radical nephrectomy and resection of the inferior vena cava and right atrial tumor thrombi (Figure 4). She simultaneously underwent a single vessel coronary artery bypass for her right coronary artery disease. There were no surgical complications and the patient's postoperative course was unremarkable.

## DISCUSSION

Renal cell carcinoma tumor thrombus has a propensity to invade the main renal veins as well as the IVC and in rare circumstances can extend into the right atrium of the heart[1,2]. In order to properly classify RCC extension and plan the appropriate surgical technique and approach, one would imagine that establishing the location of the superior margin of the tumor thrombus would be essential[1,3]. At this time the mainstay or gold standard of renal mass detection and characterization (including RCC) is CT scan and MRI[1,4,5]. CT scan has shown to be

**Table 1 Classification of renal cell carcinoma tumor thrombus**

| Tumor thrombus level[6] | Characteristics[6] |
|---|---|
| Level Ⅰ | Extension to 2 cm above the renal vein into the IVC |
| Level Ⅱ | Extension to the subhepatic level, > 2 cm above the renal vein BUT below the diaphragm |
| Level Ⅲ | Extension into the intrahepatic IVC BUT below the diaphragm |
| Level Ⅳ | Extension into the right atrium of the heart |

IVC: Inferior vena cava.

most accurate in evaluating the extent of local growth as well as the presence or absence of metastasis (*i.e.*, to the pancreas, bone). On the other hand MRI has been more accurate in delineating the superior margin of any tumor thrombus, and thereby classifying RCC tumor thrombus, as well as differentiating between bland/hematologic thrombus and tumor thrombus[1,4,5]. Traditionally TTE has been used to further delineate the supradiaphragmatic extension of tumor thrombus. In our case, TTE accurately illustrated the cranial extent of tumor thrombus into the right atrium which was in fact missed on the traditionally used CT scan.

For level IV tumors (Table 1) such as was found in our patient, cardiopulmonary bypass (CPB) with or without hypothermic circulatory arrest (HCA) is necessary for safe and complete extraction of the thrombus[1,3,6]. This surgical approach provides a bloodless surgical field that allows optimal visualization of the hepatic veins, IVC and Right Atrium for complete tumor thrombus resection. As incomplete resection of these tumors confers a higher rate of metastatic recurrence and decreased postoperative survival, it is imperative to clearly delineate the superior margin of any tumor thrombus[1,3,6].

In our case, the patient's preoperative evaluation included a CT abdomen/pelvis, CT chest, MRI abdomen, and TTE. Unexpectedly, it was the TTE that provided the most accurate determination of the cranial extent of the tumor thrombus. Proper classification of the tumor thrombus allowed for the appropriate surgical approach to be undertaken ensuring the best patient outcome.

## COMMENTS

### Case characteristics

A 61 years old African-American female with past medical history of hypertension, hyperlipidemia, and diabetes mellitus initially presented to her primary care physician for progressively worsening fatigue, anorexia, and weight loss.

### Clinical diagnosis

A large right sided renal mass with possible invasion of the right renal vein and inferior vena cava.

### Imaging diagnosis

Chest computed tomography angiogram revealed a filling defect in the inferior vena cava (IVC) in the intrahepatic and subhepatic regions consistent with known tumor thrombus, the transthoracic echocardiogram (TTE) showed a large right atrial mass with diastolic prolapse into the right ventricle and extension into the IVC.

### Experiences and lessons

In this case, TTE accurately illustrated the cranial extent of tumor thrombus into the right atrium which was in fact missed on the traditionally used computed tomography scan.

### Peer review

The case report illustrates the diagnostic power of transthoracic echo in diagnosis of cardiac extension of renal cell carcinoma. The manuscript is well written.

## Abstract

We report the first case of acute renal failure secondary to prucalopride, a novel agent for the treatment of chronic constipation. The 75 years old male patient was initiated on prucalopride after many failed treatments for constipation following a Whipple's procedure for pancreatic cancer. Within four months of treatment his creatinine rose from 103 to 285 μmol/L (eGFR 61 decrease to 19 mL/min per 1.73 $m^2$). He was initially treated with prednisone for presumed acute interstitial nephritis as white blood casts were seen on urine microscopy. When no improvement was detected, a core biopsy was performed and revealed interstitial fibrosis and tubular atrophy. The presence of oxalate and calcium phosphate crystals were also noted. These findings suggest acute tubular necrosis which may have been secondary to acute interstitial nephritis or hemodynamic insult. The use of prednisone may have suppressed signs of inflammation and therefore the clinical diagnosis was deemed acute interstitial nephritis causing acute tubular necrosis. There are no previous reports of prucalopride associated with acute renal failure from the literature, including previous Phase Ⅱ and Ⅲ trials.

**Key words:** Prucalopride; Acute kidney tubular necrosis; Renal insufficiency; Constipation; Adverse drug event

**Core tip:** Prucalopride is a novel agent used in the treatment of chronic constipation. We report the first case of acute renal failure secondary to prucalopride four months after treatment initiation. A core renal biopsy after prednisone therapy revealed interstitial fibrosis and tubular atrophy. These findings suggested acute tubular necrosis secondary to acute interstitial nephritis. There are no previous reports of prucalopride associated with acute renal failure from the literature, including previous Phase Ⅱ and Ⅲ trials. This case reports highlights the need for monitoring renal function in all patients treated with prucalopride.

Sivabalasundaram V, Habal F, Cherney D. Prucalopride-associated acute tubular necrosis. *World J Clin Cases* 2014; 2(8): 380-384 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/380.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.380

## INTRODUCTION

Chronic constipation is very common and affects 14% of the general population[1]. The incidence rises with age, and is higher in women and those with lower socioeconomic status[2]. It is characterized by infrequent bowel and often associated with abdominal discomfort, bloating and cramps. Patients are susceptible to complications such as hemorrhoids and anal fissures. The consequences on quality of life, health care costs and activity impairment are also significant[3].

The treatment of constipation requires a multifaceted approach which includes lifestyle changes, dietary adjustments, stool softeners, osmotic agents and laxa-

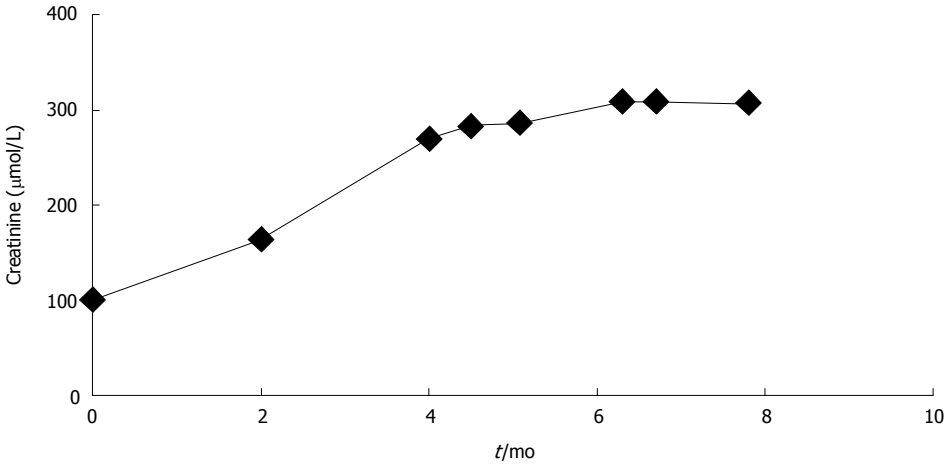

**Figure 1 The level of patient's creatinine.**

tives[4,5]. Another target for intervention is the 5 hydroxytryptamine-4 (5-HT$_4$) receptor. Until recently, drugs have lacked specificity for the 5-HT$_4$ receptor resulting in an unfavourable risk-benefit ratio with side effects of serious cardiovascular arrhythmias[6,7]. Prucalopride however has demonstrated a high selectivity and affinity for this receptor in the gut with a high efficacy compared to placebo in patients with severe constipation[8-10] and in those who have failed previous laxative therapy[11,12]. The most common adverse effects were headache, nausea, diarrhea and abdominal pain, with no significant cardiovascular effects. Renal failure was not found to be associated with prucalopride and no change in chemical laboratory data was reported from baseline in all of the phase 3 studies[8,12,13]. Randomized trials in elderly patients also found prucalopride to be safe with no effect on renal or cardiac function[10,14]. We report the first case of pruaclopride associated renal failure which was irreversible following discontinuation of the medication.

## CASE REPORT

A 75 years old male developed chronic constipation following a Whipple's pancreaticoduodenectomy for pancreatic cancer 19 mo earlier. Over this period, he had multiple emergency room visits for abdominal cramps and pain which were on occasion related to severe constipation and obstipation. He required regular cleansing regimens in hospital, and repeated upper and lower endoscopies revealed no significant pathology. He was referred to a gastroenterologist and his pain resolved with discontinuation of his pancrealipase preparation. After failing several months of therapy for constipation with various bulking, osmotic and stimulant laxatives, he was initiated on prucalopride (Resotran), a new enterokinetic agent, at a dose of 2 mg once daily.

Besides his Whipple's procedure, his surgical history is also significant for an open prostatectomy nine years prior for benign prostatic hyperplasia, remote appendectomy, and a hernia repair. His medical history includes hypertension, dyslipidemia, and a cerebrovascular ischemic stroke with minimal neurologic deficits. His medications at this time were clopidogrel, pantoprazole, candesartan, indapamide, gabapentin, sennoside, as well as 30 g of fiber daily.

The patient was seen four months after the initiation of prucalopride and was now having regular bowel movements for the first time since his Whipple's surgery. He required no further admissions to hospital and his quality of life significantly improved while using prucalopride as the sole agent for management of his constipation. It was however noted that his creatinine was had risen from a baseline of 103 (eGFR baseline 61 mL/min per 1.73 m$^2$, stable for at least 4 years) to 165 μmol/L (eGFR 35 mL/min per 1.73 m$^2$) in two months, and further to 270 μmol/L (eGFR 19 mL/min per 1.73 m$^2$) by four months (Figure 1). He endorsed no symptoms of decreased oral intake, oliguria, abdominal pain, nausea, vomiting, peripheral swelling, or shortness of breath. He also denied any irritative or obstructive urinary symptoms. There were no recent changes to his medications, or any use of over the counter medications such as non-steroidal anti-inflammatory drugs. His candesartan was held and he was referred to a nephrologist for an urgent assessment.

At this appointment he was found to have a normal blood pressure on examination, with no signs of a rash, peripheral edema, or volume overload. His blood work now demonstrated an elevated creatinine of 285 μmol/L at 4.5 mo following prucalopride administration. A complete work up for other renal disease including glomerular based diseases was negative and the patient did not have peripheral eosinophilia. Urinalysis showed +1 proteinuria, trace blood, and urine microscopy revealed many white blood cell casts. An ultrasound of his kidneys showed no signs of obstructive uropathy and Doppler examination of his renal arteries and veins were normal. He was diagnosed with acute interstitial nephritis secondary to his exposure to prucalopride and was instructed to stop this medication. He was started on prednisone 40 mg daily for one week, followed by a taper of 5 mg weekly. The patient was seen in follow-up two weeks later for repeat blood work. Unfortunately his creatinine remained elevated at 310 μmol/L while on prednisone at a dose of 30 mg daily. Given the lack of renal recovery, a renal biopsy

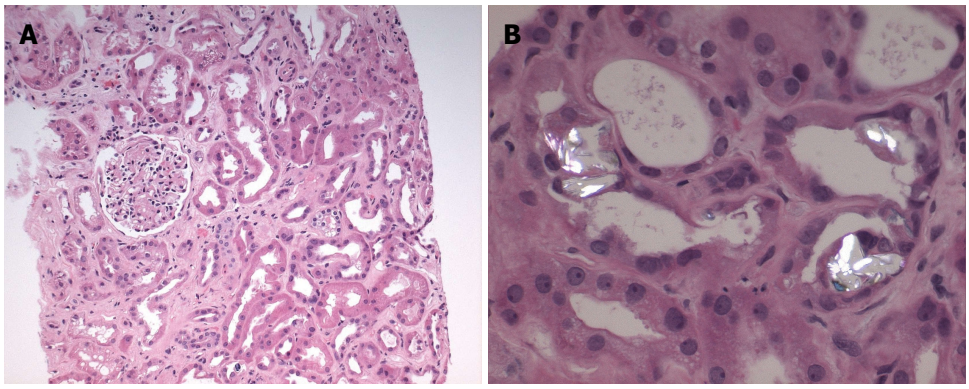

**Figure 2 Hematoxylin and eosin stain.** A: Hematoxylin and eosin stain demonstrating moderate interstitial fibrosis and tubular atrophy; B: Hematoxylin and eosin stain with polarized light demonstrating calcium oxalate deposition within the tubules.

was performed within one week.

The core biopsy specimen from the left kidney showed 11 of 39 glomeruli globally sclerosed, while the remainder of the glomeruli showed no increase in mesangial matrix or cellularity (Figure 2A). There was minimal interstitial inflammation, with moderate degenerative and regenerative changes within the tubules. There was moderate (40%) interstitial fibrosis and tubular atrophy. There was no arteriolar hyalinosis and moderate arterial sclerosis. Many of the tubules also contained oxalate and calcium phosphate crystals (Figure 2B). Immunofluorescence was negative for immunoglobulin A, G and M, as well as C3, C1q, kappa or lambda. Electron microscopy of the non-sclerosed glomeruli revealed no immune-type deposits, nor any tubuloreticular inclusions. The glomerular basement membranes were mildly wrinkled and within normal limits of thickness. There was moderate effacement of the podocyte foot processes (30%). These findings were consistent with acute tubular necrosis with no evidence for interstitial nephritis.

According to the Naranjo probability score of adverse drug reactions[15], our patient's case was classified as a 'probable adverse drug reaction' of prucalopride induced kidney injury. Points were given for temporal causality, lack of an alternative cause of the reaction, lack of progression with drug discontinuation, and objective confirmation of kidney injury with the renal biopsy.

The patient remained on prednisone at 20 mg daily until seen in follow-up three weeks later. Repeat creatinine remained elevated at 309 μmol/L. His prednisone taper was resumed at 5 mg per week and was ultimately discontinued since there were no signs of ongoing inflammation in the biopsy specimen. The patient unfortunately did not have any further renal recovery and his symptoms of constipation returned while off prucalopride. The search for alternative regimen to treat his chronic constipation is ongoing.

## DISCUSSION

Prucalopride is a novel highly selective 5-HT$_4$ receptor agonist developed for the treatment of chronic constipation among patients with an inadequate response to laxatives. The safety of this medication was assessed in all the Phase Ⅱ trials, and in three Phase Ⅲ pivotal trials. A total of 1974 patients were evaluated in the phase Ⅲ trials, with 1313 receiving prucalopride[8,12,13]. The most frequent adverse events reported were headache, abdominal pain, nausea and diarrhea, with most symptoms occurring on the first day. None of the phase Ⅲ trials reported changes in renal function as measured by blood work at baseline and throughout the study. Two smaller placebo-controlled randomized trials in elderly patients with a mean age of 76 and 83, randomized a total of 301 patients to prucalopride[10,14]. The same profile of adverse events were seen in these trials with elderly patients as the larger phase Ⅲ trials. However, in both trials, prucalopride was only administered for 4 wk and while no kidney injury was reported after short-term use, there is a lack of long-term data in the elderly. Numerous other smaller randomized trials with prucalopride also found no associated reports of renal impairment[9,11,16,17]. Elderly patients are at increased risk for baseline renal dysfunction. In the patient described in this report, although stable for least 4 years, the eGFR of 61 mL/min per 1.73 m$^2$, likely reflected some degree of underlying chronic kidney disease. The elderly patient demographic and potential for underlying chronic kidney disease emphasize the importance of including this group in study trials for safety outcomes.

Our case demonstrates the first report of acute tubular necrosis associated with prucalopride administration. A thorough search on PubMed, Embase and Medline demonstrated no other reports of acute kidney injury secondary to prucalopride. A search for an association with alternative serotonin receptor agonists, such as cisapride or tegaserod, with kidney injury also found no previous case reports. Whether the acute tubular necrosis was due to acute interstitial nephritis or hemodynamic insult cannot be definitively known in this case, since the patient was treated empirically with steroids based on the prominent white blood cell casts on urinalysis. However it remains likely that interstitial inflammation was suppressed by steroid administration prior to the renal biopsy and the working clinical diagnosis was therefore acute interstitial nephritis causing acute tubular necrosis.

The key feature which differentiates prucalopride from other 5-HT$_4$ receptor agonists such as cisapride and tegaserod is its increased selectivity for its receptor[18]. The lack of selectivity of the other older agents resulted

in an appreciable affinity for other receptors, channels or transporters. For example, cisapride had an affinity for the human ether-a-go-go-related gene (hERG) K+ channel found in cardiac cells[19] while tegaserod would also bind to 5-$HT_1$ and 5-$HT_2$ receptors[18]. These agents subsequently demonstrated cardiovascular side effects which were independent of their action on the 5-$HT_4$ receptor[19,20]. The characteristic of high selectivity is important as serotonin receptors are found throughout the body, including the kidney. The primary receptors in the kidney are the 5-$HT_2$ receptors on smooth muscle cells and the 5-$HT_1$ receptors on endothelial cells[21]. Stimulation of the 5-$HT_2$ receptors directly causes renal vasoconstriction, while activation of 5-$HT_1$ receptors leads to vasodilation indirectly *via* nitric oxide[22]. It has been found that administration of serotonin impairs autoregulation of the glomerular filtration rate of the kidney, leaving it vulnerable to ischemic damage[23]. While prucalopride has agonistic effects on the serotonin receptor, given that it has not been shown to activate the specific subtypes of 5-$HT_2$ and 5-$HT_1$, this mechanism of kidney injury is less likely. It is not known whether the concurrent use of candesartan in this patient may have also played a role in the development of acute tubular necrosis, since angiotensin Ⅱ blockade can also cause impaired renal autoregulation and a decline in glomerular filtration rate through postglomerular vasodilatation.

Our patient's renal biopsy also demonstrated increased deposition of crystals, with predominantly oxalate crystals as well as calcium phosphate crystals. Increased absorption of oxalate from the colon occurs in fat malabsoprtion states, such as pancreatic insufficiency[24]. In such instances, calcium preferentially binds to free fatty acids instead of oxalate, which allows the free soluble oxalate to be absorbed through the colon. Other factors which can increase oxalate absorption include the presence of bile salts[25] and the absence of bacteria such as *Oxalobacter formigenes* and certain strains of *Entercoccus fecalis* which are able to degrade oxalate[26]. Our patient had discontinued his pancrealipase preparation at the time prucalopride was started due to side effects of abdominal pain. Given his history of Whipple's pancreatectomy and the discontinuation of his pancreatic replacement enzymes, this fat malabsorption state may have induced hyperoxaluria.

Oxalate nephropathy can occur from tubular obstruction caused by calcium oxalate crystals, or by direct tubular injury which results in progressive tubular atrophy and interstitial fibrosis[25]. It is also common to see small numbers of oxalate crystals within tubules after acute tubular necrosis as well as in other chronic renal impairment conditions. Given the mixture of both oxalate and calcium phosphate crystals in our patient's renal biopsy, an underlying oxalate nephropathy as the etiology of the acute kidney injury is less probable. In addition, the creatinine stabilized with cessation of prucalopride and the patient did not yet resume his pancrealipase preparation. Cases of oxalate nephropathy reported in the literature are often associated with oliguria and a marked decline in renal function requiring hemodialysis[27]. Fortunately, our patient's renal failure was not as severe. Follow up urinalyses have failed to demonstrate crystals of any type, further suggesting that a crystal nephropathy is not playing an important contribution to the patient's renal failure. Furthermore, high-fluid intake and low oxalate diet recommendations along with calcium carbonate supplements have not been associated with improved renal function.

In conclusion, given the lack of literature to support prucalopride and other serotonin receptor agonists as nephrotoxins, our patient's case of acute renal failure was treated initially as allergic interstitial nephritis. However, when his renal function did not improve with discontinuation of the medication and prednisone therapy, a renal biopsy was performed to confirm the diagnosis. This case demonstrates the importance of a renal biopsy when the diagnosis is unclear or when there is lack of improvement with therapy. In addition, this case also highlights the importance of routine blood work to follow cell count, biochemistry and renal function when starting a medication which is new to both the patient and the medical community. Adverse effects which were not documented by clinical trials may still occur in our patients and reporting of such outcomes is required for ongoing drug safety and monitoring. In addition, given the limited long-term data available for elderly patients, and unreliability of serum creatinine in estimating renal function, a lower 1 mg of prucalopride should be initiated in this population. Without routine blood work, this case of renal failure may have been missed until the patient presented with more significant symptoms related to renal failure such as oliguria, vomiting, volume overload or uremia.

## COMMENTS

### *Case characteristics*

A 75 years old gentleman initiated on prucalopride for chronic constipation with subsequent elevation of serum creatinine from 100 μmol/L to 270 μmol/L within four months.

### *Clinical diagnosis*

He was treated with prednisone for presumed acute interstitial nephritis and a subsequent renal biopsy demonstrated acute tubular necrosis secondary to acute interstitial nephritis.

### *Differential diagnosis*

Acute interstitial nephritis secondary to a drug allergic reaction, oxalate nephropathy, and acute tubular necrosis following hemodynamic insult, angiotensin Ⅱ blockade or interstitial nephritis.

### *Laboratory diagnosis*

Serum creatinine rose from a baseline of 103 μmol/L to a peak of 310 μmol/L and urine microscopy revealed many white cell casts.

### *Imaging diagnosis*

Abdominal ultrasound showed no signs of obstructive uropathy, and Doppler examination was negative for renal artery stenosis.

### *Pathologic diagnosis*

A renal biopsy was performed after cessation of prucalopride and administration of prednisone revealing moderate interstitial fibrosis and tubular atrophy with deposition of oxalate and calcium phosphate crystals.

### *Treatment*

Therapy with prednisone was initiated once white cell casts were seen on uri-

nary microscopy and prucalopride was discontinued resulting in stabilization of the serum creatinine but no further recovery of renal function.

### Related reports

This is the first case of acute renal failure reported in the literature, with no previous occurrences documented from several previous Phase II and III trials.

### Term explanation

Prucalopride is a novel highly selective 5 hydroxytryptamine-4 receptor agonist developed for the treatment of chronic constipation after failure of laxative therapy.

### Experiences and lessons

This case highlights the need for monitoring of routine blood work with cell count, biochemistry and renal function when using medications new to both the patient and the medical community as previously undocumented adverse events may develop.

### Peer review

This is an important case report in regard to clinical use of prucalopride.

## Abstract

Actinic prurigo is a photodermatosis that can affect the skin, conjunctiva and lips. It is caused by an abnormal reaction to sunlight and is more common in high-altitude living people, mainly in indigenous descendants. The diagnosis of actinic prurigo can be challenging, mainly when lip lesions are the only manifestation, which is not a common clinical presentation. The aim of this article is to report two cases of actinic prurigo showing only lip lesions. The patients were Afro-American and were unaware of possible Indian ancestry. Clinical exam, photographs, videoroscopy examination and biopsy were performed, and the diagnosis of actinic prurigo was established. Topical corticosteroid and lip balm with ultraviolet protection were prescribed with excellent results. The relevance of this report is to show that although some patients may not demonstrate the classical clinical presentation of actinic prurigo, the associated clinical and histological exams are determinants for the correct diagnosis and successful treatment of this disease.

**Key words:** Actinic prurigo; Follicular cheilitis; Photodermatosis; High-altitude; Lip diseases

**Core tip:** The diagnosis of actinic prurigo can be challenging in the absence of classic clinical manifestations. Actinic prurigo is found in high-altitude living people, mainly in indigenous descendants. Disease onset is usually in childhood and rarely presents only on the lips. This study describes two rare cases from Rio de Janeiro city, Brazil, which is located at sea level. The patients were unaware of possible Indian ancestry. Moreover, actinic prurigo appeared in adulthood and lip lesions were the only manifestation. The associated clinical and histological exams are determinants for the correct diagnosis and successful treatment of this disease.

Miranda AMO, Ferrari TM, Werneck JT, Silva Junior A, Cunha KS, Dias EP. Actinic prurigo of the lip: Two case reports. *World J Clin Cases* 2014; 2(8): 385-390 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/385.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.385

## INTRODUCTION

Actinic prurigo (AP) is a type of photodermatosis, and is a rare familial inflammatory disease that primarily affects areas of skin exposed to the sun and can affect the lips and ocular conjunctiva (pseudopterygium formation)[1]. Pseudopterygium does not appear as a unique lesion in patients with AP, it is always preceded by skin and lip lesions, suggesting that this expression tends to appear later in the disease course. For this reason, the diagnosis of AP in its early stages is important to prevent subsequent complications[2]. AP of the lip, also known as follicular cheilitis, is mainly found on the vermillion of the lower lip. Lip lesions may appear early in the development of

this disease and, consequently, its observation and accurate diagnosis can alert physicians or dentists to the possible development of other more severe lesions on the skin or conjunctiva[2]. AP occurs mainly in residents of high altitudes and affects ethnic groups, particularly in North and South America, who express major histocompatibility complex class I and Ⅱ (HLA I and Ⅱ), suggesting a genetic predisposition[3]. The aim of this article is to describe two cases of AP of the lips without the classical features of this disease (young age at onset, familial history, high-altitude living people, and an association with skin lesions).

## CASE REPORT

### *Case one*

A 63-year-old Afro-American woman presented to our Oral Diagnostic clinic complaining of lower lip lesions of 10 mo evolution, which had worsened in the last 6 mo. She was referred by two centers that had failed to establish the diagnosis. During physical exam, the lower lip showed edema, as well as multiple ulcers covered with yellowish crusts on the semimucosa (Figure 1A). The slightest touch or mouth opening resulted in significant bleeding, which, according to the patient was commonly observed. No alterations during intraoral examination were observed. The lesions were documented by clinical and videoroscopy images (Figure 1B) and were scraped for cytopathologic evaluation, which revealed moderate inflammation. Lip balm with ultraviolet (UV) protection was prescribed.

On the second visit, debridement of the lesions was performed, as well as a biopsy (the selected area was chosen by clinical and videoroscopy exam) (Figure 1C). The clinical diagnostic hypotheses were erythema multiforme and contact cheilitis. Microscopically (Figure 1E-H), the surface epithelium showed orthokeratosis, with some areas of parakeratosis, atrophy and areas of acanthosis, as well as basal layer degeneration and lymphocytic exocytosis. Ulceration was also present. The connective tissue exhibited pigmentary incontinence close to the overlying epithelium, dilated blood vessels, edema and intense and diffuse lymphocytic inflammatory infiltrate, with some plasma cells, extending deep into the fatty tissue. Some secondary lymphoid follicles were also present. Several mast cells were present predominantly in the deeper area of the connective tissue, mainly in the perivascular and perineural areas. Nonspecific chronic sialadenitis with ductal ectasia was also observed. There was no solar elastosis. The diagnosis of follicular cheilitis was established.

Following diagnosis, a combination of triamcinolone acetonide cream, neomycin sulfate, gramicidin and nystatin cream was prescribed three times a day. The patient was instructed to use gauze compresses with cold physiological saline and to continue using lip balm with UV protection. The patient was also referred to the dermatology and ophthalmology service for evaluation of signs and symptoms of AP. No ocular or skin lesions were observed.

Complete remission of the lip ulcers and crusts was observed after one month of treatment (Figure 1D). The patient was followed-up monthly for three months without evidence of recurrence. Two months after diagnosis and during the follow-up period, the patient reported she was of indigenous Brazilian descent. After the third consecutive monthly follow-up, the patient was followed-up every 4 mo to date (2 years after the first visit), and showed no lip lesions (Figure 1D). The patient did not develop any skin or ophthalmic lesions.

### *Case two*

A 58-year-old Afro-American woman, presented to our Oral Diagnostic clinic complaining of a painful lesion on the lower lip of four years evolution. Physical examination showed the presence of a yellowish crust of 1.3 cm × 0.8 cm, on the left side, which was easily seen during the examination, revealing an ulcerated area. The lips were swollen and dry (Figure 2A). The lesions were documented by clinical and videoroscopy images (Figure 2B) and were scraped for cytopathologic evaluation, which revealed moderate inflammation. No alterations were observed during the intraoral examination. Lip balm with UV protection was prescribed. On the second visit, a biopsy was performed (the selected area was chosen by clinical and videoroscopy exam). The diagnostic hypotheses were erythema multiforme and acute actinic cheilitis. Microscopically (Figure 2C and D), the lesion was covered by stratified ortokeratinized squamous epithelium showing atrophy, ulceration, spongiosis and hydropic degeneration of the basal layer. The underlying connective tissue showed pigmentary incontinence close to the overlying epithelium, dilated blood vessels with areas of intense inflammatory infiltrate, mainly composed of lymphoplasmacytic cells, and the formation of well-formed secondary lymphoid follicles. Mast cells were also observed between the lymphocytes and plasma cells. The inflammatory infiltration extended deep into the fatty tissue. There was no solar elastosis. The diagnosis of follicular cheilitis was established.

The patient was followed-up (one month after the first visit) and showed remission of the ulceration on the left side, with only a small ulcer on the right side of the lip (Figure 2B). She was referred for dermatological and ophthalmological evaluation and asked to return to our clinic one month later. The patient did not return.

A search of the medical literature was performed by two authors separately, using Pubmed, Lilacs, Scielo and Cochrane databases, without year and language restriction, using the terms: (1) prurigo AND actinic; and (2) follicular AND cheilitis. The last search was performed in November 2013. A paper considered eligible for inclusion on review had to include a case report or a study with at least one case under the name "actinic prurigo" or "follicular cheilitis" and with lip lesions as the only manifestation (Table 1). Only two papers satisfied the criteria: Vega-Memije *et al*[2] and Mounsdon *et al*[4]. In the

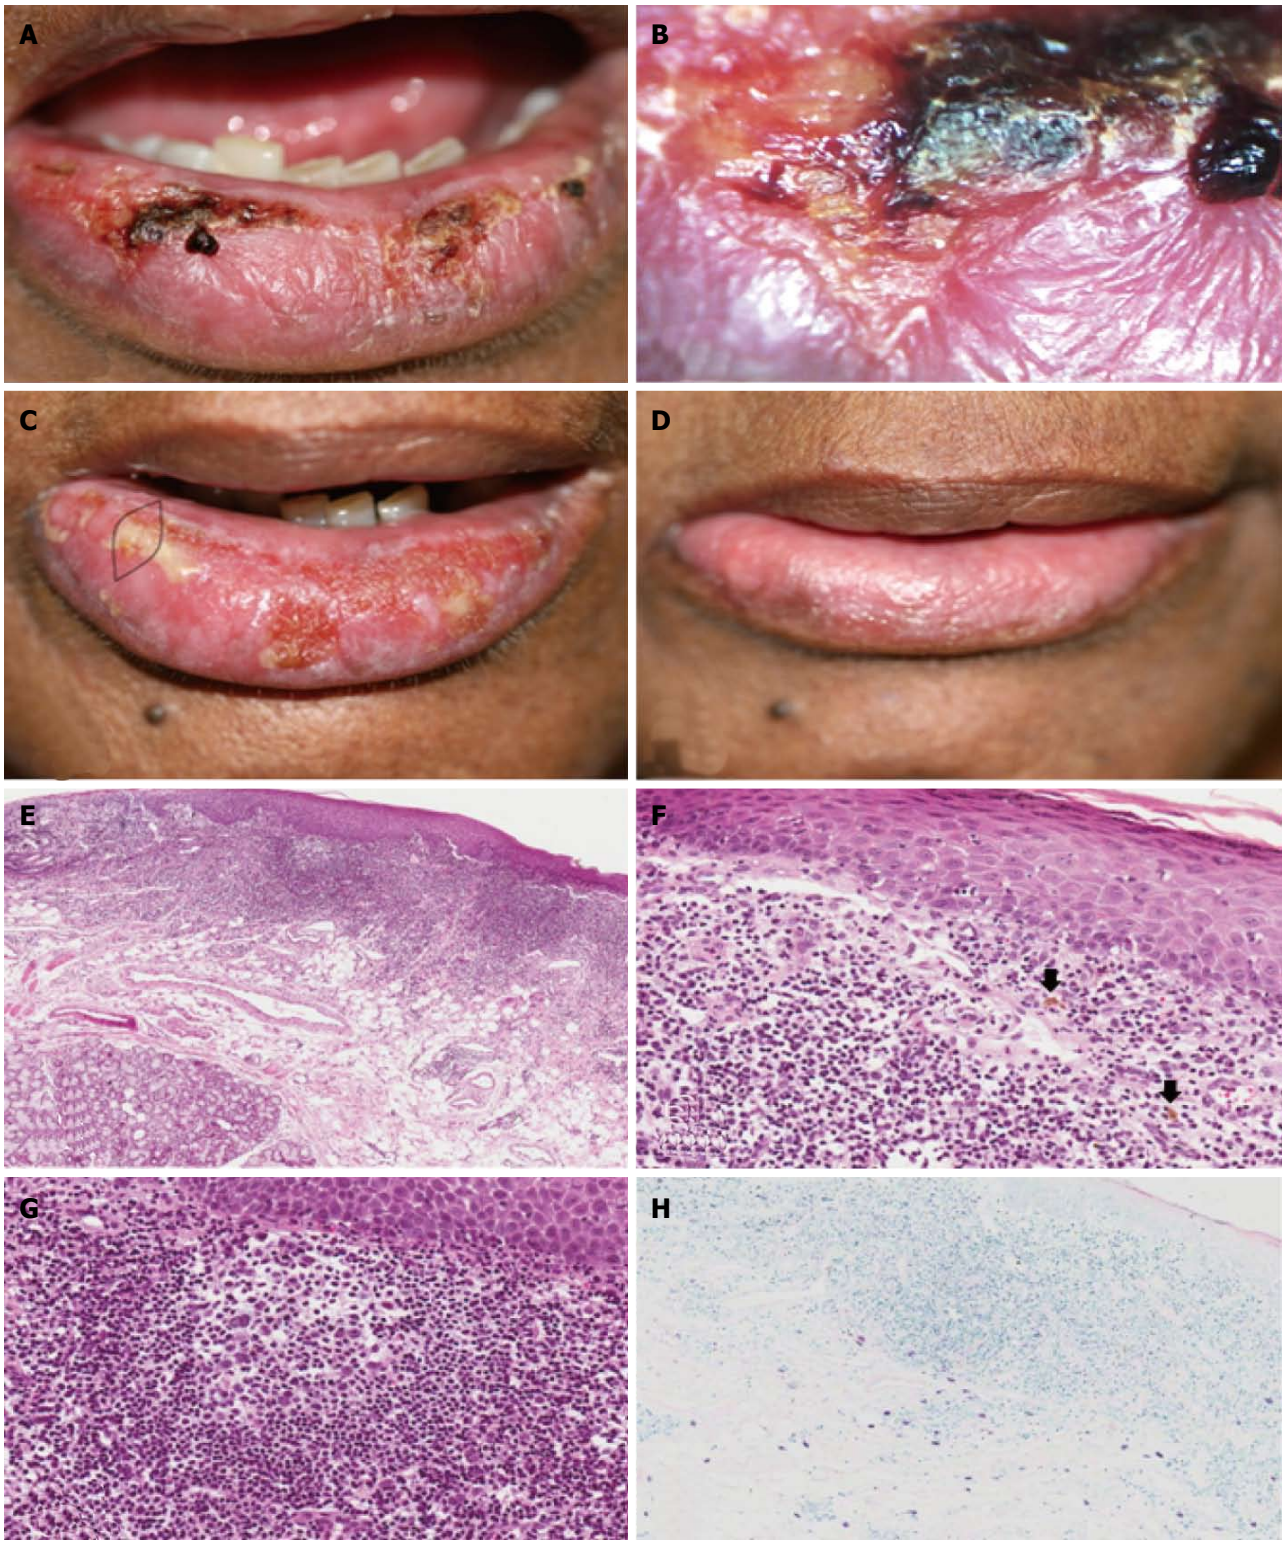

**Figure 1 Case 1.** A: Clinical aspect at the first appointment, showing lower lip edema, ulcers and crusts; B: Videoroscopy image showing in detail the presence of ulcer and crust; C: Clinical aspect at the second appointment showing the area of biopsy; D: Clinical aspect one month after treatment, showing remission of the lip edema, ulcers and crusts; E: Histological aspects. Epithelial atrophy and intense diffuse lymphoplasmacytic inflammatory infiltrate extending deep into the fatty tissue (× 10, HE); F: Epithelium showing spongiosis, hydropic degeneration of the basal layer cells and lymphocytic exocytosis. In the connective tissue, lymphocytic inflammatory infiltrate and pigmentary incontinence (arrows) were observed (× 40, HE). G: Secondary lymphoid follicle (× 40, HE); H: Mast cells mainly in the deeper area of the connective tissue (× 20, Giemsa).

study by Vega-Memije *et al*[2], 116 patients presented with actinic prurigo cheilitis; of these, 74 (63.8%) were female, aged from 9 to 82 years (mean, 27.8 years). Ninety-nine percent of the patients lived in areas more than 1000 m above sea level and only one case was from a geographic area below this altitude. AP cheilitis was the only manifes-

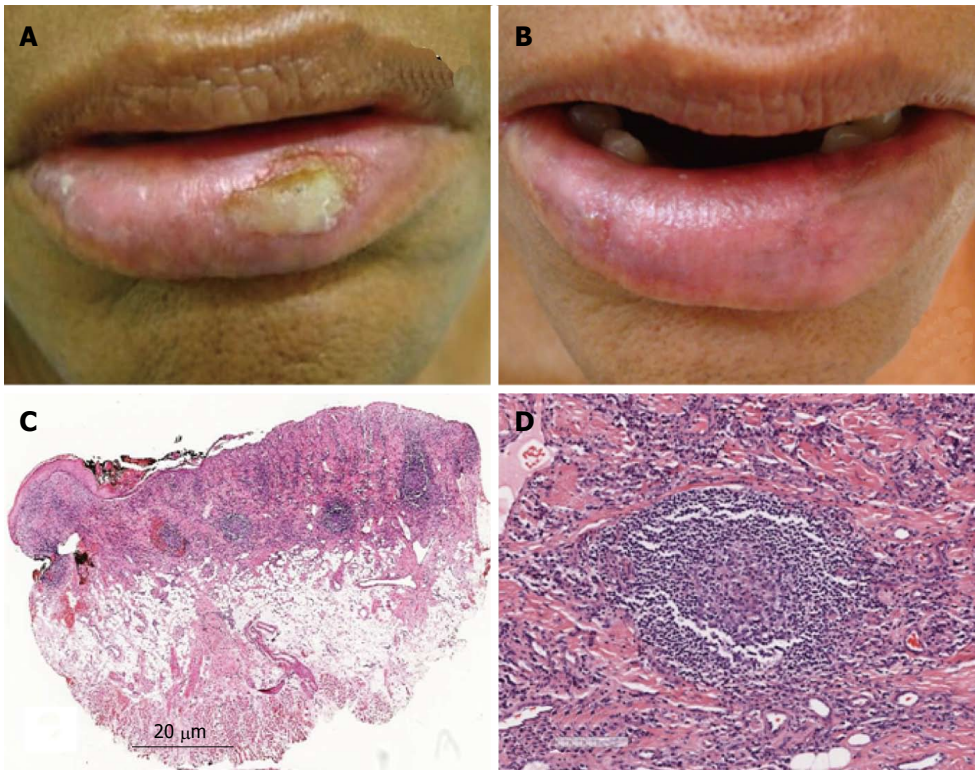

**Figure 2 Case 2.** A: Clinical aspect at the first appointment, showing lower lip edema, dryness and ulcer on the left side of the semimucosa; B: Clinical aspect at the second appointment, showing remission of the ulceration on the left side, and only a small ulcer on the right side of the semimucosa; C: Histological aspects. Lower power view showing epithelial atrophy and ulceration. In the connective tissue, an intense, diffuse inflammatory infiltrate extending deep into the fatty tissue, with some lymphoid follicles was observed (HE); D: Secondary lymphoid follicle (HE).

[1]A paper considered eligible for inclusion in the review had to include a case report or a study with at least one case under the name "actinic prurigo" or "follicular cheilitis", and show lip lesions as the only manifestation.

tation of the disease in 32 (27.6%) patients. Mounsdon *et al*[4] described two North American Indians, one man and one woman, who showed only lip lesions, however, there was no information on their place of residence. In addition, a thesis describing a study of 43 patients with actinic prurigo of the lips was found in Google Scholar[5]. Although this study was carried out in Brazil, it was a retrospective analysis of patients resident in Mexico, where this disease is very common. In 17 (39.54%) cases, the lesion was located only on the lips. To make comparative analyses with the cases presented in our paper, 16 patients in this study were included; one was excluded because the age of the patient was not provided. Patient age ranged from 11 to 63 (mean 26 years). Information on where the patients lived was not provided (Table 2).

## DISCUSSION

Photodermatoses form an important group of skin diseases, which can be disabling to the patient, and represent a challenge in diagnosis and treatment[6]. Although dark skin has larger quantities of melanin compared to white skin, which gives greater protection against the sun's rays, photodermatoses are common in dark-skinned people[7]. AP is an example of a photodermatosis that affects mostly Mestizos in the Americas. This is the result of miscegenation between Europeans and Indians, which prevails in Mexico, Guatemala, Honduras, Colombia, Ecuador, Peru, Bolivia, and Argentina, and in some indigenous communities in North America and Canada[8-10]. AP usually begins in childhood, around 4-5 years old[5], although it can manifest at any age, affecting more women than men (2:1), and in some cases with familial history[11].

The severity of the disease is altitude-dependent, presumably because of the sustained intensity of sun exposure. It is believed that this is the reason why AP is found mostly in regions with altitude above 1000 m[3]. These data make our cases interesting, as both patients lived in Brazil, in cities at sea level, and did not report being indigenous descendants during anamnesis, did not have a positive familial history, and showed the first signs and symptoms in adulthood.

AP lesions are mainly found in sun-exposed areas[3,12,13]. Lips and conjunctiva can also be affected[3,12].

**Table 2 Data from patients with actinic prurigo, with only lip lesions**

Nevertheless, in Asians, conjunctivitis and cheilitis are not common[14]. The patients presented in this paper showed lip lesions as the only manifestation of AP. Although there are few reports and studies in the literature regarding patients with AP showing only lip lesions, this may occur in up 40% of cases[5]. In cases of AP with lip lesions as the only manifestation it is more difficult to establish an accurate diagnosis, which should alert clinicians to the possibility of the development of other more severe lesions, such as skin or conjunctival lesions. Therefore, it is important to refer these patients for ophthalmological and dermatological evaluation.

AP lip lesions are characterized by swelling, peeling, cracking, crusting, itching, exudation, and secondary ulceration[3,12]. Cheilitis intensity is variable. In the acute phase, yellow crusts adhered to the surface are observed, whereas in the chronic phase, the lesions are covered with dry scales, and the course is generally prolonged, with relapses worsened by constant sun exposure[2,8,5].

During the evaluation of our patients, we used videoroscopy which enabled better visualization of the lip lesions. As both patients showed extensive lesions, the choice of the biopsy area was difficult and videoroscopy was used to help choose the best biopsy area. The lesions were similar to those of AP lip lesions described in the literature.

Clinical differential diagnoses regarding AP include actinic cheilitis, frictional contact cheilitis and granulomatous cheilitis[5]. In the present cases, we also considered the possibility of acute actinic cheilitis, which was later rejected due the evolution time and because the patients did not report intense sunlight exposure. The other clinical diagnoses were erythema multiforme, which was rejected due to the course of the lesions, and contact cheilitis, but we were unable to identify a substance which could cause the lip lesions, especially over such a long time. Although several clinical factors associated with follicular cheilitis were not observed in the present cases, the clinical exam associated with the histopathological diagnosis was a determinant in establishing the final diagnosis.

Studies in the literature define the histopathological pattern of AP lip lesions as showing acanthosis, spongiosis and basal layer hydropic degeneration[2]. Areas of ulceration may also be seen. Edema, dilated and congested vessels, with dense predominantly lymphocytic inflammatory infiltrate, which may contain lymphoid follicles and eosinophils are also seen in the connective tissue[2,4,12]. Furthermore, some studies report that discrete exocytosis in the basal epithelium and pigmentary incontinence in the sub epithelial connective tissue may be observed[2]. The presence of lymphoid follicles is considered by some authors to be a pathognomonic feature of AP and this is the reason why the term follicular cheilitis is used[12]. Mast cells and macrophages may be found in the inflammatory infiltrate[5]. The histopathological findings in our cases are consistent with the description in the literature. The identification of lymphoid follicles in both cases was important in establishing the diagnosis.

No solar elastosis was found in the AP lesions, which facilitates the differential diagnosis from actinic cheilitis[2,4,5,12]. It is necessary to differentiate AP from polymorphic light eruption, which is clinically similar, but microscopically does not show lymphocytic infiltrate with lymphoid follicles[12].

With regard to the treatment of AP, as a general measure, it is recommended to reduce sun exposure, use protective clothing including hats, and sunscreen. However, these measures are not sufficient to treat AP. There is evidence that AP is an autoimmune disease, and therefore immunosuppressive drugs produce good results[3]. Treatment of AP varies according to the severity and extent of the lesions, and includes topical and systemic corticosteroids to reduce the inflammation and itching of active lesions, antibiotics for secondary infections, antihistamines, antimalarials and thalidomide, which have been shown to be the most effective drugs for the treatment of AP[12,15-18].

AP prognosis is not good, despite several treatment options, the lesions may have a chronic course and are difficult to control if patients live in sunny areas, are occupationally exposed to the sun or live in high altitudes[19]. In case 1, the patient responded well to treatment with a topical corticosteroid and prevention measures; she had no lesions up to the last follow-up (14 mo after diagnosis). The patient in case 2 was treated only with prevention measures (including the use of lip balm with UV protection). In the follow-up, one month after diagnosis, the lesions disappeared, but she did not return for her follow-up appointment.

AP is a well-known disease, occurring mainly in Mestizos, living in high altitudes with onset during childhood. The cases presented here were a challenge to diagnose as the clinical characteristics were different from the classical manifestations of AP: the lesions began in adulthood, the patients lived at sea level and did not report, at least during the interview, being indigenous descendants, and neither reported having a familial history of alterations. In these cases, without skin lesions, the diagnosis of AP in the early stages is important, as it can alert the clinician to the possible development of other more severe le-

sions, and, thus, referring the patients for an ophthalmologic and dermatologic evaluation is mandatory.

## COMMENTS

### *Case characteristics*

This paper reports two cases of actinic prurigo in which the lower lips were the only sites of involvement.

### *Clinical diagnosis*

The relevance of these cases is that, although some important aspects do not follow the classical features of actinic prurigo, the associated clinical and histological exams can be determinants of the correct diagnosis and successful treatment.

### *Imaging diagnosis*

Clinical exam, photographs, videoroscopy examination and biopsy were performed, and the diagnosis of actinic prurigo was established.

### *Peer review*

It is an interesting case, it is well written.

## Abstract

Double cecal appendix is a rare anatomical variation. Approximately 100 cases have been reported worldwide. It is usually diagnosed incidentally during emergency appendectomies due to inflammatory processes in the cecal appendix. Case presentation: male, white, 36 years old, obese, presenting with pain in the lower abdomen for 24 h followed by nausea, vomiting and mild fever. He was subjected to additional tests, with the leukogram showing leukocytosis and abdominal ultrasonography depicting cecal appendix with thickened wall, locally associated with small quantities of liquid and intestinal loop obstruction. He underwent laparotomy, revealing acute appendicitis. Another intestinal loop obstruction was identified next to the ileum, leading to recognizing another cecal appendix after local dissection. Double appendectomy and segmental iliectomy were performed although not needed. Results of the anatomopathological examination of the surgical samples showed acute inflammation in the two cecal appendices. So, performing a routine retroperitoneal release and a complete cecum evaluation during such surgical procedures is recommended and suggested due to the possibility of not identifying a second cecal appendix.

**Key words:** Appendix; Anatomic variation; Appendicitis; Appendectomy; General surgery

**Core tip:** Double cecal appendix is a rare (about 100 cases reported worldwide) anatomical variation often incidentally diagnosed in the face of inflammation in the organ. The current paper presents the first case reported in South America. The case is extremely important for the study of this possible anatomical variation since the lack of a diagnosis in a second cecal appendix can cause further complications for the patient and the physician. Moreover, it is associated with the presence of other anatomical variations, such as intestinal, genitourinary and bone. Such variations will be investigated in cases of the aforementioned diagnosis.

Alves JR, Maranhão IGO, Oliveira PVV. Appendicitis in double cecal appendix: Case report. *World J Clin Cases* 2014; 2(8): 391-394 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/391.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.391

## INTRODUCTION

Double cecal appendix is a rare anatomical variation, found in 0.004%[1] to 0.009%[2] of performed appendectomies. Approximately 100 cases of double cecal appendix[3-5] have been described worldwide so far, with no case reports in South America[2,3,6-37].

## CASE REPORT

A male, white, 36 years old, slightly obese [body mass

**Figure 1 A photograph taken during a laparotomy procedure depicting an inflamed double cecal appendix.** Minor (black arrow) and major (green arrow) inflamed cecal appendix. Surgeon's hand is on the left side of the picture, holding the proximal segment of the ileum (arrow with white edges).

index (BMI) = 31.1 kg/m$^2$], presented with abdominal pain in the lower abdomen for 24 h, followed by nausea, vomiting and mild fever (axillary temperature = 37.9 ℃). He was subjected to blood tests that only showed leukocytosis without left shift. In addition, abdominal ultrasonography depicted cecal appendix with thickened wall, locally associated with small quantities of intra-abdominal fluid and local obstruction of intestinal loops.

He underwent laparotomy with a McBurney's incision. The presence of an inflamed cecal appendix in its usual position after lysis of adhesions and cecum release was identified. Another intestinal loop obstruction was identified near the ileum. After the release of dense adhesions, it was possible to recognize the presence of a second cecal appendix, also with an inflammatory aspect (Figure 1), with its origin along the taenia coli.

A double appendectomy and segmental iliectomy in the part of the devascularized intestinal loop, resulting from ileum dissection, was performed in order to provide the release and excision of the second cecal appendix. Both appendices showed no sign of perforation despite the inflammatory aspect, *i.e.,* the occurrence of increased dimensions, thickened and erythematous wall, associated with fibrin and local tissue fragility.

The anatomopathological examination of the surgical samples corroborated the diagnosis of inflammation in both cecal appendices and resected segment of small intestine (ileum), with subserosal congestion and acute fibrinous serositis with eosinophils.

The patient had no postoperative complications and was discharged on the third day after surgery.

## DISCUSSION

Since 1892 after the first case of double cecal appendix[27] was reported, less than 100 cases have been reported worldwide[3]. It demonstrates the rarity of such variations and why the current reported case is the first one to be described in South America[2,3,6-37].

Over time, some authors have presented classifications to categorize anatomical variations of cecal appendix. The first classification was developed in 1936 by Cave[28]. His classification was modified in 1962 by Wallbridge[29]. Since then, a number of authors have made some changes to it, leading to the modified classification by Cave-Walbridge, which is now the most widely used[17,30].

The classification modified by Cave-Wallbridge categorizes double cecal appendix into three types: A, B and C. Type A is characterized by the presence of two cecal appendices with a common origin in a single cecum. In type B, two appendices emerge from different cecal origins from a single cecum. This type is also subdivided into B1 and B2. In subtype B1, the two appendices emerge from a single cecum, one from each side of the ileocecal valve, symmetrically. On the other hand, in subtype B2, one of the appendices is in its usual position and the second one is located alongside the taenia coli. Finally, type C is characterized by the existence of two caeca, each with a cecal appendix (Figure 2).

The present reported case describes the occurrence of a patient with double cecal appendix type B. There are reports of other rarer forms presenting with anatomic variations of the cecal appendix, such as the horseshoe appendix[31] and the triple appendix[32].

The existence of an cecal appendix duplication is asymptomatic and its diagnosis only comes during investigations on inflammation processes[3,17,33,34]. This is what happened in our patient's case. According to clinical data, he had no complaints related to his cecal appendix duplication until the occurrence of acute appendicitis.

Despite the rarity of anatomical variations in the cecal appendix, the awareness of them is of great importance to surgeons. An inadequate surgical evaluation of the cecum due to unawareness of such variations can leave a second or third cecal appendix[17,30] unidentified. This may lead to further reoperations, diagnostic difficulties and medicolegal problems regarding malpractice because of the possibility of new inflammation in the remaining appendices[17,30].

For instance, this happened in a child whose cecal appendix duplication was not identified in the first appendectomy. Five months later, another laparotomy was needed in order to remove a second appendix which had also become inflamed[35]. Such a situation is most commonly found in patients with double cecal appendix type B[30]. It is worth mentioning that there is an increase in the postoperative morbidity and mortality[17,30] in patients in whom anatomical variations of the cecal appendix are not identified.

Finally, the importance of being aware of the association between double or triple cecal appendix and other anatomical variations, intestinal, genitourinary and osseous, should be highlighted[36,37]. These are most often associated with duplications of the cecal appendix types B1 and C[3]. Thus, when two or three cecal appendices are identified, investigating these other anatomical variations is recommended[3].

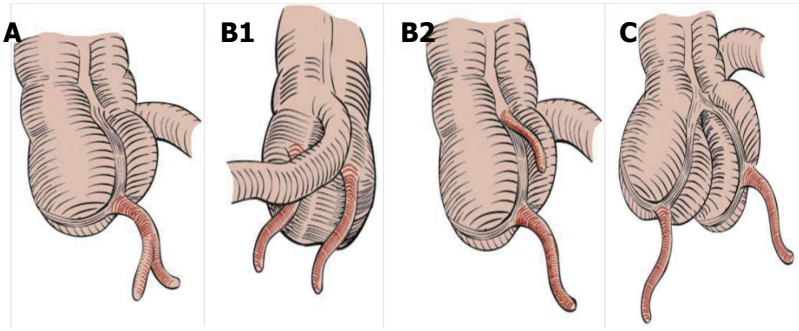

**Figure 2 Classification modified by Cave-Wallbridge[30], including type A, subtype B1, subtype B2 and type C.**

As a final conclusion, although double or triple cecal appendices are rare, surgeons must be aware of them and identify cecal appendix anatomical variations. Such a procedure is recommended when doctors surgically approach a patient with acute appendicitis. They should perform a complete cecum evaluation after the retroperitoneal release in order to avoid further complications. Surgeons should remember that in the face of such changes, they will need to investigate the presence of intestinal, genitourinary or bone anatomic variations.

## ACKNOWLEDGEMENTS

We thank the patient for allowing the disclosure of his medical report and intraoperative photographic records.

## COMMENTS

### *Case characteristics*

Male, white, 36 years old, slightly obese, presenting with acute appendicitis.

### *Clinical diagnosis*

Abdominal pain in the lower abdomen for 24 h, followed by nausea, vomiting and mild fever (axillary temperature = 37.9 ℃).

### *Differential diagnosis*

Causes of acute inflammatory abdomen.

### *Laboratory diagnosis*

Leukocytosis without left shift.

### *Imaging diagnosis*

Abdominal ultrasonography depicting cecal appendix with thickened wall, locally associated with small quantities of intra-abdominal fluid and intestinal loop local obstruction.

### *Pathological diagnosis*

Inflammation in both cecal appendices.

### *Treatment*

Laparotomy with a McBurney's incision, followed by the performance of a double appendectomy and segmental iliectomy.

### *Related reports*

Double cecal appendix is a rare (about 100 cases reported worldwide) anatomic variation most often incidentally diagnosed in face of inflammation of that organ.

### *Term explanation*

The classification modified by Cave-Wallbridge categorizes double cecal appendix.

### *Experiences and lessons*

The surgeon must be aware and identify cecal appendix anatomical variations. The procedure is recommended when surgeons surgically approach a patient with acute appendicitis. It is worth performing a complete cecum evaluation after the retroperitoneal release.

### *Peer review*

This case report is well designed and presents a wide range of information about the subject, spreading the right messages and broadly contributing to the literature.

## Abstract

Cystic fibrosis, a common autosomal recessive genetic disorder among Caucasians, is caused by defects in the transmembrane conductance regulatory (*CFTR*) gene. The analysis of *CFTR* gene mutations is useful to better characterize the disease, and for preconceptional screening, prenatal and preimplantation genetic diagnosis. Here we report the results of a genetic analysis in a 16-year-old boy from southwestern Iran diagnosed as having cystic fibrosis in infancy based on gastrointestinal and pulmonary manifestations, with positive sweat chloride tests. He lacked both normal and mutant forms of the fragment corresponding to the ΔF508 allele in initial genetic studies. Multiplex ligation-dependent probe amplification-based testing revealed a homozygous deletion spanning exons 4 to 10 of the *CFTR* gene. We predict an in-frame deletion removing 373 amino acids based on our sequencing results. Determining *CFTR* gene mutations in patients and their family members would be helpful to prevent the occurrence of new cases, especially in populations in which consanguinity is common.

**Key words:** Cystic fibrosis; Transmembrane conductance regulatory gene; Homozygous deletion

**Core tip:** Genetic analysis of the transmembrane conductance regulatory (*CFTR*) gene is helpful to characterize patients with cystic fibrosis, but sequencing and multiplex ligation-dependent probe amplification-based testing are only done to diagnose rare or unknown variants. Here we report a 16-year-old boy, the son of consanguineous healthy parents, who lacked both the normal and mutant forms of the ΔF508 alleles in initial molecular tests. Further analysis disclosed a rare large homozygous *CFTR* gene deletion in this patient.

Farjadian S, Moghtaderi M, Zuntini R, Ferrari S. Rare large homozygous *CFTR* gene deletion in an Iranian patient with cystic fibrosis. *World J Clin Cases* 2014; 2(8): 395-397 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/395.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.395

## INTRODUCTION

Cystic fibrosis (CF), a common autosomal recessive genetic disorder among Caucasians, is caused by defects in the transmembrane conductance regulatory (*CFTR*) gene. This gene spans more than 250 kb on chromosome 7q31.2 and comprises 27 exons encoding a 170 kDa chloride channel expressed exclusively in secretory epithelial

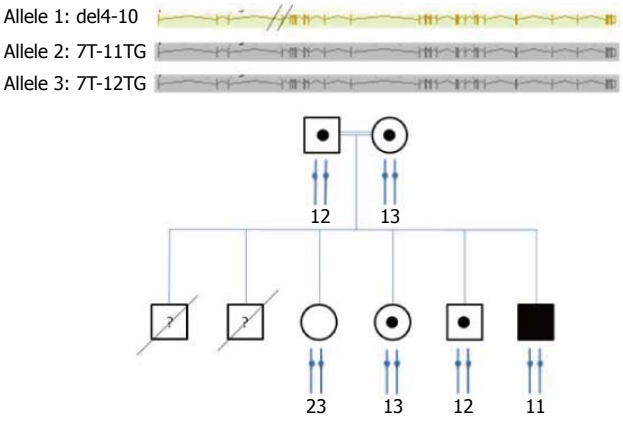

**Figure 1 Pedigree of a family of a 16-year-old boy with cystic fibrosis, showing the three transmembrane conductance regulatory alleles transmitted to the sibs.** Allele 1 carries the deletion of exons 4 to 10; alleles 2 and 3 are distinguishable by the different numbers of TG associated to the polypyrimidine tract in intron 8.

cells[1]. To date, more than 1969 sequence variations have been identified in the *CFTR* gene, including mutations that are involved in disease expression and polymorphisms which have no effect on the phenotype[2]. The rate of *CFTR* gene mutations varies greatly among different populations. Although the prevalence of CF in Iran is not known, current data suggest that the disease is not rare in this country. The most common mutation is ΔF508 with a frequency of 16% to 24% in different parts of Iran; these rates are much lower than in European countries[3].

The clinical presentations of CF varies widely from atypical mild disease to the classical form characterized by multiorgan involvement. The highly variable presentation depends on specific mutations, gene penetrance, the presence of genetic modifiers and environmental factors[4]. The diagnosis of classical CF is straightforward and based on specific clinical features, family history and positive sweat chloride tests, whereas the diagnosis of nonclassical CF is often delayed because of its unusual presentation or the late onset of symptoms. Delays in the diagnosis usually lead to progressive disease and even irreversible multiorgan damage[5]. The analysis of *CFTR* gene mutations is useful to better characterize the disease, especially when the results of sweat chloride tests are uncertain or variable. DNA-based testing is also useful for preconceptional screening, prenatal diagnosis for couples with a family history of CF, and preimplantation genetic diagnosis for couples with known *CFTR* genetic mutations who hope to have a healthy child by *in vitro* fertilization[5,6]. These tests are usually performed with a panel of known *CFTR* mutations for the ethnic group of interest. Sequencing the *CFTR* gene and multiplex ligation-dependent probe amplification (MLPA)-based testing are only done to diagnose rare or unknown variants[4].

## CASE REPORT

A 16-year-old boy from Southwestern Iran with chronic productive cough and dyspnea was diagnosed as having CF in infancy based on typical findings of gastrointestinal and pulmonary manifestations with a positive sweat chloride test. He was the sixth child of healthy consanguineous parents and had two healthy older sisters and one healthy brother. The results of sweat chloride tests were normal for the parents and siblings, and none of them reported any symptoms or problems related with CF. Two of the patient's older brothers had died at the age of 6 mo; their medical history was unremarkable.

This patient had been hospitalized several times during infancy due to severe dehydration. He suffered from numerous recurrent pulmonary infections and greasy stools, which required frequent visits to his physician. Physical examination showed scattered bilateral coarse crackles, increased anteroposterior diameter of chest and digital clubbing.

At his most recent visit his bone age was estimated at about 12-year-old based on left-hand X-ray, and he also had symptoms compatible with delayed sexual maturation and delayed puberty. Laboratory parameters including blood cell count, fasting blood glucose, blood urea nitrogen, serum creatinine, calcium, phosphorus, erythrocyte sedimentation rate, C-reactive protein levels and liver function tests were normal at this visit, but his sweat chloride test results were higher than normal (> 100 mEq/L). Chest X-ray revealed bilateral infiltration and bronchiectasis in both lung fields. Abdominal and pelvic ultrasound examination disclosed no abnormal findings. Because of his abnormal heart sounds, echocardiography was performed which showed mild pulmonary artery hypertension. The patient was advised to continue treatment with antibiotics, chest physiotherapy, pancreatic enzyme replacement and vitamin supplementation.

An initial genetic study was done with the Elucigene CF29 v.2 kit (Tepnel, Oxfordshire, United Kingdom). Our patient lacked of both the normal and mutant forms of the fragment corresponding to the ΔF508 allele, whereas all his first-degree relatives carried the normal allele. This test was repeated three times with new blood samples, and the results were consistent across tests. Genetic analysis was then performed with the Elucigene CF-EU2 v.1 kit (Gen-Probe Life Science Ltd., Manchester, United Kingdom), which is designed to identify 50 mutations. This kit is also able to identify the number of TG repeats associated to the polythymidine tract at the junction of intron 8 and exon 9, which affects the splicing efficiency of exon 9 and influences the gene transcription rate. This analysis showed the absence of PCR amplification products for all fragments mapping to exons 4-10, suggesting that he was homozygous for a deletion spanning exons 4 to 10 of the *CFTR* gene (*CFTR* del 4-10), as a result of first-degree consanguinity between his parents. This homozygous deletion was confirmed by MLPA and was detected in the heterozygous state in both parents (Figure 1), in one of the sisters and in his brother. The 40-kb del 4-10 CF mutation was previously reported in compound heterozygous patterns in two patients with CF: an 8-year-old French girl with the ΔF508/

CF 40-kb del 4-10 genotype combination[7] and a 19-year-old Caucasian female with the c.1220del20/CF 40-kb del 4-10 genotype combination[8]. In contrast to the latter patient with a frameshift mutation in the *CFTR* gene because of a 40-kb deletion, in our patient we predict an in-frame deletion removing 373 amino acids based on our sequencing results.

In conclusion, although there is no evidence to prove the relationship between *CFTR* gene mutations and disease severity or response to therapy, determining *CFTR* gene mutations in patients and their family members would be helpful to prevent the occurrence of new cases, especially in populations in which consanguinity is common.

## ACKNOWLEDGEMENTS

The authors thank Professor Romeo G for coordinating this collaboration, the Institute of Advanced Studies, University of Bologna, Italy for providing accommodations for Dr. Farjadian S while she was in Bologna for the molecular analysis and Shashok K (Author AID in the Eastern Mediterranean) for improving the use of English in the manuscript.

## COMMENTS

### *Case characteristics*

A 16-year-old boy with chronic productive cough and dyspnea was diagnosed as having cystic fibrosis (CF) in infancy based on gastrointestinal and pulmonary manifestations with a positive sweat chloride test.

### *Clinical diagnosis*

Hospitalization during infancy due to severe dehydration and recurrent pulmonary infections and greasy stools.

### *Differential diagnosis*

Celiac disease, primary immunodeficiency disorders.

### *Laboratory diagnosis*

Positive sweat chloride test and lack of both normal and mutant forms of the fragment corresponding to the ΔF508 allele in molecular analysis.

### *Imaging diagnosis*

Left-hand X-ray: bone age about 12-year-old based on. Chest X-ray: bilateral infiltration and bronchiectasis in both lung fields. Echocardiography: mild pulmonary artery hypertension.

### *Treatment*

Antibiotics therapy, chest physiotherapy, pancreatic enzyme replacement and vitamin supplementation.

### *Related reports*

Homozygous 40-kb del 4-10 in cystic fibrosis transmembrane regulatory *(CFTR)* gene was detected in this patient by multiplex ligation-dependent probe amplification (MLPA).

### *Experiences and lessons*

Determining *CFTR* gene mutations in CF patients and their family members would be helpful to prevent the occurrence of new cases, especially in populations in which consanguinity is common.

### *Term explanation*

MLPA is a technique for detecting deletions or duplications of one or more parts of a gene.

### *Peer review*

The manuscript reports a patient with homozygous exon 4-10 *CFTR* gene deletion mutation. Overall, this manuscript is well written and suitable as a case-report.

## Abstract

As patients with carcinoma of the esophagus live longer, complications associated with the use of a gastric conduit are increasing. Ulcers form in the gastric conduit in 6.6% to 19.4% of patients. There are a few reports of perforation of a gastric conduit in the English literature. Almost all of these were associated with serious complications. We report a patient who developed a tension pneumothorax consequent to spontaneous perforation of an ulcer in the gastric conduit 7 years after the index surgery in a patient with carcinoma of the gastroesophageal junction. He responded well to conservative management. Complications related to a gastric conduit can be because of multiple factors. Periodic endoscopic surveillance of gastric conduits should be considered as these are at a higher risk of ulcer formation than a normal stomach. Long term treatment with proton pump inhibitors may decrease complications. There are no guidelines for the treatment of a perforated gastric conduit ulcer and the management should be individualized.

**Key words:** Gastric conduit; Ulcer formation; Perforation; Carcinoma of the esophagus; Proton pump inhibitors

**Core tip:** We report a patient with a spontaneous perforation of an ulcer in the gastric conduit of a patient who had surgery for carcinoma of the gastroesophageal junction. He responded to conservative management with continuous decompression of the conduit with Ryle's tube aspiration, proton pump inhibitors and enteral nutrition through a feeding jejunostomy for 4 wk. Periodic endoscopic surveillance should be considered as gastric conduits are at a higher risk of ulcer formation than a normal stomach and management of a perforated gastric conduit ulcer should be individualized.

Patil N, Kaushal A, Jain A, Saluja SS, Mishra PK. Gastric conduit perforation. *World J Clin Cases* 2014; 2(8): 398-401 Available from: URL: http://www.wjgnet.com/2307-8960/full/v2/i8/398.htm DOI: http://dx.doi.org/10.12998/wjcc.v2.i8.398

## INTRODUCTION

The stomach is preferred as the conduit after esophageal resection. Complications following gastric conduits are being reported more often as patients with carcinoma of the esophagus are living longer after resection. The incidence of an ulcer occurring in a gastric conduit is reported to be between 6.6% and 19.4%[1,2]. Perforation of a gastric conduit ulcer, although rare, may be catastrophic. The ulceration in a gastric conduit is often due to tumor recurrence. However, it may be due to other causes too. We report a patient with spontaneous perforation of a gastric conduit ulcer into the right pleural cavity that was successfully managed conservatively.

## CASE REPORT

A 50-year-old man underwent a transhiatal esophagec-

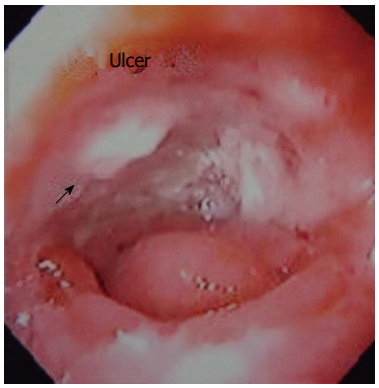

**Figure 1 Endoscopic view of gastric conduit ulcer.**

**Figure 2 Chest X-ray showing right sided tension pneumothorax with mediastinal shift.**

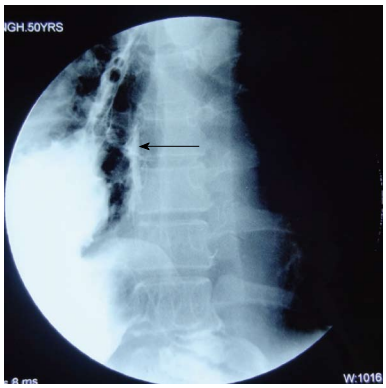

**Figure 3 Oral Gastrografin study showing leak of contrast from the medial aspect of upper part of the conduit (arrow).**

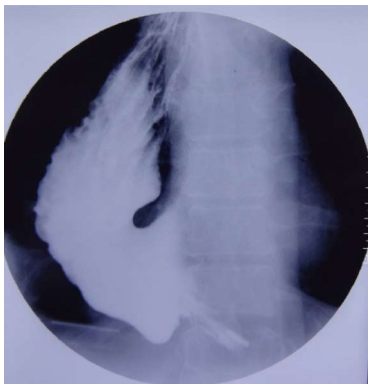

**Figure 4 Repeat study after 4 wk shows no evidence of contrast leak.**

tomy and stapled cervical esophagogastric anastomosis without pyloromyotomy for carcinoma of the gastroesophageal junction in 2005. He had a minor anastomotic leak in the immediate postoperative period which was managed conservatively. The histology revealed a well differentiated adenocarcinoma of the gastroesophageal junction, infiltrating the adventitia. The resected margins were free of tumor and metastasis was seen in one of six lymph nodes. He did not receive any adjuvant treatment. In January 2006 he presented with dysphagia. A barium swallow revealed a stricture at the anastomotic site and an endoscopic biopsy did not show any local recurrence. The stricture was dilated with Savary-Gilliard dilators (Wilson Cook) up to 14 mm in two sessions and the patient became euphagic. He remained asymptomatic until June 2012 when he started complaining of pain in the neck and epigastric region. Endoscopy showed a large ulcer in the gastric conduit just below the anastomotic site. A biopsy from the ulcer did not reveal any malignancy (Figure 1). He was started on proton pump inhibitors (PPI) and *Helicobacter pylori* (*H. pylori*) eradication therapy. In July 2012, he had sudden onset of difficulty breathing and pain in the right side of the chest. At the time of presentation to our hospital the patient was hemodynamically stable. His hemoglobin was 13 g/dL, total leukocyte count of 16000 per cumm, and the blood urea and serum creatinine was 45 mg/dL and 1.2 mg/dL, respectively. The chest X-ray showed a tension pneumothorax on the right side with mediastinal shift to the left (Figure 2). The week before the patient had taken non-steroidal anti-inflammatory drugs for pain. A liter of purulent fluid with gastric contents was drained from the right hemithorax after insertion of an intercostal drainage (ICD) tube and his respiratory distress subsided. An oral Gastrografin study revealed a leak from the proximal part of the gastric conduit into the right hemithorax (Figure 3). A feeding jejunostomy was done because of the poor nutritional status of the patient. He was managed conservatively with continuous decompression of the gastric conduit using a Ryle's tube (Romsins), antibiotics, PPIs, enteral nutrition through the feeding jejunostomy, serial chest X-rays and monitoring the ICD output. A follow up oral Gastrografin study at 4 wk revealed no evidence of any contrast leak from the gastric conduit (Figure 4). He was then allowed oral nutrition which he tolerated. There was no change in the nature and amount of the ICD fluid output. The ICD tube was subsequently removed and chest X-ray did not show any pleural effusion or pneumothorax. He is doing well with no symptoms at the 6 mo follow up. We did not manage this patient with insertion of an endoscopic stent as the leak was from the proximal part of the gastric conduit and the stent would have impinged on the cricopharynx. Stent migration was also likely because of the large diameter of the gastric

conduit.

## DISCUSSION

Increasing use of the stomach as a conduit has led to increasing reports of peptic ulcers in the conduit. In a prospective study of annual endoscopic evaluations in 114 patients who underwent gastric tube reconstruction after esophagectomy, 47% of patients had secondary gastric tube diseases, including gastritis [35.1% (40/114)], benign gastric tumors [10.5% (12/114)], gastric ulcers [6.1% (7/114)] and gastric adenocarcinoma [3.5% (4/114)][1]. Gastric tubes are reported to be at a higher risk of developing an ulcer than the normal stomach. The cause of a gastric conduit ulcer remains controversial. Several mechanisms have been postulated for the formation of gastric conduit ulcers, including normalization of the intraluminal pH profile over time, *H. pylori* infection (especially in patients with a history of peptic ulcer before surgery), delayed gastric emptying as a result of vagal denervation, bile reflux, ischemia due to mobilization of the gastric conduit, radiation, use of non-absorbable sutures and intake of non-steroidal anti-inflammatory drugs (NSAIDs), aspirin or steroids[3]. Most ulcers develop within 20 cm of the esophagogastric anastomosis, as in our patient, because the microcirculation is most disturbed in the upper part of the conduit[2]. The time for development of these ulcers has varied widely, from one month to as long as 150 mo.

Peptic ulcer of the gastric conduit can present with anemia, retrosternal or epigastric pain, fullness after eating or dysphagia[3]. It could be asymptomatic and vagotomy may be one of the reasons for the absence of pain[4]. A gastric conduit ulcer often causes serious complications, such as bleeding and perforation[5]. It may penetrate into any adjacent organ (left ventricular or atrial wall, thoracic aorta and other major vessels) or cavity, including the right pleural cavity, bronchi and pericardial cavity[5].

Only a few cases of gastric conduit perforation have been reported in the English literature and almost all of them had serious complications. More than half the patients were treated conservatively and all of them died[5]. All patients whose conduit ulcer perforated into the tracheobronchial tree or cardiovascular system died. Only patients with perforation into the sternum and thoracic cavity survived. Patients who had a gastric conduit perforation in the thoracic cavity underwent either primary closure of the perforated ulcer or resection of the ulcer followed by an interrupted closure buttressed with a pleural patch. Both these procedures are associated with high leak rates and mortality. In our case, the patient responded to conservative treatment, although we cannot recommend this for all cases.

Endoscopic surveillance should be done at least once every 6 mo as gastric conduits are at a higher risk of ulcer formation than a normal stomach and many such ulcers tend to be asymptomatic. Successful healing of a gastric ulcer by PPIs has been reported[1]. This could prevent potentially lethal complications associated with it.

While complications in the gastric conduit are being reported increasingly, there are no guidelines for the treatment of a perforated gastric conduit ulcer. These patients are usually sick and may not tolerate major surgery. The conservative management protocol cited above resulted in a good outcome in our case, showing that surgery is not always required and the management should be individualized. Avoidance of analgesics and periodic surveillance of the conduit may prevent complications.

## COMMENTS

### *Case characteristics*

The patient presented with sudden onset chest pain and difficulty breathing.

### *Clinical diagnosis*

On clinical examination, decreased breath sounds in the right hemithorax with hyper resonant note on percussion.

### *Differential diagnosis*

Differential diagnoses were pneumothorax secondary to spontaneous rupture of pulmonary bullae, acute myocardial infarction and recurrence of disease.

### *Laboratory diagnosis*

Laboratory investigations were inconclusive.

### *Imaging diagnosis*

On imaging, chest X-ray revealed right sided tension pneumothorax with mediastinal shift to left, gastric contents on insertion of intercostal drainage tube and oral Gastrografin study showed leak from the gastric conduit.

### *Pathological diagnosis*

Previous endoscopy showed a large ulcer in the proximal part of gastric conduit, biopsy was consistent with peptic ulcer and also ruled out any recurrence.

### *Treatment*

He was treated conservatively with continuous decompression of the conduit through Ryle's tube aspiration, proton pump inhibitors and enteral nutrition through feeding jejunostomy for 4 wk.

### *Experiences and lessons*

The possibility that ulceration in the gastric conduit may be due to causes other than tumor recurrence deserves greater recognition. Periodic endoscopic surveillance should be considered as gastric conduits are at a higher risk of ulcer formation than a normal stomach.

### *Peer review*

This is a rare morbid complication of gastric conduit which responded to conservative management. However, a firm conclusion cannot be drawn on the management guidelines of perforated gastric conduit ulcer and treatment should be individualized.

## Abstract

Interspinous posterior device (IPD) is a term used to identify a relatively recent group of implants used to treat lumbar spinal degenerative disease. This kind of device is classified as part of the group of the dynamic stabilization systems of the spine. The concept of dynamic stabilization has been replaced by that of dynamic neutralization of hypermobility, with the intention of clarifying that the primary aim of this kind of system is not the preservation of the movement, but the dynamic neutralization of the segmental hypermobility which is at the root of the pathological condition. The indications for the implantation of an IPD are spinal stenosis and neurogenic claudication, assuming that its function is the enlargement of the neural foramen and the decompression of the roots forming the cauda equina in the central part of the vertebral canal. In the last 10 years, use of these implants has been very common but to date, no long-term clinical follow-up regarding clinical and radiological aspects are available. The high rate of reoperation, recurrence of symptoms and progression of degenerative changes is evident in the literature. If these devices are effectively a miracle cure for lumbar spinal stenosis, why do the utilization and implantation of IPD remain extremely controversial and should they be investigated further? Excluding the problems related to the high cost of the device, the main problem remains the pathological substrate on which the device is explicit in its action: the degenerative pathology of the spine.

**Key words:** Interspinous posterior device; Interspinous fusion device; Interspinous distraction; Motion preservation surgery; Spine surgery; Minimally invasive surgery

**Core tip:** If interspinous posterior devices are effectively a miracle cure for lumbar spinal stenosis, why does their use and implantation remain extremely controversial and should they be investigated further? The aim of this editorial is to analyze and underline why these devices have poor outcomes, focusing on a biomechanical point of view, trying to define indications and limits. Is important to underline that these implants must not become a trend but only a weapon in the surgeon's hands and, as with every weapon, is extremely dangerous in the wrong hands. So the spinal surgeon is the only one who can decide when to use it and must know the effects of this weapon in detail to use it correctly with no damage for the patient.

## INTRODUCTION

Interspinous posterior device (IPD) is a term used to identify a relatively recent group of implants used to treat lumbar spinal degenerative disease. This kind of device is classified as part of the group of the dynamic

stabilization systems of the spine. The concept of dynamic stabilization has been replaced by that of dynamic neutralization of hypermobility, with the intention of clarifying that the primary aim of this kind of system is not the preservation of the movement, but the dynamic neutralization of the segmental hypermobility which is at the root of the pathological condition[1-9].

The indications for the implantation of an IPD are spinal stenosis and neurogenic claudication, assuming that its function is the enlargement of the neural foramen and the decompression of the roots forming the cauda equina in the central part of the vertebral canal.

IPDs have evolved, being classified into not restricted and restricted, based on the presence or the absence of a dynamic control of movements only in extension or flexion and extension respectively[10-27].

A further evolution has brought the development of the interspinous fusion device (IFD), another group of implants, whose aim is interspinous bone fusion. The aim of these devices is not the dynamic neutralization of the hypermovement, but bone fusion with a complete block of the metameric movement. In light of this, in my opinion, IFDs cannot be classified as movement dynamic control systems because their aim is the osseous fusion of the segment, so are completely different from IPD[16-21].

In the last 10 years, use of these implants has been very common but to date, no long-term clinical follow-up are available regarding clinical and radiological aspects. The high rate of reoperation, recurrence of symptoms and progression of degenerative changes is evident in the literature. But the real question is this: If these devices are effectively a miracle cure for lumbar spinal stenosis, why does the utilization and implantation of IPD remain extremely controversial and should they be investigated further? Excluding the problems related to the high cost of the device, the main problem remains the pathological substrate on which the device is explicit in its action: the degenerative pathology of the spine.

## BIOMECHANICAL CONSIDERATIONS

If we consider that IPD can be implanted in stenosis of a mild and moderate degree in central or foraminal stenosis, or in low grade spondylolisthesis without spondylolysis (with poor or at least controversial results), we take for granted that the degenerative lumbar cascade, as described by Kirkaldy-Willis, is in the active phase[22-27].

Degenerative lumbar spondylosis in the active phase as a first step has the damage of the intervertebral disc, whose degree of degeneration is related to the entity of the damage and the persistency of the damage itself in time[22-27].

Normally, the biomechanical behavior of the lumbar spine is subject to the rule of spine loading. According to this rule, the axial load of the body is discharged and consequently neutralized on the intervertebral disc and the posterior structures (articulations, ligaments and muscles) in proportions of 80% and 20% respectively[27].

Any disc degeneration transfers the axial load to the posterior elements of the spine, determining an inversion in the distribution of the axial load related to the loss of viscoelastic and shock absorber properties of the disc itself. This condition promotes the insurgence of a functional overload of the facet joints, determining a greater mechanical stress than the physiological one, with consequent hyperlaxity of the facet joints, reduced competence of the articular capsule and hypermobility of the lumbar segment[22-27].

The hypermobility stimulates the inflammatory reaction in the adjacent tissues, activating chemokines (fractalkine in particular) in the ligamentum flavum, promoting chemotaxis in the ligamentum itself. The inflammatory cells cause extracellular matrix degradation of the ligamentum, determining loss of elasticity and hypertrophy. The role of fractalkine is well documented in the development of numerous inflammatory diseases (rheumatoid arthritis, dermatitis, *etc.*) and in ligaments and joints involved in inflammatory processes caused by instability (*e.g.*, joint capsules, ligaments and synovium). The inflammatory process involves these tissues so the fractalkine overexpression is activated, thus causing the recruitment of mononuclear cells within the LF, feeding the inflammation and causing vascular injury and angiogenesis[20]. Moreover, the increase in mononuclear activity causes a proliferation of fibroblasts (for overexpression of TGF beta mRNA resulting in increased collagen fibers) and inflammatory cells in LF. This inflammatory cell activity in the LF causes rupture of the extracellular matrix (for activation of metalloproteinase MMP2) due to the elastin degradation, resulting in loss of elasticity of the ligament and subsequent hypertrophy[22-27].

The collapse of the intervertebral disc causes ligamentum flavum redundancy and its prominence in the vertebral canal reduces the diameter of the canal itself, determining spinal stenosis.

Only in this phase, the articular hypertrophy generates foraminal stenosis, the collapse of the disc generates ligamentous stenosis and the stenosis becomes symptomatic, but the main pathological substrate remains the hypermobility[22-27]. The treatment of a hard or soft stenosis has to be strictly linked to the concept of vertebral instability as a basic pathological condition. Relating to this concept, the commercialized IPDs have many biomechanical weaknesses that, in my opinion, should make their use extremely rare if not contraindicated.

## MECHANICAL PROPERTIES OF IPD

Non-restricted IPD is a heterogeneous and very populous group of implants (X-STOP, Aperius, Bacjac, Ellipse *etc*). When implanted, their main aim is the interspinous posterior distraction to open the intervertebral foramina. Their primary effect is the decompression of nerve roots in their passage through the foramina. From a biomechanical point of view, the implant of this device has

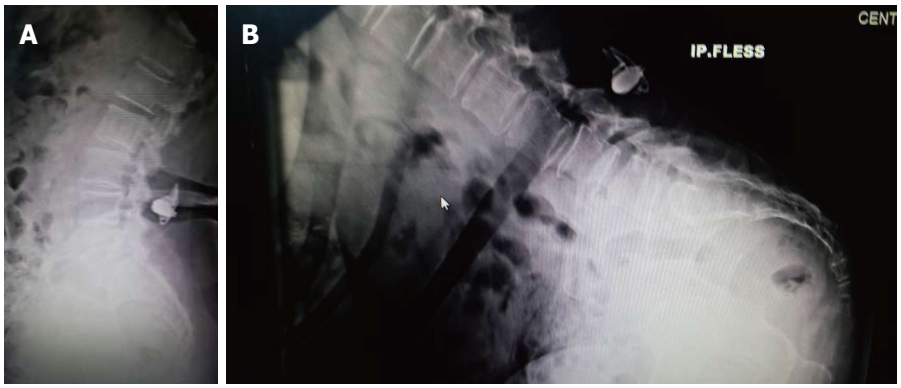

**Figure 1 Dynamic X-ray.** A: Patient treated for L3-L4 disc herniation (without instability at the dynamic X-rays) with an interspinous posterior device (IPD) implant. The Dynamic X-ray in extension showed a metameric instability at L3-L4 developed 1 year after an IPD implantation; B: Dynamic X-ray in flexion that showed an increase in L3-L4 slipping, developing a I° grade spondylolisthesis, due to the IPD implantation. The patient underwent revision surgery with removal of the IPD, decompressive laminectomy and L3-L4 stabilization with screws and rods.

**Figure 2 Dislocation of the L3-L4 interspinous posterior device in a patient with double level implant.** The patient underwent revision surgery with removal of both interspinous posterior devices followed by decompression and stabilization with screws and rods.

consequences on the involved and adjacent segments: (1) The axial load is shifted anteriorly on a degenerated intervertebral disc in which degeneration promotes the lumbar stenosis. The anterior load statically and dynamically over-solicits a degenerated disc, which has partially lost its features of shock absorber and elastic resistance against movements, promoting a faster degeneration of the disc; and (2) The distraction needed to open the intervertebral foramina causes an alteration of the lumbar spine sagittal balance[28-42].

Sagittal balance is the axial equilibrium that the whole spine has towards the outside world; its integrity provides elastic properties to the spine and tolerance to loads. Sagittal balance is based mainly on an adequate equilibrium of the physiological curvatures of the spine so that they can transfer the axial load to the floor, passing through the hips and the heads of the femora. The load line of the axial load is a vertical vector perpendicular to the floor passing through the external acoustic meatus, the midpoint of the endplate of L5 and the head of the femur. This vector has to always be posterior to the line connecting the two heads of the femora: to achieve this aim, the spine curvatures have to be maintained physiologically as much as possible. In particular, the preservation of physiological lumbar lordosis is fundamental[36-42].

The purpose of these devices is their implant between the spinous processes and their distraction; this movement of distraction transfers the axial load in the anterior compartment on a degenerated disc and alters the biomechanics of the whole spine, with a negative impact on the sagittal balance. This action has consequences on the spine, determining postural alterations, rotations of the spino-pelvic alignment and alterations in the thoracic and cervical curvatures, trying to compensate the alteration of the sagittal balance but actually accelerating the progression of the spinal degeneration. These patients are in a condition of spinal imbalance[36-42].

Initially, patients can have an improvement of their symptoms due to the foraminal decompression but long-term the alteration of the spinal biomechanics can only accelerate the degenerative process, with involvement of the treated and adjacent segments (Figure 1).

Furthermore, the overload applied to the spinous processes can cause a fracture of the processes themselves or lacerations of the posterior longitudinal ligament, causing the mobilization of the device (Figure 2)[36-49].

The restricted IPDs (such as Wallis, Diam, Intraspine, *etc.*) have the presumed function of neutralizing the movements of flexion and extension at excessive degrees. These implants have the distraction of the spinous processes to widen the intervertebral foramina as a fundamental step, altering the biomechanics of the lumbar spine and determining sagittal imbalance, with the same mechanism as the non restricted IPD. Although these devices can control the excessive degrees of movements in flexion and extension, they cause a non physiological alteration in the movements of the spinal motor unit, with the same consequences described before. Furthermore, the segmental instability is not limited to the simple movements of flexion and extension, but also the movements of lateral bending and axial rotation, often associated with the movements of flexion and extension while the spine executes complex movements.

An interspinous device cannot control the movements of axial rotation and lateral bending, highly solicited after the implant of the device, accelerating and fastening the degenerative process.
