APPENDIX I-V Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Clinical Oncology*, Tzu-Chen Yen, MD, PhD, Professor, Director, Department of Nuclear Medicine, Chang Gung Memorial Hospital, Taoyuan 333, Taiwan

AIM AND SCOPE *World Journal of Clinical Oncology* (*World J Clin Oncol*, *WJCO*, online ISSN 2218-4333, DOI: 10.5306) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJCO covers a variety of clinical medical topics, including etiology, epidemiology, evidence-based medicine, informatics, diagnostic imaging, endoscopy, tumor recurrence and metastasis, tumor stem cells, radiotherapy, chemotherapy, interventional radiology, palliative therapy, clinical chemotherapy, biological therapy, minimally invasive therapy, physiotherapy, psycho-oncology, comprehensive therapy, and oncology-related nursing. Priority publication will be given to articles concerning diagnosis and treatment of oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJCO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING *World Journal of Clinical Oncology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Key words: Breast reconstruction; Conservative breast surgery; Partial mastectomy; Oncoplastic; Reduction mammoplasty; Outcome; Complications

Abstract

Breast-conservation surgery (BCS) is established as a safe surgical treatment for most patients with early breast cancer. Recently, advances in oncoplastic techniques are capable of preserving the breast form and quality of life. Although most BCS defects can be managed with primary closure, the aesthetic outcome may be unpredictable. Among technical options, therapeutic reduction mammoplasty (TRM) remains a useful procedure since the BCS defect can be repaired and the preoperative appearance can be improved, resulting in more proportional breasts. As a consequence of rich breast tissue vascularization, the greater part of reduction techniques have based their planning on preserving the pedicle of the nipple-areola complex after tumor removal. Reliable circulation and improvement of a conical shape to the breast are commonly described in TRM reconstructions. With an immediate approach, the surgical process is smooth since both procedures can be carried out in one operative setting. Additionally,

Core tip: Recently, advances in oncoplastic techniques are capable of preserving the breast form and quality of life. Among technical options, therapeutic reduction mammoplasty remains a useful procedure since the breast-conservation surgery defect can be repaired and the preoperative appearance can be improved. Additionally, it permits wider excision of the tumor, with a superior mean volume of the specimen and potentially reduces the incidence of margin involvement. The main advantages of the technique utilized should include reproducibility, low interference with the oncological treatment and long-term results. The success of the procedure depends on patient selection, coordinated planning and careful intra-operative management.

Munhoz AM, Montag E, Gemperli R. Current aspects of therapeutic reduction mammoplasty for immediate early breast cancer management: An update. *World J Clin Oncol* 2013; 5(1): 1-18

INTRODUCTION

Breast-conservation surgery (BCS) is an important component of early breast cancer treatment, with a survival outcome comparable to that of radical procedures^[1]. In fact, the long-term survival of BCS with radiation is not statistically different when compared with mastectomy in patients with Stage I or II breast cancer^[2].

BCS with concomitant reconstruction has been developed over the past decades. In essence defined as oncoplastic surgery, the procedure refers to a number of surgical techniques by which breast tumors are resected while the remaining glandular tissue is transposed to achieve a satisfactory aesthetic outcome^[2-4]. A variety of such techniques has been described, including volume replacement by local glandular flaps and breast reshaping by therapeutic reduction mammoplasty (TRM) or regional/distant flaps^[5-12].

In spite of the acceptance that most BCS defects can be managed with primary closure, some lesions are complex to resect without the risk of aesthetic deformity. In fact, favorable aesthetic outcome can be difficult to achieve and an example of this is in patients with large breast tumors in relation to breast size^[2,6,11]. In addition, radiation can also have a negative effect on the glandular and skin tissue. In our experience, the main clinical aspects are related to skin pigmentation changes, telangiectasia and skin fibrosis^[11,13-17].

Recently, clinical experience with oncoplastic surgery has demonstrated the freedom to perform wider tumor excisions, potentially reducing margin involvement. Additionally, another benefit is the possibility of allowing the excision of larger tumors without compromising cosmetic outcome^[6-18]. Thus, by means of customized techniques the surgeon ensures that oncological principles are not jeopardized while meeting the needs of the patient from an aesthetic point of view^[3].

In general, the oncoplastic procedures are related to volume displacement or replacement techniques and sometimes include contralateral breast surgery. Regardless of the fact that there is no consensus concerning the best approach, the criteria are determined by the surgeon's experience and the size of the defect in relation to the size of the remaining breast^[11]. The main advantages of the technique utilized should include low interference with the oncological treatment, reproducibility and long-term results. Probably, all these objectives are not achieved by any single procedure and each technique has advantages and limitations^[11].

LITERATURE SEARCH/DATA EXTRACTION

Two independent reviewers evaluated titles and abstracts

without language restrictions to assess eligibility in terms of outcome measures and study design. A literature search was carried out up to August 2013 to identify studies of breast cancer patients treated with oncoplastic surgery procedures and to determine if any use of mammoplasty techniques was recorded. In an attempt to minimize the omission of potentially relevant clinical studies, we also reviewed the reference lists of included studies and relevant reviews for additional eligible articles. Potential studies were identified by searches of Medline and PubMed databases using the terms "oncoplastic breast surgery", "conservative breast surgery reconstruction", "partial mastectomy reconstruction", "therapeutic mammoplasty" and "reduction mammoplasty". Studies identified were screened for those that focused on techniques, surgical and oncological outcomes after therapeutic mammoplasty reconstruction and references of each study were further investigated to include all relevant published data.

A total of 1382 potential articles were identified during the primary evaluation. After appraisal of the inclusion criteria, 311 articles were identified for potential inclusion and reviewed in detail. A total of 226 articles were excluded, leaving 77 articles to form the basis of this review.

THERAPEUTIC REDUCTION MAMMAPLASTY

Among the main technical options, TRM remains a useful procedure. Usually, the application of TRM involves resection of the tumor and remodeling the breast using an aesthetic breast reduction technique. As a consequence of rich breast tissue vascularization, the greater part of TRM has based their planning on preserving the pedicle of the nipple-areola complex (NAC) after tumor removal. Usually, the procedure is adequate for patients with moderate/larger breasts requiring excision of significant volumes of tissue and contralateral symmetrization. With TRM, the BCS defect can be repaired and the preoperative appearance can be improved, resulting in more proportional breasts^[15-17]. In addition, the technique reduces the difficulty of providing radiation therapy to the remaining breast tissues with acceptably low complication rates^[19-21]. In terms of local control and oncological outcome, the added removal of a substantial volume of breast tissue could add a significant amount of safety in terms of surgical margins^[22,23].

INDICATIONS OF TRM: TIMING, TECHNIQUES

Timing of reconstruction

With immediate reconstruction, the surgical process is smooth since BCS and TRM can be carried out in one operative setting. Additionally, because there is no scar and fibrosis tissue, breast reshaping is easier and the aes-

thetic is improved^[6,8,9,11,12,24-27]. In fact, Kronowitz *et al*^[9] observed that immediate repair is preferable to being delayed because of a decreased incidence of complications. In our previous experience utilizing TRM for BCS reconstruction, we observed that our post-radiation complication rate (delayed BCS reconstruction) was higher than that expected for TRM without radiotherapy (immediate BCS reconstruction)^[24]. This finding is similar to previous studies that suggest that delayed BCS reconstruction has a significantly higher complication rate compared with immediate procedures^[8,9].

In terms of oncological benefits and adjuvant treatment, immediate reconstruction can be advantageous. Some clinical series have observed that patients with large volume breasts present with more radiation related complications than patients with normal volume breasts^[19-21]. Additionally, some studies observed that there is an increased fat content in large breasts and the fatty tissue results in more fibrosis after radiotherapy than glandular tissue^[21]. Thus, TRM can increase the eligibility of large-breasted patients for BCS since it can reduce the difficulty of providing radiation therapy^[15-17,19,23]. Gray *et al*^[21], in a series of 257 patients, found that there was more retraction and asymmetry in the large-breasted *vs* the small-breasted group. Usually, these deformities are complicated to manage and habitually necessitate secondary reconstruction with autologous tissue.

Another aspect is the possibility of accomplishing a negative resection margin. In fact, the immediate reconstruction with TRM allows for wider local tumor excision, potentially reducing the incidence of margin involvement^[15-17,22,23]. Kaur *et al*^[22] compared patients submitted to oncoplastic procedures and to BCS. The immediate reconstruction permitted larger resections, with a superior mean volume of the specimen and negative margins.

In spite of the benefits, the immediate TRM reconstruction presents some negative aspects. The surgical time can be lengthened and require specialist training to learn and properly apply these procedures^[2,3,15]. Another point is related to the postoperative breast volume and shape^[26]. In fact, in some cases the final contour of the breast cannot be predicted at the time of the BCS and although the aesthetic result can be adequate, the outcome of the radiated breast is sometimes less favorable than the nonradiated breast^[5-8,23,26]. Despite there being no consensus, in delayed reconstruction, the plastic surgeon could wait until the postoperative changes in the deformed breast stabilize.

Another important point is related to the postoperative recovery. In theory, some complications of the immediate TRM reconstructions can unfavorably defer the adjuvant therapy. With delayed oncoplastic reconstruction, operative time is shortened and the surgical process is less extensive than an immediate one. Additionally, depending on the technique of reconstruction utilized, surgical techniques can be complicated and lengthy, and

potentially associated with relatively high postoperative complication rates. In fact, some surgeons are concerned that immediate application of TRM may delay adjuvant systemic and locoregional treatment and compromise prognosis. However, our previous experience with TRM^[11,14-17] and that of others^[8,18,23] has shown that an immediate approach does not compromise the start of radio and chemotherapy in the overall treatment of breast cancer. Besides the evidence in the literature, it has been our impression that nothing suggests that immediate application of TRM is not safe enough in terms of starting adjuvant therapy. In fact, Kahn *et al*^[28] in a series of 169 patients submitted to BCS provide evidence that immediate reconstruction does not lead to a delay in the commencement of adjuvant chemotherapy when compared to three adequate control groups from the same institution and time periods.

Breast defect definition

BCS reconstructive planning should include the breast volume, tumor location, the extent of glandular tissue resected, and chiefly address individual reconstructive requirements^[11]. Evaluation of BCS reconstruction must subsequently consider these important points and only then should the proper TRM procedure or a combination of procedures be chosen^[2,11]. It has been our experience that each BCS defect has its own special reconstructive necessities varying expectations for aesthetic outcome. On the basis of our 15 years of experience, it is possible to identify trends in types of breast defects and to develop an algorithm for immediate BCS reconstruction on the basis of the initial breast volume, the extent/location of glandular tissue resection and the remaining available breast tissue^[11]. To make possible development of a BCS reconstructive algorithm, immediate partial breast defects are classified into one of three types (Figure 1).

Type I : Defects include tissue resection in a smaller breast without ptosis. Type I A defects involve minimal defects that do not cause volume alteration/distortion in the breast shape and the tissue resected is less than 10%-15% of the total breast volume. Type I B defects involve moderate defects that do originate from moderate volume alteration/distortion in the breast shape or symmetry and the tissue resected is between 15% and 40% of the total volume. Usually, the skin above the tumor is resected with the tumor. Type I C defects involve large defects that do cause significant volume alteration/distortion in the breast shape and symmetry and the tissue resected is more than 40% of the total breast volume.

Type II : This group includes tissue resection in medium sized breasts with/without ptosis. Type II A involves small defects that do not cause enough volume alteration/distortion in the breast shape. Type II B defects involve moderate defects that cause minor/moderate volume alteration in the breast shape. Type II C defects

Figure 1 Algorithm for immediate conservative breast surgery reconstruction based on the type of breast and extent of defect.

involve large defects that cause moderate/large volume variations in the breast shape and symmetry.

Type III: This group includes tissue resection in large sized breasts with ptosis. Type IIIA involves small defects that do not cause enough aesthetic deformity. Type IIIB defects involve moderate defects that originate from minor/moderate volume alterations in the breast shape or symmetry. Type IIIC defects involve large defects that cause significant volume alteration in the breast.

Surgical techniques and the role of TRM

BCS defects can be scored and classified according to the proposed classification^[11]. In our experience, the majority of reconstruction techniques are performed with one of six surgical options: breast tissue advancement flaps (BAF), lateral thoracodorsal flap (LTDF), TRM (bilateral mastopexy and bilateral reduction mammoplasty), latissimus dorsi myocutaneous flap (LDMF) and abdominal flaps.

Habitually, TRM may be indicated if the patient has a moderate/large breast volume or if there is breast ptosis. Patient selection should be primarily limited to those who desire breast reduction and those who have at least moderately sized breasts with a defect that is suspected to be at least small and moderate in size (Figure 1). Surgi-

cal planning should include breast characteristics, extent of breast tissue resected, and chiefly address individual reconstructive requirements. Additionally, the decision is usually determined by the surgeon's preferences and the size of the defect in relation to the size of the remaining breast. In fact, it is important to identify trends in types of breast defects on the basis of the initial breast volume, the extent/location of glandular tissue resection and the remaining available breast tissue.

Type I A, II A and III A: Defects are usually repaired with BAF in which the defect created is usually spherical or rectangular. The breast tissue is advanced along the chest wall or beneath the breast skin flap to fill the tumor defect. Usually, in these patients no contralateral breast procedure is performed.

Type I B: In patients with lateral defects, the LTDF is performed. Previously described elsewhere^[14], this local flap is planned as a wedge-shaped triangle located on the lateral aspect of the thorax. Although additional scars are created, they will be placed in the lateral region. The defect margins are sutured to the margins of the flap and the donor site is closed primarily. In patients with central and medial tumors, the LDMF can be utilized^[11,13]. The flap is designed into a horizontal position and the width

Figure 2 A 62-year-old patient with invasive ductal carcinoma (1.7 cm) of the left breast. The patient underwent a left central quadrantectomy and sentinel lymph node biopsy, immediately followed by a therapeutic reduction mammoplasty Inferior Pedicle Technique reconstruction (A-B, above left and right); A total of 78 g was removed from the left breast (C-D, center left and right); One year postoperative appearance after the radiotherapy (E-F, below left and right).

of the paddle is measured according to the skin previously resected.

Type I C: Defects are converted to a skin-sparing mastectomy (SSM) and reconstructed with an appropriate technique. In patients with enough abdominal tissue, an abdominal flap (pedicled/free TRAM or DIEP) can be an option according to the surgeon's preference. In patients without an adequate abdomen, a LDMF associated with an implant can be performed.

Type II B: Defects are frequently reconstructed with TRM techniques when there is sufficient breast tissue to perform the reconstruction (Figure 2).

Type II C: Defects are analyzed individually according to the size of the breast defect in relation to the remain-

ing breast tissue available. For this purpose, the patient is positioned upright to assess the amount of the remaining glandular tissue. Thus, type II C can be subclassified into favorable and unfavorable defects. If there is enough tissue to perform an adequate breast mound shaping, the defect is classified as favorable. For the lateral defects, the extended LTDF is most commonly employed. In patients with central and medial defects, the extended LDMF can be utilized^[13]. Conversely, if not enough breast tissue remains, the breast defect is classified as unfavorable and a SSM and total reconstruction is indicated.

Type III B: Defects are frequently reconstructed with TRM techniques when the patient presents with large volume breasts and there is a sufficient amount of breast tissue. The most favorable tumor location is in the lower breast pole where a conventional superior pedicle or

Figure 3 A 48-year-old patient with invasive ductal carcinoma (3.2 cm) of the inferior-medial quadrant of the left breast. The patient underwent a left inferior-medial quadrantectomy and sentinel lymph node biopsy, immediately followed by a therapeutic reduction mammoplasty Superior-Lateral Pedicle Technique reconstruction (A-B, above left and right); A total of 125 g was removed from the left breast (C-D, center left and right); Six months postoperative appearance after the radiotherapy with a very good outcome (E-F, below left and right).

superior-medial technique can be utilized^[15,16]. In patients with central tumors, an inferior pedicle is used to carry parenchyma and skin into the central defect^[17] (Figure 3).

Type III C: Breast defects are analyzed individually. When the defect is favorable, the deficiency is most frequently reconstructed with TRM (Figure 4). A marked reshaping of the breast with available tissue and a similar contralateral breast reduction is then performed. In patients in whom the relationship is not favorable, a skin-sparing mastectomy and total breast reconstruction can be indicated.

TYPES OF TRM TECHNIQUES

In spite of the reduction mammoplasty being a well

documented and commonly performed procedure for aesthetic objectives, less information is available regarding the outcome following immediate reconstruction for oncological objectives. To date, there are few large clinical reports that specifically address the use of the technique for immediate reconstruction and its outcome^[8,15-19] (Table 1). In addition, there is no consensus regarding the best TRM technique for immediate BCS reconstruction. Possibly, an ideal procedure does not exist and each case should be planned individually. The main advantages of the TRM technique utilized should include reproducibility, safety and long-term results. As any surgical technique, all these goals are probably not met by any single procedure and this is supported by the large number of TRM techniques available^[13].

Concerning the techniques, TRM procedures present

with a variety of glandular pedicle types with an inverted T scar design. Most of the techniques are predictable and permit management over the extent of resection

and the breast-shaping process. Because of rich breast tissue vascularization, the majority of techniques have based their planning on preserving the pedicle of the

Figure 5 Schematic illustration of the therapeutic reduction mammoplasty surgical markings and Superior (A) and Inferior pedicle (B) techniques.

Figure 6 The superior-lateral pedicle technique for inferior-medial quadrantectomy reconstruction. For tumors located in the lower pole of the breast, the tumor resection can be incorporated into the sector of breast tissue removed as part of a superior pedicle mammoplasty (A-B); For inner region tumors, the reduction pattern can be rotated and a superior-lateral (C); The opposite breast surgery is usually performed to match the appropriate symmetry (D).

NAC after tumor removal. Each technique presents particular advantages for their indications, tumor location, additional skin and glandular resections and resultant scar^[15]. Typically, one of two procedures can be utilized: the superior pedicle and the inferior pedicle technique (Figure 5). A range of other approaches have been described, which are adaptations of the superior and inferior procedures.

Superior pedicle techniques

For tumors located in the lower pole of the breast, the tumor resection can be incorporated into the sector of breast tissue removed as part of a superior pedicle mam-

maplasty^[15,16]. For inner and outer region tumors, the reduction pattern can be rotated and a superior-lateral (Figure 6) or a superior-medial pedicle mammoplasty (SMDP) can be performed^[16] (Figure 7). The opposite breast surgery is usually performed to match the appropriate symmetry, particularly in breasts with severe ptosis. In our previous study analyzing different TRM for BCS reconstruction, the superior pedicle represented almost 90% of cases^[15].

In our clinical practice and with a well-trained surgical team, the procedure can be conducted on both sides at the same time, consequently reducing the operative time. When performing symmetrization, the surgeon can use

Figure 7 The superior-medial pedicle technique for superior-lateral quadrantectomy reconstruction. For superior and outer region tumors, the reduction pattern can be rotated and a superior-medial (A-D).

this opportunity to resect any suspicious breast lesion that may have been revealed by preoperative exams^[15,24].

Described originally by Orlando and Guthrie in the 1970s, the SMDP technique presents advantages in terms of pedicle safety and aesthetic outcome^[29]. The technique is designed to preserve the pedicle blood flow as well as to provide a better breast shape^[29-31]. The superior-medial pedicle receives its blood supply directly from the internal mammary vessels which are the main pedicle in the majority of patients^[31,32]. This anatomical characteristic permits a better NAC vascularization and can minimize vascular pedicle complications when planned and performed effectively.

In our previous experience, the SMDP was indicated in patients with medium or large volume breasts with ptosis^[16]. According to our algorithm, all tumors were located in the lower breast pole and the patients presented with small or moderate defects where there was enough breast tissue to perform the reconstruction^[11]. Similar to our previous study with superior pedicle techniques^[11,15], the planning of the SMDP procedure was based on preserving the pedicle of the NAC before tumor removal. In this situation, the tumor resection was incorporated into the sector of breast tissue removed as part of a conventional SMDP technique and it usually results in an inverted T scar pattern. Normally, the NAC is de-epithelialized and a minimum pedicle base of 4 cm is maintained, depending on the extension of tumor resection. If a large pedicle is maintained, it may be that more vascular supply can be incorporated. It is important to

maintain the distal aspect of the pedicle with a minimum 2 cm margin around the NAC in order to preserve the local vascular plexus. Concerning the final breast shape and projection, some authors in aesthetic reductions advocate the addition of extra glandular tissue in the pedicle to form a platform for the NAC so that it does not become depressed postoperatively. One important point is that the pedicle should rotate without difficulty into its new position^[31]. At this point, the most crucial aspect is to avoid some degree of kinking or compression^[32]. If too much glandular tissue is maintained in the pedicle, it will also make it more difficult to rotate and insert it in the new NAC position. Moreover, Hall-Findlay has suggested that there is a risk to the glandular tissue in excess drop down which might result in a pseudoptotic breast^[32].

In spite of the main advantages, the SMDP technique has some negative aspects. Since the NAC flap is not an axial flap, tissue vascularization to the most distant parts is difficult to foresee during the NAC pedicle planning and breast molding. This situation can predispose to partial necrosis of the NAC flap and even a total NAC loss. With the objective of improving the NAC vascularization and to avoid pedicle torsion, it is important to define the right position of the NAC pedicle according to the degree of breast ptosis and hypertrophy. Similar to the proposal by Cárdenas-Camarena *et al.*^[33], in the superior lateral technique we advocate locating the pedicle lower down when the degree of ptosis and migration of the NAC is greater to avoid marked rotation (Figure 8).

Figure 8 Schematic illustration of the superior-medial pedicle technique according to the degree of breast ptosis and the rotation of the pedicle. With the objective of improving the nipple-areola complex (NAC) vascularization and to avoid pedicle torsion, it is important to define the right position of the NAC pedicle according to the degree of breast ptosis and hypertrophy. It is important to locate the pedicle lower down when the degree of ptosis and migration of the NAC is greater to avoid marked rotation.

Figure 9 Inferior pedicle technique for central quadrantectomy reconstruction. For central region tumors (A), the lower breast and skin tissue may be moved into the defect as a skin-glandular flap and an inferior pedicle mammaplasty can be utilized (B-D).

Inferior pedicle techniques

For upper region tumors, the lower breast tissue may be moved into the defect as a glandular flap and an inferior pedicle mammaplasty (IPM) can be utilized^[17]. Introduced originally by Ribeiro^[34] in the 1970s and subsequently modified by Courtiss and Goldwyn^[35], the technique described the transposition of the NAC on an inferiorly based dermoglandular flap.

Concerning the IPM technique, there are some advantages in terms of pedicle safety and results. The inferior pedicle receives its blood supply directly from the fourth, fifth and sixth intercostal perforating vessels of the internal mammary arteries. In fact, Courtiss and Goldwyn^[35] demonstrated by cadaver dissections that the principal sources of blood flow are the perforating and intercostal branches of the internal mammary artery and the ex-

ternal mammary branches of the lateral thoracic artery. Thus, the IPM provides a breast that is easily shaped, without neurovascular changes to NAC^[36-39].

In our experience, the IPM was performed to repair skin and breast tissue and was indicated in patients with medium or large volume breasts with ptosis^[17]. All tumors were located in the upper and central breast pole and the patients presented with small or moderate defects where there was enough breast tissue to perform the reconstruction. In the central tumors, the NAC is resected and the lower pole tissue is preserved to perform the reconstruction (Figure 9). Despite no cases of contralateral tumor being observed in our series utilizing the IPM, the contralateral mammaplasty provides an opportunity for histological examination of tissue from the opposite breast. In fact, Petit *et al*^[40] reported a 4.5% incidence of

Figure 10 Inferior pedicle technique for upper quadrantectomy reconstruction. For upper region tumors (A), the lower breast and skin tissue associated with the nipple-areola complex may be moved into the defect as a skin-glandular flap and a conventional inferior pedicle mammoplasty can be utilized (B-D).

occult carcinomas in the contralateral breast in a series of 440 patients. Similarly, in our previous larger study, 4.3% of the patients submitted to contralateral mammoplasty presented with the diagnosis of occult breast cancer^[24].

IPM for BCS reconstruction can be a helpful technique for early breast cancer patients; nevertheless, important technical details must be considered. Preoperative evaluation can permit optimal positioning of the skin resection and to preserve the perforator vessels. Normally, the inferior pedicle is de-epithelialized and a minimum pedicle base of 6 cm is maintained. Concerning the breast contour close to the partial mastectomy area, it is practical to bend the inferior pedicle over itself to provide extra glandular tissue so that it does not become depressed postoperatively. For this purpose, the inferior pedicle should lie comfortably within the defect and it is important to avoid additional undermining to preserve the local vascular plexus (Figure 10). Even although we observed a low incidence of vascular complications, care must be taken in treating high risk patients, such as smokers and patients with a longer sternal notch to NAC distance. It has been our impression and that of some authors that the inferior pedicle length and the pedicle placement without tension are the main determinants of complications.

In spite of the advantages, the IPM presents some limitations. Although some authors have observed that the technique does not represent a problem with surveillance, with breast remodeling techniques it may be difficult to establish the location of a positive tumor

margin that is diagnosed postoperatively. In cases of re-exploration, it is rational to execute it in association with the plastic surgery team to identify the original tumor bed and to avoid injury to the inferior pedicle.

In our experience, we observed that the majority of the complications utilizing IPM for BCS reconstruction were immediate, minor and did not interfere with the adjuvant treatment^[17]. Similarly, as we have observed in superior pedicle techniques, the most frequent complications in the late period were related to skin disorders and fat necrosis which were diagnosed by mammography during the follow-up. According to Losken *et al.*^[23], postoperative surveillance is not impaired by immediate mammoplasty. In fact, calcifications and fat necrosis from postoperative scarring can mimic cancer recurrence; nevertheless, these changes can be distinguished on mammography, fine-needle aspiration or core biopsy.

CLINICAL RESULTS OF TRM IN BCS RECONSTRUCTION

Various oncoplastic procedures have been demonstrated to improve aesthetic outcome following BCS. Techniques range from simple glandular flaps to TRM and distant flaps^[11]. At the present time, optimal treatment should be correct, adequate and preventive by performing immediate reconstruction before radiotherapy^[9,24,25]. However, to date there is limited evidence in the plastic and breast surgery literature on the safety and aesthetic clinical results of the TRM techniques^[8,9,10,24,25,27,28]. In fact, most

of these clinical series are retrospective studies, generally based on a limited number of patients and sometimes only a single surgeon's experience. In addition, there are a small number of data on its impact on local recurrences, distant metastasis and overall survival^[9,41,42].

Some retrospective clinical studies with long-term follow-up have shown that TRM is not associated with a higher rate of recurrence or lower survival rate than conventional techniques. Clough *et al.*^[41] with a median follow-up of 46 mo reported 101 patients who underwent BCS and oncoplastic reconstruction. Local recurrence developed in 11 cases (5 years local recurrence rate was 9.4%). Thirteen patients developed metastases and eight died of their disease (5 years metastasis-free survival of 82.8% and an overall survival rate of 95.7%). Similarly, Kronowitz *et al.*^[9] in a review of 69 patients observed local recurrence in 2% of immediate oncoplastic reconstructions and in 16% of delayed ($P = 0.06$). The difference observed between the two groups can be explained by the advanced tumor stage for the patients who had a delayed reconstruction. Recently, Rietjens *et al.*^[42] reported the long-term oncological results of the oncoplastic reconstruction in a series of 148 patients. With a median follow-up of 74 mo, 3% developed an ipsilateral breast cancer recurrence and 13% developed distant metastasis. According to the authors, the rate of local recurrence after 5 years was low in their series when compared with the 14.3% of cumulative incidence in the NSABP trial, the 9.4% after 5 years in the Institut Curie study and the 0.5% after 5 years in the Milan I trial. Consequently, the oncoplastic approach associated with BCS can be considered as safe as mastectomy in tumors less than 2 cm and possibly safer than the BCS.

Another important point is related to tumor size and volume resection. In fact, the use of TRM presents a significantly higher volume of tissue excised compared to standard wide local excision. Kaur *et al.*^[22] in 2005 compared quadrantectomy with TRM procedures and observed a higher mean volume of tissue excised during TRM. However, they demonstrated no significant difference in margins between the two groups. Similarly, Giacalone *et al.*^[43] demonstrated mean specimen volumes of 190 cm³ for oncoplastic techniques and 99 cm³ for standard quadrantectomy.

There is limited evidence of the oncoplastic procedures concerning the aesthetic outcome. In addition, the methods of aesthetic evaluation vary significantly^[9,10]. Some authors reported that the volume of tissue resection is directly associated with the aesthetic outcome^[7,44-52]. Gendy *et al.*^[44] compared the aesthetic outcomes of 106 patients. Although the panel scored the aesthetic outcome as high, the aesthetic failure rate was 18% on breast retraction assessments. The authors demonstrated an advantage for the BCS reconstruction with regards to the incidence of complications (8% *vs* 14%), additional surgery (12% *vs* 79%) and restricted activities (54% *vs* 73%). Olivotto *et al.*^[45] and Mills *et al.*^[46] have docu-

mented that excision of a volume greater than 70 cm³ in medium-size breasts often leads to unsatisfactory aesthetic results. Clough *et al.*^[41], in a panel of three, assessed cosmetic results at 2 and 5 years. At 2 years, 88% and at 5 years, 82% of patients had a fair to excellent outcome. A significantly worse aesthetic outcome was observed in patients that received pre-operative radiotherapy compared to the remainder which were given radiotherapy post-operatively.

Fitoussi *et al.*^[47] retrospectively used a similar aesthetic evaluation method as proposed by Clough *et al.*^[41], with a panel made up of a surgeon, a nurse and a layman, using a five-point scale from excellent to poor. The cosmetic outcome in this retrospective study was satisfactory in 98% of patients at 12 mo and in 90% of patients at 5 years following BCS reconstruction.

Although oncological safety remains the primary objective of BCS, surgical management is increasingly focusing on improved aesthetic outcomes. Immediate application of TRM has evolved to meet this need and the extensive body of literature published in recent years demonstrates the widespread use of these techniques. Recognizing that there is a small risk for local recurrence, we believe that immediate application of TRM could be a safe option for early breast cancer patients who desire BCS.

LIMITATIONS OF TRM

Adjuvant treatment

There is evidence that oncoplastic breast conservation surgery and immediate application of TRM does not lead to a delay in the commencement of adjuvant chemotherapy^[15,18,23,25,28,42,50,53-56]. Although this is an integral part of overall oncological safety, few controlled studies have been published. In fact, most of the studies focus on recurrence rates and long-term survival; however, the evidence described is mostly based on single center retrospective analyses with relatively low patient numbers and no control groups (Table 2).

Time between BCS and commencement of adjuvant chemotherapy is only one aspect of oncological safety after early breast cancer management. In fact, patients who undergo complex surgery may be more susceptible to immunosuppression caused by chemotherapy. This may increase surgery related complication rates, which can lead to an internal delay between chemotherapy cycles, requiring frequent administration of granulocyte colony-stimulating factor or repeat hospital admissions^[28].

In a recently published meta-analysis, the average complication rate in the TRM group was 16% and 14% in the flap reconstruction group^[49]. However, it does not seem that complications in the oncoplastic groups, although potentially higher, have any negative impact on patient care from an oncological point of view. In fact, adequate technique and patient selection is crucial in order to minimize morbidity when this oncoplastic tech-

N/D: Not disclosed; N/A: Not applicable; (+): Positive; (-): Negative.

nique is selected. Despite the poor scientific evidence, nothing suggests that TRM is unsafe in terms of starting adjuvant therapy on time. In fact, Kahn *et al*^[28] provide evidence that immediate BCS reconstruction does not lead to a delay in the commencement of adjuvant chemotherapy when compared to three adequate control groups from the same institution and time periods.

Concerning adjuvant radiotherapy, one might surmise that techniques that involve rearrangement of breast tissue may jeopardize the boost radiation dose delivery since the target area is defined as the site of the original tumor^[15,57-59]. For this reason, coordinated planning with the radiotherapy center is important since TRM modifies the normal architecture of the breast^[15,16]. To locate the original tumor area, we advocate orienting the original tumor area by skin markings and also placing surgical clips at the tumor margins. It has been our impression, similarly observed by other authors^[57,58], that identification of the original tumor bed based only on physical exam, without precise imaging information, can result in missing the primary tumor bed. In our previous studies^[15-17], clips have not interfered with mammography and have actually helped recognize areas at risk for recurrence. Additionally, clips have not been mentioned as interfering with physical examination or aesthetic outcome^[57]. On the other hand, Poortmans *et al*^[60] mentioned that the location of clips can be misleading in cases where volume displacement techniques are utilized, especially where the boost area is not the entire surgical cavity. According to other authors, this usually results in larger boost volumes than actually necessary, potentially leading to local fibrosis and poorer aesthetic outcome^[60,61].

Another important issue is related to delayed reconstruction following BCS and radiotherapy. Frequently, the appearance of the radiated breast is less pleasing than the nonradiated one and the total dose, boost therapy and number of radiation fields may be involved^[19,21,23,24].

Spear *et al*^[18] mentioned that, besides the differences observed in the normal healing process, the radiated breast has a longer induration and swelling than the opposite breast^[18]. In our previous experiences utilizing TRM, the majority of patients presented with good or very good results in terms of breast shape and symmetry^[15-17]. In spite of this, almost 10% of patients presented with complications of breast skin necrosis and wound dehiscence, 92.3% of patients were either very satisfied or satisfied with their result and none regretted the surgery. Losken *et al*^[23] advocated that when radiation is expected, the possibility of fibrosis and glandular atrophy should be taken into account in an attempt to preserve breast symmetry. The authors suggested less aggressive reductions on the ipsilateral breast to accommodate for any additional size distortion. Additionally, some authors advocated that oncoplastic reconstruction with radiation is best achieved using autologous, nonirradiated flaps^[6,9,11,24].

Postoperative surveillance

According to Losken *et al*^[49,62] postoperative surveillance is not significantly affected by the rearrangement of breast tissue. These results corroborate with the findings of Roberts *et al*^[63] concerning the incidence of abnormal mammograms after reduction mammoplasty. In fact, these authors observed that, despite the substantial mobilization of tissue, postoperative mammography did not lead to more diagnostic interventions than nonoperative controls^[63,64].

Concerning late complications, the most common event is related to fat necrosis and this aspect is well defined in conventional mammograms. In our previous experience comparing immediate and delayed BCS reconstruction with reduction mammoplasty techniques, this complication was significantly higher in the delayed group^[24]. It has been our impression that radiation therapy played a significant role and contributed to de-

velopment of fat necrosis. One might surmise that in delayed reconstructions, a slower reestablishment of a local blood supply to rearranged breast tissues from the underlying irradiated chest wall can be observed. In addition, previous breast tissue scarring and local effects of radiotherapy can also disrupt the local blood supply and the ability to create a safe parenchymal pedicle^[9,24]. Thus, in these patients, careful surveillance is prudent since the risk of local recurrence is always possible. According to Losken *et al*^[25,49,62], postoperative surveillance is not impaired by simultaneous TRM. In some cases, calcifications and fat necrosis can simulate tumor recurrence; however, these aspects can be distinguished on mammogram or core biopsy^[15-17,25].

Final surgical margins assessment and immediate reconstruction

When margins are found to be positive following BCS reconstruction, there is no consensus as to whether or not additional re-excision is possible as there may be difficulty in identifying the area of the original quadrantectomy. Some breast surgeons therefore indicate skin-sparing mastectomy if margins are compromised following definitive pathology evaluation.

In fact, TRM involves rearrangement of glandular tissue and could make re-excision difficult in cases where close or positive margins are observed^[64,65]. This fact could make it difficult to locate the residual tumor and to perform margin re-excision. In our previous studies^[14-17,65], intraoperative margin evaluation was assessed by pathological monitoring, which is based on macroscopic, radiological and histological examination of frozen sections. In our experience, positive margins discovered on permanent pathology in a previously negative margin patient were observed in 5.5%^[65]. Overall, the oncological outcome of our data corroborate the study of Fitoussi *et al*^[47], which is the largest study describing the oncological outcomes of 540 patients over a period of two decades. This study described clear margins in 438 patients (81%), focal involvement in 77 patients (14%)

and tumor-involved margins in 25 patients (5%). According to the authors, eleven patients underwent re-excision (2%), 40 patients received an additional radiotherapy boost (7%) and 51 patients required a mastectomy (9% overall) (Table 3).

Previous studies have investigated risk factors to identify patients with a high probability of having positive margins^[25,64-75]. Age (younger)^[25,65,67,68], tumor type (in situ carcinoma)^[25,64-75] and larger tumor size^[65,69] have all been associated with positive margins. Our results were comparable to those of the previous studies, with young patients and larger tumor size as more likely to have positive margins^[64]. Concerning the reoperative rates, Weinberg *et al*^[69] observed that 6.2% had later re-excisions and Cendán *et al*^[70] reported that 19.6% of subjects required additional operations to clear surgical margins. Despite these aspects, the positive margins can be effectively managed with either re-excision with/without reconstruction or with skin-sparing mastectomy and total reconstruction, depending on the extension of tissue resection, preference and pathology. The decision to re-operate depends on the extent of tumor involvement, whether the dissection had already been extended to the chest wall or skin, or whether the patient had opted to proceed with a total reconstruction. It has been our impression that reoperation was not a negative aspect and the disadvantage of a more extensive surgery is negligible. In cases of re-exploration, it is rational to carry it out in association with the plastic surgery team to identify the original tumor bed and to avoid injury to the NAC pedicle^[15-17,64].

Thus, intraoperative assessment of surgical margins requires multidisciplinary cooperation among oncological and plastic surgeons and pathologists. According to Losken *et al*^[25], all patients should be informed preoperatively of the potential need for a delayed-immediate approach. Additionally, these high-risk patients can be better managed by staged procedures and confirmation of negative margins prior to CBS reconstruction.

Opposite breast surgery

Another important issue is related to the OB surgery. Previous studies have differed with regard to the timing of opposite breast symmetrization. In fact, Gray *et al*^[21] described an association between breast irradiation in large volume breasts or obese patients and greater retraction at 5 years and an inferior overall cosmetic result. Another concept advocated was to perform symmetrization 6 mo after BCS following neoadjuvant treatment, as they suspected an unpredictable effect of radiotherapy on the breast and an alteration of body weight during chemotherapy.

In our previous experiences, almost all patients submitted to TRM had bilateral procedures^[15-17]. In fact, Kronowitz *et al*^[50] observed a significant relationship between the reconstructive technique and the need for an OB reduction. This aspect can be viewed as a negative point; however, it also has the advantages of allowing for sampling of glandular tissue^[15-17,19,24,27,50]. In our previ-

ous study^[24], we reported our experience with surgical management and outcome in BCS reconstruction with TRM techniques with regards as to whether immediate or delayed reconstruction is better in terms of complication rates. In this series, in 2.8% of patients, an unexpected cancer in the OB was observed in immediate TRM reconstruction. Although the diagnosis of occult cancer is not a reason to perform an OB reduction, this procedure can be advantageous for high-risk patients and especially for patients with previous breast cancer^[24].

Delayed BCS reconstruction and outcome

Another important issue is related to the complication rates and the timing of reconstruction. In our previous series, delayed reconstruction complication rates have been shown to be higher than immediate reconstruction (31% *vs* 22% respectively)^[24]. However, this aspect was not significant ($P = 0.275$). Thus, our results indicate that timing of reconstruction is not a significant predictor of complications following BCS reconstruction with TRM. This finding is contradictory to published reports that suggest that delayed BCS reconstruction has a significantly higher complication rate compared with immediate procedures. In fact, Kronowitz *et al*^[9] observed that delayed reconstruction was associated with a complication rate almost twice that of immediate. In our study, the relatively small number of patients and especially the small number of obese patients in the delayed group (21.7% *vs* 10.5%) may have influenced this comparison. Thus, a large number of patients and a prospective and controlled sample are necessary for definitive conclusions.

CONCLUSION

BCS defects represent an anatomic variety that ranges from small defects that may repair with primary closure to large defects that involve skin, NAC and a significant amount of glandular tissue. Each defect has its own special reconstructive necessities and varying expectations for aesthetic outcome. Recently, increasing attention has been focused on the oncoplastic approach and although surgical techniques have advanced, BCS reconstruction remains a challenging impasse. It has been our impression that a number of procedures have been described involving primary closure, breast reshaping, local and distant flaps. In addition, some different classifications have been proposed to describe the extent of resection, which has consequently created a wide-range of surgical options with different indications.

TRM in combination with BCS is not a new concept but is becoming increasingly accepted by oncological breast surgeons. In selected patients, this approach has allowed us to perform wide resections and obtain good oncological control with favorable aesthetic outcome. The majority of the complications were immediate, minor and comparable to other aesthetic reduction techniques. The main indication is in patients with enough breast tissue to perform the reconstruction. Although the combined

approach requires more preoperative planning and intra-operative care, the concept can reduce deformities, favor the oncological treatment and optimize the aesthetic outcome in most early stage cancer patients.

Key words: Temozolomide; Solid tumours; Brain metastases; Clinical trials; Clinical outcomes

Core tip: Temozolomide has been used in glioblastoma multiforme as well as melanoma. Recently, studies showed that it might be also effective in patients with brain metastases from various malignancies. In this study, we carried out a review of 21 published clinical trials to determine whether temozolomide would benefit patients with brain metastases from solid tumours. As a result, a modest therapeutic effect was observed when temozolomide was used as a single agent, however, the combination of temozolomide with whole-brain radiotherapy and/or other anticancer drugs exhibited encouraging activity. This study for the first time provided a systematic evaluation of temozolomide in the treatment of brain metastases.

Abstract

Brain metastases from solid tumours are associated with poor prognosis despite aggressive treatment. Temozolomide can be used for the treatment of glioblastoma multiforme as well as melanoma. It has also been shown to have activity in patients with brain metastases from various malignancies, since it can cross the blood-brain barrier. To better understand the efficacy of temozolomide in the treatment of brain metastases, we carried out a review of 21 published clinical trials to determine whether temozolomide would benefit patients with brain metastases from solid tumours. Information regarding complete response, partial response, stable disease, objective response and objective response rate were collected to assess clinical outcomes. A modest therapeutic effect was observed when temozolomide was used as a single agent, however, the combination of temozolomide with whole-brain radiotherapy and/or other anticancer drugs exhibited encouraging activity. Thus, future high quality studies are warranted to confirm our findings.

Zhu W, Zhou L, Qian JQ, Qiu TZ, Shu YQ, Liu P. Temozolomide for treatment of brain metastases: A review of 21 clinical trials. *World J Clin Oncol* 2013; 5(1): 19-27 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i1/19.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i1.19>

INTRODUCTION

Brain metastases are a common complication in patients with cancer, occurring in approximately 25% of patients with disseminated diseases. The most common primary tumours, which metastasize to the brain, are lung cancer (25%-30%)^[1,2], breast cancer (10%-15%)^[3,4] and melanoma (12%-20%)^[5]. Over two thirds of patients with brain metastases suffer debilitating neurologic symptoms, including headaches, focal weakness, cognitive dysfunction, and seizures. Prognosis in these patients is particularly

grim, and without treatment, median survival period is 1-2 mo, depending on the extent of cranial disease and the degree to which it can be controlled.

No standard systemic therapy exists for patients with brain metastases. Researchers continue looking for optimal treatments. Whole-brain radiotherapy was the standard of care in patients with multiple or inoperable brain metastases. Nevertheless, radiosurgery was becoming an increasingly attractive option for patients with up to four lesions^[6,7], especially young patients with good performance status and satisfactory control of extra-cranial disease. Chemotherapy options were limited and generally used as salvage therapy in patients who failed to respond to whole-brain radiotherapy or radiosurgery^[8,9]. However, the assumption that the blood-brain barrier prevented the passage of chemotherapy agents into the brain discouraged the use of systemic chemotherapy in treating brain metastases, even though the blood-brain barrier might already be disrupted by the presence of brain metastases and/or the treatment with whole-brain radiotherapy^[10,11].

Temozolomide is an orally administered alkylating agent. It belongs to the imidazotetrazines and reaches the central nervous system in therapeutic concentrations. It can be rapidly absorbed following oral administration and undergoes spontaneous conversion at physiological pH to the active metabolite (3-methyltriazen-1-yl) imidazole-4-carboxamide in the tissues^[12]. Clinical activity of temozolomide is closely linked to the activity of O6-alkylguanine-DNA alkyltransferase, a DNA repair protein which removes O6-alkylguanine adducts in DNA^[13]. More importantly, temozolomide's ability to cross the blood-brain barrier has been demonstrated^[14]. Temozolomide also has a good toxicity profile. The dose-limiting toxicity is non-cumulative myelosuppression that rarely requires treatment delay or dose reduction and may improve patients' life quality. Currently, temozolomide is a standard therapy in patients with refractory anaplastic astrocytomas. However, the optimal treatment of brain metastases is still under investigation. Theoretically, an efficacious and well-tolerated chemotherapeutic, such as temozolomide, might also show great potential to treat brain metastases. Therefore, we carried out a review of published clinical trials to better understand the efficacy of temozolomide in the treatment of brain metastases from solid tumours.

IDENTIFICATION OF ELIGIBLE STUDIES

We searched the PubMed database (until 5 April 2012) for the relevant articles by using the term "Temozolomide" with no limitations. In addition, another search strategy was employed by using the key term "Temozolomide", limited to "Humans", "Clinical Trial" and "Cancer". All relevant publications were reviewed and repetitive articles were eliminated. The articles in reference lists were also hand-searched for potentially relevant publications.

INCLUSION CRITERIA

All human-associated studies, regardless of tumour type, were included once they met the following criteria: (1)

solid tumour with brain metastases (except primary brain tumour); (2) monotherapy or combination therapy with temozolomide; (3) histological confirmation; (4) relatively stable administration dosage of temozolomide; and (5) sufficient data of clinical outcomes.

DATA EXTRACTION

For each study, the following information was collected: first author, year of publication, country of the first author, the number of total and evaluable patients, median age, gender, cancer type, prior treatment, name of drugs, dose regimen, median cycle of treatment, clinical outcomes including the number of patients who achieved complete response, partial response, stable disease, objective response and progressive disease. For studies including different types of tumour, data were separately extracted by tumour type if information was enough.

LITERATURE SEARCH

A total of 2448 articles were identified from the PubMed database, of which 1987 were excluded due to repeated and unrelated contents. Among the rest, phase I studies were excluded as the administration dosage of temozolomide was not relatively stable. In addition, only trials on solid tumours with brain metastases were included in this review. Therefore, 21 papers were chosen from the remaining 461 articles for this study. Among these 21 articles, seven used temozolomide as a single agent while the others combined temozolomide with other anti-tumour drugs and/or radiotherapy.

Because of the heterogeneity of patients, regimens, clinical settings and a variety of outcome measurement in these trials, conducting a meta-analysis was inappropriate. Results were therefore analyzed qualitatively.

STUDY CHARACTERISTICS

Study characteristics information was summarized in Tables 1 and 2. Among all first authors, seven were from United States, five from Greece, four from Italy, two from Germany and one from each of United Kingdom, France, and Poland. The number of patients in these trials ranged from 11 to 157, with median age from 48 to 66. There were 12 cancer types described in these 21 trials, including non-small cell lung cancer, breast cancer, melanoma, small cell lung cancer, colorectal cancer, ovarian cancer, endometrial cancer, oral cavity cancer, renal cancer, bladder cancer, gastric cancer and carcinoma of the head and neck. Besides, there were five studies including unknown primary tumours. Most patients had received prior therapies and had metastatic or recurrent diseases at baseline.

TREATMENT ADMINISTRATION

In Tables 3 and 4, treatment administration information for each therapy type was recorded. In trials of mono-

therapy, temozolomide was administered at a dose of 150-200 mg/m² per day on days 1-5 of a 28-d cycle^[15-19] or 125-150 mg/m² per day on days 1-7, 15-21 of a 28- or 35-d cycle^[20,21]. The median cycle of each treatment is summarized in Tables 1 and 3.

In trials that combined temozolomide with radiotherapy, patients were treated as follows: (1) 30 Gy of whole-brain radiotherapy with concomitant temozolomide (75 mg/m² per day) for 10 d, and subsequent temozolomide at a dose of 75 mg/m² per day for 21 d every 4 wk^[22]; (2) A total dose of 30 Gy with ten daily fractions of 3.0 Gy was given 5 d per week over 2 wk, and temozolomide was administered at a dose of 95 mg/m² per day for the entire radiation treatment duration including days without radiation treatment^[23]; (3) temozolomide was given at 60 mg/m² per day (days 1-16) concomitantly with whole-brain radiotherapy (36 Gy/12 fractions given in 16 d), and subsequent temozolomide at a dose of 200 mg/m² per day for 5 consecutive days every 28 d^[24]; (4) temozolomide was given at 200 mg/m² per day on days 1-5 every 28 d. This therapy regimen was combined with stereotactic radiotherapy (20 Gy) or whole-brain radiotherapy (30 Gy)^[25]; and (5) temozolomide was administered at a dose of 75 mg/m² per day concurrent with 40 Gy fractionated conventional external-beam radiotherapy (2 Gy, 5 d/wk) for 4 wk, and subsequent temozolomide

at a dose of 200 mg/m² per day for 5 consecutive days every 28 d^[26].

Among those studies that combined temozolomide with other drugs and radiotherapy or with other drugs alone, three added cisplatin^[17,27,28], two combined thalidomide^[29,30], and the rest used vinorelbine^[31], lomustine^[32], doxorubicin^[33], arsenic trioxide^[34] or docetaxel^[27] as a part of chemotherapy protocol or radiation. The median cycle of each treatment is summarized in Tables 2 and 4.

CLINICAL OUTCOMES

Response criteria were used as defined by World Health Organization criteria, response evaluation criteria in solid tumors criteria, Macdonald criteria, Eastern Cooperative Oncology Group criteria or Standard response criteria. Objective response was based on the total number of patients who achieved complete response or partial response. Objective response rate was defined as the proportion of patients who got complete response or partial response. There were seven studies mentioning extracerebral or global responses as an endpoint^[17,21,25,27,28,30,32]. The extracerebral and global objective response rates ranged from 0.027 to 0.291, and 0.088 to 0.428, respectively. Seventeen trials evaluated cerebral response. Interestingly, efficacy of monotherapy and combination therapy was

response, and 3 stable disease. However, in another study of advanced non-small cell lung cancer with brain metastases^[18], no objective response was achieved.

In trials that used combination therapy, objective response was observed in all studies with objective response rates greater than 0.1 except two studies. One trial evaluated vinorelbine and intensive temozolomide in patients with recurrent or progressive brain metastases with an objective response rate of 0.055^[31]. Another one was temozolomide, thalidomide, and whole brain radiation therapy for patients with brain metastasis from metastatic melanoma with an objective response rate of 0.077^[29]. The highest objective response rate in trials that combined temozolomide with radiotherapy was 0.959, achieved in the study of temozolomide and concurrent radiotherapy in patients with brain metastases from advanced lung cancer and breast cancer^[26]. Whereas, in the trial of concurrent temozolomide and whole brain radiation therapy for multiple brain metastases which was conducted by Mikkelsen *et al.*^[23], objective response rate was 0.176 with 3 patients achieving partial response. In two studies that combined temozolomide with other drugs and radiotherapy, objective response rates were 0.077^[29] and 0.128^[28]. Among those studies that used combination chemotherapy, the highest objective response rate was observed in the trial of temozolomide plus pegylated liposomal doxorubicin in the treatment of brain metastases from solid tumours^[35,36]. Stable disease was achieved in all studies. Other evaluation data,

such as median overall survival, progression-free survival and time to progression, were also collected, if available and summarized in Tables 1-4.

DISCUSSION

Brain metastases from solid tumours are associated with poor prognosis despite aggressive treatment. Also, the majority of patients have suffered debilitating neurological symptoms. Standard systemic therapy for patients with brain metastases is still under investigation. However, many clinical investigations had been discouraged by the concern that although chemotherapy drugs would have efficacy against the primary tumour (*e.g.*, lung cancer), they would not cross the blood-brain barrier. Therefore, chemotherapy would not be active against the metastatic brain disease. Even though data suggested that the blood-brain barrier was disrupted when brain metastases were present and chemotherapy could be effective against brain metastases from chemosensitive solid tumours^[37], unfortunately, the severe adverse events would be very difficult for pre-treated patients who had already received radiation and multiple regimens of myelosuppressive chemotherapy to tolerate. Temozolomide, a derivative of imidazotetrazine, is the prodrug of 3-methyl-(triazene-1-yl) imidazole-4-carboxamide. The therapeutic benefit of temozolomide depends on its ability to alkylate/methylate DNA, which most often occurs at the N-7 or O-6 positions of guanine residues. This methylation

agents as treatment for brain metastases. Studies combining temozolomide with whole-brain radiotherapy reported more favourable response rates ranging from 0.176 to 0.959 with median overall survival ranging from 4.1 to 12 mo. In these trials, temozolomide might be shown to possess a radiosensitizing effect^[37,38]. In a large review of 1292 patients to define the prognostic factors in patients with brain metastases, Lagerwaard *et al.*^[39] concluded that the three strongest prognostic factors were performance status, response to steroids, and evidence of systemic disease^[40]. In the trial conducted by Addeo *et al.*^[22], a promising objective response rate of 0.48 (13 of 27 patients) was observed. A possible explanation would be that in this study, 11 of 27 patients were included in first RPA class according to RTOG classification. An objective response rate of 0.82 and two (8%) cases of stable disease were obtained in this group. In contrast, among the 6 patients (22%) included in the third RPA class, no objective response was observed. Besides, the proportion of metastases of lung origin was significantly higher in several studies which got favourable outcomes. Selection bias could have occurred in these trials.

Studies that combined temozolomide with other drugs had also been reported to yield high response rates in patients with brain metastases. The difference between monotherapy and combination therapy could be attributed to the efficacy of other agents. For example, pegylated liposomal doxorubicin had the ability to accumulate in both brain tissue and tumour tissue within the brain^[41,42]. Cisplatin, an active cytotoxic drug in solid tumours, might enhance the anti-tumour activity of temozolomide by reducing the activity of the DNA repair enzyme. However, most of patients involved in the studies were heavily pre-treated and failed prior therapy. Perhaps, the chemotherapeutic sensitization of temozolomide could be attributed to the improvement of the therapeutic effect in combination therapy. In addition, the dosage of other chemotherapeutic agents might be reduced to alleviate toxic reaction and improve patients' quality of life. The trial of temozolomide plus pegylated liposomal doxorubicin indicated that this chemotherapy regimen was well tolerated in elderly patients. This implied that temozolomide/pegylated liposomal doxorubicin could

be an effective therapeutic strategy for patients who were not suitable for conventional treatments because of the presence of brain metastases or old age.

In conclusion, since the studies in which temozolomide was used as a single agent usually achieved minimal outcomes, monotherapy might not be an optimal therapeutic strategy. However, the combination of temozolomide with whole-brain radiotherapy or other agents showed the potential to improve clinical outcomes of patients with brain metastases. It is worth re-examining the effects of temozolomide combined with other drugs or whole-brain radiotherapy on survival of patients with brain metastases from solid tumours in a randomized phase III study.

Clitoris metastasis from a retroperitoneal leiomyosarcoma: A case report. *World J Clin Oncol* 2014; 5(1): 28-32 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i1/28.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i1.28>

Abstract

Leiomyosarcoma is a rare form of cancer commonly found in the retroperitoneum, uterus, stomach, small intestine and vascular tissue. Surgery with a wide margin of resection is the most effective treatment. Nevertheless, metastasis is common and generally occurs within the first 3 years. The liver and lungs are the most common sites of metastasis in leiomyosarcoma. Other sites of metastasis include bone, spleen, soft tissues and brain. Metastatic tumours of the clitoris are extremely rare. As cited in the literature, the most common cancers that metastasize to the clitoris are breast, bladder, renal and gastric. Here, we report a case of a clitoral mass in a 64-year-old woman who received an operation for retroperitoneal leiomyosarcoma 4 years prior. Mass resection was performed. The pathological diagnosis was a leiomyosarcoma metastasis. The patient also presented with brain and lung metastases at the time of the clitoral metastasis. This

INTRODUCTION

Leiomyosarcoma is the third most frequently diagnosed soft-tissue sarcoma in adults, after malignant fibrous histiocytoma and liposarcoma^[1]. Leiomyosarcomas can arise at any site in the human body where smooth muscles are present; however, the tumours primarily arise in the retroperitoneum, subcutaneous tissue of the extremities, uterus, gastrointestinal tract and large vessels^[1,2]. Leiomyosarcomas have a propensity for haematogenous spread and rarely metastasize to the lymph nodes. The liver and lungs are the most common sites of metastasis for leiomyosarcomas^[2] and most patients develop distant metastases within long years following primary tumour resection^[2-4]. Here, we report a case of a metastasis to the clitoris an unexpected metastasis site, in a 64-year-old woman who received an operation for retroperitoneal

Figure 1 Macroscopic appearance of clitoral leiomyosarcoma.

leiomyosarcoma 4 years prior.

CASE REPORT

A 64-year-old woman was referred with a 1-mo history of a painful mass in the clitoris. A 2 cm polypoid mass with regular margins in the clitoris was revealed upon vaginal examination (Figure 1). The computed tomography of the chest indicated multiple bilateral pulmonary metastases (Figure 2), and abdominal magnetic resonance imaging showed a mass lesion on the left psoas muscle (Figure 3A). In addition, brain magnetic resonance imaging showed a metastatic mass lesion located in the left temporo-parietal region (Figure 3B). The patient's medical history revealed that she had undergone a total hysterectomy and bilateral salpingo-oophorectomy at the age of 60 years. During the surgery, a retroperitoneal mass lesion on the psoas muscle under the left kidney had been incidentally determined. The mass lesion was completely removed. A histological examination revealed chronic cervicitis, endocervical polyps, endometrial polyps, corpus albicans in the right and left ovary, paratubal cysts, bilateral chronic salpingitis in total abdominal hysterectomy and bilateral salpingo-oophorectomy specimens, and retroperitoneal leiomyosarcoma in the mass lesion on the psoas muscle under the left kidney. Surgical margins were clearly detected. Distant metastasis was not determined. The patient had refused to undergo chemotherapy and radiotherapy.

Based on this information, a diagnosis of metastatic retroperitoneal leiomyosarcoma was proposed, and the mass in the clitoris was removed with a wide local excision. The diameter of the clitoral metastatic mass was 2 cm × 1.8 cm, and 6-8 mitoses were microscopically detected per 10 high-power fields. The tumour was well differentiated and immunoreactive for α -smooth muscle actin and desmin (Figure 4A). The histological diagnosis was low-grade leiomyosarcoma of the clitoris. A retroperitoneal leiomyosarcoma specimen was re-examined to distinguish whether the clitoral mass was a metastasis or the primary tumour. The retroperitoneal tumour was composed of spindle-shaped cells with abundant eosinophilic cytoplasm and elongated nuclei (Figure 4B).

Figure 2 Bilateral pulmonary metastases in the chest computed tomography image.

Most nuclei were centrally located, blunt-ended and “cigar-shaped”. In some areas of the tumour, the nuclear hyperchromatism and pleomorphism were notable. The tumour was composed of compact cellular areas with focal myxoid change. Coagulative necrosis was evident. Mitotic figures were frequent (7-8/10 high-power fields), and atypical mitoses were common. The atypical spindle cells appeared yellow after histochemical staining using the Van Gieson elastic stain. Upon immunohistochemical analysis, the tumour cells were diffusely and strongly positive for smooth muscle actin (Figure 4C), caldesmon and vimentin. In contrast, the tumour cells were negative for desmin (Figure 4D), S-100 protein, epithelial membrane antigen, CD117 and CD 34 (Figure 4E). Approximately 15% of the tumour cells were Ki-67 positive. The surgical margins were clear. Thus, the histopathological and immunohistochemical findings were consistent with leiomyosarcoma of the retroperitoneum. The morpho-

logical and immunohistochemical results of the clitoral mass were similar to that of the retroperitoneal mass except for desmin positivity. Based on these findings, chemotherapy and radiotherapy were advised, but the patient refused.

DISCUSSION

Leiomyosarcomas can originate throughout the body, but the most common site is the retroperitoneum (20%-67% of cases)^[1,2]. Retroperitoneal leiomyosarcomas are more frequent in females and typically affect middle-aged to older adults^[3]. Diagnosis is delayed because most retroperitoneal leiomyosarcomas are asymptomatic. The primary tumour masses are typically large, and distant metastases are present at the time of diagnosis in approximately 40% of cases^[4]. In our patient, retroperitoneal sarcoma was detected incidentally during a gynaecological operation. Although the mass was 8 cm, the patient had no complaints, and distant metastasis was not evident at the time of the diagnosis.

Surgery was the main treatment. Given that the survival of patients with retroperitoneal sarcomas depends on complete resection of the tumour, extensive surgery is recommended^[5,6]. Nevertheless, the prognosis of retroperitoneal sarcoma is poor due to a high incidence of local recurrence and distant metastases^[6]. However, the following characteristics are associated with a favourable prognosis: tumours less than 5 cm in diameter, low histological grade tumours, and bladder tumours^[7]. Tumours that occur in the retroperitoneum have the worst prognosis. Mitotic activity is the primary prognostic factor; specifically, tumours with 5 mitoses per 10 high-power fields are considered malignant^[8]. Accordingly, the retroperitoneal leiomyosarcoma in our patient has poor prognostic factors (8 cm size, low grade, retroperitoneal site). Although the mass in the retroperitoneal region was fully removed and the surgical margins were histologically negative, local recurrence and lung, brain and clitoris metastases were detected approximately 4 years after the patient's first surgery. The recurrent mass detected in our patient can be explained by microme-

tastasis or tumour seeding. Furthermore, it has been reported that local invasion may be an important factor for tumour recurrence and distant metastasis^[7].

The distant spread of these tumours occurs via the bloodstream principally to the lung, liver, and peritoneal cavity. Metastasis may also be found in the bone, spleen, and soft tissues^[2-7]. A clitoris metastasis from retroperitoneal leiomyosarcoma have not been reported previously. The brain is an uncommon metastasis site in prior case reports; metastases from previously reported leiomyosarcomas were generally located in the uterus^[9,10]. The diameter of the clitoral metastasis was 2 cm × 1.8 cm and 6-8 mitoses per 10 high-power fields were observed. The tumour was well differentiated and immunoreactive for α -smooth muscle actin and desmin. Histopathological examination of the resected lesion revealed features consistent with leiomyosarcoma; therefore, based on the patient's past medical history and these histological similarities, the patient was diagnosed as having a clitoris metastasis to the from the retroperitoneal leiomyosarcoma. We discussed a potential mechanism of metastasis to the clitoris and brain in the patient. Soft-tissue sarcomas rarely show lymphatic spread; therefore, we hypothesize that clitoris and brain metastases occurred by the haematogenous route.

Other case reports of tumours that metastasize to the clitoris include breast, bladder, renal and gastric cancers^[11-14]. Metastatic leiomyosarcomas are treated with surgery and/or adjuvant chemotherapy, but no standard treatment has been established given the small number of patients^[6,15]. Increased survival has been reported in patients undergoing a metastasectomy^[15]. Because our case refused the chemotherapy or radiotherapy, we only performed the clitoral mass excision. Despite surgery, the patient died six months after metastasis identification.

Herein, we report the case of a 64-year-old woman who was diagnosed with a clitoral metastasis form a retroperitoneal leiomyosarcoma. In addition lung and brain metastases were detected in the work-up examination. In a known case of leiomyosarcoma, a newly developed clitoral mass should be considered as a metastasis and

Figure 4 Diagnosis of metastatic retroperitoneal leiomyosarcoma. A: Strong positive SMA immunohistochemical staining in clitoral tumor ($\times 100$); B: Immunohistochemically, spindle-shape tumour cells revealed staining for desmin in the clitoral tumor ($\times 100$); C: Spindle shaped tumour cells with eosinophilic cytoplasm and nuclear polymorphism in retroperitoneal leiomyosarcoma ($\times 100$ magnification, Haematoxylin-Eosin staining); D: The retroperitoneal tumour cells were negative for desmin in retroperitoneal leiomyosarcoma ($\times 100$); E: Immunohistochemistry reveals CD34 negative tumour cells and CD34 positive vascular endothelial cells (arrows) in retroperitoneal leiomyosarcoma ($\times 200$).

histologically confirmed. Leiomyosarcomas usually recur within several years from the initial diagnosis. Therefore, patients should be observed and clinicians should be aware of areas of atypical metastasis.

COMMENTS

Case characteristics

A 64-year-old woman has a painful mass in the clitoris.

Clinical diagnosis

A 2 cm polypoid mass with regular margins in the clitoris was revealed upon vaginal examination.

Differential diagnosis

The differential diagnosis of the clitoral mass should be performed from infective organisms, cysts, invasion from cancers in the vicinity and metastasis from distant organs and should be confirmed with biopsy.

Laboratory diagnosis

The diagnosis of clitoral tumors includes radiological diagnosis, surgical procedures (biopsies) and histo-pathological examination.

Imaging diagnosis

The computed tomography of the chest indicated multiple bilateral pulmonary metastases, abdominal magnetic resonance imaging showed a mass lesion on the left psoas muscle, and brain magnetic resonance imaging showed a metastatic mass lesion located in the left temporo-parietal region.

Pathological diagnosis

The retroperitoneal and clitoral tumour were composed of spindle-shaped cells with abundant eosinophilic cytoplasm and elongated nuclei and most nuclei were centrally located, blunt-ended and "cigar-shaped" and immunohistochemically, tumor cells were diffusely and strongly positive for smooth muscle actin, caldesmon and vimentin, S-100 protein, epithelial membran antigen, CD117 and CD 34.

Treatment

Because our case refused the chemotherapy and radiotherapy, the authors only performed clitoral tumour excision.

Experiences and lessons

Leiomyosarcoma usually recurs within several years from the initial diagnosis. Therefore, patients should be subject to such an observation period at least and clinicians should be aware of areas of atypical metastasis.

Peer review

The authors observed a clitoris metastasis originated from retroperitoneal leiomyosarcoma. This is a very interesting case and should be published so that the observation can be shared with colleagues in the field. There are some spelling mistakes in the article.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Clinical Oncology (*World J Clin Oncol*, *WJCO*, online ISSN 2218-4333, DOI: 10.5306) is a peer-reviewed open access (OA) academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

Aim and scope

WJCO covers a variety of clinical medical topics, including etiology, epidemiology, evidence-based medicine, informatics, diagnostic imaging, endoscopy, tumor recurrence and metastasis, tumor stem cells, radiotherapy, chemotherapy, interventional radiology, palliative therapy, clinical chemotherapy, biological therapy, minimally invasive therapy, physiotherapy, psycho-oncology, comprehensive therapy, and oncology-related nursing. The current columns of *WJCO* include editorial, frontier, diagnostic advances, therapeutics advances, field of vision, mini-reviews, review, topic highlight, medical ethics, original articles, case report, clinical case conference (Clinicopathological conference), and autobiography. Priority publication will be given to articles concerning diagnosis and treatment of oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJCO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

WJCO is edited and published by Baishideng Publishing Group (BPG). BPG has a strong professional editorial team composed of science editors, language editors and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15 471 editorial board members or peer reviewers, and is a world first-class publisher.

Columns

The columns in the issues of *WJCO* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future research directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write

commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers; (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, etc.; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in clinical oncology; (12) Brief Articles: To briefly report the novel and innovative findings in clinical oncology; (13) Meta-Analysis: Covers the systematic review, mixed treatment comparison, meta-regression, and overview of reviews, in order to summarize a given quantitative effect, e.g., the clinical effectiveness and safety of clinical treatments by combining data from two or more randomized controlled trials, thereby providing more precise and externally valid estimates than those which would stem from each individual dataset if analyzed separately from the others; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJCO*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of clinical oncology; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

Indexed and Abstracted in

PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit

analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJCO* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and report-

ing of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/2218-4333/g_info_20100722172206.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjco@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-85381892 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/..."), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g., 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Core tip

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ... etc. It is our principle to publish high resolution-figures for the E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement,

Instructions to authors

but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g., PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/2218-4333/g_info_20100723153305.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

Examples for paper writing

All types of articles' writing style and requirement will be found in the link: <http://www.wjgnet.com/esps/NavigationInfo.aspx?id=15>

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the

revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/2218-4333/g_info_20100723153117.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/2218-4333/g_info_20100723152755.htm.

Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

STATEMENT ABOUT ANONYMOUS PUBLICATION OF THE PEER REVIEWERS' COMMENTS

In order to increase the quality of peer review, push authors to carefully revise their manuscripts based on the peer reviewers' comments, and promote academic interactions among peer reviewers, authors and readers, we decide to anonymously publish the reviewers' comments and author's responses at the same time the manuscript is published online.

PUBLICATION FEE

WJCO is an international, peer-reviewed, OA online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium and format, provided the original work is properly cited. The use is non-commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 600 USD per article. All invited articles are published free of charge.

APPENDIX I-V Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Clinical Oncology*, J Voortman, MD, PhD, Department Internal Medicine, VU University Medical Center, Postbus 7057, 1007 MB Amsterdam, The Netherlands

AIM AND SCOPE *World Journal of Clinical Oncology* (*World J Clin Oncol*, *WJCO*, online ISSN 2218-4333, DOI: 10.5306) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJCO covers a variety of clinical medical topics, including etiology, epidemiology, evidence-based medicine, informatics, diagnostic imaging, endoscopy, tumor recurrence and metastasis, tumor stem cells, radiotherapy, chemotherapy, interventional radiology, palliative therapy, clinical chemotherapy, biological therapy, minimally invasive therapy, physiotherapy, psycho-oncology, comprehensive therapy, and oncology-related nursing. Priority publication will be given to articles concerning diagnosis and treatment of oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJCO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING *World Journal of Clinical Oncology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Skin sparing mastectomy (SSM) can facilitate immediate breast reconstruction and is associated with an excellent aesthetic result. The procedure is safe in selected cases; including invasive tumours < 5 cm, multi-centric tumours, ductal carcinoma in situ and for risk-reduction surgery. Inflammatory breast cancers and tumours with extensive involvement of the skin represent contraindications to SSM due to an unacceptable risk of local recurrence. Prior breast irradiation or the need for post-mastectomy radiotherapy do not preclude SSM, however the aesthetic outcome may be compromised. Preservation of the nipple areola complex is safe for peripherally located node negative tumours. An intraoperative frozen section protocol for the retro-areolar tissue should be considered in these cases. The advent of acellular tissue matrix systems has enhanced the scope of implant-based immediate reconstruction following SSM. Cell-assisted fat transfer is emerging as a promising technique to optimise the aesthetic outcome.

Core tip: Skin sparing mastectomy (SSM) is oncologically safe in selected cases and is aesthetically superior to

INTRODUCTION

Despite the increasing popularity of breast conserving surgery, approximately one third of women diagnosed with breast cancer still require or opt to have total mastectomy as a loco regional treatment. There is a growing body of evidence that immediate reconstruction following total mastectomy is associated with aesthetic and psychological benefits^[1]. The preservation of the skin envelope of the breast facilitates immediate reconstruction with a superior aesthetic result compared with conventional mastectomy. In standard skin sparing mastectomy (SSM), the nipple areolar complex is sacrificed and reconstructed at a later date. However, the nipple areolar complex can be preserved in certain cases [nipple sparing mastectomy (NSM)] and this further enhances the aesthetic outcome and is associated with psychosexual benefits^[1,2].

ONCOLOGICAL SAFETY

The preservation of the skin envelope of the breast had previously raised concerns regarding the oncological safety of SSM. This concern has been based on the fact that the skin envelope of the breast contains residual glandular breast tissue and can harbour a residual disease^[3,4]. However, numerous retrospective and prospective studies have shown that SSM is oncologically safe with no compromise of loco-regional control or overall survival

(OS). This is particularly true for ductal carcinoma in situ (DCIS) and T1 and T2 invasive breast cancer. There are limited data regarding the oncological safety in patients with T3 tumours, however, the published data show no compromise of clinical outcome^[1,5].

A recent meta-analysis of all published studies (9 studies, 3739 SSMs) related to SSM demonstrated a similar disease-free survival to non-SSM. In fact, the meta-analysis showed that the OS was slightly superior in the SSM group, however, this observation should be interpreted with caution since the meta-analysis do not include the tumour grade in the pooled analysis^[6].

Furthermore, NSM has been growing in popularity, due to increasing data supporting its oncological safety. A recent meta-analysis of the NSM ($n = 6615$) was published in 2013 and demonstrated an acceptable incidence of local recurrence, distant relapse and nipple-related complications^[2]. Preservation of the nipple areolar complex is oncologically safe provided that the tumour-nipple distance exceeds 2.5 cm and the local recurrence is lowest for node-negative, unifocal tumours, which are estrogen receptor-positive and human epidermal growth factor receptor 2 negative. It is very important that an intra-operative frozen section protocol is in place when the nipple areolar complex preservation is considered and if intra-operative frozen section analysis of the sub-areolar tissue demonstrates malignancy, then the nipple areolar complex is sacrificed^[1]. Prophylactic mastectomy for risk reduction represents a good indication for NSM.

SSM has been found oncologically safe for extensive DCIS. However, it is important that adequate surgical margins are obtained and the DCIS does not extensively involve the surgical margins. If there is significant DCIS involvement of the margins (< 1 mm at more than one site), then surgical excision of the overlying skin flap should be considered and, if this is not feasible, then post-mastectomy radiation should be considered as an adjuvant treatment after multidisciplinary discussion especially for high grade DCIS. For focally positive or close margins, post-mastectomy radiation can be omitted since the incidence of local recurrence is lower than the risk of developing cancer in the contra-lateral breast^[7].

Due to the fact that it is not feasible to conduct randomised controlled trials, there is a continuous need to publish updated meta-analyses from time to time, in order to ensure that the oncological safety of SSM remains intact^[2]. Such meta-analyses should assess the risk of bias (selection bias, detection bias, attrition and reporting bias) and study heterogeneity. OS and disease-free survival (DFS) should be the primary end points of the meta-analysis while the secondary endpoints should include surgical complications and quality of life.

In relation to T3 tumours, it is feasible to downstage the tumour with neo-adjuvant treatments, such as neo-adjuvant systemic therapy or even radiation prior to carrying out SSM. Neither prior radiotherapy nor post-mastectomy radiation represent contraindications to SSM, however, one has to accept that the aesthetic outcome will be compromised by radiation treatment, due to a higher incidence of capsule formation, which will require

surgical intervention, if it becomes symptomatic^[2,8].

BREAST RECONSTRUCTION FOLLOWING SSM

Following SSM, volume replacement is most commonly carried out using a mammary tissue expander or a fixed volume implant. The advent of the acellular dermal matrix devices has enhanced the scope of using implants in the context of immediate reconstruction and increased the rate of single-stage SSM and immediate reconstruction^[9]. Other options for breast reconstruction include free autologous tissue transfer with the free deep inferior epigastric perforator flap being the commonest^[10]. In relation to conventional pedicled flaps, the latissimus dorsi myocutaneous has its role in the field of immediate reconstruction.

Finally, the advent of cell-assisted fat transfer has been recently introduced, in order to improve the aesthetic outcome in women undergoing SSM and immediate reconstruction. The cell-assisted fat transfer is useful in improving the aesthetics of the breast contours and providing soft tissue covering in areas where the implant is palpable and visible. Furthermore, there is evidence suggesting that the use of cell-assisted fat transfer is associated with improvement of the severity of the capsule that develops in some patients undergoing breast reconstruction^[11].

Abstract

Large cell neuroendocrine carcinoma (LCNEC) of the ovary is a rare diagnosis and only a few dozen cases have been reported in the literature. It is characterized by large pleomorphic cells with large round or oval nuclei, presence of mitoses and staining for neuroendocrine (NE) markers such as chromogranin A, synaptophysin, neuron specific enolase. This editorial gives a brief overview of this histologic type of ovarian carcinomas. LCNEC of the ovary is a pathologic entity that may not be diagnosed purely on clinical grounds due to the similarity of its clinical features with those of the more common epithelial ovarian cancers. Nevertheless the diagnosis is worth-making from a practical point of view in order to consider treatments tailored towards the NE component if it is dominant or it becomes dominant during the natural evolution of the disease. Establishment of an international tumor registry with an accompanying tumor tissue bank of ovarian LCNEC could be a means of obtaining further knowledge on clinical characteristics and advance research on this rare entity. This will further inform on treatment strategies and could identify future molecular treatment targets.

INTRODUCTION

Large cell neuroendocrine carcinoma (LCNEC) of the ovary is a rare diagnosis and only a few dozen cases have been reported in the literature. It is characterized by large pleomorphic cells with large round or oval nuclei, presence of mitoses and immunohistochemical staining for one or more neuroendocrine (NE) markers such as chromogranin A, synaptophysin, neuron specific enolase or CD56^[1]. LCNEC was first described in the lung and, although initially classified as a variant of large cell carcinoma (which is a non-small cell carcinoma), was noticed to behave more similarly to small cell carcinomas^[2]. Similar neoplasms have been described arising from uterine body and cervix as well as other organs such as stomach, gallbladder, kidney, urinary bladder, prostate and parotid glands^[3-8]. Rare metastatic cases with an unknown primary have been reported^[9]. In most cases a concomitant epithelial ovarian component is present while presentation with pure large cell NE histology is less common^[10,11].

Presentation of LCNEC of the ovary is similar to the usual presentation of epithelial ovarian cancer with an abdominal mass, pain or distention and the diagnosis of

Table 1 Summary of basic characteristics of ovarian large cell neuroendocrine carcinoma

Pathologically distinct entity from epithelial ovarian cancers
Clinically similar presentation with common epithelial ovarian cancers
Often co-exists with non-neuroendocrine components
Several lines of data argue for a common origin of neuroendocrine and epithelial components (common co-existence, monoclonality analysis, neuroendocrine features arising in epithelial prostate cancer following treatment)
Treatment; suggested to be addressing the epithelial component except if neuroendocrine component is clearly dominant

a tumor is confirmed after radiologic evaluation (Table 1). Many of the cases are stage III or IV but earlier cases are often reported. Metastatic sites include the abdominal cavity and liver, typical of epithelial ovarian cancer, while other sites such as lung, brain and bone have been reported less commonly^[10,12]. Thus a more diverse metastatic pattern in LCNEC of ovary compared to epithelial cancers is encountered. This is also exemplified in the skin metastasis seen in the accompanied case report. In some cases with available information metastatic deposits are solely of NE histology^[12].

Diagnostic pathology shows large cells usually with significant pleiomorphism, large nuclei with coarse and granular chromatin, prominent nucleoli, often significant mitotic activity and palisading with rosette formation. Immunohistochemistry confirms the diagnosis with positivity for one or more of the standard NE markers. Almost all cases evaluated have elevations of Ca-125 tumor marker. The great majority of cases have an adjacent epithelial ovarian cancer component, most often endometrioid and more rarely serous^[13]. Of note the epithelial component often, but not always, expresses NE markers despite its differing morphology^[1,13]. The pathologist needs to be alert to the diagnosis and include LCNEC in the differential diagnosis of undifferentiated carcinomas of both the ovary and the endometrium^[14].

Prognosis of LCNEC of the ovary is difficult to ascertain because of the rarity of the disease, the small number of reported cases and the lack of systematic population based studies or registry data. These shortcomings in addition to pathologic diagnosis inconsistencies prevent a solid data-based prognostication in comparison with epithelial ovarian cancer. The experience of many authors is that LCNEC of the ovary is more aggressive than epithelial ovarian cancer and may not respond as well to chemotherapy^[13]. Nevertheless others have observed LCNEC to display chemosensitivity similar to other epithelial ovarian cancers^[1,15].

Pathogenesis could be an informative element for prognosis but most importantly for therapy. The fact that the great majority of ovarian LCNEC are diagnosed as part of a biphasic tumor combined with epithelial elements implies that the two components have a common cellular origin and represent two divergent clones of the same neoplastic process. Indeed a monoclonality analysis using human androgen receptor analysis disclosed a com-

mon origin of the two components in a case of composite LCNEC and mucinous epithelial ovarian carcinoma^[16]. Similarly monoclonality was shown by the same authors in a case of composite LCNEC and cervical adenocarcinoma^[17]. Thus, based on both the fact of common concurrence with epithelial components and the monoclonality studies, it appears that ovarian LCNEC and the even more rare endometrial LCNEC^[18] represent a dedifferentiated clone of an epithelial carcinoma. This reminds the case of endometrial carcinosarcomas (malignant mixed müllerian or mesodermal tumors) in which the sarcomatous component is derived from an epithelial to mesenchymal transition program during which epithelial malignant cells obtain mesenchymal morphologic and functional properties that allow them to become mobile and metastasize^[19]. The case of LCNEC in the prostate may be informative for the pathogenesis of LCNEC in general, arguing also for a common origin of epithelial and NE components. LCNEC of this origin often arise after patients are on androgen repression therapy for an epithelial prostatic carcinoma and may represent a result of therapy pressure on the tumor cells^[7]. According to this theory prostatic LCNEC represent clones of the initial epithelial cancer that have become dominant following endocrine therapy because of their innate resistance to it. The minority of ovarian LCNEC cases in which no epithelial component is discernible (pure LCNEC) may represent either epithelial tumors in which the totality of cancer cells have undergone NE transition or true NE tumors derived from resident NE cells. A dual origin with concomitant transformation of epithelial cells and NE cells may be true in the exceedingly rare case of composite LCNEC and serous ovarian cancer^[20].

Regarding therapy, these pathogenic considerations imply that the optimal first line treatment for mixed epithelial and LCNEC ovarian tumors should be against the epithelial component. In case of pure LCNEC or NE element preponderance or selection of the NE clone post-treatment consideration should be given to a NE type combination (platinum-etoposide).

In conclusion, LCNEC of the ovary is a pathologic entity that may not be diagnosed purely on clinical grounds due to the similarity of its clinical features with those of the more common epithelial ovarian cancers. Nevertheless the diagnosis is worth-making from a practical point of view in order to consider treatments tailored towards the NE component if it is dominant or it becomes dominant during the natural evolution of the disease. Establishment of an international tumor registry with an accompanying tumor tissue bank of ovarian LCNEC could be a means of obtaining further knowledge on clinical characteristics and advance research on this rare entity. This will further inform on treatment strategies and could identify future molecular treatment targets.

Abstract

Targeted therapies that deliver the expected anti-tumor effects while mitigating the adverse effects are taking the cancer world by storm. The need for such therapies in non-small cell lung cancer (NSCLC), where systemic cytotoxic chemotherapies still remain the backbone of management, is felt more than ever before. Runway success of immunotherapies such as Ipilimumab for melanoma has brought excitement among oncologists. Immune-based treatments are in various stages of evaluation for NSCLC as well. Immunotherapies using strategies of antigen based or cell based vaccines, and blocking immune checkpoints are of substantial interest. Meaningful clinical responses are yet to be reaped from these new treatment modalities.

Key words: Immunotherapy; Non-small cell lung cancer; Programmed death-1; Programmed death ligands 1; Cytotoxic T-Lymphocyte Antigen-4

Core tip: Lung cancer is the leading cause of cancer-death worldwide. Majority of these patients have non-small cell lung cancer (NSCLC). Traditional chemotherapy is limited by its high toxicity. Emerging data have

demonstrated promising outcome of immunotherapy in NSCLC. This review delineated the rationale and potential targets of cancer immunotherapy, with a summary of immunotherapeutic agents for treatment of NSCLC. Protein/peptide-based and cell-based vaccines, as well as immune checkpoint targeted agents such as Ipilimumab and PD-1 pathway inhibitors were discussed. In addition, we reviewed ongoing immunotherapy-based studies including several major phase II/III clinical trials, results of which will be available soon for incorporation into clinical practice.

INTRODUCTION

Lung cancer remains the leading cause of death in the United States with about 160000 estimated deaths in 2013^[1]. Majority of these patients have non-small cell lung cancer (NSCLC). Over the past few decades, platinum based chemotherapy is the standard of care for advanced stages of NSCLC. These systemic therapies have significant toxicities and confer unacceptable morbidity. A decade ago, it was realized that advancement in treating NSCLC could not be reached with the use of cytotoxic agents alone^[2]. While entering the era of personalized medicine, focus of cancer therapy has been recently shifted to identifying and targeting certain driver mutations. This has been successful in certain solid tumors including NSCLC, wherein identifying the genetic mutation in epidermal growth factor receptor (EGFR) and fusion gene rearrangement in anaplastic lymphoma kinase has become the standard of care. Historically lung cancer was not seen as an “immunologic malignancy”. However recent success of Ipilimumab in melanoma^[3] and Sipuleucel-T in prostate cancer^[4] opened up a new realm

of cancer immunotherapy. Emerging data demonstrate promising outcome of immunotherapy in lung cancer. Herein we review the basics of cancer immunotherapy and development of immunotherapeutic agents for management of NSCLC.

We conducted a review of articles in the past 10 years, that harbored the terms “immunotherapies”, “non small cell lung cancer” in the Pubmed and Medline database as well as trials that are ongoing in clinicaltrials.gov.

BASIC IMMUNOLOGY PRINCIPLES AND ITS APPLICATION IN NSCLC

Immunity acts as a double edged sword when it comes to cancer. The cross talk between tumor and immunity is complex. Cancer immunoediting plays an important role in this context. Three phases of cancer immunoediting have been described: elimination, equilibrium and escape^[5].

In the initial phase of elimination, innate and adaptive immune systems work in concert to eradicate tumor cells, after which the survived cells enter a state of dormancy called the equilibrium phase. Under immune pressure, tumor cells may undergo phenotypic or genomic modification, resulting in the survival and proliferation of tumor variants that are capable of escaping immune attack. Important modulations of this immune escape include down-regulation of HLA class I, loss of tumor antigens, lack of death receptor signaling, insufficient costimulation, and negative regulation pathways including regulatory T cells, inhibitory cytokines and molecules involved in immune checkpoints.

The potential targets for immunotherapy can be tumor specific antigen or each component of the cross talk between the immune system and tumor. It has been proposed that targeting tumor specific antigen may be ideal in treating early stage cancers when the tumor cells are highly immunogenic; whereas targeting non antigen specific immune pathways may be optimal in managing advanced stage cancers. Advancement of our knowledge in cancer immunology has resulted in better cancer vaccine designs with hope to improve clinical outcomes^[6].

Previously lung cancer was not seen as immunogenic. However recent studies have shown the association of immune response with overall outcome, indicating a role of immunotherapy in lung cancer management. Histochemical analysis of lung tumors in retrospect, showed that increased infiltration of the stroma by CD4⁺/CD8⁺ cells was an independent favorable prognostic factor^[7]. In addition, it has been observed that in advanced NSCLC, favorable prognosis has been associated with higher number of macrophages and CD8 T in tumor nests as compared with surrounding stroma^[8]. In contrast, increased infiltration by Foxp3⁺ lineage Treg cells is associated with poor outcome. Furthermore depletion of Treg achieves prolonged survival in mouse models^[9,10]. Current development of NSCLC immunotherapy is mainly focused on tumor vaccines and blockade of immune checkpoint pathways.

CANCER VACCINES

A therapeutic cancer vaccine intends to treat an existing cancer by strengthening the body's natural defense against cancer. Broadly, cancer vaccines can be divided into protein/peptide based vaccines and cellular vaccines.

PROTEIN/PEPTIDE BASED VACCINES IN NSCLC

L-BLP25 vaccine

MUC1 is a transmembrane glycoprotein that is upregulated in many solid tumors including NSCLC. It is purported that aberrant up regulation of MUC1 in tumor cells favors tumor angiogenesis *via* activating Erk and Akt pathways^[11]. L-BLP25 is a peptide vaccine that targets the exposed core peptide of MUC1^[12].

The vaccine was studied in an open label, phase II randomized trial in 171 patients with stage III B/IV NSCLC with response or stable disease after first line therapy^[13]. The trial evaluated effect of L-BLP25 liposome vaccine on survival and toxicity in the above patients. Quality of life and immune related responses due to the vaccine were the secondary end points. Patients were prestratified by stage and randomly assigned to either L-BLP25 plus best supportive care (BSC) or BSC alone. Patients in the L-BLP25 arm received a single intravenous dose of cyclophosphamide 300 mg/m² followed by eight weekly subcutaneous immunizations with L-BLP25; and then every 6 wk, as this had been previously shown to boost immune response in certain other cancers^[14]. Though the study failed to achieve the primary end point of overall survival (OS); subgroup analysis of patients with stage III B disease showed strong positive trend towards 2 years survival. Update on these patients published later showed continued improved survival in patients on the L-BLP-25 arm^[15]. These results were achieved with minimal toxicity.

Based on the above results, a phase III trial, Stimulated Targeted Antigenic response to NSCLC (START, NCT00409188) was undertaken. One thousand two hundred and thirty-six patients with stable unresectable stage III disease were randomized to receive either intravenous cyclophosphamide followed by weekly BLP-25 *vs* placebo. The trial did not meet its primary end point of OS, however the subgroup that was pretreated with prior chemoradiation (either concurrent or sequential) had significant improvement in OS^[16]. They reported the vaccine to be well tolerated with some flu-like symptoms, but no significant immune associated adverse effects.

Other clinical trials of L-BLP25 include the multinational, double blinded, placebo controlled trial in Asian population, with unresectable stage III NSCLC who have been stable or responded to primary chemoradiation, L-BLP25 trial In Asian NSCLC Patients: Stimulating Immune Response^[17].

A phase II study of L-BLP-25 is looking in combination with bevacizumab in patients who have undergone

chemoradiation for stage III NSCLC is ongoing as well^[18].

Melanoma-associated antigen-A3 vaccine

Melanoma-associated antigen (MAGE) is a family of tumor specific antigens that is expressed on variety of tumor cells and specifically the MAGE-A3 is detected in about 35%-50% of NSCLC^[19,20]. It is also expressed on cells of other tumors such as melanoma, renal, bladder and liver cancer^[21]. MAGE-A3 is also expressed on normal testicular and placental. However with unique immune tolerance mechanisms these organs were able to escape immune attack. Hence MAGE-A3 is a unique tumor antigen and the vaccine against it should be well tolerated in theory^[22,23]. Presence of MAGE-A3 is independently associated with poor prognosis in NSCLC^[24].

MAGE-A3 vaccine is composed of recombinant fusion protein, in combination with immune-enhancing adjuvant. A phase II trial studying the efficacy and safety of the vaccine was performed in 182 patients with MAGE-A3 positive, resected stage I B/ II NSCLC. This was an international, double blinded, placebo controlled trial, where patients were randomized to receive either MAGE-A3 vaccine or placebo. The results were encouraging as the long term analysis showed a positive trend in OS, disease progression time and disease-free survival in those receiving the MAGE-A3. The vaccine was very well tolerated leading to good compliance^[25]. These encouraging results lead to the ongoing randomized trial in lung cancer, MAGE-3 as Adjuvant Non-Small Cell Lung Cancer Immunotherapy. It is a phase III trial looking at MAGE-A3 vaccine *vs* placebo used in adjuvant setting for patients with MAGE-A3 positive stage I B, II or IIIA resected NSCLC. Disease free survival is the primary end point and OS, lung cancer specific survival and adverse events (AE) amongst others are secondary end point. The results of the study are eagerly expected in early 2014^[26].

Epidermal growth factor vaccine

EGFR is a transmembrane receptor tyrosine kinase belonging to the Erb family of receptors and is activated by binding of its specific ligand epidermal growth factor (EGF), hypothesized to be responsible for pathways that regulates cell survival, cell death *via* controlling the extracellular growth factors^[27]. EGFR expression is altered in many cancer, including NSCLC. In NSCLC harboring mutated EGFR, use of EGFR tyrosine kinase inhibitors as first line therapy has been shown to improve survival and safety profile in a number of clinical trials and are approved for this indication^[28-30].

Recombinant human EGF vaccine is an antigen-based vaccine which prevents binding of the endogenous EGF to the receptors by stimulating production of anti-EGF antibodies that clear it from circulation.

A phase I clinical trial conducted in 43 patients with advanced NSCLC was randomized to receive either single or double dose EGF vaccination. Patients receiving double dose of vaccination had higher antibody titers,

were found to have a positive survival trend. Antibody titers and serum EGF levels appear to correlate with patient survival^[31]. Significant positive outcome between higher antibody response and increased survival was confirmed in a phase II trial by García *et al*^[32]. A phase III trial for safety and efficacy of EGF vaccine in inoperable advanced stage NSCLC is currently ongoing^[33].

WHOLE TUMOR CELL VACCINE

Belagenpumatucel vaccine

Transforming growth factor $\beta 2$ (TGF $\beta 2$) converts CD4⁺CD25⁻ naïve T cells to CD4⁺CD25⁺Treg cells by inducing transcription factor Foxp3^[34] which in turn mediate immunosuppression in NSCLC by blocking dendritic cells, natural killer cells and lymphokine activated killer cells. Higher levels of TGF $\beta 2$ are associated with worse outcomes in NSCLC^[35]. Belagenpumatucel is a non-viral gene based allogeneic vaccine that carries TGF $\beta 2$ antigen modification of tumor cells. It consists of 4 cell lines of NSCLC (2 adenocarcinoma, 1 squamous carcinoma and 1 large cell carcinoma)^[36] which downregulates TGF $\beta 2$ upon administration.

The vaccine was investigated in early as well as advanced NSCLC where patients were randomly assigned to receive a dose of either 1.25, 2.5 or 5×10^7 cells/injection. Patients with any prior therapy were able to participate in the trial. Antibodies reactive against the cell lines were evaluated using enzyme-linked immunosorbent assay. The vaccine was well tolerated with minimal side effects. Survival was significantly improved in cohorts who received higher doses of the vaccine ($\geq 2.5 \times 10^7$ cells/injection); however difference across dose cohorts for advanced NSCLC was only marginal. Estimated probabilities of surviving 1 and 2 years were 68% and 52% respectively for higher dose groups combined and 39% and 20% respectively for the low dose group. Patients in the advanced stage disease had a 15% response rate^[36]. A smaller phase II trial by the same group in 21 patients confirmed the safety and efficacy of the vaccine. They also suggested the possibility of using CTC (circulating tumor cells) as surrogate of OS^[37].

Encouraged by the above results, a phase III trial of belagenpumatucel is underway as maintenance therapy for patients with T3N2-III A, IIIB and IV NSCLC who did not progress after front line chemotherapy (STOP trial)^[38]. Findings were reported in September 2013 at the European Cancer Congress from the STOP trial. Of 532 patients enrolled, 42 had stage II A and 490 had stage IIIB/IV disease. Patients were randomized 1:1 to receive either the vaccine or placebo until disease progression or withdrawal. Though STOP did not meet its predefined primary end point in the entire population, it was noted that patients who were randomized to receive the vaccine within 12 wk of the end of their first line chemotherapy had better OS (20.7 mo) as compared to those with placebo (13.4 mo). In addition, pretreatment radiation showed improved median OS with treatment

Figure 1 Interaction between T cells and antigen presenting cells or tumor cells. The quality and amplitude of T cells depends on the balance of the above co-stimulatory and inhibitory signals and ultimate orchestration of death of tumor cells. Agonists of costimulators or antagonist of inhibitors are the main topic of the study as described. MHC-Ag: Major histocompatibility complex antigen; TCR: T cell receptor; PD-1: Programmed death-1; PD-L1: Programmed death ligand 1; CTLA-4: Cytotoxic T lymphocyte antigen-4.

arm OS of 40.1 mo compared to 10.3 mo receiving placebo. The trial will be continued with focus on these specific subgroups^[39].

Immune checkpoints inhibitors

T cell receptors activate antigen specific cytotoxic T cells after recognition of the antigen peptide along with major histocompatibility complex. This activation usually requires costimulatory signal obtained *via* interaction of CD28 expressed on T cells with molecules expressed on antigen presenting cells (Figure 1). CD28 can also interact with inhibitory receptors on antigen presentation cells or tumor cells such as Cytotoxic T-Lymphocyte Antigen (CTLA)-4, PD-1, PD-L1 and B- and T-lymphocyte attenuator^[40], therefore inhibits T cell functions, a process called immune check point^[41,42]. Two promising strategies for immune check point modulation are currently being investigated in NSCLC.

CTLA-4 inhibitors

CTLA-4 inhibitors have been extensively studied and are thought to be responsible for initiating and maintaining peripheral tolerance as a part of physiological immune mechanism. Ipilimumab is a fully humanized mAb targeting the CTLA-4 inhibitory coreceptor, thus rescuing cytotoxic T cell activity and potentiating tumor death^[43]. It was approved for malignant melanoma^[3] and since then has been evaluated in various other malignancies.

A phase II study of Ipilimumab enrolled 204 patients with stage III B/IV NSCLC who had not received any prior chemotherapy^[44]. Patients were randomly assigned 1:1:1 to receive a concurrent Ipilimumab regimen (four doses of Ipilimumab plus paclitaxel and carboplatin followed by two doses of placebo plus paclitaxel and carboplatin), a phased Ipilimumab regimen (two doses of placebo plus paclitaxel and carboplatin followed by four doses of Ipilimumab plus paclitaxel and carboplatin), or a control regimen (up to six doses of placebo plus paclitaxel and carboplatin). In a previous study, lower dose of paclitaxel was found to be equally efficacious, with prospects of decreased toxicity when combined with Ipilimumab^[45]. Patients who tolerated the treatment well without evidence of progression then went on to receive either Ipilimumab or placebo for another 12 wk until disease progression or death. Clinical response patterns to Ipilimumab differs

from conventional cytotoxic therapies and hence a novel parameter, immune related response criteria (irRC) has been recently established to capture this phenomenon. Ipilimumab may cause regression of index lesions in the face of new lesions and initial progression followed by tumor stabilization or decrease in tumor burden. The irRC uses the total tumor burden obtained by adding measurable new lesions to index lesions in determining the tumor response. Changes in non-index or nonmeasurable lesions are discounted. Thresholds for immune-related complete response (CR, complete disappearance of all lesions), immune-related partial response (PR, decrease of total tumor burden from baseline by $\geq 50\%$), immune-related progressive disease (PD, increase of total tumor burden from nadir by $\geq 25\%$), and immune-related stable disease (all other settings including a slow steady decline in total tumor burden from baseline) were the same as for the CR, PR, PD, and stable disease^[44,46]. Here, immune related progression free survival (irPFS) which was defined as time from randomization to immune related progression or death was used as the primary end point.

Patients receiving phased Ipilimumab and carboplatin/paclitaxel showed improved irPFS as compared to carboplatin/paclitaxel alone, however no such benefit was seen in the group receiving concurrent Ipilimumab and carboplatin/paclitaxel. Also further subgroup analysis showed better outcome in patients with squamous histology. Hence the timing of Ipilimumab with cytotoxic chemotherapy seems to play an important role in the outcome.

Incidence of grade 3 or 4 AE was similar in all 3 arms. Though non hematologic AE related to carboplatin (alopecia, fatigue, nausea/vomiting, neuropathy) were similar across all arms, immune mediated adverse effects (rash, pruritis, diarrhea, colitis, transaminitis and pituitary dysfunction) showed a trend for increased incidence in Ipilimumab containing arms. These immune related side effects from Ipilimumab are thought to be secondary to CTLA4 inhibition. It is to be noted that though dose of Ipilimumab used in this trial was higher than that used in melanoma (10 mg/kg *vs* 3 mg/kg), the incidence of AE was comparable^[47].

A larger phase III trial of phased carboplatin/ paclitaxel and Ipilimumab in patients with stage IV NSCLC is underway^[48]. In addition, a safety and efficacy study of

Table 1 Ongoing clinical trials of programmed death-1 antibodies in non-small cell lung cancer

NSCLC: Non-small cell lung cancer; OS: Overall survival.

Ipilimumab in stage IV NSCLC *vs* Pemetrexed in recurrent stage IV NSCLC who have not progressed after first line platinum based chemotherapy is also ongoing^[49]. A similar study of Ipilimumab and carboplatin/paclitaxel is also being conducted in Japan^[50].

Programmed death-1 pathway inhibitor

Programmed death-1 (PD-1) is another key receptor that can mediate immunosuppression by interacting with PD ligands 1 (PD-L1) and PD-L2. The anti-tumor activity of cytotoxic T cells can be enhanced by blocking this pathway^[51,52].

Anti PD-1 pathway agents gained momentum when a phase I dose escalation study of Nivolumab, a humanized IgG4 mAb, was performed in 39 patients with various cancers (melanoma, colorectal, prostate, NSCLC and renal cell). Among the 6 patients with NSCLC, all of whom had received multiple chemotherapies in the past, 1 patient achieved partial remission for over 14 mo, and the other 5 patients had stable disease post treatment^[53].

A larger phase I study then was conducted in patients with NSCLC, melanoma, castration resistant prostate cancer, colorectal cancer or renal cell cancer who largely had multiple lines of chemotherapy in the past. Nivolumab was administered Intravenous every 2 wk of 8 wk until CR, disease progression, unacceptable side effects or consent withdrawal. Of the 129 NSCLC patients, 17% had objective responses with best responses (24%) at the 3 mg/kg dose. The responses were rapid, durable and the unprecedented OS rate of 24% at 2 years was provocative and is termed “landmark OS”. Major AEs were rash/pruritis (16%), colitis (12%) and specifically pneumonitis (6%). Drug related pneumonitis was severe in 3 patients resulting in 2 early deaths. Better management and monitoring strategies have been introduced since then to prevent such AE related deaths in future. This study opened the realm of possibility that multiple types of cancer could be responsive to immunotherapy if appropriate population is selected even if heavily pre-

treated^[41].

A follow up report on above trial was presented and confirmed the durable response and encouraging OS across all histological subtypes in NSCLC subgroup^[54]. Currently a number of studies are ongoing to test the efficacy of Nivolumab and another investigational PD-1 inhibitor, Lambrolizumab (Table 1).

Data on MK-3475 (Lambrolizumab) from phase I study of 38 patients with advanced NSCLC who had received atleast 2 prior therapies was presented at the 15th World conference on Lung cancer by Garon *et al*^[61]. Early responses were seen in 24% of patients even at 9 wk assessment in both squamous and non squamous subtypes. One patient had PR after a single dose. Median duration of response had not been reached and at the time of abstract presentation, 7 of 9 responding patients were continuing therapy. Median OS was 51 wk. Common AEs were fatigue, rash, pruritus and diarrhea. One case each of grade 2 pneumonitis and grade 3 pulmonary edema were reported, no fatalities occurred.

PD-L1 pathway inhibitor

As described above, PD-L1 is one of the 2 ligands for PD-1 receptor. Presence of PD-L1 has been associated with poor prognosis^[62].

A high affinity, fully humazined PD-L1 IgG4 monoclonal antibody, BMS-936559 was studied in phase I trial in patients with advanced cancers^[42]. Total of 207 patients, 75 of whom had advanced NSCLC, were given escalating dose of BMS-936559. Objective responses were seen in 5 of 49 patients who were evaluable; with both squamous and non-squamous histologies. Also 6 other patients with NSCLC had stable disease at 6 mo.

In all tumor types, it was encouraging to see both durable tumor regression and prolonged disease stabilization. Grade 3 or 4 AEs were seen in up to 9% of patients, however as compared to some other immune therapies, such as anti CTLA-4; these were milder. Again, the response with this agent was promising, and further

MPDL3280A	NCT01903993	Advanced NSCLC, failed platinum based chemo	MPDL-3280A <i>vs</i> Docetaxel after failure of platinum based therapy in patients with advanced NSCLC	[65]

NSCLC: Non-small cell lung cancer; PD-L1: Programmed death ligand 1; IHC: Immunohistochemistry.

studies are needed to outline the patient population and tumor type that would derive benefit from this therapy.

Another anti PD-L1 agent, MPDL-3280A, was studied in a phase I clinical trial, the results of which were exciting as it shows remarkable and durable outcomes in patients with either squamous cell carcinoma or adenocarcinoma. More pronounced effect was seen in smokers, who typically have a poor response to other immunotherapies. This suggests an association between smoking and PD-1/PD-L1 pathway. In this phase I study, 85 patients with advanced NSCLC were evaluated for safety and 53 for efficacy. They received monotherapy with MPDL-3280A every 3 wk and then assessed after a median duration of 48 wk. Objective response rate was 21%, with higher rate observed in patients whose tumor stains positive for PD-L1. The responses were sustained and dramatic response was seen in the smoking cohort. AEs were mild and limited to cough and diarrhea^[63]. Ongoing clinical trials using PD-L1 mAbs are summarized in Table 2.

CONCLUSION

Improved understanding of cancer and its interplay with immune system has now rendered more insight into NSCLC which is being looked at as a “immunogenic” cancer. The application of immunotherapy to NSCLC is being brought back in a big way. It is exciting to see that preclinical success of some of the immunotherapeutic agents is being reflected onto actual clinical success as seen with PD-1 and PD-L1 inhibitors. Data from some major phase II / III clinical trials will be available soon for incorporation into our clinical practice. There are still many unanswered questions regarding the precise timing of these therapies, targeted population, patient selection and appropriate bio-immuno markers to assess response. Ultimately, it would be a high point in medical science if these agents are able to confer survival benefit and improve quality of life of patients who otherwise struggle with the disease. The hope is to identify the best effective “immunotherapeutic targeted agent or combination” and change the treatment paradigm of NSCLC.

Abstract

MicroRNAs (miRNAs) are small non-coding RNAs generated by a two-step complex process and are post transcriptional negative regulators of their target mRNAs. Dysregulation of many of these miRNAs has been associated with tumorigenesis in various cancers including breast cancer. Aberrantly high expression of specific miRNAs in breast cancer cells is demonstrated to be linked with inhibition of tumor suppressor genes and promote tumorigenesis. They are classified as oncogenic miRNAs. However, the tumor suppressor miRNAs are downregulated in breast cancer cells, since their major targets are oncogenic mRNAs. Understanding mechanism of action of specific miRNAs in breast cancer cells can be utilized to develop newer anti-cancer therapies. Recently, newer techniques are also developed to detect abundance of specific miRNA in the blood plasma samples and can be used in early diagnosis or prognosis in breast cancer. In this review article, we have discussed several miRNAs dysregulated in breast cancer and their therapeutic potential.

INTRODUCTION

MicroRNAs (miRNAs) were discovered two decades ago while studying the development of *Caenorhabditis elegans*. They are conserved, endogenous non-coding RNAs, which are crucial in post transcriptional regulation of several genes involved with various biological functions, such as apoptosis, differentiation, proliferation, *etc.* Many of these miRNAs have been implicated to take part in various pathological conditions including cancer^[1,2].

Mature miRNAs are 18-24 nucleotide long single-stranded RNA synthesized from precursor hairpin shaped double-stranded RNAs^[3]. Biosynthesis of miRNAs is an extremely complex process. The majority of miRNAs are being transcribed by RNA Pol II into primary miRNA (pri-miRNA) with long stem loop structure^[4]. These pri-miRNAs are then cleaved into approximately 70 nt long precursor microRNA (pre-miRNA) by RNase III endonuclease Drosha with DiGeorge syndrome critical region in gene 8 in humans^[5]. This pre-miRNA is transported to the cytoplasm from nucleus by Exportin-5. Once in

Table 1 List of major oncogenic microRNAs in breast cancer

MiRNA	Known target mRNA	Function	Ref.
MiR-10b	HOXD10	Promotes cell proliferation, metastasis and angiogenesis	[108]
MiR-126	IGFBP2, MERTK, PTPN1	Promotes angiogenesis	[18]
MiR-155	SOCS1, TP53INP1, FOXO3, RhoA	Promotes cell proliferation	[12,20,21,62]
MiR-21	PTEN, TPM1, PDCD4, Maspin	Promotes cell proliferation	[22-24,109]
MiR-375	RASD1	Epigenetic modification of tumor suppressor genes	[110,111]
MiR-221/222	TRPS1	Induce metastasis	[28,29,65]
MiR-373	CD-44	Induce metastasis	[14,26]
MiR-520c	CD-44	Induce metastasis	[14,26]

MiR-203	SOCS3	Promotes cell proliferation	[25]

HOXD10: Homeobox D10; IGFBP2: Insulin-like growth factor binding protein 2; MERTK: C-mer proto-oncogene tyrosine kinase; PTPN1: Phosphatidylinositol transfer protein, cytoplasmic 1; SOCS1: Suppressor of cytokine signaling 1; TP53INP1: Tumor protein p53 inducible nuclear protein 1; FOXO3: Forkhead box O3; RhoA: Ras homolog family member A; PTEN: Phosphatase and tensin homolog; TPM1: Tropomyosin 1 (alpha); PDCD4: Programmed cell death 4; RASD1: Rat Sarcoma dexamethasone-induced 1; TRPS1: Trichorhinophalangeal syndrome 1; DNAJB6: DnaJ (Hsp40) homolog, subfamily B, member 6; HOXB3: Homeobox B3; MiRNA: MicroRNA.

the cytoplasm, the pre-miRNAs are cleaved into mature 18-24 nucleotide long miRNA by RNase III type enzyme Dicer. Dicer is a highly specific enzyme which forms a complex with two other proteins TRBP and PACT to form miRNA induced silencing (RISC) complex. The RISC complex is responsible for the degradation of the complementary strand of miRNA and directs miRNA to its mRNA target^[4,6]. This results in mRNA degradation or destabilization and subsequently translation inhibition^[4,7]. This review summarizes the role of different miRNAs associated with breast cancer progression, breast cancer stem cells (BCSCs) and their implications in cancer diagnosis, prognosis and treatment.

ROLE OF miRNAs IN BREAST TUMORIGENESIS

Breast cancer is a leading cause of mortality due to cancer among women. Despite a decrease in mortality due to the advancement of scientific research, it is estimated that approximately 1.3 million females develop breast cancer each year with around 465000 expected to succumb to the disease^[8,9]. Early detection and newer treatments are urgently required to inhibit the cancer progression in breast cancer patients. In 2005, a role of miRNA dysregulation in breast cancer was first demonstrated. Since then many studies have found out several different miRNAs which are being deregulated in breast cancer^[10]. Some of these miRNAs act as oncogenic miRNAs by suppressing tumor suppressor genes. Whereas, some of the miRNAs exhibit tumor suppressor properties by down-regulating oncogenic genes^[7].

KNOWN ONCOGENIC MiRNAs IN BREAST CANCER

Usually, miRNAs promote oncogenesis by either destabi-

lizing or degrading tumor suppressor mRNAs in various types of human cancers^[11]. The miRNAs affecting oncogenesis and/or metastasis are classified as oncogenic miRNAs. Several miRNAs have been identified in breast cancer to have such oncogenic potential. Different oncogenic miRNAs exhibit their oncogenic potential by inducing cell proliferation and tumorigenesis and/or metastasis, promoting angiogenesis or inducing epigenetic changes^[12-16]. The Table 1 summarizes some of the most commonly deregulated oncogenic miRNA in breast cancer.

The miR-10b is shown to be upregulated in breast cancer cells and correlated with increased cell migration and metastasis^[11]. Overexpression of miR-10b disrupts the homeobox D10 (HOXD10) mRNA, which leads to the increased expression of RhoC [a Rat Sarcoma (RAS) family member] known to promote proliferation and metastasis^[17,18]. Several studies have suggested that miR-155 is an oncogenic miR by demonstrating that, its upregulation results in inhibition of tumor suppressor genes in breast cancer cells^[12,19-21]. The miR-155 exhibits its oncogenic ability by suppressing the expression of protein Suppressor of cytokine expression 1 (SOCS1) both *in vitro* and *in vivo*^[21]. Inhibition of SOCS1 is inversely correlated to pro-tumorigenesis. The miR-155 also represses tumor suppressor forkhead box O3a expression in breast cancer^[19,20]. Similarly, miR-21 is also demonstrated to be upregulated in breast cancer cells by multiple studies and also considered as oncogenic miRNA. Research thus far have shown that miR-21 inhibits the expression of various tumor suppressor proteins such as TIMP3, PDCD4 and tropomyosin 1 (alpha)^[22-24]. Recently, miR-203 also has been shown to inhibit SOCS3 expression in breast cancer cells^[25]. Inhibition of miR-203 leads to the activation of several tumor suppressor proteins including p53, Bax and p21^[25].

Oncogenic miRNAs such as miR-520c, miR-373, miR-221 and 222, miR-9 and others are known to promote metastasis in breast cancer and are sometimes referred

Table 2 List of major tumor suppressor microRNAs in breast cancer

MiRNA	Known target mRNA	Function	Ref.
Let-7 family	RAS, HMGA2	Inhibit cell proliferation and mammosphere formation	[11,114]
MiR-125	HuR, HER2, ETS1, Cyclin J, MEGF9	Inhibit cell proliferation and invasion	[38,39,115,116]
MiR-205	ZEB1 and ZEB2	Reduces EMT and metastasis	[1,40]
MiR-200 family	ZEB1/2	Reduces EMT and metastasis	[117]
MiR-206	Cyclin D2	Inhibits Cyclin D2 in MCF-7 cells	[118]
MiR-34a	Bcl2, SIRT1	Inhibits migration, invasion and metastasis	[69]
MiR-335	SOX-4, TNC	Inhibits metastasis	[41,42]
MiR-342	HER2	Increases cell proliferation	[119]
MiR-15a/16	HER2	Increases cell proliferation	[68]
MiR-302	RAD52 and AKT1	Affects DNA repair	[78]
MiR-31	RhoA, ITGA5, RDX	Reduces invasion and metastasis	[44]
MiR-519c	HIF-1 α	Inhibits angiogenesis	[45]

MiRNA: MicroRNAs; Let-7: Lethal-7; RAS: Rat Sarcoma; HMGA2: High mobility group AT-hook 2; HuR: ELAV like RNA binding protein 1; ETS1: V-ets avian erythroblastosis virus E26 oncogene homolog 1; MEGF9: Multiple EGF-like-domains 9; ZEB1/2: Zinc finger E-box binding homeobox 1/2; Bcl2: B-cell CLL/lymphoma 2; SIRT1: Sirtuin 1; SOX-4: SRY (sex determining region Y)-box 4; TNC: Tenascin C; HER2: Human epidermal growth factor receptor 2; RAD52: RAD52 homolog (S. cerevisiae); AKT1: V-akt murine thymoma viral oncogene homolog 1; RhoA: Ras homolog family member A; ITGA5: Integrin, alpha 5 (fibronectin receptor, alpha polypeptide); RDX: Radixin; HIF-1 α : Hypoxia inducible factor 1, alpha subunit; EMT: Epithelial to mesenchymal transition.

as MetastamiRs^[11,26,27]. MiRNAs 520c and 373 have been shown to increase migration and invasion both *in vitro* and *in vivo* by targeting the expression of CD44^[26]. miR-221 and 222 induce metastasis by targeting trichorhinal syndrome 1^[28,29]. The miR-9 is also shown to be significantly upregulated in breast cancer, by targeting E-cadherin to promote metastasis^[27]. A recent study has also revealed that miR-632 stimulates metastasis by down regulating the HSP40 family member: DNAJB6 in breast cancer^[30].

Several oncogenic miRNAs are also known to deregulate angiogenesis. The expression of miR-126 has been seen to be upregulated in many breast cancer cells^[31]. Recent studies suggests that miR-126 affects angiogenesis by inhibiting the protein synthesis of insulin-like growth factor binding protein 2, c-Mer tyrosine kinase and phosphatidylinositol transfer protein cytoplasmic 1. MiRNAs 10b and 196b have also been shown to regulate angiogenesis targeting vascular endothelial growth factor (VEGF) signaling through HOXD10^[16].

Some miRNAs are known to inhibit tumor suppressor genes by affecting epigenetic changes. In breast cancer cells MDA-MB-231 and MCF-7 miRNAs miR-7 and miR-218 affects histone modification and DNA methylation by targeting HOXB3. This results in inhibition of RASSF1A and Claudin 6 expression^[16].

KNOWN TUMOR SUPPRESSOR MiRNAs IN BREAST CANCER

Tumor suppressor miRNAs target mRNAs of various oncogenes and their dysregulation is critical in carcinogenesis^[11]. The most commonly deregulated tumor suppressor miRNAs in breast cancer are compiled in the Table 2. The Lethal-7 (let-7) family of miRNA due to their abundance was among first to be identified. This family of miRNA contains 12 members^[32,33]. Various studies

have shown that, expression of let-7 family members is downregulated in malignant breast cells, compared to the healthy tissues^[1,33,34]. Oncogenes RAS and High-Mobility Group AT-hook 2 (HMGA2) are found to be the direct targets of let-7^[33]. Increased expression of let-7 reduces cell proliferation and mammosphere formation by breast cancer initiating cells and also decreases metastasis *in vivo*^[33]. Another study revealed that let-7a directly binds to the 3'-Untranslated Regions (UTR) region of C-C chemokine receptor type-7 (CCR7) gene. Signaling of CCR7 and its ligand CCL21 has been demonstrated to play key role in cancer progression and metastasis^[35]. It was shown that expression of let-7a inhibits CCR7 expression and suppresses migration and metastasis in Zebrafish^[36].

In many breast cancer cell lines and breast cancer patient samples, the levels of miR-125a and miR-125b are often found to be greatly downregulated. miR-125b directly targets ETS: an oncogenic transcription factor and functions as a tumor suppressor miRNA^[37]. Further, both miR-125a and miR-125b are shown to be downregulated in human epidermal growth factor receptor (HER2) overexpressing cells. Expression of miR-125 in SKBR3 cells lead to the suppression of HER2 transcripts, which eventually lead to the slower cell growth and decreased invasiveness^[38]. Recently, several novel targets such as cyclin J (CCNJ) and multiple EGF-like-domains 9 (MEGF9) were found to be the direct targets of miR-125b^[39]. Both CCNJ and MEGF9 are potential oncogenes and their roles in tumorigenesis are only recently emerging^[39].

Another frequently down regulated tumor suppressor miRNA in breast cancer is miR-205, which is suggested to be the negative regulator of epithelial to mesenchymal transition (EMT) and metastasis^[1]. The miR-205 like the miR-200 family members targets Zeb1 and Zeb2 to prevent cells from undergoing EMT. Even though miR-200 and miR-205 share similar functionality, their expression levels differ in normal mammary gland and BCSCs. The expression of miR-205 is found to be elevated, whereas

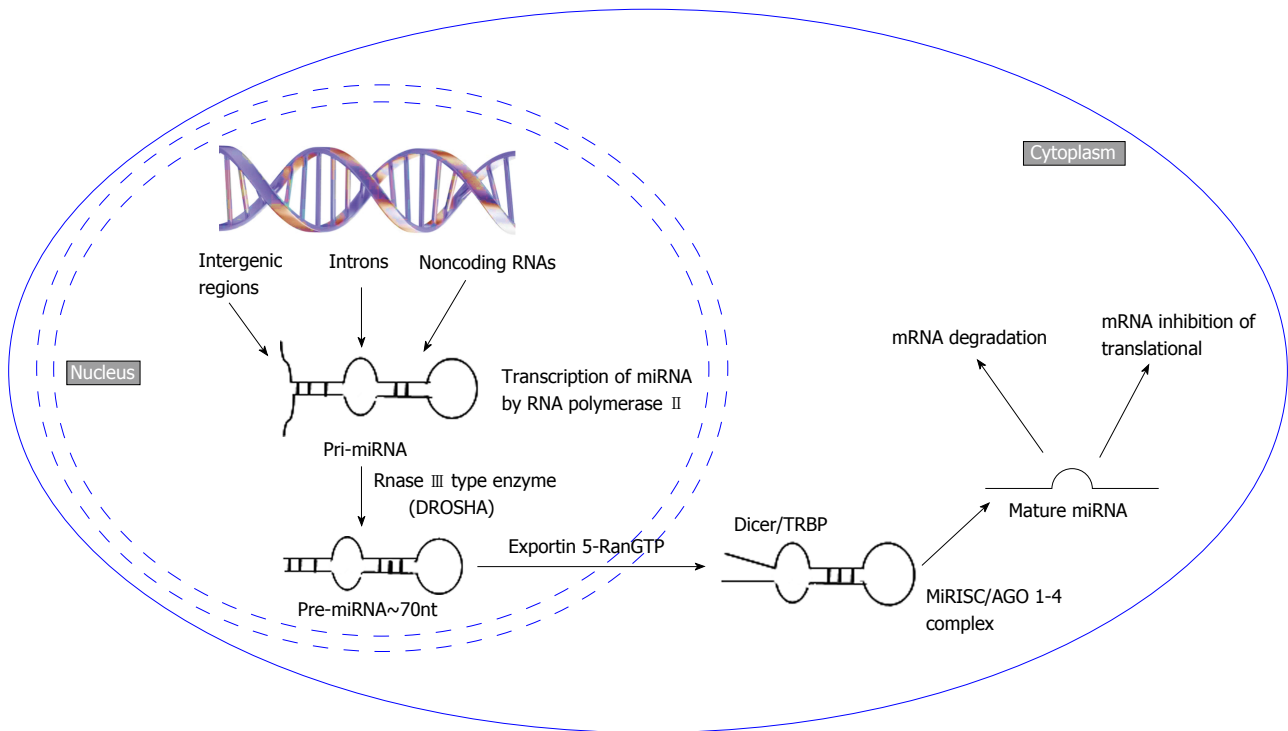

Figure 1 General mechanism of microRNA biosynthesis. Pri-miRNA: Primary microRNA; MiRNA: MicroRNA; Pre-miRNA: Precursor microRNA.

expression of miR-200 family members is decreased in normal mammary gland stem cells and BCSCs^[40]. This indicates the unique functionality of miR-205 in breast cancer.

The miR-335 act as a tumor suppressor miRNA in breast cancer cells because its expression suppressed the migration, invasion and metastasis^[41]. It was discovered that miR-335 targets transcription factor SOX4 and matrix protein Tenascin-C (TNC)^[42]. Both SOX4 and TNC were recently discovered to promote metastasis in pancreatic and liver cancers^[42].

miR-31 also recently came into light when it was demonstrated that multiple genes involved in the metastatic pathway of breast cancer were being targeted by it, including radixin, RhoA and integrin- α -5. When miR-31 is over-expressed expression of all three target genes is reduced and cells become less invasive and metastatic^[43]. In another study it was also seen that the ectopic expression of miR-31 in MDA-MB-231 and SUM-159 cell lines both *in vivo* and *in vitro* suppressed invasion and metastatic ability^[44].

The anti-tumor activity of miR-519c is attributed to its ability in regulating angiogenesis. In a study miR-519c directly targeted the hypoxia inducible factor 1 α (HIF-1 α), which regulates the angiogenesis by activating VEGF, interleukin-8 (IL-8) and basic fibroblast growth factor. Ectopic expression of miR-519c significantly suppressed HIF-1 α and reduced angiogenesis in a nude mouse model^[45]. Also, miR-519a/b/c expression is reduced in ovarian, kidney and lung tumor samples as compared to the healthy samples. Expression of miR-519 is found to be inversely correlated to the RNA binding protein HuR expression^[46].

MiRNAs AND CANCER STEM CELLS

Around a decade ago a concept was proposed that a small subset of cancer cells with stem-like characteristics might be the key factor in tumor development and metastasis in various types of cancers^[47]. Cancer stem cells (CSCs) gained more attention when its role was suggested in providing chemoresistance^[48]. In breast cancer, CD44⁺/CD24^{-/low} or high aldehyde dehydrogenase 1 (ALDH1) expression are typical characteristics of BCSCs. To enrich BCSCs, breast cancer cells are stained with fluorescently labelled antibodies for these markers and then sorted using Fluorescence-activated cell sorting^[49]. However, it should be noted that even after sorting, it is virtually impossible to get a pure cancer stem cell population. Recent researches have shown that the expression profile of specific miRNAs in BCSCs is distinct compared to the normal breast cells^[33,50]. The dysregulation of miRNA might contribute to the self-renewal of BCSCs and cancer progression^[33]. Here we have summarized the several miRNAs identified to be deregulated in BCSCs and their mechanism of action (Figure 1).

MiRNAs DOWNREGULATED IN BCSCS

One of the first group of miRNAs discovered to be dysregulated in BCSCs were the let-7 family members. It was noticed that expression of let-7 miRNA was significantly downregulated in SKBR-3 tumor-initiating cells than non-self-renewing population^[33]. These two population of cells were separated using CD44⁺ CD24^{-/low} phenotype. Let-7 miRNAs act as tumor suppressors mainly by

targeting RAS oncogene as described earlier^[33]. Upon induced expression of let-7 miRNAs led to the decreased BCSCs and decreased mammosphere formation^[33]. Another study have shown that decreased expression of let-7 is attributed to the RNA binding protein Lin28^[51]. It is also demonstrated that activation of STAT3 *via* inflammatory cytokines activates Lin28 expression and this results in let-7 downregulation. Consequently, target of let-7, HMGA2 is increased, which in turn enhances the EMT in CSCs.

The BCSCs can be enriched also by cultivating cancer cells as mammospheres. The 3D mammosphere is believed to be enriched with BCSCs. In a recent finding, miRNAs belong to miR-30 family are found to be downregulated in BCSCs enriched *via* mammosphere. The miR-30e downregulation increases the ubiquitin-conjugating enzyme 9 and integrin β 3 expression. Increasing the expression of miR-30e reduced self-renewal ability of CSCs and tumorigenesis^[52]. Overexpression of miR-30a reduces total number of mammospheres in MCF-7 cells and its downregulation leads to the increase in the number of mammospheres^[53].

MiR-200 family members (miR-200a, miR-200b, miR-200c, miR-141 and miR-429) have been shown to regulate the BCSC population. The miRNAs belong to the miR-200 family are significantly downregulated in BCSCs (CD44⁺ CD24^{-/low}) when compared to non-cancerous cells. Expression of tumor suppressor miR-200c decreased the self-renewal ability of BCSCs *in vitro* and tumor formation ability *in vivo*^[40]. The decreased expression of miR-200b lead to the reduction of E-cadherin expression, which results in increase EMT^[54]. Another group has also demonstrated that re-expressing the miR-200 family members reprograms BCSCs to a more non-stem like cells and also promotes mesenchymal to epithelial transition^[55].

The miR-128 was also found to be downregulated in BCSCs (in both CD44⁺ CD24^{-/low} and mammospheres) compared to the non-cancerous cells. The miR-128 targets polycomb ring finger oncogene (Bmi-1) and ATP binding cassette sub-family C member 5 (ABCC5). Both of these genes are known to induce chemoresistance in breast tumor initiating cells. Induced expression of miR-128 reduces the levels of both Bmi-1 and ABCC5 and increases the drug efficacy^[56]. Also, similar to other miRNAs mentioned in this section, reduction in miR-128 expression results in the increase number of mammospheres^[57].

Another miRNA recently shown to be downregulated in BCSCs (high ALDH1) is miR-93. Ectopic expression of miR-93 prevents tumor growth in xenografts. In this study it was demonstrated that miR-93 regulates BCSCs by reducing the expression of several stem cell regulatory genes such as *SOX4*, *STAT3* and *AKT3*^[58].

BCSCs enriched from MCF-7 and SK-3rd (CD44⁺ CD24^{-/low}) cells were found to have lower levels of miR-34c. Decreased expression of miR-34c promotes self-renewal and EMT. When re-expressed, miR-34c inhib-

ited the expression of Notch4, reduced the number of mammospheres^[59].

Another tumor suppressor miRNA often down-regulated in BCSCs (enriched using mammosphere) is miR-16. It targets the oncogene Wip1 and ectopic expression of miR-16 inhibits Wip1 expression in MCF-7 cells and also increases the sensitivity to chemotherapeutic drugs^[60].

MiRNAs UPREGULATED IN BCSCS

In the mammospheres of human breast cancer cell lines MDA361, MCF-7 and BT474, miR-181 levels are found to be elevated compared to non-cancerous cells. Potential target of miR-181 seems to be the tumor suppressor gene: Ataxia telangiectasia mutated (ATM). ATM levels are usually reduced in mammospheres treated with transforming growth factor- β .

Another miR-found to be significantly upregulated in BCSCs is miR-495. The miR-495 is found to be upregulated in two distinct subpopulations of BCSCs based on two surface markers: (1) commonly used CD44⁺ CD24^{-/low}; and (2) novel surface marker PROCR⁺/ESA⁺ (PROCR stands for protein C receptor). Also, overexpression of miR-495 increased tumor formation *in vivo*. Moreover, expression of E-cadherin was lowered with overexpression of miR-495 which enhances the stem like phenotype in BCSCs^[61].

MiRNAs implicated to promote resistance against chemotherapy

So far it has been established that, miRNAs play critical role in regulation of several genes associated with various cancers including breast cancer^[4,11,62]. Many recent studies have implicated that several miRNAs can confer resistance against common chemotherapeutic drugs in breast cancer^[63,64]. The proposed mechanisms to explain this drug resistance in breast cancer are (1) intracellular drug depletion *via* transporters and enzymes; (2) impairing cellular functions through cell cycle arrest, DNA damage or apoptosis; (3) Inducing signaling cascade which promote transformation; and (4) Inducing epigenetic changes such as DNA methylation^[63-65].

The miR-7, miR-27, miR-326, miR-328, miR-451, miR-489 confer resistance to chemotherapeutic drugs such as Doxorubicin, Cisplatin or taxol *via* drug depletion by targeting transporters and enzymes in breast cancer cells^[63,66]. Some of these miRNAs target the ABC drug transporters and affect drug availability in the cell. The decrease in miR-451 leads to the increase in its target P-glycoprotein, a member of the ABC transporter family^[67]. Another family of genes associated with the drug resistance is multidrug resistance associated proteins (MRP-1). Various independent studies have revealed that miR-7 and miR-345 directly bind at the 3'-UTR region of MRP-1 mRNA and decrease their expression levels correlated with resistance to Cisplatin in MCF-7 cells^[64]. Similarly, miR-489 targets MRP-2 and affects the drug ef-

flux in breast cancer cells^[63].

Dysregulation of tumor suppressor miRNAs miR-342 and miR-15a/16 are related to the tamoxifen resistance in HER2 overexpressing tumors. HER2 overexpression is found in approximately 30% of breast cancers and is one of the major factors responsible for the chemoresistance^[11]. A new study revealed that a splice variant of HER2, HER2Δ16 is linked to metastatic breast cancer and chemoresistance^[68]. It was demonstrated that decreased levels of miR-342 and miR-15a/16 expression contribute to tamoxifen resistance by increasing anti-apoptotic protein B-cell lymphoma 2 (Bcl-2) expression in cell lines overexpressing HER2Δ16^[68].

Similarly, expression of miR-34a is also found to be downregulated in breast cancer. It is suggested that the miR-34a is regulated by p53. Breast cancer cell line MDA-MB-231 with low levels of miR-34a was more resistant to radiation therapy compared to cells with elevated levels of miR-34a^[69]. In a separate report, miR-34a was found to be downregulated in multiple breast cancer cell lines. Here it was shown that miR-34a suppresses proliferation and migration by inhibiting Bcl-2 and sirtuin^[70].

Several chemotherapeutic drugs used in the treatment of breast cancer interfere with cellular functions such as DNA repair, cell cycle and apoptosis. Over activation of DNA repair pathways are associated with resistance to chemotherapy^[71]. MiR-373 down regulation is shown to increase DNA repair efficiency and resistance to drugs^[72]. Similarly, miR-21 and miR-141 are also associated with drug resistance, which target the mismatch repair pathway^[73,74]. One of the most studied genes in breast cancer, BRCA1 also achieves drug resistance by inducing repair in double strand DNA breaks generated by anticancer drugs^[75]. The miR-17, miR-182, miR-146 and miR-28 have a potential binding site at the 3'-UTR of BRCA1 transcript^[63,76,77]. Another, miRNA affecting dsDNA repair is miR-302. The expression of miR-302 is associated with radioresistant breast cancer cells. The miR-302 directly inhibits the expression of RAD52 and AKT that are known to provide radioresistance in many cancers including breast cancer^[78] to provide radioresistance in many cancers including breast cancer. The PI3K/AKT is found to be one of the major pathways in various mechanisms to confer radioresistance in breast cancer. RAD52 is important in dsDNA repair mechanism and its activation leads to radioresistance upon down regulation of miR-302^[79].

As mentioned above, miRNA dysregulation can trigger several signaling pathways to alter the levels of various receptors or hormones. The estrogen receptor (ER) is expressed in the vast majority of breast cancers and induces cell proliferation. Anticancer drugs like Tamoxifen inhibit the expression of steroid receptors to prevent ER-driven cell proliferation. Increased expression of miR-221/222 and miR-101 decreases the sensitivity to Tamoxifen in ER-positive tumors^[65]. Overexpression of HER2 (or HER2) is found in approximately 30% of malignant breast cancer patients and known for poor prognosis^[80]. The downregulation of miR-125 and

miR-331 is suggested to be responsible for reduced efficacy of HER2 targeted therapy such as trastuzumab. Both miR-125 and miR-331 can decrease the expression of HER2^[63].

Several genes responsible for induction of breast cancer can be regulated epigenetically, and several of them are known to induce drug resistance in breast cancer cells. Abnormal DNA methylation is one of the major characteristic of cancer cells. DNA methyl transferases DNMT1, 2 and 3 are crucial for DNA methylation. Often levels of DNMTs have been found to be elevated in breast cancer cells. Several recent studies have suggested that miR-148, miR-152, miR-29, miR-194 and miR-143 regulate the expression of various DNMTs in breast cancer, thereby inducing drug resistance^[81-84]. Moreover, it is shown that upregulation of DNMTs leads to the hypermethylation of miRNAs such as miR-148 and represses their expression. Increasing the miR-148 expression resulted in decreased tumor growth and metastasis^[85]. Recent studies clearly demonstrated that miR-143 is downregulated in breast cancer cells and regulates the expression of DNMT3A. Restoring the expression of miR-143 can decrease the phosphatase and tensin homolog (PTEN) hypermethylation^[81]. Other than DNA methylation, aberrant change in chromatin structure can induce drug resistance in cancer cells^[86]. The miR-101 and miR-221/222 upregulation leads to aberrant histone H3 modification and is associated with chemoresistance^[87,88]. Similarly, miR-342 downregulation affects histone demethylation and is associated with Cisplatin resistance^[64].

MiRNA as new diagnostic and prognostic markers

Chances of survival of a breast cancer patient is significantly more when detected at an early stage over late detection^[89]. Moreover, biomarkers which can predict the treatment outcome are also very important in managing breast cancer therapy. Various approaches have been used to identify different biomarkers to diagnose breast cancer at an early stage. In recent years miRNAs have emerged as important diagnostic and prognostic tool in breast cancer research.

Dysregulation of miRNA in breast cancer cells as novel prognostic biomarkers

Other than early detection of breast cancer, prediction of treatment response is also very critical in better outcome of the treatment and patient survival. It was hypothesized that dysregulation of specific miRNAs in breast tumors can be used in determining prognosis of drug treatment in breast cancer patients. Data from various findings with breast tumor samples have supported this hypothesis. In this section role of different miRNAs in breast cancer prognosis is briefly discussed.

A recent study showed that expression levels of miR-10B, miR-21, and miR-335 were higher in 112 breast tumor samples compared to the healthy tissues and directly correlated with disease free survival^[13]. Also, upregulation of miR-21 can be used as prognostic tool for the

lung metastasis of breast cancer^[90]. In this study it was also reported that down regulation of tumor suppressor miR-205 correlates with disease free interval and overall survival^[13]. Recent computational analysis indicated that association of miR-330-3p with MAF mRNA directly correlates with lower survival rates of breast cancer patients^[91]. Further validation of these miRNAs can be useful in identifying reliable prognostic biomarker of breast cancer.

Among all breast cancer patients around 30% patients are HER2 positive and found to have poor prognosis than PR⁺ or ER⁺^[92]. Moreover, around 10% breast cancer patients acquire triple negative (PR⁻/ER⁻/HER2⁻) phenotype with worse prognosis^[77,92]. Finding a better prognostic marker is urgently required for these types of breast cancers. In a study RNA samples of 49 HER2 positive and 48 triple negative breast cancer (TNBC) patients were subjected to the deep sequencing to identify potential prognostic markers of these relatively resistant breast cancers to chemotherapy. This study revealed that patients who developed metastasis, had increased levels of miR-184 and decreased levels of miR-375 and miR-423^[10]. This data suggest that these miRNAs can be used as prognostic markers for HER2⁺ or TNBC breast cancer. Further, research is required to confirm these findings with bigger sample size.

Circulating miRNA as a diagnostic and/or prognostic tool for breast cancer

Specific miRNAs are very stable in serum of various breast cancer patients, making them very valuable targets in early diagnosis of the disease. Recent advances in high-throughput techniques provided an instrumental platform to detect dysregulation of miRNA in serum samples of breast cancer patients. Various studies have identified several miRNA specifically deregulated in the blood plasma of breast cancer patients compared to a healthy individual^[6,9,32]. Moreover, these findings also demonstrated that dysregulation of miRNA in plasma is attributed to the primary tumor site^[6,9,32]. In this section, several of these miRNAs identified as biomarkers of breast cancer diagnosis are discussed.

A recent study has identified miR-571, miR-139-3p, miR-206, miR-193a, miR-526b, miR-519 to be more than 1.5 fold downregulated in breast cancer patients of age 50-53^[9]. In the same study they also found elevated levels of miR-376c, miR-801, miR-148b, miR-424, miR-184, miR-409, miR-376a, miR-190 and miR-127-3p in the blood plasma of breast cancer patients^[9]. It is important to determine that the dysregulation of miRNA found in the serum samples of patients is tumor-derived. To test this, Ng *et al.*^[93] developed a method, in which miRNA levels of serum samples of patients are compared with their tumor samples. During the profiling they found that 8 miRNAs (miR-16, miR-21, miR-27a, miR-150, miR-191, miR-200c, miR-210, miR-451) up-regulated and miR-145 down-regulated in both plasma and tumor tissues in breast cancer patients. Further it was demon-

strated that miR-451, miR-21 and miR-16 levels were significantly elevated in the serum of breast cancer patients compared to the healthy individuals^[93]. Interestingly miRNA levels measured in the postoperative samples were drastically lowered when compared with preoperative samples. These findings indicate that miRNAs from serum samples can be used as diagnostic tool in breast cancer^[9,93].

Another recent study found that miR-18a, miR-181a and miR-222 showed the highest percentage difference in the serum samples of 205 women who eventually developed cancer and 205 women who remained cancer free^[94]. This study shed light on detecting miRNAs which can predict increased risk of getting breast cancer. Together all these results clearly demonstrates that using the high-throughput methods, dysregulation of miRNA can be used as a diagnostic tool in various cancers including breast cancer to predict disease progression, risk of metastasis and/or treatment outcome^[9,93,94].

Few reports have suggested that a limited number of specific miRNAs detected in blood plasma can also be used as both diagnostic and prognostic marker of breast cancer. One study demonstrated that miR-155 levels are significantly higher in 81.9% breast cancer patient samples and is an excellent diagnostic marker. After surgical removal of breast tumor and four rounds of chemotherapy, 79% of patients exhibited reduced levels of miR-155 and sustained treatment response^[95]. In the blood plasma elevated levels of miR-200a/b/c, miR-203 and miR-210 were also shown to have prognostic significance in breast cancer patients^[96].

TARGETING MiRNAs FOR BREAST CANCER TREATMENT

So far we established that several miRNAs are play critical role in breast cancer initiation, progression and metastasis, and thus become attractive targets for therapy^[31,49,79]. Various research groups have demonstrated different approaches to regulate these target miRNA expression to improve therapy. Two distinct ways miRNA based therapy can be utilized as anticancer treatment: (1) by antagonizing oncogenic miRNA; or (2) by enhancing expression of tumor suppressor miRNAs.

Antagonizing oncogenic miRNA in breast cancer

There are various approaches being utilized to inhibit oncogenic and metastatic functions of miRNA. One of the most obvious strategies is to silence these oncogenic miRNAs using an anti-microRNA oligonucleotide (AMO) to prevent interaction with their target proteins. The AMO competes with the target mRNA of oncogenic miRNAs and inhibits their function^[17]. These anti-sense miRNAs are chemically modified to increase their stability in the system. These chemical modifications also make them more stable in the hybridization state^[7].

Use of anti-sense RNA of miR-10b in mouse reduced mammary tumor metastasis^[17]. It was clearly observed that

upon treatment with AMO against miR-10b decreased the levels of miR-10b significantly and by simultaneously increased the levels of its target, HOXD10. Also, it was observed that anti-sense miR-10b did not reduce the size of primary tumor but prevented lung metastasis. These results suggest that anti-miR-10b can be a good candidate as an anti-metastatic agent but might not be useful in reducing primary tumor burden in breast cancer^[17].

Another strategy used in miR-therapeutics is modification of 2'-hydroxyl to 2'-O-methyl in ribonucleotide. This chemical modification also prevents the degradation of these miRNAs and improves their stability. The anti-sense of oncogenic miR-21 is used in the xenograft carcinoma model using MCF7 breast cancer cells. It was observed that mice treated with anti-miR-21 had half the size of tumors when compared to the control group^[97]. The miR-21 is an oncogenic miRNA and known to induce cell proliferation by targeting PTEN. Using 2'-O-methyl antisense oligonucleotide only destabilizes the mRNA and does not degrade them. Therefore, any change in their levels can be measured only by measuring the levels of their targets^[98].

Another novel method to inhibit miRNAs was introduced as an alternative to the chemically modified AMO. Here, miRNA-inhibitors are directly expressed in cells under the strong promoter which contains multiple sites complementary to the target miRNA and are known as "miRNA sponges"^[99]. Utilizing this novel approach a very recent investigation have revealed that inhibition of miR-22 by providing complementary binding site *via* reporter gene in 3'UTR reduced the cell migration and metastatic phenotype of breast cancer cell line LM2. Oncogenic miR-22 is known to increase breast cancer metastasis and stemness. Moreover, using same approach inhibition of miR-22 also led to the inhibition of breast cancer metastasis *in vivo*^[100].

Several studies have made it apparent that dysregulation of multiple miRNAs seems to be responsible for oncogenesis and/or metastasis. Thus targeting single miRNA might not be sufficient to achieve the optimal result in inhibiting cancer progression. To address this issue, a novel method has been proposed where AMO is designed to target more than one miRNA. In a study it was shown that a longer multiple target AMO (MTg-AMO_{21/155/17}) decreased the cell viability of MCF-7 cancer cells to 18% at 10 nmol/L concentration. To achieve the similar levels of cell death by individual AMOs against miR-21, miR-155 or miR-17 required 10 times higher concentration of AMOs. These results indicated that targeting multiple miRNAs by longer AMOs can be a better approach to inhibit the disease progression^[101].

Recently, libraries of active clinical small molecule compounds have been tested for their ability to inhibit specific miRNA of interest^[102,103]. A recent finding demonstrated that levels of miR-21 were effectively reduced by the small molecule inhibitor "azobenzene"^[102]. Similarly, another study identified two small molecule inhibitors polylysine and tryptaflavine as effective inhibitors of various onco-

genic miRNAs and attenuation of tumorigenesis^[103].

Another novel approach in miRNA antagonism is by using peptide nucleic acid (PNA) as a miRNA inhibitor. Chemically in PNA the sugar-phosphate backbone is replaced by N-(2-aminoethyl) glycine, which makes them efficient hybridization agent resistant to DNases and proteases. In aggressive breast cancer cells PNAs targeting miR-221 and miR-210 reduced the levels of miR-221 and miR-210 respectively. Also, inhibition of these miRNAs resulted in the elevated levels of a major apoptosis player p27Kip1^[104]. Treatment with PNA targeting miR-21 showed inhibition of tumorigenesis of MCF-7 breast cancer cells in female nude mice compared to the control group of mice^[105].

Restoration of tumor suppressor miRNAs

Several tumor suppressor miRNAs are shown to be downregulated in various types of cancers. It is proposed that restoring their levels should be beneficial in inhibiting cancer progression. One approach to restore the tumor suppressor miRNA in cancer cells is by using the miRNA mimics. A study demonstrated that in aggressive breast cancer cell MDA-MB-231 restoring the levels of miR-200c using the miR-200c mimic results in reduced cell proliferation, invasion and migration^[106]. Similarly, in breast cancer cells increasing the levels of let-7 miRNA by let-7-lentivirus infection reduced the cell proliferation and mammospheres formation^[33].

CONCLUSION

Accumulating evidences supports that dysregulation of specific miRNAs is crucial in breast cancer progression. Targeting these miRNAs can have tremendous potential in breast cancer diagnosis and treatment. This review summarizes the impact of various deregulated miRNAs in breast cancer progression, metastasis and angiogenesis. Understanding the molecular mechanisms of these miRNAs with their target genes is critical in utilizing them as a therapeutic tool. To manage more aggressive types of breast cancers, other than development of novel therapies, early diagnosis and prognosis markers are urgently required. Recently, various online databases of miRNA targets are made available to predict the role of specific miRNA in regulating biological pathways. Better use of these databases can save a lot of time and efforts for clinical research in finding better target miRNA for cancer therapeutics or diagnosis. Also, for future a better collaboration among clinicians and researchers is required to develop novel miRNA based anti-cancer therapies.

Several publications have indicated that differences in specific miRNA levels among blood plasma samples of breast cancer patients compare to the healthy individuals can be used as diagnostic markers of breast cancer. However, it is not fully understood that, what is the source of these miRNAs? And how are they released in the blood stream? Future research is necessary to find this mechanism to develop better diagnostic tools using miRNAs.

Despite of all the advances, miRNA based therapy faces some stiff challenges. One of them is specificity. Also, therapeutic miRNAs are subjected to degradation. This results in inefficient treatment in cancer cells. Further research is required to address these issues to improve their specificity and enhancing efficiency of treatment. Moreover, future research warranted to improve delivery of these miRNA to prevent their degradation^[1,80].

Studying the function of various miRNAs in different biological pathways have improved our understanding of their role in cancer development. Also, several studies have shown very encouraging data in breast cancer treatment using miRNA both *in vitro* and *in vivo*. Despite of these successes it is believed that, it will take several years for miRNA based therapy to enter clinics to treat human cancers because of the limitations we discussed above^[1,107].

Abstract

Early detection and diagnosis of breast cancer are essential for successful treatment. Currently mammography and ultrasound are the basic imaging techniques for the detection and localization of breast tumors. The low sensitivity and specificity of these imaging tools resulted in a demand for new imaging modalities and breast magnetic resonance imaging (MRI) has become increasingly important in the detection and delineation of breast cancer in daily practice. However, the clinical benefits of the use of pre-operative MRI in women with newly diagnosed breast cancer is still a matter of debate. The main additional diagnostic value of MRI relies on specific situations such as detecting multifocal, multicentric or contralateral disease unrecognized on conventional assessment (particularly in patients diagnosed with invasive lobular carcinoma), assessing the response to neoadjuvant chemotherapy, detection of cancer in dense breast tissue, recognition of an occult primary breast cancer in patients presenting with cancer metastasis in axillary lymph nodes, among others. Nevertheless, the development of new MRI technolo-

gies such as diffusion-weighted imaging, proton spectroscopy and higher field strength 7.0 T imaging offer a new perspective in providing additional information in breast abnormalities. We conducted an expert literature review on the value of breast MRI in diagnosing and staging breast cancer, as well as the future potentials of new MRI technologies.

INTRODUCTION

Breast cancer is the most common malignant disease

occurring in women worldwide with a lifetime risk of 12.4%^[1,2]. Early detection and diagnosis of breast cancer are prerequisites for successful treatment selection. Although mammography and ultrasound are the most commonly imaging tools used for the detection and characterization of breast abnormalities, the relatively low sensitivity and specificity of these techniques (especially in patients with dense breast tissue, with breast implants or postsurgical scar distortions)^[3-6] resulted in a demand for new imaging modalities. Contrast enhanced magnetic resonance imaging (CE-MRI) with its high soft tissue contrast, multiplanar sectioning and three dimensional representation of the breast provides high sensitivity (over 90%) in the detection of breast cancer. However, the specificity for lesion characterization is still low to moderate (72%)^[7-19], turning the discrimination between cancer and benign lesions into a challenge. The main additional diagnostic value of MRI relies on (1) detecting foci of multifocal, multicentric or contralateral disease unrecognized on conventional assessment (physical examination, mammography and ultrasound); (2) recognition of invasive components in ductal carcinoma in situ (DCIS); (3) assessing the response to neoadjuvant chemotherapy (NAC); (4) detecting an occult primary breast cancer in patients presenting with metastatic cancer in axillary nodes; and (5) detection of cancer in dense breast tissue^[14,20-26]. The development of new technologies has also resulted in information gain concerning breast lesions. We reviewed the recent literature to clarify the role of MRI in diagnosing and staging breast cancer with focus on the implementation of new techniques, such as MR spectroscopy, diffusion-weighted imaging (DWI) and higher field strength 7.0 T imaging.

SEARCH

In this expert literature review, we conducted a literature search on Pubmed in papers published between 1990 and 2013 using the keywords “breast”, “MRI”, “staging”, “spectroscopy”, “diffusion-weighted imaging” and “high field breast MRI”. Articles published in English pertaining to adult humans with available abstracts were included. References of articles were also included. First we present main guidelines on the use of MRI in diagnosing and staging of breast cancer and, subsequently, we will discuss the new technologies currently available for research.

RESULTS

Detection of additional disease

The main evidence in favor of MRI is based on the superior capability of this technique in detecting ipsilateral and contralateral disease, when compared to mammography and ultrasound (Figure 1)^[21,26,27]. In a prospective trial, Schelfout *et al.*^[26,27] found that MRI detected 96% of multifocal/multicentric disease, while mammography and ultrasound depicted only 28.6% and 26.5%, respec-

Figure 1 Magnetic resonance imaging scanner with closed bore magnet and a dedicated 8 channel phased-array breast coil (top right). Technically any magnetic resonance imaging scanner could be used in breast image acquisition. However, in daily practice, field strengths of 1.5 T and 3 T are often used due to higher spatial resolution at similar temporal resolution, providing better diagnostic efficacy.

tively. Taking the histological types of breast cancer into account, invasive lobular carcinoma (responsible for 5% to 15% of all cases of invasive breast cancers)^[28-30] is well known to have a higher incidence of multifocal, multicentric and contralateral disease when compared to invasive ductal carcinoma. MRI is, therefore, particularly important in the preoperative work-up and staging of these patients^[7,11,12,30-32]. In a recent retrospective study, Menezes *et al.*^[33] also found a high incidence of multifocal, multicentric and contralateral disease in patients with mixed tumors containing different percentages of lobular component. This might corroborate the hypothesis that MRI would also be valuable in the work-up of patients with mixed breast tumors (Figure 2). MRI also has shown higher accuracy in determining tumor size (correlated to histopathology) than ultrasound or mammography^[26]. However, some studies emphasize that MRI tends to overestimate lesion size, particularly in patients diagnosed with invasive lobular carcinoma and DCIS^[34-38].

An additional value of MRI is the detection of invasive component in DCIS lesions. In a retrospective study, Kim *et al.*^[38] concluded that MRI was more accurate for the detection and assessment of the size of DCIS than mammography. In a prospective cohort, Hwang *et al.*^[22] demonstrated MRI to be superior to mammography in detecting invasive components in patients diagnosed with DCIS. MRI also showed a higher sensitivity and superior negative predictive value for detection of residual DCIS. However, the small number of patients in this study (51) might not be representative of a large population with DCIS. Further research might be necessary in order to confirm the use of MRI in detecting invasive component in DCIS.

Patients with an increased risk

MRI has an important role in screening high-risk patients. The American Cancer Society Guidelines for the Early Detection of Cancer advises annual breast MRI beginning at the age of 25-30 years in patients carrying

Figure 2 A 48-year-old woman, with positive family history for breast cancer, presented with a palpable lump on the left breast, finally diagnosed as invasive ductolobular carcinoma. A: Sagittal contrast-enhanced fat-suppressed T1-weighted gradient echo images obtained at 3 T shows a spiculated mass, with rim enhancement and small satellite lesion (multifocal disease); B and C: Color parametric enhancement map in axial postcontrast maximum intensity projection and sagittal projection indicates predominantly a plateau enhancement behavior, with some areas of washout.

a *BRCA* gene mutation, in women who are untested but have a first-degree relative with a *BRCA* mutation and women with an approximately 20% to 25% or greater lifetime risk of breast cancer^[39-41]. In a cohort of 496 women, Passaperuma *et al.*^[42] concluded that MRI surveillance of women with *BRCA* mutations detects most breast cancers at an early stage. Although the results of this study are promising, data on longer-term follow up is needed in order to encourage MRI surveillance as a safe alternative to prophylactic mastectomy. Likewise, patients diagnosed with breast cancer under the age of 50 have a 20% lifetime risk of recurrence (even after radiotherapy to the tumor bed following surgical approach)^[43,44]. In

these particular cases, the European Society of Breast Imaging also recommends annual MRI screening^[45].

Patients with dense breast parenchyma

Additional MRI can be beneficial in patients with dense breast parenchyma. Mammography has a high false negative rate in patients with dense breast tissue^[46-49], and the sensitivity remains low in dense breasts even when computer-aided detection is applied to digital mammography^[50]. In a large multicenter study, Schnall *et al.*^[51] proved that MRI has superior capability to detect additional occult cancer foci when compared to mammography, particularly in women with radiographically dense breasts and larger index cancers (18% *vs* 7.2%). Many other studies confirm that MRI has the highest diagnostic value when used in patients with heterogeneous or extremely dense breast parenchyma^[21,26,27]. The European Breast Imaging Society also advises the use of pre-operative MRI in staging malignant lesions in patients with dense breast tissue^[45]. MRI also has a substantial advantage in detecting breast lesions in scattered fibroglandular breast parenchyma^[20,52,53].

Impact on treatment

Despite all advantages of MRI, there is no consistent evidence supporting the clinical benefit of pre-operative MRI for all patients with breast cancer. In the MONET trial, 418 patients with non-palpable BI-RADS 3-5 lesions were randomized to undergo routine clinical care (211 patients) or standard clinical care associated to contrast enhanced MRI (207 patients) prior to large core needle biopsy^[54,55]. In total 74 patients had 83 malignant lesions in the MRI group and 75 patients had 80 malignant lesions in the control group. The choice of prioritizing non-palpable breast tumors was based on the difficulty in determining the margins of a lesion that cannot be seen or palpable during surgery. Thus, additional surgical intervention is often required in those cases. The authors hypothesized that the use of CE-MRI of the breast would reduce the need of additional surgical procedure, once MRI would add important three-dimensional information about the lesion, would be an important tool in defining tumor margins and in detecting multifocal and multicentric disease.

Surprisingly the re-excision rate due to positive resection margins after breast conserving therapy was even higher in the MRI group (34%) than in the control group (12%). Also the rate of additional surgical interventions after initial breast conserving therapy was higher in the MRI group than in the control group (45% *vs* 28%), although significance was not reached ($P = 0.069$). The COMICE trial attempted to determine whether the addition of breast MRI in 1623 breast cancer patients proven by triple assessment (clinical, radiological and pathological) would aid tumor localization and reduce re-operation rates. Patients were randomized to undergo or not MRI. The results showed no difference in the re-operation rates between the study arms (18.8% in patients who un-

derwent MRI *vs* 19.3% in patients who did not undergo MRI). The economic analysis of this trial showed no significant difference in cost-effectiveness between the research arms. The addition of MRI to triple assessment did not reduce the re-operation rates, and the use of MRI consumed extra resource with few benefits^[56]. Differently from the MONET study, the COMICE trial included patients with breast cancer proved by biopsy and most patients presented with palpable tumors. Both trials have a high level of evidence and, in both studies, the authors admonished the use of pre-operative breast MRI as a routine clinical care in patients with non-palpable breast cancer^[55]. Up to now, the results of these randomized controlled trials discourage the standard use of pre-operative MRI in all patients with breast cancer.

TECHNOLOGICAL DEVELOPMENTS AND ONGOING RESEARCH

Morphologic assessment can be a subjective task. It is strongly related to the experience of the radiologist and it is vulnerable to interobserver variations (especially in small lesions and nonmass-like lesions). An adjunct method which could provide a higher specificity would be of value. The use of new available technologies, such as breast MR spectroscopy and DWI is being verified in order to improve the accuracy and specificity of CE-MRI^[57-60].

Diffusion weighted imaging

DWI is a non-invasive MRI technique that measures the mobility of water molecules in tissue, providing information such as cellular density, viscosity, membrane integrity, and tissue microstructure, without the need of contrast injection^[59,61]. DWI is able to differentiate between tissue types based on the use of the apparent diffusion coefficient (ADC). Malignant breast tumors usually have a higher cellularity and generally present with restricted water diffusion and lower ADC values when compared to benign lesions^[62,63]. CE-MRI enables the assessment of morphological and kinetic patterns of benign and malignant breast tumors, but has a low specificity and high false-negative rates^[17,64,65]. The use of DWI is being considered as a new approach in order to improve the sensitivity and specificity of breast lesion characterization and may be incorporated into routine breast MRI assessment of breast lesions. In a retrospective study, El Khoully *et al*^[66] selected 93 women with 101 lesions (68 malignant tumors and 33 benign tumors) who underwent MRI using a 3.0 T magnet and both CE-MRI and DWI were performed. The association of DWI with ADC significantly improved the diagnostic performance and lesion characterization when compared to conventional 3D T1-weighted and CE-MRI at 3.0 T. In a study with 70 patients, Partridge *et al*^[67] showed that CE-MRI added to ADC criteria providing a superior positive predictive value than contrast enhanced MRI alone (47% *vs* 37%). Tan *et al*^[68] analyzed 44 breast lesions (31 malignant and 13 benign) on 3.0 T MRI. The cut-off ADC values

for benign and malignant lesions were $1.21 \times 10^{-3} \text{ mm}^2/\text{s}$ for $b = 500 \text{ s/mm}^2$ and $1.22 \times 10^{-3} \text{ mm}^2/\text{s}$ for $b = 1000 \text{ s/mm}^2$, respectively. Although the authors had a small sample size, the values obtained between ADC values of benign and malignant lesions were significant ($P < 0.001$). The sensitivity of CE-MRI was 100% with a specificity of 66.7%. CE-MRI combined with $b = 1000 \text{ s/mm}^2$, showed a specificity of 100% and a sensitivity of 90.6%. There was no significant between ADC values and prognostic factors^[68]. Marini *et al*^[69] investigated 81 breast lesions. Considering a mean diffusivity threshold value of $1.1 \times 10^{-3} \text{ mm}^2/\text{s}$, malignant lesions were differentiated from benign lesions with a sensitivity of 80% and specificity of 81%. A meta-analysis from Chen *et al*^[70] described 964 lesions (maximum $b = 1000 \text{ s/mm}^2$, 95%CI, area under curve of summary receiver operating characteristic 0.9085). ADC measurement of DWI showed a sensitivity and specificity of both 84% to differentiate between benign and malignant lesions. DWI also has the advantage of not requiring the use of intravenous contrast and the use of this technique could be an alternative to CE-MRI. For example, in a retrospective study with 118 breast lesions (12 DCIS, 15 invasive carcinomas and 91 benign lesions), 89% of malignant breast tumors were found to be clearly hyperintense on DWI. ADC values helped in differentiating malignant from benign lesions. In a study of Yabuuchi *et al*^[71], the authors compared the detection of non-palpable breast cancers in mammography, DWI and CE-MRI. DWI was significantly more accurate than mammography, although it has shown to be not as accurate as CE-MRI.

The use of DWI in patients with DCIS has also been described. Partridge *et al*^[72] reported that ADC values of DCIS were lower when compared to benign lesions and invasive carcinoma. Rahbar *et al*^[73] found 96% of pure DCIS lesions to be hyperintense in DWI.

Considering pre-treatment prediction of response to NAC in breast cancer patients, results suggest DWI associated to ADC to be useful for predicting tumor response. Park *et al*^[74] performed DW-MRI (1.5 T, b values 0 and 750 s/mm^2) and CE-MRI of 53 invasive breast cancers before and after chemotherapy prior to surgery. The percentage of ADC increase in responders was bigger than in non-responders ($P < 0.001$), the best cutoff to differentiate responders from non-responders was $1.17 \times 10^{-3} \text{ mm}^2/\text{s}$ (sensitivity of 94% and a specificity of 71%).

Sharma *et al*^[75] assessed the response of 56 patients with breast malignant lesions at four different times, before and after three cycles of NAC. ADC has shown a statistically significant change in volume and diameter in responders (sensitivity 68% and specificity 100%) and the authors suggested ADC would be useful in predicting early tumor response. According to Pickles *et al*^[76], significant alterations on ADC could be observed even before changes in tumor size in patients undergoing chemotherapy. Therefore the authors suggested that DWI might have the ability to provide indication of response to treatment, preceding changes in tumor size.

Proton spectroscopy

Spectroscopy is an additional non-invasive method that can provide chemical information from a selected region in the body. In clinical practice, spectroscopy is used mainly for brain applications and prostate cancer^[77,78]. Breast cancer spectroscopy is slightly behind that of prostate in development and in determining the suitability of this technique for clinical practice.

In mammary gland area, total choline (tCho), or just Cho, is considered the most important metabolite in proton MR spectroscopy. Many different metabolites overlap and contribute to the Cho peak, such as choline, phosphocholine, glycerophosphocoline, taurine and myo-inositol, among others^[79-81]. The Cho peak is centered at 3.2 ppm.

Cholines are precursors of phospholipids which are components of cell membranes and increased Cho signals are associated with increased cellular turnover^[82-84].

The use of breast MR spectroscopy to distinguish between benign and malignant lesions (using elevated tCho level as an indicator of malignancy) can potentially improve the accuracy of an MRI scan by offering increased specificity. In a recent systematic review and meta-analysis, Baltzer *et al.*^[85] included 19 studies with 1183 patients in order to evaluate the diagnostic performance of spectroscopy in differentiating breast lesions in field strengths of 1.5 and 3.0 T. They found a high pooled specificity (88%) and sensitivity (73%). Higher field strength, post contrast acquisition or qualitative *vs* quantitative MR spectroscopy had no significant influence on the results. Katz-Brull *et al.*^[86] performed a similar meta-analysis and found a combined sensitivity and specificity of 83% and 85%, respectively.

In a study with 184 patients with breast cancer, Shin *et al.*^[87] have shown that the use of absolute tCho-containing compound peak integral, normalized tCho-containing compound integral, and signal-to-noise-ratio determined by spectroscopy could be valuable in differentiating between IDC and DCIS. These same parameters could also be useful in determining tumor aggressiveness.

Many researchers suggest measurements of tCho with breast spectroscopy to be useful to monitor the response to NAC.

In a recent study, Tozaki *et al.*^[81] concluded that changes in Cho after NAC determined by ¹H MR spectroscopy are more sensitive to predict the pathological response than changes in the tumor size. Meisamy *et al.*^[88] used a 4 T strength field to evaluate the concentration of tCho in patients diagnosed with breast cancer before NAC, within 24 h after the first dose and after the fourth dose. Twenty-four hours after the first dose there was a significant variation in concentration of tCho (compared to baseline) and this change had a significant positive correlation with the change in lesion size ($P = 0.001$). The change observed in tCho concentration after first dose of NAC was significantly different between responders and non-responders ($P = 0.007$).

Jacobs *et al.*^[89] evaluated NAC response using magnetic

resonance spectroscopy, and ²³Na magnetic resonance. According to the authors, multiparametric and multi-nuclear imaging parameters were reduced after the first cycle of NAC in responders, specifically, Cho signal-to-noise ratio and sodium ($P \leq 0.01$).

To evaluate if applying DWI and spectroscopy together would help to improve the differentiation of breast lesions at 3.0 T, Tsougos *et al.*^[90] selected 51 women with known breast abnormalities (18 benign lesions and 33 malignant lesions). DWI and spectroscopy together provided higher accuracy and higher specificity for the differentiation between malignant and benign lesions when compared to these techniques used separately.

High field breast MRI at 7.0 tesla

Recently, high-field MRI (7.0 T) has become available for research. 7.0 T MRI has an inherent advantage over lower field's strengths and is, therefore, able to provide better signal to noise ratio, improve morphology assessment of breast lesions and increase the modality's sensitivity and specificity (Figure 3)^[57,58,60]. However, there are limitations in the use of 7.0 T. Higher magnetic field results in longer T1 relaxation time, shorter T2* decay time, greater radiofrequency, specific absorption rate, and increased B1 + field inhomogeneity. Nevertheless, some studies indicate that these disadvantages can be overcome.

Stehouwer *et al.*^[57] observed 7.0 T images in 20 patients with 23 suspicious breast lesions. The radiologist correctly identified all malignant tumors (BI-RADS 4 or 5) and in most cases image quality was considered good or excellent by both radiologists.

Field strength is considered an important factor affecting sensibility of spectroscopy. Particularly, 7.0 T is expected to provide increased signal to noise ratio and achieve more accurate information between closely overlapping resonances in the spectral domain^[57,58,60,91,92]. In a recent study, Korteweg *et al.*^[92] selected 3 patients who received NAC and tried to establish if DWI and spectroscopy could provide diagnostic information in breast cancer patients. One of the patients had nonspecific reaction to NAC and, during the whole NAC course, an increment of values of ADC was observed, suggesting either tumor responsiveness or cystic development/tumoral necrosis. In addition a decrease in Cho concentration during NAC cycles was reported, which could also mean responsiveness of the tumor. After the last NAC course, Cho concentrations and tumor size increased, suggesting acquired resistance to treatment. Pathology assessment confirmed this hypothesis. A second patient had no visible index lesion on 3.0 T or at 7.0 T and Cho was undetectable on both examinations. No tumor was observed in pathologic analysis, which is suggestive that NAC was effective. Even low Cho levels (0.77 mmol/kg-water) were detected, suggesting high sensitivity of 7.0 T in detecting alterations in Cho Metabolism.

7.0 T is still in its early stages and studies with larger number of patients are required in order to confirm these results and check clinical applications.

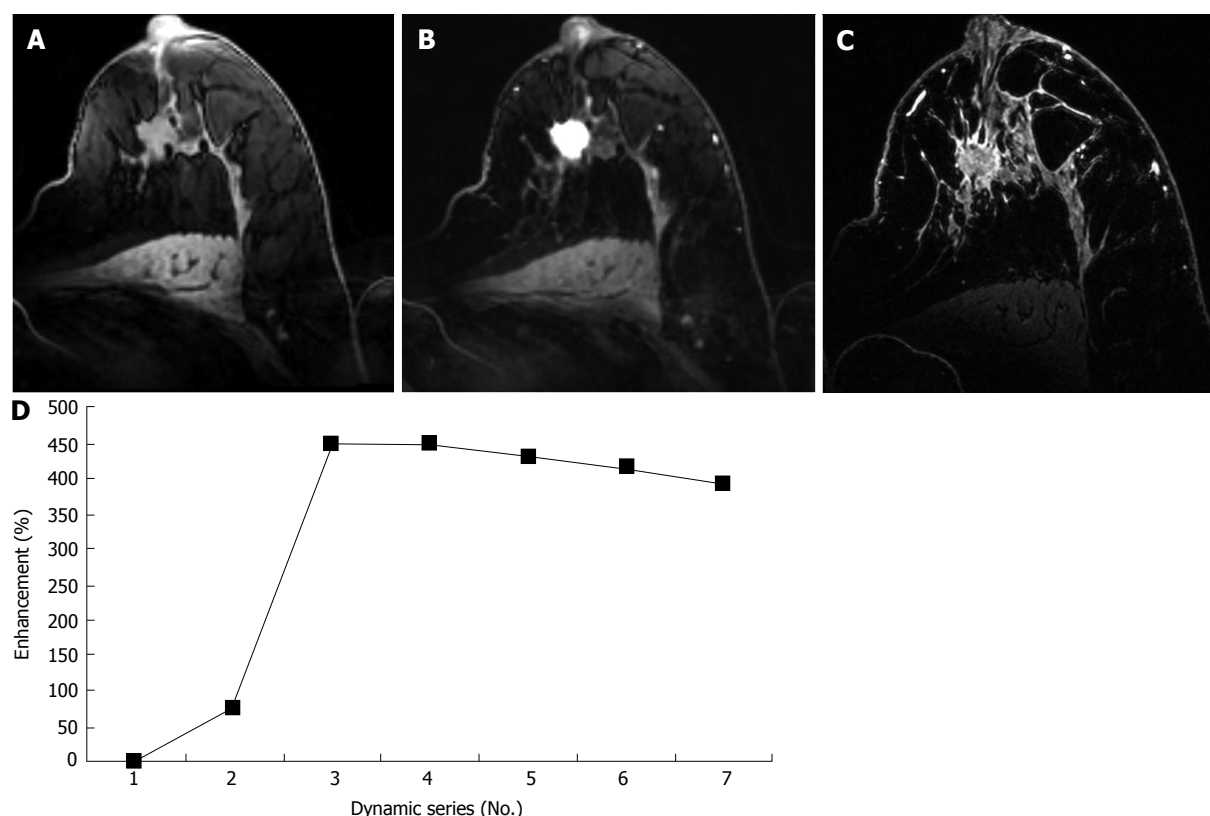

Figure 3 A 62-year-old patient with nipple withdrawal, finally diagnosed as ductolobular carcinoma. A, B and C: Axial T1-weighted gradient-echo images obtained at 7 T before and after contrast injection. An irregular mass with spiculated margins can be observed on pré-contrast imaging (A). An intense homogeneous enhancement (B) and a rapid wash-out kinetic curve (D) can be observed following contrast administration. In Figure 3C, an ultra-high-resolution T1-weighted gradient-echo sequence with fat suppression was performed, and the morphological aspects of the lesion can be more clearly seen.

CONCLUSION

To date, pre-operative MRI is indicated in defined groups of patients in which a potential benefit of local staging is expected, *i.e.*, women with mammographically heterogeneous or extremely dense breasts, at high risk for breast cancer, diagnosed with invasive lobular carcinoma and/or with multifocal, multicentric or contralateral disease^[93-95]. These recommendations are based on high-quality randomized controlled trials with narrow confidence intervals and on The American Cancer Society Guidelines for the Early Detection of Cancer and on the Guidelines from the European Breast Imaging Society^[45,55,56,95]. MR spectroscopy, DWI and 7.0 T MRI of the breast are promising, but the clinical value of these techniques still remains unclear mostly due to the fact that the number of studies investigating these techniques is small and they are still in early stage. Larger studies with more statistical power are necessary to confirm the clinical value and the cost-benefit of these new modalities.

INTRODUCTION

Breast cancer (BC) is the most frequent type of non skin cancer among women and a major leading cause of cancer-related deaths in women in Western countries^[1-3]. One in eight women has a chance of developing BC once in her lifetime^[4,5]. Early diagnosis and a followed patient-monitored therapy can lead to successful treatment of BC. However, due to the lack of sensitivity and specificity of known biomarkers, especially in early stage disease, there is no available efficient biomarker up to now for screening or early detection of BC^[6,7].

Micro-RNAs (miRNAs or miRs) belong to a novel class of endogenous interfering RNAs that play a crucial role in post transcriptional gene silencing through messenger RNA (mRNA) targeting and are thus involved in many biological processes encompassing apoptosis, cell-cycle control, cell proliferation, DNA repair, immunity, metabolism, stress, aging, *etc*^[8].

Since their initial discovery in 1993 during a study of the gene *lin-4* in *Caenorhabditis elegans*^[9], more than 2000 molecules have been determined in humans so far, regulating the expression of almost 30% of genes^[10]. MiRNAs are short, non-coding RNAs of approximately 20-25 nucleotides in length that are transcribed either from independent genes or from exons or introns of protein-coding genes^[8]. MiRNAs present unique nucleotide sequences that are strongly conserved among species^[11] and possess a specific critical region of 7 nucleotides long, known as the seed sequence, which is responsible for mRNA base pairing^[8]. Their abundant repertoire and the fact that the seed is so short may explain their combinatorial character in regulation: a given miRNA may target different mRNAs and a given mRNA could similarly be targeted by multiple miRNAs^[12].

MiRNA biogenesis is initiated in the cell nucleus with the generation of primary miRNA (pri-miRNA), usually by RNA polymerase II. The next step is the conversion of pri-miRNA into a smaller hairpin precursor miRNA (pre-miRNA) which is arbitrated by the microprocessor complex^[8]. The latter consists of the ribonuclease Drosha and the DiGeorge syndrome critical region in gene 8 protein that recognizes the hairpin loop of the pri-miRNA, ensuring unfaulty cleavage by Drosha. Pre-miRNAs are transported to the cytoplasm by the receptor exportin 5, whereas new cleavage occurs by the RNase III enzyme Dicer along with the transactivation response RNA-binding protein, resulting in a double stranded miRNA about 22 nucleotides long^[8,13]. One strand of the miRNA/miRNA duplex represents the mature miRNA which in conjunction with the Argonaute (Ago) protein and other proteins form the RNA-induced silencing complex (RISC)^[13]. Within RISC, mature miRNA is guided mainly to complementary sequences in 3' or 5' untranslated region of mRNA targets, open reading frames and promoter regions^[14]. Depending on the perfect or partial base pairing between miRNA and mRNAs molecules, the consequence is mRNA degradation or translational repression at both pre-initiation and post-

initiation stages, respectively; leading, thus, to a negative regulation of gene expression^[15]. However, studies have also shown a possible miRNAs involvement in positive regulation of their target genes (transcriptional and translational activation)^[16].

MiRNAs, as major gene-expression regulators, are implicated in the pathogenesis of many diseases, including cancer^[17]. The specific aberrant expression patterns of miRNAs in several cancer types, such as BC, that are detected with the use of high-throughput technologies reflect their key role in cancer initiation, progression, migration, invasion and metastasis^[18]. MiRNAs exert their action mainly in a tumor suppressive or oncogenic manner^[19].

The purpose of this review is to explore the ontological role of miRNAs in BC etiopathogenesis as well as to highlight their potential, not only as non-invasive circulating biomarkers with diagnostic and prognostic significance, but also as treatment response predictors and therapeutic targets aiding BC management.

ROLE OF MiRNAs IN BC ETIOPATHOGENESIS

Aberrant expression of miRNAs in BC

MiRNA expression profiling studies have detected aberrations with specific signatures of miRNA expression in breast carcinoma^[20]. Certain miRNA expression signatures have been associated with tumor classification, stage and prognosis, while others have been useful in detecting the primary site of tumors of unknown origin^[21].

Accumulating evidence has revealed that miRNAs may act either as oncogenes, commonly named oncomirs, by suppressing the expression of tumor suppressor genes or genes responsible for apoptosis; or as tumor suppressors or oncosuppressors by inhibiting genes that promote carcinogenesis and therefore controlling apoptosis and differentiation. Nevertheless, this miRNA categorization in oncogenes with an upregulated profile and tumor suppressors with a downregulated profile may be inaccurate, as many studies have shown that miRNAs may present a dual function with oncogenic or tumor suppressive properties based on tumor type and cellular context^[22].

In Figure 1, we have included a list of the most important miRNAs acting as oncogenes or tumor suppressors in BC. MiR-21 appears as a significant BC-related intracellular and extra-cellular biomarker and a therapeutic target with upregulated expression detected in human BC tissues and cell lines, playing a key role in all phases of BC pathogenesis^[23,24]. In BC clinical specimens, miR-21 increased expression was associated with advanced clinical stage, lymph-node positivity and shorter survival^[20]. Another example of a miRNA associated with an oncogenic potential in BC is miR-155, whereas the upregulation of miR-155 was correlated with advanced grade, clinical stage, estrogen receptor (ER) negative tumors, lymph node invasion, metastasis and poor prognosis^[25]. However, miR-21 and miR-155 increased expression do not characterize only BC but also colorectal and lung

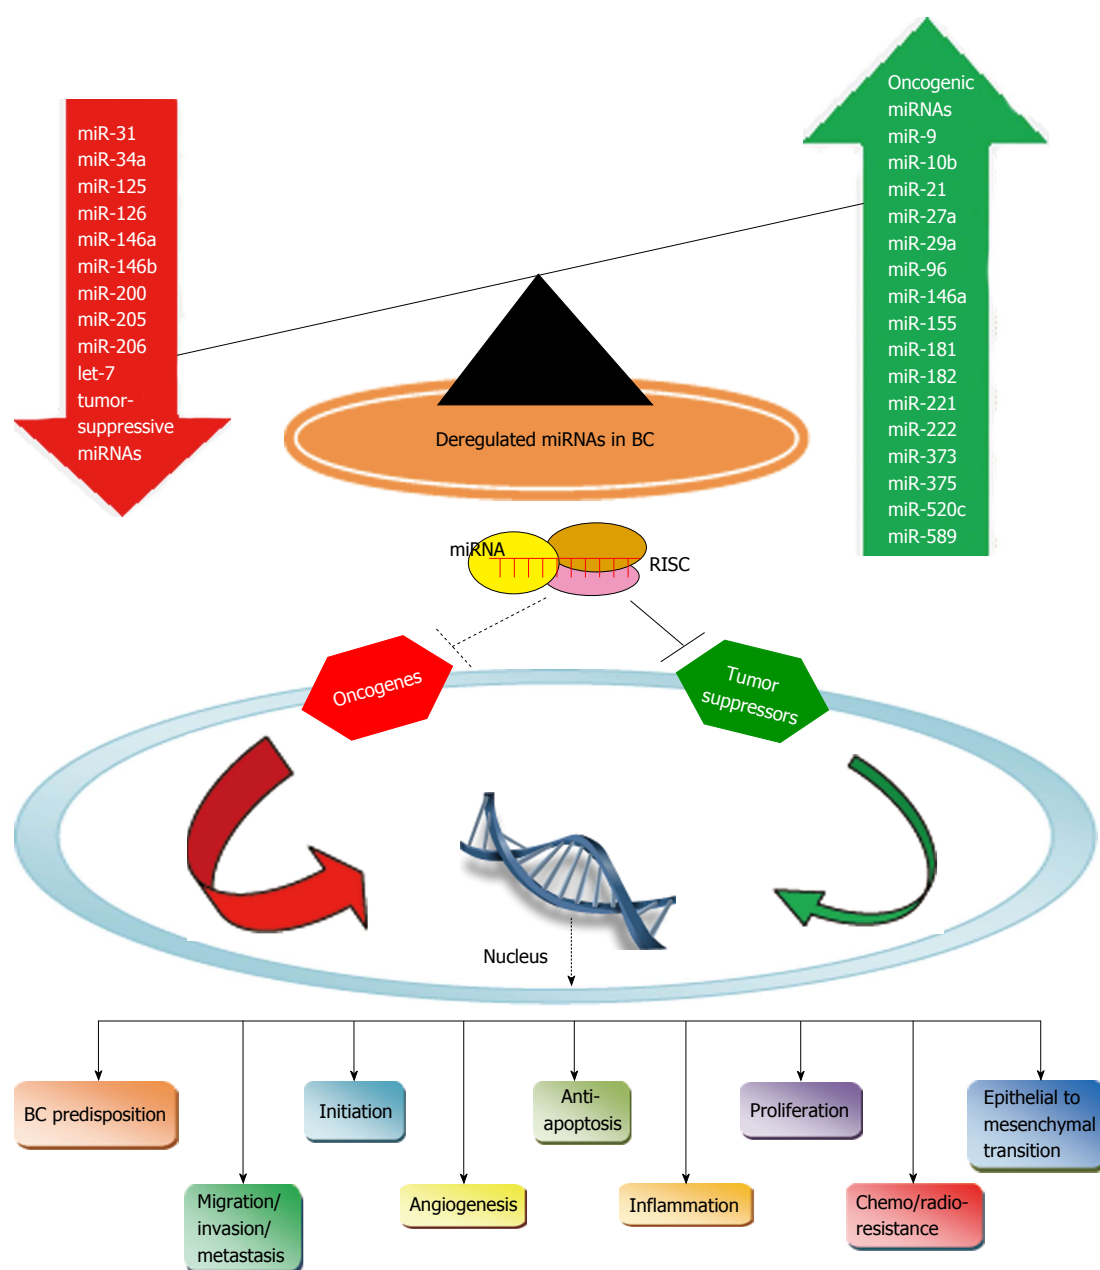

Figure 1 Dysregulation of micro-RNAs in breast cancer pathogenesis. The downregulated/tumor suppressive micro-RNAs (miRNAs) exert decreased inhibition on putative oncogenes in breast cancer (BC). The upregulated/oncogenic miRNAs show enhanced inhibition on tumor suppressors. These mechanisms may lead to increased oncogene-induced gene and decreased tumor suppressor-mediated transcription respectively. Both mechanisms lead to aberrant gene expression that play a significant role in BC predisposition, initiation, cell proliferation, resistance to apoptosis, invasion, angiogenesis, inflammation and metastasis in BC cells. RISC: RNA-induced silencing complex.

cancer as well as leukemia^[25,26].

Examples of overexpressed miRNAs in BC include miR-9/10b/21/27a/29a/96/146a/155/181/221/222/373/375/520c/589, where some of these have been validated in BC clinical specimens, highlighting their potential role in BC diagnosis, prognosis and therapeutics^[18,23]. Concerning downregulated miRNAs, miR-30a/31/34a/125/126/146a/146b/200/205/206 and let-7 emerge in BC pathogenesis through the loss of their tumor suppressor properties^[18,23]. Generally, it is important to mention that miRNA downregulation represents a more frequent event in BC pathogenesis, allowing oncogenes to be activated during BC development.

Dysregulation of miRNAs in BC predisposition, initiation, progression and metastasis

Aberrant expression of miRNAs in cancer-associated genomic regions: MiRNA genes are often situated in cancer-associated genomic regions and are subject to deletions, rearrangements, breakpoints and loss of heterozygosity^[27]. Approximately half of all annotated human miRNA genes are situated in fragile sites or genomic areas that have been associated with cancer^[27,28]. For example, miR-15a and miR-16-1, which are often down-regulated in cancer, occupy the most frequently deleted genomic region and may harbor germline mutations in familial cases of B-cell chronic lymphocytic leukemia and

BC^[22,28].

Single nucleotide polymorphisms in miRNA genes or miRNA target genes and genetic susceptibility to BC: Single nucleotide polymorphisms (SNPs) in miRNA genes, their processing machinery and their target binding sites could also increase the susceptibility to BC and affect patient prognosis and treatment efficacy^[29]. Despite the fact that SNPs are rare in miRNA genes, they may alter miRNA biogenesis and function as well as miRNA binding sites^[30]. Many SNPs in miRNA genes or in miRNA target genes in germline cells, independently from their possible/putative functional effects, have been analyzed in association (case-control) studies. For example, the SNP rs11614913 in pre-miR-196a-2 has been linked to an elevated BC risk^[31] and the SNP rs895819 in pre-miR-27a has been associated with a decreased BC risk^[32]. Therefore, miRNAs may be used as potential biomarkers for BC predisposition in populations at risk.

Aberrant expression of miRNAs in BC initiation:

Cancer stem cells (CSCs) or tumor-initiating cells lead tumor promotion, progression and heterogeneity by proliferating and forming some differentiated tumor cells. CSCs present a self-renewal (symmetric and asymmetric division) potential and the capacity to generate all types of cancer cells within the tumor^[33]. Targeting these initial CSCs may be an effective therapeutic strategy as CSCs are responsible for tumor growth and propagation of cancer and are considered more resistant to chemotherapy and radiotherapy. Breast CSCs were first reported by Al-Hajj *et al.*^[34] and are characterized by the expression of the surface biomarkers CD44⁺, CD24^{-/low}, the epithelial specific antigen and aldehyde dehydrogenase 1^[33]. Under non-adherent conditions for human mammary epithelial cells, only breast CSCs are capable of surviving, proliferating and building mammospheres, which are multicellular formations containing a large number of mammary stem cells^[33]. The Hedgehog signaling pathway activates the self-renewal of breast CSCs *via* the polycomb ring finger oncogene B lymphoma Mo-MLV insertion region 1 homolog (Bmi-1)^[35]. The aberrant expression of miRNAs may play a role in carcinogenesis and breast CSCs self-renewal by acting as oncogenic or tumor suppressive miRNAs and also regulating the stem cell-like phenotype of breast CSCs^[33]. The miRNA triad let-7/miR-200c/miR-30 suppresses the self-renewal of breast CSCs and the spontaneous conversion of immortalized mammary epithelial cells to a stem-like phenotype with less differentiated and mesenchymal properties by targeting Ras, Bmi-1, ubiquitin-conjugating enzyme 9 and integrin b3 respectively^[24,33]. On the contrary, the upregulation of miR-181 family members and miR-495 plays a significant role in modulating breast CSCs and maintaining a stem cell-like phenotype in BC by targeting respectively the tumor suppressor serine/threonine kinase ataxia telangiectasia mutated and E-cadherin and short for regulated in development and DNA damage responses. In particular, over-expression of miR-495 in human BC cells enhances

colony formation *in vitro* and carcinogenesis *in vivo*^[36].

Aberrant expression of miRNAs in BC progression:

MiRNAs may be involved in the cell cycle by controlling critical components of the regulatory pathways. In particular, miRNAs could regulate the cyclin/cyclin dependent kinase (CDK) pathway which constitutes a significant pathway in the cell cycle control. The pair miR-17-5p/miR-20a has been shown to attenuate the synthesis of cyclin D1 encoded by the gene *CCND1* in BC MCF-7 cell line, blocking S-phase entry and inhibiting cell proliferation^[37]. MiR-27a, which is also associated with the cyclin/CDK pathway, targets zinc finger and BTB domain containing 10 and Myt-1 which halt BC cell proliferation by suppressing cyclin D1 and cyclin B respectively^[38].

The estradiol (E2)/ER α /Sp1 is another important cell cycle regulatory pathway in BC that aids proliferation by activating cyclin D1, leading to the G1/S phase transition. In ER positive BC, E2 increases the expression of miR-21 and let-7 family members^[24]. The upregulation of let-7 family members in ER positive BC may result in diminished ER α activity and cell proliferation^[18]. BC cells at the stage of ductal carcinoma *in situ* and invasive ductal carcinoma are characterized by let-7 downregulation in comparison to benign lesions^[18]. In contrast to ER positive BC, the E2/ER signaling pathway is inhibited and miR-21 is downregulated in ER negative BC, whereas miR-18a, miR-18b, miR-206, miR-221 and miR-222 are upregulated leading to inhibition of ER expression and induction of other signaling pathways regulating cell growth and proliferation^[39]. The upregulation of the pair miR-221/222 in ER negative BC may lead to reduced p27kip1 levels and continuous BC proliferation^[40].

In BC, miR-31 acts as a tumor suppressor targeting the human frizzled transmembrane receptor frizzled-3 and is downregulated in all interactions with the Wnt signaling transduction pathway^[41]. The oncosuppressor miR-34a, which is downregulated in triple negative and mesenchymal-type BC cell lines, has been shown to inhibit BC proliferation and migration *via* downregulation of B-cell lymphoma 2 (Bcl-2) and sirtuin 1^[18]. The tumor suppressor miR-205 targets human epidermal growth factor receptor 3 (HER3) directly, a receptor tyrosine kinase of the epidermal growth factor receptor (EGFR) family, inactivating thereby the downstream mediator Akt, suppressing the phosphoinositide 3-kinase (PI3K)/Akt signaling pathway and inhibiting BC proliferation with improved response to targeted therapies^[42]. Finally, the overexpression of the oncogenic miR-146a may be responsible for the altered expression of the breast cancer type 1 susceptibility protein (BRCA1), which is a negative regulator of BC growth associated with the hypophosphorylated form of Rb, and the BC metastasis suppressor 1 (BRMS1), which reduces the metastatic potential of BC cells^[43].

MiRNAs also interfere with the apoptotic process in BC cells. MiR-21 has been shown to play an anti-apoptotic role by indirectly targeting Bcl-2 in MCF-7 BC cells^[44]. On the contrary, the oncosuppressor miR-145 targets

Rhotekin (RTKN), the gene coding for the Rho effector, which activates B-cell lymphoma extra large *via* the nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) signaling pathway^[45]; hence, promoting apoptosis. The oncogenic miR-155 is an effective suppressor of the execution phase of apoptosis *via* its actions in caspase 3 and its negative regulation of the tumor suppressor gene suppressor of cytokine signaling 1^[18]. The members of forkhead box protein O family (FOXO) which are often the target of miRNAs, represent transcription factors characterized by a distinctive forkhead DNA binding domain and play an important role in promoting the cell cycle arrest at the G₁/S checkpoint, apoptotic responses *via* the pro-apoptotic factor Bcl-2 homology domain 3-only molecule Bcl-2-interacting mediator (Bim) of cell death and cellular metabolism^[43]. In BC, the up-regulation of the oncogenic triad of miR-27a, miR-96 and miR-182 which targets FOXO1 may contribute to BC progression and maintenance of the oncogenic state^[46]. In addition, the oncogenic miR-155 may induce BC cell survival and anti-apoptosis by blocking FOXO3a^[47].

Aberrant expression of miRNAs in BC migration, invasion and metastasis: After initiation and progression, tumor cells proceed to invasion and metastasis, which are enabled by the epithelial to mesenchymal transition (EMT). BC cells in carcinoma *in situ* lose cell adhesion mediated by E-cadherin repression, become more motile and break through the basement membrane with increased invasive properties, progressing to invasive BC. EMT, which is essential in cancer invasion, metastatic dissemination and resistance acquisition to cancer therapy, is characterized by the loss of the epithelial phenotype marker E-cadherin^[18,43]. EMT is activated by tumor necrosis factor- α , hepatocyte growth factor and transforming growth factor- β (TGF- β), while many transcription factors, including zinc finger E-box binding homeobox 1 (ZEB1) and ZEB2, can repress E-cadherin directly or indirectly^[43]. In BC, the expression of the miR-200 family is downregulated, resulting in the overexpression of ZEB1 and ZEB2, which are crucial EMT activators by inhibiting E-cadherin expression^[48]. MiR-9 directly targets the E-cadherin coding gene CDH1, leading to an enhanced cell motility and invasiveness of SUM149 human BC cells^[49]. Ras homolog gene family member (Rho) A, a prometastatic gene regulating EMT in a multiphasic manner, is the target of both oncogenic miRNAs such as miR-155, which mediates the TGF- β induced EMT, and tumor suppressor miRNAs such as miR-31^[41].

For the invasion and metastatic processes, attachment of BC cells to matrix components must take place. Metalloproteinases (MMP) degrade the extra-cellular matrix (ECM) which mediates cell attachment, while the tissue inhibitor of metalloproteinases suppresses the MMP activities^[50]. MiRNAs may induce cell migration and invasion through ECM destruction or disruption of recognition between ECM and cells. Later, circulating BC cells exit the bloodstream to form micro-metastases, undergoing mesenchymal to epithelial transition for clonal

outgrowth at the metastatic sites.

MiR-21 inhibits TIMP3 expression in BC, promoting ECM disruption, BC invasion in multiple cell lines *in vitro* and metastasis^[51]. Furthermore, the overexpressed miR-21 directly blocks the tumor suppressor programmed cell death protein 4 (Pdc4), tropomyosin 1 and maspin, enhancing the promotion of invasion and metastasis^[52]. The prometastatic miRNAs miR-373 and miR-520c may promote cell migration and invasion *in vitro* and *in vivo* by inhibiting the expression of CD44, which is a cell surface receptor for ECM components and cell to cell interactions with ECM^[53]. The basal-like subtype-specific miRNAs miR-221 and miR-222 are associated with increased cell migration and invasion, aiding in the progression of the clinically aggressive basal-like BC^[39]. Interestingly, miR-223 transferred from macrophages to BC cells through exosomes may lead to enhanced invasiveness of BC cells; highlighting the important role of exosomal communication between BC cells and macrophages^[54]. The oncogenic miR-10b, which is overexpressed in metastatic BC, may initiate tumor invasion and metastasis *in vivo* and *in vitro* by interrupting the homeobox D10 (HOXD10) expression (a transcription factor that maintains a differentiated phenotype in epithelial cells), resulting in an increased expression of Ras homolog gene family member C which leads to BC cell invasion and metastasis^[55]. The upregulation of miR-375 contributes to breast lobular neoplasia and invasive lobular breast carcinoma progression^[18].

The miRNA pair miR-126 and miR-335 has been associated with the capacity of BC cells to metastasize to bones and lungs through blocking the expression of tenascin c, a ECM component^[56]. The downregulation of the tumor suppressive let-7 contributes to BC metastasis. Let-7 modulates the repressive action of Raf kinase inhibitory protein, a BC suppressor gene inhibiting NF- κ B, mitogen-activated protein kinases and G protein-coupled receptor kinase-2 signaling pathways in BC metastatic cells^[57]. The tumor suppressive miR-31, which is undetectable in metastatic BC cells, has been shown to inhibit the expression of multiple prometastatic genes blocking BC metastasis^[18]. The tumor suppressor miR-146a/b diminishes the expression of EGFR, inhibiting metastasis^[58].

Distant BC metastases need tumor-induced formation of new blood vessels (angiogenesis) in order to allow expansion of the primary breast tumor and to obtain sufficient oxygen and nutrients. The angiogenic factor vascular endothelial growth factor (VEGF) represents the most important inducer of angiogenesis and may be regulated by several miRNAs. In particular, miR-126 has been shown to target VEGF expression in BC whereas the VEGF/PI3K/Akt signaling cascade is activated^[59]. On the contrary, miR-9 may promote angiogenesis by enhancing VEGF-A expression in BC and downregulating E-cadherin^[49]. In hypoxic conditions within the tumor microenvironment, hypoxia inducible factor-1 may also mediate the expression of VEGF in BC cells in a miR-20b-dependent way^[60]. Also, the downregulation of the oncosup-

pressor miR-125a is associated with the overexpression of a stress-induced HuR protein in the cytoplasm, which in turn could increase the invasiveness of BC cells and angiogenesis *via* VEGF-A expression^[61]. In addition to angiogenesis, miRNAs may constitute feedback mechanisms that link inflammation to BC. In particular, the upregulation of miR-155 in BC could lead to stimulation of signal transducer and activator of transcription 3 *via* the Janus kinase pathway and activation of BC cells by interleukin-6, interferon γ and lipopolysaccharide^[62].

Finally, miRNAs may also represent key regulators of the epigenetic interaction that takes place in BC cells with DNA methylation and histone modifications. The expression of the oncosuppressor miR-200 was shown to be epigenetically modulated by DNA promoter methylation and histone modifications^[33]. The downregulation of the pro-apoptotic and tumor suppressor miR-34c, which inhibits invasion, occurs through hypermethylation of the promoter region and may lead to enhanced self-renewal and EMT of breast CSCs^[63].

MI RNAs AS EXTRACELLULAR CIRCULATING BIOMARKERS IN BC

Several blood-based profiling studies have tried to elucidate the role of extracellular miRNAs in BC biology and pathogenesis^[64]. It should be also noted that miRNAs have been detected in breast milk^[22]. MiRNAs could be used as promising diagnostic, prognostic and predictive biomarkers in BC, presenting the following advantages: (1) their remarkable stability in plasma due to their association not only with RNA binding proteins [Ago2 protein, high density lipoprotein or nucleophosmin 1 (NPM1)] but also exosomal vesicular transportation^[65,66]; (2) miRNAs represent a non-invasive diagnostic approach as a liquid biopsy in contrast to the existing tissue-dependent biopsy; and (3) miRNAs may be regarded as tumor-derived molecules that have been present early into circulation, therefore reflecting tumor status.

Genome-wide expression profiling studies of extracellular miRNAs have investigated whether serum samples could be used to identify differentiated miRNA expression levels between BC patients and healthy individuals; thus, distinguishing normal from diseased state. Wu *et al*^[67] showed that serum miR-29a and miR-21 levels were significantly increased in 20 BC patients compared to healthy controls. Kumar *et al*^[68] also demonstrated an overexpression of miR-21 and miR-146a in plasma samples of BC patients. Using microarray-based expression profiling followed by real time quantitative polymerase chain reaction (RT-qPCR), Zhao *et al*^[69] found deregulated expression levels of 49 miRNAs in plasma from 20 women with early stage BC compared to 20 matched controls. Furthermore, the authors showed that both up-regulated ($n = 26$) and downregulated ($n = 23$) miRNAs could discriminate patients from controls with acceptable specificity and sensitivity scores. Let-7c and miR-589 were significantly decreased and increased respectively in

BC patients. In a study by Chan *et al*^[70], 4 (miR-1, miR-92a, miR-133a and miR-133b) of the 7 miRNAs that were differentially expressed in a set of serum samples from a cohort of 132 Asian BC patients and 101 healthy controls were validated and identified as the most significant diagnostic markers. Interestingly, only 7 miRNAs out of the total 20 were overexpressed in both tumor and serum of BC patients, indicating that miRNAs could be released into serum selectively. Profiling results of another study have indicated that the combination of circulating miR-145 and miR-451 seems capable of predicting BC patients from normal individuals^[71].

Other investigations have shown a correlation between systemic miRNA levels and various clinicopathological features of BC. MiR-10b and miR-373 were related to lymph node status^[72], while the upregulated miR-21 was associated significantly with visceral metastasis^[73]. MiR-21, miR-126, miR-155, miR-199a and miR-335 levels were closely correlated with histological grade and hormone receptor expression. A significantly higher relationship of miRNA expression levels between BC tumor tissues and sera was also found^[74]. Roth *et al*^[75] revealed that circulating miR-10b, miR-34a and miR-155 levels were significantly related to the presence of overt metastases. Serum levels of miR-182 in ER and progesterone receptor (PR) positive BC patients were lower when compared with patients suffering from ER-PR negative BC^[76]. On the other hand, miR-155 expression levels were higher in serum of women with hormone sensitive BC (PR positive)^[77]. Similarly, in a prospective study, levels of miR-195 and let-7a were significantly correlated with ER and lymph nodal status and decreased interestingly in BC patients postoperatively following curative tumor resection^[78]. Cuk *et al*^[79] showed that a panel of 7 circulating miRNAs, including miR-127-3p, miR-148b, miR-409-3p, miR-652 and miR-801, presents a substantial diagnostic potential, not only as a screening method for benign and malignant breast tumors, but also for the detection of early BC stage. Notably, another study has linked exosomal miRNAs to poor prognosis in BC through the maintenance of dormant BC cells in the bone marrow stroma^[80]. Sieuwerts *et al*^[81] have highlighted the diagnostic potential of detecting tumor specific miRNAs in circulating tumor cells (CTCs) in the bloodstream in an attempt to discriminate BC patients with CTCs from patients with no detectable CTCs and healthy volunteers. Accumulating evidence has underscored the possible contribution of miRNAs as valuable biomarkers to predict response to chemotherapy or radiotherapy. For example, downregulated miR-34, miR-17 and let-7a were associated with chemosensitivity to fluorouracil, adriamycin and cyclophosphamide, respectively^[82]. Studies in BC cell lines have also related targeted miR-21 downregulation with increased sensitivity to topotecan and taxol^[44,83], whereas other investigations have indicated that restoration of the oncosuppressor miR-205 expression levels was associated with improved response to tyrosine-kinase inhibitors gefitinib and lapatinib through abrogating the HER3-

mediated resistance^[42]. A growing number of studies have demonstrated a correlation between circulating miRNA expression levels and patterns of chemoresistance or chemosensitivity. Zhao *et al*^[84] have found that plasma miR-221 could be a predictive biomarker for neoadjuvant chemotherapy sensitivity in BC patients. In other studies, circulating miR-210 and miR-125b were associated with sensitivity to trastuzumab and neoadjuvant chemotherapeutic resistance respectively; underlining the possibility of using them as indicators of treatment response^[85,86].

MI RNAs AS PROMISING THERAPEUTIC TARGETS IN BC

The pivotal role of miRNA as oncogenes or tumor suppressors has stimulated scientists to manipulate their expression; an effort that indicates their emerging role as therapeutic targets and replacement therapies for BC treatment. Depending on a given miRNA that is up or downregulated, various methods exist in order to inhibit or increase its expression, including miRNA inhibition *via* antisense targeting with oligonucleotides (anti-miRs) or miRNA replacement *via* viral or liposomal delivery (miRNA mimics), respectively^[87,88]. Functional analyses using knockdown mouse models and BC cell lines have revealed great therapeutic potential for the studied miRNA molecules. Potentially, every miRNA could serve as a possible therapeutic target. Si *et al*^[44] showed that inhibition of miR-21 expression using anti-miR-21 oligonucleotides resulted in reduced MCF-7 BC cell growth and tumor growth in the xenograft mouse model due to decreased proliferation and increased apoptosis. In agreement with these findings, Yan *et al*^[89] showed that knockdown of miR-21 inhibited growth and migration of MCF-7 and MDA-MB-231 BC cell lines *in vitro* and tumor growth in nude mice *in vivo*. MiR-21's potential therapeutic relevance is also supported by its capacity to sensitize BC cells to anticancer therapy. MiR-21 suppression has been reported to increase sensitivity of BC cells to topotecan and taxol^[44,83], whereas its tumor suppressive gene target phosphatase and tensin homolog has been shown to be a regulator of sensitivity to trastuzumab^[90]. These findings suggest that the combination of anti-miR-21 with classical chemotherapy may result in overcoming drug resistance and in individualizing therapy in BC patients. Furthermore, Kong *et al*^[47] demonstrated that knockdown of miR-155 led to apoptosis and increased chemosensitivity by upregulation of its direct target FOXO3a, suggesting that miR-155 inhibition could present a promising therapeutic potential for BC. Additionally, let-7 could contribute to cancer therapeutics due to its association with self-renewal ability and tumorigenicity of BC cells^[91]. Let-7 also regulates apoptosis and CSC differentiation^[92]; thus, targeting let-7 in BC could serve as an effective treatment option.

Recent studies have targeted miR-205 for inhibiting the metastatic nature of BC. Wu *et al*^[93] demonstrated that ectopic expression of the downregulated miR-205 effec-

tively hinders cell proliferation, anchorage-independent growth and cell invasion, supporting its use as a possible therapeutic target. MiRNA delivery *via* nanoparticles is also a promising technique. Jin *et al*^[94] have recently used nanoparticles to deliver anti-miR-10b for targeting the overexpressed miR-10b which is related to BC cell migration and invasion through inhibition of HOXD10 target synthesis. A RNA poly L-lysine complex has been developed; it releases concentrations of anti-miR-10b into the cytoplasm of BC cells with sustainable effectiveness.

Further therapeutic potential is likely *via* targeting breast CSCs with miRNA manipulation. Certain miRNAs seem to be responsible for breast CSCs behavior, including self-renewal characteristics, increased chemotherapeutic resistance and EMT^[33]. Thus, anti-CSC therapy with miRNAs could combat breast CSCs' positive effect on tumorigenesis. Additionally, a potential mesenchymal stem cell-mediated anti-miR delivery directly to the tumor area was proposed based on mesenchymal stem cells ability to migrate^[95].

Unmasking the precise role of miRNAs in the regulation of breast CSC renewal and the potential for combination of stem cell and novel miRNA-associated targeted therapies may represent effective therapeutic strategies of significant clinical benefit, probably when combined with the classic anticancer agents.

CONCLUSION

MiRNAs constitute a novel class of dysregulated molecules that could provide new avenues for diagnosing and classifying tumor-specific malignancies such as BC but also different phases of BC development from initiation to progression, migration, invasion and metastasis. The scientific interest is mainly concentrated on two basic aspects in regard to the clinical utility of miRNAs: their extracellular presence in body fluids, particularly blood, and their potential therapeutic applications either by miRNA replacement or miRNA inhibition. In BC, both aspects appear promising, with miRNAs being used as potential circulating non-invasive biomarkers detected in serum and plasma samples, and as therapeutic targets for cancer under current investigation, respectively. Although the available recent data are almost exclusively pre-clinical evidence, the application of miRNAs in BC therapy as adjuvant tools or targets appears exciting and very promising. A better understanding of the complex network of genes and cellular signaling transduction pathways regulated by miRNAs would enrich our knowledge of BC etiopathogenesis and hence would improve the therapeutic outcome of BC patients.

The diagnostic potential of circulating miRNAs as BC biomarkers is based mainly on their non-invasive detection in serum and plasma and on their high resistance and stability under difficult environmental conditions that could degrade the majority of RNAs, such as extended storage, frequent freeze-thaw cycles, extreme pH variations, boiling, preservation in archived human blood samples

for several years, transport, *etc.* Several methodologies are available for establishing miRNA signatures in BC, such as RT-PCR, miRNA microarrays and next-generation sequencing, with several limitations regarding their cross-comparison, various reference genes used to normalize miRNA levels and differences in blood collection.

Nonetheless, crucial issues need to be resolved before establishing extracellular miRNAs as biomarkers and therapeutic tools for BC. The lack of larger prospective clinical trials with robust and standardized analyzing methods, the necessity for clarifying the real origin of circulating miRNAs as they may be confused with by-products of normal tissues or dead cells, and the validation of a well-characterized BC-specific signature of circulating miRNAs are important limitations that need to be overcome when bringing miRNAs from bench to bedside. However, taking into account the important pace of evolution in understanding the main ways of miRNA effects on BC pathogenesis, these small molecules will amaze the scientific world with more revelations in the near future.

Abstract

Stage IV breast cancer refers to breast cancer that has already metastasized to distant regions when initially diagnosed. Treatment for stage IV is intended to "prolong survival and palliate symptoms". Resection of a primary tumor is considered to be "effective only at alleviating chest symptoms and providing local control" in spite of the advances of imaging examination and medication for breast cancer. Molecular target and endocrine drugs are very effective and useful to tailor-make a treatment strategy according to breast cancer subtypes. Positron emission tomography-computed tomography can detect and diagnose the very small metastases and recurrences which can potentially be cured even if they are distant metastases. Recently, many retrospective studies have reported the survival benefit of surgery for breast cancer patients with metastases and some clinical trials which confirm the surgical prognostic benefit for them have started to enrol patients. The goal of treatment has to be clearly identified: increase the patient's survival time, provide local control or perform histology to determine the cancer's properties. The best evidence is absolutely essential to treat patients who need surgery at the right time. We need to evaluate the treatment strategy, including primary resection for stage IV breast

cancer particularly, and find new evidence by prospective analysis.

INTRODUCTION

Stage IV breast cancer refers to breast cancer that has already metastasized to distant regions when initially diagnosed. Even if such cancer were to be treated, complete cure would not be expected. Treatment is intended to "prolong survival and palliate symptoms". Medication has made advances and treatments that are anticipated to be efficacious are administered. This situation has changed little as new drugs are coming out every year. In an increasing number of patients, appropriate use of

those drugs allows long-term control of symptoms and a longer life with disease.

In addition, marked advances in diagnostic imaging equipment have been made. Over the past few years, the prevalence of positron emission tomography-computed tomography has led to the early diagnosis of extremely small metastases that were not previously noted^[1]. Stage IV breast cancer with these small metastases is referred to as “minimal stage IV disease^[2]” and patients with this more limited form are expected to have a better prognosis than patients with full-blown stage IV breast cancer. Although it has yet to be precisely defined, the concept of “oligometastasis” is being debated^[3]. According to this concept, metastases can potentially be cured, even if they are distant metastases, depending on their location and number.

Resection of a primary tumor was previously considered to be “effective only at alleviating chest symptoms and providing local control”, but some studies have reported that resection increases survival time^[4,5]. Breast-conserving surgery is a widely used form of surgery for breast cancer. Anesthesia has also made advances and is safe. At the current point in time, surgery for breast cancer is extremely simple, depending on tumor size, and minimally invasive. A longer survival time seldom results from drug administration but it can result from surgery. Surgery for stage IV breast cancer is an important topic that may substantially alter future treatment strategies.

SIGNIFICANCE OF RESECTION OF THE PRIMARY TUMOR IN STAGE IV BREAST CANCER: STUDIES REPORTING INCREASED SURVIVAL TIMES AND RELATED ISSUES

As mentioned earlier, a number of recent studies have reported that surgery for stage IV breast cancer affects a patient's survival time. Many of these retrospective studies indicated that surgery prolonged survival time. Several systematic reviews have reported significant differences in survival time (HR of about 0.6)^[4,5]. A look at subgroups indicates that factors facilitating surgery include “complete excision of the primary tumor”, “metastasis only to bone and/or soft tissue”, “few metastases” and “being younger”^[6,7]. A study reported differences in the effectiveness of surgery for different subtypes of tumors^[8]. However, all of the findings cited were the result of retrospective analysis so they are presumed to be highly biased. “Patients who undergo surgery” are invariably “patients in good enough condition to undergo surgery” while “patients who do not undergo surgery” are possibly “patients who are unable to undergo surgery because of their worsening condition”. In addition, medication has not been studied in detail and patients who undergo surgery are likely to include a number of patients whose condition could have been satisfactorily controlled with medication. The timing of surgery is also unclear. There

is no clear answer as to whether surgery should be done during initial treatment or whether it should be a final option that is used after medication proves inefficacious.

WHY DOES RESECTION OF ONLY THE PRIMARY TUMOR HELP WHEN CANCER CELLS HAVE SPREAD THROUGHOUT THE BODY?

According to the seed and soil theory by Paget^[9], the distant metastasis is not local disease. Cancer cells have already spread to whole body circulation. So, local therapies do not affect overall survival, whereas there are several theories on the basic rationale for resection of the primary tumor increasing the survival time for patients with stage IV breast cancer. The first is a “reduction in total tumor volume”. Circulating tumor cells (CTCs) are a major indicator of tumor volume. A reduction in CTCs is reported to be correlated with prognosis^[10]. Resection of the primary tumor reduces the tumor volume and thus reactivates autoimmunity and increases the efficacy of medication^[11]. A study prospectively demonstrated that resection of the primary tumor is useful when kidney cancer is in stage IV (this is the only other solid tumor besides breast cancer for which this holds true)^[12]. According to the study, resection of the primary tumor is a theoretical basis for the effectiveness of surgery.

Another theory as to why resection of the primary tumor increases the survival time concerns the particular action of the primary tumor. “Cancer stem cells” that are prevalent in the primary tumor are resistant to medication^[13]. In addition, the concept of “cell seeding” indicates that cells released into the blood by the primary tumor return to the primary tumor, so the primary tumor activates those cancer cells^[14]. Both of these mechanisms are based on results of basic experiments and no studies have described results from actual patients. If, however, they are true, then they are sure to be key to devising cancer treatment strategies in the future. These mechanisms should be verified in the future.

LOCAL CONTROL

As mentioned at the very beginning, resection of the primary tumor has been useful in alleviating chest symptoms, such as bleeding and ulceration as well as pain due to invasion of the chest wall. However, no studies or prospective trials have determined whether or not earlier surgery is useful to achieve local control. At the current time, there are absolutely no data corroborating the contention that “earlier surgery is useful since it improves local control, even if it does not increase survival time”. When local control alone was envisioned, radiation therapy was considered in addition to surgery. Although sample sizes are small, studies have described an improvement in the prognosis for the primary tumor in stage IV breast cancer as a result of radiation therapy (like the improvement in

Table 1 Ongoing randomized trials testing the worth of local therapy for an intact primary in women with stage IV breast cancer
xvii

Netherlands	NCT01392586	2011-16	516	Surgery	For positive margins or palliation	2-yr survival
Austria	NCT01015625	2010-19	254	Surgery	Per standards for stage I -III	Survival
Japan	JCOG 1017	2011-16	410	Appropriate systemic therapy	No	Survival

JCOG: Japan Clinical Oncology Group; NCT number: A unique identification code given to each clinical study registered on ClinicalTrials.gov.

prognosis as a result of surgery)^[15]. In addition, a study has reported a satisfactory prognosis for asymptomatic rather than symptomatic patients, regardless of whether treatment was administered and regardless of the type of treatment^[16]. Results suggest that local control itself may act beneficially on prognosis, irrespective of whether treatment is classified as surgery, radiation, *etc.*

TRIALS CURRENTLY UNDERWAY TO DETERMINE THE USEFULNESS OF RESECTION OF THE PRIMARY TUMOR IN STAGE IV BREAST CANCER

As noted previously, there are absolutely no prospective data at the current time to corroborate the usefulness of resection of the primary tumor in stage IV breast cancer in terms of increasing survival time or improving local control. At the current time, there is no evidence actively in favor of such a resection. That said, many results of retrospective studies continue to be discussed in various fora. In the absence of robust evidence, this meta-analysis provides an evidence base for primary resection in the setting of stage IV breast cancer for appropriately selected patients^[17]. Resection of the primary tumor could greatly affect breast cancer care so this clinical question needs to be answered in prospective trials. Given this potential, 6 groups are currently enrolling patients^[18-20] (Table 1). The first reports of two prospective studies were indicated in the San Antonio Breast Cancer Symposium 2013^[21,22]. Both studies did not demonstrate a significant survival benefit of primary surgery. From the Indian trial, the distant disease free survival in the patients with surgery was significantly worse than that of the patients without surgery. One of the reasons was the insufficient systemic chemotherapy after surgery. They did not continue systemic chemotherapy after randomization and appropriate systemic therapies according to breast cancer subtypes were not selected in these protocols. So, the median survival time was shorter than that of retrospective European and American data. In particular, they did not use molecular target therapy for patients with human epidermal growth factor receptor type 2 positive breast cancer. Moreover, the diagnosis of metastasis was uncertain. They only used bone scintigraphy to diagnose a solitary bone metastasis. The Breast Cancer Study Group of

the Japan Clinical Oncology Group (1017) and Eastern Clinical Oncology Group (2108) began enrolling patients for a phase 3 trial in June 2011^[23]. Patients receive current standard systemic therapy before and after randomization and the latest imaging examination before treatment in these trials. A trial by the current authors is determining the significance of early resection of the primary tumor in stage IV breast cancer when that tumor can be controlled by medication. Items being assessed include the total survival time as well as the significance of local control; the results of the trial are sure to provide clinically significant evidence.

CONCLUSION

At the current point in time, one cannot say whether or not resection of the primary tumor provides a clear benefit in the management of stage IV breast cancer. Basic studies have revealed the biology of breast cancer in detail and the role of surgery is changing as treatment is better tailored to the individual in accordance with the individual's biology. The goal of treatment has to be clearly identified: increase the patient's survival time, provide local control or perform histology to determine the cancer's properties. Without a doubt, the best evidence is absolutely essential to treat patients who need surgery at the right time. Announcement of the results of clinical trials that are currently underway and examination of those results in detail are the first steps to obtain that evidence. However, obtaining results takes time and other strategies to treat breast cancer are constantly changing. In addition, the drugs used and patient attributes differ completely in different countries. An effective strategy to treat stage IV breast cancer must be devised in accordance with medication in light of the patient's symptoms while remaining mindful of the significance of surgery.

Abstract

Uterine cervical cancer is the second most common gynecological malignancy. It is estimated that over 35% of tumors are diagnosed at locally advanced disease, stage I B2- II B with an estimated 5-year overall survival of 60%. During the last decades, the initial treatment for these women has been debated and largely varies through different countries. Thus, radical concurrent chemoradiation is the standard of care in United States and Canada, and neoadjuvant chemotherapy followed by radical surgery is the first line of treatment in some institutions of Europe, Asia and Latin America. Until today, there is no evidence of which strategy is better over the other. This article describe the evidence as well as the advantages and disadvantages of the main strategies of treatment for women affected by uterine cervical cancer stage I B2- II B.

INTRODUCTION

Uterine cervical cancer is the second most common gynecological malignancy^[1]. In developing countries, it is estimated that over 70% of cases are diagnosed at an advanced stage of disease, thus being a major cause of morbidity and mortality^[2]. Based on the fact that cervical cancer tends to grow locally involving the cervix and the paracervical structures, the International Federation of Gynecology and Obstetrics (FIGO) staging system is clinical. It is based primarily on pelvic examination to estimate tumor size and local extension toward the vagina, parametria and pelvic sidewalls. Thus, cervical cancer can be divided in three groups: (1) early stage of disease, tumors up to 4 cm without involvement of extracervical structures. (FIGO stage I A- I b1); (2) locally advanced cervical cancer (LACC), tumors growing locally bigger than 4 cm or with initial involvement of paracervical tissue (FIGO stage I B2- II B); and (3) advanced stage

Figure 1 Distribution and 5-year overall survival of women with uterine cervical cancer divided by International Federation of Gynecology and Obstetrics stage disease according with International Federation of Gynecology and Obstetrics annual report^[4]. OS: Overall survival.

disease, tumors that largely involve pelvic structures or tumors with distant metastasis (FIGO stage IIIA-IVB).

Despite the fact that radiotherapy and radical surgery (RS) are equally effective for early stage disease^[3], the latter strategy is generally accepted as a standard of care with a 5-year overall survival (OS) of 90%^[4]. On the other hand, concurrent chemo-radiotherapy is used as first line treatment for patients with advanced stage disease (FIGO stage IIIA-IVB) with a 5-year OS of 40%^[4]. (Figure 1) However, there is a group of patients in the middle with locally advanced disease (FIGO stage I B2-II B) with a 5-year OS of 60%^[4] for whom there are great controversies regarding the appropriate initial treatment approach. Traditionally, these tumors were treated by radiotherapy alone.

In 1999, based on the results of five large randomized controlled trials, the National Cancer Institute of United States launched an alert recommending concurrent chemoradiation for treating women with LACC becoming the standard of care^[5]. Nevertheless, other treatment modalities with similar efficacy were developed in other regions such as Europe, Japan, South Korea, and Latin America. These include: platinum-based neoadjuvant chemotherapy (NACT) followed by radical hysterectomy^[6-8]; chemoradiotherapy followed by adjuvant chemotherapy^[9] or followed by RS^[10]. Therefore, the treatment of women with LACC seems to be multidisciplinary and the standard of treatment seems to be far from being elucidated. Thus, this article describes the different options of treatment, with their advantages and disadvantages, for women with uterine cervical cancer IFGO stage I B2- II B.

CONCURRENT CHEMORADIATION

Radiotherapy has been the standard of care for treating women affected by LACC for the past 100 years. In 1999, after publication of five randomized controlled trials (RCT)^[11-15], the National Cancer Institute issued an alert recommending that “concomitant (cisplatin-based) chemo-radiotherapy be considered instead of radiotherapy alone

in women with cervical cancer”. This led to a change in the treatment of many women with cervical cancer^[5]. Latter on, a meta-analysis evaluated 15 RCTs comparing chemo-radiotherapy *vs* radiotherapy alone in 3452 women with cervical cancer FIGO stage I B2-IV^[16]. Eleven trials used platinum-based chemoradiotherapy, either as a single agent (eight trials) or in combination regimens (three trials). Three trials used nonplatinum regimens comprising of fluorouracil, mitomycin, or a combination of the two. Each of the trials aimed to prescribe external-beam radiation at a dose to a tumor of between 40 and 61.2 Gy, and 14 trials used brachytherapy. The total planned duration of radiation treatment (external-beam plus brachytherapy) was from 40 to 70 d across all trials. The median follow-up for surviving patients across all 15 trials was 5.2 years. The study noted a 6% improvement in 5-year survival with chemoradiotherapy in comparison with radiotherapy alone (HR = 0.81, $P < 0.001$). However, a great majority of the trials evaluated in this meta-analysis included patients with cervical cancer FIGO stage I B2 to IVB and, as Figure 1 shows, there is a great disparity regarding OS between them.

It is interesting to note that only one study compared chemoradiation *vs* radiation alone in patients with cervical cancer FIGO stage I B bulky^[11]. This study included 374 patients with FIGO stage I B2 excluding high-risk patients with evidence of radiologic enlarged lymph nodes. Women were allocated to receive radiotherapy alone or radiotherapy plus weekly cisplatin intravenously at a dose of 40 mg/m². They observed a risk of progression of the disease and death of 0.51 (95% confidence interval, 0.34 to 0.75) and 0.54 (95% confidence interval, 0.34 to 0.86), respectively. The rates of both progression-free survival ($P < 0.001$) and OS ($P = 0.008$) were significantly higher in the combined-therapy group at four years. With this treatment modality, 80% of patients did not relapsed and 85% were alive at four year after initial treatment.

Current recommendations state that the total paracervical tumor dose (sum of external-beam radiotherapy and brachytherapy) be between 85 and 90 Gy, that total pelvic

sidewall dose be between 55 and 65 Gy, and that overall treatment time not exceed 8 wk^[17]. The greater majority of trials comparing radiotherapy *vs* chemoradiation were conducted in United States and Canada, under strict criteria of treatment administration and in well-equipped institutions. In this sense, radiotherapy is administered by using conventional equipment in the majority of women with cervical cancer and mainly in developing countries where this disease is more frequent^[18]. Nevertheless, by integrating computed tomographic imaging into the radiotherapy planning process, allow the dose of the radiation to match or conform to the outline of the target. The recently introduced intensity-modulated radiotherapy (IMRT) is an extension of this principle. The aim is to produce a highly shaped high-dose volume that maximizes normal tissue sparing with the goals of decreasing toxicity and possibly increasing tumor dose. Thus, the dose distribution with IMRT fits more precisely to the target volume, reducing the dose to the rectum, the central bladder and bowel. Several clinical studies have demonstrated a reduction in the mean volume received on the bladder, the rectum, and the bowel^[19], decreasing bowel adverse events and lymphedema^[20]. A pilot study compared 58 women with cervical cancer treated with radiotherapy ($n = 35$ in four-field box group, $n = 33$ in IMRT group) reporting similar local control of the disease with less toxicity in IMRT group^[21]. Other authors recently confirmed the same results^[22]. Thus, the availability of modern equipment of radiotherapy such as IMRT can help to reduce treatment's morbidity. Radiation therapy, in addition, should be taken with caution if an ideal schedule of care is not possible for some patients.

In this sense, it has been demonstrated that a prolonged treatment time, beyond 50 to 56 d, is associated with a 1% loss of local control for every additional day of treatment with radiotherapy^[23]. In addition brachytherapy, as an integral part of radiation treatment for cervical cancer, is critical for obtaining a cure. Unfortunately, 5% to 10% of patients are unable to receive brachytherapy^[24] because of technical difficulties with the insertion of the devices (*e.g.*, stenotic cervix).

NACT FOLLOWED BY RS

Cervical cancer was traditionally interpreted as chemoresistant cancer. Since 1983, where the first study reporting a response to combined systemic therapy was reported^[25], chemotherapy was evaluated in patients with cervical carcinoma. Thus, in regions such as Europe, Asia or Latin America, NACT followed by radical hysterectomy has been suggested for treating patients with LACC. The main objective of NACT is, to reduce the volume of the tumor, to achieve radical operability; and to reduce the number of patients who finally require adjuvant radiation treatment^[8]. This strategy is based on the strong surgical tradition in some centers; and the lack of accessibility of patients to the radiotherapy centers in some countries. To this regard, one Italian multicenter RCT compared NACT followed by RS *vs* radiotherapy alone in patients

with LACC^[26]. The authors found that only 23% of patients allocated to radiotherapy arm received the adequate treatment in terms of total dose and/or time of delivery of radiotherapy^[26].

The efficacy of NACT for treating LACC has been largely tested by several authors over the last 30 years^[7,8,27]. An Italian multicenter RCT compared 441 women with LACC FIGO stage I B2-III who randomly received radiotherapy alone or NACT followed by RS. The 5-year survival in patients FIGO stage I B2 to II B showed significantly longer progression-free survival (59.7%, 95%CI: 51.3%-68.1% *vs* 46.7%, 95%CI: 38.1%-55.3%, $P < 0.02$) and OS (64.7%, 95%CI: 56.5%-72.9% *vs* 46.4%, 95%CI: 37.2%-55.6%, $P < 0.005$) for patients in NACT + RS arm^[26]. Additionally, RS might play an important role in patients with stable disease after 3 courses of NACT. One study^[28] evaluated 32 patients with cervical carcinoma FIGO stage I B2-II A with stable disease after receiving 3 cycles of cisplatin and 5-fluorouracil-based NACT. The 5-year OS in patients who received RS after NACT was 76.4%, while those patients who received NACT followed by adjuvant radiation treatment experienced a 5-year OS of 37.5%, $P = 0.01$.

A meta-analysis^[16] compared the results of five studies evaluating NACT followed by RS *vs* radical radiotherapy. A total of 872 women were included, mostly with FIGO stage I B-II A tumors. The number of courses of NACT ranged between two and seven cycles of cisplatin based, chemotherapy before radical hysterectomy. Together these trials gave a highly significant (HR = 0.65, 95%CI: 0.53-0.80, $P < 0.0004$) 35% reduction in the relative risk of death, with NACT. These results translate into a 14% absolute improvement in 5-year survival and this effect did not seem to vary according to age, stage, histology, grade or performance status. Local, distant and overall disease-free survival (DFS) was similar between groups.

The optimal drug and schedule is also to be determined. During the last three decades, several institutional experiences (with disparity on the drugs combinations and schedules), few phase II trials^[29] and RCT have been reported^[30,31]. Despite some differences in design and results between trials, the reported response rate achieved a range between 70% and 100%^[32]. The main tested drugs include cisplatin, taxanes, irinotecan, vinorelbine, and gemcitabine. The combined regimen, however, have been also investigated with encouraging results^[30,31]. In 2005, the first RCT comparing different schemes of NACT was published^[30]. An Italian Multicenter study compared 219 patients with LACC FIGO stage I B2-IV who received ifosfamide 5 g/m² during 24 h plus cisplatin 75 mg/m², plus paclitaxel 175 mg/m² (TIP scheme) or ifosfamide 5 g/m² during 24 h plus cisplatin 75 mg/m² every 3 wk for three courses (SNAP-01). The authors observed grade 3 to 4 neutropenia, anemia, and thrombocytopenia to be more frequent with TIP; and a higher optimal pathologic response rate, defined as residual disease < 3 mm of stromal invasion, with TIP (48% *vs* 23%; OR = 3.22; 95%CI: 1.69-5.88; $P < 0.0003$). In the median follow-up of 43.4

Table 1 Institutional capabilities, advantages and disadvantages of the main strategies of treatment for treating locally advanced cervical cancer International Federation of Gynecology and Obstetrics stage I B2- II B

	Institutional capabilities	Advantages	Disadvantages
CT-RT	Well radiotherapy equipment (ideally, intensity-modulated radiotherapy IMRT) Availability of schedule for radiotherapy	Well-documented oncologic benefit over radiotherapy alone Standardized treatment	Limited benefit in case of delay of treatment for toxicity or difficult access to radiation treatment (schedule, few equipment, <i>etc.</i>) Possible permanent local toxicity of radiotherapy, mainly in young and sexually active women Delay local treatment such as RT or RS selection of resistant cells clones
NACT + RS	Welltrained surgeons Institutional support for complex surgical procedure (Intensive care units, Urologists, Internist, <i>etc.</i>)	Reduce the tumor size Control of metastasis Select chemosensitive patients (prognostic factor) Allow to spare RT for relapsed disease or chemorefractory patients	chemotherapy-induced immunosuppression Negative lymph nodes at RS Cumulative toxicity of multimodal treatment, mainly in case of adding postoperative RT
Chemoradiation + adjuvant chemotherapy	Similar to CT-RT strategy	Possible but not welldocumented benefit yet (limited trials)	Similar to chemoradiation cumulative toxicity of multimodal treatment

NACT: Neoadjuvant chemotherapy; RS: Radical surgery; IMRT: Intensity-modulated radiotherapy; CT-RT: Chemoradiation.

mo there were no significant differences in terms of OS between both groups of treatment^[30]. A subsequent Italian Multicenter study (SNAP-02) investigated 154 patients who were randomized to receive TIP as it was previously studied or paclitaxel 175 mg/m² + cisplatin 75 mg/m² for three cycles, followed by RS. Grades 3-4 leukopenia (6%/53%) and neutropenia (26%/76%) were significantly more frequent with TIP. The overall optimal response showed a significant benefit by using TIP OR = 2.3 (95%CI: 1.1-4.7, *P* = 0.027). No significant differences in survival were noted between groups^[31].

The possible limitation of this strategy is the fact that over 30% of patients will require adjuvant radiotherapy after surgery due to pathologic risk factors on the specimen^[33]. Thus, patients could have the adverse effect of a RS plus radical pelvic/abdominal radiotherapy (Table 1).

The question of whether NACT or chemoradiation is a more efficacious treatment for patients with LACC (FIGO stage I B2- II B) remains to be answered. The current RCT being conducted by the European Organization for Research in Cancer Therapy (EORTC) compares these two treatment modalities in patients with LACC (EORTC-55994, NCT00193739) and is expected to reveal important information for determining the most effective treatment protocol.

ADJUVANT CHEMOTHERAPY AFTER INITIAL TREATMENT

Chemotherapy could be given after initial treatment in patients with a higher risk of systemic relapse. Peters *et al.*^[13] evaluated 268 patients who were randomly treated with surgery plus radiotherapy or surgery plus chemoradiation plus adjuvant chemotherapy based on four cycles of 5 fluorouracil every 3 wk in patients with early stage disease (FIGO stage I A2- II A). Progression-free and OS was significantly improved in patients receiving chemotherapy. The hazard ratios for progression-free survival and OS in the radiation only arm *vs* the chemoradiation

arm were 2.01 (*P* < 0.003) and 1.96 (*P* < 0.007), respectively. This advantage was more pronounced in patients that received three or four cycles of adjuvant chemotherapy. In addition, a recent analysis of more mature data^[34] showed maximal benefit for patients with spread to two or more lymph nodes after postoperative radiotherapy and adjuvant chemotherapy compared with patients receiving postoperative radiotherapy alone (5-year survival 55% *vs* 75%). However, the effect was minimal in low-risk patients, such as only one metastatic lymph node or a tumor size of 2 cm or less in diameter^[34].

Adjuvant chemotherapy was also investigated after NACT followed by RS. In 1998, Sananes *et al.*^[35] evaluated the efficacy of adding 3 courses every three weeks of cis-platinum 50 mg/m², methotrexate 30 mg/m², and cyclophosphamide 500 mg/m² in 56 women with LACC FIGO stage I B- III B after NACT followed by RS. After a median follow-up of 75 mo the authors noted an OS for stage I B of 88%, Stage II B 78%, and 50% for III B. Angioli *et al.*^[36] reported a case series of 246 women affected by a LACC FIGO stage I B2- II B who had undergone NACT followed by RS and postoperative adjuvant chemotherapy based on 4 cycles of Cisplatin 100 mg/m² and Paclitaxel 175 mg/m². The study showed a 5-year OS and DFS are 77% and 61%, respectively.

In summary, adding chemotherapy after initial treatment for treating women with LACC requires further investigation. Despite the fact that this strategy should be used under clinical trials, it seems reasonable its indication in high-risk patients, such as node metastasis and lymphovascular space involvement.

AORTIC LYMPH NODE TREATMENT

Lymph node involvement and tumor size are the most important prognostic factors in women with LACC^[37,38]. Based on the results of positron emission tomography-computed tomography (PET-CT), over 20% of patients with LACC have aortic node metastasis, and 93% of them have concomitant pelvic node involvement^[39]. De-

termination of nodal involvement before treatment has been suggested as an important factor for disease control and for obtaining better oncologic outcomes^[40]. Surgical staging has been demonstrated to be the best option for establishing the status of aortic node in women with LACC. A prospective study on 60 women with LACC without evidence of aortic involvement on CT scan underwent PET-CT and aortic surgical staging. A total of three out of 26 patients (21%) with negative pelvic and aortic node on PET-CT had histological positive aortic nodes (false negative rate). In addition, 6 (22%) patients with positive pelvic but negative aortic nodes on PET-CT had positive aortic node at final histology report^[41]. Other similar study on 125 patients performed by Leblanc *et al.*^[42] found similar results. Standard treatment for patients with aortic nodal involvement is based on the extension of radiation field to the aortic area up to the level of the renal veins. As it was previously mentioned, that using IMRT the intestinal toxicity can be reduce without effect on survival^[43].

Despite the fact that aortic lymph node dissection can be performed by laparoscopy or robotic surgery, arguments against lymphadenectomy include increased morbidity, delay in starting first line treatment and the questionable advantages on the patients' OS^[40]. To this regard, the oncological outcomes of aortic lymph node dissection have been evaluated in several studies with controversial results. A sub-analysis of three gynecologic oncology group (GOG) studies (GOG 85, GOG 120, and GOG 165) analyzed the impact of surgical staging ($n = 555$) or radiographic determination (CT or magnetic resonance imaging) ($n = 130$) on survival in women with LACC after chemoradiation treatment^[44]. Despite the fact that the multivariate analysis demonstrated a positive benefits of surgical staging on progression free survival and OS, the study had some limitations. Inclusion criteria for this sub-analysis were heterogeneous and the population was unbalanced not only in the sample size, but also regarding the pre-surgical nodal evaluation^[40]. The effect on survival of aortic node dissection in women with LACC and negative aortic nodes on PET-CT is currently being investigated in two phase III RCT. (NCT01049100 and NCT01365156).

CONCLUSION

During the last years, several strategies of treatment have been evaluated for treating LACC FIGO stage I B2- II B. After reviewing the literature, there is clear evidence that chemoradiotherapy is better than radiotherapy alone but there is no evidence for using chemoradiotherapy in lieu of NACT followed RS as standard of care. Until definitive trials currently ongoing are published, the strategy of treatment should be individualized after adequate patient counseling and based on specific institution capability.

Abstract

Head and neck cancer (HNC) is the sixth most common human malignancy worldwide. The main forms of treatment for HNC are surgery, radiotherapy (RT) and chemotherapy (CT). However, the choice of therapy depends on the tumor staging and approaches, which are aimed at organ preservation. Because of systemic RT and CT genotoxicity, one of the important side effects is a secondary cancer that can result from the activity of radiation and antineoplastic drugs on healthy cells. Ionizing radiation can affect the DNA, causing single and double-strand breaks, DNA-protein crosslinks and oxidative damage. The severity of radiotoxicity can be directly associated with the radiation dosimetry and the dose-volume differences. Regarding CT, cisplatin is still the standard protocol for the treatment of squamous cell carcinoma, the most common cancer located in the

oral cavity. However, simultaneous treatment with cisplatin, bleomycin and 5-fluorouracil or treatment with paclitaxel and cisplatin are also used. These drugs can interact with the DNA, causing DNA crosslinks, double and single-strand breaks and changes in gene expression. Currently, the late effects of therapy have become a recurring problem, mainly due to the increased survival of HNC patients. Herein, we present an update of the systemic activity of RT and CT for HNC, with a focus on their toxicogenetic and toxicogenomic effects.

Key words: Chemotherapy; Head and neck cancer; Radiotherapy; Toxicogenetic; Toxicogenomic

Core tip: The main therapies for head and neck cancer (HNC) are surgery, radiotherapy (RT) and chemotherapy. Considering that both RT and chemotherapeutic drugs can interact with the DNA, one of the important, late-occurring complications is a therapy-related secondary tumor resulting from the genotoxic effects of the therapy on the healthy cells. This review presents an update of the toxicogenetic and toxicogenomic effects of HNC treatments, highlighting the main mechanisms evolved in the secondary damage caused by RT and chemotherapies.

INTRODUCTION

Head and neck cancer (HNC) is the sixth most common

human malignancy^[1], representing 3% of all types of malignant tumors. The head and neck are anatomically complex regions where a wide variety of cancers with different phenotypes, histologies and invasiveness may occur^[2]. Approximately 48% of the cases are located in the oral cavity, and 90% of these cases are squamous cell carcinoma (SCC), which affects the lips, mouth, tongue, nasopharynx, oropharynx, hypopharynx, larynx and paranasal sinuses^[2,3]. Annually, more than 500000 new cases of SCC are diagnosed^[4]. High rates of morbidity and mortality are observed^[5], mainly because of the advanced clinical stage at the time of diagnosis^[6]. However, the use of concurrent chemotherapy (CT) and radiation demonstrates that survival has substantially improved over the past decades for patients with most of the forms of HNC^[7]. Data from some studies have suggested that SCC develops through two mechanisms: directly from the normal mucosa, called “*de novo*”, and following the sequence “dysplasia-carcinoma”^[8-10].

Tobacco, alcohol consumption and human papillomavirus (subtypes 16, 18 and 33) are responsible for, at least, 75% of HNC^[11]. However, other factors, such as diet^[12], mechanical trauma^[13], occupational factors, oral hygiene, inflammation^[14,15] and some gene polymorphisms, are also associated^[12,16]. Little is known about the molecular mechanism of HNC. Some studies have shown that alterations in the PI3K pathways, such as mutations in the *PIK3A* gene, have been reported in HNC^[17,18]. The PI3K/AKT/mTOR pathway is activated in 57%-81% of SCC patients, and AKT is usually upregulated^[19]. Moreover, it has been reported that *TP53* mutations are frequently detected in the tissues of young adult SCC patients^[20], and *NOTCH* mutations have also been found in head and neck carcinomas^[21]. Furthermore, EGFR expression has been described in up to 90% of cases, and it is associated with poor prognosis^[22].

Several therapies and treatment protocols are used for HNC, including surgery, CT^[2] and radiotherapy (RT) and more recently, immunotherapy^[23], gene therapy^[24] and photodynamic therapy^[25]. While treatment for loco-regionally recurrent HNC may include surgery or RT, systemic CT is used in locally advanced tumor, recurrence or metastasis^[26]. CT may, or may not, be associated with surgery and/or RT^[27]. The choice of HNC therapy depends on the tumor staging and the approaches for organ preservation^[28]. Currently, the late effects of therapies have become a recurring problem, mainly due to the increased survival of HNC patients.

In the following paragraphs, we highlight some toxicogenetic (stable and heritable alterations in the genome that are able to influence the relative susceptibility of an individual to the adverse effects that may result from exposure to an exogenous material) and toxicogenomic (relationship between the genome and the biological response of the body after exposure to toxic agents or stressors) effects of HNC therapies.

RT

In recent years, RT has technically and biologically im-

proved, aiming at including only the target, with minimal unnecessary irradiation to normal tissue^[29,30]. Actually, RT fractionation schedules includes more fractions per day in order to reduce the overall treatment time (accelerated fractionation) and/or the use of multiple small fraction doses (hyperfractionation), which allows a higher total dose to be given without enhancing the risk of morbidity induced by radiation^[31].

Radioresistance is one of the main determinants of treatment outcome in HNC patients, and it can be related to tumor hypoxia and changes in gene expression^[32,33]. A meta-analysis study showed that when hypoxic modification is given in conjunction with curative intended RT result in a significant improvement in loco-regional control, disease specific control and overall survival^[34]. However, another study showed that RT (5 Gy radiation) had no effect on hypoxia-inducible factor-1 α (*HIF-1 α*) gene expression in human oral SCC cell lines (SAS, Ca9-22, TT, BSC-OF and IS-FOM). Conversely, SCC cells expressing high levels of *HIF-1 α* were resistant to radiation^[35].

Several genes, such as sensors, transducers and effectors of DNA damage, have been associated with the ionizing radiation-induced cellular response^[36]. One of the main molecules is the tumor-suppressor protein p53, which acts through the transcriptional control of target genes, influences multiple response pathways and leads to a diverse response to ionizing radiation in mammalian cells^[37]. Additionally, one study demonstrated that the radiation-resistant capacity of nasopharyngeal tumors was mostly due to changes in the expression of genes related to cell Ca²⁺ homeostasis. This same study also showed that cell proliferation induced by extracellular and intracellular factors may maintain the tumor size during RT, leading to recurrence after treatment^[38]. Bohn *et al.*^[39] showed that RT induces a systemic stress response, as revealed by the induction of stress relevant gene expression in blood cells. However, the authors discuss that further studies are still needed to confirm that these changes reflect a systemic effect or are biomarkers of the tumor microenvironment. Moreover, a genomic (transcriptomic and proteomic) study of the response to radioresistance showed 265 up-regulated and 268 down-regulated genes, 30 of which were cancer-related genes. The proteomic analysis identified 51 proteins with altered expression in the radioresistant cell lines, 18 of which were cancer-related proteins. In both methodologies, the over-expression of NM23-H1 and PA2G4 were identified^[33]. The influence of GP96 protein in radioresistance has been also described^[40-43]. GP96 is a multifunctional protein^[44] that acts as a chaperonin for peptides and modulates the innate and adaptive immune responses that are mediated by antigen-presenting cells and other immune cells^[40-43]. Furthermore, GP96 is important for protein maturation and protein homeostasis^[45]. In patients undergoing RT, it was shown that GP96 may serve as a novel prognostic marker of RT and may play important role in radioresistance, favoring tumor invasiveness^[46].

In addition to gene expression changes, it is well

known that ionizing radiation damages the DNA, causing single (SSB) and double-strand breaks due to direct action or by the generation of free radicals^[47], resulting in oxidative stress^[48], base damage and DNA-protein cross-links^[49-51]. The oxidative DNA damage arising from RT can be responsible for both therapeutic and adverse effects^[52]. In other words, RT may kill the tumor cells, but it can also damage normal tissues^[53]. A second tumor may develop immediately or years after the primary tumor treatment^[54]. Therefore, the most important dose-limiting factor is the tolerance of the adjacent normal tissue, which depends on the stage and location of the primary tumor^[55]. Quantification of chromosome aberrations in circulating lymphocytes is used to estimate the effects of the RT dose^[56].

RT mutagenicity on tumor and healthy tissues depends on the DNA repair capacity^[57]. Genomic integrity following irradiation is maintained by specific DNA repair pathways that are initiated based on the type of DNA damage^[58]. Double-strand DNA breaks are repaired *via* homologous recombination repair and/or non-homologous end joining repair^[58]. In HNC, variants of the *XRCC2*, *XRCC3* and *RAD-51*^[59] genes were found to be associated with acute mucositis^[60,61]. The alkaline comet assay has become a popular technique for detecting a range of DNA damage types during the last decade^[62], including the effects of RT. In this sense, DNA damage and repair efficiency were evaluated by comparing the peripheral blood lymphocytes, which were isolated from tissue biopsies and from metastases biopsies of SCC patients after treatment with gamma radiation (Cobalt 60). It was observed that the repair mechanisms were less effective in patients with metastasis than in the healthy controls. Thus, the differences in radiation sensitivity of the cancer and control cells suggests that DNA repair might be critical for the treatment of SCC^[57]. On the other hand, the 8-oxoGua is one of the most common DNA lesions that results from reactive oxygen species (ROS)^[63], and this lesion can lead to mismatched pairing^[64]. The repair hOGG1 glycosylase removes 8-oxoGua from the cellular DNA and repairs the base excision^[52,65,66]. Thus, Cooke *et al.*^[65] showed that urinary excretion of 8-oxoGua and 8-oxodG can be used to measure the activity of the enzymes that are involved in the removal of oxidative DNA damage. In this sense, Roszkowski *et al.*^[52] demonstrated that fractionated RT of HNC patients resulted in elevated urinary excretion of 8-oxodG and a significant reduction of uric acid in the blood. The authors suggested that the RT is responsible for oxidative stress/oxidative DNA damage throughout the whole body and, therefore, may be responsible for a significant increase in the level of 8-oxodG in a distinct subpopulation of HNC patients^[52]. The lack of increase of urinary 8-oxoGua in irradiated patients may reflect a reduction in the activity of hOGG1. Recently, it has been observed that HNC patients have a significantly reduced ability to repair the 8-oxoGua lesion that is generated by oxidative stress^[67]. However, the decreased activity

of the main enzyme responsible for 8-oxoGua removal should result in the accumulation of the lesion in cellular DNA^[52]. Some authors have also shown different inter-individual responses in patients after RT. Kadam *et al.*^[68] studied gamma radiation-induced SSBs in peripheral blood leukocytes of SCC HNC patients with different lifestyles, both during and after RT. The results indicated that gamma radiation caused considerable DNA damage in all of the dose intervals of the treatment. However, a comparison between the smokers and non-smokers revealed the significantly greater DNA damage in the smoking patients at the pre-therapy level (10 Gy and 60 Gy of irradiation), indicating a higher sensitivity of the smokers to gamma radiation at these doses. At doses of 20-50 Gy, gamma irradiation failed to cause increased DNA damage in smokers, indicating the radio-protective or shielding effect of the tobacco (nicotine) that is possibly related to the antiapoptotic property of nicotine in the targeted/non-targeted cells. This may have important implications for RT that could indicate less effective treatment in smokers. Prolonged exposure to gamma radiation (40-60 Gy) led to a gradual decline in the intensity of the DNA damage, suggesting saturation of DNA damage in the peripheral blood leukocytes^[68].

One of the cytogenetic biomarkers that is widely used to predict cancer risk in humans is the presence of micronuclei (MN)^[69,70]. MN are chromosome fragments or whole chromosomes that are not incorporated into the main nucleus during mitosis. Therefore, they only appear in cells that have undergone a nuclear division^[71]. The MN test is being applied to cytokinesis-blocked peripheral blood lymphocytes and exfoliated cells to monitor human exposure to mutagens^[72-74]. The evaluation of cytogenetic damage by measuring the frequency of micronucleated cells (MNC) in peripheral blood and buccal mucosa of HNC patients undergoing RT showed a significant increase in the number of MNC during RT. The number of micronucleated lymphocytes remained high 30 to 140 d after the end of treatment. These data confirmed the clastogenic potential of RT in the circulating lymphocytes and buccal cells of HNC patients^[75] (Figures 1 and 2).

The severity of radiotoxicity can be directly associated with the radiation dosimetry and the dose-volume differences^[76]. While epidemiological studies have demonstrated the correlation between the formation of a secondary tumor with exposure to moderate-to-high doses of ionizing radiation, a statistically significant increase has hardly been described with low doses of radiation^[77]. The principal RT effects in normal tissue are acute radiotoxicity (mucositis, dysphagia and dermatitis) that occurs in tissues with rapid turnover rates and late radiotoxicity [subcutaneous skin fibrosis and osteoradionecrosis (ORN)] in tissues with slower turnover rates; these effects may become evident months or years after therapy^[78]. There are variable normal tissue responses to RT^[79], and this may be due to the stochastic or deterministic variation effects in radioresponsiveness^[76]. Mucositis, for in-

Figure 1 Micronucleated lymphocytes. Stained with 5% Giemsa (increased $\times 400$).

stance, is characterized by mucosal ulceration in the oropharyngeal and gastrointestinal tract, resulting in pain, dysphagia and diarrhea, depending on the dysfunction of the affected tissue^[80]. Some authors have demonstrated that intestinal mucositis is the consequence of a complex cascade of biological events, rather than solely due to direct clonogenic cell death of the epithelial cells^[81]. However, evidence suggests that EGF and its receptor do not have a critical role in prevention or repair of fluorouracil CT-induced intestinal damage^[82]. In addition to cell death events that are associated with the pathogenesis of mucositis, the activation of a wide variety of transcription factors, the production of proinflammatory cytokines, matrix metalloproteinases, leukotrienes, and ceramide^[81], caspase activation and the generation of oxidative stress and ROS by chemotherapeutic agents or radiation appear to be primary events in most pathways leading to mucositis. ROS causes DNA damage and subsequent clonogenic cell death in the epithelial layer^[81]. Of the transcriptional factors that may be significant, nuclear factor κ B (NF- κ B), which is activated by either RT or CT, has many of the characteristics that suggest it may be a key element in the genesis of mucositis. Once activated, NF- κ B leads to the up-regulation of many genes, including those that result in the production of the pro-inflammatory cytokines *TNF- α* , *IL-1 β* and *IL-6*. This leads to tissue injury and apoptosis^[81].

Moreover, evidence of genetic mutations and the role of single nucleotide polymorphisms (SNPs) have been shown to underlie the inter-individual differences in the adverse responses of normal tissues to radiation^[83-85]. Interindividual variations in radiotoxicity responses exist despite the uniform treatment protocols. It is speculated that normal genetic variations, particularly SNPs, may influence normal head and neck tissue radiotoxicity^[78]. The first systematic review of the association of SNPs with the occurrence of HNC radiotoxicity evaluated the association of 11 polymorphisms in 8 genes with acute radiotoxicity and 6 polymorphisms in 4 genes for late radiotoxicity^[78]. The risk of severe acute mucositis was associated with the G allele of *XRCC1* (1196 A > G) in patients treated with RT alone or CT. Severe acute dysphagia was associated with the T allele of *XRCC3* (722

Figure 2 Micronucleated buccal mucosa cells. Stained with feulgen/fast-green (increased $\times 400$).

C > T) and the G allele of *XRCC6* (1310 C > G), and severe acute dermatitis was associated with the T allele of *RAD51* (3392 G > T). The G allele of *XRCC1* (1196 A > G) was associated with a lower grade of subcutaneous fibrosis, suggesting that the wild-type alleles were the risk alleles^[86]. ORN was found to be associated with the T allele of the *TGF β 1* (509 C > T) polymorphism, while the CC genotype was significantly associated with post-extraction related ORN^[78] (Figure 3).

In addition to gene expression changes and DNA damage, microRNAs have been associated with the RT response. In oral SCC cells, it was observed that *ICAM2* gene inhibition by miR-125b expression downregulation induces radiosensitization, suggesting that this miRNA was associated with proliferation and radioresistance mechanisms. Therefore, the control of the expression or activity of miR-125b might contribute to the suppression of proliferation and overcoming radioresistance in OSCC^[87].

CT

Cisplatin-based CT is still the standard protocol for treating SCC^[26,88]. However, simultaneous treatment with cisplatin, bleomycin (radiomimetic antitumoral drug) and 5-fluorouracil (anti-metabolite drug) has also been used^[89]. Other protocols have added paclitaxel to the traditional cisplatin regimen^[90,91]. Combinations with methotrexate and docetaxel may be also used. The administration of the combination therapies can be curative or palliative^[92].

Considering that these drugs can induce DNA damage, one of the important late-occurring complications from treatment of the primary tumor is therapy-related secondary cancer that can result from the genotoxic activity of the drugs on healthy cells^[89,93]. Desai *et al*^[94] showed that head and neck SCC patients were predisposed to chromosomal rearrangements by anticancer drug treatment, which may promote secondary tumorigenesis. Furthermore, Minicucci *et al*^[95] observed higher frequencies of micronucleated lymphocytes in children with malignant tumors before therapy than in healthy children. The authors suggest that the presence of malig-

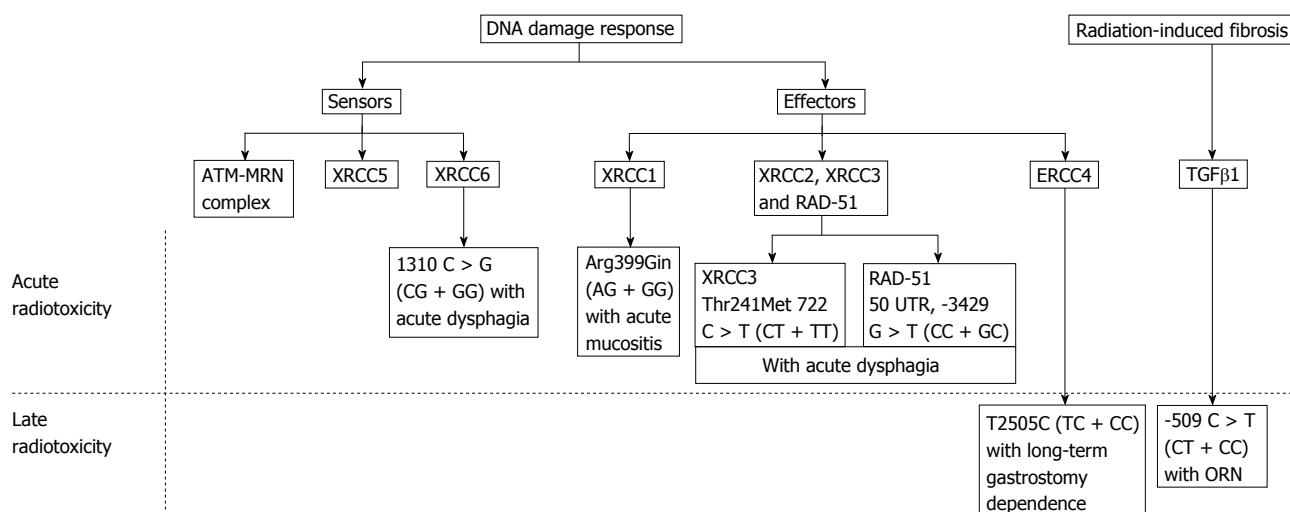

Figure 3 Diagram summarizing the genetic variants associated with radiotoxicity. Extracted from Ghazali *et al.*^[78].

nant tumors may increase the frequency of DNA damage in circulating lymphocytes. Other authors have shown that adjacent tumor tissues shared common genetic changes, and it appears that multiple tumors can arise from a single transforming event that spreads throughout the mucosa surface. On the other hand, some authors have demonstrated the presence of a second tumor that is not clonally-related to the first, which supports the hypothesis of widespread genetic changes after exposure to carcinogen^[96]. In this sense, Ronchetti *et al.*^[97] studied patients with HNC and found that the pattern of microsatellite changes observed in the primary cancer exhibited a completely different genetic arrangement than the second tumor, indicating an independent origin in about three-quarters of the cases.

Cisplatin activity is based on the formation of DNA adducts that block DNA replication and transcription^[98]. These crosslinks represent about 90% of the total DNA damage induced by this drug and are the major contributing factor to its cytotoxic effects^[99]. Carboplatin is another CT drug used for HNC. It belongs to the same group as cisplatin; thus, it is a platinum-based antineoplastic agent. However, when compared to cisplatin, a higher concentration of carboplatin is required to reach equivalent DNA binding because it forms intrastrand DNA crosslinks at a slower rate, and the elimination of free platinum is 10-fold lower than cisplatin^[100]. In relation to treatment with cisplatin, bleomycin and 5-fluorouracil, some authors using the wing somatic mutation and recombination test (Smart) in *Drosophila melanogaster* (*D. melanogaster*) have shown that the combination of these drugs produced synergistic and antagonistic genotoxic effects depending on the concentrations used, and these studies suggest that secondary effects associated with their genotoxic effects could exist, emphasizing the importance of long-term monitoring in these patients^[101]. The anti-metabolite 5-fluorouracil was developed by Heidelberger *et al.*^[102] and is based on the observation that, during DNA synthesis, the uracil base was used more

effectively by tumor cells than normal cells. 5-fluoracil is considered to be an S-phase active chemotherapeutic agent and causes DNA damage, such as double and single-strand breaks^[103]. The genotoxicity of treatment with paclitaxel and cisplatin was also studied, as their effects are not restricted to malignant cells. Using the wing Smart method in *D. melanogaster*, the authors suggested that the combination of paclitaxel and cisplatin did not appear to increase the risk of secondary cancer development; however, the aneugenic activity of paclitaxel could be responsible for the reduced genotoxicity of cisplatin^[104]. Methotrexate blocks the formation of tetrahydrofolic acid because of its high affinity for dihydrofolic acid reductase and suppresses protein synthesis in the G1 phase. Thus, high dose methotrexate could be possible in combination with leucovorin rescue, which prevents normal cells from being affected by the methotrexate-induced folic acid deficiency^[92].

Effects of the genotype are also observed. In patients with prior HNC, 13-cis-retinoic acid (13-cRA) has been shown to prevent second primary tumors (SPT)^[105]. However, other authors demonstrated that low dose 13-cRA treatment did not significantly reduce the occurrence of SPT. The results seem to be influenced by the genotype of the patient. The GST-M1 genotype is an influential risk factor for the development of SPTs in patients who were successfully treated for HNC, and the absence of the GST-T1 enzyme demonstrated a protective effect against SPT^[106].

To avoid late effects of systemic CT, targeted therapy has been also used for treating HNC patients. Bevacizumab, an antiangiogenic monoclonal antibody that targets vascular endothelial growth factor^[107]; trastuzumab, a monoclonal antibody that targets human epidermal growth factor receptor 2 (HER-2)^[108]; lapatinib, a dual EGFR and HER-2 receptor tyrosine kinase inhibitor^[109]; rapamycin, an mTOR inhibitor with antiproliferative effects^[110]; sorafenib, an ERCC1 protein expression DNA repair inhibitor^[111] are some of the drugs currently used

in target therapy.

Among the chemoradiation-induced toxicities, mucosal barrier injury has been well studied. In this sense, peripheral blood cells of patients treated with carboplatinum, paclitaxel and radiation demonstrated the potential impact of the chemoradiation on healthy tissues. Of potential relevance to the development of mucosal injury, it has been observed that Dkk-1, a specific Wnt inhibitor, is upregulated in the tumors^[112]. Some authors suggest that the presence of the Wnt inhibitor provides a mechanism for a reduction in epithelial proliferation, as studies have demonstrated that the presence of Dkk-1 is associated with crypt loss in mice^[113].

CONCLUSION

Nowadays, due to advances in cancer therapies, a significant increase of survival has been observed for cancer patients. Reduction of the toxicogenetic and toxicogenomic side effects has been one of the major goals in the search for new anticancer drugs and therapy protocols.

Rapid innovations in RT have resulted in an urgent need for methods to predict cancer risks from RT, as direct observation of the late effects of newer treatments will require patient follow-up for a decade or more^[114]. Cancer RT involves the eradication of the cancer cells while sparing the surrounding normal tissues. Currently, global tissue responses to RT appear to be directed towards limiting the damage, inducing repair processes and restoring tissue homeostasis^[115]. These newer treatments aim to reduce the amount of healthy tissue exposed to high doses of radiation, but this may occur by increasing the amount of normal tissue exposed to lower doses of radiation^[114]. Combined chemotherapeutic protocols have also been used aiming synergistic effects and decreased toxicity. Furthermore, the concurrent use of chemo and RT has shown a substantial improvement of survival over the past decades^[7]. Alternative therapies, as well as target therapy have also been developed for treating HNC patients. Prevention of second primary tumors is also a field of research that has increased considerably, because of its impact on long-term survival.

Abstract

The purpose of this article is to review the role of maintenance therapy in the treatment of advanced non-small cell lung cancer (NSCLC). A brief overview about induction chemotherapy and its primary function in NSCLC is provided to address the basis of maintenance therapies foundation. The development of how maintenance therapy is utilized in this population is discussed and current guidelines for maintenance therapy are reviewed. Benefits and potential pitfalls of maintenance therapy are addressed, allowing a comprehensive review of the achieved clinical benefit that maintenance therapy may or may not have on NSCLC patient population. A review of current literature was conducted and a table is provided comparing the results of various maintenance therapy clinical trials. The table includes geographical location of each study, the number of patients enrolled, progression free survival and overall survival statistics, post-treatment regimens and if molecular testing was conducted. The role of molecular testing in relation to therapeutic treatment options for

advanced NSCLC patients is discussed. A treatment algorithm clearly depicts first line and second line treatment for management of NSCLC and includes molecular testing, maintenance therapy and the role clinical trials have in treatment of NSCLC. This treatment algorithm has been specifically tailored and developed to assist clinicians in the management of advanced NSCLC.

Key words: Maintenance therapy; Clinical trials; Non-small cell lung cancer; Molecular aberrations; Progression-free survival; Overall survival

Core tip: This review article addresses the role of maintenance therapy in the treatment of advanced non-small cell lung cancer (NSCLC). Maintenance therapy utilization in NSCLC patient population and review of current guidelines for maintenance therapy are discussed. A treatment algorithm was created to depict first line and second line treatment for managing NSCLC and includes molecular testing, maintenance therapy, and the role of clinical trials in the treatment of NSCLC. A comprehensive review of the achieved clinical benefit that maintenance therapy may or may not have on the NSCLC patient population is presented.

CURRENT FIRST-LINE THERAPY MANAGEMENT OF ADVANCED NSCLC

Lung cancer remains one of the leading causes of cancer-

related death in men and women worldwide and attributes approximately 1.37 million deaths per year worldwide^[1]. Non-small cell lung cancer (NSCLC) is the most common form of lung cancer and approximately 2/3 of patients with NSCLC present with advanced disease^[2]. This advanced disease state leads to limited treatment options^[3], primarily systemic therapy. According to National Comprehensive Cancer Network guidelines, 4-6 cycles of platinum-based doublet chemotherapy is recommended as first-line treatment in patients without a driver mutation, such as, epidermal growth factor receptor (*EGFR*) mutation or anaplastic lymphoma kinase (*ALK*) rearrangement^[4]. For those patients with an *EGFR* mutation or *ALK* rearrangement, use of a specific inhibitor directed at that target is indicated either as the initial treatment or as therapy when progressive disease develops.

The platinum doublet generally consists of cisplatin or carboplatin with another cytotoxic agent, sometimes in combination with a biologic agent such as bevacizumab (B). Multiple cytotoxic agents in addition to cisplatin and carboplatin have antitumor activity in NSCLC. These include pemetrexed, taxanes (docetaxel, paclitaxel, nanoparticle albumin bound paclitaxel), gemcitabine, vinorelbine, and camptothecins (irinotecan, topotecan). The use of cytotoxic chemotherapy as the initial treatment for patients not selected based upon *EGFR* mutation status and for those whose tumors do not contain an *EGFR* mutation is supported by the results of the tarceva or chemotherapy trial^[5]. In that trial, 760 patients were randomly assigned to either first-line erlotinib followed by chemotherapy (cisplatin plus gemcitabine) upon progression or the same first-line chemotherapy followed by erlotinib upon progression. Overall survival (OS) was significantly longer in unselected patients assigned to initial chemotherapy followed by second-line erlotinib (median 11.6 mo *vs* 8.7 mo, HR = 1.24, 95%CI: 1.04-1.47). For patients known to be *EGFR* mutation negative, OS was significantly longer with initial chemotherapy (median 9.6 mo *vs* 6.5 mo). Combination chemotherapy regimens using a platinum doublet result in median OS of 8-11 mo^[5].

EVALUATION OF THE ROLE OF MAINTENANCE THERAPY

Extending the duration of treatment with the initial platinum based chemotherapy beyond four to six cycles has been evaluated. Currently, there is little evidence to support continuous doublet cytotoxic chemotherapy after 4-6 cycles being given until disease progression^[6], although longer treatment duration increases progression-free survival (PFS), it has at most only a modest effect on OS^[7]. Maintenance therapy is an extension of induction chemotherapy and is continued for a determined period of time unless there is disease progression or significant toxicities develop^[8]. The goal is to extend a favorable patient response from first-line platinum based combination chemotherapy^[9]. There are two types of maintenance therapy, known as continuation and switch maintenance

therapy. Continuation maintenance therapy is the administration of one chemotherapy agent that was part of the initial chemotherapy regimen. Continuation maintenance therapy can involve either a non-platinum cytotoxic drug or a molecular targeted agent. Switch maintenance therapy, involves administration of a new chemotherapy agent that was not part of the original chemotherapy regimen and a potentially non-cross-resistant agent that is started immediately after completion of first-line induction chemotherapy^[9]. Currently, switch-maintenance therapy with pemetrexed or erlotinib is food and drug administration (FDA)-approved. With the standard 4-6 cycles of platinum based chemotherapy, patients may have a response within the first 2-4 cycles; however, many patients cannot tolerate long-term treatment^[10]. Disease progression and co-morbidities that arise due to disease progression contribute to the intolerance of long-term treatment.

Historically, treatment for advanced NSCLC involved waiting until disease progression before a second-line therapy was started^[8]. After first-line therapy, “drug holidays” rarely lasting more than 3 mo in duration can pose a risk for rapid clinical deterioration leading to ineligibility for second-line treatment^[11,12]. This led to clinical trials investigating the role for maintenance therapy using 3rd generation cytotoxic agents and targeted therapy^[8]. Many of these studies either did not have adequate power to detect statistical significance for survival benefits or did not have a placebo control arm^[8].

Advocates of maintenance therapy point to potential merits including: higher probability that tumor will be exposed to effective therapies, decreased development of chemotherapy resistance, maximizing the efficacy of chemotherapy, potentiating the anti-angiogenic effects of chemotherapy, and enhancing anti-tumor immunostimulation^[9]. Many patients do not go on to receive second-line therapy due to rapid progression of disease, decrease in their performance status, or increase cancer-related symptoms. By treating patients with maintenance therapy, the window of opportunity for treatment may be extended. Those patients that benefit from maintenance therapy have better performance status and responded to first-line therapy^[9].

Critics of maintenance therapy argue that the trials evaluating maintenance therapy have: inconsistent clinical trial endpoints, impose a detrimental effect on quality of life, prevent some patients from having a drug holiday, add increased associated costs^[9], and eliminate from the armamentarium standard second-line chemotherapy agents if they are used as maintenance therapy. Patients on maintenance chemotherapy with stable disease may also be exposed to additional toxicities^[6] although some maintenance therapies like pemetrexed have limited grade 3-4 toxicities, such as fatigue and neutropenia^[8], and may be better tolerated.

There are currently five medications that are United States FDA approved for maintenance therapy in NSCLC (B, cetuximab, pemetrexed, gemcitabine, and erlotinib)^[4]. Data exist on some agents that perform better or worse based on tumor histology. For example, regimens con-

taining pemetrexed are more effective in patients with adenocarcinoma and have not demonstrated a meaningful clinical benefit for patients with squamous cell carcinoma. The impact of histology was illustrated by a phase III trial in which cisplatin plus pemetrexed was compared with cisplatin plus gemcitabine as initial therapy^[13,14]. Survival in the 847 patients with adenocarcinoma was significantly prolonged with cisplatin plus pemetrexed compared to cisplatin plus gemcitabine (median 12.6 mo *vs* 10.9 mo, $P = 0.03$). Conversely, cisplatin plus gemcitabine was superior to cisplatin plus pemetrexed in the 473 patients with squamous cell carcinoma (median 10.8 mo *vs* 9.4 mo, $P = 0.05$). Ultimately, the outcome from this study and review of previous trial data led to the re-labeling of pemetrexed for use in non-squamous NSCLC.

REVIEW OF MAINTENANCE THERAPY TRIALS

A list with pertinent details of large randomized maintenance therapy trials in NSCLC is provided in Table 1.

In a study published in 2005, vinorelbine 25 mg/m² was evaluated as a maintenance therapy given weekly for 6 mo until disease progression compared with observation alone in stage IIIB/IV NSCLC patients after induction with MIC treatment (mitomycin 6 mg/m², ifosfamide 1.5 mg/m², cisplatin 30 mg/m² given every four wk \times 2-4 cycles \pm radiotherapy)^[15]. A total of 91 patients were randomized to vinorelbine maintenance therapy. Median PFS for vinorelbine was 5 mo *vs* 3 mo with observation, but the difference was not statistically significant. Median OS for both groups were the same at 12.3 mo and evaluation of molecular subtypes were not performed.

A phase III trial evaluating continuation maintenance therapy with gemcitabine 1250 mg/m² every 3 wk until disease progression or request for removal *vs* best supportive care (BSC) was reported^[2]. Advanced NSCLC patients were given gemcitabine 1250 mg/m² and cisplatin 80 mg/m² every 3 wk for 4 cycles as an induction regimen. Two hundred six patients were given gemcitabine while 138 patients received BSC alone. Median time to progression (TTP) from induction was measured and was a median of 6.6 mo with gemcitabine *vs* 5 mo with BSC ($P < 0.001$, HR = 0.7, 95%CI: 0.5-0.9). Median OS from induction for gemcitabine was 13 mo compared to 11 mo, but not significantly different ($P = 0.195$). Karnofsky performance status (KPS) was taken into consideration with OS and patients were split into KPS > 80 *vs* KPS \leq 80. Patients with KPS > 80 had a HR = 2.1 of dying while on gemcitabine and patients with KPS \leq 80 had HR = 0.8. Using continuation maintenance therapy with gemcitabine after induction with gemcitabine and cisplatin did demonstrate a longer TTP *vs* BSC for patients with advanced NSCLC. No molecular testing was conducted in this study.

The Eastern Cooperative Group (ECOG) 4599 study evaluated the effectiveness of B maintenance therapy in

patients with advanced NSCLC nonsquamous histology only^[16]. Patients completed carboplatin 6 mg/mL AUC and paclitaxel 200 mg/m² induction chemotherapy every three weeks for six cycles or carboplatin 6 mg/mL AUC, paclitaxel 200 mg/m² and B 15 mg/kg every three weeks for six cycles. Patients were randomized to B 15 mg/kg maintenance therapy or surveillance (only patients without progressive disease after induction therapy were eligible for this arm). Median PFS was significantly higher for B *vs* surveillance at 6.2 mo *vs* 4.5 mo ($P < 0.001$). Median OS was significantly higher for B *vs* surveillance at 12.3 mo *vs* 10.3 mo ($P = 0.003$). No tumor molecular testing was completed for this study.

In 2009, the JMEN study, an international randomized, double-blind, phase III study of maintenance pemetrexed with BSC *vs* placebo plus BSC for NSCLC resulted in pemetrexed being approved by the FDA for use as maintenance therapy in NSCLC^[10]. Patients were treated with one of six induction regimens (gemcitabine-carboplatin, gemcitabine-cisplatin, paclitaxel-carboplatin, paclitaxel-cisplatin, docetaxel-carboplatin or docetaxel-cisplatin) every 3 wk for four cycles. Patients were assigned randomized 2:1 to receive pemetrexed 500 mg/m² or placebo. Median PFS plus induction was 7.7 mo for pemetrexed *vs* 5.9 mo for placebo ($P < 0.0001$, HR = 0.50, 95%CI: 0.42-0.61). Median OS plus induction was 16.5 mo with pemetrexed *vs* 13.9 mo with placebo ($P = 0.012$, HR = 0.79, 95%CI: 0.65-0.95). Overall, switch maintenance therapy with pemetrexed demonstrated improved PFS and OS and was well-tolerated. In this study, no tumor tissue molecular testing was conducted.

In a phase III study of advanced NSCLC patients receiving induction therapy with gemcitabine 1000 mg/m² and carboplatin AUC = 5 every 21 d for four cycles, patients that did not demonstrate disease progression were randomized to immediate docetaxel 75 mg/m² every 21 d for six cycles or were given docetaxel with the same dosage and schedule once they presented with disease progression^[12]. Immediate administration of docetaxel maintenance therapy demonstrated a statistically significant increase in median PFS compared with delayed docetaxel (5.7 mo *vs* 2.7 mo, $P = 0.001$). Median OS was not statistically significant for either arm of the study and no molecular testing on patients' tumors was completed.

The "PointBreak" study randomized advanced NSCLC patients to pemetrexed 500 mg/m², carboplatin AUC = 6, B 15 mg/kg induction every 21 d with four cycles, with maintenance pemetrexed 500 mg/m², B 15 mg/kg [pemetrexed and bevacizumab (PB)] *vs* paclitaxel 200 mg/m², carboplatin AUC = 6, B 15 mg/kg induction every 21 d for four cycles, with maintenance B 15 mg/kg^[17,18]. The maintenance therapy for both arms was given until disease progression. Median PFS was significantly higher for PB *vs* B at 6 mo *vs* 5.6 mo, respectively ($P = 0.012$, HR = 0.83, 95%CI: 0.7-0.96). Median OS was not significantly different for PB *vs* B at 12.6 mo *vs* 13.4 mo, respectively. The primary endpoint of improved median OS was not met. While tumor molecular testing was conducted, the

types of testing and results have not been reported.

The FLEX study, randomized previously untreated advanced NSCLC patients to cisplatin 80 mg/m² plus vinorelbine 25 mg/m² every 3 wk for six cycles, with or without cetuximab 400 mg/m² day 1 and 250 mg/m² day 8 and all subsequent doses weekly^[19]. Cetuximab maintenance was given until disease progression/toxicities. Median PFS was not statistically significant ($P = 0.39$, HR = 0.94, 95%CI: 0.82-1.07). Median OS for cetuximab *vs* observation was 11.3 mo *vs* 10.1 mo ($P = 0.044$, HR = 0.87, 95%CI: 0.76-0.99). Tumor molecular testing was conducted for EGFR immunohistochemistry and was part of the entry criteria for study eligibility.

The AVAIL study, randomized advanced NSCLC patients to cisplatin 80 mg/m² plus gemcitabine 1250 mg/m² every three weeks for six cycles, with either B (7.5 mg/kg), B (15 mg/kg), or placebo every three weeks until disease progression^[20]. Median PFS for low dose B *vs* placebo was 6.7 mo *vs* 6.1 mo ($P = 0.003$, HR = 0.75, 95%CI: 0.62-0.91). Median PFS for high dose B *vs* placebo was 6.5 mo *vs* 6.1 mo ($P = 0.03$, HR = 0.82, 95%CI: 0.68-0.98). Median OS was not analyzed due to insufficient follow-up duration at the time of data reporting. Overall, B as maintenance therapy does improve PFS. No tumor molecular testing was conducted.

The SATURN study evaluated erlotinib as maintenance therapy in advanced NSCLC patients who received one of seven different platinum based doublet chemotherapy regimens (type of regimens were not specified)^[3]. Induction therapy was given for four cycles followed by erlotinib 150 mg/d *vs* placebo until disease progression, toxicity, or death. No B or pemetrexed were used in the induction chemotherapy regimens. Median PFS for erlotinib *vs* placebo was significantly prolonged at 4.1 mo *vs* 2.75 mo, respectively ($P < 0.0001$, HR = 0.69, 95%CI: 0.58-0.82). Median OS with erlotinib *vs* placebo was also significantly improved at 12 mo *vs* 11 mo ($P = 0.0088$, HR = 0.81, 95%CI: 0.70-0.95). From this trial, molecular testing of EGFR immunohistochemistry was reported.

The BMS-099 study, randomized advanced NSCLC patients to carboplatin AUC = 6 plus either docetaxel 75 mg/m² or paclitaxel 225 mg/m² every three weeks for six cycles or carboplatin AUC = 6 plus either docetaxel 75 mg/m² or paclitaxel 225 mg/m² every three weeks for six cycles with cetuximab 400 mg/m² day 1, 250 mg/m² day 8 and each subsequent dose^[21]. Cetuximab was given weekly until disease progression/toxicities. Median PFS and OS were not statistically significant. Maintenance cetuximab added no clinical benefit to PFS or OS. No tumor molecular testing was included in this study.

The PARAMOUNT study evaluated the use of pemetrexed as continuation maintenance therapy in patients with advanced NSCLC nonsquamous histology^[22,23]. Patients were given pemetrexed 500 mg/m² and cisplatin 75 mg/m² every three weeks for four cycles. Patients were then randomized to pemetrexed 500 mg/m² continuation maintenance every three weeks until disease progression or placebo. Median PFS was significantly higher for pemetrexed maintenance *vs* placebo at 4.1 mo *vs* 2.8 mo,

respectively ($P < 0.0001$, HR = 0.62, 95%CI: 0.49-0.79). Median OS was significantly higher for pemetrexed maintenance *vs* placebo at 13.9 mo *vs* 11 mo, respectively ($P = 0.0195$, HR = 0.78, 95%CI: 0.64-0.96). The use of pemetrexed as continuation maintenance therapy can significantly increase median PFS and OS in patients with advanced nonsquamous NSCLC. No tumor molecular testing was conducted.

The IFCT-GFPC 0502 study evaluated gemcitabine (continuation maintenance) *vs* erlotinib (switch maintenance) *vs* observation as maintenance therapy after induction therapy with cisplatin 80 mg/m² and gemcitabine 1250 mg/m² every three weeks for four cycles in patients with advanced NSCLC^[11]. Patients were then randomized to gemcitabine 1250 mg/m² every three weeks, erlotinib 150 mg/d every three weeks, or observation until disease progression, toxicity, or death. Median PFS for gemcitabine *vs* erlotinib *vs* observation was 3.8 mo ($P < 0.001$, HR = 0.56, 95%CI: 0.44-0.72) *vs* 2.9 mo ($P = 0.003$, HR = 0.69, 95%CI: 0.54-0.88) *vs* 1.9 mo. Median OS was not significantly different for gemcitabine *vs* erlotinib *vs* observation at 12.1 mo *vs* 11.4 mo *vs* 10.8 mo; respectively. Molecular testing was completed for EGFR immunohistochemistry (IHC) ($n = 261$) and EGFR mutation ($n = 188$). Fourteen different EGFR mutations were noted [exon 19 deletion ($n = 10$), exon 21 ($n = 4$)]. EGFR IHC had no significant effect on median PFS for gemcitabine or erlotinib therapy and there were too few cases of EGFR mutations for analysis.

The AVAPREL study evaluated the use of B with or without pemetrexed as maintenance therapy in advanced NSCLC with nonsquamous histology with B 7.5 mg/kg, cisplatin 75 mg/m² and pemetrexed 500 mg/m² every three weeks for four cycles as induction chemotherapy regimen^[24]. Patients were randomized to B 7.5 mg/kg alone or B 7.5 mg/kg plus pemetrexed 500 mg/m² (PB) given every three weeks until disease progression/toxicities. Median PFS for PB *vs* B was 7.4 mo *vs* 3.7 mo ($P < 0.001$, HR = 0.48, 95%CI: 0.35-0.66). Median OS was not significantly different between the two arms. No tumor molecular testing was completed in this study.

MOLECULAR ANALYSIS AND ITS IMPACT ON MAINTENANCE THERAPY

Therapy for advanced NSCLC should be individualized based upon the molecular features of the tumor. Whenever possible, tumor tissue should be assessed for the presence of a somatic driver abnormality (*e.g.*, mutated EGFR, ALK rearrangement) which confers sensitivity to a specific inhibitor^[25]. Unfortunately, many clinical trials do not require collection of tumor tissue for molecular analysis as either entry criteria or for subsequent analysis. There are no randomized trials conducted in patients known to have an EGFR mutation or other driver abnormality prior to the initiation of maintenance chemotherapy. After review of maintenance therapy trials cited here, three of ten had molecular subtypes identified

and two of these three trials had pre-planned analysis for molecular subtype *EGFR* mutations. Furthermore, structuring of clinical trials that identify patients with molecular alterations and evaluating their response to standard maintenance therapy has been minimal^[26]. An improved understanding of the molecular pathways that drive malignancy in NSCLC has led to the development of agents that target specific molecular pathways in malignant cells. These agents have been a significant step forward in the treatment of patients whose tumors contain specific mutations in these pathways. Most patients with advanced NSCLC whose tumors contain a driver mutation are initially treated with the appropriate targeted agent (*e.g.*, erlotinib, gefitinib, or crizotinib). For patients with advanced NSCLC who were initially treated with chemotherapy but in whom a driver mutation has subsequently been identified, continuation of therapy with an appropriate targeted agent after the initial cycles of chemotherapy are complete is recommended^[3].

By taking into consideration patient demographics and obtaining molecular testing target treatment plans can be made. *EGFR* mutations and *ALK* rearrangements are more common in NSCLC tumors of patients that have a history of never to light smoking, compared to Kirsten rat sarcoma viral oncogene homolog (*KRAS*) mutations which are often found in tumors of heavy smokers^[27]. Treatment with *EGFR* tyrosine kinase inhibitors (TKIs) (such as erlotinib, gefitinib, or afatinib) as single agents is indicated for the initial management of patients whose tumors contain an activating mutation in *EGFR*. In this setting, first-line treatment with an *EGFR* TKI improves PFS compared to standard platinum-based chemotherapy. The impact on OS is less clear, since *EGFR* TKIs were frequently used as second line therapy after chemotherapy in the clinical trials demonstrating the efficacy of this approach. *EGFR* TKIs generally are not combined with platinum-based doublet chemotherapy as initial therapy, since these combinations have not prolonged survival even when patients were selected for sensitivity to these *EGFR* TKIs based upon clinical criteria. In the absence of significant toxicity, treatment with an *EGFR* TKI is continued until there is evidence of progression. An example of second-line therapy that has been shown to be more effective in a specific patient population is pemetrexed and *ALK* rearranged tumors. *ALK*-positive tumors have a significant response to pemetrexed leading to longer PFS when compared to *KRAS* mutant, *EGFR* mutant, or triple negative tumors in patients treated with pemetrexed^[27]. Information on molecular subtypes should be considered^[26]. Pemetrexed is cost effective for patients with non-squamous cell histology and shows the importance in identifying patients who will benefit from pemetrexed maintenance therapy^[8].

Crizotinib, an inhibitor of the *ALK* tyrosine kinase, is preferred as first-line therapy in patients whose tumor contains the *ALK* fusion oncogene. Phase II studies using crizotinib demonstrated an objective response rate over 50 percent in previously treated patients with *ALK* rearrangements, with a median duration of response

greater than 40 wk in responders. A phase III trial demonstrated a significant increase in PFS compared to standard chemotherapy in patients who had previously received one platinum-containing regimen^[28]. Further development and research can help distinguish if *ALK*-positive tumors are responsive to cytotoxic agents or specifically responsive to pemetrexed alone. Such findings can improve the way NSCLC patients with distinct tumor molecular phenotypes are treated and how these treatments can impact outcomes^[27].

DISCUSSION

The role of maintenance treatment for patients with advanced NSCLC is under active investigation. There are several factors to consider when choosing to start a patient on maintenance therapy. These factors include deciding how and whether to continue therapy including patient's tolerance for these agents, absence or presence of molecular mutations, patient specific factors like comorbidities, toxicity associated with the original treatment, and desire to balance clinical benefit vs toxicity of immediate further treatment. The studies reviewed have shown that maintenance therapy could provide clinical benefit in specific advanced NSCLC patients. However, as alluded to earlier, few features that can help identify those most likely to benefit from maintenance therapy have been identified.

Not all advanced NSCLC lung cancer patients are made equal and continuation maintenance therapy to date may improve OS in first-line therapy responders^[11], whereas switch maintenance therapy, can improve OS in patients with stable disease after first-line therapy^[29]. More research into identifying factors that contribute to response rate of various maintenance therapies would allow for better selection of patients to receive maintenance therapy^[26]. A recent study identified patients who normally were not qualifying candidates based on common clinical trial inclusion guidelines (such as socioeconomically disadvantaged and patients with greater symptom burden requiring pre-chemotherapy palliative radiation therapy), and observed that this subset of patients maintained stable disease after first line chemotherapy without additional therapy and at time of disease progression responded well to second-line chemotherapy. This is an example of how some patients may benefit successfully without the use of maintenance therapy^[30]. Identification of these factors will assist providers to better define patient populations who should receive maintenance chemotherapy and decrease costs and toxicities in patients who may or may not benefit from having maintenance chemotherapy.

Measurement of PFS and OS should not be the only factors determining the success of maintenance therapy. Patient perspectives need to be taken into consideration. PFS is valued if disease symptoms are minimal, but these gains can be offset as disease symptoms progress or toxicity burden from treatment impacts that patient^[30]. Clinical benefit is an important determinant in deciding

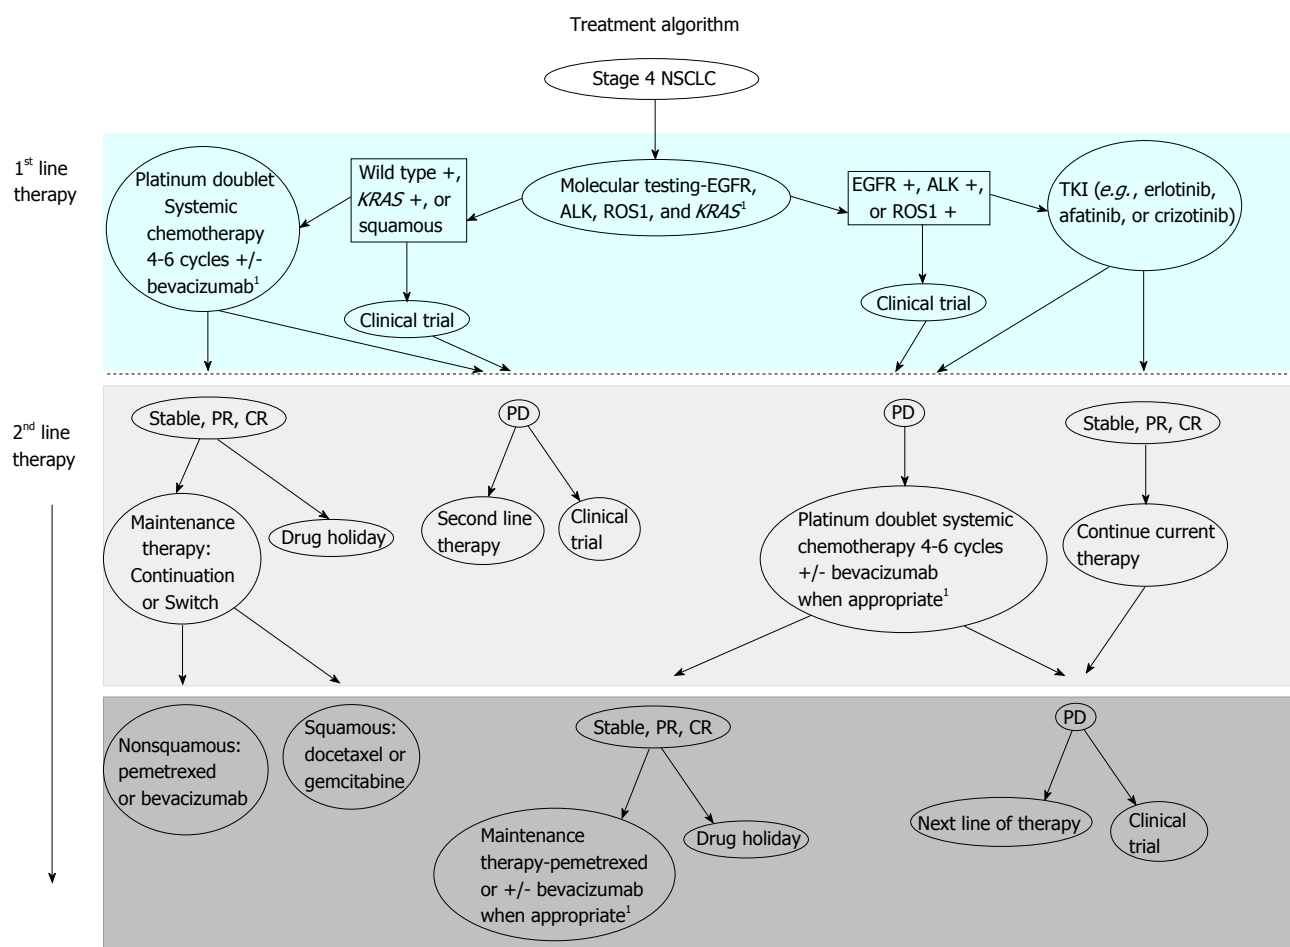

Figure 1 Treatment algorithm. Stage 4 nonsquamous non-small cell lung cancer (NSCLC) should have their tumors analyzed for epidermal growth factor receptor (*EGFR*) mutation or anaplastic lymphoma kinase (*ALK*), Kirsten rat sarcoma viral oncogene homolog (*KRAS*) and ROS1 in a Clinical Laboratory Improvement Amendments-certified laboratory setting. For patients with *EGFR* mutation, we recommend first-line therapy is erlotinib or afatinib or a clinical trial. For patients with *ALK* or ROS1 rearrangements, we recommend first-line crizotinib therapy. We recommend continuation of targeted therapy until disease progression. Upon disease progression, provided the patient is eligible to receive additional therapy, we next recommend a clinical trial or platinum-doublet systemic chemotherapy for 4-6 cycles with or without bevacizumab (drug holiday). Upon disease progression, provided the patient is eligible to receive additional therapy, we next recommend a clinical trial or another National Comprehensive Cancer Network (NCCN) guideline recommended cytotoxic therapy. For patients with squamous, *KRAS* mutation, or wild-type for these 4 molecular phenotypes, we recommend platinum-doublet systemic chemotherapy for 4-6 cycles with or without bevacizumab or a clinical trial. Note: bevacizumab should not be administered to patients with squamous cell carcinoma. Those patients with stable disease or better can proceed on maintenance therapy or have a drug holiday. Those with disease progression on first-line therapy or developing disease progression during maintenance therapy or drug holiday, can be evaluated for a clinical trial or another NCCN guideline recommended cytotoxic therapy, provided the patient is eligible to receive additional therapy. Not for squamous cell lung cancer. TKI: Tyrosine kinase inhibitor; PD: Progressive disease; CR: Complete response.

if patients are candidates for maintenance therapy. By identifying patients' goals and their tolerance of adverse symptoms, determination about the appropriate use of maintenance therapy can be made.

An additional factor when determining the utilization of maintenance therapy is cost effectiveness of maintenance therapy, which can vary depending on location. For example, maintenance pemetrexed is more cost effective compared to other maintenance therapies in the United Kingdom, but is not cost effective in the United States^[30]. Identification of those patients who will gain the greatest benefit from maintenance therapy will help balance efficacy, cost, and patient preferences.

Several of the studies displayed statistically significant results for primary or secondary endpoint PFS. Although PFS was prolonged in many studies, the concern of "statistical significance" in relation to clinical significance

needs attention by the critical eye of a clinician. A result that is statistically significant does not mean that the result is clinically significant and *vice versa*^[31]. Historically and currently, the trend for reporting and interpreting clinical trial results are not based on the prospect of clinical importance^[32]. When interpreting clinical trial results, the *P* value is not the only "value" indicating that the study was statistically significant. The number of subjects in the study contributes largely to reaching a statistically significant number, but not a clinically significant result^[31]. For example, a study with a very large number of subjects commonly will show significant *P* values but overall, the clinical significance and treatment differences are very small^[31].

There have been four maintenance studies to date reporting statistically significant improved PFS and OS. Three out of the four studies, ECOG4599, JMEN, and

PARAMOUNT, did not report tumor molecular analysis. The former study involved B maintenance and the latter two studies involved pemetrexed maintenance. The fourth study, SATURN, did evaluate patient tumors for *EGFR* mutation retrospectively, however, those with *EGFR* mutations had the most dramatic “benefit” of significantly prolonged PFS and OS^[3]. Unfortunately, the majority of maintenance studies reviewed did not conduct molecular testing. To accurately measure the clinical benefit of maintenance therapy in advanced NSCLC patients, their molecular tumor analysis or prospective sample collection should be included as criteria for future clinical trials. As discussed above, the question of clinical *vs* statistical significance is important to point out with all four of these studies. All were very large study populations (at least 663 subjects each) and while the primary results demonstrated statistically significant improvements in median OS, the reality is these are not blockbuster changes for clinically meaningful improvement over standard platinum based doublet therapy in exchange for potential increased treatment-related toxicity and financial-related toxicity.

Other considerations to take into account for maintenance therapy as more oral biologic agents come to the clinic, is patient adherence with their prescribed anticancer therapy. Adherence to treatment is a major factor that can impact outcomes, though the quality of data on this topic and interventions to improve adherence need improvement as well^[33].

Precision-based oncology care allows treatment of advanced NSCLC to be personalized to the patient not the cancer. Just as TKIs have been incorporated into standard of care for treatment of patients with specific tumor molecular mutations^[4], TKIs and metabolic inhibitors have and may continue to demonstrate more significant prolongation of PFS and OS in patients with molecular mutations. As oncologists and advanced practitioners create treatment plans for advanced NSCLC patients, testing for molecular mutations is crucial for selecting the right treatment and stratifying how best to treat patients eligible for systemic therapy. A suggested algorithm for treating stage 4 NSCLC is outlined in Figure 1. By taking histology and molecular subtypes into consideration, more succinct and clear identification of patients that would benefit from one maintenance therapy agent *vs* other alternatives is likely important. Molecular subtypes may behave differently to various standard therapies resulting in the need for developing of targeted therapies for patients with NSCLC^[27]. More advancement is needed in treating NSCLC patients that do not display molecular mutations^[9]. By recognizing these new developments as well as limitations, there is a need for clinicians to be able to identify patients who will have the greatest benefit and effectiveness from maintenance therapy.

Abstract

Due to a lack of substantial improvement in the outcome of patients suffering from oral squamous cell carcinoma (OSCC) during the past decades, current staging methods need to be revised. This disease is associated with poor survival rates despite considerable advances in diagnosis and treatment. The early detection of metastases is an important indicator of survival, prognosis and relapse. Therefore, a better understanding of the mechanisms underlying metastasis is crucial. Exploring alternative measures apart from common procedures is needed to identify new prognostic markers. Similar to previous findings predominantly for other solid tumours, recently published studies demonstrate that circulating tumour cells (CTCs) and disseminated tumour cells (DTCs) might serve as prognostic markers and could supplement routine staging in OSCC. Thus, the detection of CTCs/DTCs is a promising tool to

determine the individual need for therapeutic intervention. Encouraging results and new approaches point to the future use of targeted therapies for OSCC, an exceedingly heterogeneous subgroup of head and neck cancer. This review focuses on summarising technologies currently used to detect CTCs/DTCs. The translational relevance for OSCC is highlighted. The inherent challenges in detecting CTCs/DTCs will be emphasised.

Key words: Circulating tumour cells; Disseminated tumour cells; Oral squamous cell carcinoma; Head and neck squamous cell carcinoma; Bone marrow; Peripheral blood; Micrometastasis; Minimal residual disease; Epithelial-mesenchymal transition

Core tip: Oral squamous cell carcinoma (OSCC), among head and neck cancer, is related to poor survival rates despite considerable advances in diagnosis and treatment. Therefore, detecting tumour cell dissemination early and understanding the underlying mechanisms are crucial for predicting prognosis, relapse and survival. According to previous findings, circulating tumour cells (CTCs) and disseminated tumour cells (DTCs) might serve as prognostic markers to supplement routine staging and support determining individual therapeutic interventions. This review focuses on summarising the current knowledge about the detection of CTCs/DTCs with special emphasis on patients suffering from OSCC. The translational relevance of CTCs/DTCs and challenges for clinical application are highlighted.

INTRODUCTION

Because of its biological heterogeneity and complex behaviour, head and neck cancer must be considered a conglomeration of several tumour types. The vast majority of patients are diagnosed with squamous cell carcinoma (SCC). With an estimated yearly incidence worldwide of half a million persons, nearly 50% of patients die due to tumour-related complications^[1,2]. The disease ranks age dependently among the leading types of solid cancer and is responsible for more than 65000 annual deaths in Europe^[3,4]. Early stage carcinomas are only observed in one third of the patients [Union for International Cancer Control stage (UICC) I - II] while two thirds present with advanced disease (UICC-Stage III-IV). More than 50% of patients suffering from head neck squamous cell carcinoma (HNSCC) sustain local relapses while only up to 25% develop distant metastases. However, the prognosis of these patients is still poor^[5-7].

Although the most important prognostic indicator for relapse is lymph node metastasis in the neck, the incidence of distant metastasis has increased dramatically^[8,9]. Despite considerable advances in diagnosis^[10] and therapeutic options^[11], the 5-year survival rate has remained stable at approximately 50% during the past decades among all tumour stages^[12,13]. This finding might also be due to an altered pattern of the clinical disease itself. While fewer patients currently present with a locoregional relapse, more patients develop a distant disease and recurrences due to occult cervical metastasis. These micrometastases are assumed to contribute to increased mortality and morbidity^[14,15]. Thus, improved methods in staging oral squamous cell carcinoma (OSCC) are needed to detect early metastatic spread and any residual tumour, hence improving decisions about individual therapeutic interventions. The establishment of a resilient model of genetic instability, such as a loss of heterozygosity at distinct chromosomes and the consecutive progression from premalignant lesions to invasive tumours in head and neck cancer, led to a better understanding of the disease^[2,16-19]. Due to the paradigm shift of considering solid cancers a systemic disease, the value and promise of circulating tumour cells (CTCs) in peripheral blood (PB) and disseminated tumour cells (DTCs) in bone marrow (BM) for cancer patients regarding diagnosis, prognosis, and response to therapy came into focus. While sampling BM from the easily accessible iliac crest is well established in diagnosing leukemic diseases, the full acceptance of this practice as an additional diagnostic tool for patients with solid tumours is still lacking. For carcinomas, including SCC, BM should operate as a so-called “homing organ” for CTCs becoming DTCs in the nomenclature. The clinical relevance of CTC/DTC detection in carcinoma patients has been part of extensive research, and encouraging results exist for an association between CTC detection and the prognosis in patients with other solid tumours, such as metastatic breast, prostate, and gastrointestinal cancers^[20-28]. For HNSCC, a putative prognostic value was identified as well, revealing a positive correla-

tion between CTCs/DTCs to relapse and metastasis^[29-32]. In this context, it is important to note that the clinical behaviour and outcome of OSCC differ from those of the oropharynx and other HNSCC. Although there is no sharp distinction between OSCC and HNSCC in general, not all aspects and findings are transferrable. Even the main therapeutic options vary between the OSCC and other HNSCC. For OSCC, surgical removal is the primary treatment, whereas there is an ongoing debate about the preferred treatment options, such as primary radiation, (induction-) chemotherapy and supplemental targeted therapy, for laryngeal or nasopharyngeal SCC^[33,34]. However, recently published data suggest that DTCs and CTCs in patients with OSCC are independent prognostic markers of disease-free survival^[35]. Identifying clinical behaviour and understanding the inherent patterns of OSCC dissemination might result in meaningful contributions to the treatment of those patients. The application of new technologies that make the detection of CTCs/DTCs feasible might allow for more accurate staging and could help select patients and provide targeted therapies. To identify patients in need of systemic therapy in addition to local resection and irradiation, it is important to identify patients suffering from non-localised but “circulating” disease to expand the indication for systemic therapy. With new prognostic markers in prospect, the therapeutic options could substantially improve^[36-38].

DETECTION AND CHARACTERISATION OF CTCs

Several techniques have been established to detect the rare CTCs/DTCs. To put the rarity of these cells in perspective, by applying currently available methods, it is estimated that there might be only one tumour cell among millions of other cells, even in metastatic disease. To increase the efficiency of detecting these cells, an initial enrichment step is needed. Basic enrichment approaches rely on either physical properties, such as size, density or dielectrophoretic mobility that might be characteristic at least for subgroups of CTCs/DTCs, or on the expression of specific surface molecules captured by magnetic bead-coated antibodies. Subsequently, one has to decide between cytometric/immunological approaches on one hand and molecular [mostly real-time reverse transcription-polymerase chain reaction (RT-PCR)-based] techniques on the other hand to detect the CTCs/DTCs among the simultaneously enriched non-tumoural cells^[37].

A widely used method is gradient centrifugation using Ficoll-Hypaque, which utilises the density of different cell types. However, during enrichment, a substantial loss of cell-material is described^[39]. The advantages of using immunocytochemical detection of enriched CTCs/DTCs include the possibility to characterise these cells by size and shape as well as by the nucleus-plasma relation. A set of monoclonal antibodies against various epithelial proteins is available, including various keratins of the cytoskeleton, surface adhesion molecules or growth fac-

tor receptors. The pan-keratin-antibody A45-B/B3 is still widely used for detecting DTCs *via* an alkaline phosphatase anti-alkaline phosphatase technique with New Fuchsin as a substrate^[35,40]. Automated screening for potential CTCs/DTCs and visualisation can be performed with the ACISTM-system (Chromavision, San Juan Capistrano, CA, United States)^[41,42].

Thus far, one of the most advanced methods for capturing and enumerating CTCs from PB is represented by the CellSearchTM-system (Veridex, Raritan, NJ, United States), which provides automated enrichment and immunostaining of CTCs. It is the first food and drug administration-cleared device in CTC detection for solid cancers and has been approved for metastasised prostate, breast and colon cancers^[23,43-46]. Gröbe *et al.*^[35] succeeded in detecting CTCs in a small subset of OSCC patients as well. The underlying principle uses immunomagnetic bead separation of EpCAM-positive tumour cells followed by immunofluorescent staining with anti-keratin antibodies and the exclusion of leukocytes using an anti-CD45-antibody. The CellSearch system benefits from selecting for epithelial features, such as the epithelial cell adhesion molecule (EpCAM) exposed at the surface of the vast majority of epithelial but not on normal blood cells.

A semi-automated process *via* fluorescence microscopy scans visualises the results. Subsequently, nucleated cells, with a diameter of at least 4 µm and characterised by keratin-positivity and CD45-negativity, are accepted and designated as epithelial cells as surrogates for tumour cells^[20,44]. Other promising EpCAM-based tools were presented recently, including the microfluidic-based “CTC”-chips consisting of arrays of anti-EpCAM antibody-coated microposts able to capture EpCAM-positive cells under controlled laminar flow of whole blood^[47,48]. However, these techniques still lack tumour cell specificity and an application for head and neck tumours. Moreover, widespread application must be proven in large clinical trials.

Furthermore, other techniques were used for the detection of CTCs in patients with HNSCC. The Surfaced enhanced Raman Spectroscopy with epidermal growth factor receptor (EGFR) as a targeting ligand has been proven for the detection of putative CTCs in 19 patients by Wang *et al.*^[49]. The potential use of EGFR expression and activation in finding CTCs during the course of combined chemo- or bioradiotherapy regimens, accentuating the aspect of monitoring the therapeutic response in HNSCC, was described by Tinhofer *et al.*^[50] using flow cytometry^[49-51]. Alternative approaches should be mentioned, however, these approaches still lack proof for their utilisation in OSCC. For example, the detection of CTCs from large blood volumes after leukapheresis is promising and paves the way for the analysis of higher numbers of CTCs either by fluorescence-activated cell sorting, immunocytochemistry or molecular approaches^[52,53]. Moreover, real time monitoring of CTCs is desirable, such as during the course of therapeutic interventions. In this context, CTC detection *in vivo* is provided by

the GILUPI cell collector device using a wire coated with anti-EpCAM antibodies ready to accumulate CTCs after insertion into a vein for 30 min. The detection of CTCs and the exclusion of leukocytes can be confirmed by immunostaining with anti-keratin and anti-CD45-antibodies, respectively^[54]. To prove reliability and applicability for different tumour types and clinical relevance, several clinical trials are ongoing^[37].

The detection of viable CTCs/DTCs after secretion of specific proteins during a 48 h short term culture is possible using epithelial immunospots (EPISPOT)^[55]. For the EPISPOT approach, leukocytes must be depleted by negative selection of haematopoietic cells, such as using the common leukocyte antigen CD45.

To conclude, of the various introduced techniques, consideration should be given to molecular technologies. These technologies involve either DNA or complementary DNA (mRNA)-based PCR-amplification. These methods rely on gene expression patterns or the detection of known gene mutations, amplifications, other genomic aberrations or methylation patterns in tumour cells with the restriction that currently no universally applicable marker exists due to strong inter- and intra-tumoural heterogeneity. Nevertheless, using epithelium-specific targets, such as keratin 19 encoding transcripts, RT-PCR approaches are promising^[56,57].

Wicha *et al.*^[58] have recently suggested, for breast and other carcinomas, that not all CTCs in these patients can be found with the approaches that are currently available and that not all detected CTCs are aggressive and have the potential to initiate metastases or recurrences, and these suggestions might also be true for OSCC. Therefore, strong efforts must be made to detect CTCs that have lost their epithelium-specific features and instead favour mesenchymal characteristics as the cells may be undergoing epithelial-mesenchymal transition (EMT). Investigations applying ultrasensitive imaging procedures, gene expression analyses and next generation sequencing approaches are ongoing and have already yielded interesting data^[38,59-61].

A DISCUSSION OF THE RESULTS FROM STUDIES ON HEAD AND NECK CANCER

In comparison to other cancer types, the clinical impact of CTCs in OSCC and other HNSCC patients (Table 1) is still unclear. Therefore, investigating a correlation between these cells and clinico-pathological features is crucial. The research on the outcome of patients suffering from OSCC is impaired by comorbidities, such as chronic obstructive pulmonary disease, malnutrition, loss of function due to surgery and therapy, which can influence decisive parameters. Moreover, a sharp distinction between OSCC and HNSCC is hindered by similar but different causative pathogens, such as the contribution of human papillomaviruses (HPV) in the carcinogenesis of a subset of HNSCC, which is found less often in OSCC^[62]. The incidence of the distinctly different disease

Table 1 Detection of circulating and disseminated tumour cells in oral squamous cell carcinoma and head neck squamous cell cancer

Source	Entity	n	Assay system	CTC-positive (%)	DTC-positive (%)	Clinical relevance	Number of analysed OSCC	Ref. yr of release

of HPV-related head and neck cancers from other head and neck carcinomas is increasing^[63]. This finding will influence further studies regarding etiology and outcome and therefore must be included when evaluating these studies, especially those of patients undergoing different therapy-regimens.

With reference to the concept of field cancerisation (FC) introduced by Slaughter *et al.*^[64] in the 1950's, related problems in OSCC should also be considered because locoregional failure can lead to distant metastasis in HNSCC^[65]. FC is thought to be undetectable by routine procedures thereby potentially causing a second primary tumour^[66]. Furthermore, the entire mucous membrane of the respiratory and upper digestive tract is at risk for neoplasia^[67]. Graveland *et al.*^[68] investigated the potential association of minimal residual cancer in deep surgical margins and DTCs in BM aspirates with clinico-histopathological parameters and outcomes and concluded that the presence of vaso-invasive and

infiltrative growth in HNSCC is a significant risk factor for locoregional recurrence and disease-free survival. Furthermore, they concluded that, at present, there seemed to be no role for the molecular analysis of deep surgical margins and BM aspirates in predicting outcomes with the methods used for 105 HNSCC patients enrolled in this study. To improve histopathological staging in previously tumour cell-negative margins, the overexpression of p53 frequently found in primary tumours was revealed to be indicative of an increased risk of local recurrence^[69,70]. Clinically relevant tumour cell spread is rarely found beyond the level of histopathological detection. Thus, a molecular assessment of minimal residual disease is needed to fill the gap between histopathological findings and outcomes in HNSCC, including OSCC^[71]. Several serum tumour markers have been evaluated with regard to clinical value in HNSCC and OSCC, but most of them demonstrated poor sensitivity^[72,73]. This article focuses on the potential haematogenous spread of tumour cells while OSCC most often spreads in lymphatic vessels^[74-76], potentially decreasing the relevance regarding OSCC/HNSCC. However, there are increasing signs that CTCs are clinically relevant in the pathogenesis and recurrence of head and neck tumours. The total number of suspicious cells most likely depends on the method applied. OSCC is characterised by specific expression patterns for different keratins, capable of being detected in CTCs/DTCs^[77], leading to technical limitations that must be considered. The detection methods have been optimised for CTCs or DTCs derived from adenocarcinomas such as breast, prostate, colorectal or hepatocellular carcinomas, as reported by Schulze *et al.*^[78] in the latter case. Therefore, an adaption to the unique biology of OSCC may be required.

Nevertheless, one of the first reports of prognostic value in a homogenous group of OSCC has been recently published by Gröbe *et al.*^[35], which describes a strong and independent prognostic impact of CTCs and DTCs for disease-free survival, which outperformed current prognosticators. This finding might provide evidence that patients who are positive for tumour cells in the BM or PB may suffer from a more aggressive disease. Thus, CTCs/DTCs detected in OSCC patients might serve as prognostic markers, predicting relapse at various disease stages, supplementing the current routine staging procedures. In this study, 110 patients were enrolled. Anti-keratin immunostaining after Ficoll density gradient centrifugation to detect DTCs and applying the CellSearch™-System to analyse PB represent techniques with the current highest degree of international standardisation^[42,44]. Nineteen patients (21%) exhibited DTCs in the BM, while 11 patients (13.6%) were positive for CTCs in the PB. According to other literature data, CTCs/DTCs are traceable in the PB of HNSCC patients^[29,31]. Wollenberg *et al.*^[29], for example, detected DTCs from BM aspirates, depending on tumour stage.

Gröbe *et al.*^[35] found no significant correlation between the detection of CTCs and the presence of DTCs ($P = 0.68$), suggesting that both analyses might provide

supplementary results. Distant haematogenous metastases were less frequently observed compared to locoregional relapses. Consistent with other studies examining more heterogeneous groups of HNSCC patients^[29,79,80], the subsequent development of recurrent disease was observed more frequently when patients were positive for CTCs/DTCs^[35,81]. However, there are several incongruous and moderately significant results demonstrating that the higher the disease stage, the higher the yield of detected CTCs. Although statistically not significant, a trend regarding this conclusion was shown by Buglione *et al.*^[82] last year, comparing T1 to higher tumour stages in HNSCC, but in the OSCC subgroup (13/152 patients), no CTCs were found. Previously, Guney *et al.*^[83] found similar results for HNSCC but in a smaller cohort of patients. A correlation to tumour stage was found, though not significant for DTCs, and the total number of CTCs was higher in T3-4 tumours compared to T1-2 tumours^[29]. These findings suggest that the size of the primary tumour is not always prognostically relevant. This hypothesis is strengthened by significantly higher incidences of CTC positivity in patients with locally advanced disease when considering the N-stage, holding true even in a multivariate analysis^[31]. Moreover, CTC detection was significantly associated with the presence of lung nodules^[84]. The tumour mass limits local resection by potentially decreasing safety margins because of neighbouring structures, such as the sinus at the skull base, which reaffirms the problem of an assumed CF. Nevertheless, a longer disease-free survival of patients without detectable CTCs compared to CTC-positive patients was stated by Jatana *et al.*^[32]. Unfortunately, most of the studies cited were performed on small patient cohorts for other groups of HNSCC^[83,84]. In a distinctly larger group of 176 HNSCC patients, the presence of DTCs in BM showed prognostic relevance for overall survival. In half of the DTC-positive patients, the disease recurred, whereas in the total cohort, recurrences were only observed in 27% of the patients^[29].

The importance of CTC detection in the context of therapy is still controversially discussed. For OSCC patients, there are studies investigating the dissemination of tumour cells after surgery and tumour cell spread due to surgical procedures^[32,85], but among these studies, only a few have investigated the impact of metastases and survival regarding this issue. These facts are crucial in OSCC as surgery is the current gold standard and primary treatment option.

Before, during and following radiotherapy the detection of keratin-19-positive cells coincided with local failure, distant metastasis and moreover, the diagnosis of anaemia^[79]. Regarding the therapeutic response in HNSCC with decreased levels of previously detected CTCs, a positive effect on outcome was presumed by Buglione *et al.*^[82] because partial or complete response could be stated along with these findings.

A fact that might impair the analysis of detected CTCs/DTCs is the subjective evaluation by even experienced independent readers of common immunocytochemical methods, such as the use of the anti-keratin

antibody A45-B/B3. However, false-positive results are seldom found^[86]. The criteria to evaluate the morphology of potential CTCs and immunostaining reactions are crucial in defining comparable results^[39,42]. This knowledge is even important to evaluate results obtained for blood samples analysed with the semi-automated, highly standardised CellSearch system. To overcome these problems, different international ring studies have begun to reduce interobserver variability of the results^[44,87]. The successful CellSearch system has proven its usefulness in OSCC/HNSCC, although not in all advanced stage patients. However, even in metastasised, advanced disease, CTCs were not detectable in all cases^[35]. Nichols *et al.*^[84] detected almost 100% of spiked HNSCC cell line cells (FaDu) using the CellSearch system, however only 6 out of 15 HNSCC patients tested CTC-positive using this approach. The results are in accordance with those of other studies but suggest that, in patients, either the incidence or number of potentially detectable CTCs is very low or that not all present CTCs are detectable with the currently applied approaches. Furthermore, the system is ruling out non-EpCAM and/or non-keratin expressing CTCs. This escape from detection has been previously demonstrated for breast cancer where, in aggressive tumours, EpCAM expression might be down-regulated, and this finding has also been assumed for aggressive forms of solid cancers other than OSCC^[88].

Hence, serious consideration should be given to EMT, which is associated with a loss of epithelial features, enhancing the migratory capability due to altered plasticity^[88,89]. Stem cell-like cells seem to be most notably affected, as dynamic changes in these cells were identified by Mani *et al.*^[90] and Yu *et al.*^[91]. Thus, increasingly false-negative results might correlate to EMT^[92]. The detection of EpCAM-negative cells might be possible by using other surface markers, such as N-cadherin, EGFR or cancer stem cell markers, such as CD44^[89,93,94]. In colorectal carcinomas, *platin3* was identified as a potential target for cells undergoing EMT because its expression is not altered during this process^[95]. Superiority over EpCAM-based methods must be proven, and expression of *platin3* in cancers other than colorectal cancer must be analysed. EGFR, frequently overexpressed in HNSCC, is a meaningful target for CTC enrichment^[50,96]. Due to the biological heterogeneity of CTCs/DTCs, the most aggressive subsets initiating metastasis must still be categorised^[97,98]. In OSCC, Nagata *et al.*^[99] performed molecular analyses, identifying integrins as potential biomarkers for the risk of locoregional and haematogenous dissemination. The role of the expression rates of integrin α -3 for locoregional and ITGB4 for haematogenous dissemination and, therefore, cancer cell motility and anchorage-independent survival, which are vital for OSCC recurrence and metastasis, has previously been shown. Furthermore, the importance of integrin β 1 in HNSCC and stimulated vascular endothelial growth factor secretion by α B-crystallin in HNSCC was specified^[100,101].

In addition to these considerations, there might be a spread of tumour-derived molecules on a subcellular lev-

el, such as micro-RNAs. Their role in the formation of metastases derived from OSCC is currently unclear^[102,103].

According to current hypotheses, most DTCs remain in a dormant state and probably never initiate a relapse or metastasis^[56,104], whereas others return to a proliferating state by still unknown molecular alterations or changes in environmental conditions^[105,106]. Interestingly, also a re-circulation from the dormant site back to the primary location of the cancer has been reported in an mouse breast cancer model^[107], but because of the high rate of locoregional failure, the concept does not seem apparent for OSCC in the reviewers opinion due to the concept of FC^[67]. Therefore, more obvious challenges must be faced when considering of this phenomenon. The spread of tumour cells during surgery remains unclear but has been proven for fine needle aspiration or incision biopsy in OSCC^[85,108]. A total of 71% of 48 patients harboured CTCs detected by Jatana *et al.*^[30] in HNSCC. Here, samples were taken at the time of surgery. Circulating epithelial cells also can be found in non-malignant diseases, such as inflammatory diseases of the colon, with the current assays^[109].

Nevertheless, the appealing potential of detecting CTCs/DTCs as prognostic markers in OSCC from non-invasively accessible blood samples must be emphasised. When occult tumour cells are ubiquitously spread, PB may be a way to detect these cells, facilitating a “liquid biopsy”^[37]. Out of a set of several markers, a decision must be made, and the occurrence of CTCs is a very rare event. Researchers are faced with the problem that often processed samples cannot be used a second time for other methods, and the samples display only a cross section of the entire circulating blood. A reliable, morphological identification, for example, with fixation of the cells and nuclear staining might prevent subsequent molecular characterisation. These analyses provide just a snapshot of tumour cell dissemination in contrast to BM, which may represent a reservoir where DTCs can be collected over a longer period of time^[104]. Many CTCs are assumed to undergo apoptosis quickly^[110], as the lifespan of CTCs in the circulation is estimated to be only between one and two hours^[111]. Alternative approaches, such as the “CTC-Chip”, punctuate an improvement in CTC yield and purity but only give a possible outlook due to the small number of examined cohorts and have not been tested for OSCC yet^[47,112].

To identify potential targets for individualised therapies and to use repeated CTC assessments in individual patients for treatment surveillance is of the utmost importance^[37]. A potential marker in breast cancer is the human epidermal growth factor receptor 2 (HER2), the expression of which can also be monitored on CTCs, thus giving patients with HER2-negative primary tumours but HER2-positive CTCs a chance to be treated by a HER2-targeted therapy^[113,114]. Currently, there is no biomarker available for OSCC yet. BM might be an interesting target organ for therapeutic interventions by considering DTCs as therapeutic targets. The data described here point to the potential future utility of drugs targeting DTCs in the

BM of OSCC patients. The present high expenses will decrease when evidence is found that these methods are suitable for OSCC and can be included in standard protocols for tumour staging.

CONCLUSION

A set of promising techniques for the detection of CTCs/DTCs has been developed in the past decade, proving their usefulness in solid cancers with predominantly haematogenous dissemination. Less invasive diagnostic tools might be appropriate to refine the current staging methods. The non-invasiveness of collecting samples from PB and obtaining BM specimens might provide additional treatment options in patients suffering from OSCC. For OSCC, the current data show that CTCs/DTCs might have a clinical impact on the prognosis and survival, even outperforming current prognosticators. Circulating tumor cells and DTCs must be considered independent markers in OSCC as a subgroup of head and neck tumours, but the ongoing debate remains too controversial to be considered evidence. The findings presented in this review are not convincing for oral cancer in all aspects yet. Nevertheless, the potential is striking, guiding therapy towards individual-centred medicine with the possibility of early intervention in this severe disease. Despite encouraging results, further investigation of the clinical relevance of CTCs and DTCs is needed as validation in large multicentre trials with synchronised measuring methods and defined outcomes and time points is lacking. In particular, the risk of an early locoregional relapse is difficult to assess because of different problems in the field of HNSCC and OSCC. It is important to continue investigations in homogenous cohorts to decrease the still unaltered morbidity in patients suffering from OSCC. Due to being one of the most active areas of translational cancer research, the technologies presented herein offer a number of compelling advantages. The enumeration of CTCs and DTCs as biomarkers to predict tumour relapse may become feasible in the near future, but researchers in this extraordinarily dynamic field are still facing technical and clinical hurdles. In addition to further improvements, there are challenges beyond the mere detection of CTCs/DTCs. In particular, the detection of carcinoma cells undergoing EMT, a down-regulation of epithelial features when entering vessels, the transient circulation of cells, the mechanisms behind leaving the “homing organs” and the states of dormancy need to be investigated. Whether EpCAM- or keratin-positive cells detected by the described techniques are involved in initiating metastasis is also controversially discussed. To address this question further, molecular analysis of CTCs/DTCs is needed.

A profound understanding of OSCC as a systemic disease supported by molecular investigation of CTCs/DTCs gives new perspectives on the disease and provides the chance to identify potential targets for individualised therapies. Repeated CTC assessments might offer treatment surveillance in individual patients prospectively and

might predict local and systemic relapse with a higher sensitivity at various disease stages compared to routine staging procedures in OSCC.

Abstract

Triple-negative breast cancer (TNBC) is defined by the lack of immunohistochemical expression of the estrogen and progesterone receptors and human epidermal growth factor receptor 2 (EGFR2). Most TNBC has a basal-like molecular phenotype by gene expression profiling and shares clinical and pathological features with hereditary *BRCA1* related breast cancers. This review evaluates the activity of available chemotherapy and targeted agents in TNBC. A systematic review of PubMed and conference databases was carried out to identify randomised clinical trials reporting outcomes in women with TNBC treated with chemotherapy and targeted agents. Our review identified TNBC studies of chemotherapy and targeted agents with different mechanisms of action, including induction of synthetic lethality and inhibition of angiogenesis, growth and survival pathways. TNBC is sensitive to taxanes and anthracyclins. Platinum agents are effective in TNBC patients with *BRCA1* mutation, either alone or in combination with poly adenosine diphosphate polymerase 1 inhibitors. Combinations of ixabepilone and capecitabine have added to progression-free survival (PFS) without survival benefit in metastatic TNBC. Antiangiogenic agents, tyrosine kinase inhibitors and EGFR inhibitors

in combination with chemotherapy produced only modest gains in PFS and had little impact on survival. TNBC subgroups respond differentially to specific targeted agents. In future, the treatment needs to be tailored for a specific patient, depending on the molecular characteristics of their malignancy. TNBC being a chemosensitive entity, combination with targeted agents have not produced substantial improvements in outcomes. Appropriate patient selection with rationale combinations of targeted agents is needed for success.

Key words: Breast cancer; Triple negative; Basal like; *BRCA1*; Poly (ADP-ribose) polymerase 1; Targeted therapy; Chemotherapy

Core tip: Breast cancer is a heterogeneous disease entity with different biological characteristics and clinical behavior. There are no treatment guidelines for triple-negative breast cancer (TNBC). TNBCs are sensitive to taxanes and anthracyclins but there are high rates of local and systemic relapses. Recently there has been great interest in platinum agents, either alone or in combination with poly adenosine diphosphate polymerase 1 inhibitors. Combinations of ixabepilone and capecitabine have shown improved response rates (RRs). Other useful drugs are antiangiogenic agents, tyrosine kinase and epidermal growth factor receptor inhibitors with variable RRs but no survival benefit. In this review, we discuss various systemic treatment strategies available for TNBC and the benefit from each of them.

INTRODUCTION

Breast cancer is the second most common cancer in the world and the most common cancer among women. However, in the past three decades, the mortality rate has declined as a result of a range of measures, including implementation of screening, improvements in the local management of early breast cancer and most importantly, the introduction of adjuvant systemic treatment and the development of directed therapies for hormone receptor-positive and human epidermal growth factor receptor-2 (HER-2/neu)-positive tumors^[1].

Breast cancer is a complex disease entity with different biological characteristics and clinical behavior. Many clinical and pathological features have been defined to predict treatment response and outcome in breast cancer. Classically these include: age, tumor size, axillary node involvement, angio-lymphatic invasion, histological grade, hormonal receptor status (estrogen and progesterone) and HER-2/neu expression. If the last three features are not expressed in breast cancer cells it is called triple-negative breast cancer (TNBC)^[2]. Chemotherapy is the only systemic therapy for TNBC patients.

Management of TNBC is challenging because of a lack of targeted therapy, aggressive behavior and relatively poor prognosis. There are no specific treatment guidelines for TNBCs and they are managed with standard treatment. Treatment options are limited as most patients have been treated with adjuvant anthracyclins, taxanes and cyclophosphamide. It has been evidenced by various studies that these tumors are highly chemosensitive^[3-7] and in some cases are represented by complete pathological response (pCR), but the results remains unsatisfactory^[8-18]. pCR to the neoadjuvant chemotherapy (NACT) is higher in the TNBC subset of patients but the disease free survival (DFS) and OS are still lower than non-TNBC patients^[3,5]. Sporadic TNBCs show heterogeneity in response to chemotherapy, with pCR rates ranging from 12% for single-agent to 27%-65% in multi-agent NACT trials^[3,5,11,19]. Since the achievement of pCR with primary chemotherapy is of crucial importance in TNBC patients, a maximal effort should be made in selecting the best possible drugs, doses and administration timing. The following are the therapeutic options available in TNBC.

CYTOTOXIC AGENTS

Anthracyclins

Anthracyclins are considered to be among the most active drugs for the treatment of breast cancer. These agents that act by destabilising the DNA through intercalation also prove useful in TNBC due to a degraded DNA repair cascade. Many studies show that TNBC is sensitive to anthracyclin containing regimens^[3-5]. The impact of NACT in patients with TNBC was clearly analyzed by Liedtke *et al*^[3] and in a retrospective analysis they reported a pCR rate of 22% in TNBCs compared to 11% in non-TNBCs with paclitaxel/5-FU, doxorubicin,

Table 1 Pathological complete response to triple-negative breast cancer in triple-negative breast cancer and non-triple-negative breast cancer patients

Ref.	Yr	No.	Therapy	PCR (%)

Liedtke <i>et al</i> ^[3]	2008	255	FAC → P	22	11
Chappuis <i>et al</i> ^[4]	2002	9	FEC 3 wk × 3-4	44	4
Skrypnikova <i>et al</i> ^[10]	2011	15	ACC	29.4	NR
Rouzier <i>et al</i> ^[11]	2005	82	P → FAC	45	6

FAC: 5-Fluorouracil, doxorubicin, cyclophosphamide; ACC: Doxorubicin, cyclophosphamide, capecitabine; P: Paclitaxel; PCR: Pathological complete response; TNBC: Triple-negative breast cancer; FEC: 5-Fluorouracil, epirubicin, cyclophosphamide.

cyclophosphamide/5-Fluorouracil, epirubicin, cyclophosphamide (FEC) (Table 1). The 3-year DFS was similar in both the groups (pCR 94% *vs* 98%, $P = 0.24$), while those who failed to achieve pCR had worse 3-year DFS compared to non-TNBCs (68% *vs* 88%, $P = 0.0001$). This was because the rate of early relapse in patients with residual tumor was dramatically higher in TN patients compared with the others.

In a study by Chappuis *et al*^[4] of TNBC patients treated with FEC regimen, pCR was 44%. Carey *et al*^[5] showed that the clinical response to doxorubicin and cyclophosphamide was markedly higher among patients with TNBCs than non-TNBCs. pCR to NACT was higher in patients with TNBCs but still these patients had a worse DFS and OS compared to non-TNBCs. An intergroup study (C9741) found differences in favor of dose density with adriamycin and paclitaxel in patients with negative ERs, but not in ER-positive patients (32% *vs* 19%). This study highlights the importance of chemotherapy in hormone-independent tumors^[6]. Review of TNBC subgroups in the CALGB 9344 study in node positive patients where they compared the addition of paclitaxel to different anthracyclin doses showed significant benefits for this combination. Although the benefits were independent of HER2 status, ER negative patients derived the greatest benefit in both DFS and OS^[7]. In a large cohort of patients with TNBC treated with anthracyclins and taxanes, Hernandez-Aya *et al*^[9] concluded that, independently of the size of the tumor, once there is evidence of lymph node involvement, the prognosis may not be affected by the number of positive lymph nodes.

Recently, Skrypnikova *et al*^[10] in a prospective pilot trial evaluated the efficacy of a metronomic schedule of doxorubicin, cyclophosphamide and capecitabine in locally advanced and metastatic TNBC. The overall response rate (RR) was 58% with 24% of CR and 34% of PR. Five patients (29.4%) achieved a pCR. In MBC patients, the median progression-free survival (PFS) was 8.3 mo. The most common grade 3 toxicities were hand-foot syndrome (HFS) (28.8%) and mucositis (17.7%), which resulted in discontinuation of doxorubicin in 7 patients. There was 26.4% of grade 3-4 neutropenia. Although the RR was good, this combination is quite toxic.

Table 2 Chemotherapy regimen with their outcomes in triple-negative breast cancer

Ref.	Yr	No.	Therapy	Outcome
Martin <i>et al</i> ^[12]	2010	171	FEC	7 yr DFS 56% <i>vs</i> 74%
			FEC + P	
Byrski <i>et al</i> ^[23]	2009	25	Cisplatin + P + GSF	5 yr DFS-76% DDFS-84%
Koshy <i>et al</i> ^[32]	2010	17	Cisplatin + gemcitabine	PFS-5.3 mo TNBC <i>vs</i> 1.7 mo non-TNBC
Maisano <i>et al</i> ^[31]	2011	31	Carboplatin + gemcitabine	ORR-32% PFS-5.5 mo

Anthracyclin and taxane pretreated TNBC patients. GSF: Granulocyte stimulating factor; ORR: Overall response rate; PFS: Progression free survival; DFS: Disease free survival; DDFS: Distant disease free survival; TNBC: Triple-negative breast cancer; P: Paclitaxel; FEC: 5-Fluorouracil, epirubicin, cyclophosphamide.

Taxanes

Taxanes produce benefits in TNBC by targeting genomic instability. Many studies reveal the benefits produced by paclitaxel when added to other chemotherapeutic agents. In the neoadjuvant setting, Rouzier *et al*^[11] showed that TN and Her2-positive subtypes of breast cancer are more sensitive to paclitaxel and doxorubicin chemotherapy than the luminal and normal-like cancers. pCR was seen in 45% patients with basal like breast cancer (BBC) compared to 6% in luminal subtypes. In a retrospective analysis by Hayes *et al*^[8] where paclitaxel was added to cyclophosphamide and doxorubicin in node positive patients, they observed a 5 years DFS and OS of 27% and 32% respectively. The results were similar in TNBC and HER-2/neu positive patients.

In an adjuvant setting, two meta-analyses have shown benefit with taxanes^[12,13]. Many studies have demonstrated that taxanes are more effective in receptor-negative patients. Jones *et al*^[14] found that docetaxel and cyclophosphamide were equally effective in TNBC and non-TNBC patients. In a study by Jacquemier *et al*^[15], there was greater benefit with the addition of docetaxel to the conventional 6 cycles of FEC in BBC patients. A further study (Table 2) showed maximum benefit in TNBC patients when 4 cycles of FEC were followed by weekly paclitaxel for 8 wk compared to just 6 cycles of FEC^[16]. Loesch *et al*^[17] with the same kind of combination, paclitaxel 3 times weekly *vs* weekly after 4 courses of adriamycin-paclitaxel every 3 wk, showed statistically significant results in 378 TNBC patients treated with weekly paclitaxel. As far as a schedule is concerned, weekly paclitaxel is much more effective than paclitaxel every 3 wk and at least as effective as docetaxel every 3 wk^[18]. On the whole, shortening the administration interval from 3 to 2 wk could substantially improve efficacy, at least in TN patients. The role of anthracyclins alone in TNBC is debatable; however, a definite benefit is seen when used in combination with taxanes.

Platinum agents

It has been postulated that TNBC has phenotypic and

¹Cisplatin or carboplatin; ²In *BRCA1* mutation carriers. AC: Doxorubicin + cyclophosphamide; 5-FU: 5-Fluorouracil; PCR: Pathological complete response; cCR: Clinical complete response; GSF: Granulocyte stimulating factor.

molecular similarity to *BRCA1* related cancers that would confer sensitivity to cytotoxic agents like cisplatin. The platinum agents act by producing intra and inter strand cross links of double stranded DNA, prevent the replication fork formation and produce double strand breaks and replication lesions, and finally due to *BRCA1* mutation, the DNA repair cascade is non functional and produces cell death^[19]. In the last few years, there has been a renewed interest about the role of platinum compounds in the treatment of breast cancer patients. Clinical studies have also suggested that TNBC are more sensitive to DNA damaging agents like cisplatin. In a phase-II study, Garber *et al*^[20] have shown a pCR of 21% with neoadjuvant cisplatin in patients with TNBC. Among 28 patients, two were *BRCA1* carriers, both (100%) of whom achieved pCR; 4 (15%) of the 26 women with sporadic TNBC also achieved pCR to cisplatin. Overall, 50% of the patients had a good response to cisplatin. In a similar study by Silver *et al*^[21] with 4 cycles of single agent cisplatin, a pCR rate of 22% was seen (Table 3). Two patients with *BRCA1* mutation had pCR. They also found a significant association of tumor p53 protein-truncating mutations with cisplatin response. The largest series of *BRCA1* mutation was reported by Byrski *et al*^[22]; out of 6903 patients, 102 patients had *BRCA1* mutation. Out of this, 12 patients were treated with neoadjuvant cisplatin and 10 (83%) had pCR. Anthracyclins and taxane based regimens could only produce a pCR ranging from 7% to 22%. In another study which explored role of platins in TNBC with *BRCA1* mutation, out of 25 patients, 72% had a pCR. Projected 5 year DFS and DDFS were 76% and 84% respectively^[23]. Ryan and co-investigators found that when VEGF-A inhibitor bevacizumab was added along with cisplatin, a pCR rate of 16% was observed^[24]. The results with a single agent or in combination with

bevacizumab are somewhat disappointing as the proportions of CRs are significantly less (16%-22%) than that achieved with multiagent NACT (30%-65% in other studies).

Platin and taxane-based primary chemotherapy has also proven to be highly effective in patients with locally advanced breast cancer (LABC). In a study by Frasci *et al.*^[25] where neoadjuvant cisplatin was used with paclitaxel and epirubicin in a weekly schedule for 8 cycles in LABC patients, a pCR of 65% was achieved. After surgery, patients were treated with 4 or 8 cycles of CMF based on whether lymph nodes were positive at the time of surgery. Patients with pCR had a 5-year DFS of 90% compared to 56% with residual disease. Severe neutropenia and anemia occurred in 23 (31%) and 8 (10.8%) patients, respectively. Thus, lack of achievement of pCR in TNBC is a poor prognostic factor.

Sirohi *et al.*^[26] found that when platins are used in combination with epirubicin and 5-FU, a very high complete clinical response of 88% was achieved. This may be contributed to by epirubicin and 5-FU which was given as a 24 h infusion for 18 wk. Other investigators^[27,28] have observed a pCR from 29% to 50% with platins in combination with taxanes (Table 3). The results are encouraging and merit further validation and testing. At present, platinum agents in the neoadjuvant setting cannot be recommended over established regimens outside of a clinical trial. So, platins should always be used in combination with taxanes or anthracyclins to increase response and survival rates. However, patients with *BRC41* mutation tend to have maximum benefit in the neoadjuvant setting.

In the metastatic setting, cisplatin or carboplatin have shown an ORR of 20%-40%. Cisplatin is very active in first line chemotherapy in MBC with a RR of 50%, whereas carboplatin is moderately active with an ORR of 30%. In a study by Fountzilas *et al.*^[29], carboplatin in combination with paclitaxel demonstrated an ORR of 41% in MBC. PFS was better in the paclitaxel and carboplatin arm compared to paclitaxel and epirubicin. However, there was no difference in ORR and OS between the two arms. Gemcitabine (GC) and platinum agents in combination have synergistic antitumor activity that results in inter strand DNA crosslinks and double strand DNA breaks, both of which are preferentially repaired by homologous recombination. Both agents have demonstrated activity in MBC^[30], with RR ranging from 26% to 50%. Maisano *et al.*^[31], in a phase-II study with combination of carboplatin and GC in pretreated 31 metastatic TNBC patients, reported a RR of 32%. Median PFS was 5.5 months and median OS was of 11 mo. Many patients required dose reductions. Similarly, in a study by Koshy *et al.*^[32] in MBC patients, TNBC had a better PFS (5.3 *vs* 1.7 mo) compared to non-TNBC when treated with a cisplatin and GC combination (Table 2).

Lastly, in a retrospective study Staudacher *et al.*^[33] reported that median OS and median PFS were improved in patients responding to platinum based chemotherapy: 27 *vs* 8 mo ($P < 0.001$) and 10 *vs* 4 mo ($P < 0.001$), respectively. Therefore, combination of platins with taxanes or

GC or vinorelbine are good alternatives for patients in whom anthracyclins may pose as toxic or who are already exposed to these in the adjuvant setting. So, once again platins have generated interest among investigators for its role in TNBC. The heterogeneous outcome with platins may be related to the heterogeneity of TNBC. Cisplatin appears to be more effective than carboplatin.

Newer chemotherapeutic agents, antitubulin agents

Ixabepilone is a potent tubulin polymerizer that has recently been added to the armamentarium of drugs available for the treatment of breast cancer. Similarly to taxanes, ixabepilone stabilizes microtubules and causes cell cycle arrest and apoptosis. It is active in taxane refractory and LABC as well as in TNBC. The clinical activity and toxicity profile of ixabepilone are similar to the taxanes, with neuropathy and myelosuppression as dose-limiting toxicities^[34,35]. It has the advantage of bypassing the resistance mechanisms associated with drug efflux pumps and specific paclitaxel resistance associated with β -tubulin. In the neoadjuvant setting, a pCR rate of 26% in breast tumor and 19% when there was axilla involvement was seen in 42 patients with TNBC. A low expression of ER gene was identified as a predictor of response to ixabepilone^[34].

In patients with anthracyclin and taxane resistant metastatic TNBC, a combination of ixabepilone and capecitabine has an improved RR and PFS compared to capecitabine alone (RR 27% *vs* 9%; PFS 4.1 *vs* 2.1 mo)^[35]. Subsequently, in the pooled results of the 046 study (taxane resistant) and the 048 study (population pretreated with anthracyclins and taxanes), benefits were found for the ixabepilone-capecitabine combination in terms of objective responses (31% *vs* 15%) and PFS (4.2 *vs* 1.7 mo), but not for OS (10.3 *vs* 9.0 mo)^[36]. These outcomes are comparable to cisplatin combination regimens. So, the ixabepilone and capecitabine combination can be used in patients who do not tolerate cisplatin combinations or when renal function is compromised. The magnitude of benefit also appears comparable to other combinations, such as GC plus paclitaxel or capecitabine plus docetaxel. Another novel mitotic inhibitor currently being studied for the treatment of breast cancer is eribulin. Its activity in TNBC is yet to be seen.

TARGETED THERAPY

Currently, a lot of research is going on to further characterize TNBC with different molecular markers and find targets for therapy in order to improve its outcome.

PARP inhibitors

Poly (adenosine diphosphate ribose) polymerase also plays a vital role in DNA repair like *BRC4*. Unlike *BRC4*, it recognises single strand breaks and repairs by the base excision repair pathway. PARP inhibitors are effective in TNBC because damage to one strand of DNA cannot be repaired by homologous recombination due to *BRC4* mutation and PARP inhibition in synergism creating a state of "synthetic lethality". The inhibition of

poly (ADP-ribose) polymerase 1 (PARP1) potentiates the effects of ionizing radiation, DNA methylating agents, topoisomerase I inhibitors and platinum compounds^[19]. Several *PARP1* inhibitors are at different stages of clinical development. In a phase- I study of olaparib in patients with ABC, 9 (15%) patients had an objective response. Of the 3 patients with *BRC42* mutation, CR occurred in one and another one had SD for 7 mo^[37]. In a phase- II study by Tutt *et al*^[38] in 54 patients with known *BRC4* mutations in ABC, 27 received olaparib 400 mg twice a day, of which 11 (41%) experienced a response with a median PFS of 5.7 mo. A second cohort of 27 women received 100 mg of per day and 6 patients (22%) experienced a response with a median PFS of 3.8 mo. The majority of patients in the 400 mg dose had *BRC41* mutation. This agent was fairly well tolerated, with nausea and fatigue being the most common adverse events. A recent phase- I study by Dent *et al*^[39] demonstrated that it was not feasible to administer the 200 mg daily dose of olaparib in combination with weekly paclitaxel due to significant myelosuppression, in spite of prophylaxis with growth factor support.

In a phase- II randomised study, O'Shaughnessy *et al*^[40] found that the addition of iniparib to carboplatin and GC in metastatic TNBC resulted in significant improvements in RR, PFS (Table 4) and OS from 7.7 to 12.3 mo. The addition of iniparib was well tolerated. However, a randomised phase- III study by the same investigators failed to prove significant benefit of iniparib in combination with GC in metastatic TNBC in terms of PFS (4.1 *vs* 5.1 mo) or OS (11.1 *vs* 11.8 mo); although, the addition of iniparib did not significantly add to the toxicity profile of GC alone^[41].

Another drug, veliparib, is a novel oral inhibitor of PARP1 and PARP2. It has shown a synergistic effect with temozolamide in TNBC^[42]. In *BRC41* and *BRC42* mutation carriers, ORR was 37.5% and CBR was 62.5% with a PFS of 5.5 mo. Since both the drugs are given orally, they can be good options for patients in whom there is difficulty in accessing a venous line from the above subgroup.

PARP inhibitors have shown clinical activity in *BRC4* mutation carrier breast cancer and TNBC. These drugs are also being evaluated in the neoadjuvant setting but experience is limited and patient selection, combination with other chemotherapy drugs, route of administration, duration of therapy and toxicity of combination therapy are factors that need to be addressed. However, their role in unselected TNBC patients is uncertain and future trials may address these issues.

Epidermal growth factor receptor inhibitors

Epidermal growth factor receptor (EGFR) is over expressed in TNBC and so it is also one of the targets in its treatment. Cetuximab, a chimeric monoclonal antibody, binds specifically to the extracellular domain of the EGFR and inhibits its activation^[43]. In a phase- II randomised study by Carey *et al*^[44] in metastatic TNBC, patients were treated with cetuximab alone or in combination with carboplatin. Patients in the combination arm had a high RR and CBR (Table 4). In patients with cetuximab monotherapy, carboplatin was added at the time of disease progression. However, patients in both arms had a rapid progression, with a median PFS of only 2 mo. In another randomised phase- II study, pre-treated patients with MBC (78 patients had TNBC) were randomised to receive carboplatin and irinotecan with or without ce-

tuximab^[45]. TNBC patients in the cetuximab arm had a higher RR than the control arm. However, there was no significant improvement in PFS. Patients in the cetuximab arm had more toxicity in the form of neutropenia, thrombocytopenia and diarrhea. The above trials have failed to achieve the expectation of EGFR being a target for treatment in TNBC. In another study by Baselga *et al*^[46] in metastatic TNBC with cetuximab alone or in combination with cisplatin, ORR and PFS was better in the combination arm compared to cetuximab alone (Table 4). Several phase I - II studies with cetuximab in combination with cytotoxic agents or with other targeted therapies, such as trastuzumab, are currently ongoing in metastatic TNBC.

Tyrosine kinase inhibitors

Tyrosine kinase (TK) is also over-expressed in breast cancer and is associated with metastatic disease progression. There are many agents that target the phosphorylation of the receptor by acting at TK, such as imatinib, erlotinib, gefitinib and lapatinib, used for the treatment of many solid tumors. Lapatinib is more effective in HER-2/neu positive breast cancer patients^[47]. Cristofanilli *et al*^[48] presented data from a small open-label phase-II study of 23 patients with newly diagnosed inflammatory breast cancer treated with neoadjuvant lapatinib 1500 mg once daily and paclitaxel 80 mg/m² weekly for 12 wk. RR was 95% (20/21) in HER-2-positive and 100% (2/2) in HER-1 positive/HER-2 negative patients. Dasatinib is an oral inhibitor of multiple TKs, including the Src and Abl family, c-kit and platelet derived growth factor receptor (PDGFR)- β . Finn *et al*^[49] in a phase II trial showed a CBR of 9% in metastatic TNBC, but discontinuation of therapy and dose reductions weakened the results (Table 4). Presently, several studies are evaluating dasatinib as monotherapy or in combination regimens in this setting.

Antiangiogenic drugs

VEGF expression is higher in TNBC than non-TNBC. Targeted therapy against angiogenesis can cause tumor suppression. Bevacizumab is a recombinant humanised monoclonal antibody targeted against VEGF.

The efficacy of first-line bevacizumab-containing therapy for MBC has been proven in three randomized trials^[50,52]. The E2100 trial showed that adding bevacizumab to paclitaxel as first-line treatment in TNBC patients doubled RR (48% *vs* 22%) and PFS (11.8 *vs* 5.2 mo)^[50]. In the AVADO trial where docetaxel was paired with two different doses of bevacizumab (7.5 and 15 mg/kg) given every 3 wk in 167 patients with TNBC (22%), the addition of bevacizumab at 15 mg/kg led to an improvement in PFS from 6.0 to 8.1 mo^[51]. RIBBON-1 offered investigators the choice of capecitabine, once every 3 wk taxane (docetaxel or nab-paclitaxel), or anthracyclin-cyclophosphamide combinations, each given with or without bevacizumab^[52]. A subset analysis of patients with TNBC demonstrated an improvement in PFS when bevacizumab was used both with capecitabine (6.1 *vs* 4.2 mo) and taxane/anthracyclin cohort (8.2-14.5 mo). In all three trials, there

was statistically significant improvement in PFS and RR with the addition of bevacizumab to chemotherapy but no OS benefit (Table 4). There was also a greater risk of hypertension with any bevacizumab regimen and adverse effects such as headache and nasal congestion, although rarely scored as grade 3 or 4, were also more frequent with bevacizumab. When bevacizumab is paired with taxanes taken once every 3 wk, there is a greater chance of neutropenia. Altogether, between 34% and 57% of patients receiving bevacizumab-based treatment in RIBBON-1 experienced toxicity \geq grade 3, suggesting that there may be limitations for adding extra therapy to these combinations. For instance, attempts to add sunitinib, the multitargeted TK inhibitor, to chemotherapy with bevacizumab have proven unsuccessful as a result of extensive toxicity in patients with breast cancer. In further analysis of RIBBON-2 for the role of bevacizumab as second line therapy in metastatic TNBC, there was significant RR and PFS benefit but again no OS advantage^[53]. Its cost is also a limiting factor and its toxicity further adds to the overall cost. Currently, its accelerated approval in breast cancer has been withdrawn due to the only modest risk-benefit ratio.

In a recent study by Gerber *et al*^[54] where neoadjuvant bevacizumab and anthracyclin-taxane-based chemotherapy was given in 686 TNBC patients, the effect of bevacizumab on pCR was more in patients with TNBC (40.1% *vs* 32.3%). The long term results of this trial will show if this pCR benefit translates to DFS and OS.

Other agents that target VEGF

Sunitinib is a TK inhibitor and inactivates VEGF and PDGFR. Two phase-III trials have shown that combining sunitinib with docetaxel or capecitabine does not offer any benefit in prolonging PFS compared to the cytotoxic regimen alone in patients with ABC when used as a first line therapy or in pre-treated patients^[55,56]. Sunitinib is currently being evaluated in addition to carboplatin and paclitaxel as adjuvant treatment for TNBC. It should always be used in combination as monotherapy is not recommended.

In the clinical trials so far, sorafenib has not shown any absolute benefit when used as the only therapeutic strategy in breast cancer^[57,58]. Median PFS was extended by 2 mo in patients treated with the combination of sorafenib-capecitabine in comparison with the combination sorafenib-placebo, but at the cost of high toxicity (grade III HFS 45% *vs* 13%)^[57]. The second trial evaluated sorafenib in combination with paclitaxel or placebo as first-line therapy in patients with locally recurrent or MBC. Forty percent of patients had TN disease. The hazard ratio for PFS was 0.78 ($P = 0.08$), a trend favoring the sorafenib-paclitaxel group^[58]. The incidence of grade III HFS was 30% *vs* 3% in the placebo group. Such a high incidence of grade III HFS is unacceptable and therefore careful monitoring of patients for HFS and timely dose-reduction should be done. The other agents like vandetanib and montesanib are still in the trial stages.

Currently, a lot of research is going on in TNBC. Recently, Melhem-Bertrandt *et al.*^[59] investigated 1413 patients treated with NACT who used β -blockers (BB), comparing those without BB exposure for pCR, DFS and OS. In 377 TNBC patients, there were significant effects for BB use on both DFS ($P = 0.03$) and OS ($P = 0.05$). Many agents and treatment approaches are under investigation for the treatment of TNBC. Many targets such as α V β 6, cyclin E, c-kit, E-cadherin, O⁶MGMT, FOXp3 and mitogen-activated protein kinase pathway need further exploration to dissect TNBC and may possibly identify new targets for therapy.

Future phase-III breast cancer treatment trials should endeavour to collect prospective data on relevant medication exposures, weight and weight gain, comorbid conditions, and behaviors that have the potential to influence the microenvironment of the tumor as these may be potent mediators of prognosis and survival and may or may not be effectively accounted for in randomization. Key areas of research should include appropriate patient sub-classification for new and existing treatment options in their rationale combination.

CONCLUSION

TNBC is a heterogeneous disease entity. There are no specific treatment guidelines for TNBC and it is managed with standard treatment. Targeted agents have not produced substantial improvements in outcomes. The result of targeted therapy depends on the existence and level of expression of the target protein. The treatment of TNBC will continue to evolve as we learn more about the heterogeneity of this disease and this will underscore the need for treatments to be tailored for a specific patient, depending on the molecular characteristics of their malignancy. The tumor microenvironment may be a critical target for future cancer treatment and prevention of recurrence.

Abstract

An overwhelming majority of the transcribed genome encodes for non-coding RNA (ncRNA) sequences. Deep sequencing of the transcriptome has uncovered tens of thousands of long ncRNA (lncRNA) sequences. However, little is known regarding the possible functions for a vast majority of these sequences. Among those lncRNAs whose function has been experimentally validated, most serve as regulators of gene expression. lncRNAs have been found to be critical to development and homeostasis and they have been implicated in several pathologies including cancer. Here, we examine the functions and underlying mechanisms of lncRNAs in stem cells and in cancer biology, areas linked by the actions of lncRNAs.

INTRODUCTION

A surprising revelation from the human genome project was that less than 2% of the human genome was composed of protein-coding genes^[1]. Although originally thought of as junk DNA, the ENCODE project revealed that 76% of the genome is actively transcribed^[2]. Although transcription alone is not a demonstration that these are indeed functional molecules, through careful examination we now know that a great deal of this non-coding RNA (ncRNA) is functionally relevant to physiology and disease. One important class of ncRNA is long ncRNA (lncRNA). ncRNA species greater than 200 nucleotides in length are all grouped together as lncRNAs. This arbitrary limit to their size likely ignores the diversity present among lncRNAs.

The GENCODE consortium (version 18) has annotated 13562 lncRNAs^[3]. Around 2/3 of lncRNAs are intergenic [long intergenic ncRNAs (lincRNAs)], the rest are overlapping, antisense, or intronic to protein coding genes. Although some lncRNAs have been found to be transcribed by RNA Pol III, a majority of lncRNA is thought to be transcribed by RNA pol II, to be polyadenylated, spliced and 5'-capped^[4]. lncRNAs show lower evolutionary conservation than protein coding genes and show less conserved than other ncRNAs, *i.e.*, microRNAs (miRNAs). This may be because lncRNAs have rapidly

evolved or because selection pressure maintains only short critical sequences or secondary structures of the lncRNAs.

lncRNAs are functionally very diverse, interacting with ncRNAs, mRNAs, proteins and genomic DNA and acting as tethers, guides, decoys, and scaffolds^[5]. Most lncRNAs have been found to be critical regulators of gene expression. lncRNAs have been found to act at nearly every level of gene regulation: epigenetic, transcriptional, posttranscriptional, and translational.

Here, we will discuss lncRNAs in stem cells, where they are shown to be critical regulators of pluripotency and self-renewal. Next, we will examine lncRNAs role in regulating the epigenome. Finally we will summarize the suspected involvement of lncRNAs in tumorigenesis.

LNCRNAS IN STEM CELLS

One area of biology where lncRNAs are emerging as major players is in stem cell biology. Several studies have found that lncRNAs can regulate pluripotency and differentiation in embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs). Furthermore, lncRNAs are also emerging as important regulators of adult stem cells.

LncRNAs in Embryonic Stem Cells

Guttman *et al.*^[6] examined lincRNA expression and function in ESCs. They first profiled lincRNA expression in ESCs and then performed knockdown of 147 lincRNAs that were expressed in ESCs (out of 226 lincRNAs they could detect in ESCs). They found that a majority of these lincRNAs (93%) were able to influence gene expression patterns in ESCs. Furthermore, they found that 26 lincRNAs were able to significantly impact expression levels of the critical pluripotency factor Nanog. This suggests that lincRNAs are heavily involved in maintaining pluripotency and preventing the differentiation of ESCs. Next, they examined differentiation of ESCs and identified 13 lincRNAs associated with endoderm differentiation, 7 lincRNAs associated with ectoderm differentiation, 5 with neuroectoderm, 7 with mesoderm, and 2 with trophectoderm differentiation. This demonstrates that lincRNAs are critical regulators of lineage-specific differentiation of ESCs. Next, they examined whether lincRNAs in ESCs were regulated by pluripotency-associated transcription factors (Oct4, Sox2, Nanog, cMyc, nMyc, KLF4, ZFX, Smad and TCF3). At least one pluripotency factors was associated with the promoter region of 75% of the 226 lincRNAs expressed in ESCs suggesting that these lincRNAs serve as direct gene targets of pluripotency transcription factors. Finally, they found that 74 (30%) of these lincRNAs were associated with chromatin-modifying proteins known to be important in ESCs. Sheik Mohamed *et al.*^[7] also examined the role of lncRNAs in regulating pluripotency of ESCs. They examined high-confidence binding sites of OCT4 and Nanog as determined by paired end-tag sequencing

of ChIP-PET DNA. Ten percent of the OCT4 binding sites (105/1083) and 11% of the Nanog binding sites (335/3006) occupied proximal regions of lncRNA genes. This strongly suggests that regulation of lncRNA is a critical aspect of pluripotency.

Ng *et al.*^[8] examined pluripotency associated lncRNAs by examining expression following differentiation of ESCs to Neural Progenitor Cells (NPCs). Using custom lncRNA microarray technology they revealed over 934 lncRNAs that were differentially expressed. They identified 36 lncRNAs that were downregulated greater than five-fold in NPCs. Next they chose 3 candidate lncRNAs for functional characterization, lncRNA ES1, ES2, ES3. They found that knockdown of any of these 3 lncRNAs resulted in ESC differentiation. They performed RNA Immunoprecipitation experiments and found that ES1 and ES2 were associated with SUZ12 [Polycomb Group (PcG)] and pluripotency factor SOX2 in the nucleus.

These studies reveal that maintenance of pluripotency and lineage-specific differentiation are carefully regulated by lncRNA networks, many of which are direct targets of master pluripotency transcription factors. Additional functional studies of the lncRNAs should shed more light on the mechanism and interacting partners of these lncRNAs in ESCs.

LncRNAs in iPSCs

Loewer *et al.*^[9] examined lincRNA expression in iPSCs. They discovered that the lincRNA-ST8SIA3 [or Regulator of Reprogramming (ROR)] was upregulated in iPSCs. They found that pluripotency transcription factors (OCT4, SOX2 and NANOG) directly regulated expression of ROR. Furthermore they found that ROR knockdown could inhibit reprogramming and iPSC colony formation. Furthermore, overexpression of ROR enhanced iPSC colony formation. Wang *et al.*^[10] examined ROR function in ESCs and found that ROR was able to regulate self-renewal and differentiation of ESCs. Furthermore, they identified a possible mechanism through which ROR may act, serving as a competitive endogenous RNA (sponge) for miR-145, which is known to target OCT4, SOX2, KLF4 and regulate ESC differentiation^[11].

LncRNAs in adult stem cells

There are several reports of lncRNAs regulating adult stem cell self-renewal and differentiation. Zuo *et al.*^[12] examined osteoblast differentiation of Mesenchymal stem cells and found that 116 lncRNAs were differentially expressed upon differentiation. Next, Kretz *et al.*^[13] found that the lncRNA ANCR was down-regulated during differentiation of epidermal cells and found that ANCR regulates gene expression to suppress differentiation of epidermal progenitors. Ramos *et al.*^[14] found that the lncRNAs Six3os and Dix1as were regulators of glial-neuronal lineage specification from adult neural stem cells. Finally, Yildirim *et al.*^[15] found that the lncRNA Xist was essential for long term survival of hematopoietic stem cells.

Adipocytes and adipogenesis

Much of the information involving lncRNA regulation of adipogenesis came from the recent discoveries by Sun *et al.*^[16] who identified 20 candidate lncRNAs up-regulated during adipogenesis using RNA-seq to analyze gene expression of *in vitro* cultured mouse preadipocytes and brown/white adipocytes, alongside primary isolated mature adipocytes. Using RNAi based loss of function screening and unique score metrics, they found that loss of many of these lncRNAs resulted in either partial or near complete reversion of mature adipocyte to precursor phenotype. In another study, Pang *et al.*^[17] found that an antisense lncRNA for the *PU.1* gene promotes adipogenesis by an forming mRNA/lncRNA duplex with *PU.1* mRNA and blocking translation.

EPIGENETIC REGULATION

lncRNA is emerging as a major player in chromatin remodeling and epigenetic regulation of gene expression. Evidence indicates that lncRNAs play important roles in the critical physiological processes of X-chromosome inactivation (XCI) and genomic imprinting. Furthermore, dysregulation of lncRNAs has been indicated in epigenetic reprogramming in human cancer.

XCI

One of the X chromosomes in female mammalian cells is epigenetically inactivated during early development to ensure balanced expression of X-chromosomal genes known as dosage compensation. The lncRNA, X-inactive specific transcript (Xist), was discovered due to its surprisingly only being expressed by inactive X-chromosomes. Curiously, Xist was not expressed in male cells and was only shown to be expressed in cells with at least two X-chromosomes. It was revealed that Xist plays a central role directing XCI by coating one X-chromosome leading to its epigenetic silencing^[18].

XCI initiation begins with one of the X-chromosomes randomly activating Xist expression in early development. Xist then recruits Polycomb repressor complex 2 (PRC2) to the Xist promoter region in the future inactive chromosome. The Xist promoter is then methylated in cis resulting in further activation of Xist^[19]. The transcribed Xist RNA transfers to specific loci in cis across the X-chromosome using a targeting mechanism based on the three-dimensional conformation of the X-chromosome^[20]. The attachment of Xist to the future inactive X-chromosome (Xi) is mediated by a transcription factor, YY1, which can bind simultaneously both DNA and RNA through different motifs^[21]. Xist finally spreads and coats the Xi and PRC2 is recruited by interacting with the Repeat A region of Xist^[19]. At the end, Xi chromatin is extensively ubiquitinated at histone H2A, resulting in the formation of heterochromatin. This process is suppressed at the active X-chromosomes through the action of the transcribed antisense of Xist, the lncRNA Tsix, which through its complementary sequence can inhibit

Xist expression.

Genomic imprinting

Genomic imprinting is an epigenetic process by which certain autosomal genes express only the maternal or paternal allele. Imprinted genes are usually clustered on chromosomes and these imprinted gene clusters contain both protein-coding genes and lncRNA genes. The *Igf2r* locus contains three imprinted, maternally expressed protein-coding genes, *Igf2r*, *Slc22a2*, *Slc22a3*, and an imprinted, paternally expressed lncRNA gene, *Airn* (antisense *Igf2r* RNA non-coding), which is antisense to *Igf2r* RNA and required for the silencing of *Igf2r*, *Slc22a2* and *Slc22a3* on the paternal chromosome^[22].

The gene product of *Airn*, *Air* lncRNA, represses genes from the *Igf2r* locus *via* multiple different silencing mechanisms. In mouse placenta, the *Air* RNA recruits the H3K9 histone methyltransferase G9a to the *Slc22a3* promoter chromatin, resulting in H3K9 methylation and *Slc22a3* transcriptional silencing^[23]. In contrast, *Air* silences *Igf2r* gene through a transcriptional interference mechanism, in which *Airn* transcriptional overlap of the weaker *Igf2r* promoter results in the silencing of *Igf2r* gene^[24]. The silenced *Igf2r* promoter is then subject to DNA methylation that along with *Airn* expression, maintains *Igf2r* silencing^[25].

lncRNA may also function as scaffolds allowing multiple chromatin modifying complexes to regulate target genes. For example, lncRNA HOTAIR in the mammalian *HOXC* locus can bind both PRC2 and LSD1/CoREST/REST complexes mediating histone H3K27 trimethylation and H3K4 demethylation of target genes^[26]. This complex has been shown to target and silence the *HOXD* gene cluster^[27].

LNCRNA IN CANCER

Profiling of normal and tumor tissues has revealed that lncRNAs are dysregulated in many human cancers including prostate^[28], colorectal^[29], breast^[30], bladder^[31], liver^[32], and brain cancer^[33]. They have been found to function as oncogenes and tumor suppressors and regulate many of the hallmarks of cancer.

Tumor Suppressor lncRNAs

The lncRNA Xist was found to be a potent tumor suppressor of hematologic malignancies *in vivo*. Yildirim *et al.*^[15] found that knockdown of Xist in hematopoietic cells in mice resulted in aggressive myeloproliferative neoplasm and myelodysplastic syndrome. They also demonstrated that Xist was critical for hematopoietic stem cell survival. The authors hypothesized that X reactivation *via* Xist silencing could lead to genomic instability and cancer.

Huarte *et al.*^[34] examined lncRNAs regulated by the tumor suppressor p53. They identified lncRNA-p21 as a direct p53 target. Furthermore, they found that lncRNA-p21 is critical in regulating many of the genes that are repressed in response to p53 activity and they

found that lincRNA-p21 associates with hnRNP-K. The lincRNA-p21/hnRNP-K interaction was found to be necessary for hnRNP-K genomic localization at sites of gene repression.

Oncogenic lncRNAs

Gupta *et al.*^[30] found that lncRNA HOTAIR overexpression was a strong predictor of breast tumor metastasis. Furthermore, they found that HOTAIR overexpression could promote breast tumor cell invasion and knockdown of HOTAIR could inhibit invasiveness. Prensner *et al.*^[35] examined lincRNA expression prostate tumors and found that the lincRNA PCAT-1 was overexpressed in high-grade and metastatic tumors. They found that PCAT-1 expression promoted proliferation of prostate cancer cells.

Epigenetic reprogramming in cancer

Since lncRNAs play such a large role in epigenetic regulation and chromatin remodeling in normal physiology it is possible that they may play a role in the epigenetic reprogramming that is a hallmark of human cancer. One hundred and seventy ncRNAs including HOTAIR are differentially expressed among normal human breast tissue, primary breast tumors, and metastatic breast tumors^[30]. Forced expression of HOTAIR in epithelial cancer cells altered the localization of PRC2 on chromatin. Genome-wide studies revealed PRC2 localization more resembling occupancy in embryonic fibroblasts. This correlated with increased tumor cell invasiveness. Conversely, knockdown of HOTAIR was shown to inhibit cancer cell invasiveness in cells with high levels of PRC2 expression. Similar findings were reported in colorectal cancer^[36].

It has also been shown that the tumor suppressor gene p15 is silenced by its natural antisense RNA, a lncRNA ANRIL^[37,38]. ANRIL directs PRC2 to the p15 locus inhibiting p15 expression^[38]. Similarly, the expression the tumor suppressor gene p21 was shown to be epigenetically repressed by its antisense RNA^[39]. These reports suggest that tumor suppressor gene silencing may be a result of an imbalance in bidirectional transcription.

Prensner *et al.*^[28] found that the lncRNA SCHLAP1 was overexpressed in prostate tumors and where it is critical for tumor cell metastasis. They found that SCHLAP1 antagonized localization of the SWI/SNF chromatin-remodeling complex and inhibited tumor suppressive action of SWI/SNF.

Microvascular invasion and angiogenesis

Angiogenesis is an important hallmark of human cancer. New vasculature is required for providing nutrients and oxygen for tumor growth and proliferation as well as proving an avenue for metastatic spread. Although a variety of genes which can stimulate angiogenesis have been discovered, recently there has been a focus on investigating the roles of ncRNA in the angiogenic switch.

Yuan *et al.*^[40] discovered that the lncRNA MVIH (long noncoding RNA associated with microvascular invasion

in hepatocellular carcinoma) was overexpressed in hepatocellular carcinoma. MVIH overexpression was associated with frequent microvascular invasion and a higher tumor node metastasis stage as well as decrease in recurrence-free survival. Further data showed MVIH could promote tumor inducing angiogenesis through inhibiting the secretion of phosphoglycerate kinase phosphoglycerate kinase 1. This is clear evidence that dysregulation of lncRNA promotes tumor growth through angiogenesis.

Angiogenic signaling can also be activated in response to hypoxia. Normal hypoxia can induce gene expression in response to oxygen sensing accompanied by adaptive responses to the hypoxic environment. However, during tumor growth, hypoxia can alter gene expression to promote angiogenesis, cell proliferation and even metastasis. Ferdin *et al.*^[41] found the tight link between long non-coding transcripts from ultraconserved regions, termed transcribed-ultraconserved regions (T-UCRs) and oxygen deprivation. Several T-UCR were upregulated during hypoxia (several were induced directly by hypoxia-inducible factor), these hypoxia-induced noncoding ultra-conserved transcripts (HINCUTs) were also found overexpressed in colon cancer patients. The author also hypothesized that protein modification through addition of O-linked N-acetyl glucosamine was involved in the sensing oxygen tension as one specific HINCUT lncRNA (HINCUT-1) was part of retained intron of the host protein-coding gene O-linked N-acetyl glucosamine transferase.

Another potential angiogenic lncRNA, Maternally expressed gene 3 (MEG3) was found to be silenced in pituitary adenomas. MEG3 knockout mice showed enhanced angiogenic signaling and increased microvascular density in embryonic brains^[42]. Since MEG3 stimulated p53 pathways and regulated p53 target genes, it is highly desirable to examine MEG3 expression in other cancers.

Metabolism imbalance

Metabolic imbalance is a key hallmark of human cancer. One mechanism lncRNA may contribute to tumorigenesis is through regulating tumor cell metabolism. However, very little is known regarding the role of lncRNAs in metabolism. One report demonstrated that a particular lncRNA on paternal chromosome 15q11-q13 was critical to maintaining energy balance^[43]. The loss of noncoding RNAs on this site is followed by genetic disease called Prader-Willi syndrome (PWS). These imprinted PWS locus cover a long noncoding RNA transcript which are processed into SNORD116 small nucleolar RNA and spliced exons of the host gene 116HG. The author found 116HG are concentrated subnuclearly with transcriptional activator RBBP5 at active genes involved in metabolism. 116HG deficient mice showed dramatic increases in energy expenditures. Although the inculcated tissues are mainly in the brain and the syndrome is characteristic of disorders of neurodevelopment and obesity in children, whether it is also a genetic risk factor for certain cancers is unknown and needs to be examined.

Another well-known lncRNA, ANRIL, is implicated

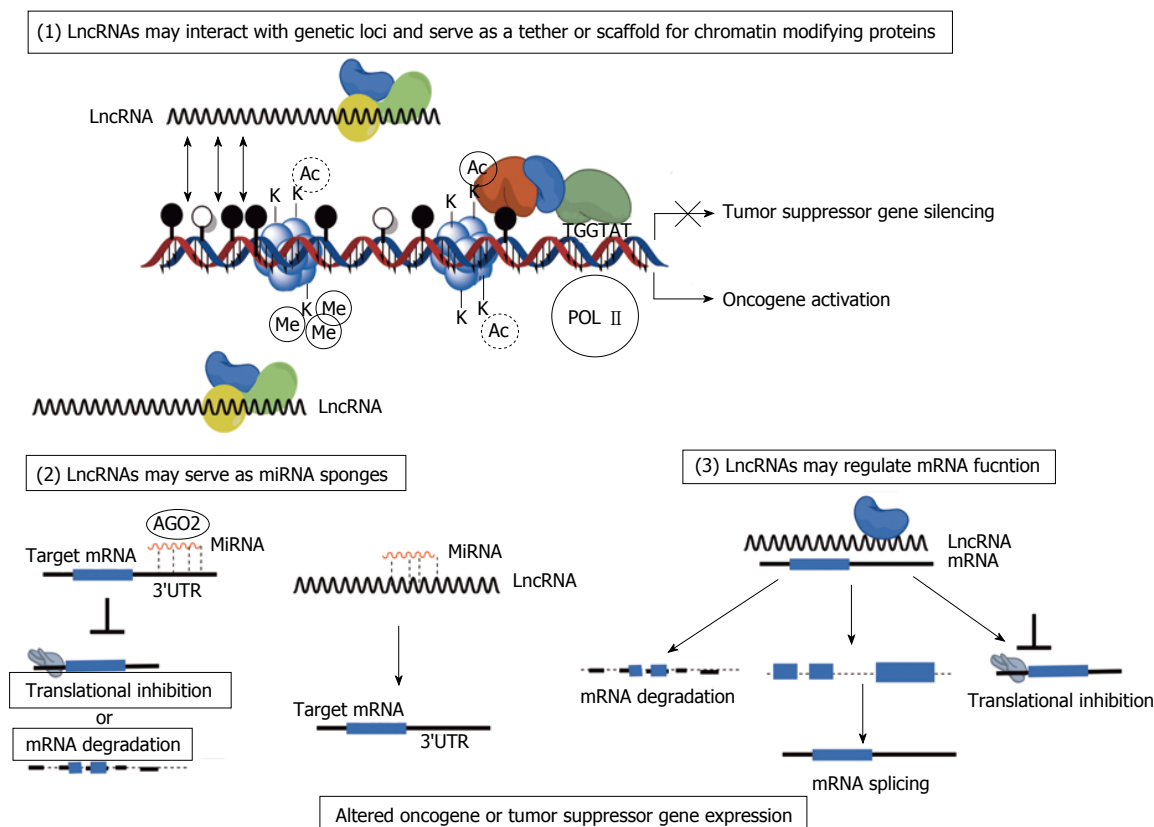

Figure 1 Diverse functions of long non-coding RNA in human cancer cells. Long non-coding RNA (lncRNA) are known to be active regulators of gene expression through transcriptional, post-transcriptional, and translational mechanisms. LncRNA dysregulation in cancer may provide oncogenic signaling or loss of tumor suppressive function. LncRNAs are known to serve as tethers and scaffolds that direct chromatin modifying enzymes such as Polycomb group proteins to regulatory regions of DNA. This may result in upregulated transcription of oncogenic protein coding genes or loss of transcription of tumor suppressor protein coding genes. LncRNAs also may serve as competitive endogenous RNA for microRNAs (miRNAs) (sponges) that then inhibit miRNA function thereby preventing miRNA from interacting with target mRNAs. Finally, lncRNAs can interact directly or indirectly with mRNAs in the nucleus and cytoplasm regulating mRNA splicing, mRNA stability, and mRNA translation.

as a risk factor for breast cancer and is overexpressed in prostate cancer^[44]. Recently, knockdown of ANRIL resulted in downregulation of 3 genes, *ADIPOR1*, *VAMP3* and *C11ORF10*, all of which have a well-established role during the metabolism of fatty acid and glucose and in inflammation^[45].

Extracellular matrix

Extracellular matrix (ECM) is an important component of both normal and malignant tissues. In addition to structural support the ECM supports the communication between nearby cells in order to coordinate signaling and tissue function. The role of lncRNA in the ECM during malignancy has only recently been investigated. In one study, Zhuang *et al.*^[46] investigated the expression of lncRNA during type I collagen stimulation in a 3-D culture. Type I collagen has been shown enriched in tumor microenvironment and can promote tumor growth. In this study, the lncRNA HOTAIR was upregulated in lung adenocarcinoma cells grown in 3-D cell culture supplemented with collagen. Furthermore, the authors observed loss of acini, a sign of hyperproliferation and poor differentiation. This might be the first attempt to determine the function of lncRNA at the level of organ-

otypic culture and it is a very useful strategy for further characterization of lncRNA molecules functional in the tumor microenvironment.

Tumor microenvironment

It is known that the tumor microenvironment plays a role in tumor formation, invasive progression and metastatic dissemination^[47]. Tumor microenvironment is composed of mesenchymal stromal cells, adipocytes, fibroblasts, endothelial and immune cells. The tumor microenvironment is abundant in proinflammatory cytokines that are derived from both cancer cells and nearby endothelial and adipocyte like cells; these secreted cytokines not only stimulate inflammation but also recruit mesenchymal stromal cells and preadipocytes to the tumor. Furthermore, tumor microenvironment can influence tumor cell metabolism and metabolic changes can also affect inflammatory signaling and this feedback can further alter the tumor microenvironment and promote tumor invasion. LncRNAs have been found to be critical regulators of mesenchymal stem cells^[12], endothelial cells^[48], adipocytes^[16] and immune cells^[49,50]. It remains untested what role lncRNAs may have in promoting tumorigenesis through signaling within the tumor microenvironment.

Cancer stem cells

As was discussed earlier, lncRNAs play critical roles in regulating pluripotency in ESCs. The two defining characteristics of stem cells, self-renewal and differentiation capacity, are hijacked by some neoplastic cells in what are often referred to as cancer stem cells. Many of the signaling pathways that are critical in ESCs (OCT4, SOX2, KLF4 and PcG^[51-54]) have been found activated in cancer stem cells. Since the regulation of OCT4, SOX2, KLF4 involves feedback loops with lncRNAs^[10], and as lncRNAs are known to be dysregulated in cancer, it seems likely that lncRNAs may be involved in regulating stem cell signaling in cancer cells. Examining the functions of lncRNAs in cancer stem cells may reveal new therapeutic targets and mechanisms for overcoming chemoresistance.

Many lncRNAs are shown to interact with chromatin modifying complexes. In particular the PcG is known to regulate pluripotency and self-renewal of ESCs. As polycomb signaling has been implicated in some types of cancer^[54], it is likely that lncRNAs may serve to target polycomb complexes to sites in chromatin to silence differentiation programs in cancer stem cells

It is already known that ncRNAs, specifically miRNAs, play critical roles regulating cancer stem cells, e.g., the miR-200 family^[55], let-7^[56], miR-140^[57]. One potential function of lncRNAs is to competitively inhibit miRNAs as a molecular sponge (also referred to as competing endogenous RNAs) (Figure 1). Kallen *et al.*^[58] recently discovered that lncRNA H19 can serve as a sponge for let-7 family of miRNAs in muscle tissues. There is potential for this or other lncRNAs to regulate miRNA signaling in cancer stem cells and future studies will provide further evidence of the importance of ncRNA, both lncRNA and miRNA, in regulating cancer stem cell signaling.

DISCUSSION

It is clear that lncRNAs are critical regulators of gene expression in stem cell biology and in tumorigenesis. Further study of lncRNA will increase our understanding of the complex networks involved in regulating stem cell circuitry and may uncover the mechanisms by which differentiated cancer cells can hijack embryonic or developmental programs to promote self-renewal of cancer cells. Future studies of lncRNAs in cancer stem cells including profiling of sorted cancer cell populations as well as genetic approaches for manipulating lncRNA expression should provide information as to how these molecules regulate cancer stem cells. Ongoing *in vivo* work will provide the strongest evidence for the importance of lncRNAs in physiology and disease. Furthermore, additional tumor profiling should identify which lncRNAs might serve as clinical biomarkers and which are the best candidates for future therapeutic strategies.

GKRS as salvage therapy for malignant gliomas, nine articles from 2005 to July 2013 were identified which evaluated rGBM treatment. In this review, we compare overall survival following diagnosis, overall survival following salvage treatment, progression-free survival, time to recurrence, local tumor control, and adverse radiation effects. This report discusses results for rGBM patient populations alone, not for mixed populations with other tumor histology grades. All nine studies reported median overall survival rates (from diagnosis, range: 16.7-33.2 mo; from salvage, range: 9-17.9 mo). Three studies identified median progression-free survival (range: 4.6-14.9 mo). Two showed median time to recurrence of GBM. Two discussed local tumor control. Six studies reported adverse radiation effects (range: 0%-46% of patients). The greatest survival advantages were seen in patients who received GKRS salvage along with other treatments, like resection or bevacizumab, suggesting that appropriately tailored multimodal therapy should be considered with each rGBM patient. However, there needs to be a randomized clinical trial to test GKRS for rGBM before the possibility of selection bias can be dismissed.

Core tip: Glioblastoma is the most common malignant primary neoplasm of the brain. Despite aggressive, upfront therapy, most patients will experience a recurrence of their tumor six months after treatment. This review article analyzes the outcomes of clinical trials that utilized Gamma Knife radiosurgery as salvage therapy for recurrent glioblastoma. Other modalities of radiosurgery were excluded from this study as there is variability in the targeting precision and radiation dos-

Abstract

Glioblastoma multiforme (GBM) is the most common malignant primary brain tumor with a survival prognosis of 14-16 mo for the highest functioning patients. Despite aggressive, multimodal upfront therapies, the majority of GBMs will recur in approximately six months. Salvage therapy options for recurrent GBM (rGBM) are an area of intense research. This study compares recent survival and quality of life outcomes following Gamma Knife radiosurgery (GKRS) salvage therapy. Following a PubMed search for studies using

age fall off. Gamma Knife can be used to target tumors that are adjacent to eloquent brain tissue, thus allowing it to treat a wider population of patients, improving overall survival.

INTRODUCTION

Glioblastoma multiforme (GBM) remains the most common malignant primary brain tumor in adults and is uniformly fatal^[1]. Without treatment, most patients die within a few weeks after presentation of symptoms^[2]. For newly diagnosed GBM, median survival can be extended to 14-16 mo using a standard treatment protocol that includes maximal surgical resection followed by temozolomide chemotherapy and 60 Gy of external beam radiation therapy (EBRT)^[3,4].

Strong predictors of prognosis with these treatments for patients with GBM have been outlined by Radiation Therapy Oncology Group recursive partitioning analysis (RTOG-RPA). These include tumor histopathology, age, Karnofsky Performance Score (KPS), neurologic function, and initial treatments^[5,6]. Patients with GBM histology are categorized in one of four groups, RPA Classes III, IV, V, and VI, with Class VI having the worst prognosis. In 2011, Li *et al*^[7] analyzed the RTOG-RPA with a renewed focus on GBM alone. They suggest that there is not a significant difference between Classes V and VI, and that these groups could be combined. They report median overall survival times for the updated classification as 17.1, 11.2, and 7.5 mo for patient populations in Classes III, IV, and V + VI, respectively^[7]. Additional prognostic factors that may improve survival include small tumor volume, unifocal lesions, use of additional salvage therapies, and O6-methylguanine-DNA methyltransferase (MGMT) promoter methylation^[8-11]. MGMT status, however, was either not known, or not reported for any of the studies reviewed herein.

Despite aggressive adjuvant therapy for GBM, tumors typically recur within 6 mo of treatment. This may be due in part to microscopic infiltrative growth up to 4 cm from visible tumor location along white matter tracts in normal brain tissue^[12] as well as the resistance of the tumor to radiation and chemotherapy treatments. Salvage therapy for recurrent GBM (rGBM) is an area of current interest in order to extend overall survival beyond the aforementioned median survival of 17.1 mo for the most functional patients. Some patients may not be eligible for repeated surgery because of the location of the tumor in critical structures or its diffuse nature. Others may find

that recovery from surgery is too burdensome during the terminal stage of illness. Salvage chemotherapy may be an option for patients who can tolerate the side effects. Repeated conformal radiation therapy comes with uncertain benefit and increased risk of adverse radiation effects including radionecrosis or radiation-induced edema. Stereotactic radiosurgery has shown not to be superior to standard EBRT for newly diagnosed GBM^[13]. However, its role in rGBM is still under investigation.

There are multiple modalities of stereotactic radiosurgery; one of which often utilized for this recurrent disease is Gamma Knife radiosurgery (GKRS). GKRS is capable of delivering a high dose of radiation to a tumor while sparing healthy surrounding tissue. Its advantages in rGBM include the convenience of a single outpatient treatment, minimization of potential radiation necrosis to adjacent brain, and a cost benefit over open resection^[14]. Its disadvantage includes the lack of treatment to regions of tumor not well visualized on magnetic resonance imaging. Therefore, its effect on both local tumor control and overall survival is unclear. Previous review articles on stereotactic radiosurgery for malignant gliomas have taken a broad approach, including gliomas of multiple grades or a variety of radiosurgery treatment modalities. These other articles have excluded some of the smaller studies of radiosurgery for rGBM. The present article reviews the outcomes of clinical studies which used GKRS alone or as part of multimodal treatment regimens as salvage therapy for rGBM. While other modalities, such as CyberKnife® or linear accelerator based systems may have similar outcomes, these radiosurgery modalities are not included in this review due to the differences in cost, conformity, homogeneity, maximum dose, treatment times, dose fall off, invasiveness, treatment planning, and beam properties^[15-20]. Different radiosurgical delivery systems may be more appropriate for other tumor types and locations which are not discussed here^[18,20].

RESEARCH

A PubMed search was performed to identify clinical studies that used GKRS salvage for treatment of rGBM between 2005 and 2013. Key words for this search included "Stereotactic Radiosurgery", "Gamma Knife", "Glioblastoma", "recurrent GBM", "Glioma", and "Glioma salvage therapy". To expand the search strategy, references from articles found in this search were also analyzed for inclusion in this review. Studies which treated World Health Organization Grade I - III Gliomas without treating Grade IV (GBM) were also excluded. Finally, studies which used Gamma Knife as upfront therapy only for newly diagnosed GBM were excluded.

The median overall survival outcomes as compared to RTOG-RPA prognostic indicators^[7] were extracted and collated from these research studies. Other results were also analyzed including median survival post-GKRS salvage, progression-free survival, and time to repeat tumor recurrence. This article will discuss additional factors that may contribute to improved outcomes based on

these combined results. Additionally, barriers to effective GKRS salvage treatment are considered. Some studies did not report segregated data for GBM versus Grade I - III gliomas^[11,21-23] or salvage GKRS versus upfront GKRS^[24,25] in all categories; however, we considered data as available.

RESULTS

Table 1 outlines the characteristics of patients from the various studies who were newly diagnosed with GBM. Table 2 shows which upfront treatment modalities were used for newly diagnosed GBM and the time until the first recurrence. In Table 3 we show the available details for salvage treatment modalities. Finally, Table 4 describes the outcomes of these salvage therapies.

Median overall survival from initial diagnosis compared to RPA prognosis

Primarily, salvage therapies for rGBM, such as GKRS, are designed to prolong the life of the patient. Taken as a whole, these studies showed an improved survival compared to classical results from the RTOG-RPA study.

Considering the KPS scores and ages of patients in each study, it is expected that the majority of patients would be classified as RTOG-RPA Classes III or IV with an expected overall median survival of 17.1 or 11.2 mo, respectively^[7]. The longest median survival for these salvage studies was reported in the cohort of eleven patients studied by Park *et al*^[10] in 2012 who were treated with both GKRS and bevacizumab as salvage: 33.2 mo (95%CI: 23.7-42.7 mo) survival after initial GBM diagnosis. These patients were matched to a group of 44 patients who were treated with GKRS salvage without bevacizumab resulting in median overall survival of 26.7 mo (95%CI: 21.8-31.6 mo). While the authors attributed this longer survival to selection bias (KPS scores ≥ 70), it is worth mentioning that four of the eleven patients in the bevacizumab treatment group would be classified in RPA Class V + VI as they were older than 50 and received biopsy only when initially diagnosed, and thus their survival would have classically been very limited.

A 2012 study by Skeie *et al*^[9] demonstrated a survival advantage in patients who received salvage GKRS with salvage gross total resection (median 21 mo) or without salvage gross total resection (median 18 mo). Improved

¹Kong *et al*^[23] (2008) includes data from 0-5 cases treated with LINAC. rGBM: Recurrent glioblastoma multiforme; GK: Gamma Knife; ARE: Adverse radiation effects; GTR: Gross total resection; BZ: Bevacizumab; NR: Data not reported or not segregated for rGBM patients.

survival was shown for salvage GKRS patients in all RPA Classes, the majority of whom were in Class IV. In 2011, Elliott *et al*^[11] showed that salvage GKRS with repeat resection for rGBM patients resulted in 26.1 mo survival. This longer than average survival could be due, in part, to the relatively small volume tumors which were selected: median 1.35 mL (range, 0.37-6.2 mL).

There were two other studies which compared median overall survival outcomes to the RPA Classes of their patients: Hsieh *et al*^[24] and Pouratian *et al*^[25] reported 16.7 and 17.4 mo survival, respectively. Pouratian *et al*^[25] showed that their patients who had GKRS as salvage had significantly longer survival than those who received upfront GKRS therapy and the group which received the greatest benefit were patients in RPA Class III. Contrarily, the study conducted by Hsieh *et al*^[24] found that patients in Class VI received the greatest survival benefit. It is

worth mentioning that both of these studies used a relatively low median marginal dose for the GKRS therapy: 12 Gy in the Hsieh study and 6.0 Gy in Pouratian.

There have not been large studies assessing the number or frequency of repeated salvage GKRS for recurrent GBM. However there have been some reports that suggest that eligible patients may be offered as many repeated therapies as can be tolerated or are feasible with some initial promising results^[26,27].

Other outcomes

Without treatment, the natural history of a recurrent GBM is grim^[2]. It is expected that the same prognostic indicators mentioned previously are the best predictors of survival following recurrence. It is therefore useful when evaluating the efficacy of GKRS salvage therapy to consider the length of median overall survival after treat-

ment, length of progression-free survival, and time to repeat tumor recurrence post-GKRS salvage.

Median overall survival post-GKRS salvage ranged from 9-17.9 mo, and was reported for all nine of these studies ($n = 322$ patients)^[9-11,21-25,28]. Longer survival was associated with a combination salvage treatment of bevacizumab^[10], or repeated surgical treatment^[9]. Those patient cohorts with a shorter post-salvage survival did not use these combined therapies, used a lower radiation dose for GKRS salvage, or did not report any information for other modes of rGBM salvage therapy^[9,22,24,25,28].

Three of these studies reported progression-free survival data following salvage GKRS for their rGBM patients, which might be useful in counseling a patient on their treatment options^[10,23,25]. Park *et al.*^[10] described 6.7 mo progression-free survival in the 44 patient cohort receiving GKRS salvage compared to 14.9 mo progression-free survival in the 11 patients who received GKRS + bevacizumab salvage ($P = 0.035$). Kong *et al.*^[23] reported only 4.6 mo median progression-free survival following GKRS salvage while their patients demonstrated promising median overall survival of 23 mo. Unfortunately, many of the other patient characteristics, treatment histories, and prognostic factors that they reported were grouped together with Grade III gliomas. This makes it difficult to independently assess their rGBM patient population. Lastly, the smaller dosage GKRS study by Pouratian *et al.*^[25] showed median progression-free survival of 7.1 mo.

Only two of the reviewed studies reported the time to tumor recurrence following GKRS salvage^[9,10]. Predicting the timeline of a second recurrence could be helpful in planning later salvage options. Skeie *et al.*^[9] indicated that the second recurrence was at a median of 6 mo after GKRS compared to 2 mo following repeat resection without GKRS ($P = 0.009$). The study by Park *et al.*^[10] found that the pattern of recurrence was dependent upon initial tumor volume. The tumors which were larger than 10 mL tend to recur in approximately 6 mo while smaller tumors did not recur until around 9 mo independent of the addition of bevacizumab treatment^[10].

Factors contributing to outcomes

Due to the infiltrative nature of GBM, most tumors will recur locally, within 4 cm from the original resection bed^[12]. In the hope of stopping or delaying this progression, it is important to develop a treatment strategy that will achieve local control. Skeie *et al.*^[9] assessed 98 of their treated patients and found that 18.8% of those treated with salvage GKRS achieved local control compared to only 2.0% of those receiving repeat resections only ($P = 0.032$). Koga *et al.*^[28] demonstrated 93% local control in their patients who received 20 Gy to a 0.5-1.0 cm extended field GKRS compared to 47% of patients who were treated with 20 Gy to the gadolinium-enhancing margin only.

Other strategies for delaying progression of GBM include radiosensitization methods such as bevacizumab^[10], chloroquine^[29], or hyperbaric oxygen therapy^[22]. If the tu-

mor tissue can be sensitized to radiation, it may be possible to prescribe a smaller dose of radiation while achieving the same therapeutic effect and reducing adverse side effects. This could open up GKRS salvage to a wider patient population: those with larger volume tumors and/or tumors in close proximity to eloquent brain areas (*e.g.*, basal ganglia, optic chiasm, and brainstem). Kohshi *et al.*^[22] used hyperbaric oxygen therapy combined with fractionated GKRS as salvage in an effort to sensitize the tumor while reducing adverse effects of radiation, resulting in a median survival of 21 mo in their rGBM patients. There has not yet been a randomized clinical trial to test these results so the benefits remain theoretical.

Barriers to effective GKRS salvage

Radionecrosis or radiation induced edema present a challenge for repeat conformal radiation treatment as well as aggressive GKRS salvage. In the studies reviewed, the highest rates of symptomatic radiation side effects were associated with the highest prescribed GK dose to the tumor margin. Koga *et al.*^[28] reported adverse radiation effects in 28.6% of patients who received 20 Gy to the extended margin, this suggests that achieving improved local tumor control may come with an increased risk of side effects. Park *et al.*^[10] demonstrated that bevacizumab not only prolonged survival but also reduced detectable adverse radiation effects from 46% to 9% ($P = 0.037$). Two studies reported 0% radiation side effects in their patients: Pouratian *et al.*^[25] used a median margin dose of 6.0 Gy while Kohshi *et al.*^[22] delivered 22 Gy in 8 fractions (2-3 Gy per fraction).

CONCLUSION

The benefits of salvage GKRS for rGBM appear to be promising in a selected group of patients. However selection bias is uncontrolled in these studies, and poses a significant limitation in these retrospective studies. Without a randomized clinical trial, it is unclear whether these salvage therapies truly prolong survival. A future randomized trial is necessary to demonstrate that radiosurgery is beneficial for rGBM. Future studies should evaluate which RPA Classes benefit most from salvage GKRS.

In our center, Gamma Knife of Spokane, each case of rGBM undergoes a multi-disciplinary review followed by individualized treatment. Temozolomide and EBRT are used as upfront therapy and bevacizumab upon recurrence of GBM. When identifying patients for salvage GKRS *via* surveillance magnetic resonance imaging, treatment is typically offered to those with a KPS of 60 or better, at any age. In patients who are candidates for GKRS, we typically treat rGBM to a marginal dose of 16 Gy. The median tumor volume treated has historically been 16.2 cc (range 0.6-52.2 cc).

Abstract

Bone metastasis is a common and debilitating consequence of lung cancer: 30%-40% of patients with non-small cell lung cancer develop bone metastases during the course of their disease. Lung cancer cells find a favorable soil in the bone microenvironment due to factors released by the bone matrix, the immune system cells, and the same cancer cells. Many aspects of the cross-talk among lung tumor cells, the immune system, and bone cells are not clear, but this review aims to summarize the recent findings in this field, with particular attention to studies conducted to identify biomarkers for early detection of lung cancer bone metastases.

INTRODUCTION

Lung cancer is the most common tumor worldwide, and in Europe alone, it is responsible for the 20.6% of cancer mortality^[1]. It has poor overall survival rates: the majority of advanced stage lung cancer patients die within 18 mo from diagnosis^[2]. The predominant form of lung cancer is non-small cell lung cancer (NSCLC), and is responsible for 80%-85% of all lung tumors^[3].

Lung cancer frequently metastasizes to bone, with 36% of patients presenting with bone lesions at autopsy^[4] and 22%-60% showing bone marrow micro-metastases^[5]. The early diagnosis of NSCLC is difficult, and 30%-40% of patients with NSCLC develop bone metastases during the course of their disease^[6,7]. The prognosis of lung cancer patients with bone metastases is poor, with a median survival time from detection of lesions measured in months^[4]. Even though NSCLC patients have a relatively short survival time, a large percentage develop skeletal-related events (SREs), thus clinicians show particular attention to the management of bone metastases to prevent debilitating skeletal complications. Indeed, bone metastases are often not diagnosed in NSCLC patients until they cause pain and SREs^[8], but once a patient has a first SRE, he is likely to experience subsequent events, leading to debilitating bone lesions and a reduction in the quality of life. Lung cancer bone metastases normally appear as areas of radiolucency and are osteolytic, with poor margination, no matrix and cortical destruction^[9]. They commonly affect the spine, ribs, pelvis and proximal long bones. At an early stage, bone metastases may occur easily at an axial bone through the vertebral vein system, then at appendicular bone in more advanced

stages of the disease^[10]. A unique feature of this tumor is the ability to spread to the bones of the hands and feet. This is probably due to the ability of lung cancer to shed malignant cells directly into the arterial blood flow, from where they can be seeded far and wide.

In this review, I summarize the current knowledge on the cross-talk among lung tumor cells, the bone micro-environment, and the immune system, that lead to bone metastasis formation.

BONE MICROENVIRONMENT IS A FERTILE SOIL FOR DORMANT AND PROLIFERATING TUMOR CELLS

Tumor dissemination is an early event and is not related to the size of the tumor mass, supporting the idea of concomitant progression of the primary tumor and metastasis^[11]. Several studies have shown that disseminated cells, shed from a primary tumor, may lie dormant in distant tissues for long periods before they can be activated to form metastases. The skeleton has a large surface area and a microenvironment conducive and protective to tumor cell growth. Indeed, disseminated tumor cells (DTCs) can persist in a quiescent state in the bone marrow of cancer patients for years, particularly if they lie in the hematopoietic stem cell (HSC) niche^[12], which expresses adhesion molecules and secretes factors contributing to tumor cell dormancy. At present, it is not clear how dormancy is induced or what leads to activation of the dormant cells. One hypothesis is that molecules that induce HSC dormancy are likely to induce dormancy of metastatic tumor cells^[13]. For instance, osteoblasts (OBs) which are a crucial component of the stem cell niche, express stromal derived factor-1 (SDF-1) and annexin-II (Anxa2), that attract both HSCs and cancer cells expressing their receptors, CXCR4 and Anxa2r, respectively^[14]. In this way, the niche attracts, protects and induces dormancy of DTCs, which may be released from quiescence and grow as a consequence of a stimulatory microenvironment, like bone. DTCs detected in bone marrow of breast cancer patients exhibited features of mesenchymal and cancer initiating cells (CICs)^[15]. These latter cells are responsible for both primary tumor generation, maintenance, recurrence and drug resistance^[16,17]. In lung cancer, a subset of cells expressing CD133 and CXCR4 has been shown to have CIC features and to be essential for tumor metastasis formation^[18]. Moreover, chemotherapy may select resistant CICs^[19], as also demonstrated by Bertolini *et al*^[20] who showed that lung CICs developed resistance to cisplatin. The monitoring of DTCs is a potential method to follow the dissemination of tumors, but a recent work reported that in NSCLC patients, DTC detection is not particularly useful to determine the presence of the disseminated disease in its early stages^[21].

Bone has physical properties such as low pH, hypoxia and high levels of extracellular calcium^[22], which sustain the proliferating tumor cells that secrete high quantities of lactic acid, creating a local area of bone with a low

pH, which stimulates osteoclasts (OCs) activity. On the other hand, tumor cells grow better with a low pH and release proteolytic enzymes, that maintain the low pH, thus tumor expansion is perpetuated^[23]. The active bone resorption causes an increase in extracellular calcium level that stimulates the calcium-sensing receptors on surrounding cells and tumor cells, leading to an increased secretion of parathyroid hormone-related peptide (PTHrP), a potent stimulator of OCs^[24,25]. Bone is a hypoxic tissue, thus it promotes the ability of cancer cells to grow under hypoxic conditions, stimulating the expression of hypoxia inducible factor-1 (HIF-1). HIF-1 activates the transcription of target genes which encode proteins that play important roles in many critical aspects of cancer biology^[26]. For instance, HIF-1 is involved in many steps of breast cancer metastasis, including metastatic niche formation, recruitment of bone marrow-derived cells to the metastatic niche, OC formation and OB inhibition^[27-29].

FACTORS PRODUCED BY BONE AND TUMOR CELLS MODULATE OC ACTIVITY

The interaction of tumor and bone cells induces the formation of a vicious cycle leading to bone metastases^[30]. Indeed, tumor cells disrupt normal bone remodeling, a perfectly balanced activity of bone resorption by OCs and bone formation by OBs. Bone resorption induced by cancer cells creates a physical space for tumor expansion, and it induces the release of growth factors and cytokines supporting tumor metastasis^[31].

Bone marrow produces factors, such as SDF-1, which attracts cancer cells expressing the chemokine receptors, CXCR4 and CXCR7, thus it represents a favorable soil for secondary tumor localization^[32,33]. Moreover, activated OCs resorb bone and release growth factors enmeshed in the bone matrix, such as bone morphogenetic proteins, transforming growth factor- β (TGF- β), insulin-like growth factor (IGF), fibroblast growth factor and others that stimulate the growth of metastatic tumor cells in bone, and the production and release of bone resorbing factors from tumor cells^[34,35]. In particular, TGF- β stimulates HIF-1 signaling within bone, contributing to the vicious cycle driving the development of metastatic osteolysis^[36]. Malignant cells produce cytokines, such as interleukin-6 (IL-6), IL-8 and IL-11, which activate OCs^[37]. IL-6 can stimulate tumor cell proliferation, migration and invasion of lung and other tumors^[38,39], and it may induce bone resorption or formation according to the interactions with other factors like PTHrP, IL-1 and receptor activator of nuclear factor-kB ligand (RANKL). IL-8 stimulates OC maturation through binding with its receptor CXCR1 expressed on OC precursors^[40]. IL-11 stimulates osteoclastogenesis and it has been reported to be a predictive factor for development of osteolytic bone metastasis^[41]. Cancer cells also secrete molecules such as parathyroid hormone, PTHrP, prostaglandins, activated vitamin D and TNF, which stimulate RANKL expression on OBs and bone marrow stromal cells^[42].

RANK, the RANKL receptor, is expressed by solid tumors, with high concordance between bone metastasis and corresponding primary tumors^[43]. The activation of the RANK/RANKL axis leads to an increase in OC number, survival and activity, and it may induce migration and homing of tumor cells to the RANKL-rich bone microenvironment^[44]. In clinical practice the use of target therapy to reduce bone metastases gave encouraging results: the fully human monoclonal antibody directed against RANKL reduces bone metastases in breast and lung tumors^[45-47]. Nuclear factor-kappa B is the downstream target of RANKL and it is also activated in lung cancer cells by epidermal growth factor receptor (EGFR), implicating this pathway as pivotal in lung cancer bone metastases^[46]. EGFR-tyrosine kinase inhibitors (TKIs), such as erlotinib, show dramatic anti-tumor activity in a subset of NSCLC patients with an active mutation in the *EGFR* gene. Some lung cancer patients with wild type EGFR respond to EGFR-TKIs, thus EGFR-TKIs have an effect on host cells as well as tumor cells, preventing bone metastases by affecting the host microenvironment irrespective of its direct effect on tumor cells^[48].

PTHrP promotes OC bone resorption^[49-51], and it stimulates OBs and stromal cells to express RANKL, which induces OC maturation^[52,53]. Among the inhibitors of PTHrP, recent data report that the microRNA miR-33a is downregulated in lung cancer cells, and it directly targets PTHrP leading to decreased osteolytic bone metastasis^[54]. Indeed, the downregulation of PTHrP, induced by miR-33a, causes a decreased secretion of IL-8, with consequent reduction in OC differentiation and bone resorption^[54]. Novel data derived from a pre-clinical model of NSCLC reports that miR335 inhibits the expression of RANKL and IGF-1 receptor by lung cancer cells, thus skeletal metastasis is reduced^[55].

In the bone marrow, a direct activation of osteolysis by cancer cells has been shown through the interaction between Notch and Jagged. Jagged1, a downstream mediator of the pro-metastatic TGF- β , promotes tumor growth through stimulation of IL-6 production from OBs, and directly activates OC differentiation^[56]. Moreover, Jagged is overexpressed by bone metastatic tumor cells^[57], whereas its receptor Notch is frequently expressed by progenitors and mature cells in the bone marrow^[58]. In breast cancer, Notch-Jagged interactions activate biological responses in OCs and OBs, which promote both tumor invasion of bone and tumor cell growth in bone^[56]. In NSCLC, the expression of Notch-3 receptor correlates with a poor prognosis and the stage of the disease^[59].

ROLE OF IMMUNE SYSTEM CELLS IN REGULATION OF OCS AND TUMOR GROWTH IN BONE

Oxidative stress is implicated in the initiation and progression of lung cancer^[60]. In particular, myeloid-derived suppressor cells (MDSC), which infiltrate different tumors,

generate reactive oxygen species (ROS) and cytokines, that suppress host T cell responses, promoting tumor progression and metastasis^[61]. Both the production of ROS and nitric oxide are involved in osteoclastogenesis, and bone marrow-derived MDSCs have been showed to be able to differentiate into OCs; thus, all these factors contribute to enhanced bone destruction in tumor osteolysis^[62,63].

Direct involvement of T cells in regulating OC activity has been demonstrated in patients affected by multiple myeloma, lung cancer and other solid tumors with bone metastasis^[64-67]. These bone metastatic patients showed an increase in circulating OC precursors compared with both healthy controls and cancer patients without bone metastases^[66]. OC precursors differentiate into mature, multinucleated and bone resorbing OCs *in vitro*, without adding exogenous pro-osteoclastogenic factors, such as TNF- α and RANKL, which instead are released by T cells. Cell cultures of PBMCs derived from cancer patients without bone metastasis, and depleted of T cells, do not differentiate into OCs without adding macrophage colony stimulating factor and RANKL^[65,66], confirming that T cells regulate osteoclastogenesis and play an important role in the cancer cycle of bone destruction.

Recently, it has been demonstrated that T cells are additional regulators of bone tumor growth. In particular, their activation diminishes bone metastases, whereas their depletion enhances them, even in the presence of zoledronic acid^[68]. Indeed, some patients treated with anti-resorptive therapies develop further skeletal metastases, suggesting that T cells modulate bone tumor growth. Zoledronic acid can activate cytotoxic γ/δ -T cells and inhibit populations of myeloid-derived cells with T-cell-suppressor capabilities^[69]. The anti-bone metastatic therapy based on the blockade of TGF- β at metastatic sites may locally activate an anti-tumor T cell response, because normally TGF- β , released in bone marrow by OC activity, inhibits T cell proliferation^[70]. Tumor cell-derived IL-6, IL-1 and TGF- β can drive T-cell differentiation towards a Th17 secretory helper-cell phenotype able to induce RANKL production by OB and OC activation through IL-17 production^[71]. All these data demonstrate the fundamental role of immune system cells in the control of bone metastatic disease.

SERUM MARKERS FOR EARLY DETECTION OF LUNG CANCER BONE METASTASES

The delayed demonstration of skeletal involvement may seriously affect survival, thus an early diagnosis of bone metastases is necessary. The early detection of asymptomatic bone disease due to lung cancer can be obtained through positron-emission tomography scans^[72], but European guidelines recommend a bone scan only in the presence of bone pain^[3], thus other systems for an early diagnosis are required. The sensitivity of common serum tumor markers is low, and they are used mainly for monitoring the efficacy of therapy and detection of

recurrence. The use of serological markers is desirable, but unfortunately, the identification of potentially useful and specific biomarkers is difficult. According to data in the literature, serum markers of bone turnover may be able to determine the time to tumor progression, the metastatic potential, and the overall survival of NSCLC patients. Furthermore, they may contribute to a more accurate follow-up and tailored treatment options^[73,74]. In particular, there is a statistically significant relationship between levels of biochemical markers of bone metabolism and clinical outcome: both N-telopeptide and bone-specific alkaline phosphatase levels were highly predictive of SRE recurrence, the time to a first SRE, and the occurrence of disease progression and death^[7,75]. Also, the carboxy-terminal telopeptide of type I collagen and amino-terminal propeptide of type I collagen measurement can be useful in monitoring patients with NSCLC during follow-up, with the aim of detecting bone metastases early^[76].

Among the molecules potentially involved in the pathogenesis of bone metastases from lung cancer, there is IL-7, which has been studied as serum marker for monitoring bone metastasis development in NSCLC patients. Indeed, IL-7 is an important regulator of the interaction between bone and immune system, and it has a role in bone homeostasis, in particular in bone loss in estrogen-deficient conditions^[77,78], psoriatic arthritis^[79] and periodontitis^[80]. Other studies support an active role of IL-7 in promoting bone lesions from solid tumors^[81,82] and multiple myeloma^[83]. In culture of PBMCs derived from patients with bone metastases due to lung cancer and other solid tumors, IL-7 was mainly released by B cells, and it directly sensitized T cells to produce pro-osteoclastogenic factors, such as tumor necrosis factor- α and RANKL, which enhanced osteoclastogenesis^[82,83]. Moreover, in lung cancer patients with bone metastases, IL-7 serum levels were found to be significantly higher than in non-bone metastatic patients and in healthy controls^[84]. This increase in serum IL-7 directly depends on tumor production, and indeed strong IL-7 expression was detected in human tumor masses in a mouse model of bone metastases and in human bone metastatic biopsies^[85]. Further studies on a large cohort of patients needs to be performed, but IL-7 could be very useful to monitor the progression and early development of lung cancer bone disease.

CONCLUSION

The current literature reports the existence of an important interaction among lung tumor cells, the bone micro-environment and immune system cells. Many factors are involved in this cross-talk, which may lead to the discovery of new biomarkers useful for early detection of lung cancer bone metastases.

Abstract

AIM: To examine the expression of downstream of tyrosine kinase (DOK)1-6 genes in normal and breast cancer tissue and correlated this with several clinico-pathological and prognostic factors.

METHODS: DOK1-6 mRNA extraction and reverse transcription were performed on fresh frozen breast cancer tissue samples ($n = 112$) and normal background breast tissue ($n = 31$). Tissues were collected between 1991 and 1996 at two centres and all patients underwent mastectomy and ipsilateral axillary node dissection. All tissues were randomly numbered and the details were only made known after all analyses were completed. Transcript levels of expression were determined using real-time polymerase chain reaction and analyzed against TNM stage, tumour grade and clinical outcome over a 10-year follow-up period.

RESULTS: DOK-2 and DOK-6 expression decreased with increasing TNM stage. DOK-6 expression decreased with increasing Nottingham Prognostic Index (NPI) [NPI-1 vs NPI-3 (mean copy number 15.4 vs 0.22, 95%CI: 2.7-27.6, $P = 0.018$) and NPI-2 vs NPI-3 (mean copy number 7.6 vs 0.22, 95%CI: 0.1-14.6, $P = 0.048$)]. After a median follow up period of 10 years, higher

levels of DOK-2 expression were found among patients who remained disease-free compared to those who developed local or distant recurrence (mean copy number 3.94 vs 0.0000096, 95%CI: 1.0-6.85, $P = 0.0091$), and distant recurrence (mean copy number 3.94 vs 0.0025, 95%CI: 1.0-6.84, $P = 0.0092$). Patients who remained disease-free had higher levels of DOK-6 expression compared to those who died from breast cancer.

CONCLUSION: Decreasing expression levels of DOK-2 and DOK-6 with increased breast tumour progression supports the notion that DOK-2 and DOK-6 behave as tumour suppressors in human breast cancer.

Key words: Adaptor protein; Breast cancer; Downstream of tyrosine kinase-2; Downstream of tyrosine kinase-6; Mitogen-activated protein kinase; Tyrosine kinase, Tumour suppressor

Core tip: Several members of the downstream of tyrosine kinase (DOK) protein family are identified as modulators of cell proliferation/growth pathways. In addition deregulation of specific DOK members has been associated with specific cancers. This study identifies DOK-2 and DOK-6 as potential tumor suppressors in breast cancer.

INTRODUCTION

Downstream of tyrosine kinase (DOK) family of adaptor proteins consists of 7 members (DOK1-7) that share a structural topology characterized by an NH2-terminal

pleckstrin homology domain, a central phosphotyrosine-binding domain, followed by SH₂ target motifs in the carboxyl-terminal moiety^[1-9]. They act as common substrates for multiple protein-tyrosine kinases (PTK's), including receptor tyrosine kinases (RTK's) and non-RTK's from which they modulate signalling pathways involved in various natural cellular processes including proliferation, apoptosis, growth and migration^[3,5-8,10-17]. Additionally, PTK signalling has been implicated in the development and progression of various cancers, including breast cancer^[18-22].

Principally based on patterns of expression, two sub-groups exist within the DOK family. DOK-1, DOK-2 and DOK-3 comprise one sub-group primarily expressed in haematopoietic tissues^[7,9,11,23-28], whereas, DOK-4, DOK-5 and DOK-6 are expressed in non-haematopoietic tissues, predominantly within the nervous system^[2-4,29-33]. Separately, expression of DOK-7 is concentrated to skeletal muscle and the heart^[34,35]. DOK-1(p62) was initially identified as a substrate for the Bcr-Abl tyrosine kinase oncoprotein in chronic myelogenous leukaemia (CML)^[7,9]. Consequently, DOK-1 knockdown in murine bone marrow-derived mast cells resulted in increased cell proliferation following mitogenic stimulus^[23]. It was discovered that DOK-1 opposes leukemogenesis by Bcr-Abl through inhibition of the mitogen-activated protein kinase (MAPK) pathway^[7,9,10,12,23].

DOK-1, DOK-2 and DOK-3 have all been found to negatively regulate immunoreceptor signalling^[6,7]. It was initially posited, DOK-1 and DOK-2 both inhibit the Ras/ERK pathway through interaction with RasGAP^[6,7]. Conversely, DOK-3 is understood to inhibit c-Jun N-terminal kinase activation by interacting with SHIP-1 and Grb2^[5,36]. However, evidence exists that DOK-1 and DOK-2 can inhibit the MAPK pathway independent of RasGAP *via* epidermal growth factor receptor (EGFR) signalling^[18,37,38]. DOK-2 can facilitate the successive recruitment of c-Src and its inhibitor Csk to EGFR, inhibiting MAPK^[38]. Individual and concomitant up-regulation of EGFR and c-Src is associated with breast cancer progression. Tyrosine-kinase inhibitors targeted against EGFR are currently in use for breast cancer treatment whilst several against c-Src are being trialled^[20,39-41]. Since DOK-1 association with CML, down-regulation of the DOK-1, DOK-2 and DOK-3 sub-group has been linked with several other haematopoietic cancers, including histiocytic sarcoma and Burkitt's lymphoma^[6,7,9,24-26]. Investigation into non-haematopoietic tissues identified lung adenocarcinoma development in DOK-1, DOK-2 and DOK-3 knockout mice and down regulation of DOK-2 expression in human lung cancer^[1]. Additional non-haematopoietic cancers have since been associated with the DOK-1, DOK-2 and DOK-3 sub-group^[42,43]. In particular, DOK-2 has recently been proposed as a potential marker of poor prognosis in patients with gastric cancer after curative resection^[43].

The other sub-group of the DOK family, consisting of DOK-4, DOK-5 and DOK-6, are positive regulators of the MAPK pathway and promote neurite out-

growth^[3,4,29,32,44]. DOK-4 and DOK-6 are phosphorylated by the tyrosine kinase encoded by the proto-oncogene RET (rearranged by transfection)^[3,31,32,44]. Over expression of RET is primarily observed in oestrogen-receptor-positive (ER+) breast cancers where, in models, it is seen to cause increased cell migration and proliferation. In addition, studies have observed RET expression to correlate with poor prognosis of metastasis-free and overall survival in breast cancer patients^[18,21,45,46]. Conflictingly, DOK-4 has also been found to inhibit Ret-mediated activation of Elk-1, a member of the ETS oncogene family. Elk-1 is a transcription activator associated with cell survival in breast cancer and has previously been implicated as a potential therapeutic target^[18,21,45,46]. Aberrant expression of DOK-4 has been witnessed in non-small cell lung cancer and clear cell renal cell carcinoma^[29,30]. Increased expression of DOK-5 is observed in malignant pheochromocytoma and has been suggested to promote cell survival *via* tropomyosin-receptor-kinase (Trk)C receptor signalling, of which DOK-6 is also a substrate^[33,47]. Jin *et al.*^[48] identified TrkC as a critical regulator of breast cancer cell growth and metastasis. It has been established that DOK-7 plays a relatively unrelated role to the rest of the DOK-family in which it promotes acetylcholine receptor clustering on post-synaptic membranes at neuromuscular junctions *via* activating muscle-specific kinase^[34,35].

In view of DOK proteins adaptor role in tyrosine kinase signalling pathways regulating cell growth and proliferation and their altered levels of expression in other cancers, we have examined the expression profile of DOK1-6 in a cohort of archival normal and breast cancer specimens. Transcript levels were evaluated against established pathological and prognostic parameters in addition to clinical outcome.

MATERIALS AND METHODS

Patients and samples

Institutional guidelines, including ethical approval and informed consent were followed. Primary breast cancer tissues ($n = 112$) and adjacent non-cancerous mammary tissue ($n = 31$) were collected immediately after surgical excision and stored at -80°C until use. Tissues were collected between 1991 and 1996 at two centres (St Georges Hospital in London and University Department of Surgery at Cardiff University School of Medicine). All patients underwent mastectomy and ipsilateral axillary node dissection. All tissues were randomly numbered and the details were only made known after all analyses were completed. Follow-up data were recorded in a custom database. Patients were routinely followed up after surgery (June 2004 was the final comprehensive follow up for the cohort). An independent specialist pathologist examined haematoxylin and eosin stained frozen sections to verify the presence of tumour cells in the collected samples. Where normal non-neoplastic tissues were used, no tumour cells were found in the sections.

All patients were treated according to local algorithms

of management following a multidisciplinary discussion. Patients treated with breast-conserving surgery received adjuvant radiotherapy. Those with hormone-sensitive malignancy received tamoxifen. Fit patients with node-positive breast cancer or hormone-insensitive large and/or high-grade cancer were offered adjuvant chemotherapy. Medical notes and histology reports were used to extract clinico-pathological data (Table 1)^[49].

Materials

RNA extraction kits and reverse transcription kits were obtained from Sigma-Aldrich Ltd (Poole, Dorset, England, United Kingdom). The polymerase chain reaction (PCR) primers were designed using Beacon Designer (Palo Alto, CA, United States) and synthesized by Sigma-Aldrich. Custom made hot-start Master mix for quantitative PCR was obtained from Abgene (Surrey, England, United Kingdom)^[49-51].

Tissue processing, RNA extraction and cDNA synthesis

Frozen sections of tissue were cut at a thickness of 5-10 µm and kept for routine histological analysis. Additional 15-20 sections were mixed and homogenized using a hand-held homogenizer in ice-cold RNA extraction solution. The concentration of RNA was determined using UV spectrophotometry. Reverse transcription was carried out using a reverse transcription kit with an anchored oligo (dT) primer supplied by Abgene, using 1 µg of total RNA in a 96-well plate. The quality of cDNA was verified using Cytokeratin 19 (CK19) primers (Table 2)^[49].

Quantitative analysis

pared DNA were determined using real-time quantitative PCR based on the Amplifluor technology, modified from a method reported previously^[49,52]. The PCR primers were designed using Beacon Designer software, but to the reverse primer an additional sequence, known as the Z sequence (5'-ACTGAACCTGACCGTACA-3') which is complementary to the universal Z probe (Intergen Inc., Oxford, United Kingdom) was added. The product expands one intron. The primers used are detailed in Table 2. The reaction was carried out using Hotstart Q-master mix (Abgene), 10 pmol of specific forward primer, 1 pmol reverse primer which had the Z sequence, 10 pmol of FAM (fluorogenic reporter dye, carboxyfluorescein) tagged probe (Intergen Inc.), and cDNA from 50 ng of RNA. The reaction was carried out using the IcylerIQ (Bio-Rad Ltd, Hemel Hempstead, England, United Kingdom), which is equipped with an optic unit that allows real-time detection of 96 reactions, under the following conditions: 94 °C for 12 min and 50 cycles of 94 °C for 15 s, 55 °C for 40 s, and 72 °C for 20 s. The levels of the transcript were generated from a standard that was simultaneously amplified with the samples. The levels of gene expression were then normalized against the reference gene *CK19*, which was already quantified in these specimens, to correct for varying amounts of epithelial tissue between samples^[53]. The primers used for CK19 are detailed in Table 2. With every PCR run, a negative control without a template and a known cDNA reference sample as a positive control, were included.

Statistical analysis

The two-sample *t* test was used for statistical analysis of absolute and normalised gene copy number. The transcript levels within the breast cancer specimens were compared to normal background tissues and analyzed against conventional pathological parameters and clinical outcome over a 10 year follow-up period. The statistical analysis was carried out using Minitab version 14.1 (Minitab Ltd. Coventry, England, United Kingdom) using a custom written macro (Stat 2005.mtw).

DOK: Downstream of tyrosine kinase; NPI: Nottingham Prognostic Index; DF: Disease Free; LR: Local Recurrence; DR: Distant Recurrence.

RESULTS

DOKs1 - 6 mRNA expression by quantitative PCR

The DOKs1-6 expression profiles were determined both in absolute terms and normalised against CK19.

DOK-1: DOK-1 (Table 3) was found to be expressed in both normal/benign breast tissue and breast cancer specimens. No significant difference was found between DOK-1 expression in breast cancer specimens and its expression in normal background tissue. The expression of DOK-1 mRNA did not significantly differ with increasing Nottingham Prognostic Index (NPI) or between normal background breast tissue and tumour tissues of patients with different NPI levels. No significant difference in the transcript levels observed with different tumour grades or TNM classes. After a median follow up of 10 years, we found DOK-1 mRNA expression levels did not differ among women who remained disease free compared to those who developed recurrence (local or distant) and compared to those who died from breast cancer.

DOK-2: DOK-2 (Table 3) was found to be expressed in both normal/benign breast tissue and breast cancer specimens. No significant difference was found between DOK-2 expression in breast cancer specimens and its expression in normal background tissue. No significant difference in the transcript levels observed with different tumour grades and the decrease in DOK-2 with increasing NPI was not significant. The expression of DOK-2 mRNA was demonstrated to significantly decrease with increasing TNM stage; TNM-1 vs TNM-3 (mean copy number 6.6 vs 0.0056, 95%CI: 1.4-11.8, $P = 0.015$), and TNM-1 vs TNM-4 (mean copy number 6.6 vs 0.0000072, 95%CI: 1.4-11.8, $P = 0.015$). After a median follow up

of 10 years DOK-2 expression was significantly higher among those who remained disease free compared to those who developed local (mean copy number 3.94 vs 0.0000096, 95%CI: 1.0-6.85, $P = 0.0091$), and distant recurrence (mean copy number 3.94 vs 0.0025, 95%CI: 1.0-6.84, $P = 0.0092$).

DOK-3: There was neither significant difference in DOK-3 (Table 3) mRNA expression levels between cancer tissue and normal background tissue nor there was a significant difference in the transcript levels with different tumour grades or NPI.

DOK-3 mRNA expression was found to significantly decrease with increasing tumour TNM stage: TNM-1 vs TNM-4 (mean copy number 27175 vs 83.2, 95%CI: 41-52143, $P = 0.05$); and TNM-2 vs TNM-4 (mean copy number 4508 vs 83.2, 95%CI: 956-7894, $P = 0.014$).

DOK-4: DOK-4 (Table 4) was found to be expressed in both normal/benign breast tissue and breast cancer specimens. No significant difference was found between DOK-4 expression in normal background tissue and its expression in breast cancer tissue. The expression of DOK-4 mRNA did not significantly differ with increasing NPI or between normal background breast tissue, tumour tissues of patients with different NPI levels and tumour grade. After a median follow up of 10 years, we found DOK-4 mRNA expression levels to be higher among women who remained disease free compared to those who developed local recurrence (mean copy number 328 vs 2.22, 95%CI: 19-631.4, $P = 0.038$). No significant difference in expression levels were found between patients who remained disease free and those that developed distant recurrence or died from breast cancer.

DOK-5: There was neither significant difference in

DOK: Downstream of tyrosine kinase; NPI: Nottingham Prognostic Index; DF: Disease Free; LR: Local Recurrence; DR: Distant Recurrence.

DOK-5 (Table 4) mRNA expression levels between cancer tissue and normal background tissue nor there was a significant difference in the transcript levels with different tumour grades or TNM classes. The expression of DOK-5 mRNA did not significantly differ with increasing NPI and after a median follow up of 10 years, no significant difference in expression was observed between survival statuses.

DOK-6: DOK-6 (Table 4) was found to be expressed in both normal/benign breast tissue and breast cancer specimens. No significant difference was found between DOK-6 expression in normal background tissue and its expression in breast cancer tissue. The expression of DOK-6 mRNA was found to decrease with increasing NPI; NPI-1 *vs* NPI-3 (mean copy number 15.4 *vs* 0.22, 95%CI: 2.7-27.6, $P = 0.018$) and NPI-2 *vs* NPI-3 (mean copy number 7.6 *vs* 0.22, 95%CI: 0.1-14.6, $P = 0.048$), but there was no significant decrease with higher tumour grade. The expression of DOK-6 mRNA was demonstrated to significantly decrease with increasing TNM stage; TNM-1 *vs* TNM-4 (mean copy number 10.3 *vs* 0.073, 95%CI: 0.1-20.3, $P = 0.048$), and TNM-2 *vs* TNM-4 (mean copy number 13.7 *vs* 0.073, 95%CI: 0.2-27.04, $P = 0.047$). After a median follow up of 10 years, patients who died from breast cancer had significantly lower DOK-6 expression compared those whom remained disease free (mean copy number 11.4 *vs* 0.21, 95%CI: 2.5-19.9, $P = 0.013$).

DISCUSSION

Here we analyze the mRNA expression profiles of the DOK1-6 family members in breast cancer specimens and identify decreased expression of individual members with

increasing clinical and pathological stage.

The results show a decreased DOK-2 expression with increasing TNM stage. Down regulation of DOK-2 has previously been documented in several human epithelial cancers including lung, colorectal and gastric cancer^[1,24,42,43]. Additionally, we have found higher DOK-2 levels to correlate a significantly lower chance of both local and distant recurrence within the 10-year period following surgical resection. Similarly, a recent study also found higher DOK-2 expression to be a good indicator of non-recurrence in gastric cancer patients following resection^[43]. The prediction of recurrence and metastasis after curative resection can determine the need for intensive follow-up and adjuvant therapy.

In addition to this the *DOK2* gene is localized to chromosome 8p21.3, one of the most frequently deleted regions in human lung cancer and a region hypothesized to contain multiple tumour suppressor genes^[54,55]. DOK-2 has previously been thought to associate with cancer progression *via* its regulatory role of the MAPK pathway. Initially, DOK-2 was found to inhibit the MAPK pathway through interaction with the Ras inhibitor RasGAP^[12,23]. Further studies identified a RasGAP-independent route of MAPK inhibition with DOK-2 shuttling c-Src to the EGFR where, after transient activation of c-Src, a phosphorylated DOK-2 recruits the negative regulator of c-Src, Csk. Both EGFR and c-Src are up-regulated in a large percentage of human breast tumours supporting a potential tumour suppressor role of DOK-2 in breast cancer^[38].

Furthermore, our results display decreased DOK-6 expression with increased TNM stage as well as NPI, suggesting DOK-6 could hold prognostic value. Interestingly, significantly higher levels of DOK-6 expression were found in specimens of patients that remained dis-

ease free compared to those that died of breast cancer within the following 10-year period. Together these results highlight DOK-6 as potentially possessing tumour suppressor function. In comparison to other family members, less research has been undertaken into DOK-6 function and to our knowledge it has not previously been directly associated with any human cancer, *in vivo*^[3,32]. DOK-6 has been suggested to play a role in neurite outgrowth *via* both Ret and TrkC signalling^[3,32]. However, it has been indicated that DOK-6 is involved in Ret signalling with less influence when compared with DOK-1 and DOK-4^[32]. The exact function of DOK-6 in TrkC signalling has of yet to be established, although knockdown of DOK-6 has been observed to decrease neurite outgrowth in cortical neurons upon NT-3 stimulation^[33]. TrkC has recently been proposed to act as a critical regulator of breast cancer cell growth and metastasis. Interaction between TrkC and c-Src was found to activate MAPK cascade *in vivo* in human breast cancer tissues^[21,38,48,56,57]. It is worth noting that despite DOK-5 also regulating MAPK activity *via* TrkC interaction, unlike DOK-6, we observe no difference in its expression^[47].

DOK-2 and DOK-6 are members of different subgroups within the DOK adaptor protein family and although each is a substrate of multiple tyrosine kinases, current literature places their natural functions and interactions relatively distinct from one another. Our results, however, indicate that they both function within breast tumour cells and loss of their expression is associated with tumour progression. The two DOK proteins may regulate independent pathways or could potentially function together in an as yet undefined pathway.

Goel *et al.*^[58] have recently published qualitative data of a lucid differential pattern of DOK-1 expression in 8 breast cancer cell lines compared to a non-tumourigenic breast epithelial-derived cell line. We believe our study to be the first that has quantitatively measured DOK-1 expression in human breast cancer specimens. No significant difference was observed between normal/background tissue and breast cancer tissue. Using histologically normal appearing samples as the sole control tissue is probably less appropriate. The use of donor tissues from reduction mammoplasty specimens (ideally obtained under similar conditions as the tumour tissue) will serve as a better control. Donor control, in addition to normal adjacent to tumours, precancerous lesions, and tumour samples will provide the best sample set for resolution of genetic alterations that are relevant to the disease process by minimizing the potential implications of field cancerisation. As there was no normal donor tissue used in this study, it was not clear whether the absence of a difference in DOK family expression between tumour and matched normal background tissue in our cohort was due to the effect of field cancerisation.

To our knowledge, this study is the first to analyze the mRNA expression of the DOK family members 1-6 in breast cancer specimens. Our data support the notion that DOK-2 behave as a tumour suppressor. For

the first time we also provide novel data predicting a role of DOK-6 as a potential tumour suppressor in breast cancer. Nevertheless, our understanding of the molecular mechanisms involved, across all DOK members, in their adaptor function to multiple tyrosine kinases requires further study. Our data could be used in further validation studies in order to define clear mechanisms attributing to the development and progression of breast cancer and develop new prognostic markers and novel therapeutic strategies.

COMMENTS

Background

Identification of molecular biomarkers has shown great promise in the identification of metastatic risk and survival rate in breast cancer as well as requirement for adjuvant therapies. The downstream of tyrosine kinase (DOK) family of adaptor proteins have previously been associated with the progression of other cancers including other human epithelial cancers.

Research frontiers

Several members of the DOK protein family are identified as modulators of cell proliferation/growth pathways. In addition deregulation of specific DOK members have been associated with specific cancers. This study identifies DOK-2 and DOK-6 as a potential tumor suppression in breast cancer.

Innovations and breakthroughs

The identification of molecular biomarkers and their subsequent use to determine risk of recurrence and prognosis in breast cancer has begun to make real clinical impact. This is the first study correlate expression of several DOK family members with clinical and pathological parameters of breast cancer and identify DOK-2 and DOK-6 as having potential tumour suppressor function as well as hold prognostic value.

Applications

Further understanding and identification of members of pathways through which breast cancer can progress is essential in the development of effective therapeutic strategies. In addition, the potential prognostic value of DOK-2 and DOK-6 may determine need for post-curative therapies.

Peer review

This work tackles a novel and interesting issue: the expression profile of DOK proteins in breast cancer. The importance of this study lies in that by first time it is suggested a role of DOK proteins as tumour suppressors in breast cancer.

RESULTS: The overall costs of cancer drugs increased gradually between 2004 and 2008 (from €1911947 to €3666284), with an increase in the number of patients treated during this period. The expenditure decreased in 2009 (€3438155) and increased again in 2010 (€3673116), but the costs increment was not the same as in previous years. Chemotherapy and targeted therapy were responsible for most of the expenditure. Drugs placed on the national market before 1999 accounted for more than 50% of the expenditure up to 2007. From 2008, these drugs represented less than 50% of the total expenditure. Cancer drugs placed between 1999 and 2002 accounted for 25%-35% of the costs in all the years studied, while drugs placed between 2003 and 2005 accounted for less than 30%. Drugs placed between 2006 and 2010 were responsible for less than 10% of the expenditure.

CONCLUSION: In this study, older drugs were responsible for most of the expenditure up to 2007, which is in agreement with the Karolinska study.

Abstract

AIM: To analyze the costs of cancer drugs administered in a Portuguese Hospital compared with the Karolinska Institute study.

METHODS: To evaluate spending on cancer drugs, we retrospectively analyzed data on the overall costs of cancer drugs, obtained at the Department of Medical Oncology of the Centro Hospitalar de Entre Douro e Vouga, between 2004 and 2010. In this comparative study we selected only drugs belonging to the following groups: chemotherapy, targeted therapy, immunotherapy and endocrine therapy. The selected drugs were further grouped according to their market placement year: ≤ 1998, 1999 to 2002, 2003 to 2005, and 2006 to 2010. Drugs used as supportive therapy and bisphosphonates were excluded.

Core tip: In the last decade costs related to cancer drugs have increased significantly. This growth seems to be explained by the increase in cancer incidence, new indications for treatment with previously approved cancer drugs and to placement of new drugs on the market, which are frequently more expensive than those already on sale. The results of the Karolinska Institute study demonstrated a substantial increase in available cancer drugs and costs between 1998 and 2007. The cost increment was not only related to the introduction of new drugs, but 68% of the costs in 2007 were due to drugs approved before 1999.

INTRODUCTION

In Portugal, the number of inhabitants and the average life expectancy at birth have increased in the last century^[1,2]. The most recent data revealed that the average life expectancy in Portugal is 80.8 years, similar to the European average^[3]. This increase reflects improvements in the population's socioeconomic conditions and in the resources dedicated to health care^[1,4,5].

In the aging population, among other aspects, an increase in the incidence in chronic and incurable diseases has been observed^[4,6,7]. Of these diseases, the incidence of cancer dominates^[4,6,7]. Cancer incidence has increased over the last decades and in 2008 there was an estimated 12.7 million new cancer cases worldwide^[4,6,7]. In Portugal, the cancer incidence rate standardized by age is 428:100000 in men and 289:100000 in women^[1]. Globally, cancer is the second most common cause of death after cardiovascular diseases^[1,8]. In recent years, there has been a slight decrease in the mortality rate related to cancer^[1,4,6-8]. However, this rate is still high^[1,3-5]. In 2008, 7.6 million cancer deaths occurred worldwide^[7].

The burden of cancer to society can be measured by direct and indirect costs^[4,6,9,10]. Direct costs are related to prevention and treatment, while indirect costs include loss of production due to inability to work caused by disease, disability and death^[4,6,9,10]. Drugs are one of the most investigated components of Oncology, consuming most of its economic resources^[4,8,11]. In the past few years, direct costs related to cancer treatment have increased significantly^[4,12-15]. This increment in costs can be explained by the increase in cancer incidence, new indications for treatment with previously approved cancer drugs and to placement of new drugs on the market, which are frequently more expensive those already on sale^[4,12,16-19]. Despite the continuous growth in expenditure due to cancer drugs, this growth is not expected to be the same as in the last decade^[4].

According to the Karolinska Institute study, in 2007 the cost increment was not only related to the introduction of new drugs, but 68% of the costs were due to drugs approved before 1999 in Europe^[4]. The increased cost of these drugs, from €4.3 to €26.3 per capita, was the major cause of the rise in costs related to cancer drugs^[4]. In this study, cancer drugs (chemotherapy, targeted therapy, endocrine therapy and immunotherapy) were grouped according to their market placement year: ≤ 1998; 1999 to 2002; 2003 to 2005; 2006 to 2007. Supportive drug treatments were excluded^[4].

In Portugal, the growth in public spending on cancer drugs has been the subject of great debate^[1,9]. However, data related to cancer treatment, particularly the direct

costs of drug treatments are scarce^[9]. For this reason, we conducted the current study to better understand the costs involved in cancer drug therapies in Portugal.

The aims of the current study were the analysis the cost evolution of cancer drugs from data collected from 2004 to 2010 at the Department of Medical Oncology of the Centro Hospitalar de Entre Douro e Vouga. An analysis of costs according to the type of drug and the date of its placement on the national market was also performed and compared with the results obtained in the Karolinska Institute study.

MATERIALS AND METHODS

Study design

After obtaining the necessary authorization from our Administration Board, we conducted a retrospective observational study to analyze the evolution of costs of cancer drugs from 2004 to 2010 in the Department of Medical Oncology of the Centro Hospitalar de Entre Douro e Vouga. The first year studied was 2004 because there was difficulty in obtaining data relating to previous years, and the last year studied was 2010 as data collection was conducted in 2011.

The Centro Hospitalar de Entre Douro e Vouga, Portugal, is a medium-sized hospital, established in 1999, with 409 beds and is responsible for the health care of 350000 inhabitants. Until 2010, the Department of Medical Oncology treated solid (unless sarcomas, melanomas and tumors of the central nervous system) and hematologic malignancies, mostly in outpatient settings. Thereafter, the Department only treats solid malignancies.

Patients and drug selection

The patients selected were treated in the Department of Medical Oncology from 2004 to 2010. Due to incomplete records on the number of patients treated by the various types of treatment in the first four years analyzed, it was not possible to calculate the average cost per patient and the cost per type of treatment.

According to data provided by the Pharmacy Department, we selected all the cancer drugs used during the study period in both inpatients and outpatients, and divided this by the type of drug: chemotherapy (cytostatics), targeted therapy (monoclonal antibodies, tyrosine kinase inhibitors, mammalian target of rapamycin inhibitors), immunotherapy and endocrine therapy. To analyze the costs, we considered the absolute global cost (purchasing cost to the hospital) for each drug, which was provided by the Pharmacy Department.

To compare our results with the Karolinska Institute study, drugs used in the Department of Medical Oncology were grouped according to their market placement year: ≤ 1998; 1999 to 2002; 2003 to 2005; 2006 to 2010. To access dates of placement on the national market, we consulted the Portuguese National Authority for Medication and Healthcare Products database. As supportive drugs were not analyzed in the Karolinska study, these drugs were excluded in the present study. Other drug

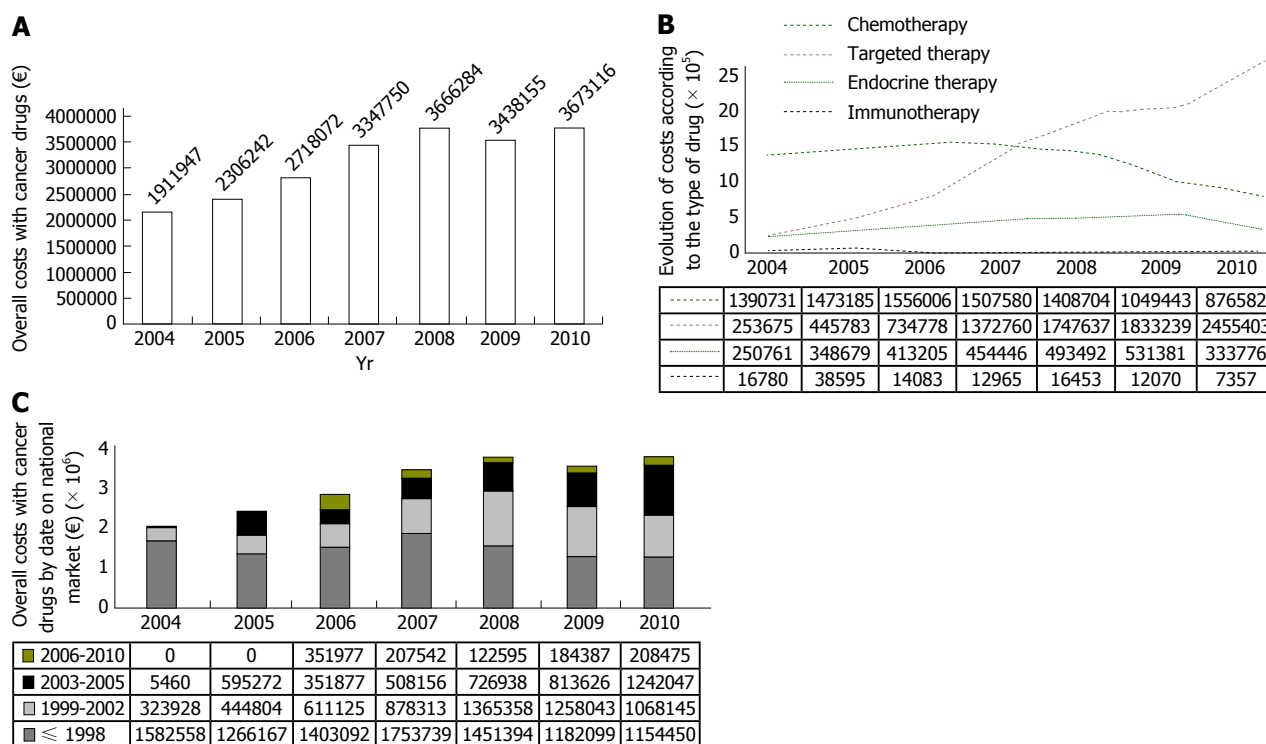

Figure 1 Evolution of global costs of cancer drugs. A: Evolution of global costs of cancer drugs used at the Department of Medical Oncology of Centro Hospitalar de Entre Douro e Vouga; B: Evolution of costs by type of drug administered at the Department of Medical Oncology of Centro Hospitalar de Entre Douro e Vouga; C: Evolution of costs of cancer drugs used at the Department of Medical Oncology of Centro Hospitalar de Entre Douro e Vouga, according to their market placement year.

costs not used in cancer treatment were also excluded.

RESULTS

From 2004 and 2010 there was a gradual increase in the number of patients treated in the Department of Medical Oncology (924 patients in year 2004, 1111 in year 2005, 1222 in 2006, 1376 in 2007, 1550 in 2008, 1589 in 2009 and 1560 patients in year 2010). According to data provided by the Pharmacy Department and specifically for the period under analysis, this increase was followed by an increment in the overall costs of cancer drugs up to 2008 (Figure 1A). In 2009, the global expenditure decreased, and in 2010 there was an increase in expenditure to values similar to those in 2008 (Figure 1A).

The evolution of costs, according to the type of drug, is presented in Figure 1B. Chemotherapy and targeted therapy accounted for most of the expenditure, followed by endocrine therapy. The drugs studied according to the year of placement on the national market are described in Table 1.

The global distribution of the drugs used by the Department, according to placement on the national market, is shown in Figure 1C.

Drugs placed on the national market before 1999 accounted for more than 50% of the expenditure on drugs up to 2007 (in 2004 these accounted for 83%; in 2005 for 55%; in 2006 and 2007 for 52% of the expenditure, respectively). After 2008, these drugs represented less than 50% of the total expenditure, and in the last two years

of the study expenditure overlapped in drugs placed between 2003 and 2005 (in 2008 these represented 40%; in 2009 34% and in 2010 31% of the costs). Drugs placed between 1999 and 2002 accounted for 25%-35% of the expenditure on drugs in each year analyzed. When the drugs placed between 2003 and 2005 were analyzed, there was a progressive increase in the costs (in 2004 these accounted for 0.3% of the expenditure; in 2005 for 26%; in 2006 for 13%; in 2007 for 15%; in 2008 for 20%; in 2009 for 24% and in 2010 for 34%). The most recent drugs (from 2006 to 2010) accounted for less than 10% of the expenditure, with higher spending in 2006 and increased expenditure again after 2008.

Expenditure on chemotherapy, targeted therapy and endocrine therapy according to the date of placement on the national market is shown in Figure 2, respectively. The expenditure on immunotherapy is not represented here as it was found to have the lowest cost.

With regard to the expenditure on chemotherapy (Figures 1B and 2A), the costs of cytostatics decreased after 2006 and these drugs were no longer responsible for the main costs related to cancer treatment after 2007. The drugs placed on the market before 1999 accounted for the largest expenditure in all the years analyzed, while drugs placed between 1999 and 2002 accounted for less than 25% of the expenditure. The drugs placed between 2003 and 2005 accounted for about 20% of costs, showing a progressive decrease. More recent cytostatics accounted for less than 10% of the expenditure.

The expenditure for targeted therapy increased over

Figure 2 Evolution of costs associated with therapy. A: Evolution of costs associated with chemotherapy treatment at the Department of Medical Oncology of Centro Hospitalar de Entre Douro e Vouga according to the market placement year; B: Evolution of costs associated with targeted therapy at the Department of Medical Oncology of Centro Hospitalar de Entre Douro e Vouga according to the market placement year; C: Evolution of costs associated with endocrine therapy at the Department of Medical Oncology of Centro Hospitalar de Entre Douro e Vouga according to the market placement year.

the years, and was responsible for most costs after 2007 (Figures 1B and 2B). Drugs placed on the market be-

tween 1999 and 2002 cost most in each year studied, except in 2010 where most of the expenditure was on

more recent drugs (placed between 2003 and 2005). When analyzing the drugs placed before 1999, there was an increase in expenditure due to these drugs up to 2006, after which a decrease in costs was observed, with a new increment in the last year studied. The cost of drugs placed between 2003 and 2005 increased gradually during the study period. The most recent drugs (placed between 2006 and 2010) used in cancer treatment cost least and this cost remained stable.

When analyzing the expenditure on drugs for endocrine therapy (Figure 2C), it was observed that drugs placed before 1999 represented the biggest share of the expenditure. Drugs placed between 1999 and 2002 accounted for 25% to 33% of the expenditure in each year and drugs placed between 2003 and 2005 showed a progressive increase in costs, and was more prominent in 2010.

DISCUSSION

Oncology has registered important progress in available treatments, especially cancer drugs, resulting in a significant improvement in healthcare in recent years, both in terms of overall survival and quality of care^[20-24].

In Europe, between 1998 and 2007, there was an important increase in direct costs related to cancer drugs^[4,16,25]. The primary reasons for this were new indications for already approved drugs and the introduction of new drugs which cost significantly more than most of the older cancer drugs^[4,6,7]. According to the Karolinska study, the increase in costs was mainly due to the growth in sales of drugs already on the market^[4]. In 2007, drugs placed on the market before 1999 accounted for 68% of the total costs of drugs for cancer; drugs placed between 1999 and 2002 accounted for 17%; drugs placed between 2003 and 2005 accounted for 11%; and drugs placed between 2006 and 2007 accounted for 3%^[4].

In our study, chemotherapy was mainly responsible for the costs of cancer drugs up to 2007, after which targeted therapy was responsible for most of the expenditure. In this work, we observed an increase in global costs between 2004 and 2008. Explanations for this increment may be related to the increased number of patients treated, to more drug administration cycles per patient (data not shown) in part due to better overall survival, and to the placement of new drugs on the market, which are frequently more expensive than those already on sale. The expenditure decreased in 2009 and increased again in 2010, but the costs increment was not the same as in previous years. Possible reasons for the cost stability over the last 3 years of the study may be at the local level. The Department of Medical Oncology has adopted certain strategies which may explain this cost stability, such as the acquisition of drugs in smaller doses, a study of cytostatics stability to determine the time allowed to administer a drug after its reconstitution, implementation of treatment guidelines at the Department for the most frequent cancer pathologies, and specific scheduling during weekdays to administer certain drugs such as monoclonal antibodies,

and reducing waste. Other reasons for this observed stability in expenditure may be more general, but of great importance, and related to patent expiration, greater use of generics, increased competition and optimization on the negotiation of prices between the Healthcare Centers Board and Pharmaceutical Industries.

The overall results of our study were in accordance with those published by the Karolinska Institute^[4]. Up to 2007, drugs placed on the national market before 1999 were responsible for most of the expenditure. Reasons for this may include new treatment indications for these drugs and the loss of some drug patents leading to a reduction in their price. Drugs available between 1999 and 2002 were the second leading cause of expenditure, followed by drugs placed on the market between 2003 and 2005. Recently placed drugs (from 2006) accounted for a smaller percentage of the costs. However, after 2008 there was a reduction in costs for previously available drugs followed by a gradual increase in the expenditure for new drugs.

Nevertheless, these results may be affected by several confounding factors which influence the price of pharmaceuticals, such as reimbursement and pricing policy, and the Portuguese financial system. Other limitations in our study are related to the retrospective analysis and the period studied that may have resulted in selection bias with many confounding factors.

In summary, in this study older drugs were responsible for most of the expenditure in cancer treatments up to 2007, after which we observed an increase in expenditure related to new drugs. Despite this increase in expenditure on new drugs in the last 3 years analyzed, the increase in costs for cancer drugs was not the same as in the previous years. However, more studies must be undertaken to fully understand this situation in Portugal.

COMMENTS

Background

Drugs are one of the most investigated components of Oncology, consuming most of its economic resources. Over the past few years, direct costs related to cancer treatment have increased significantly. This growth seems to be explained by the increase in cancer incidence, new indications for treatment with previously approved cancer drugs and to the placement of new drugs on the market, which are frequently more expensive than those already on sale. However, data related to cancer treatment cost is scarce in Portugal.

Research frontiers

The results of the Karolinska Institute study demonstrated a substantial increase in available cancer drugs and costs between 1998 and 2007. This cost increment was not only related to the introduction of new drugs, as 68% of the costs in 2007 were from drugs approved before 1999. In 2007, drugs placed on the market between 1999 and 2002 accounted for 17% of the total costs; drugs placed between 2003 and 2005 accounted for 11%; and drugs placed between 2006 and 2007 accounted for 3%.

Innovations and breakthroughs

In this work the authors observed an increase in the global costs of cancer drugs which may be explained by the increased number of patients treated, new indications for treatment with previously approved drugs, and the placement of new drugs on the market. These results were in accordance to those published by the Karolinska Institute. Up to 2007, drugs placed on the national market before 1999 were responsible for cancer drug expenditure. Reasons for this may be new treatment indications for these drugs and loss of some drug

patents leading to a reduction in their price. Drugs available between 1999 and 2002 were second regarding expenditure, followed by drugs placed on the market between 2003 and 2005. Recently placed drugs (from 2006) accounted for a smaller percentage of the costs. However, after 2008 there was a reduction in costs for previously available drugs followed by a gradual increase in expenditure for new drugs.

Applications

The study results suggest that older drugs were responsible for most of the expenditure in cancer treatment, but costs of new cancer drugs are increasing.

Terminology

The burden of cancer to society can be measured by direct and indirect costs. Direct costs are related to prevention and treatment, while indirect costs include loss of production due to inability to work caused by disease, disability and death. The costs of chemotherapy drugs are related to expenditure for cytostatics, and costs for targeted therapy such as monoclonal antibodies, tyrosine kinase inhibitors and mammalian target of rapamycin inhibitors.

Peer review

The paper is interesting. It will benefit readers in the field of hospital economic.

Abstract

AIM: To evaluate the prognostic value of preoperative carcinoembryonic antigen (CEA), carbohydrate antigen (CA)19-9, and CA50 in patients undergoing D2 resection.

METHODS: We evaluated 363 patients with gastric cancer who underwent gastrectomy at our hospital from January 2006 to December 2009. Blood samples were obtained from each patient within 1 wk before surgery. The cut-off values for serum CEA, CA19-9, and CA50 were 5 ng/mL, 37 U/mL, and 20 U/mL, respectively. The correlation between preoperative tumor marker levels and prognosis was studied by means of univariate and multivariate analyses.

RESULTS: The preoperative serum positive rates of CEA, CA19-9 and CA50 were 24.0%, 18.9% and 24.5%, respectively. The positivity rate of serum CEA was significantly correlated with age ($P < 0.001$), sex ($P = 0.022$), tumor size ($P = 0.007$) and depth of invasion ($P = 0.018$); CA19-9 with tumor size ($P = 0.042$) and lymph node metastasis ($P < 0.001$); and CA50 only

with lymph node metastasis ($P = 0.001$). In multivariate analysis, tumor size, T category, N category, vascular or neural invasion, and adjuvant chemotherapy were independent prognostic factors for overall survival. CA19-9 had an independent prognostic significance in patients without adjuvant chemotherapy ($P = 0.027$).

CONCLUSION: Preoperative serum CEA, CA19-9 and CA50 are prognostic in patients with gastric cancer. Only CA19-9 is an independent prognostic factor after surgery without adjuvant chemotherapy.

Key words: Gastric cancer; Carcinoembryonic antigen; Cancer antigen 19-9; Cancer antigen 50; Prognosis

Core tip: Recent researches have investigated the prognostic value of tumor markers in gastric cancer. The results were not conclusive and consistent. Most researchers did not account for some confounding factors, especially the use of adjuvant chemotherapy, so we investigated the prognostic value of carcinoembryonic antigen, carbohydrate antigen (CA)19-9 and CA50 in Chinese gastric cancer patients when considering the use of adjuvant chemotherapy. CA19-9 is an independent prognostic factor for gastric cancer patients after surgery without adjuvant chemotherapy.

and mortality over the past decades, but due to its poor prognosis, it is still the second leading cause of cancer-related death worldwide^[1]. Surgery is the main approach for gastric cancer, and the most important prognostic factor of gastric cancer is tumor node metastasis (TNM) classification^[2]. However, it is difficult to obtain complete data preoperatively. For this reason, it may be important to find some other preoperative prognostic factors for evaluating the outcome of gastric cancer patients.

Tumor markers, including carcinoembryonic antigen (CEA), carbohydrate antigen (CA)19-9 and CA50, are not applied to TNM staging according to the American Joint Committee on Cancer (AJCC) 7th edition, but they have been applied in clinical practice for several decades and shown to have prognostic value in gastric cancer. CEA, a member of the immunoglobulin superfamily, was originally used as a serum marker for colorectal cancer^[3]. Now, it is widely used in the diagnosis and monitoring of gastric cancer. CA19-9 is one of the antigens of the Lewis family and has been reported to be elevated in the sera of patients with gastrointestinal cancer, particularly in pancreatic cancer^[4]. CA50 is a glycolipid antigen that plays an important role in cell growth and differentiation and can also be observed in a variety of malignancies, especially gastrointestinal cancers^[5]. According to previous studies of the association between preoperative tumor markers and outcome of gastric cancer (Table 1), a high preoperative CEA or CA19-9 level is associated with high tumor recurrence^[6-9] and poor survival rates^[6-8,10-17]. Some studies have suggested that preoperative CEA, CA19-9 or CA50 level is an independent prognostic factor of gastric cancer^[6-8,10,12-14,18]. However, some of these studies did not calculate the disease-free survival (DFS) time, which could indirectly reflect tumor recurrence. Moreover, most studies did not account for other factors, especially the use of adjuvant chemotherapy, which may be expected to be associated with long-term oncological outcomes.

In this retrospective study, we investigated the relationship between preoperative serum levels of CEA,

CA19-9 and CA50 and clinicopathological features, and the prognostic value of these three tumor markers in patients who underwent D2 resection for gastric cancer with adjuvant chemotherapy.

MATERIALS AND METHODS

Patient data

We included 363 patients who underwent D2 surgical resection at the First Affiliated Hospital of Nanjing Medical University between January 2006 and December 2009. The patient inclusion criteria in this study were as follows: (1) pathological diagnosis of gastric cancer; (2) D2 surgical resection; (3) Stage I - III cancer; (4) adjuvant chemotherapy regimen of cisplatin or oxaliplatin combined with 5-fluorouracil; (5) death due to gastric cancer; and (6) availability of follow-up data. The end of follow-up was April 2013. The study protocol was approved by the Ethics Committee of this hospital. Patients were staged according to the criteria of the AJCC 7th edition. CEA, CA19-9 and CA50 were assayed by enzyme linked immunosorbent assay. Blood samples were obtained from each patient within 1 wk before surgery. CEA, CA19-9, and CA50 were assayed with magnetic particle enzyme immunoassay in UniCel™ DxI 800 Access immunoassay system (Beckman Coulter Inc. Miami, United States). The cut-off values for serum CEA, CA19-9 and CA50 were 5 ng/mL, 37 U/mL and 20 U/mL, respectively, according to the manufacturer's instructions. These patients were monitored every 3 mo for the first 2 years after surgery, and every 6 mo thereafter. Follow-up examinations included physical examination, ultrasonic inspection, chest radiography, computed tomography, positron emission tomography, magnetic resonance imaging, endoscopy, and histological biopsy. Recurrence was determined by clinical and radiological examinations or by histological confirmation.

Statistical analysis

The χ^2 test was used to evaluate the associations between

tumor markers and the existing prognostic factors. Univariate survival analysis was performed using the Kaplan-Meier method. Survival curves were compared with the log-rank test. Multivariate analysis was performed using the Cox proportional hazards regression model. $P < 0.05$ was considered significant. All statistical analyses were performed using SPSS version 18.0.

RESULTS

Patient characteristics

The characteristics of 363 patients are presented in Table 2. These patients had a median age of 60.67 ± 11.91 years (range: 24-93 years) and included 266 (73.3%) men and 97 (26.7%) women. Only two patients (0.6%) had Stage I cancer, 97 (26.7%) were Stage II, and 264 (72.7%) were Stage III. Poorly differentiated tumors were observed in 302 patients (83.2%), and moderately and well-differentiated tumors in 61 (16.8%). And 261 patients (71.9%) received platinum-based adjuvant chemotherapy.

Association between clinicopathological features and tumor markers

Preoperative serum CEA levels were assayed in all 363 patients, however, for some unknown reasons, CA19-9 was assayed for 354 patients and CA50 for 290. The

preoperative serum positive rates of CEA, CA19-9 and CA50 were 24.0%, 18.9% and 24.5%, respectively. As shown in Table 2, positivity rate of CEA was significantly correlated with age ($P < 0.001$), sex ($P = 0.022$) and tumor size ($P = 0.007$), while CA19-9 was correlated with tumor size ($P = 0.042$). Compared with CA19-9 and CA50, CEA showed a more significant difference in depth of invasion ($P = 0.018$). In contrast, lymph node metastasis was significantly more frequent in patients with elevated levels of CA19-9 ($P < 0.001$) and CA50 ($P = 0.001$). Nevertheless, the tumor location, tumor differentiation, and vascular or neural invasion did not influence the positivity of the three tumor markers.

Survival and tumor markers

Overall survival (OS) was recorded for all patients, and DFS was recorded for 160. At the end of follow-up in May 2013, 167 (46.0%) patients were still alive.

On univariate analysis, by Kaplan-Meier method with the log-rank test, the OS of all patients was lower in those with elevated CEA, CA19-9 and CA50 compared to those with normal tumor marker levels ($P = 0.023$, $P = 0.009$ and $P = 0.004$, respectively). DFS showed no significant difference between elevated tumor marker levels and normal ones (Table 3). We divided these patients into two groups: those with and those without adjuvant che-

Table 3 Univariate model for disease-free survival and overall survival by log-rank test

CA19-9 (+) and CA50 (+)	0.991	0.132	0.303	< 0.001
CEA (+) and CA19-9 (+) and CA50 (+)	0.991	0.132	0.867	0.298
CEA (+) or CA19-9 (+) or CA50 (+)	0.742	0.196	0.107	< 0.001

CEA: Carcinoembryonic antigen; CA: Carbohydrate antigen; DFS: Disease-free survival; OS: Overall survival.

mothy (Table 4). In the non adjuvant chemotherapy group, patients with elevated CEA, CA19-9 and CA50 had a significantly worse prognosis than patients with normal tumor marker levels. The adjuvant chemotherapy group did not show similar results. To evaluate combination assays of serum CEA, CA19-9 and CA50 levels, cumulative survival was compared among five groups: all three tumor markers elevated (CA50⁺/CEA⁺/CA19-9⁺), at least two markers elevated (CEA⁺/CA19-9⁺, CA50⁺/CEA⁺, CA19-9⁺/CA50⁺), and at least one marker elevated (CEA⁺, CA19-9⁺ or CA50⁺). As shown in Tables 2 and 4, the CEA⁺/CA19-9⁺, CA19-9⁺/CA50⁺ and CEA⁺, CA19-9⁺ or CA50⁺ groups displayed poor OS rates in all patients and in the adjuvant chemotherapy group.

On multivariate analysis, tumor size, T category, N category, vascular or neural invasion, and adjuvant chemotherapy were independent prognostic factors for OS. Meanwhile, only tumor size was a significant risk factor for DFS. Preoperative serum CEA, CA19-9 and CA50 were not independent prognostic factors for OS (Table 5), but CA19-9 was an independent prognostic factor

in patients without adjuvant chemotherapy ($P = 0.027$) (Table 6).

DISCUSSION

Tumor markers are often used to determine the prognosis of cancer patients after radical surgery, but the role of tumor markers in gastric cancer is still controversial. α -Fetoprotein, CEA, CA19-9, CA50 and CA72-4 were considered as relatively specific markers for gastric cancer in some studies^[12]. In our hospital, we began to use the preoperative serum levels of CEA, CA19-9 and CA50 to evaluate the prognosis of gastric cancer patients several years ago. That is the reason why we chose these three tumor markers in the present retrospective study.

The preoperative rate of positivity for serum CEA was 24.0%, which is similar to other studies using the same cutoff value^[7,19,20]. The corresponding proportion of patients with elevated serum CA19-9 and CA50 levels was 18.9% and 24.5%, respectively, which was also similar to previous studies^[6,9,12]. Some authors have reported that tumor marker positivity is associated with tumor stage^[6]. However, no such correlation was found in our study. The reason may be that most of our samples were Stage II or III tumors, and there was no patient with Stage IV disease. Nevertheless, we found that CA19-9 and CA50 were associated with pN stage, and CEA with pT stage, which indicated that the positive rates of tumor markers increased as the tumor progressed. Our analysis showed that the positive rate of CEA was higher in male and elderly patients. The proportion of patients with elevated serum CEA and CA19-9 was significantly higher in those with large tumors. Also, there was a tendency for CA50 to be a marker for tumor size. It has been reported in animal studies that the elevation of serum CEA was caused by the increase in weight of primary cancer, as well as the increase in CEA production in cancer tissues^[21]. It has also been reported that elevated CEA levels are related to the degree of differentiation^[22]. However, we did not find any correlation between the tumor markers studied and the degree of differentiation. Similar to our findings, tumor location has previously been noted to have no association with tumor marker positivity^[23].

On the basis of our univariate analysis, patients positive for CEA, CA19-9 and CA50 had significantly poorer OS than those who were the marker negative. We found that the correlations between CEA, CA19-9, CA50 and OS were consistent with previous studies^[6,7,10,13,15,16]. These correlations reflected the worse prognosis in patients with positive values for tumor markers. Marrelli *et al*^[7] observed that the combined assay of CEA and CA19-9 provided more useful prognostic information than CEA or CA19-9 alone. Combination of these three markers, with positivity for at least two, resulted in a significant difference in OS, and proved to be a better prognostic indicator with respect to the three markers used alone. This finding suggests the complementary role of the three markers, which is also supported by the increase in overall sensitivity obtained with their concomitant use.

CEA: Carcinoembryonic antigen; CA: Carbohydrate antigen; OS: Overall survival.

On the contrary, there was no significant difference in OS when all three markers were positive. This may have been due to the limitations of the small sample size and that the levels of the three markers in the patients were not high in our analysis. We found that when CA50 was positive, there was a 77.5% chance for at least one of the other two markers to be positive. This revealed that all three markers were sensitive in gastric cancer. Also, there may be similarities in the mechanism of generation of the three markers. We also intended to compare cumulative survival in patients who were positive for only one of the tumor markers, but the numbers of these patients were too small to reach statistical significance. Not many previous studies considered the confounding factors such as the use of adjuvant chemotherapy. Therefore, to exclude the potential bias of adjuvant chemotherapy, we observed the oncological outcomes in patients without chemotherapy after surgery. As a result, these patients who were positive for CEA, CA19-9 or CA50 had a poor prognosis by univariate analysis, while there was no association between tumor markers and oncological outcomes in patients with adjuvant chemotherapy. This may have been because adjuvant chemotherapy after surgery improved the prognosis of gastric cancer patients. In our multivariate analysis, adjuvant chemotherapy was an in-

dependent prognostic factor. To evaluate whether CEA, CA19-9 and CA50 could provide information about tumor recurrence, we compared cumulative survival curves for DFS. Choi *et al*^[22] reported that patients with an elevated tumor marker were at higher risk for recurrence. However, in our study, we did not find any correlation between recurrence and tumor markers.

In order to clarify the value of tumor markers in prognosis of gastric cancer patients, we performed multivariate analysis using a Cox proportional hazards model. The results showed that tumor size, T category, N category, vascular or neural invasion, and adjuvant chemotherapy had independent prognostic value for OS. However, the three tumor markers that we studied did not provide independent predictive value for recurrence and OS. Nevertheless, Tocchi *et al*^[16] reported that preoperative serum CEA and CA19-9 were independent prognostic factors in gastric cancer patients. Liu *et al*^[12] showed that CA50 had prognostic significance in T4a gastric cancer. Other studies did not show similar results^[13]. This may have been because of the heterogeneity of patients included in these studies. Our study revealed that adjuvant chemotherapy played an important role in prognosis of gastric cancer patients. When excluding the impact of chemotherapy, increased preoperative CA19-9 level was associated independently with oncological outcomes in patients without adjuvant chemotherapy. Duraker *et al*^[24] assessed CEA when investigating adjuvant chemotherapy in patients with colon cancer, but found no difference in patients with or without chemotherapy. Thus, we suppose that increased preoperative CA19-9 level could be a reason for initiating adjuvant chemotherapy in gastric cancer patients after surgery.

There were some limitations to our study. We did not obtain sufficient details about recurrence, and just calculated the DFS, which might not provide sufficient information about the correlation between tumor markers and recurrence. Also, not all three tumor markers were assayed in all the patients, so there was loss of some data. Further research with a more complete patient data is needed to obtain definitive results.

In conclusion, preoperative serum levels of CEA,

CA19-9 and CA50 can provide prognostic information in patients with gastric cancer. Furthermore, only CA19-9 is an independent prognostic factor for gastric cancer patients after surgery without adjuvant chemotherapy.

COMMENTS

Background

Gastric cancer is the second leading cause of cancer-related death worldwide. To predict the outcome of patients before surgery, it is important to find some preoperative prognostic factors. Tumor markers have prognostic significance in several neoplasms. This retrospective study evaluated the prognostic value of preoperative carcinoembryonic antigen (CEA), carbohydrate antigen (CA)19-9 and CA50 in patients who underwent D2 resection for gastric cancer.

Research frontiers

Many tumor markers are widely used clinically. CEA, CA19-9 and CA50 are relatively important in gastric cancer. The preoperative levels of these markers may indirectly reflect tumor load and prognosis. Therefore, it is becoming more important to explore the prognostic value of these tumor markers. Especially for clinicians, these markers can help them to choose appropriate treatment strategy.

Innovations and breakthroughs

Many studies have investigated the prognostic value of tumor markers, but most researches did not account for the confounding factors, especially the use of adjuvant chemotherapy. The authors investigated the prognostic value of CEA, CA19-9 and CA50 in gastric cancer patients when considering the use of adjuvant chemotherapy. To eliminate the influence of chemotherapy, the authors divided the patients in non-adjuvant chemotherapy and adjuvant chemotherapy groups for subgroup analysis.

Applications

CA19-9 is an independent prognostic factor for gastric cancer patients after surgery without adjuvant chemotherapy. The authors suggest that patients with a high preoperative level of CA19-9 may relapse earlier than those with a normal level; therefore, for patients with a high level of markers, more frequent physical examinations are needed.

Terminology

Tumor markers, including CEA, CA19-9 and CA50, have been applied in clinical practice for several decades and shown to have prognostic value in gastric cancer. Adjuvant chemotherapy: it is additional treatment given after surgery to lower the risk of the cancer recurrence.

Peer review

The authors evaluated the prognostic value of preoperative CEA, CA19-9 and CA50 in patients who underwent D2 resection for gastric cancer. They concluded that CA19-9 is an independent prognostic factor for gastric cancer patients after surgery without adjuvant chemotherapy. This study was important and interesting.

exercise training with statistical analyses performed in at least one of the following outcome measurements: Cardiorespiratory function, body composition, muscular strength, fatigue, depression, and overall quality of life. Five reviewers independently identified the studies that met the criteria for the review and discrepancies were resolved by consensus among all authors.

RESULTS: Fifty-one studies were included in this review with 5 from the period between 1989-1999, 11 from 2000-2006, and 35 from 2007-2013. The evolution of study designs changed from aerobic only exercise training interventions (1989-1999), to a combination of aerobic and resistance training (2000-2006), to studies including an arm of resistance training or examining the effects of resistance training as the main mode of exercise (2007-2013). Overall, the benefits of exercise showed improvements in cardiorespiratory function, body composition, strength, and patient reported outcomes including fatigue, depression, and quality of life.

CONCLUSION: Exercise training appears to be safe for most breast cancer patients and improvements in physiological, psychological, and functional parameters can be attained with regular participation in moderate intensity exercise.

Abstract

AIM: To investigate the role of exercise training the past 25 years on major physiological-psychological outcomes studied thus far in this patient population.

METHODS: PubMed, MedlinePlus, the Cochrane Library, Web of Science, SportDiscus, Embase, Scopus, and Google Scholar were searched from September to November 2013 to identify exercise training studies that used objective measurements of fitness and/or patient reported outcomes assessed pre and post-

cise training appears to be safe for most breast cancer patients and improvements in physiological, psychological, and functional parameters can be attained with regular participation in moderate intensity exercise.

Battaglini CL, Mills RC, Phillips BL, Lee JT, Story CE, Nascimento MGB, Hackney AC. Twenty-five years of research on the effects of exercise training in breast cancer survivors: A systematic review of the literature. *World J Clin Oncol* 2014; 5(2): 177-190 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i2/177.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i2.177>

INTRODUCTION

Despite being the most commonly diagnosed cancer among women and the second most diagnosed type of cancer overall in the world (approximately 1.7 million diagnosed cases in 2012, 11.9% of all cancer cases) the incidence of breast cancer continues to rise with a concerning increase of 20% of newly diagnosed cases since 2008^[1]. This worldwide increase in new breast cancer cases has been attributed, in part, to changes in lifestyle in developing countries due to economic growth and societal changes similar in nature to those of developed industrialized nations^[1]. These lifestyle changes are often associated with poor dietary choices and lack of physical activity; both considered major risk factors for the development of the disease^[2]. However, in developed countries, new diagnostic tools that allows for faster detection and technological advances in anti-cancer treatments, have been credited as the main factors for the increased longevity observed in oncology patients, especially in the breast cancer population^[2,3].

Living longer with a history of the disease often comes with the deleterious effects of treatments, which regrettably are associated with reduced quality of life in the patients. Marked reductions in physical capacities (*i.e.*, reduced cardiac function and muscular strength), negative body composition alterations (*i.e.*, increase in body mass, reduction in muscle mass, and increases in fat mass), and detrimental patients reported outcomes (PROs) (*i.e.*, increased levels of fatigue, depression, and anxiety) are among the common side-effects of cancer treatments that negatively impact the overall quality of life of these patients and also put them at a greater risk for the development of other co-morbidities^[4]. If not addressed, these side effects can increase the likelihood for the development of secondary cancers as well as diminish life expectancy^[2].

During the past 3 decades, complementary therapies known as Complementary Alternative Medicine, have received more attention by the medical community due to its ability to mitigate some of the side-effects commonly experienced by cancer patients during and post-completion of cancer treatments. One intervention that has gained increasingly more attention due its efficacious

ability to positively impact many physiological systems that are altered during cancer treatment, its non-invasive nature, and relatively low cost, is exercise.

The effects of exercise training in breast cancer patients began to be examined in the late 1980's. The first study examining the effects of exercise in breast cancer patients was published in 1989^[5] and demonstrated that the patients tolerated exercise training and significant improvement in cardiorespiratory functional capacity [represented by the variable $\text{VO}_{2\text{max}}$ (L/min)] was observed in the exercise-training group. Since then, an ever-growing number of studies examining the effects of exercise in breast cancer patients has continued to be one of the most studied populations in this relatively new and exciting area of exercise oncology research. The results of the evaluation of these studies are promising and affirming, but clearly warrant further and more extensive investigations.

The purpose of this systematic review of the literature on the effects of exercise training in breast cancer patients was to present and evaluate the results of studies conducted in this area of research during the past 25 years, divided into the following time periods: (1989-1999, 2000-2006, 2007-2013). Most specifically, this review focuses on presenting and discussing the results of the effects of exercise training on the most commonly evaluated outcomes in the area including physiological parameters of cardiorespiratory function, body composition, and muscular strength, and PROs that evaluated fatigue, depression, anxiety, and overall quality of life. For organizational purposes a chronological description of studies results, studies common characteristics, and commentaries on changes observed in this area of research over the past 25 years are discussed.

MATERIALS AND METHODS

A systematic review of the literature using PubMed, MedlinePlus, the Cochrane Library, Web of Science, SportDiscus, Scopus, Embase, and Google Scholar was conducted from September to November 2013 to identify exercise-training studies in breast cancer patients. The MeSH terms and text word used for the search of studies included: exercise and cancer, exercise oncology, breast cancer, breast cancer and exercise, oncology, exercise training, exercise therapy, neoplasms, and malignancies. All references relevant to the topic were hand-searched.

Studies selection criteria

Included in the review were all exercise training studies that used aerobic training or aerobic in combination with resistance exercise training, or had a study arm evaluating the effects of aerobic training or aerobic in combination with resistance exercise training. These studies objectively assessed the effects that these exercise training modes had in breast cancer patients on at least one of the following fitness and/or patient rated outcomes variables including: cardiorespiratory function, body composition,

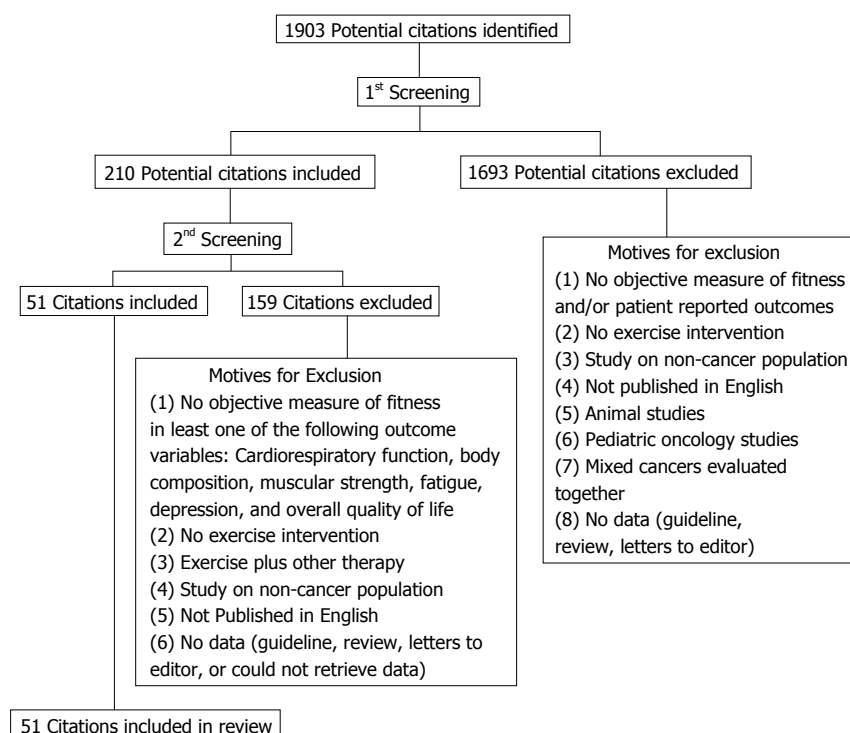

Figure 1 Literature review citation selection flow chart.

muscular strength, fatigue, depression, and overall quality of life. These outcome variables were chosen because they have been the most commonly evaluated variables in the area of exercise oncology during the past 25 years. Studies excluded from the review involved those conducted in pediatric patients (age below 18 years); that used non-conventional exercise prescriptions (*i.e.*, Yoga, aqua aerobics, Tai Chi, *etc.*); not published in English; used traditional exercise training programs in combination with other interventions (*i.e.*, dietary manipulations, psychosocial therapies, counseling, *etc.*); secondary articles from the same research team with data previously published on initial original article of outcome variables of interest of this review; studies that evaluated the results of the exercise intervention in breast cancer patients mixed with other types of cancers; studies with non-retrievable incomplete data sets, review articles, guidelines articles, letters to editor, and animal based studies. Since very few studies have used resistance training as the main mode of exercise, a separate evaluation summarizing the results of studies that objectively measured muscular strength using the 1 maximum repetition (1-RM) and presented data on at least one of the major outcomes mentioned above are also presented. Five reviewers (Mills RC, Phillips BL, Lee JT, Story CE, Nascimento MGB) independently identified the studies that met the criteria for the review mentioned above and discrepancies were resolved by consensus among all authors.

Statistical analyses

Descriptive statistics were used in the form of mean and standard deviations for the presentation of main out-

come variables data at baseline and post-exercise intervention. Comparisons between baseline and post-exercise training data were conducted using dependent samples *t* tests for both the exercise and control (non exercise training) groups. For studies where there was more than one exercise arm (*i.e.*, self-directed and supervised exercise), when no differences were observed for changes between groups, both groups were included in the analyses. An alpha of 0.05 set a priori was used for all tests. No alpha level adjustment was performed for the multiple comparisons. Due to differences of instruments used to evaluate the main outcome variables included in this review, only variables evaluated by at least two independent studies were included in the analyses. For variables evaluated by only one study, means, standard deviations, and change from baseline to post-intervention values were provided when data was retrievable.

RESULTS

Between September and November of 2013, 1903 potential citations for inclusion in the review were identified. After an initial screening of all of 1903 potential citations, 210 citations were included in a second screening for further evaluation of inclusion eligibility criteria. After the second screening, 51 citations were deemed eligible. The literature review citation selection process flow chart is presented in Figure 1.

For organizational purposes a chronological description of studies results conducted in this area of research during the past 25 years was arbitrarily divided into the following time periods: (1989-1999, 2000-2006, 2007-2013).

1989-1999

During the decade between 1989 and 1999, only 5 studies met the inclusion criteria for this review^[5-9]. All 5 studies were conducted while patients were receiving active treatment including chemotherapy and/or radiation therapy and the average age was 46.4 ± 1.5 for the patients who participated in the exercise interventions and 46.6 ± 3.4 for patients in the control groups. Four of the studies were randomized controlled trials and more than half of the studies were home-based interventions ($n = 3$)^[7-9]. The summary of the results of the studies is presented in Table 1.

Only 1 study^[6] assessed the effects of exercise training on cardiorespiratory function using a direct measurement through a cardiopulmonary exercise test (CPET) on a cycle ergometer with gas exchange; 2 evaluated overall physical function using the 12-min walk test; 1 focused on the effects of exercise training on body weight and body composition^[5]; the other 3 studies focused on patient reported outcomes^[7-9]. The overall exercise prescription used in these 5 initial studies included 100% aerobic exercise training prescriptions, with two studies using an interval-training methodology^[5,6]. The frequency of training ranged from 3-5 sessions per week (average of 3.7 sessions per week), with training sessions of 15-45 min (average of 27 min). The only modes of exercise used on these studies included either walking or cycle ergometry

with an exercise training program length varying from 6-24 wk of training (average of 11 wk). For the studies that used heart rate for the prescription of exercise intensity, 60%-85% of heart rate reserve was used. The majority of studies that used walking as the mode of exercise, the description of exercise intensity was subjective and included terms such as brisk walk, self-paced, low to moderate, or incremental exercise.

No statistical significance was observed for changes in any outcome variable analyzed. However, within the results the most noticeable effect of the exercise training was observed for the variable fatigue. A trend towards significance was observed for the variable fatigue in the control group with increased values from baseline to post-exercise training of 22 points in a scale from 0-100 representing a 22% increase in fatigue levels. This increase was of clinical relevance since the exercise group showed a much lower fatigue response. No data on body composition was analyzed, however, a trend towards a reduction in body fat % and gain in lean body mass was observed in the exercise group while the control group experienced the opposite effect. Even though no statistical analysis was performed on the variable cardiorespiratory function (only one study), an increase of VO_{2max} of 0.43 L/min was observed, representing a clinically relevant improvement on this variable with exercise training. No adverse events resulting from the exercise training

was reported in any study.

2000-2006

From 2000 to 2006, 11 studies^[10-20] met the review inclusion criteria with 6 of them being randomized controlled trials. More than half of the studies during this time period were conducted in patients who had completed chemotherapy and/or radiation therapy ($n = 6$, 54.5%) while all of the other studies (45.5%) were conducted with patients undergoing treatment ($n = 4$), and 1 study including patients in and off-treatment as part of the study design^[12]. The average age for patients that participated in the exercise interventions was 51.09 ± 4.6 and 51.03 ± 4.9 for patients in the control groups. The majority of studies used an exercise prescription that combined aerobic with resistance training (68.8%) with only 31.2% of the studies using aerobic training only. The major modes of aerobic exercise included walking, swimming and cycling. No studies during this time period used resistance training exclusively as the major mode of exercise. On average, aerobic exercise was prescribed 2-4 d/wk for approximately 30 min, with intensities varying from 50%-80% of peak heart rate, 50%-75% of heart rate reserve, rate of perceived exertion between 11-15 with overall training duration between 8-14 wk. The resistance training portion of the exercise prescription lasted approximately 40 min (37 ± 17 min) and consisted of exercises targeting major muscles groups performed for 2-3 sets, with approximately 10-12 repetitions using weight training machines, dumbbells, and rubber bands. The description of exercise intensity used in the 2000-2006 studies that included resistance training as a portion of the exercise intervention varied significantly and clear descriptions of the intensities used were often missing. For example, one study used the patient's own body weight to induce a training response^[14] while one study would increase the resistance between 5%-10% of the previous load as soon as patients were able to achieve the maximum number of repetitions prescribed^[19]. All other studies that used resistance training did not describe the intensity used during the resistance portion of the exercise intervention. The duration of training in studies that used aerobic or a combination of aerobic and resistance training was approximately 11 wk (10.9 ± 6.78). As mentioned, six studies were randomized controlled trials^[11,13,16,17,19,20]. The primary mean for prescribing and monitoring exercise intensity was heart rates, which varied from 70%-75% of $\text{VO}_{2\text{peak}}$, 40%-70% of estimated $\text{VO}_{2\text{max}}$, 60%-90% of predicted maximum heart rate, and 60%-70% of heart rate reserve. This heterogeneity in prescribing exercise intensity is troublesome since significant differences in the determination of exercise intensity from using one method versus the other can produce significantly different prescriptions. Eleven studies were performed between 2000-2006^[10-20]. Seven were conducted in a supervised setting^[11,12,13,15,16,19,20], while 3 were home-based interventions^[10,14,17,18]. One study used a supervised exercise session plus 2 self-monitored exercise

sessions at home per week^[14], while 1 study used a period of two weeks familiarizing subjects to the exercise intervention in a supervised setting followed by a home-based self-monitored exercise training for the remaining of the study^[18]. The summary of the results of the studies conducted between 2000-2006 is presented in Table 2.

Cardiorespiratory function, when assessed directly using maximal CPET with gas exchange *via* cycle ergometer, showed significant improvements in patients who underwent exercise training ($P < 0.0001$). An improvement corresponding to an approximately 9% (2.14 mL/kg per minute) from baseline testing was observed for the exercise group while the control group showed no significant changes^[11,13,14,18,19]. When cardiorespiratory function was indirectly measured (*i.e.*, using submaximal/estimated $\text{VO}_{2\text{max}}$ testing protocols), no significant changes in either the exercise or control groups were observed, however, a trend towards improvements in the exercise group was observed. Conversely, patients in the control group did not change or end up decreasing cardiorespiratory function from baseline to completion of study protocols^[6]. Due to the small number of studies that have assessed some strength parameter and the lack of a control group in studies conducted during the period of 2000-2006, it is not possible at this time to provide an evaluation on the effects of a combined aerobic and resistance training exercise intervention on measurements of strength in breast cancer patients.

The only body composition parameter that significantly changed from baseline was body fat % in the exercise group (change of 1.51%). No significant changes in any other body composition parameter was observed in either exercise or control groups. However, a trend towards positive changes for the exercise group (*i.e.*, reduction in body mass and fat mass) and some negative changes in the control group such as increases in body mass, fat mass, and body fat %, suggesting that exercise training may be a promising intervention in alleviating negative body composition changes in breast cancer patients warranting further research^[5].

Significant improvements in overall quality of life assessed using the Functional Assessment of Cancer Therapy-Breast was observed in the exercise group ($P = 0.027$) with no changes in the control group. No other PROs were significant in either group; however, trends of reductions in fatigue and depression were observed in the exercise but not in the control group^[9]. A few adverse events were reported during 2000-2006 and included lymphedema (3 cases), gynecologic complications (1 case), and influenza (1 case)^[13].

2007-2013

From 2007 to November 2013, 35 exercise studies involving breast cancer patients were conducted^[21-55]. Twenty-seven (77%) of all studies conducted during this time period were randomized controlled trials. Out of all 35 exercise studies, 22 examined the effects of exercise training in patients undergoing treatment (62.8%), 1

study studied patients in and off treatment^[40] and 1 study examined the effects of exercise in patients receiving neo-adjuvant therapy^[55]. The average age for patients that participated in the exercise interventions was 58.0 ± 3.9 and 53.7 ± 4.5 for patients in the control groups. Most of the studies were conducted in a supervised setting ($n = 27$, 77% of all studies conducted between 2007 and November 2013). Sixteen studies used aerobic exercise as the main mode of exercise training, 12 used a combination of aerobic and resistance exercise training, while only 7 used resistance exercise training as the main mode of exercise training or had a study arm that examined the effects of resistance training on outcome measurement/variables of interest to this review. The modes of exercise for the aerobic exercise training interventions included walking, jogging, treadmill, cycle ergometer, elliptical, low-impact aerobics, stepping, arm ergometer, rowing ergometer, mini-trampolines, step-up blocks, and circuit training. For studies that used resistance training as their major mode of exercise or as the mode of a study arm, weight machines, free weights, elastic bands, tubing, therapeutic balls, and resistance-training circuits were used. The average frequency of training was 3 d/wk ranging from 2-5 training sessions per week, with overall training duration average of 23 wk (range of 3-48 wk). Each training session lasted on average 46 min, with training sessions ranging from 15-90 min. The intensity for aerobic training varied from 40%-85% of maximum heart rate, 40%-90% of VO_{2peak}, while the intensity for resistance training ranged from 55%-85% of 1RM. Minimal adverse events due to exercise were reported; when reported, events such as lightheaded, hypotension, nausea, and weakness during exercise testing were basically the extent of the complications with patients recovering quickly afterwards.

Most studies assessed cardiorespiratory function using estimated measurement protocols. When using estimated measurements derived from a submaximal treadmill testing protocol, a significant improvement in cardiorespiratory function was observed for the exercise group (improvement from baseline of 3.54 mL/kg per minute, $P < 0.0005$). When cardiorespiratory function was measured directly using a cycle ergometer maximal oxygen uptake test protocol with gas exchange, improvement from baseline approached significance in the exercise group (improvement from baseline of 2.38 mL/kg per minute, $P = 0.057$). Significant decrease in meters walked

during a 6 min and 2 km walk tests was observed in the control group (-9.52 m, -0.61 m, $P = 0.008$ and $P = 0.010$ respectively) while improvements in a 12 min walk test approached significance in the exercise group (improvement of +162 m, $P = 0.062$). A summary of the results of the effects of exercise on cardiorespiratory function is presented in Table 3.

Positive body composition changes with exercise training were observed in the exercise group, with the most notorious changes in significant decrease in body fat % ($P = 0.037$) and increase in lean body mass ($P = 0.002$). The control group experience significant increases in body fat % ($P = 0.009$) and a trend toward an increase in overall body mass ($P = 0.065$). Table 4 provides a summary of studies that evaluated changes in body composition outcomes.

Quality of life significantly improved in the exercise group when the Functional Assessment of Cancer Therapy-General was used (improvement of +6.90 points, $P = 0.022$). Also, when using the Beck Inventory, the effects of exercise training significantly reduced depression levels in the exercise group (reduction of -3.40 points, $P = 0.037$). Even though many of the analyses performed on other PROs showed no significant changes in either group, there is a clear trend towards greater improvement in quality of life, reduction in fatigue and depression in the exercise group when compared to the control group. The summary of the analyses performed on reported PROs is presented in Table 5.

Resistance training

Due to the limited number of studies that used resistance training as the main mode of exercise training^[42,46,52,54], and those that used resistance training as an arm part of the study design^[27,29,43], we were unable to conduct analyses to evaluate the effects of resistance training on cardiorespiratory function measured directly through CPET with gas analyses. However, the effects of resistance training on cardiorespiratory function evaluated using a 12-min walk test, showed improvement in the exercise group of 35 m while a decline of 91 m was observed for the control group. Regarding the effects of resistance training on changes in body composition, a significant increase in body mass and lean body mass was observed in the exercise group (increase of 1.20 and 0.65 kg, $P = 0.016$ and $P = 0.049$, respectively). Upper body strength significantly increased in the exercise group (increase of +5.31

kg, $P = 0.005$) while for lower body, strength significantly increased in both, exercise and control groups ($P = 0.25$, $P = 0.008$ respectively) with a greater increase observed in the exercise group (increase of +17.82 kg *vs* +5.42 kg, respectively). No significant changes in quality of life were observed in either the exercise and control groups. The summary of the results of the effects of resistance training on outcomes included in this review is presented in Table 6.

DISCUSSION

During the past 25 years, studies examining the effects of exercise training in breast cancer survivors have steadily increased. Based on the inclusion criteria adopted by this systematic review, from 5 initial studies published between 1989-1999, 35 studies were published during the last 7 years. The increase in published studies in this area of research is a testament of the growing interest

by health care professionals and the medical community on exploring complementary therapies that have the potential to improve the overall care and health of breast cancer patients while promoting alleviation of cancer treatment-related side-effects. The evolution of the science examining the effects of exercise in breast cancer patients has progressed from studies using simpler exercise prescriptions (*i.e.*, aerobic exercise only prescriptions) to more complex designs incorporating prescriptions that combined aerobic and resistance training exercises. Interestingly, however, of the studies conducted during first decade^[5-9], all examined the effects of exercise while patients were undergoing major cancer treatments (*i.e.*, surgery, chemotherapy and/or radiation therapy) and the majorities were home-based interventions^[7-9]. Besides some limitations presented by these initial studies^[5-9] (including relatively small sample sizes and lack of more rigorous exercise prescriptions) the overall results were promising. Breast cancer patients, who exercised while undergoing cancer treatments, were not only able

to tolerate the exercise prescriptions but also presented a more favorable trend towards alleviation of decrements in functional capacity, fatigue levels, and depression when compared to patients who did not exercise. Also, and very importantly, no adverse events were reported and patients seemed to have no problems engaging in regular exercise training. Although limited data were available for a more precise evaluation of these initial studies, the results were promising and served as the basis for subsequent trials conducted with breast cancer patients.

The most noticeable differences between the initial studies conducted between 1989-1999 and those between 2000-2006 were the use of aerobic exercise combined with resistance training in the majority of the studies (68.8%) and the fact that over 50% of these studies were conducted in patients who had completed their major cancer treatments. Furthermore, the heterogeneity of exercise prescriptions and a variety of different measurements used to assess the major outcome variables included in this review makes it impossible for direct com-

parison to be made between studies. Importantly during 2000-2006, a significant increase in number of breast cancer patients studied and overall improvements in the quality of study methodologies, marked a new era in this area of research with significant improvements observed in physiological (*i.e.*, improved VO_{2max}, decreases in body fat %) and overall quality of life in the exercise group, while the control patients continued to present not so favorable outcomes during and post completion of cancer treatments. Out of studies that utilized exercise prescrip-

tions following a training progression (*i.e.*, considered by the exercise physiology scientific community as efficacious training methodologies in the promotion of more pronounced training responses) a study conducted by Courneya *et al*^[14], showed a remarkable improvement in cardiorespiratory function using a prescription derived from the results of a gold standard evaluation of cardiopulmonary function (CPET with gas analyses). Not only did Courneya's study show an improvement of 17.4% in cardiorespiratory function in patients randomized

into the exercise group, the patients in the control group decreased their cardiopulmonary function by 3.4%. Furthermore, these authors provided a better description of the sample, exercise testing procedures, and exercise prescription, along with the reporting of adverse events that occurred during the study improved the scientific rigor in this area, which was later followed by many groups around the world.

Overall, the results of all studies conducted during 2000-2006 continued to show promising results, mainly on cardiorespiratory function, body composition, and overall quality of life of patients, increasing even more the interest of the medical community for the use of exercise as an intervention to alleviate treatment-related side effects. With improved science approaches, the challenges faced by investigators around the globe began to surface even more. The heterogeneity in exercise prescriptions characteristics, different instruments that were used to evaluate major outcome variables, different treatment regimens, and testing of different exercise interventions designed to provide the most benefit to patients were among major issues that preclude one's ability to evaluate the real benefit of exercise in breast cancer patients.

During the last 7 years of research evaluating the effects of exercise in breast cancer patients, more pronounced improvements were observed in all major outcome variables included in this review when compared to previous years. Significant improvements in cardiorespiratory function of 2.38 mL/kg per minute, when measured directly using cycle ergometry and slightly higher values (3.54 mL/kg per minute) observed when cardiorespiratory function was estimated used submaximal testing protocols were reported. The larger improvement in cardiorespiratory function can be explained, in part, by the more rigorous exercise prescriptions as well as due to the inclusion of the resistance training as a component of training. Furthermore, more pronounced improvements were also observed in various body composition parameters. Significant decreases in body fat % and increases in lean body mass were observed in the exercise group while significant increase and no change in body fat % and lean body mass were observed for the control group. Furthermore, a trend of overall weight gain was more noticeable in the control group than the exercise group. Again, the inclusion of resistance training on study design of a large portion of the studies conducted between 2007-2013 may help explain the more pronounced positive changes observed in the exercise groups. Lastly, significant decrease in depression along with improvements in quality of life observed in the exercise group (PROs), while no change in quality of life and slight increases in depression in patients on the control group, once again support the idea that exercise during breast cancer helps patients to live a higher overall quality of life than patients that do not engage in regular exercise training.

The inclusion of resistance training on the study designs during 2007-2013 as a study arm or even as the main exercise training mode, has been utilized with the

objective of producing more effective changes in overall functionality and to alleviate the negative alterations in body composition commonly observed in breast cancer patients during the entire cancer continuum (*i.e.*, increases in body mass, with concomitant increase in fat mass and loss of muscle mass; condition known as sarcopenic obesity). The inclusion of this type of training has also provided for variety in the training prescription of cancer patients, which results in increased adherence; a key factor to promote more robust physiological adaptations. A few studies did not meet the inclusion criteria for this review, however, those studies examined the effects of exercise on biological markers associated with the negative changes in body composition. This area of study is highly significant due to the influence negative changes in body composition may have on the development of secondary cancers, mortality and co-morbidities (*e.g.*, sarcopenic obesity development consequences)^[2]. Recently, an exercise-related model proposed by our group on the alleviation of negative changes in body composition and its potential associations with biomarkers of inflammation and androgenic hormones has been developed and initial investigations are promising^[56].

Very little data available today allow for a good understanding on the effects of resistance training on the outcomes included on this review. However, as expected, due to the known effects of resistance training on muscle mass gain and muscular strength, significant improvements were observed on lean body mass and upper and lower body strength on patients who participated in exercise training and were objectively measured on these outcomes.

Unfortunately, due to the small number of studies that met the rigorous criteria for inclusion in this review, the data on effects of strength training on PROs are very limited and no definite conclusion can be drawn at this time regarding the effects of resistance training on fatigue, depression, and overall quality of life in breast cancer patients. More research is desperately needed in this area of study.

There are limitations within this systematic review on the effects of exercise in breast cancer survivors that must be considered when evaluating the overall results; including a small number of studies per outcome variable included in this review, the heterogeneity of tools used to evaluate the outcome variables of interest, significant differences in the characteristics of the exercise prescription utilized, and to a much lesser extent, the evaluation of patients in and off treatment included together in the analyses of the data. The latter could impose difficulty in interpreting the results, however, a priori evaluation of the overall changes in the parameters included in this review indicated very little clinical difference between results of studies that evaluated patients undergoing treatment and those off treatment. Therefore, we decided that for a chronological overview of the current literature in the topic, the clinical difference observed between patients in and off treatment would not drastically under

or overestimate the evaluation of the outcome variables studied. Since this is a relatively new area of research and until larger randomized trials are completed (controlling for many variables that can confound study results such as type, frequency, intensity of exercise, different types of cancer treatments, age of patients, previous fitness levels, and other co-morbidities that can further diminish the tolerability for exercise participation) definite conclusions and more precise exercise summary guidelines can be presented.

Despite these methodological limitations and our inability to currently provide specific exercise guidelines for breast cancer patients, general-generic exercise guidelines^[2] are available and can be used to guide safer participation in exercise programs. It is recommended by the exercise guidelines set forth by the American College of Sports Medicine^[2], that patients should engage, whenever possible, in 150 min/wk of moderate-intensity exercise spread throughout the week, that the exercise prescription should include aerobic and resistance modes of exercise, and that the prescription should be individualized taking into consideration the limitations of each patients.

In conclusion, order to improve the knowledge in the area of research examining the effects of exercise in breast cancer patients more studies are necessary. These studies should include larger samples sizes, involve randomized clinical controlled trials, provide more detailed descriptions of the sample studied (*i.e.*, presence of other co-morbidities, previous physical activity levels, amount of therapies received, *etc.*) and all testing and exercise protocols (extremely important consideration for improvement in the quality of the science) in their published reports, and provide better reporting on adverse events due to exercise testing and training. Furthermore, studies examining the mechanisms involved in the plasticity of different physiological systems due to different exercise training protocols in breast cancer patients are critical for continued progress of this area of research. Nevertheless, based on the current data available in this area of research, exercise training appears to be safe for most patients and improvements in physiological, psychological, and functional parameters can be attained with regular participation in moderate intensity exercise.

COMMENTS

Background

An ever-growing number of studies in the area of exercise oncology, especially those examining the effects of exercise training in breast cancer survivors, speak loudly to the increased interest by the medical community in exploring complementary interventions that can alleviate treatment-related side effects and improve quality of life of cancer patients.

Research frontiers

Most specifically, this review focuses on presenting and discussing the results of the effects of exercise training on the most commonly evaluated outcomes in the area including physiological parameters of cardiorespiratory function, body composition, and muscular strength, and patients reported outcomes that evaluated fatigue, depression, anxiety, and overall quality of life.

Innovations and breakthroughs

For organizational purposes a chronological description of studies results, stud-

ies common characteristics, and commentaries on changes observed in this area of research over the past 25 years are discussed.

Peer review

The arm of this study was to review the effect of exercises for patients with breast cancer in the past 25-years. It is fairly well designed and the statistical analyses appear reasonable. It is worthy of recommending for publication.

Abstract

To evaluate the overall effectiveness of treatments for metastatic colorectal cancer, a meta-regression was undertaken in which randomized studies from 2000 to 2012 were evaluated and the temporal trend for both overall survival (OS) and progression-free survival (PFS) was determined. Our literature search was essentially based on PubMed but information sources were scanned. Trials were included if a fluoropyrimidine regimen was given to at least one arm and information on PFS and OS was available. Medians for OS and PFS were our end-points. Covariates included temporal trend, arm allocation and Kirsten rat sarcoma status. In analyzing 130 treatment arms identified through our literature search, meta-regression showed an improvement with time for both OS ($P < 0.001$) and PFS ($P < 0.001$). The increase in median OS was from 14.9 mo in 2000 to 18.8 mo in 2012. Likewise, the improvement in PFS was from 5.7 to 8.1 mo. Multivariate analysis confirmed these findings. A post-hoc multivariate analysis was focused on patient arms treated with bevacizumab ($n = 17$) or without bevacizumab ($n = 113$); the multivariate-adjusted improvement attributable to bevacizumab was 1.66 mo for OS ($P = 0.071$) and 1.59 mo for PFS ($P = 0.002$). Overall, our results indicate

that OS and PFS have improved from 2000 to 2012 but the extent of this improvement is small and seems to have quite a questionable clinical relevance.

Key words: Metastatic colorectal cancer; Chemotherapy; 5-Fluorouracil; Chemotherapy; Irinotecan; Oxaliplatin; Bevacizumab; Meta-analysis; Meta-regression

Core tip: We conducted out a meta-regression in which randomized studies from 2000 to 2012 were evaluated and the temporal trend was analyzed [end points: overall survival (OS), and progression-free survival (PFS)]. Our literature search identified all trials employing a fluoropyrimidine regimen. Covariates included temporal trend, arm allocation and Kirsten rat sarcoma status. According to meta-regression of 130 treatment arms, the improvement between 2002 and 2012 was from 14.9 to 18.8 mo for OS ($P < 0.001$) and from 5.7 to 8.1 mo for PFS ($P < 0.001$). Our study indicates that OS and PFS have improved from 2000 to 2012 but the extent of this improvement is small.

Messori A, Conti M, Fadda V, Maratea D, Trippoli S. Meta-regression of treatments for metastatic colorectal cancer: Quantifying incremental benefit from 2000 to 2012. *World J Clin Oncol* 2014; 5(2): 191-193 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i2/191.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i2.191>

TO THE EDITOR

It is widely accepted that treatments for metastatic colorectal cancer (mCRC) have considerably improved over the past decade^[1-7], but quantitative estimates of increased benefits with time are scarce and have rarely

Figure 1 Meta-regression: temporal trend of medians for overall survival (A) and progression-free survival (B). These graphs refer to 130 treatment arms from 52 randomized studies. The regression lines were the following: A: Median (mo) = $0.331 \times \text{yr} - 674.138$ ($P < 0.001$); B: Median (mo) = $0.2026 \times \text{yr} - 399.538$ ($P < 0.001$). Symbols: each study is represented by a circle, the area of which is proportional to its statistical weight. Experimental arms are depicted in red while control arms are in black. OS: Overall survival; PFS: Progression-free survival.

relied on meta-analysis techniques. The temporal trend of this therapeutic improvement has mostly been based on narrative reviews or, in some cases, on traditional meta-analyses focused on hazard ratios^[8-10]. No attempt has been made to apply meta-regression. Furthermore, the only studies available in this area^[8,9] have generally preferred relative indexes (*e.g.*, hazard ratios) rather than absolute end-points like median values of survival^[11].

We describe the results of a meta-regression of randomized studies conducted from 2000 to 2012, in which we determined the temporal trend of overall survival (OS) and progression-free survival (PFS). The literature search for our analysis was nearly identical to that of Sidhu *et al.*^[8], although we extended our time horizon up to December 2012. Randomized trials were included if they met two simple criteria: fluoropyrimidine-based regimens in at least one arm and data available on PFS and OS. Our statistical methods were the same as those described previously^[12-15]. Temporal trends (focused on medians as end-point) were determined for OS and PFS. Time as covariate was defined as publication year for each trial. The statistical model was random effect. Both univariate and multivariate analyses were performed; in the latter case, two additional covariates were tested (arm = experimental group versus controls; Kirsten rat sarcoma (KRAS) status = wild-type, not reported, or mutant type). After

completing our literature search, 130 treatment arms were found to meet our inclusion criteria. Most of these trials employed oxaliplatin or irinotecan; bevacizumab was given to a total of 17 treatment arms.

On the basis of these 130 treatment arms, our meta-regression (univariate analysis) found a significant improvement with time for both end-points of OS and PFS (Figure 1). From 2000 to 2012, median OS increased from 14.9 to 18.8 mo. Likewise, median PFS improved from 5.7 to 8.1 mo. The absolute improvement for every 10 years was 3.3 and 2.0 mo for OS and PFS, respectively.

At multivariate analysis, our results for OS showed that the difference between the experimental groups and the control groups was not statistically significant ($P = 0.24$). Although this result seems to be surprising, one should recall that, over this long time period, there has been a progressive adoption of more and more effective treatments firstly in the experimental groups and then in the control groups. In other words, treatments showing a small but significant incremental benefit when given to the experimental arms have then been incorporated as new standards for the control groups. So, this fact has contributed in this analysis to reduce the magnitude of the overall benefit (expressed with reference to the comparison of experimental arms *vs* control arms). On the other hand, a significant effect at meta-regression was found for publication year ($P < 0.001$; direction of the benefit: improvement with time) and KRAS type ($P = 0.014$; direction of the benefit: improvement with wild-type). The multivariate adjusted improvement in OS was 3.2 mo per decade (nearly identical to that of the unadjusted analysis).

As regards PFS, our multivariate analysis showed that KRAS type was not statistically significant ($P = 0.23$), whereas significance was achieved by publication year ($P < 0.001$; improvement with time) and arm ($P = 0.033$; improvement for experimental arm *vs* controls). The improvement in PFS per decade was identical to that of the unadjusted analyses. Further details on our meta-regression are reported in the appendix.

Our results highlight the profound difference in this area between statistical significance and clinical relevance. While an improvement in OS (and also in PFS) has clearly occurred from 2000 to 2012, the extent of this improvement is small and so the effect of innovation in this area seems to be scarcely relevant from a clinical standpoint.

In a post-hoc multivariate analysis, we tested whether the patient arms treated with bevacizumab ($n = 17$) had better outcomes than those not given this antibody ($n = 113$); this analysis included all previous covariates except “experimental *vs* control arm” (omitted to avoid confounding with the bevacizumab-based covariate). The multivariate-adjusted improvement with bevacizumab was 1.66 mo for OS ($P = 0.071$) and 1.59 mo for PFS ($P = 0.002$); the corresponding univariate (unadjusted) values were 2.21 mo ($P = 0.023$) and 1.74 mo ($P = 0.001$), respectively.

Estimating the magnitude of incremental benefits expected from treatments for mCRC has important implications both for this specific therapeutic area and from a more general perspective. For example, from a cost-effectiveness viewpoint, the prolongation of about 3 mo in OS observed in these mCRC patients does not justify the increased expenditure of more than 20000 euros that is frequently claimed for targeted agents; thresholds in this area are in fact at around 5000 euros per month gained.

This approach of evidence synthesis focused on temporal trends deserves to be tested in as many therapeutic areas as possible because a systematic application can be helpful to decision-makers, in particular to balance costs and benefits across different treatments. Finally, the main strength of our study is that a formal analytical tool was employed to determine the temporal trend of outcomes; quantifying these trends through meta-regression can generate more reliable results than those obtained through a purely narrative approach. The limitations of our study include the lack of patient-level data and the small number of studies focused on bevacizumab.

APPENDIX I-V Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Clinical Oncology*, Vaclav Vetvicka, Professor, Department of Pathology and Laboratory Medicine, University of Louisville, 511 S. Floyd St., MDR Bldg., Rm. 224, Louisville, KY 40202, United States

AIM AND SCOPE *World Journal of Clinical Oncology* (*World J Clin Oncol*, *WJCO*, online ISSN 2218-4333, DOI: 10.5306) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJCO covers a variety of clinical medical topics, including etiology, epidemiology, evidence-based medicine, informatics, diagnostic imaging, endoscopy, tumor recurrence and metastasis, tumor stem cells, radiotherapy, chemotherapy, interventional radiology, palliative therapy, clinical chemotherapy, biological therapy, minimally invasive therapy, physiotherapy, psycho-oncology, comprehensive therapy, and oncology-related nursing. Priority publication will be given to articles concerning diagnosis and treatment of oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJCO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING *World Journal of Clinical Oncology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Ductal carcinoma *in situ* (DCIS) is a non-obligate precursor of invasive breast cancer with a variable biological behavior which is difficult to accurately predict using the current clinico-pathological parameters. Randomized controlled trials have demonstrated that adjuvant radiotherapy (RT) reduces the risk of local recurrence after adequate local excision of DCIS. Tamoxifen may be considered as an adjuvant endocrine treatment in patients with high risk estrogen receptor positive disease. There is however a growing consensus that RT can be safely omitted in a subgroup of patients with favorable biological features in order to avoid overtreatment. The sentinel node biopsy is not routinely indicated but should be considered in women undergoing mastectomy for DCIS. The discovery of molecular signatures that accurately predict the biological behavior of this common malignancy will facilitate a personalized treatment approach in the future.

Key words: Ductal carcinoma *in situ*; Treatment; Radiotherapy; Tamoxifen

Core tip: Localized ductal carcinoma *in situ* (DCIS) is treated with adequate local excision followed by radiotherapy (RT) in most cases whereas extensive disease

INTRODUCTION

Ductal carcinoma *in situ* (DCIS) represents an intra-ductal epithelial proliferation of malignant cells and is considered to be a non-obligate precursor of invasive breast cancer. It currently accounts for approximately one fifth of newly-diagnosed breast cancers and its incidence has been rising due to the wider adoption of screening mammography and the introduction of high spatial resolution magnetic resonance imaging (MRI)^[1,2]. DCIS usually presents as mammographic micro-calcifications or non-mass enhancement (with segmental distribution) on MRI. The latter is more sensitive imaging modality than mammography in detecting intermediate and high grade DCIS and is more accurate in estimating the disease extent^[2]. Symptomatic DCIS is much less common nowadays and clinically presents as a palpable mass or nodularity, pathological nipple discharge or occasionally found as an incidental pathological finding during surgery for other reasons such as reduction mammoplasty. Furthermore symptomatic DCIS is associated with higher rates of local recurrence (LR) after treatment compared with screen-detected disease^[1].

The overall risk of DCIS progressing to invasive breast cancer has been reported to range from 14% to 75% depending upon the nuclear grade^[1]. This indicates that a significant proportion of DCIS cases are not life-threatening and do not require any treatment. The challenge however is to accurately identify such cases in order to avoid overtreatment. Unfortunately the current

Figure 1 Skin-sparing mastectomy technique (with or without nipple-areola preservation) facilitates immediate reconstruction with improved aesthetic outcomes in women opting to have immediate reconstruction.

clinico-pathological parameters used in clinical practice are unable to identify clinically less relevant disease and therefore all DCIS lesions require at least surgical excision.

SURGICAL TREATMENT

Optimal treatment of DCIS requires adequate surgical excision of the lesion with tumor-free surgical margins^[1]. The surgical treatment may consist of breast conservation surgery (BCS) or mastectomy with or without immediate breast reconstruction.

The sentinel node biopsy (SNB) is not routinely indicated for pure DCIS and should be reserved for patients undergoing mastectomy^[1]. There is a growing consensus that a 2 mm tumor-free margin represents an adequate surgical margin^[1]. The skin-sparing mastectomy (SSM) technique (with or without nipple-areola preservation) facilitates immediate reconstruction with improved aesthetic outcomes (Figure 1) in women opting to have immediate reconstruction^[3].

ADJUVANT TREATMENTS

Having addressed the issue of surgical treatment and the need for complete removal of DCIS lesions in the light of current knowledge, the next issue to address is the need for adjuvant treatments.

Patients undergoing mastectomy for DCIS have an excellent prognosis and do not usually require further treatment. Post-mastectomy radiation should be considered for extensive high grade DCIS with significant involvement of the surgical margins^[1]. If the DCIS is ER positive, then adjuvant endocrine therapy can be considered in such cases (extensive disease involving surgical margins) and in the context of chemoprevention of malignancy in the contra-lateral breast.

For women undergoing BCS, all randomized controlled trials (RTCs) have demonstrated that adjuvant radiotherapy (RT) reduces the risk of LR after adequate local excision of localized disease^[4-6].

A recent update from the NSABP B-17 and NSABP B-24 trials^[4] has demonstrated that adjuvant RT is as-

sociated with a significantly lower LR rate after a median follow up of 15 years. Approximately one half (54%) of the recurrences were invasive, and for these patients the overall survival (OS) was significantly lower [hazard ratio (HR) of death = 1.75, 95%CI: 1.45 to 2.96, $P < 0.001$].

The EORTC 10853 randomized trial also showed that RT reduced the risk of any LR by 48% (HR = 0.52; 95%, $P < 0.001$) after a median follow up of 15 years^[5].

The UK/ANZ DCIS trial investigated the effect of adjuvant treatment with tamoxifen after BCS and RT for DCIS^[6]. After a median follow-up of 12.7 years, tamoxifen use was associated with a significant reduction in LR and the incidence of contra-lateral breast cancer (HR = 0.71, 95%; $P = 0.002$).

A combined analysis of the UK/ANZ DCIS and B-24 trials revealed that the addition of tamoxifen to BCS and RT for DCIS reduced the risk of invasive LR and the incidence of *in situ* disease in the contralateral breast regardless of age with no improvement in OS^[7]. Taken together these studies suggest that tamoxifen is not routinely indicated after BCS for ER+ DCIS, but can be considered in selected cases at an increased risk of LR. The results of these trials should be communicated to patients in order to help them make informed decisions in the context of adverse effects of tamoxifen. The NSABP B-35 and IBIS II trials are currently evaluating whether aromatase inhibitors are more effective than tamoxifen as an adjuvant endocrine treatment after BCS for DCIS.

IS IT SAFE TO OMIT RT AFTER BCS?

It is clear that adjuvant treatments following BCS for DCIS significantly reduce the risk of LR which is invasive in 50% of LR cases. Although adjuvant therapy has not been shown to improve OS, it is reasonable to assume that reduction in invasive LR will translate into an OS benefit over time. The uncertainty remains however whether adjuvant treatments especially RT could be safely omitted in certain subgroups of patients at a low risk of LR.

Numerous prospective and retrospective studies have reported the lesion size, nuclear grade, patient's age, the presence/absence of necrosis, margin's width and the

comedo morphology to be significantly associated with the risk of^[8]. The use of these factors in combination can guide adjuvant treatment recommendations in order to minimize overtreatment in the context of multidisciplinary management. For example a woman who had complete excision of a low grade DCIS measuring less than 2 cm with a tumor-free margin of at least 1 cm does not require any further treatment, whereas a premenopausal woman who had BCS for a 3 cm high grade ER+ DCIS will benefit from RT and tamoxifen. The Van Nuys prognostic index includes tumor size, nuclear grade and margin width. Patients with low Van Nuys scores can avoid adjuvant treatment after BCS^[9].

There is a consensus however that the above predictive factors are crude and that there is a need to develop more accurate predictors of DCIS behavior based on the molecular profile of the tumor. The Oncotype-DX-DCIS genomic score has been recently introduced to guide RT recommendations after BCS^[10]. This multi-gene expression assay calculates a score based on 7 cancer-related genes and 5 reference genes. It was validated using formalin-fixed paraffin embedded tumor tissues and clinical outcome data from the ECOG 5194 trial which included patients treated with BCS with or without adjuvant RT^[11]. A low score (< 39) indicates a very low risk of LR and suggests that adjuvant RT can be safely omitted.

The expression of $\alpha v\beta 6$ on myoepithelial cells of DCIS has been recently reported to predict disease progression to invasive malignancy and LR. This protein up-regulates MMP-9 through TGF β causing tumor progression^[12].

Further research focused on molecular and biological profiling is likely to facilitate a personalized treatment approach to patients with newly-diagnosed DCIS in order to optimize the clinical outcome while minimizing harm from overtreatment. However such research is likely to be complicated by intra-tumor molecular heterogeneity and the role of the microenvironment in tumor development and progression^[13].

Abstract

Paraneoplastic syndromes are signs or symptoms that occur as a result of organ or tissue damage at locations remote from the site of the primary tumor or metastases. Paraneoplastic syndromes associated with lung cancer can impair various organ functions and include neurologic, endocrine, dermatologic, rheumatologic, hematologic, and ophthalmological syndromes, as well as glomerulopathy and coagulopathy (Trousseau's syndrome). The histological type of lung cancer is generally dependent on the associated syndrome, the two most common of which are humoral hypercalcemia of malignancy in squamous cell carcinoma and the syndrome of inappropriate antidiuretic hormone secretion in small cell lung cancer. The symptoms often precede the diagnosis of the associated lung cancer, especially when the symptoms are neurologic or dermatologic. The proposed mechanisms of paraneoplastic processes include the aberrant release of humoral mediators, such as hormones and hormone-like peptides, cyto-

kines, and antibodies. Treating the underlying cancer is generally the most effective therapy for paraneoplastic syndromes, and treatment soon after symptom onset appears to offer the best potential for symptom improvement. In this article, we review the diagnosis, potential mechanisms, and treatments of a wide variety of paraneoplastic syndromes associated with lung cancer.

Key words: Paraneoplastic syndrome; Small cell lung cancer; Non-small cell lung cancer; Symptom; Diagnosis; Treatment; Endocrine; Neurologic; Hematologic; Trousseau's syndrome

Core tip: A wide variety of paraneoplastic syndromes are associated with lung cancer, including endocrine, neurologic, dermatologic, rheumatologic, hematologic, and ophthalmological syndromes, as well as glomerulopathy and coagulopathy (Trousseau's syndrome). The histological type of lung cancer is generally dependent on the associated syndrome, the two most common of which are humoral hypercalcemia of malignancy in squamous cell carcinoma and the syndrome of inappropriate antidiuretic hormone secretion in small cell lung cancer. The symptoms of paraneoplastic syndromes often precede the diagnosis of lung cancer. The early detection and treatment of the underlying lung cancer offers the best outcomes for paraneoplastic syndromes.

Paraneoplastic syndromes associated with lung cancer. *World J Clin Oncol* 2014; 5(3): 197-223 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i3/197.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i3.197>

INTRODUCTION

Paraneoplastic syndromes are a group of clinical disorders that are associated with malignant diseases and are

Table 1 Criteria for the diagnosis of paraneoplastic endocrine syndromes

Abnormal endocrine function without physiologic feedback regulation
The absence of metastasis in the respective endocrine gland
Deterioration with increasing tumor burden
Improvement in endocrine function with the treatment of the tumor
Evidence of the presence of hormones in the tumor or hormone synthesis by the tumor

not directly related to the physical effects of the primary or metastatic tumors^[1]. In the current understanding, these conditions arise from secretion of functional peptides or hormones from the tumor, or inappropriate immune cross-reaction between normal host cells and initially targeted tumor cells^[2]. Although paraneoplastic syndromes can be associated with many types of malignancies, they are most frequently associated with lung cancer^[3]. The histology of lung cancer influences the type of associated paraneoplastic syndrome. Paraneoplastic syndromes occur in approximately 10% of patients with lung cancer^[1], and two of the most common are humoral hypercalcemia of malignancy (HHM) in squamous cell carcinoma and the syndrome of inappropriate antidiuretic hormone secretion (SIADH) in small cell lung cancer. There is no relation between the severity of symptoms and the size of the primary tumor, and in some cases, paraneoplastic syndromes are manifested before the diagnosis of cancer^[1]. The early recognition of paraneoplastic syndromes may contribute to the detection of a highly treatable, early-stage tumor^[2]. At other times, the syndromes may occur late in the course of disease or may appear as the first sign of recurrence^[1]. Some syndromes, such as hypercalcemia and hematologic syndromes, are associated with a poor prognosis; others, such as onconeural antibody-related neurologic syndromes, may predict longer survival. This review provides an overview of a wide variety of paraneoplastic syndromes associated with lung cancer, with an emphasis on the diagnosis and treatment of the most frequently encountered syndromes. We searched the literature on PubMed (<http://www.ncbi.nlm.nih.gov/pubmed>) using the terms “lung cancer” and “paraneoplastic syndrome”. As a result, we found more than 1000 studies published in the 21st century, and we cited these studies with priority. However, we also cited some older studies when only a few studies associated with the syndromes had been published in the 21st century.

PARANEOPLASTIC ENDOCRINE SYNDROMES

Lung cancers have a potential to synthesize and secrete peptides or hormones that lead to a variety of endocrine syndromes^[4]. There are several criteria for diagnosing a paraneoplastic endocrine syndrome (Table 1)^[4]. However, all of these criteria may not be satisfied in a given patient^[4]. In particular, the presence of hormones in the tu-

(4) Granulocyte colony-stimulating factor
Osteolytic activity at the sites of skeletal metastases

mor tissue is not always necessary for a clinical diagnosis. Several paraneoplastic endocrine syndromes have been reported (Table 2), and the three most common of which are HHM, SIADH, and ectopic Cushing's syndrome (ECS)^[4].

HHM

The incidence of hypercalcemia in patients with lung cancer ranges from 2%-6% at the initial diagnosis to 8%-12% throughout the course of the disease^[1]. The most common type of cancer related to hypercalcemia is squamous cell carcinoma, in which higher incidences up to 23% has been reported^[2,4]. The two major mechanisms of hypercalcemia in cancer patients are: (1) HHM; and (2) osteolytic activity at sites of skeletal metastasis (Table 2). HHM is considered a paraneoplastic syndrome and accounts for 46%-76% of hypercalcemia in lung cancers^[5]. Although four mechanisms of HHM have been described, the majority of HHM cases are caused by the secretion of parathyroid hormone (PTH)-related protein (PTHrP) from the tumor. Rare cases of HHM with ectopic PTH secretion by lung cancers have also been reported^[6-8]. Although ectopic 1,25-dihydroxyvitamin D secretion is frequently observed in patients with malignant lymphoma^[5], no cases of 1,25-dihydroxyvitamin D-producing lung cancer have been reported, to our knowledge. Another mechanism of HHM may be mediated by granulocyte colony-stimulating factor (G-CSF)^[9,10]. Long-term exposure to G-CSF results in the stimulation of osteoclastic bone resorption or an increase in osteoclast progenitors^[9,10].

The PTHrP has significant homology with PTH in the amino-terminal region^[11], and both PTH and PTHrP bind to a common PTH/PTHrP receptor^[12]. PTHrP and PTH exert equivalent actions in regulating bone resorption and renal calcium/phosphorus levels^[5]. However, unlike PTH, PTHrP does not increase 1-hydroxylase activity and 1,25-dihydroxyvitamin D production^[5]. In two lung squamous cell carcinoma xenograft models of hypercalcemia, the inhibition of autocrine epidermal

Table 3 Syndrome of inappropriate antidiuretic hormone secretion

Hyponatremia (serum sodium < 134 mEq/L)
Hypoosmolality (plasma osmolality < 275 mOsm/kg)
Inappropriately high urine osmolality (> 500 mOsm/kg)
Inappropriately high urinary sodium concentration (> 20 mEq/L)
Absence of hypothyroidism
Absence of adrenal insufficiency
Absence of volume depletion

growth factor receptor (EGFR) signaling has been shown to reduce plasma PTHrP and total calcium concentrations^[13]. Amphiregulin stimulation of EGFR resulted in high levels of PTHrP gene expression in squamous cell carcinomas^[14]. Furthermore, the reconstitution of the amphiregulin-EGFR signaling system in a squamous cell carcinoma line led to HHM and rapid osteolytic growth in animal models^[14].

HHM is usually found in patients with an increased tumor burden^[4], and therefore, the incidence increases late in the course of illness. A very poor prognosis has been reported in patients with hypercalcemia, with a median survival of 1-3 mo^[9,15]. The clinical features of hypercalcemia include circulatory effects (thirst, polyuria, dehydration, and renal failure), gastrointestinal effects (anorexia, nausea, vomiting, abdominal pain, and constipation), neurologic effects (fatigue, muscular weakness, confusion, lethargy, irritability, and coma), and psychiatric manifestations (depression, anxiety, and cognitive dysfunction)^[1,2,4,5]. The severity of the symptoms are influenced by the patient's baseline renal functions, neurologic conditions, and the rapidity of progression of hypercalcemia as well as the degree of hypercalcemia^[2,5,16]. Pancreatitis due to hypercalcemia is a less common but serious complication^[17].

In the absence of ionized calcium measurements, total calcium, which represents both bound and unbound calcium, should be corrected for the albumin concentration using the following formula: corrected Ca (mg/dL) = measured Ca (mg/dL) + [0.8 × (4.0 - albumin (mg/dL))]^[2]. It is important to measure the calcium and albumin concentrations at the same time because the albumin concentration is often lower than 4.0 mg/dL in patients with cancer. In addition, including the constant 0.8 in the calculation is important to avoid the overestimation of hypercalcemia when the serum albumin level is very low.

Although the optimal approach to paraneoplastic hypercalcemia is to treat the underlying tumor^[2], fluid replenishment with normal saline should be the initial treatment. This replenishment corrects the dehydration, increases the glomerular filtration rate, and also decreases renal calcium reabsorption^[2]. Loop diuretics should not be routinely used for all patients with hypercalcemia although these agents inhibit renal calcium reabsorption. However, these agents may be added after adequate fluid replenishment in order not to deteriorate the dehydration and hypercalcemia^[2,16]. Bisphosphonates such as zoledro-

nate and pamidronate have been widely used because of their inhibitory effect of bone resorption mediated by osteoclasts and less toxicity^[2]. The calcium levels in serum generally decrease within 2-4 d and reach a nadir 4-7 d after intravenous bisphosphonate administration, and the favorable efficacy usually continues for up to 3 wk^[2,16]. The time to achieve normocalcemia is positively correlated with the pretreatment level of PTHrP^[18]. The main adverse effects of bisphosphonates are renal dysfunction and osteonecrosis of the jaw^[2]. Osteonecrosis of the jaw is caused by reduced local blood flow and leads to pain, swelling, loosened teeth, and exposed bone^[2]. Calcitonin is a useful adjunctive initial therapy that inhibits bone resorption and increases the renal excretion of calcium^[4,5]. The efficacy of calcitonin appears rapidly, but the effect is often partial and temporary^[4,19]. Denosumab, a receptor activator of nuclear factor-kappa B ligand-targeted monoclonal antibody, was superior to zoledronic acid in delaying or preventing skeletal-related events in patients with bone metastases and was generally well tolerated^[20]. The efficacy of denosumab for treating HHM is currently being evaluated in a phase II clinical trial^[5].

SIADH

SIADH manifests as euvolemic hypoosmolar hyponatremia characterized by low serum osmolality and inappropriately high urine osmolality in the absence of diuretic treatment, adrenal insufficiency, heart failure, cirrhosis, or hypothyroidism (Table 3)^[21]. Clinical SIADH has been reported to occur in 7%-16% of SCLC cases^[22-24]. Approximately 70% of paraneoplastic SIADH cases are associated with SCLC^[25]. Non-small cell lung cancer (NSCLC) has also been reported as a rare cause of SIADH^[26-28]. The stage of SCLC is not related to the incidence of SIADH^[22,23]. Patients with SCLC with hyponatremia had shorter survival times than patients with normal serum sodium levels^[29,30]. In a study of 61 patients receiving two or more cycles of chemotherapy, the patients who did not fully regain normal serum sodium levels had poorer survival compared with the patients who did^[30].

Non-ADH-mediated causes of hyponatremia, including insufficient intake of sodium, sodium wasting because of drug nephrotoxicity, and infusion of hypotonic fluid, should be distinguished from SIADH in the differential diagnosis of hyponatremia^[21]. Paraneoplastic hyponatremia secondary to elevated atrial natriuretic peptide (ANP) has also been reported^[31]. Most SCLC cell lines have been shown to produce ANP^[32,33]. Of the 23 SCLC lines examined, 16 (70%) had elevated ANP levels^[33], whereas only two (8.7%) had elevated ADH levels, and these two also had elevated ANP levels^[33]. Of 11 cell lines derived from SCLC patients with hyponatremia, 9 produced ANP mRNA, 7 produced ADH mRNA, and 5 produced both ANP and ADH mRNAs^[29]. Other studies have found that the plasma levels of ANP were also elevated in SIADH^[34-37]. In addition, when hyponatremia was corrected *via* water restriction or demeclocycline administration, the plasma ANP levels decreased significantly into

the normal range^[35].

The symptoms of SIADH are affected by the development speed and the degree of hyponatremia^[2]. Headache, general fatigue, muscle weakness, and memory loss are common symptoms. Serum sodium levels less than 125 mEq/L, particularly if they develop within 48 h of hyponatremia onset, can lead to the alterations of mental and emotional status, loss of consciousness, seizures, and in some cases, even death^[2,38]. On the other hand, when hyponatremia develops slowly, neurologic complications are less likely to occur^[2,39].

The most effective long-term therapy for SIADH associated with SCLC is the treatment of the tumor itself^[4,22,23]. Chemotherapy for SCLC results in the improvement of more than 80% of cases of clinically manifested SIADH^[4,22,23]. However, with SCLC recurrence, 60%-70% of patients will experience a recurrence of SIADH as well^[4]. Rarely, chemotherapy-induced tumor lysis may be associated with the sudden onset of SIADH^[40]. In addition to the therapy directed to SCLC, other treatments are also required to normalize serum sodium levels. There are no evidence-based guidelines for managing SIADH^[21]; the recommended management is based on expert opinion^[21,39,41]. Free water restriction (< 1 L/d) is the first-line treatment for mild, asymptomatic SIADH. Adequate sodium intake, if necessary by the salt tablets, also contribute to correcting hyponatremia. In life-threatening or acute cases of severe (< 120 mEq/L), symptomatic hyponatremia, a hypertonic 3% saline infusion is administered at a rate of approximately 1 mL/kg per hour for the first several hours. In SIADH, the urine osmolality is often higher than that of normal saline (308 mOsm/kg), and in these cases, administration of normal saline will lead to the increase in volume of free water, which results in further deterioration of hyponatremia^[2]. Demeclocycline, an antibiotic in the tetracycline group, has been demonstrated to be effective in treating SIADH^[4,42]. Demeclocycline decreases the renal response to ADH, resulting in a dose-dependent and reversible decrease in the urine-concentrating ability of the kidney. Vasopressin (ADH) receptor antagonists, such as conivaptan, an intravenously administered agent, and tolvaptan, an oral agent, are also available for the treatment of SIADH^[2,43,44]. In the renal collecting ducts, these antagonists can block ADH to bind to the receptors, resulting in the urinary free water excretion rate^[39]. Although high sensitivity to tolvaptan in SIADH has been reported^[45], the United States Food and Drug Administration (FDA) announced restrictions on the use of tolvaptan in 2013 because of the risk of serious and potentially fatal liver injury. Other adverse effects of vasopressin receptor antagonists include nausea, vomiting, diarrhea, and infusion site reaction^[2]. These agents are usually administered only in the cases of the fluid restriction failure^[2]. When possible, medications that exacerbate SIADH, such as opioids, certain antidepressants, vinca alkaloids, and cisplatin, should be discontinued^[46].

ECS

The manifestations of ECS are due to hypercortisolism, which generally resulted from the uncontrolled secretion of adrenocorticotrophic hormone (ACTH) from nonpituitary tissue^[4,21]. ECS represents approximately 12% of all patients with CS^[47]. ECS caused by the production of corticotropin-releasing hormone (CRH) is rare, and only a few patients with ECS and SCLC have been reported^[48,49]. Approximately 50% of ECS cases are neuroendocrine lung tumors; carcinoid tumors and SCLC constitute 36%-46% and 8%-20% of ECS cases, respectively^[50-52]. ECS is clinically apparent in 1.6%-4.5% of SCLC cases^[53,54], although immunoreactive ACTH was found in almost all tissue extracts of lung cancer from patients without clinical evidence of CS^[55]. Rarely, ECS cases from NSCLC have also been reported^[56].

The clinical features of ECS include moon face, acne, purple striae, proximal muscle weakness, peripheral edema, hypertension, and metabolic alkalosis with hypokalemia^[21]. Almost all ECS patients show hypokalemia, and in the majority, hyperglycemia is observed^[53,54,57]. However, ECS secondary to SCLC rarely exhibits all of the classic signs of CS^[58]. One reason for this finding could be the brief duration of exposure to excessive ACTH due to the aggressive nature of SCLC^[4]. The poor prognosis of patients with ECS has been reported compared with that of patients without ECS^[57,59].

If the clinical features of CS are present in a patient with lung cancer, iatrogenic causes of CS, such as exogenous glucocorticoid use, must be excluded^[21]. The clinical practice guidelines of the Endocrine Society recommend the initial use of one of the following first-line tests with high diagnostic accuracy, based on the suitability for a given patient: (1) at least two measurements of 24-h urinary free cortisol (greater than the normal range); (2) two measurements of late-night salivary cortisol (at bedtime or between 23:00 and 00:00, greater than 145 ng/dL); and (3) the 1-mg overnight dexamethasone suppression test (the administration of dexamethasone at 23:00 or 00:00 combined with blood cortisol measurements at 08:00 or 09:00 revealing a concentration greater than 1.8 µg/dL) or, in certain populations, the 2-mg 48-h dexamethasone suppression test^[60,61]. If one of these tests produces abnormal results, further evaluation by an endocrinologist is recommended and should include one of the above tests or, in some cases, a serum midnight cortisol or dexamethasone-CRH test^[61]. For the high-dose (8 mg) dexamethasone test, urinary or serum cortisol suppression greater than 50% is considered indicative of Cushing's disease with a sensitivity of 84%-89%^[62-65]. Based on the high-dose dexamethasone test, 6%-31% of ECS patients also exhibit the suppression of serum or urinary cortisol or 17-OHCS^[65-67]. Computed tomography (CT) scanning is useful for identifying ectopic sources of cortisol. Although ¹¹¹In-octreotide scintigraphy (Octreoscan) generally does not reveal a source that is undetectable on CT, it can provide supportive functional data^[68,69].

The ideal treatment for ECS is the radical excision of the tumor^[68]. In addition to the treatment of the underlying lung cancer, the direct inhibition of cortisol secretion is the considerable treatment for ECS^[2]. Ketoconazole, metyrapone, etomidate, mitotane, and mifepristone can be used to reduce circulating glucocorticoids^[21]. Among these agents, ketoconazole might have the best tolerance in spite of having some toxicity such as nausea and liver injury^[2,70]. An additional option is octreotide, which blocks the release of ACTH, although it is not universally effective^[4,71,72]. When these medications have unsuccessful result, bilateral adrenalectomy might be considered^[4].

The prognosis of patients with ECS is influenced by tumor histology and by the severity of hypercorticolesmia because both factors affect mortality and morbidity^[68]. Most patients with ECS due to SCLC present at an advanced stage and have a poor response to chemotherapy^[1,4].

Hypoglycemia

Tumor-associated hypoglycemia is rare and insulin-producing islet cell tumor is the best known cause. Nonpancreatic tumors may also cause recurrent hypoglycemia, known as non-islet cell tumor hypoglycemia (NICTH). NICTH is usually caused by the production of insulin-like growth factor (IGF)-2 from the tumor cells^[2]. NICTH is suspected when low levels of serum insulin (usually < 1.44 IU/mL) and C-peptide (usually < 0.3 ng/mL) in addition to low levels of blood glucose with acute episodes. Moreover, the characterization of NICTH includes low levels of growth hormone (GH) and IGF-1 and normal or elevated levels of IGF-2^[2]. The IGF-2 produced by nonpancreatic tumors is usually incompletely processed or unprocessed, referred to as “big” IGF-2 because its molecular weight is 10-17 kDa, in contrast to mature IGF-2, which has a molecular weight of 7.5 kDa^[73]. Big IGF-2 impairs the formation of the heterotrimeric, 150 kDa IGF-binding protein (IGFBP) complex, which consists of IGF-1, IGF-2, IGFBP-3, and an acid-labile subunit^[73,74]. In normal individuals, most circulating IGF is bound to this complex and is prevented from displaying its insulin-like potential^[73]. When the formation of the 150-kDa complex is impaired, IGF is sequestered in a binary complex with IGFBP-3^[73,75]. In the latter complex, the bioavailability of IGF is increased and its insulin-like potential is unmasked, leading to hypoglycemia^[73,75]. Rarer cases of NICTH of the lung due to the production of insulin or IGF-1 have also been reported^[73,76].

The treatment of the underlying tumor is the optimal approach to NICTH^[2]. However, the first-line treatment should be the maintenance of adequate blood glucose levels. In the acute situation, parenteral dextrose administration is usually performed although oral intake can also be considered if possible. Intravenous administration of one 50 mL ampule of 50% dextrose fluid results in a rapid elevation in blood glucose levels^[2]. Chronic and/or recurrent hypoglycemic episodes have also been observed

in NICTH, and continuous infusion or oral intake of dextrose may be necessary. Other longer-term management includes glucagon, GH, or corticosteroids^[73,74,77,78].

Acromegaly

In the vast majority of cases, acromegaly is caused by a pituitary adenoma. Ectopic acromegaly is rare (< 1% of cases) and is usually caused by ectopic growth hormone-releasing hormone (GHRH) or, less frequently, by ectopic GH secretion from the tumors^[79,80]. The most common tumors that secrete ectopic GHRH or GH are bronchial carcinoids and pancreatic islet cell tumors^[79,81]. Other types of lung cancer associated with acromegaly have also been reported, including SCLC, bronchioloalveolar carcinoma, and epidermoid carcinoma^[82-84]. In some cases, IGF-I might play a role in the development of acromegaly^[83,85].

The routine evaluation of circulating GHRH in acromegalic patients may enable the early recognition of overproduction of GHRH because plasma levels greater than 0.3 ng/mL are virtually diagnostic of a GHRH-producing tumor^[79]. In contrast, the dynamics of ectopic GH secretion in ectopic acromegaly are characterized by high basal GH levels, which are not suppressed by glucose load, and by low or undetectable plasma GHRH levels^[80].

Complete surgical resection of the tumor is the best treatment for ectopic acromegaly, and it usually leads to the normalization of GH levels and the regression of acromegalic features^[80,86,87]. Residual, recurrent, and inoperable lesions have been successfully treated with octreotide and other somatostatin analogs^[88-91].

PARANEOPLASTIC NEUROLOGICAL SYNDROMES

Paraneoplastic neurological syndromes (PNSs) are neurological disorders caused by the remote effects of cancer and are not caused by the tumor itself, its metastasis, infection, ischemia, or metabolic disruption^[92]. In response to the development of a tumor, some antibodies against the tumor can be generated, that are known as onconeural antibodies^[2]. These onconeural antibodies and the associated onconeural antigen-specific T lymphocytes inadvertently attack both the components of the nervous system and tumor cells^[2]. Fewer than 50% of patients with PNS harbor known antibodies although many types of antibodies have been reported^[92]. Therefore, the absence of known antibodies does not rule out a diagnosis of PNS^[92]. In 80% of cases, the neurological disorder develops before the cancer becomes clinically overt, and the patient is referred to a neurologist for the identification of a neurological disorder as paraneoplastic^[92].

In 2004, an international panel of neurologists advocated two levels of evidence for the diagnosis of a PNS: “definite” and “possible”^[93]. They defined “classical” syndromes and “well-characterized” onconeural antibodies,

Table 4 Classical and non-classical paraneoplastic neurological syndromes^[93]

Syndromes of the central nervous system
Encephalomyelitis ¹
Limbic encephalitis ¹
Brainstem encephalitis
Subacute cerebellar degeneration ¹

Syndromes of the neuromuscular junction and muscle
Myasthenia gravis
Lambert-Eaton myasthenic syndrome ¹
Acquired neuromyotonia
Dermatomyositis ¹
Acute necrotizing myopathy

¹Classical syndromes.

and determined each level by combining the criteria with the evidence of cancer status (presence or absence)^[93]. PNS can affect the central nervous system (CNS), the peripheral nervous system, and the neuromuscular junction and muscles. The classical and non-classical syndromes identified by the panel are shown in Table 4. It should be noted that these syndromes are also seen in non-paraneoplastic^[2]. Particularly, more than 70% of patients with subacute sensory neuropathy and limbic encephalitis (LE) are not associated with cancer^[92]. Well-characterized and partially characterized onconeural antibodies determined by the panel are shown (Table 5). A study of 200 patients with SCLC reported prevalence rates of onconeural antibodies for Hu, CRMP5, amphiphysin, Yo, Ri, and Ma2 of 22.5%, 5.0%, 2.5%, 0.5%, 1.5%, and 1%, respectively^[94]. These antibodies may be detected in individuals without neurologic symptoms^[2,93]. In particular, a high frequency of anti-Hu antibody has been reported, including 16% of 196 SCLC patients without PNS in one study^[93]. In this regard, anti-Hu antibody titers may be important because none of the 109 SCLC patients without PNS had high titers of anti-Hu, whereas 44% of 57 patients with PNS had high titers (> 1:10000). Antibodies that occur in both cancer- and non-cancer-associated syndromes were not defined as onconeural antibodies, which include anti-acetylcholine receptor (AChR), anti-nicotinic AChR, anti-voltage-gated calcium channel (VGCC), anti-voltage-gated potassium channel (VGKC), anti-NR1/NR2 subunits

ANNA: Anti-neuronal nuclear antibodies.

of the N-methyl-D-aspartate (NMDA) receptor, and anti-glutamic acid decarboxylase (GAD) antibodies^[2,93,95]. The diagnostic criteria for PNS described by the panel are presented in Table 6. When cancer and a classical syndrome develop, the diagnosis of a PNS can be made without the presence of onconeural antibodies. The time period of five years determined in the criteria was based on previous work demonstrating that cancers almost always developed in five years after the occurrence of neurological symptoms^[93]. Importantly, even in the absence of a detected cancer, a neurological syndrome accompanied by the presence of well-characterized onconeural antibodies leads to the diagnosis of definite PNS. However, false-positive cases can exist in this set of criteria, in which cancer will never develop, although a very small number of cases are applicable^[93]. The most plausible explanation is the elimination of cancer mediated by the host immune systems^[96]. The panel emphasized that in cases of both definite and possible PNS, all other causes that might lead to the neurological symptoms should be excluded on the diagnosis of a PNS, even if onconeural antibodies are detected^[93]. In fact, neurological alterations arise from many conditions other than PNS in the patients with cancer: brain metastasis, leptomeningeal disorders, nerve root or spinal cord invasion or compression, uncontrolled electrolytes and blood glucose, and adverse effects due to treatments such as irradiation and cytotoxic agents, including vinca alkaloids, taxanes, and platinum^[2]. Opioids such as morphine, phentanyl, and oxycodone, which are often administered during cancer treatment, can also cause neurologic and psychiatric changes.

Although PNSs are rare and occur in fewer than 1% of cancer patients overall, up to 3%-5% of patients with SCLC develop PNSs^[95,97]. The irreversible destruction of neurons and nervous systems by the inflammation con-

tributes to the severity in most PNSs^[92,98,99]. PNSs are usually progressive, and they debilitate patients deeply within weeks to months in many cases^[92]. In general, a paraneoplastic case is highly suspected when symptoms are progressive in a subacute course and disability remains severe^[92]. SCLC accounts for more than 90% of cases of PNS that are positive for anti-Hu antibody [also known as type 1 anti-neuronal nuclear antibodies (ANNA1)]^[1]. The Hu antigen is normally found in neurons. However, healthy adults do not have anti-Hu antibodies because the developing CNS is sequestered from the immune system by the blood-brain barrier^[1]. Most SCLCs express the Hu antigen, and approximately 20% of patients with SCLC have detectable levels of circulating anti-Hu antibodies, although PNS will not develop in all of these patients^[1,96]. Because many types of PNS are associated with anti-Hu antibody, the term “anti-Hu syndrome” has been used as an independent entity^[21]. The clinical manifestations of anti-Hu syndrome may include encephalomyelitis, LE, brainstem encephalitis, cerebellar degeneration, opsoclonus-myoclonus, sensory neuropathy, and chronic gastrointestinal pseudo-obstruction (CGP)^[21,93]. In several patients with anti-Hu antibody-positive SCLC, the spontaneous regression of SCLC without treatment has been reported, suggesting a host immune response directed against both cancer and the nervous system^[100-102]. T and natural killer (NK) cell-mediated autoimmunity may play a role in the pathogenesis of the neurologic damage caused by SCLC^[21,103-105].

Successful treatment of SCLC favorably affects the course of PNS^[106]. Limited experience suggests that immunosuppressive therapy with a combination of IV immunoglobulin (IVIg), methylprednisolone, and cyclophosphamide may transiently stabilize the PNS; however, these treatments cannot improve PNS over the long term^[98].

Encephalomyelitis

In response to the obstacle of various levels of the CNS, patients with encephalomyelitis exhibit relevant clinical dysfunction^[93]. The terms “encephalomyeloneuritis” and “encephalo neuropathy” have also been used to describe this entity^[93]. The main clinical syndromes observed in encephalomyelitis vary and include the following: subacute cerebellar degeneration, myelitis, LE, brainstem encephalitis, and even several peripheral nervous system dysfunction such as subacute sensory neuropathy^[93]. However, if the clinical signs and symptoms are elucidative by a single level dysfunction of the CNS, the term “encephalomyelitis” should not be used, and the above described syndromes should be chosen according to the prominent symptoms^[93].

LE

LE is clinically suspected with the acute or subacute progression, over the period of several days to three months, and symptoms including personality changes, irritability, depression, seizures, memory loss, confusion, and some-

times dementia^[93,107]. Twenty percent of LE cases are associated with neoplasms^[92]. In a study of 50 paraneoplastic LE patients, 50% had lung cancer, including 40% of the SCLC patients and 10% of the NSCLC patients^[107]. Anti-Hu antibody is present in 36-50% of patients with paraneoplastic LE^[107,108]. Anti-Ma2 antibody (Ta) was detected in 20% of patients with paraneoplastic LE, typically those with testicular cancer^[107]. Anti-CRMP5 (CV2) and anti-amphiphysin antibodies have been reported less frequently^[95]. The presence of anti-VGKC antibodies has been reported in idiopathic and paraneoplastic LE^[109,110]. The electroencephalographic findings include focal or generalized slow activity, and epileptic activity in the temporal lobes^[111]. The magnetic resonance imaging (MRI) findings reveal high signal intensities in unilateral or bilateral temporal lobes in 70%-80% of the patients using with T2 emphasized or fluid-attenuated inversion recovery (FLAIR) image^[107,111]. CSF analysis has been reported to show evidence of inflammation, including pleocytosis, elevated protein, elevated IgG, and oligoclonal bands, in 80% of LE patients and may support the clinical diagnosis^[93,107]. CSF analysis is also important to exclude carcinomatous meningitis.

Unlike most paraneoplastic syndromes of the CNS, paraneoplastic LE is well known for its favorable response to therapy^[112]. Therapy for underlying SCLC is the best treatment for paraneoplastic LE, although immunosuppressive therapy is sometimes encouraged for paraneoplastic LE. The treatment of the tumor was found to improve the neurological syndrome in 73% of patients^[107]. Chemotherapy improved neurologic symptoms accompanied by regression of the tumor^[113] or the resolution of the temporal lobe signal abnormalities^[114].

Subacute cerebellar degeneration

This syndrome has often been described using other terms, such as paraneoplastic cerebellar degeneration (PCD) or cerebellar ataxia^[2,92]. To define subacute cerebellar degeneration (SCD), the following criteria are required: no evidence of significant cerebellar atrophy more than the expected on MRI, subacute development of the symptoms within three months, and a severity of at least 3 (moderate disability; requires some help) on the Rankin scale^[93]. Approximately 50% of SCD cases have a paraneoplastic origin^[92].

Purkinje cells represent one of the most common targets of the immune response in patients with cancer, and the death of Purkinje cells results in SCD^[95]. In an analysis of 50 patients with antibody-associated SCD, the following antibodies were detected: anti-Yo (19 patients), anti-Hu (16 patients), anti-Tr (7 patients), anti-Ri (6 patients), and anti-mGluR1 (2 patients)^[115]. In contrast to limbic encephalitis, the frequency of the anti-Hu antibody in cerebellar degeneration is low (18%-31%)^[115-117]. The underlying tumor is associated with the types of antibodies present: gynecological and breast cancers are associated with anti-Yo and anti-Ri, lung cancer with anti-Hu, and Hodgkin's lymphoma with anti-Tr and anti-

Table 6 Criteria for the diagnosis of paraneoplastic neurological syndromes^[93]

Definite PNS
A classical syndrome and cancer that develops within five years of the diagnosis of the neurological disorder
A non-classical syndrome that resolves or improves significantly after cancer treatment without concomitant immunotherapy, provided that the syndrome is not susceptible to spontaneous remission
A non-classical syndrome with onconeural antibodies (well characterized or not) and cancer that develops within five years of the diagnosis of the neurological disorder
A neurological syndrome (classical or not) with well-characterized onconeural antibodies and no cancer
Possible PNS
A classical syndrome, no onconeural antibodies, and no cancer, but a high risk of an underlying tumor
A neurological syndrome (classical or not) with partially characterized onconeural antibodies and no cancer
A non-classical syndrome, no onconeural antibodies, and cancer present within five years of the diagnosis

PNS: Paraneoplastic neurological syndromes.

mGluR1^[115]. In fact, 14 (88%) of 16 anti-Hu-positive SCD patients had lung cancer^[115]. Lung cancers associated with anti-Ri^[118] or anti-Tr^[119] have also been reported, with the most common being SCLC, although NSCLC has also been reported^[119-121]. It has been reported that P/Q-type VGCC antibodies, which are thought to be associated with the development of Lambert-Eaton myasthenic syndrome (LEMS), were present in 20%-44% of SCD cases^[116,122]. A recent study found that the intrathecal injection of P/Q-type VGCC antibodies from PCD led to ataxia in mice, suggesting a pathogenic role in the development of PCD^[123]. It is also interesting that LEMS was reported to be present in 16%-40% of SCD cases associated with lung cancer^[116,122]. Serum from a patient with SCD without typical onconeural antibodies showed reactivity to protein kinase C of the Purkinje cells^[121], which may suggest another immune response-mediated mechanism. In addition, ZIC antibodies were identified in 15% of patients with SCD and SCLC^[124], although the role of ZIC antibodies in the development of SCD is not fully understood.

The clinical presentation of SCD includes ataxia, diplopia, nystagmus, dysphagia, dysarthria, vertigo, dizziness, nausea, and vomiting^[2,92]. Nystagmus and positional vertigo have also been reported^[118,125]. In contrast to LEMS, the treatment of the tumor and/or immunomodulation have not been reported to alter the course of SCD^[122]. This finding might be due to a difference in the reversibility of VGCC-induced damage to terminal neurons and Purkinje cells in the cerebellum. However, early treatment after onset has the potential to improve these symptoms^[126,127].

LEMS

LEMS is a presynaptic disorder of neuromuscular transmission characterized by impaired quantal release of acetylcholine, which causes proximal muscle weakness,

Table 7 Criteria for the diagnosis of Lambert-Eaton myasthenic syndrome

Clinical features
(1) Proximal muscle weakness
(2) Autonomic symptoms
(3) Reduced tendon reflexes
Anti-voltage-gated calcium channel antibodies
Repetitive nerve stimulation abnormalities
(1) Low compound muscle action potential
(2) Decrease > 10% at low frequency (1-5 Hz)
(3) Increase > 100% after maximum voluntary contraction or at high frequency (50 Hz)

depressed tendon reflexes, and post-tetanic potentiation, as well as autonomic changes^[128]. Approximately 50% of patients with LEMS have a tumor^[129,130]. The tumor type that occurs in these patients is almost always SCLC, although there have been a few reports of NSCLC^[130,131]. Higher frequencies of limited disease in patients with SCLC-LEMS have been reported than in patients with SCLC without LEMS (66% *vs* 40%), most likely because of early detection^[132]. In almost all patients (96%), SCLC was found within 1 year of LEMS diagnosis^[132]. In the most patients, a symptom of LEMS comes first, and then SCLC is diagnosed. In only 7% of SCLC-LEMS cases, the diagnosis of SCLC preceded the recognition of LEMS^[132].

The diagnosis of LEMS is based on clinical symptoms and signs, electrophysiological studies, and the detection of autoantibodies (Table 7)^[133]. In 80% of patients, the first symptom is muscle weakness of proximal legs^[134]. The muscle weakness usually spreads proximal to distal regions, involving the feet and hands, and caudal to cranial regions, finally reaching the oculobulbar regions^[133]. It has been reported that the rapidity of development is more significant in SCLC-LEMS compared with LEMS without SCLC^[134]. In contrast to myasthenia gravis (MG), limited muscle weakness of the external eye regions is rarely observed^[133]. Characteristically, the impaired reflexes and the muscle weakness can improve after a brief isometric muscle contraction (post-exercise facilitation)^[135]. However, a lack of facilitation does not exclude a diagnosis of LEMS^[135]. Autonomic dysfunction is also found in more than 80% of patients with LEMS^[129,130,134,136]. The most common symptom of autonomic dysfunction is dry mouth, and others include constipation and erectile dysfunction in men^[133]. Even if a patient does not volunteer the presence of these symptoms, it is important to specifically inquire about them^[135].

On electrodiagnostic study, the first compound muscle action potential (CMAP) amplitude is low in the basal condition, and it becomes even lower at low-frequency stimulation (2-5 Hz)^[133]. This phenomenon is due to a lack of release of Ach molecules at the junction. In contrast, post-exercise stimulation or high-frequency stimulation (50 Hz) results in an increase in CMAP amplitude. The easiest and most reliable means of repairing the transmission defect is to provide a brief isometric

voluntary muscle contraction and to measure the CMAP amplitude before and after exercise^[133]. In typical patients with LEMS, the amplitude increases significantly, by greater than 100%, which establishes the presynaptic blockage of the neuromuscular transmission^[135]. Although comparable sensitivity has been reported at high-frequency stimulation, this test should be avoided if possible because it is very painful^[133]. A greater than 100% increase in post-exercise stimulation or high-frequency stimulation has a sensitivity of 78%-85% and a specificity of 100% for LEMS^[137,138]. A cut-off of a 60% increase showed a sensitivity of 97% for LEMS and a specificity of 99% for excluding MG^[137]. In practice, an increase in the amplitude to greater than 60% in several muscles can be used to confirm the diagnosis^[135]. Higher diagnostic sensitivity with the 10-second exercise compared with 30-second exercise has been reported^[139].

Antibodies against the P/Q-type VGCC are elevated in more than 95% of patients with SCLC-LEMS, whereas antibodies against the N-type VGCC are elevated in approximately 40% of these patients^[135]. These antibodies are also elevated in approximately 70% of patients with LEMS without tumors^[135]. Patients who are positive for N-type VGCC antibodies usually have the P/Q-type VGCC. However, two cases with only N-type VGCC antibodies have also been reported in patients with squamous cell lung carcinoma^[140]. Although it has been reported that P/Q-type VGCC antibodies are very specific for LEMS, they have also been detected in 1%-4% of patients with SCLC without any neurological dysfunction^[133]. SOX1 is the antigen recognized by anti-glial nuclear antibody-positive sera^[117]. SOX1 antibodies were present in 64% of patients with LEMS and SCLC but in no patients with idiopathic LEMS^[117]. In another report that assessed several types of SOX, SOX antibodies had a sensitivity of 67% and a specificity of 95% for discriminating between LEMS with SCLC and non-tumor LEMS^[141].

The treatment of LEMS is threefold, including treatment of the underlying cancer, symptomatic treatment, and immunotherapy^[135]. After the detection of cancer, the patient should be treated accordingly. It is important to remember that two-thirds of patients with SCLC-LEMS have a limited form of the disease, in which effective treatment could lead to sustained clinical remission^[132,142,143]. The 3,4-diaminopyridine has been used as the first-line treatment for the patients with symptomatic LEMS^[133]. This agent blocks VGKC, and prolongs the opening time of VGCC and the action potentials at terminals of the motor nerves^[135,144]. As a result, there is an increase in the influx of calcium into the nerve terminal, which is subsequently followed by a release of Ach^[135]. A recent study showed that aminopyridines could target the VGCC β subunit leading to enhancement of synaptic and neuromuscular transmission^[145]. Four controlled trials of 3,4-diaminopyridine compared with placebo in a total of 54 patients with LEMS reported significant improvements in the primary outcome, muscle strength score,

or myometric limb measurement for hours to one week following treatment and significant improvements in the resting CMAP amplitude following 3,4-diaminopyridine administration^[128,146-149]. Adverse events reported for 3,4-diaminopyridine treatment during the trials include epigastric discomfort, brief perioral tingling, digital paresthesia, and insomnia^[128,146-149]. The starting dose is 5-10 mg 3-4 times per day, and a maximum dose is 60-80 mg per day^[135,150]. The risk of seizures increases in a dose-dependent manner although it is mostly reported by administration of approximately 100 mg per day^[133,146,148,150]. In addition, treatment with prednisolone and azathioprine for long time might be chosen if some symptoms remain^[133]. In 46 of 104 (44%) patients with SCLC-LEMS, prednisolone was required, and in many patients, azathioprine was also administered for the management of LEMS^[133]. However, the effects of corticosteroids and immunosuppressive agents have not been tested in randomized controlled trials. A single cross-over trial reported a significant improvement in myometric limb strength with intravenous immunoglobulin (IVIg) compared to placebo^[151]. IVIg treatment resulted in an improvement in resting CMAP amplitudes compared with placebo, but this difference did not reach statistical significance^[151]. However, a combination of 3,4-diaminopyridine, prednisolone, and azathioprine could lead to the satisfactory management in most patients with SCLC-LEMS, in addition to chemotherapy^[133].

CGP

Pseudo-obstruction as a paraneoplastic manifestation of SCLC was first reported in 1975^[152]. An autopsy of a patient who had abdominal pain and obstipation revealed autonomic neuropathy limited to the gastrointestinal tract, which was considered to be a remote effect of carcinoma^[152]. CGP is now a well-known autonomic neuropathy^[153]. This syndrome is characterized by severe gastrointestinal dysmotility without evidence of mechanical obstruction, leading to chronic pseudo-obstruction accompanied by abdominal pain, nausea, vomiting, and, more frequently, severe constipation^[92,153]. Gastroparesis is a disorder of the stomach caused by delayed gastric emptying in the absence of mechanical obstruction^[154]. Gastroparesis has been described as a complication of several malignancies, including lung cancers, although diabetes mellitus is the most common identifiable cause of benign gastroparesis^[154]. This "malignant gastroparesis" includes postvagotomy syndrome, cancer invasion to the autonomic nervous system, and paraneoplastic dysmotility of the stomach as a subtype of CGP^[154].

In an analysis of 162 anti-Hu antibody-positive patients, 142 patients (88%) had cancer^[155]. Of these 142 patients, SCLC was proven in 132 (93%). Although sensory neuropathy was the most common neurologic syndrome, 23% of patients had gastrointestinal symptoms^[155]. In another report, anti-Hu antibody was detected in 8 of 9 patients with CGP associated with SCLC (one patient was not tested)^[156]. CGP is often the first

manifestation of the malignancy^[155,157]. Although SCLC is most common in CGP, NSCLC has also been described as an underlying malignancy^[155,156].

Histopathology has shown marked mononuclear cell infiltration of the myenteric plexus with less involvement of the submucosal plexus and a decrease in the number of myenteric plexus neurons^[158]. Immunohistochemical staining showed infiltration by a mixture of B-cell and T-cell lymphocytes and plasma cells, and sparse and disorganized interstitial cells of the Cajal network^[158,159]. The inflammatory/immune response in enteric ganglionitis leads to neuronal dysfunction and degeneration over time and sometimes results in the complete loss of enteric neurons^[160]. The early treatment of cancer appears to offer the greatest chance for the improvement of CGP^[161]. A case of successful treatment with octreotide, a somatostatin analog, has also been reported^[153].

Polymyositis /dermatomyositis

Polymyositis (PM)/dermatomyositis (DM) is an autoimmune-based systemic inflammatory myopathy. In the case of DM, the characteristic cutaneous manifestations include scaly and erythematous plaques on the dorsal sides of the both hands (Gottron's sign), edematous rash of the eyelids and periorbital (heliotrope rash), photosensitive poikilodermatous eruptions, and periungual telangiectasia^[92]. In a review of 2439 patients with DM, 574 patients (24%) have been reported to be associated with malignancy, and 97 (10.2%) of 947 patients with PM had an associated malignancy^[162]. A wide variety of malignancies has been associated with DM and are significantly influenced by the patient ethnicity^[162]. Carcinomas of the nasopharynx (21%), breast (15%), lung (15%), ovary (9%), and colon (5%) have been reported as the most common malignancies associated with DM^[162-166]. In an analysis of population-based cohorts derived from the Caucasian populations of Sweden, Denmark, and Finland, 115 of 618 patients (18.6%) with DM developed malignancies after the diagnosis of DM^[167]. The types of malignancy that increase in relative risk significantly were carcinomas of ovary (standardized incidence ratio 10.5), lung (5.9), pancreas (3.8), stomach (3.5), and non-Hodgkin's lymphoma (3.6)^[167]. In a report of 138 Chinese patients with DM and cancer, the most common malignancies were carcinomas of nasopharynx, breast, and the lung^[168]. More severe signs and symptoms in skin and muscle often indicate an underlying malignancy in patients with DM^[162]. The characteristic cutaneous manifestations associated with malignancy include cutaneous leukocytoclastic vasculitis^[169], bullous DM^[170], cutaneous necrosis^[164,165], periungual erythema^[165], and necrotizing myopathy^[171]. Regarding myositis-specific antibodies, a low frequency of anti-Jo-1 antibody has been reported in cancer-associated myositis, whereas anti-p155/140 antibodies have been identified in 50% of cancer-associated myositis cases, much higher than in non-cancer-associated myositis (4.1%)^[172].

In PM/DM associated with lung cancer, the com-

mon histological types were SCLC (29%) and squamous cell carcinoma (21%)^[173]. PM/DM associated with lung adenocarcinoma appears to be rare^[171,174,175]. A case of PM with bronchopulmonary carcinoid has also been reported^[176]. The onset of PM/DM is frequently observed before the diagnosis of lung cancer^[173].

The role of internal malignancies in the development of DM remains controversial. Several case reports have highlighted a causal role of cancer on development of DM because DM significantly improved after the successful therapy of lung cancer^[162,174,177]. Furthermore, among 22 patients with cancer-associated DM who received effective antitumor therapy, 16 patients (73%) experienced remission of DM^[178]. In contrast, the improvement of DM after treatment for cancer has been observed only in 18%-37% of cases^[179-183]. It has been reported that myositis-associated autoantigens, Jo-1 and Mi-2, were expressed at high levels in myositis muscle, particularly in regenerating muscle fibers, and in adenocarcinomas of the lung and breast, but not in the corresponding healthy tissues^[162,184]. Thus, a model of "cross-over" immunity was proposed in which an initial cellular immune response directed at tumor cells overexpressing antigens can also target muscles commonly expressing antigens in patients with myositis^[162,184]. In this setting, a causative role of malignancy in the development of DM can be considered. However, malignancy may also trigger the development of DM. In a case report, DM developed in a patient with SCLC, and the DM went into remission after the successful treatment of SCLC. The DM recurred 10 years later without any malignancy^[180]. In this case, internal malignancy was not a prerequisite for DM relapse; the patient had had an occult autoimmune mechanism of DM. SCLC triggered the expansion of an autoreactive T cell clone as an autoantigen, and DM resulted^[180]. Because of the aging of the immune system, the autoreactive clone gradually increased over 10 years and induced DM again^[180].

A combination of corticosteroids and tumor resection or chemotherapy can improve the symptoms of DM associated with lung cancer^[173,180]. It has also been reported that an epidermal growth factor receptor (EGFR)-tyrosine kinase inhibitor (TKI), gefitinib, resulted in the dramatic recovery of a patient with DM associated with adenocarcinoma^[174].

Opsoclonus-myoclonus

Opsoclonus-myoclonus (OM), or opsoclonus-myoclonus-ataxia (OMA), is a unique movement disorder characterized by conjugate, randomly directed, rapid eye movements (opsoclonus) and by myoclonus occurring in the face, head/neck, trunk, and limbs^[185]. Some patients also exhibit cerebellar dysfunction with dysarthria and truncal ataxia, and a few become confused or even comatose^[186]. Various etiologies have been implicated in OM, including infectious, toxic, metabolic, degenerative, and paraneoplastic disorders^[185]. An underlying malignancy accounts for 20% of cases with OM^[187]. In

a Spanish survey in which infectious, toxic, or metabolic disorders were excluded, 14 (58%) of 24 patients with OM were paraneoplastic, and the remaining 10 cases were idiopathic^[186]. Among tumors associated with OM, the most common were SCLC (9 patients; 64%) and breast cancer (2 patients; 14%). Rarely, NSCLC has also been reported^[186,188-191]. Antineural antibodies have been found in only a few patients with paraneoplastic OM^[186]. Antineural antibodies detected in lung cancer include anti-Ri^[190,192], anti-Hu^[186,191], anti-amphiphysin^[186], and P/Q-type VGCC^[191] antibodies. A case of OM associated with SCLC with a high anti-mitochondrial antibody titer has also been reported^[193].

In contrast to most of the other PNSs, paraneoplastic OM may remit either spontaneously, following the treatment of the tumor, or in association with clonazepam or thiamine treatment^[194]. Paraneoplastic OM has been reported to exhibit a more severe clinical course than idiopathic OM, despite treatment with IVIg or corticosteroids^[186]. When underlying tumors were treated, however, a complete or partial neurological recovery could be observed^[186]. With appropriate treatment for SCLC, approximately half of reported patients have experienced improvements in neurologic function^[195]. Tumor control is essential for the successful long-term management of paraneoplastic OM.

Subacute sensory neuropathy

A diagnosis of subacute sensory neuropathy (SSN) could be performed when the following criteria are all fulfilled: subacute development in less than 12 wk, severity of at least 3 (moderate disability) assessed by a Rankin score, onset of numbness with often pain and sensory disturbance, involvement of arms and legs (so-called gloves and stockings area), and often asymmetry at onset. Furthermore, electrophysiological findings have shown the significant sensory fibers disturbance and, in at least one sensory nerve, the absence of sensory nerve action potentials sensory nerve^[93]. The motor nerves may also be minimally disturbed^[196]. Tendon reflexes are depressed or absent^[194], and patients often exhibit autonomic, cerebellar, or cerebral abnormalities^[196]. SSN occurs in approximately 75% of patients with paraneoplastic encephalomyelitis, is predominant in 50%, and is clinically pure in 25%^[194,197,198]. In a review of 26 patients with paraneoplastic SSN, 19 (73%) had SCLC^[196]. There was a striking predominance of females (20:6)^[196]. SSN usually predates the diagnosis of cancer, with a median delay of 3.5-4.5 mo^[194,197,198].

SSN in patients with SCLC is typically associated with anti-Hu antibody^[194,199]. Less frequently, SSN in patients with SCLC is associated with anti-CV2 (CRMP-5), anti-amphiphysin, or anti-Yo antibodies^[194,199]. A patient with SSN associated with SCLC who was positive for ganglionic neuronal acetylcholine receptor (nAChR) antibody has been reported^[200].

The early treatment of the underlying tumor appears to offer the best chance of stabilizing the neurological

symptoms^[198]. The complete response of SCLC appears to produce an improvement in neurological function^[100,106,201]. Several cases of spontaneous SCLC regression and SSN progression have been reported, suggesting a host immune response directed at both the cancer and the nervous system^[100-102]. However, immunotherapy consisting of corticosteroids, plasma exchange, and IVIg is ineffective in most cases^[194,201,202].

PARANEOPLASTIC DERMATOLOGIC SYNDROMES

The paraneoplastic dermatologic syndromes associated with lung cancer are presented in Table 8. Several dermatologic syndromes represent very specific conditions that suggest the presence of associated lung cancer. In the paraneoplastic cases, the responsiveness to the therapy is generally weaker compared with the non-paraneoplastic equivalents^[2]. Dermatomyositis is involved in neurologic, dermatologic, and rheumatologic syndromes. We describe dermatomyositis as a PNS because both the neuromuscular system and the skin are affected. Generally, paraneoplastic dermatologic syndromes improve in response to the treatment of the underlying neoplasm; the efficacy of ectopic local treatments is partial or insufficient.

Acrokeratosis paraneoplastica (Bazex syndrome)

The typical features of acrokeratosis paraneoplastica, also called Bazex syndrome, are erythematous scaly lesions on the extremities, ears, and bridge of the nose in association with a malignancy^[203]. The most common malignancies are squamous cell carcinomas of the laryngopharyngeal region or of the esophagus, tongue, or lung^[203,204]. Other histological types of lung cancer, such as adenocarcinoma and SCLC, have also been reported, although squamous cell carcinoma is the most common^[204-207]. In a review of 109 patients, psoriasiform lesions preceded the diagnosis of the associated malignancy in 73 (67%) patients, whereas cutaneous manifestations followed the diagnosis of the neoplasm in only 16 (15%) of 109 patients^[204]. The cutaneous lesions are erythematous to violaceous in color with an associated scaling eruption, and the most common sites of involvement are the ears, nose, hands, and feet, including the nails^[204,208]. These lesions are typically non-pruritic, have ill-defined margins, and are symmetric^[209,210]. The psoriasiform dermatitis begins in the fingers, toes, nose, and helix of the ears and progresses to involve the palms, soles, and cheeks, finally extending centripetally to the arms, legs, scalp, and trunk^[205,211].

The underlying mechanisms of acrokeratosis paraneoplastica have not been elucidated. One theory proposes that antibodies against the tumor cross-react with keratinocyte or basement membrane antigens^[210]. Alternatively, a T cell-mediated immune response to tumor-like antigens in the epidermis has been proposed^[210]. Squamous cell carcinoma lines have been shown to synthesize and secrete growth factors, such as transforming growth fac-

tor (TGF)-1, which is active in autocrine growth^[212,213]. The excessive expression of growth factors by the tumor might lead to epidermal hyperplasia and cancer cell proliferation.

The treatment of the underlying neoplasm often significantly improves the cutaneous symptoms^[210]. For some patients, cutaneous lesions, most commonly nail dystrophy, may persist despite successful tumor eradication^[210].

Acanthosis nigricans, tripe palms and the sign of Leser-Trélat

The characteristic manifestations of acanthosis nigricans (AN) are thickening and hyperpigmentation of the skin, and develop predominantly in the neck to axilla^[2]. Although AN is usually observed in benign conditions accompanied by endocrinopathies, such as insulin resistance, obesity, erythema nodosum, or medications such as sex hormones or nicotinic acid^[2,214], a paraneoplastic form has also been documented. Among paraneoplastic AN cases, the most common histologic type is adenocarcinoma, of which 70%-90% are located intra-abdominally and 55%-61% are gastric adenocarcinomas^[215]. Less commonly, paraneoplastic AN is associated with NSCLC^[216-218]. The major features of AN are darkening and thickening of the skin (hyperkeratosis), which occurs mainly in the folds of the skin in the axilla, groin, and back of the neck^[216]. Oral lesions, observed in 50% of cases, are generally located on the lips, tongue, and buccal mucosa^[219]. Gross and eruptive AN with florid cutaneous papillomatosis and palmar/plantar keratoderma are typical features of AN associated with malignancy^[215]. Rapid onset is also typical in paraneoplastic dermatoses^[219].

“Tripe palms” is also known as acanthosis palmaris,

pachydermatoglyphy (PDG) or palmar hyperkeratosis^[220]. This condition is characterized by a yellowish rugose hypertrophy of the palms and sometimes the soles, leading to an exaggeration of the skin lines^[218,221]. Tripe palms are usually associated with AN. More than 90% of cases are associated with neoplasms; in the majority of these cases, lung and gastric cancers are the underlying malignancies^[218,221].

The sign of Leser-Trélat (LT) refers to the eruption of numerous seborrheic keratoses^[215]. A rapid onset, rather than the number of seborrheic keratoses, suggests the presence of an underlying malignancy^[219]. Although gastric adenocarcinoma is the most common malignancy^[215,219], NSCLC has also been reported^[217,222]. In patients with tripe palms, the coexistence of AN (72%) and LT (10%) has been reported^[219,221].

The pathogenesis of AN is poorly understood. However, one possibility is that interactions between excessive amounts of circulating insulin with insulin-like growth factor receptors on keratinocytes and dermal fibroblasts lead to the development of AN^[223]. An increased production of TGF- α by the tumor could be responsible for an increased proliferation of keratinocytes and the development of paraneoplastic AN^[217,218]. No specific treatment has been established for AN. However, the treatment of the underlying malignancy usually improves AN as well^[215].

Erythema gyratum repens

Erythema gyratum repens (EGR) is rare, and the primary lesion is a serpiginous macular, occasionally popular, erythema^[210]. Most of the body is covered in numerous serpiginous bands arranged in a parallel configuration of concentric red swirls or a wood-grain pattern resembling a knotty cypress board^[210,224]. *Gyratum* means “coiled or winding around a central point”, and *repens*, from the Latin, means “to crawl or creep”; the name itself describes the classic eruption of concentric erythematous rings, which develop a trailing scale at their edges and advance at a rapid rate (≤ 1 cm per day)^[224]. All reported patients with EGR have been Caucasian^[210]. In a review of 49 cases of EGR, 41 (84%) were associated with a neoplasm, most commonly of the lung^[225]. Cases of NSCLC, including adenocarcinoma and squamous cell carcinoma, but not SCLC, have been reported^[224,226-228]. The skin symptoms usually disappear with therapy for the underlying lung cancer^[225,227,228].

Cutaneous leukocytoclastic vasculitis

Cutaneous leukocytoclastic vasculitis (CLV) is an inflammatory vascular disease characterized by the prominent involvement of the skin and the infiltration of the small blood vessels with polymorphonuclear leukocytes and the presence of leukocytosis, fibrinoid necrosis, and extravasation of red blood cells^[229]. In cases of paraneoplastic vasculitis, CLV (45%) and polyarteritis nodosa (36.7%) were the most frequently observed subtypes of vasculitis^[230]. In 71% of CLV cases, manifestations of vasculitis

appeared before or concurrent with the initial identification of the tumor or at the relapse of the tumor^[231]. The most common malignancies were hematologic malignancies and carcinomas of urinary organs, gastrointestinal tract, and lung (20%-26%)^[231,232]. The associated lung cancers were adenocarcinoma and squamous cell carcinomas^[229,231-233]. The mechanism by which neoplasms cause vasculitis has not been defined. However, it has been postulated that tumor antigens may induce immune complexes, which could be deposited on blood vessel walls, stimulating a direct autoimmune reaction against the host's vessels; alternatively, the tumor emboli or the tumors themselves may invade the vascular structures^[231,233].

The rash associated with CLV can present as a multitude of morphologic appearances, including urticaria, purpura, hemorrhagic vesicles, ulcers, nodules, livedo reticulares, infarcts, or digital gangrene; a skin biopsy is the gold standard for the diagnosis of CLV^[233,234]. The rash is usually symmetric and most commonly involves the lower extremities, often accompanied by pain or burning^[2,233]. Most patients demonstrate concordance of disease activity and treatment response for both cancer and vasculitis^[232]. Treatments for vasculitis include corticosteroids and immunosuppressants, such as cyclophosphamide^[230]. Successful surgical resection of lung cancer has resulted in the complete improvement of the skin rash in a few cases^[229,233].

PARANEOPLASTIC RHEUMATOLOGIC SYNDROMES

Many rheumatologic syndromes, such as rheumatic arthritis and systemic lupus erythematosus occur without an association with malignancy^[2]. However, several conditions have been reported to be associated with lung cancer (Table 8). Dermatomyositis is a symptom of several conditions, such as neurologic, dermatologic, and rheumatologic syndromes. In addition to the standard treatments for the non-paraneoplastic cases, the therapy directed to the cancer is important for the management of paraneoplastic rheumatologic syndromes^[2]. The paraneoplastic cases are generally less responsive to therapy compared with their non-paraneoplastic cases^[2]. We describe hypertrophic pulmonary osteoarthropathy (TPO) as a rheumatic syndrome here, although it may also be classified as a skeletal syndrome^[1].

Hypertrophic pulmonary osteoarthropathy

Hypertrophic osteoarthropathy (HOA) is characterized by the abnormal proliferation of the cutaneous and osseous tissues at the distal regions of the extremities^[235,236]. The triad of clinical signs and symptoms includes clubbed fingers, symmetric polyarthritis, and periostitis of the long tubular bones^[237,238]. Hypertrophic pulmonary osteoarthropathy (HPO) is defined as HOA secondary to pulmonary disease^[239]; it is frequently described in association with lung cancer, cystic fibrosis, or right-to-left cardiac shunts^[235]. More than 70% of HPO cases are

associated with lung cancer^[237,239]. In a review of 2625 lung cancer cases, 19 patients (0.72%) were found to have HPO^[239]. Of 19 lung cancers, 10 (53%) were adenocarcinomas and 4 (21%) were squamous cell carcinomas^[239]. HPO differs from rheumatoid arthritis in several key ways: the presence of non-inflammatory synovial fluid, a lack of radiographic erosions of the joints, negative rheumatoid factor, and pain that involves both joints and bones^[238]. Periostitis is the hallmark of HPO. Most cases involve the tibiae and fibulae, and severe cases have included all the tubular bones, such as ulnae and femurs^[238]. Bone radiography reveals periosteal membrane thickening and periosteal new bone formation^[237,239]. Unlike osteoarthritis, HPO is not associated with joint space narrowing or subchondral sclerosis^[238]. Bone scintigraphy is a useful, widespread medical imaging procedure that facilitates the detection of HPO^[239]. Characteristic findings include symmetric bilateral increased uptake in the long bones^[238]. Although FDG-PET may also show diffusely increased FDG uptake in the periosteal lesions^[240,241], the reliability of FDG-PET in the diagnosis of HPO has not been established.

Although the exact mechanism of HOA remains unclear, several theories have been proposed^[237,238,242]. The most promising explanation involves megakaryocytes and platelet clumps. Megakaryocytes continually emerge from the bone marrow; they are trapped by the pulmonary capillary bed and fragment there into platelets^[242]. In disorders in which megakaryocytes or megakaryocyte fragments bypass the pulmonary capillary network, these large particles can enter the systemic circulation and reach the fingertips in axial vascular streams^[237,242]. These large megakaryocyte fragments then interact with endothelial cells, leading to the release of growth factors, including platelet-derived growth factor (PDGF), prostaglandin E, and vascular endothelial growth factor (VEGF)^[238]. These growth factors cause fibroblast proliferation, digital clubbing, vascular hyperplasia, edema, and new bone formation^[237,238,243]. Significantly higher levels of PDGF and VEGF have been reported in HOA patients compared with healthy controls or subjects with pulmonary diseases other than HOA^[244-246].

Conventional analgesic medications, including non-steroidal anti-inflammatory drugs, have limited effects on HPO. In contrast, the treatment of lung cancer often resolves HPO^[237,238,247-249]. In particular, the complete resection of lung cancer may result in long-term improvements in HPO^[248,249]. The successful treatment of HPO with gefitinib has also been reported in a case of lung adenocarcinoma^[250]. Recently, it was reported that bisphosphonates (pamidronate or zoledronic acid) could dramatically resolve pain and swelling related to HPO^[235,251,252]. Although the mechanism of bisphosphonate-mediated improvement of HPO is unclear, the anti-tumor and anti-inflammatory effects of these drugs might be beneficial. In this regard, it has been reported that pamidronate is a potent inhibitor of VEGF^[253]. In addition, the effectiveness of octreotide in relieving pain in patients with HPO

has been reported^[254,255]. Subcutaneous octreotide at a dose of 100 g twice daily resulted in complete pain relief within several days^[254,255]. Octreotide has been reported to indirectly exert anti-angiogenic activity by inhibiting growth factors, including VEGF, or *via* immunomodulatory effects^[256]. Based on a role of VEGF in the pathogenesis of HPO, an anti-VEGF antibody, bevacizumab, might also be a potent therapeutic option.

PARANEOPLASTIC HEMATOLOGIC SYNDROMES

Paraneoplastic hematologic syndromes are often asymptomatic and are usually detected after the diagnosis of cancer, typically in the advanced stage of the disease^[2]. There is no specific treatment for these conditions, and the successful therapy for lung cancer may often improve hematologic disorders as well. In general, patients with hematologic syndromes have been reported to have a poor prognosis.

Granulocytosis (neutrophilia)

An increased level of white blood cells (leukocytosis) is often found in patients with lung cancer, either at the time of diagnosis or during the course of the disease^[257]. Leukocytosis may be caused by one or more factors, such as concomitant infections or the administration of corticosteroids^[257]. When leukocytosis is observed in the absence of these conditions, tumor-related leukocytosis should be considered. Occasionally, extreme leukocytosis ($> 50000/\text{mm}^3$ or even more than $140000/\text{mm}^3$) has been reported^[258]. In an analysis of 227 patients with lung cancer, 33 patients (14.5%) were diagnosed with tumor-related leukocytosis ($> 10000/\text{mm}^3$)^[257]. The associated histology in 14 (42%) patients was adenocarcinomas, 12 (36%) squamous cell carcinomas, 6 (18%) large cell carcinomas, and only 1 (3%) SCLC. However, the highest frequency of association was observed in large cell carcinomas (54.5%; 6 of 11 patients). The majority of the patients had granulocytosis. Of 33 patients, 16 exhibited high serum G-CSF levels (47-1103 pg/mL), 4 patients had high serum GM-CSF levels (31-61 pg/mL), and 18 patients had high serum IL-6 levels (11-1060 pg/mL)^[257]. In addition, 12 specimens exhibited positive staining against anti-G-CSF antibody, suggesting a G-CSF-producing lung cancer. Bone marrow examinations revealed a massively increased and left-shifted granulopoiesis extending to the myeloblasts, as typically develops under G-CSF stimulation^[258]. In contrast to leukemic blasts, the mature neutrophils that characterize paraneoplastic leukocytosis do not cause hyperviscosity or vaso-occlusion, and therefore do not require specific therapy^[2]. Patients with tumor-related leukocytosis have been reported to have a poor prognosis^[9,257,259]. The survival of patients with hypercalcemia and leukocytosis (MST 1.5 mo) was significantly shorter than that of patients with hypercalcemia alone (MST 3.8 mo)^[9]. Hypercalcemia and leukocytosis can occur through a common mechanism, *i.e.*, long-

term exposure to G-CSF^[9]. “Hypercalcemia-leukocytosis syndrome” has been proposed as a clinical entity of paraneoplastic syndrome, and it may indicate a poorer outcome in lung cancer^[9].

Hypereosinophilia

Excessive eosinophilia (hypereosinophilia) is a phenomenon associated with a wide variety of allergic diseases, parasitic infections, certain forms of vasculitis, and medications. Excessive eosinophilia has also been associated with malignancies, especially hematologic malignancies, including malignant lymphomas. Although case reports have described patients with various solid tumors and excessive eosinophilia, this association is thought to be less common^[260]. Several reports have described excessive eosinophilia associated with lung cancer^[260-262]. Hypereosinophilia has been reported in all types of lung cancer, including large cell carcinoma, squamous cell carcinoma, adenocarcinoma, and SCLC^[260,261,263,264]. Although the exact pathogenesis of hypereosinophilia associated with lung cancer has not been fully elucidated, bone marrow stimulation *via* circulatory factors secreted by cancer cells is the most widely accepted theory^[260,261,265-267]. Interleukin-5 (IL-5) and GM-CSF are the most frequently implicated factors^[260,262,265-267]. IL-5 has emerged as a key cytokine that controls the production, activation, and recruitment of eosinophils^[260]. In a case report of large cell carcinoma with excessive eosinophilia, the serum IL-5 level was elevated, and immunohistochemical staining of the resected primary tumor revealed large amounts of intracellular IL-5^[260]. Both the eosinophil count and IL-5 levels normalized after the surgical removal of the tumor, suggesting that the eosinophilia was mediated by IL-5 produced by the cancer^[260]. IL-5 mediates the antitumor cytotoxicity of eosinophils induced by IL-2 against various human tumor cell lines^[268]. Nevertheless, hypereosinophilia is generally associated with tumor aggressiveness and poor prognosis^[261,265,267]. A poor prognosis may reflect extensive disease and dissemination^[260]. The exact functional roles of eosinophils in human cancers remain unclear^[260].

Thrombocytosis

Thrombocytosis is generally diagnosed when a platelet count is more than $400000/\text{mm}^3$ and is associated with various diseases, including chronic inflammatory diseases and infectious diseases. Thrombocytosis is also frequently observed in patients with various malignancies, including lung cancer^[2,269]. The reported prevalence of thrombocytosis at the time of lung cancer diagnosis is 13%-32%^[269-271]. Paraneoplastic thrombocytosis is thought to be caused by the production of cytokines from the tumor, and the most representative is IL-6^[2,272]. In an analysis of 100 patients with renal cell carcinoma, serum levels of IL-6 were positively correlated with platelet counts^[272]. In addition, anti-IL-6 antibody administration reduced platelet counts in all 12 patients tested^[272]. This finding suggests that the overproduction of IL-6 is responsible

Table 9 Criteria for the diagnosis of paraneoplastic glomerulopathy

No obvious alternative etiology other than malignancy
Existence of a time relationship between the diagnosis of glomerulopathy and malignancy
Clinical improvement after the complete surgical removal of the tumor or complete remission achieved by chemotherapy/radiotherapy
Deterioration of glomerulopathy associated with recurrence of the malignancy

for paraneoplastic thrombocytosis. Survival in patients with thrombocytosis has been reported to be significantly shorter than in those without thrombocytosis^[269-271]. A multivariate analysis of prognostic factors using the Cox proportional hazards model indicated that thrombocytosis was an independent prognostic factor^[269,271]. Although the reasons for poor survival in patients with thrombocytosis remain unclear, PDGF may play a role in cancer progression^[273,274].

PARANEOPLASTIC GLOMERULOPATHY

Paraneoplastic glomerulopathies are rare manifestations of neoplastic disease, which should be distinguished from iatrogenic renal damage. Criteria for the diagnosis of paraneoplastic glomerulonephropathy have been established (Table 9)^[275]. Optimally, a diagnosis of paraneoplastic glomerulopathy should include the establishment of a pathophysiologic link between the tumor and glomerulopathy, including the detection of tumor antigens and antitumor antibodies within subepithelial immune deposits^[276]. However, establishing such a connection would be always unnecessary for a clinical diagnosis. In an analysis of 600 patients with lung cancer, the prevalence of proteinuria and hematuria was 10% and 7%, respectively^[277]. This relatively high prevalence may be attributed to the study's low cut-off value for proteinuria (0.1 g/d) or the use of the qualitative dipstick test alone to detect hematuria, without an assessment of urinary sediment. However, a prospective case-control study reported a significantly higher prevalence of proteinuria and hematuria in patients with lung cancer compared with asthmatic patients^[277]. Regarding the histology of the glomerular diseases, solid tumors, including lung cancer, are preferentially associated with membranous glomerulonephropathy^[275,278,279]. Other types of glomerular disease associated with lung cancer have also been reported, including minimal change disease^[280], IgA nephropathy^[281], focal segmental glomerulosclerosis^[282,283], membranoproliferative glomerulonephritis^[284], and crescentic glomerulonephritis^[285]. These studies reported a variable histology of lung cancer associated with glomerulopathy, including SCLC and NSCLC.

Two thirds of MGN cases are idiopathic^[275]. The etiology of secondary MGN frequently includes infections, autoimmune diseases, and drug toxicity^[275,286]. In a cohort study of 240 patients with MGN, 24 patients (10%) had a

malignancy at the time of renal biopsy or within one year thereafter^[286]. Among the patients with cancer and MGN, 40%-45% clinically manifested the nephrotic syndrome prior to the diagnosis of the tumor^[276]. Simultaneous presentation occurred in approximately 40% of patients, and in the remaining 15%-20%, glomerular disease became apparent following the diagnosis of the tumor^[276]. Regarding the pathogenesis of paraneoplastic MGN, several reports have demonstrated the presence of tumor antigens, such as carcinoembryonic antigen (CEA), in the glomeruli of patients with paraneoplastic MGN^[287-289]. The eluate of the glomeruli was found to react specifically with the surface of the cancer cells from the same patient, and it reacted not only with the cancer cell extract but also with CEA^[289]. An IgG antibody eluted from the kidney reacted with gastric and colonic carcinomas, and the reactivity was blocked by preincubating the tumor substrate with CEA^[289]. These cross-reactions between eluates from glomeruli and tumor antigens provide evidence for a role of the immune complex in the pathogenesis of paraneoplastic glomerulopathy^[275,287,289].

PARANEOPLASTIC

OPHTHALMOLOGICAL SYNDROMES

Cancer-associated retinopathy

Cancer-associated retinopathy (CAR) is a rare paraneoplastic syndrome that is often associated with SCLC^[290]. More than 100 CAR cases have been reported since CAR was first reported in 1976^[291], although the precise frequency of CAR in SCLC patients remains unclear. CAR causes progressive visual loss within several months, and it is associated with a triad of symptoms: photosensitivity, ring scotomatous visual field loss, and attenuated retinal arteriole caliber^[292]. Retinopathy may occur either before or after the diagnosis of cancer^[290]. It is believed that CAR is autoimmune-mediated *via* autoantibodies against retinal photoreceptor proteins, such as recoverin, heat-shock cognate protein 70, enolase, and transient receptor potential cation channel, subfamily M, member 1 (TRPM1)^[293-296]. In certain patients with lung cancer, high-titer serum autoantibodies against recoverin trigger the development of CAR^[297,298], whereas low-titer serum antibodies of patients with lung cancer do not necessarily cause CAR^[299,300]. In addition, the frequencies of serum autoantibodies against recoverin in patients with SCLC or NSCLC without CAR were found to be 15% and 20%, respectively^[293]. These values are much higher than the frequency of the development of CAR, suggesting that serum autoantibodies against recoverin do not necessarily trigger the development of CAR. Aberrant expression of recoverin protein resulting from altered demethylation of the recoverin gene can also trigger the host immune response, followed by the development of CAR^[301]. Regarding treatment, corticosteroids, in addition to anticancer therapy, may be effective for the control of CAR. In a review of 15 SCLC patients with CAR who received corticosteroids, 13 patients (87.7%) recovered

visual function^[290]. In those 13 patients, the mean dose of corticosteroids administered at initial treatment was 57.1 mg (25-100 mg) of prednisolone with or without induction with high-dose methylprednisolone^[290]. Lower doses of corticosteroids might not be sufficient to improve visual function^[290,302]. In addition, treatment delay after visual symptom onset may lead to irreversible injury to the photoreceptor cells^[290,291,302]. An effect of the expressed recoverin on sensitivity to anti-cancer drugs has also been reported^[303]. Compared with recoverin-negative control cells, recoverin-transfected lung cancer cells were more sensitive to several anticancer drugs [Matsuo S, 2010]. Aberrantly expressed recoverin may regulate tumor cell proliferation and drug sensitivity to anticancer drugs in patients with CAR^[303].

Diffuse uveal melanocytic proliferation

Diffuse uveal melanocytic proliferation (DUMP) is a rare paraneoplastic syndrome characterized by: (1) multiple round or oval, subtle, red patches at the level of the retinal pigment epithelium in the posterior fundus; (2) a striking pattern of multifocal areas of early hyperfluorescence corresponding to these patches; (3) the development of multiple, slightly elevated, pigmented and non-pigmented uveal melanocytic tumors, as well as evidence of diffuse thickening of the uveal tract; (4) exudative retinal detachments; and (5) rapidly progressive cataracts^[304,305]. More than 30 cases of DUMP have been reported; almost all of the cases were bilateral, except for one report of unilateral DUMP associated with SCLC^[306]. The most common associated malignancies are ovarian carcinoma in women and lung and pancreatic cancers in men^[307]. On histology, NSCLC (adenocarcinoma, large cell carcinoma, and squamous cell carcinoma) and SCLC have been reported^[306-309]. In half of the cases, DUMP manifests before the diagnosis of an underlying malignancy^[310]. Cutaneous and/or mucosal focal melanocytic proliferation has also been observed in several cases^[310]. It is believed that protein release from the primary cancer may incite an antibody response, which may cross-react with the ocular tissue^[309]. Another pathogenic mechanism may include hormonal stimuli from the cancer, leading to ocular melanocytic proliferation^[309]. The treatment of DUMP with systemic corticosteroids and orbital radiotherapy is ineffective^[308]. However, the regression of DUMP can be achieved by resecting the underlying lung cancer^[308].

PARANEOPLASTIC COAGULOPATHY

Trousseau's syndrome

In 1865, Armand Trousseau reported that unexpected and migratory thrombophlebitis could be the first symptom of visceral cancer^[311]. Ironically, two years later, he found the thrombophlebitis on himself, and was died of development of gastric cancer. Similar descriptions were repeated and extended over the years. Sack *et al*^[312] reviewed 182 patients with chronic disseminated intravascu-

lar coagulopathy (DIC) and malignancy, in whom migratory thrombophlebitis, arterial emboli in various organs, and hemorrhage were frequently observed. Hematologic data showed abnormalities associated with intravascular coagulation, such as hypofibrinogenemia and thrombocytopenia. Other abnormalities included prolonged prothrombin time, increased fibrinogen-fibrin degradation products, microangiopathic hemolytic anemia, and verrucous endocarditis^[312]. More recently, the term "Trousseau's syndrome" is sometimes even applied to patients who already have an advanced malignancy and then develop some form of thrombosis^[313]. Multiple definitions of Trousseau's syndrome have been proposed, ranging from the classic "occurrence of migratory thrombophlebitis with visceral cancer" to simply "carcinoma-induced coagulopathy", "hypercoagulability syndrome associated with cancer", and "malignancy-related thromboembolism"^[313]. Multiple mechanisms of Trousseau's syndrome have also been described^[313]. Intravascular coagulation (thrombosis or DIC) has been most frequently associated with mucin-producing adenocarcinomas^[314]. Mucins can initiate intravascular coagulation by activating factor X^[314]. Injecting carcinoma mucins into mice generated platelet-rich microthrombi dependent on P- and L-selectin, but not thrombin^[315]. The release of tissue factor (TF) and cysteine protease from cancer *via* the activation of factor X has also been reported in the pathogenesis of Trousseau's syndrome^[313]. Hypoxia may increase the expression of genes that facilitate coagulation, including TF and plasminogen activator inhibitor-1 (PAI-1)^[316].

The incidence of thrombosis in 537 patients with lung cancer was assessed^[317]. A total of 39 venous thrombotic events (VTEs), including 17 deep venous thrombi, 15 pulmonary emboli, and 7 cases of both deep venous thrombi and pulmonary emboli, were observed over 879 person-years of follow-up, resulting in 44.4 venous thrombotic events per 1000 person-years^[317]. After adjusting for age and sex, the estimated thrombotic risk in lung cancer patients was 20-fold higher than in the general population^[317]. Patients with adenocarcinoma had a higher risk than patients with squamous cell carcinoma (66.7 and 21.2 per 1000 person-years, respectively)^[317]. Patients with distant metastasis had a 6-fold increased risk compared with patients with localized tumors^[317]. It should be noted that the risk of venous thrombosis increases 3-fold when chemotherapy is started compared with the time when no chemotherapy has been administered^[317].

Heparin has been widely used as the preferred treatment for Trousseau's syndrome^[312,318]. A therapeutic range of 1.5-2.5 times the baseline activated partial thromboplastin time (APTT) has been recommended^[319]. Heparin binds to antithrombin III, causing its activation and leading to the inactivation of thrombin and other proteases, such as factor Xa. Heparin prevents the binding of mucin to L- and P-selectins and mucin-induced microthrombi^[315]. Trousseau's syndrome is often resistant to warfarin, which inhibits fluid-phase coagulation but not selectins^[315]. A serious side effect of heparin is hep-

arin-induced thrombocytopenia (HIT), which involves an immunological reaction that causes platelets to be targeted by the immunological response and results in the degradation of platelets, resulting in thrombocytopenia. Recently, low-molecular-weight heparins (LMWHs) have become popular treatments for Trousseau's syndrome, in part because of their greater bioavailability, the ability to administer single daily doses, the reduced incidence of HIT, and possibly improved safety^[320,321]. Successful treatment with long-term LMWH therapy has been reported in lung cancer patients with Trousseau's syndrome^[322,323]. However, it should be noted that the ability of some LMWHs to mediate some of heparin's actions may not be equivalent^[313]. Some LMWHs are not as effective at blocking L- and P-selectins, even at comparable levels of anti-factor Xa activity^[313,324,325], which might be a disadvantage for the treatment of Trousseau's syndrome. There is no evidence of the efficacy of other drugs that have anti-factor Xa activity, such as danaparoid sodium, fondaparinux sodium, edoxaban tosilate hydrate, and rivaroxaban. In addition, there is no evidence of the efficacy of antiplatelet drugs, such as aspirin, dipyridamole, and cilostazol, in the treatment of Trousseau's syndrome. Some of these drugs can be taken orally, which is a greater advantage for long-term management than heparin if there is an efficacy on Trousseau's syndrome. In addition to heparin, the interruption of the inferior vena cava (IVC) with a filter can be performed to prevent life-threatening PE. Potential indications for this procedure include ilio caval thrombosis^[326]. Poor survival of patients with Trousseau's syndrome has been reported. Compared with patients who did not develop a VTE, patients who developed a VTE during the course of lung cancer had decreased survival time until death^[317].

CONCLUSION

The 21st century has witnessed significant progress in the understanding of some paraneoplastic syndromes associated with lung cancer, especially paraneoplastic neurological syndromes. The elucidation of the mechanisms by which these syndromes occur could lead to the development of new therapeutic strategies. Currently, treatment for these syndromes fundamentally consists of direct therapies aimed at the underlying lung cancer. In the era of molecular-targeted therapy, newly developed drugs have resulted in favorable outcomes in some cases. Remarkable progress is occurring in the development of molecular-targeted therapies for paraneoplastic syndromes.

Key words: Autophagy; Cancer; Breast cancer; Chemotherapy; Radiation; Estrogen receptor; HER2; Triple negative breast cancer

Core tip: Autophagy is thought to be a tumor suppressor pathway. However, once a tumor is formed, it may contribute to tumor cell survival in response to metabolic stress or to therapy. On the other hand, it has also been suggested that autophagy could be induced during breast cancer therapy to kill cells that avoid apoptosis. Here, we discuss some of the recent findings relating autophagy and cancer with a particular focus on breast cancer therapy. We conclude that there are important unresolved questions that should be addressed before autophagy can be successfully targeted for breast cancer treatment.

Abstract

Macroautophagy (referred to as autophagy here) is an intracellular degradation pathway enhanced in response to a variety of stresses and in response to nutrient deprivation. This process provides the cell with nutrients and energy by degrading aggregated and damaged proteins as well as compromised organelles. Since autophagy has been linked to diverse diseases including cancer, it has recently become a very interesting target in breast cancer treatment. Indeed, current clinical trials are trying to use chloroquine or hydroxychloroquine, alone or in combination with other drugs to inhibit autophagy during breast cancer therapy since chemotherapy and radiation, regimens that are used to treat breast cancer, are known to induce autophagy in cancer cells. Importantly, in breast cancer, autophagy has been involved in the development of resistance to chemotherapy and to anti-estrogens. Moreover, a close relationship has recently been described between autophagy and the HER2 receptor. Here, we discuss some of the recent findings relating autophagy and cancer with a particular focus on breast cancer therapy.

INTRODUCTION

The term autophagy describes the lysosomal degradation, or eating (phagy) of part of the cell itself (auto). Several forms of autophagy have been described. Among them, macroautophagy (referred to here as autophagy) is a ubiquitous process in eukaryotic cells in which cytoplasmic components are engulfed in a double membrane structure called the autophagosome which delivers its contents for degradation to the lysosome. This process occurs at basal levels in all cells during nutrient rich conditions providing tissues with a housekeeping mechanism of cytoplasmic turnover and removal of damaged organelles as well as protein aggregates. Autophagy is also up-regulated in response to physiological conditions, such as starvation and in response to diverse pathological stresses, including hypoxia, formation of protein aggregates

or infection, and many others, thus allowing the cells to adapt to environmental and developmental changes^[1].

Alterations in autophagy are involved in several diseases including cancer^[2]. In cancer, autophagy is thought to have both tumor suppressive and tumor promoting functions. These paradoxical effects may be explained because the role of autophagy in cancer depends on the context and on the stage of tumorigenesis. The tumor suppressive functions of autophagy are most apparent during tumor initiation. Autophagy has been found to limit inflammation, tissue damage and genome instability which are known promoters of cancer initiation. Thus, it has been suggested that autophagy stimulation could be beneficial for cancer prevention. On the other hand, in later stages of cancer development, when tumor cells are exposed to stresses encountered during progression, metastasis and cancer therapy, autophagy is thought to be a tumor promoting mechanism by enabling survival of tumor cells^[3,4]. In this setting, it has been proposed that autophagy should be inhibited during cancer treatment in order to improve therapy, especially in those cancer cells that have high levels of autophagy and that are dependent on autophagy for survival under metabolic stress. Nevertheless, it is important to note that other studies suggest that excessive levels of autophagy could lead to cell death especially in those cells that are apoptosis deficient, which is the case of many cancer cells. It has also been suggested that autophagy modulation could have an effect on anti-tumor immune response^[5,6]. In this review, we discuss some of the recent evidence regarding the role of autophagy in cancer initiation, progression and therapy with a special emphasis on breast cancer.

AUTOPHAGIC PROCESS

The proteins mediating the formation of the autophagosome are known as Atg (autophagy-related) proteins. More than 30 Atg proteins have been identified in yeast and many have mammalian orthologs. The autophagic process (Figure 1 and Table 1) involves a series of steps which start with the initiation of the autophagosome, in which the phagophore (a cup-shaped structure that will later develop into the autophagosome) is formed. It is mediated by the Atg1/ULK kinase complex and is negatively regulated by mTORC1 (mammalian target of rapamycin complex 1), which integrates signals from growth factors, amino acids, glucose and energy status and allows autophagy to be induced in the absence of these stimuli. During nucleation, the Atg proteins are hierarchically recruited to the phagophore assembly site. This process is mediated by a complex integrated by beclin 1, hVps34/class III phosphatidylinositol 3-kinase (PI3K) and several other beclin 1 binding proteins (Figure 2). The elongation of the autophagosomal membrane is controlled by two ubiquitin-like protein conjugation systems: Atg12-Atg5 and Atg8/LC3. Autophagosomes may acquire membrane from multiple sources, including the endoplasmic reticulum (ER), the mitochondrial outer membrane, the plasma

membrane and the Golgi apparatus. Additionally, Atg8/LC3 also recruits adaptor proteins such as p62 and NBR1 to the autophagosomes mediating selective autophagy of different cellular structures, protein aggregates and microorganisms. Finally, autophagosomes move along microtubules towards the microtubule organizing center where lysosomes are enriched. Autophagosomes fuse with endosomes-lysosomes to form autolysosomes and are degraded together with their luminal content^[1,2,7].

At its basal rate, autophagy exercises quality control of the cytoplasm by removing damaged organelles and protein aggregates. Also, autophagy responds to a range of stimuli and in most cases protects the cell against stressful situations. In response to starvation, autophagy is important for lysosomal recycling of metabolites to the cytoplasm, where they are reused either as a source of energy or to provide building blocks for the synthesis of new macromolecules^[8]. Although the pro-survival functions of autophagy have been demonstrated at the cellular and organismal level in different contexts, it is also believed that autophagy can induce cell death. This has shown to be true particularly in lower eukaryotes, where autophagy seems to be directly involved in cell demise. Examples include *Dictyostelium discoideum*, a soil amoeba and midgut cell death occurring during development in *Drosophila melanogaster*^[9,10]. However, the existence of autophagic cell death in mammalian cells remains controversial. The bulk of the available data suggest that autophagic cell death occurs in specific *in vitro* models^[11-13] particularly in cells that are defective in apoptosis, or contributes to the induction of apoptosis or necrosis rather than being directly responsible for cell killing^[14,15]. Nevertheless, a recent report described a form of autophagic cell death, which the authors name autosis that is induced by an autophagy inducing peptide and is regulated by the Na⁺, K⁺-ATPase. Dead cells with morphological characteristics consistent with this type of cell death were found in a subpopulation of cells dying by starvation and in hippocampal neurons exposed to hypoxia-ischemia^[16], providing evidence of autophagic cell death in mammalian cells *in vivo*.

Several signaling molecules and cascades modulate autophagy in response to numerous cellular and environmental cues. The best characterized modulator of autophagy is mTORC1. It negatively regulates autophagy by inhibiting the ULK1 complex through direct phosphorylation and is inhibited by rapamycin, which induces autophagy. The activity of mTORC1 is stimulated by a variety of anabolic inputs, including cellular energy status as well as the presence of amino acids and growth factors. Conversely, mTORC1 is inhibited when amino acids are scarce, when growth factor signaling is reduced (*e.g.*, decreased insulin receptor signaling as shown in Figure 1) and/or ATP concentration decreases, resulting in a de-repression of autophagy. In mammalian cells, ULK1 is also directly phosphorylated and activated by the AMP-activated protein kinase (AMPK) in response to energy restriction. The class III PI3K complex is another impor-

Table 1 Some autophagy-related proteins and other proteins implicated in autophagy mentioned in the text and their autophagy-independent functions

Protein	Role in autophagy	Autophagy-independent roles
ULK1/2	Protein kinase involved in autophagy induction and phagophore biogenesis ^[105]	
Atg2	Interacts with Atg18, possibly involved in phagophore biogenesis ^[105]	Regulation of lipid droplet morphology and dispersion ^[106]
Atg3	E2-like enzyme for Atg8/LC3 ubiquitin-like conjugation system. Involved in phagophore expansion ^[105]	Atg12-Atg3 complex formation does not affect starvation-induced autophagy, increases mitochondrial mass and inhibits cell death mediated by mitochondrial pathways ^[107]
Atg4	Cysteine protease involved in Atg8/LC3 processing (removal of amino acid residues to expose the C-terminal glycine for lipidation) and in lipid removal from Atg8/LC3-PE (lipidated LC3 or LC3 II). Involved in phagophore expansion ^[105]	
Atg5	Atg12-Atg5 conjugation system, involved in phagophore expansion ^[105]	Its expression increases during DNA damage induced by chemotherapy. It induces cell cycle arrest and mitotic catastrophe ^[108]
Atg6/beclin 1	Component of the class III PI3K complex, involved in the induction of autophagy and phagophore biogenesis ^[105]	Interacts with Bcl-2 family proteins. Regulates the stability of USP10 and USP13 thus controlling p53 levels ^[92]
Atg7	E1 (ubiquitin-activating)-like enzyme for the two ubiquitin-like conjugation systems (Atg12-Atg5 and Atg8/LC3) ^[105]	Binds p53 and regulates cell cycle arrest upon metabolic stress ^[109]
Atg8/LC3	Ubiquitin-like protein that is conjugated to PE. It is involved in cargo recruitment into, biogenesis of autophagosomes and phagophore expansion ^[105]	
Atg9	Transmembrane protein that may act as lipid carrier for phagophore expansion ^[105]	
Atg10	E2 (ubiquitin-conjugating)-like enzyme for the Atg12-Atg5 ubiquitin-like conjugation system ^[105]	
Atg12	Ubiquitin-like protein that gets covalently linked to Atg5 in the Atg12-Atg5 conjugation system. Involved in phagophore expansion ^[105]	Atg12-Atg3 complex formation does not affect starvation-induced autophagy, increases mitochondrial mass and inhibits cell death mediated by mitochondrial pathways ^[107]
Atg13	Binding partner and regulator of ULK1/2, involved in induction of autophagy and phagophore biogenesis ^[105]	
Atg14/ATG14L	Component of the class III PI3K complex, involved in induction of autophagy and phagophore biogenesis ^[105]	
Atg16	Associates with Atg12-Atg5 and acts as an E3 ligase to direct LC3 lipidation, involved in phagophore expansion ^[105]	
Atg17/FIP200	Binding partner and regulator of ULK1/2 involved in induction of autophagy and phagophore biogenesis ^[105]	
Atg18/WIPs	PI3P-binding proteins possibly involved in phagophore biogenesis ^[105]	Retrograde transport from the vacuole to the Golgi complex. Regulation of PI(3,5)P ₂ synthesis ^[105]
mTORC1	Serine/threonine kinase rapamycin-sensitive complex, main down-regulator of autophagy that responds to growth factor and nutrient availability ^[105]	Regulates cell growth (accumulation of cell mass) through coordination of protein anabolism, nucleotide biosynthesis, lipogenesis, glycolysis and autophagy ^[110]
Vps34	Class III PI3K, produces PI3P and allows recruitment of PI3P-binding proteins WIP1/2 and of the two ubiquitin-like conjugation systems ^[105]	Regulation of vesicular trafficking in the endosomal/lysosomal system. Regulates signaling by recruiting proteins that bind PI3P ^[111]
Vps15	Regulatory kinase subunit of the class III PI3K ^[105]	
p62	Selective substrate of autophagy that functions as an adaptor protein that links ubiquitinated proteins to LC3 ^[105]	Serves as a scaffold to promote NFκB signaling in TNFR, IL-1βR or NGFR signaling by binding RIP1 or TRAF6. Can bind caspase-8 and stimulate apoptosis. Binds mTORC1 and Rag GTPases on the lysosomal surface to signal amino acid availability ^[112] . Activates transcription factor Nrf2, which drives expression of antioxidant and detoxifying enzymes by competitively binding to Keap1, its ubiquitin ligase ^[113]
NBR1	(Neighbor of BRCA1 gene 1), selective substrate of autophagy with structural similarity to p62 ^[105]	Negatively regulates receptor tyrosine kinase endocytic traffic ^[114]
AMPK	(AMP-activated protein kinase), a sensor of energy that is activated by an increase in the AMP/ATP ratio ^[105,115]	AMPK regulates metabolism, decreases energy expenditure, mediates cell cycle checkpoints, inhibits pro-survival growth pathways and modulates mitotic progression ^[115]
Bcl-2/Bcl-XL	Members of the Bcl-2 family of proteins that inhibit macroautophagy (by binding beclin 1) and pro-apoptotic BH3-only proteins ^[105]	Antiapoptotic proteins that inhibit pro-apoptotic BH3-only proteins (BNIP3, Bad, Bik, Noxa, Puma and BimEL) ^[105]
Survivin	Interacts with beclin-1 ^[103]	Member of the Inhibitor of Apoptosis (IAP) family of proteins that inhibits caspases. It is also involved in chromosome segregation during cell division ^[116]
PINK1	(PTEN-induced kinase 1/PARK6), mitochondrial protein that spans the outer mitochondrial membrane upon mitochondrial depolarization, recruiting Parkin to facilitate mitophagy ^[105]	Mitochondrial protein (mutated in some forms of Parkinson disease) that is processed in a membrane potential-dependent manner to maintain mitochondrial function ^[105]

VMP1	(vacuole membrane protein 1), localizes to the plasma membrane of the ER. Interacts with beclin 1 and is required for autophagy ^[105]	Required for protein secretion and Golgi organization, regulates cell proliferation, anchorage-independent growth and secretory membrane transport. It is a component of initial cell-cell contacts and tight junctions ^[117]
DAPK	Death associated protein kinase, it phosphorylates beclin 1 to activate autophagy by causing dissociation from Bcl-2 ^[105]	Regulates cell death, inhibits cell motility and adhesion, promotes membrane blebbing and stress fiber formation ^[118]
Bif-1	Bax-interacting factor 1)/endophilin B1, protein that interacts with beclin 1 <i>via</i> UVRAG and is required for macroautophagy ^[105] . It has membrane curvature-inducing activity, indicating that it may play a role in biogenesis of isolation membranes ^[119] .	Involved in mitochondrial fission and coat protein complex I (COPI)-vesicle formation ^[119] . Regulates receptor degradation and cytokinesis when present in a class III PI3K subcomplex containing Vps15, Vps34, beclin 1 and UVRAG ^[120]
UVRAG	UV irradiation resistance-associated gene, component of the class III PI3K complex that activates autophagy. It disrupts beclin 1 dimers and forms a heterodimer that activates autophagy. It binds Bif-1 to activate class III PI3K and competes with Atg14L for binding to beclin 1, directing class III PI3K to function in the maturation step of autophagy ^[105]	Regulates receptor degradation and cytokinesis when present in a class III PI3K subcomplex containing Vps15, Vps34, beclin 1 and Bif-1 ^[120] . Regulates coat protein complex I (COPI)-vesicle tethering in the ER ^[121]
Ambra1	Activating molecule in beclin 1-regulated autophagy, binds beclin 1 and positively regulates autophagy ^[105] . Regulates ULK1 stability and kinase activity and is phosphorylated and inactivated by mTOR, inhibiting its action on ULK1 ^[122] . Also, changes in its subcellular localization are important during autophagosome formation ^[123]	
HMGB1	High mobility group box 1, a chromatin-associated nuclear protein that translocates to the cytoplasm in response to stress. Binds to beclin 1, displacing Bcl-2 and promoting autophagy. Autophagy also promotes the release of HMGB1 from the nucleus and the cell which further induces autophagy ^[105]	In the nucleus it is a DNA chaperone, sustains nucleosome dynamics and chromosome stability, modulates gene transcription, recombination and participates in DNA repair and telomere maintenance. It regulates mitochondrial function and when secreted regulates inflammation, immunity, migration, proliferation, metabolism and apoptosis ^[124]
NAF-1	Nutrient-deprivation autophagy factor-1, integral membrane component of the IP3 receptor complex. It binds Bcl-2 at the ER and is required for Bcl-2 to bind beclin 1, resulting in the inhibition of autophagy ^[105]	Required for Bcl-2 dependent regulation of the IP3 channel at the ER and regulates Ca ²⁺ homeostasis ^[125]

tant point of regulation for autophagy induction. Beclin 1 is one of the subunits of the complex and its incorporation, which is essential for its kinase activity, is regulated by its association with other proteins, such as Bcl-2, Survivin, PINK1 or VMP1 (Figure 2). The phosphorylation of beclin 1 by death-associated protein kinase (DAPK) or phosphorylation of Bcl-2 by c-Jun N-terminal kinase (JNK) triggers the dissociation of beclin 1 from Bcl-2 in response to various stimuli, thereby inducing autophagy. AMPK can also stimulate autophagy in response to glucose starvation by phosphorylating beclin 1 on a residue that promotes its incorporation into the PI3K complex^[1,17]. Recent evidence also suggests that the Atg proteins are substrates for transcriptional regulation as well as post-translational modifications such as phosphorylation, ubiquitination and acetylation^[18]. The activity of the class III PI3K complex can be manipulated by pharmacological activators (such as BH3 mimetics) and inhibitors (such as spautin). Inhibitors of lysosomal enzymes (such as cystatin B) and lysosomotropic agents that increase the lysosomal pH (such as chloroquine, hydroxychloroquine and Bafilomycin A) are also used to block the degradative activity of autolysosomes and block autophagy at the degradation step (Figure 1)^[2,17].

AUTOPHAGY AND CANCER

Alterations in the autophagic pathway have been observed in several disorders, including metabolic diseases, myopathy, neurodegenerative disorders, infectious and

inflammatory diseases, autoimmune disorders, aging and cancer^[2,19]. Cancer was one of the first diseases genetically linked to an impairment of autophagy with the proposal that *beclin 1* functioned as a haploinsufficient tumor suppressor. *Beclin 1* was found to be monoallelically deleted in a high percentage of ovarian, breast and prostate cancers and its heterozygous disruption in mice results in increased spontaneous malignancies including lung cancers, liver cancers, lymphomas and mammary precancerous lesions^[20-22]. More recently, studies have established a relationship between beclin 1 expression and cancer prognosis since low levels of beclin 1 are associated with a worse prognosis in gastric, colorectal, pancreatic, oesophageal and breast cancers as well as in chondrosarcoma, whereas high levels of its expression are associated with improved survival in high-grade gliomas, hepatocellular carcinomas and B cell lymphomas^[2]. Nevertheless, deletions of *beclin 1* have recently been found mostly associated with *BRCA1* in breast and ovarian human tumors (suggesting that *BRCA1* loss is the driver mutation and that *beclin 1* is lost because of its proximity to it). Furthermore, in a recent comprehensive study no evidence was found for *beclin 1* mutations or loss in other cancers, casting doubt on whether it is a real tumor suppressor in human cancers^[23].

Other ATG proteins have been shown to be involved in the suppression of tumorigenesis. For instance, *Atg 4C* knockout mice do not develop more spontaneous tumors than their wild-type littermates but they are more prone to develop chemically-induced fibrosarcomas^[24] and *LC3* is localized to 16q24.1, a locus frequently deleted in liver,

Figure 1 The autophagic process and some of its major regulators. The phosphatidylinositol 3-kinase (PI3K) pathway is triggered by the binding of insulin or growth factors to the insulin receptor, activating PI3K. Activated PI3K converts PIP₂ to PIP₃ which then recruits PDK1 and Akt to the plasma membrane. Activated Akt then phosphorylates and inactivates TSC 1/2, leading to the activation of Rheb and mammalian target of rapamycin complex 1 (mTORC1). Under nutrient-rich conditions, mTORC1 suppresses autophagy by phosphorylating and inhibiting the ULK1 complex. Under starvation conditions or rapamycin treatment, mTOR dissociates from the ULK1 complex and autophagy gets activated. ULK1 is also directly phosphorylated and activated by the AMP-activated protein kinase (AMPK) in response to energy restriction. The autophagic process involves the degradation of cytosolic proteins and organelles in the lysosomes via autophagosomal delivery. Two complexes regulate the formation of the phagophore, the ULK1 complex and the beclin 1-VPS34 (class III PI3K) complex. The elongation of the autophagosomal membrane is mediated by two ubiquitin-like protein conjugation systems: ATG12-ATG5 and ATG8/LC3. LC3 can additionally recruit adaptor proteins such as p62 to autophagosomes mediating selective autophagy of cellular structures, protein aggregates and microorganisms. LC3II (LC3 bound to phosphatidylethanolamine) is recruited to both the inner and outer autophagosomal membrane. Autophagosomes fuse with lysosomes to form autolysosomes where they are degraded together with their luminal content. Pharmacological modulators of autophagy are labeled according to their effect on autophagy. Red: Inhibits autophagy; Green: Induces autophagy.

breast, prostate and ovarian cancers^[25]. Also, p62 has been found to be upregulated in human tumors^[26], *Bif-1* (a protein part of the beclin 1/class III PI3K complex that enhances its activity) knockout mice have a higher incidence of tumors than wild-type mice, especially lymphomas^[27], and *UVRAG* (a beclin 1 binding protein also part of the class III PI3K complex) is localized to the 11q13 human chromosomal region which is frequently implicated in the development of malignancies, including breast and colon cancers^[28].

The previous observations suggest a tumor suppressive role of autophagy. However, mosaic deletion of *Atg5* in mice resulted in benign tumor development only in the liver^[29]. When taken together, these studies do suggest that autophagy has tumor suppressor functions particularly in the liver and that its inhibition predisposes to the development of cancer induced by additional

agents or mutations in other tissues. However, it is important to note that since all the autophagy regulators also affect other things too, it is difficult to be sure that any effects seen when a particular autophagy regulator is inactivated are due to autophagy as opposed to other functions. Consistent with this, the more pronounced effects observed with heterozygous disruption of *beclin 1* when compared with other *ATG* genes might be caused by effects on autophagy together with other autophagy-independent mechanisms. The different phenotypes observed in the *Atg5* or *Atg7* knockout mice (which are viable but die after birth presumably due to nutrient and energy depletion) when compared to *beclin 1* knockout mice (which are embryonic lethal) indicates that beclin 1 has important functions independent of its role on the autophagic pathway^[30]. Indeed, beclin 1 can bind anti-apoptotic proteins of the Bcl-2 family (such as Bcl-2 and

Figure 2 Beclin 1, its protein interactions and its role in autophagy. Beclin 1 has been found to form part of different class III phosphatidylinositol 3-kinase (PI3K) complexes. Each complex consists of beclin 1, Vps34, Vps15 and Ambra1. ATG14L activates the complex and induces the formation of autophagosomes. UVRAG and ATG14L are present in mutually exclusive class III PI3K complexes and UVRAG and Bif-1 have been shown to activate the complex. UVRAG has also been shown to function in autophagosome maturation and endocytic trafficking possibly independent from its interaction with beclin 1. Rubicon has also been shown to bind beclin 1 and can inhibit autophagosome formation and maturation. TAB1/2, two upstream activators of the TAK1-IKK signaling pathway interact with beclin 1 and their dissociation seems to be necessary for autophagy induction. GPR-1 can also bind beclin 1 and inhibit autophagy probably through beclin 1 tethering in the Golgi apparatus. Bcl-2/Bcl-XL can bind beclin 1 and inhibit autophagy. JNK1 phosphorylates Bcl-2 while DAPK phosphorylates beclin 1 and disrupt their interaction. Additionally, BH3-only proteins (tBid, Bad, BNIP3) or BH3 mimetics (ABT737) bind Bcl-2 and release beclin 1. Beclin 1 has also been found to be a substrate of caspases-3, 7 and 8 during apoptosis, in which cleavage of beclin 1 suppresses autophagy. Other beclin 1 interacting proteins that induce autophagy are PINK1 and VMP1. TRAF6 and USP13 have been shown to regulate beclin 1 ubiquitination. Survivin, an anti-apoptotic protein can also bind beclin 1 and regulate TRAIL induced apoptosis. NAF-1, a component of the IP3 receptor complex contributes to the interaction of Bcl-2 with beclin 1 at the ER^[32,99-104]. Proteins and drugs shown are color-coded according to their effect on autophagy. Red: Inhibits autophagy; Green: Induces autophagy; Yellow: Unknown.

Bcl-XL^[31]) and is also known to bind USP13 and regulate p53 levels (Figure 2)^[32]; these other functions could contribute to tumor suppression effects.

The mechanisms by which autophagy itself can decrease tumor formation have been suggested to involve degradation of damaged mitochondria that could otherwise induce oxidative stress, DNA damage and genomic instability (Figure 3). This situation of chronic tissue damage can also provoke an inflammatory response that can further promote tumor growth through cytokine production, and autophagy inhibition has been shown to increase cytokine production in some cases^[6,33,34]. Also, autophagy suppression leads to up-regulation of p62 which activates a NRF2 mediated antioxidant survival response that could lead to tumor promotion^[4].

Once a tumor is formed, tumor cells are exposed to

many and varied stresses including hypoxia, starvation and lack of growth factors, all known to be autophagy inducers. Increasing evidence in the literature suggests that cancer cells robustly activate autophagy to survive such stresses as they are encountered during tumor progression and metastasis. For example, autophagy is known to be most prominent in hypoxic tumor regions, where it sustains survival of tumor cells under metabolic stress^[3,4] and autophagy is also needed for survival during detachment from the extracellular matrix so that tumor cells can avoid anoikis^[35].

Many cancer cells have high levels of basal autophagy even in fed conditions. This is in contrast to normal cells in which autophagy normally occurs at low levels and is only up-regulated in response to stresses like starvation^[4]. In this regard, it has been suggested that transformation

Figure 3 Autophagy in cancer and breast cancer. Different roles have been described for autophagy in cancer. Autophagy can limit tumor initiation by decreasing inflammation and genome instability. Once a tumor is established, autophagy can induce tumor progression by facilitating metastasis and resistance to therapy. On the other hand, it has also been proposed that autophagy could function as a cell death process that could be induced during therapy. In breast cancer, although some evidence suggests that autophagic cell death occurs in apoptosis defective cells, most of the evidence in the literature suggests a tumor promoting role for autophagy. Autophagy has been shown to promote tumorigenesis, tumor proliferation and progression. This could depend on the p53 or RAS mutation status of the cells. Also, if breast cancer is an autophagy-dependent disease remains to be determined as well as if this dependence is subtype specific. Autophagy has also been involved in resistance to anoikis, facilitation of metastasis, resistance to therapy and maintenance of breast cancer stem cells. Moreover, when cancer cells are made resistant to the therapies shown in the figure, they show increased autophagy and inhibition of autophagy reverts this resistance. Therapies that are known to induce autophagy in breast cancer are also shown. With these treatments, autophagy inhibition has been shown to increase cell death. Regarding radiation, results are controversial and the role of autophagy could depend on the p53 status of the cell.

mediated by certain oncogenes, like RAS, induces a metabolic switch in cancer cells that makes them addicted to autophagy under basal, but especially under starvation conditions and that autophagy inhibition would be particularly beneficial for the treatment of these tumors^[36,37]. This has been shown to be true in chloroquine-treated mouse xenografts models of pancreatic ductal adenocarcinoma (PDAC), in which activating Kras mutations are frequent^[38] and in a mouse model of Kras^{G12D} driven non-small-cell lung cancer (NSCLC). In the latter, autophagy inhibition diverted tumor progression from adenomas to oncocytomas, a more benign type of tumor, particularly in p53 deficient tumors^[33]. On the other

hand, in another model of NSCLC driven by Braf^{V600E}, the downstream effector of Kras, autophagy inhibition increased tumor burden. In this work, “autophagy dependence” became apparent only at later time points, when the tumors had been established. This study also shows a change in tumor type to more benign oncocytomas and a greater survival advantage than Kras^{G12D} driven tumors by autophagy inhibition^[39]. Similar to the previous study, autophagy inhibition by mosaic deletion of *Atg5* or *Atg7* in the pancreas induced increased formation of pre-cancerous lesions in a Kras^{G12D} mouse model of pancreatic ductal adenocarcinoma, but these lesions did not progress to carcinoma. Interestingly, this only occurred in a p53 wt background^[40] suggesting that a single oncogenic event such as Ras mutation may only cause dependence on autophagy in some circumstances and that the full spectrum of tumor mutations may ultimately determine just how autophagy-dependent a tumor will be. Further support for this idea comes from other studies where, in contrast to Ras-driven autophagy-dependence, it has been shown that autophagy restrains the proliferative potential of Ras transformed cells so that autophagy inhibition dramatically increased clonogenic growth^[41]. Moreover, autophagy has also been shown to restrict proliferation of cells carrying activated PI3K^[42], suggesting that autophagy might have different, and even opposing effects, depending on the cellular context and the transformation event. In conclusion, the role of autophagy in cancer is complex and is both context and probably tissue dependent (Figure 3). Thus, although numerous studies have addressed this issue, it remains inconclusive in which tumors autophagy should be targeted. This has important practical implications because current clinical trials are using chloroquine or hydroxychloroquine with the purpose of inhibiting autophagy in a variety of cancers without selecting patients who would more likely benefit from this treatment. We believe that further studies are needed to identify the tumors where autophagy inhibition will be effective before autophagy can be successfully targeted in the context of cancer treatment.

BREAST CANCER

Estimates of the worldwide incidence and mortality of cancer ranked breast cancer as the most frequent cancer among women with an estimated 1.67 million new cases diagnosed in 2012 (25% of all cancers) with slightly more cases in less developed than in more developed regions. Breast cancer mortality rates have declined in part due to therapeutic advances and it ranked as the fifth cause of death from cancer overall in 2012. However, it was still the most frequent cause of cancer death in women in less developed regions and the second in more developed regions after lung cancer^[43], underscoring the need for better strategies in both prevention and therapy.

Breast cancer is a heterogeneous disease. Clinically, it is classified as hormone receptor positive, HER2 (ERBB2) positive and triple negative breast cancer. Hor-

hormone receptor positive breast cancers are the most numerous and diverse accounting for 60%-70% of breast cancers. They express the estrogen receptor (ER) and usually respond to endocrine therapy. HER2 positive breast cancers overexpress the HER2 receptor tyrosine kinase and respond to targeted therapies against this receptor such as trastuzumab (monoclonal antibody targeting HER2) or lapatinib (a dual-kinase inhibitor targeting both the epidermal growth factor receptor and the HER2 receptor)^[44,45]. This type of cancer accounts for 10%-15% of breast cancer patients. Finally, triple negative breast cancers (TNBC) do not express hormone receptors (ER or progesterone receptor, PR) or HER2. Although the metastatic potential in these cancers is similar to that of other breast cancer subtypes, they are associated with a shorter median time to relapse and death. They have an increased incidence in younger women, in patients with germline *BRC1* mutations or of African ancestry^[46]. Cytotoxic chemotherapy remains the mainstay of treatment of triple-negative disease since there is not a clear agent that targets a defining vulnerability in this disease^[47].

More recently, gene expression analysis has led to the definition of five molecular “intrinsic” subtypes of breast cancer (Luminal A, Luminal B, HER2-enriched and basal-like) and a Normal Breast-like group which have differences in incidence, survival and response to treatment^[48]. Luminal cancers include the ER positive group and are subdivided in luminal A and luminal B subtypes. Luminal B tumors have a lower expression of ER or estrogen-regulated genes, low or no PR expression, higher tumor grade, higher expression of proliferation-related genes, and activation of growth factor receptor signaling, such as IGF-1R and PI3K/AKT/mTOR pathways when compared to Luminal A tumors. They are also considered to have a lower sensitivity to endocrine therapy and higher sensitivity to chemotherapy than luminal A tumors^[49]. The increased aggressiveness of luminal B tumors has been attributed to inactivation of the p53 pathway and hyper activation of *MYC* and *FOXM1*^[46]. Prospective trials are now evaluating the validity of prognostic gene signatures to distinguish between these two subtypes and identify those women (with luminal A cancers) who can be spared adjuvant chemotherapy^[49].

The majority of HER2+ tumors fall into the HER2 enriched subtype. About 30%-40% of these tumors are ER+, most are ER- and some of these tumors are clinically triple negative but still express the gene signature of HER2 activation. It remains unknown whether those patients with the HER2 enriched subtype but having triple negative cancers would also benefit from HER2 targeted therapies^[50].

Most basal-like tumors are triple negative and further molecular profiling has shown extensive heterogeneity of both TNBC and basal tumors. Molecularly, most, if not all of these cancers show a high frequency of *TP53* mutations or loss of the p53 pathway activity, loss of *RB1* and *BRC1*. They show increased signaling of the PI(3)K/AKT, *MYC* and HIF1/ARNT pathways and

hyper activation of *FOXM1*^[46]. The high prevalence of these mutations together makes them highly proliferative, aneuploid tumors with a very high apoptotic rate and geographic or central tumor necrosis^[48,50,51] with an inferior prognosis when compared to the luminal subtypes^[52,53]. The heterogeneity of TNBC is widely acknowledged. Another subtype belonging to this group, the claudin-low subtype, is characterized by the low expression of genes involved in cell-cell adhesion like claudins and E-cadherin, increased expression of immune response genes, high mesenchymal features, low epithelial differentiation and a stem cell-like phenotype^[48]. More recently, Lehmann *et al*^[53] defined six TNBC subtypes: basal-like 1 and 2, immunomodulatory, mesenchymal, mesenchymal stem-like and luminal androgen receptor, providing a broader classification for those TNBC tumors that do not fit in the basal-like group. In this work, the molecular signature of each subtype was used to predict which therapy should be used in cell lines belonging to each subtype with promising results, opening up the opportunity to use better molecular classification of tumors to improve the choice of treatments in the clinic^[53].

Some novel therapies in current clinical trials in TNBC include the use of fibroblast growth factor receptor (FGFR), vascular endothelial growth factor (VEGF), PI3K-AKT-mTOR pathway and PARP [poly (ADP-ribose) polymerase] inhibitors as well as the use of androgen receptor (AR) antagonists in AR positive breast cancers^[54]. Also, signaling pathways that are thought to be important for resistance to conventional breast cancer therapy are currently under investigation in clinical trials including: EGFR, HER2 and HER3 inhibitors, AMPK-activating compounds, restoration of the p53 signaling pathway by MDM2 inhibitors and inhibitors of the following proteins and signaling pathways: PI3K-AKT-mTOR, Notch signaling, CDK4/6, HDAC, HSP-90, BCR-Abl, VEGFR/PDGFR/Raf, VEGFR/PDGFR/c-kit, c-MET/VEGFR2, FGFR, Hedgehog signaling and MEK^[55].

AUTOPHAGY AND BREAST CANCER

The suggestion that beclin 1 is a tumor suppressor was particularly important for breast cancer since it was found to be deleted in 40%-75% of sporadic human breast and ovarian cancers. Beclin 1 expression is frequently low in human breast epithelial carcinoma cell lines and tissues and expressed at high levels in normal breast epithelia. However, as discussed previously, the *beclin 1* gene maps to 17q21, a region that is deleted in approximately 50% of sporadic breast carcinomas^[56], and *beclin 1* is next to *BRC1*, a tumor suppressor gene whose loss is a driver of some breast and ovarian cancers^[23]. In this regard, recent evidence suggests that although *beclin 1* is lost in breast and ovarian cancers, it is co-deleted with *BRC1*, consistent with *BRC1* loss being the primary driver mutation in these cancers and suggesting that *beclin 1* itself may not be a tumor suppressor in this context^[23]. However,

er, it would be interesting to explore if breast and ovarian cancers with loss of *BRCAl* and *beclin 1* have a different outcome than those that only lack *BRCAl*.

Even though *beclin 1* might not be a tumor suppressor gene in human tumors, overexpression of *beclin 1* in the MCF7 breast cancer cell line decreases proliferation, *in vitro* clonogenicity and tumorigenesis^[20], and the *beclin 1* loss that occurs in breast cancer could have important effects independent of autophagy through its interaction with Bcl-2. This relationship would be particularly important since Bcl-2 is itself overexpressed in 50%-70% of cancers, including breast cancer^[57]. An inverse correlation of *beclin 1* and Bcl-2 expression has been described in breast cancer tissue and Bcl-2 expression was correlated with histological grade, tubule formation, nuclear pleomorphism, mitotic count, estrogen receptor and distant metastasis^[58]. These findings suggest that the interaction between these two proteins might be particularly important for breast cancer tumorigenesis since loss, or low levels of *beclin 1* would increase free Bcl-2 and an antiapoptotic response. Moreover, it has also been shown that the growth-promoting activity of Bcl-2 correlates with its ability to bind *beclin 1* and inhibit autophagy rather than with its anti-apoptotic function, thus contributing to tumorigenesis^[59].

In contrast to the tumor suppressive role of autophagy discussed previously, autophagy has been shown to have a tumor promoting role in breast cancer. Two recent papers studied the role of autophagy in mammary tumorigenesis. In the first one, conditional knockout of the essential autophagy protein FIP200 in mammary epithelial cells in the MMTV-PyMT mouse model of breast cancer (which is known to induce mammary adenocarcinomas following PyMT-mediated activation of Ras, Src, and PI3K) reduced tumorigenesis, metastasis and increased survival. Gene expression profiling of mammary tumors in this study revealed increased expression of immune responsive genes in the autophagy deficient tumors, suggesting that FIP200 deletion might trigger enhanced anti-tumor immune response and contribute to the suppression of mammary tumorigenesis and progression^[6]. In the second study, the authors used mice deficient in *Palb2* in the mammary gland, which produced tumors with diverse histology but generally of high grade, invasive, with increased DNA double strand breaks, DNA damage and mutations in p53. In this work, autophagy inhibition by allelic loss of *beclin1* delayed tumor formation. The authors proposed that autophagy was being activated in response to DNA damage and oxidative stress and mediated survival of tumor cells in collaboration with p53, since allelic loss of *beclin1* did not have an effect in tumor formation when p53 was also deleted from the mammary gland^[60]. Both studies found a tumor promoting role of autophagy in oncogene-driven breast cancer models and thus suggest that autophagy addiction might be a potential therapeutic target in breast cancer (Figure 3).

As mentioned above, autophagy addiction has been

particularly linked to strong oncogenic insults like RAS transformation or alterations in the RAS pathway, which induce alterations in metabolic pathways to meet biosynthetic demands. Although RAS transformation is not a common event in breast cancer, other oncogene pathways activated in breast tumors, including HER2, Myc and activated PI3K, produce metabolic alterations similar to RAS transformation. Moreover, components of the PI3K and RAS-RAF-MEK pathway are amplified in basal-like cancers and autophagy addiction can be induced by RAS transformation in breast cancer cells^[3,37,46]. For instance, HRas^{V12} expressing MEFs were found to need autophagy for anchorage-independent growth and the MDAMB231 cell line (KRAS mutated) was found to need autophagy for proper proliferation in both anchorage-independent and in attached, nutrient rich conditions. In both cases, autophagy promoted survival through facilitation of glycolysis^[37]. In agreement with these observations, autophagy is necessary for lumen cell survival in breast cancer MCF10A cells expressing the oncogenic PI3KCA mutant in 3D acini. Interestingly, in this work autophagy inhibition promoted adhesion-independent proliferation in soft agar transformation assays in 3D culture but not in 2D conditions and was suggested to be mediated by an increase in p62 after autophagy inhibition^[42].

Autophagy is induced in non-transformed and oncogene-transformed breast cell lines following matrix detachment and protects them from anoikis or detachment-induced cell death^[35]. Also, chloroquine treatment, a pharmacological agent that blocks autophagy by accumulating in the lysosome and blocking the degradation of autophagosomes, decreased tumor growth, increased survival and decreased metastasis in the 4T1 model of breast cancer^[61]. Additionally, most breast cancer tumors will very likely have alterations in the autophagic pathway since mutations commonly present in breast cancers are known to be important regulators of the autophagic pathway. This is particularly the case of PI3K mutations, alterations in the PI3K-mTOR pathway, p53, EGFR and Bcl-2^[46,58].

AUTOPHAGY AND BREAST CANCER TREATMENT

Endocrine therapy is the mainstay in ER positive disease. While adjuvant endocrine therapy reduces breast cancer mortality, many ER+ tumors develop resistance and eventually recur. Although the mechanisms of endocrine therapy resistance are not well understood, autophagy has been suggested to be involved in them^[62]. In this regard, autophagy is induced in response to anti-estrogen therapy in the MCF7 breast cancer cell line and its inhibition sensitized to tamoxifen treatment in a tamoxifen-resistant cell line^[63]. It has also been shown that blocking autophagy sensitizes to restoration of antiestrogen sensitivity by Bcl-2 and BCL2L2 co-inhibition in a MCF7-derived anti-estrogen resistant cell line. Importantly, in

the former work, autophagy inhibition with 3-MA or beclin 1 knockdown, decreased necrotic cell death and induced apoptosis in the resistant cells after treatment with the antiestrogen ICI 182780 in response to Bcl-2/BCL2L2 co-inhibition^[64]. These observations suggest that autophagy is not only important for the development of anti-estrogen resistance but also for defining the type of cell death, which could also be important for a successful therapy.

Several important roles for autophagy have been described for HER2 positive breast cancers. Therapies targeting the HER2 receptor like trastuzumab (an antibody targeting HER2) or lapatinib (a small molecule tyrosine kinase inhibitor that targets both EGFR and HER2) are known to induce autophagy in both sensitive and resistant cells^[65,66]. Autophagy has also been implicated in the development of resistance to treatment since cells that have been made resistant to trastuzumab exhibit high levels of autophagy and its pharmacological or genetic inhibition sensitized to trastuzumab in cells that have acquired or inherent resistance^[66,67]. Also, a significant association has been found between loss of beclin 1 and HER2 amplification in breast cancers and this work found that loss of beclin 1 predicted response to trastuzumab alone or in combination with other drugs^[56] suggesting an important role for autophagy in this type of cancer. Additionally, a recent study found a direct interaction between both proteins. In this regard, beclin 1 overexpression was found to enhance HER2 phosphorylation and to decrease response to lapatinib whereas beclin 1 knockdown enhanced lapatinib-induced apoptosis^[65]. Also, ATG12 has been reported to be upregulated in trastuzumab resistant cell lines and its knockdown sensitized JIMT1 resistant cells to trastuzumab treatment both *in vitro* and *in vivo*^[68].

Although the previous evidence suggests that autophagy inhibition would be a promising therapeutic target in combination with HER2 targeted therapies, a recent study found conflicting results in NSCLC where a direct association between beclin 1 and EGFR was also found^[69]. Although these findings are in line with the previous observations on beclin 1 and HER2 receptor, in this work, active EGFR was found to bind and phosphorylate beclin 1 decreasing its association with VPS34 and autophagy in NSCLC cell lines. Tyrosine kinase inhibitor (TKI) treatment disrupted beclin 1 association with EGFR and restored autophagy in TKI sensitive cells. These results associated autophagy inhibition with an enhanced cancer cell survival in response to TKI inhibitors and resistance *in vitro*. Also, cells expressing a tyrosine phosphorylation mutant of beclin 1 (EGFR-phosphorylated sites), which decreased binding to VPS34 and autophagy, showed enhanced tumorigenesis and reduced response to erlotinib *in vivo*. The conclusions of this study were that autophagy should not be inhibited in combination with TKI therapy since they found that the tumors with the least autophagy and the greatest amount of cell death also were the most aggressive. It is unclear if these major differences are due to effects that are specific to lung cancer *vs* breast cancer

or if the interaction of beclin 1 with HER2 is different to the one with EGFR.

Chemotherapy in breast cancer often includes the use of anthracyclines, taxanes (docetaxel, paclitaxel), and DNA damaging agents like cyclophosphamide, fluorouracil or platinum-based compounds^[70,71]. Adjuvant systemic chemotherapy is used particularly in the management of TNBC, which lacks a targeted treatment, and is also given with or preceding trastuzumab for patients with HER2-positive, invasive breast cancer^[72]. Most of these agents are known to be good autophagy inducers in different types of cancer^[15]. In breast cancer cell lines, specifically in the MCF7 cell line, epirubicin was found to induce autophagy and a non-apoptotic form of cell death. In this work, autophagy inhibition increased drug toxicity by inducing apoptosis. Moreover, sensitivity to epirubicin was partially restored by autophagy inhibition in an MCF7 cell line that was made epirubicin-resistant^[73]. On the other hand, pharmacological inhibition of autophagy was found to enhance doxorubicin induced cardiotoxicity. Importantly, autophagy induction with rapamycin increased survival of doxorubicin-treated mice in the same work^[74]. Although the mechanisms by which rapamycin increased mice survival could have involved autophagy-independent mechanisms, this work brings up an important point about trying to manipulate autophagy systemically during cancer treatment, since it could have undesirable side-effects in other tissues even if it has the desired effects in tumor tissue and the overall effect could still be disadvantageous for treatment of a patient.

Microtubule stabilizing agents (taxanes) are used in cancer therapy because of their ability to inhibit mitosis. However, they are also known to have profound effects on autophagy. Microtubules support the assembly of pre-autophagosomal structures, direct their movement possibly to mediate formation of mature phagophores and also mediate trafficking of autophagosomes towards lysosomes. Microtubules also regulate two major complexes involved in the initiation of the autophagic response: mTORC1 and class III PI3K complex^[75]. Indeed, part of the cytotoxic effect of taxol has been shown to be dependent on its ability to block autophagosome transport and maturation, since treatment with 3MA or knockdown of ATG7 or VPS34 decreased cell death induced by paclitaxel in MCF7 and SKBR3 breast cancer cell lines. Importantly, this work also found increased expression of *ATG* genes in docetaxel sensitive primary breast tumor biopsy samples (when compared to resistant samples), probably indicating higher levels of autophagy and suggesting that levels of ATG proteins could be investigated as possible prognostic markers for clinical taxane effectiveness^[76]. Notably, other microtubule targeting drugs like vinblastine, a microtubule depolarizing drug, was found to stimulate formation of autophagosomes, decrease fusion with endosomes and disrupt autophagosome motility^[77]. So, despite having different effects on the autophagic pathway, drugs that disrupt microtubules certainly decrease autophagic flux. This is important

since it is often thought that autophagy is always induced in response to stress induced during chemotherapy, underscoring the need to understand the molecular mechanisms by which specific therapies affect the autophagic pathway.

Genotoxic stress as a result to ionizing radiation or chemotherapeutic drugs is known to increase p53 levels and induce cell cycle arrest, apoptosis, senescence or autophagy^[78]. In this regard, p53 has recently been shown to be an important regulator of autophagy with dual roles depending on its subcellular location. In the nucleus, p53 is pro-autophagic in a transcription dependent and independent manner and in the cytoplasm it can act as a repressor of autophagy^[8]. It is thus not surprising that DNA damaging agents and radiotherapy used for breast cancer treatment can induce autophagy in breast cancer cell lines^[79-81]. However, genetic inhibition of autophagy was not found to sensitize to cisplatin treatment and chloroquine treatment only mildly sensitized one mouse breast cancer cell line (67NR) but not another one (4T1)^[79]. Moreover, autophagy inhibition sensitized the MCF7^[81] but not the 4T1 cell line^[80] to radiation therapy. These different effects could be due to the p53 status (MCF-7 cells have wild type p53 and 4T1 cells are p53-null), possibly suggesting that autophagy inhibition together with DNA damaging agents should be used especially in those cancers with wild type p53 or with p53 mutants that maintain certain functions. So, despite numerous reports in the literature reporting a cytoprotective role of autophagy during DNA damaging agents in other types of cancer^[82], whether this is true for breast cancer and if this is dependent on the p53 status remains to be determined. This last statement is of particular importance since *p53* is frequently mutated in basal-like breast cancer, where the combination of *p53* mutations together with inferred pathway activity suggests that loss of p53 function occurs within most, if not all basal-like cancers^[46] and in which chemotherapy is most frequently used.

As mentioned above, triple negative breast cancers lack a molecular-directed therapy. However, recent studies have described molecular characteristics of the disease that are now targets of experimental agents, including poly (ADP-ribose) polymerase (PARP, for BRCA-associated tumors) inhibitors, angiogenesis blockers, EGFR inhibitors^[52,83] and endoplasmic reticulum stress inducers^[84]. With regards to endoplasmic reticulum stress, TNBC are known to be highly proliferative, aneuploid tumors^[48,50], conditions that are known to lead to proteotoxic stress in cancer cells and that could lead to the induction of autophagy. In this regard, autophagy inhibition seems to be a promising target since combination of autophagy inhibitors plus endoplasmic reticulum aggravators nelfinavir and celecoxib was synergistic in enhancing tumor cell killing particularly in TNBC cells^[84] and autophagy inhibition sensitized MCF7 cells to bortezomib treatment^[85]. Also, treatment with HDAC6 inhibitor panobinostat induced endoplasmic reticulum stress and autophagy in TNBC cells. Moreover,

chloroquine treatment synergized with panobinostat and induced cell death both *in vitro* and *in vivo*^[86].

Although most of the evidence described above suggests that autophagy should be inhibited in order to improve breast cancer therapy, some studies also suggest that autophagy could be involved in the cell's demise implying the opposite—that one should sometimes increase autophagy during breast cancer treatment. For example, Bcl-2 knockdown in MCF7 cells has been shown to induce autophagy and non-apoptotic cell death, which was decreased by knocking down ATG5, suggesting that autophagy could be involved in cell death in this model^[87]. These studies were performed in the MCF7 cell line, a widely used model for breast cancer and which is known to lack the executioner caspase-3 and thus have reduced susceptibility to apoptosis^[82]. Although this raises the caveat that pro-death effects of autophagy in this experimental model are due to its unusual deficiency in apoptosis, it is a relevant model for breast cancer since Bcl-2 is known to be overexpressed in breast cancers, resistance to apoptosis is thought to be an intrinsic property of many tumor cells and anti-apoptotic members of the Bcl-2 family have been found to be amplified in human cancers, including breast cancer^[88].

AUTOPHAGY AND BREAST CANCER STEM CELLS

According to the cancer stem cell hypothesis, tumorigenic cancer stem cells or tumor initiating cells (TICs) are those cells within a tumor that have self-renewal and tumorigenic capacities. They can “differentiate” into cancer cells with limited proliferative potential, creating a hierarchical organization within a tumor^[89]. Breast cancers are known to follow the cancer stem cell model, where tumors can be separated into tumorigenic (CD44⁺/CD24^{-low} or ALDH1⁺) and non-tumorigenic components, suggesting that only a minority of cells in a tumor can proliferate extensively and that some therapies that shrink tumors might not be curative because they fail to eliminate TICs. Breast cancer claudin-low tumors and cell lines have features of tumor-initiating cells since they express the same gene signature as the CD44⁺/CD24⁻ tumor fraction^[50]. Moreover, recent evidence suggests that TICs are also enriched in basal tumors and cell lines and their abundance has been associated with a worse overall survival^[90,91].

It is predicted that autophagy should be especially crucial for quality control mechanisms and maintenance of cellular homeostasis in stem cells due to their unique ability to self-renew and differentiate and relatively long life^[92]. Recent studies suggest that autophagy does in fact play a crucial role in the origin, maintenance and systemic distribution of TICs. The first paper linking autophagy to TICs described higher levels of LC3B and ATG5 in DCIS (ductal carcinoma *in situ*) derived tumorigenic spheroids when compared to epithelial cells in the same culture. Moreover, treatment of DCIS culture cells

with chloroquine suppressed xenografts tumor formation^[93]. The authors suggest that autophagy is activated in DCIS cells to persist and proliferate in the metabolically stressed intraductal space^[94]. Another recent paper reported that autophagy inhibition by ATG12, ATG8 knockdown or chloroquine treatment could decrease the number of CD44⁺/CD24⁻ cells in the MDAMB231 and JIMT1 breast cancer cell lines by increasing CD24 transcription^[95]. Finally, a recent study found increased autophagic flux in ALDH⁺ cells from mammospheres of the MCF7 cell line when compared to the bulk population of cells, increased beclin 1 expression in mammospheres when compared to adherent cells and decreased mammosphere size and formation by knockdown of beclin 1 as well as decreased tumor-forming ability in beclin 1 knockdown cells from mammosphere cultures of MCF7, SKBR3 and SK-3rd breast cancer cell lines^[96]. All these studies suggest that autophagy inhibition could preferentially target the TIC population in a tumor suggesting that combination of autophagy inhibition with other therapies would eliminate stem cells that survive the original treatment.

CONCLUSION

Research on autophagy and breast cancer treatment has dramatically increased in the past years. Despite being an area with many unanswered questions, recent discoveries in breast cancer biology and the autophagic pathway have increased our understanding on the implications and importance of trying to manipulate autophagy during breast cancer treatment. For example, it has been suggested that autophagy should be preferentially inhibited together with treatments that increase the tumor cell's dependency on it, like proteasomal inhibitors. Such combination treatment should probably be especially used to treat highly proliferative, aneuploid tumors with high proteotoxic stress, *e.g.*, basal-like tumors. On the other hand, autophagy inhibition could perhaps be avoided in combination with those therapies that themselves are known to negatively target the autophagic pathway, like microtubule-targeting agents. Therefore, autophagy manipulation will probably not be a generally applicable mechanism of sensitization to therapy in breast cancer and it will most likely depend on the type of breast cancer and on the treatment used. Moreover, evidence in the literature suggests that breast cancers (at least those with oncogenic events similar to the ones in the MMTV-PyMT or *Palb2*^{-/-} mouse models) display a certain degree of autophagy dependence and we recently found that many TNBC cell lines are particularly sensitive to autophagy inhibition when compared to luminal cells^[97], indicating that autophagy dependence in breast cancer may be subtype-dependent.

There are, however, some unresolved questions on autophagy and cancer that should be carefully addressed. For example, the fact that autophagy modulation can regulate the type of cell death in response to therapy is

an important thing to consider. In this regard, autophagy inhibition was shown to decrease necrosis and induce apoptosis in an MCF7 anti-estrogen resistant cell line in response to ICI 182780 treatment and Bcl-2/BCL2L2 co-inhibition^[64]. However, it has also been shown that although autophagy inhibition decreased survival in apoptosis deficient epithelial cells exposed to metabolic stress, it also changed the mode of cell death from apoptosis to necrosis, stimulating cytokine and chemokine production, macrophage infiltration and tumor growth *in vivo*^[34]. It has also been shown that autophagy induces ATP secretion during chemotherapy and that this is necessary for the establishment of a therapeutic immune response^[5]. Moreover, a recent study found that while autophagy inhibition sensitizes to radiotherapy both *in vitro* and *in vivo* in immune deficient mice, it increases tumor volume in an immune competent model *in vivo*. This work suggests that autophagy inhibition can decrease irradiation-induced release of ATP from tumor cells and impair an anti-tumoral immune response^[98]. This raises important questions about the immunogenicity of cell death and the possible final outcome in therapy when autophagy is inhibited-in a person, it may be better to directly kill slightly fewer tumor cells while allowing a robust anti-tumoral immune response than to obtain more direct tumor cell killing but losing the immune response. In breast cancer, autophagy has been shown to inhibit rather than stimulate the immune response (since autophagy inhibition was found to induce cytokine release) and autophagy deficient tumors had increased immune cell infiltration and decreased tumor growth and metastasis^[6]. The different effects might be related to the specific interplay of the immune system with cancer cells and to the type of therapy employed. Thus, if these effects are particular to the type of cancer (or the subtype of breast cancer) and the treatment used remains an important open question.

Finally, although most of the evidence in the literature suggests that autophagy should be inhibited in combination with breast cancer therapies, the fact that autophagy seems to be involved in cell death at least with some treatments should also be considered. If this effect is particular to a subtype of breast cancer, to specific mutations found in the tumor or to a certain treatment is something that needs to be studied further. Also, the fact that autophagy is involved in tumor suppression and that protective effects of autophagy have been described for diseases other than cancer (such as neurodegenerative, infectious diseases and ageing) raises concerns with regard to whether autophagy inhibition during cancer treatment could induce tumor formation in other tissues or promote other diseases in patients^[2]. Thus, a careful analysis of the full spectrum of effects of autophagy on cancer will be needed in order to successfully modulate it for therapeutic purposes. This may be a particular challenge for breast cancer therapy due to the high heterogeneity of this type of cancer but holds the opportunity for personalizing treatment protocols to maximize the benefit to breast cancer patients.

Abstract

The global burden of breast cancer continues to increase largely because of the aging and growth of the world population. More than 1.38 million women worldwide were estimated to be diagnosed with breast cancer in 2008, accounting for 23% of all diagnosed cancers in women. Given that the 5-year survival rate for breast cancer is now 90%, experiencing breast cancer is ultimately about quality of life. Women treated for breast cancer are facing a life-time risk of developing lymphedema, a chronic condition that occurs in up to 40% of this population and negatively affects breast cancer survivors' quality of life. This review offers an insightful understanding of the condition by providing clinically relevant and evidence based knowledge regarding lymphedema symptoms, diagnosis, risk reduction, and management with the intent to inform health care professionals so that they might be better equipped to care for patients.

Key words: Lymphedema; Breast cancer; Symptoms; Diagnosis; Risk reduction; Management

Core tip: Lymphedema is one of the most dreaded and

unfortunate outcomes of breast cancer treatment. Up to 40% of the women treated for breast cancer had lymphedema. Currently, there is no cure for this chronic condition. Even more distressing is that women who treated for breast cancer are facing a life-time risk of developing lymphedema. Lymphedema elicits daily stress and negative impact on breast cancer survivors' the quality of life. This paper offers an insightful understanding of the condition by providing clinically relevant and evidence based knowledge regarding lymphedema symptoms, diagnosis, risk reduction, and management with the intent to inform health care professionals so that they can be better equipped to care for patients.

INTRODUCTION

The global burden of breast cancer continues to increase largely because of the aging and growth of the world population. More than 1.38 million women worldwide were estimated to be diagnosed with breast cancer in 2008, accounting for 23% of all diagnosed cancers in women^[1]. Given that the 5-year survival rate for breast cancer is now 90% and currently there are more than 2.9 million breast cancer survivors in the United States^[2], experiencing breast cancer is ultimately about quality of life. Women treated for breast cancer are facing a life-time risk of developing lymphedema, a chronic condition that occurs in up to 40% of this population^[3-6].

Breast cancer-related lymphedema results from obstruction or disruption of the lymphatic system associated with cancer treatment (removal of lymph nodes and radiotherapy); patient personal factors [obesity or

Table 1 Bivariate association between each symptom and lymphedema

Symptom	OR	95%CI	P-value
Arm swelling	561	76.04-71644.49	< 0.0001

Modified from the publication Ref.[23].

higher body mass index (BMI)] can increase the risk of lymphedema; and infections or trauma can trigger lymphedema^[4-6]. Lymphedema has elicited psychosocial problems that affect breast cancer survivors' daily lives^[7,8]. Significantly lower quality of life is observed in breast cancer survivors with lymphedema than in those without the condition^[9-12]. Management of lymphedema remains a major challenge for patients and health care professionals. Routine check-ups for lymphedema management, long-term physical therapy, management equipment (compression garments, bandages, special lotions), and repeated cellulitis, infections, and lymphangitis create financial and economic burdens not only to survivors but also to the health care system^[11]. Breast cancer survivors with lymphedema have significantly higher health care costs than those without it, they spend more days annually either hospitalized or visiting physicians' offices; they also have more days absent from work, which could adversely affect employment^[11,12]. Women treated for breast cancer often report being unaware that lymphedema was a possible outcome of cancer treatment and that health care professionals are not well informed and/or not helpful in guiding them on how to reduce the risk of lymphedema and manage this debilitating condition^[8,13]. The purpose of this paper is to offer an insightful understanding of the condition by providing clinically relevant and evidence based knowledge regarding lymphedema symptom, diagnosis, risk reduction, and management with the intent to inform health care professionals so that they might be better equipped to care for patients.

LYMPHEDEMA SYMPTOMS

Symptom assessment is essential since very often observable swelling and measurable volume changes are absent

during the initial development of lymphedema^[14-16]. Breast cancer survivors with lymphedema in the ipsilateral upper extremity report experiencing multiple symptoms, including swelling, heaviness, tightness, firmness, pain/aching/soreness, numbness, tingling, stiffness, limb fatigue, limb weakness, and impaired limb mobility of shoulder, arm, elbow, wrist, and fingers^[8,13-16]. These symptoms may be the earliest indicator of increasing interstitial pressure changes associated with lymphedema^[15,16]. As the fluid increases, the limb may become visibly swollen with an observable increase in limb size. Recent research shows that limb volume change has significantly increased as breast cancer survivors' reports of swelling, heaviness, tenderness, firmness, tightness, and aching have increased^[17]. Clinicians and researchers have long recognized that lymphedema symptoms may indicate an early stage of lymphedema in which changes cannot be detected by objective measures^[8,15]. The early stage of lymphedema may exist months or years before overt swelling occurs^[14-16].

Recent research demonstrates significant bivariate associations between each symptom and lymphedema^[16] (Table 1). A significant relationship exists between an increased number of symptoms and an increase in survivors' limb volume measured by infra-red perimeter^[17]. On average, breast cancer survivors reported 4.2 mean numbers of symptoms for survivors with < 5.0% limb volume change (LVC); 5.5 mean numbers of symptoms for 5.0%-9.9% LVC, 7.0 mean numbers of symptoms for 10.0-14.9% LVC, and 12.5 mean numbers of symptoms for \geq 15% LVC^[17]. A count of lymphedema symptoms is able to differentiate healthy adults from breast cancer survivors with lymphedema and those at risk for lymphedema^[16]. A diagnostic cutoff of three symptoms discriminated breast cancer survivors with lymphedema from healthy women with sensitivity of 94% and specificity of 97% [AUC (area under the curve) = 0.98]. A diagnostic cutoff of nine symptoms discriminated at-risk survivors and survivors with lymphedema with sensitivity of 64% and specificity of 80% (AUC = 0.72)^[16].

Since swelling is one of the key observable signs of lymphedema, objective measures are usually considered superior to symptom assessment or patient's perception of lymphedema. Perhaps, from the patient's perspective it is only the symptom experience and the perception of lymphedema that matter clinically because it is symptom experience and the perception of lymphedema that elicit tremendous distress and impair survivors' quality of life more than a measurement of inter-limb volume or girth size^[8,15]. In the absence of objective measurements capable of detecting early development of lymphedema, assessing symptoms may be a useful and cost-effective screening tool for detecting lymphedema.

DIAGNOSING BREAST CANCER-RELATED LYMPHEDEMA

Breast cancer-related lymphedema is a chronic syndrome

of abnormal swelling and multiple symptoms, resulting from abnormal accumulation of protein-rich lymph fluid in the interstitial tissue spaces due to an imbalance between lymph fluid production and transport^[13,14]. Because swelling is the cardinal sign of lymphedema, traditionally, lymphedema has been clinically diagnosed by health care professionals' observations of swelling and has often arbitrarily been defined in research as a 2 centimeters increase in limb girth, a 200-mL or more increase in limb volume, or a 5% or greater limb volume change^[17-19]. Inconsistency in the criteria defining lymphedema and the use of different measures has presented tremendous difficulty in diagnosing lymphedema. Breast cancer-related lymphedema can also occur in the shoulder, breast, and thoracic regions, unfortunately, no epidemiological studies have explored the incidence of lymphedema in the shoulder, breast, and thoracic regions due to lack of instruments to quantify swelling in these difficult-to-measure areas. Quantification of lymphedema by measuring limb size or girth or limb volume has been a major objective measure in research and clinical practice for diagnosing lymphedema using sequential circumference limb measurement, water displacement, and infra-red Perometry^[16]. Bioelectrical impedance is emerging as a possible alternative^[20-23]. Emerging assessment tool such as sonagraph needs more research to determine its reliability, sensitivity, and specificity.

Sequential circumferential arm measurements

Measuring limb size or girth or limb volume has been the most widely used diagnostic method in research. A flexible non-stretch tape measure for circumferences is usually used to assure consistent tension over soft tissue, muscle, and bony prominences^[19]. Measurements are done on both affected and non-affected limbs at the hand proximal to the metacarpals, wrist, and then every 4 or 10 centimeters from the wrist to axilla. The most common criterion for diagnosis has been a finding of ≥ 2 centimeters or ≥ 200 mL difference in limb volume as compared to the non-affected limb or 5% or 10% volume difference in the affected limb^[19].

Water displacement

Water displacement is seldom used in clinical settings because of spillover and hygienic concerns. Patients submerge the affected arm in a container filled with water and the overflow of water is caught in another container and weighed or measured. This method does not provide data about localization of the edema or shape of the extremity^[19,23]. The method is contraindicated in patients with open skin lesions. Patients may find it difficult to hold the position for the time needed for the tank overflow to drain^[19,23].

Infrared perometry

The infrared perometer is an optoelectronic device that works similarly to computer-assisted tomography, but makes use of light instead of X-rays^[19,23]. The volume and

shape of the limb can be measured and volume changes can be calculated. Perometry and circumference are reliable measurement of limb volume change over time in individuals undergoing breast cancer treatment^[19].

Bioelectrical impedance analysis

Bioelectrical impedance analysis (BIA) measures impedance and resistance of the extracellular fluid using a single frequency below 30 kHz^[20,21]. The device uses the impedance ratio values between the unaffected and affected limb to calculate a *Lymphedema Index*, termed as L-Dex ratio. A recent published study has demonstrated that the L-Dex ratio with a cutoff point of $> +7.1$ can discriminate between at-risk breast cancer survivors and those with lymphedema with 80% sensitivity and 90% specificity (AUC = 0.86)^[20]. In comparison, using the industrial recommended cutoff point of L-Dex $> +10$ can only identify 66% of true lymphedema cases among at-risk breast cancer survivors, that is, miss 34% of true lymphedema cases [AUC = 0.81 sensitivity = 0.66 (95%CI: 0.51-0.79)]. Since early treatment usually leads to better clinical outcomes, it is important to have higher sensitivity to avoid missing large number of true lymphedema cases. Since there are still about 20% of true lymphedema cases are missed by BIA with a cutoff point of $> +7.1$, it is critical for health care professionals to incorporate other assessment methods, including self-report, clinical observation, or perometry, to ensure the accurate detection of lymphedema^[20]. The BIA technique currently is not appropriate in assessing bilateral limb lymphedema.

LYMPHEDEMA RISK REDUCTION

Over 50% of breast cancer survivors were found to be exceptionally worried about their risk of developing lymphedema^[6]. Multiple factors may be associated with this fear, including symptom experience, type of cancer surgery, education level, earlier experiences, or the way that health care professionals educate and counsel survivors about risk reducing practices.

While lymphedema incidence has been reported less frequently in women who underwent sentinel lymph node biopsy only (SLNB), lymphedema has by no means become a minor or disappearing problem. A large number of women each year still face the life-time risk of developing this progressive and debilitating condition even with the most conservative estimates suggesting that 3% of women with sentinel lymph node biopsies and 20% of those who have axillary dissections develop lymphedema at 12 mo following breast cancer surgery^[6]. It is essential to note that surgical removal of lymph nodes and radiation remains the optimal choice for treating breast cancer with positive cancerous lymph nodes. As a result, current surgical approaches for diagnosis of and treatment for breast cancer continue to make patients with invasive cancer susceptible to the risk of lymphedema.

Risk factors that are directly related to breast cancer treatment may be mostly unavoidable for patients treated

for breast cancer, including breast surgery (lumpectomy and mastectomy), removal of lymph nodes (sentinel lymph node biopsy and axillary lymph node dissection), radiotherapy, or chemotherapy^[4-6]. There are also known risk factors that are not directly related to breast cancer treatment. These risk factors may actually be modified, such as obesity, weight gain after diagnosis, minor upper extremity infections, injury or trauma to the affected limb, or overuse of the limb^[4-6].

For decades, patient education has emphasized on precautionary lifestyle to avoid the modifiable risk factors. Breast cancer survivors are cautioned to avoid such activities as repetitive activity, lifting weighted objects, needle punctures, blood draw, as well as to use of compression garments for air travel^[24]. A recent systematic review evaluated the scientific evidence for current recommended risk reduction recommendations. The review concluded that some commonly practiced precautionary lifestyle recommendations were proved to be not true or “fiction”, such as avoid air travel/wear compression garment for air travel, avoid pressure, avoid extremes of temperature/apply sunscreen/avoid sun burn, avoid vigorous exercise; while precautionary recommendation of avoiding needle sticks/injection needs more research evidence. Only maintaining normal weight is an evidence based recommendation^[24]. Thus, to date, the insufficiency of high quality evidence is lacking to support these practices to reduce the risk of developing lymphedema and effective management of lymphedema.

Inflammation-infection and higher body mass index (BMI) are the main predictors of limb volume change and lymphedema besides treatment-related risk^[3-6]. Women who had previous inflammation-infection in the breast, chest, or arm were 3.8 times more likely to develop lymphedema^[5]; weight gain and obesity (BMI > 30 kg/m²) increases lymphedema risk: survivors with each increase of 1 kg/m² in their BMI were 1.11 times more at risk for developing lymphedema^[5,25].

Patient education focusing on risk reduction strategies is promising for lymphedema risk reduction. A recent study of 136 breast cancer survivors demonstrated patients who received lymphedema information reported significantly fewer symptoms and more frequent practice of risk reduction behaviors than those who did not^[26]. After controlling for confounding factors of treatment-related risk factors, patient education remains an important predictor of lymphedema outcome. While rigid prevention measures may promote fears and frustration, one essential risk reduction behavior under patient control is maintaining optimal body weight, because excess body weight is associated with decreased lymphatic function^[27-29].

Preventing infection and trauma that may trigger the onset of lymphedema is vital for lymphedema risk reduction^[5,27,28]. Infection is a significant risk factor and is the most frequently occurring complication of lymphedema^[5]. Risk increases with breaches in skin integrity. Daily skin care that maintain skin moisture and integrity

may be promising to preventing infection and trauma in the affected limb^[29,30]. Fluid accumulation can cause skin dryness and irritation, increasing the risk of cellulitis and skin infection. Water-based and low pH moisturizers are recommended to discourage infection^[30,31].

In the past, breast cancer survivors were cautioned to restrict physical exercises as a way to reduce their risk for lymphedema. A growing body of evidence suggests that exercises, including whole body exercises (walking, running), weight training, resistance training, do not necessarily increase lymphedema risk^[31,32]. Breast cancer survivors should be encouraged to perform all postoperative exercises, resume normal activities as tolerated, and be as fit as possible, while monitoring their affected limbs^[31]. In addition to a broad range of benefits, from weight control, physical fitness, positive emotion, and quality of life, physical exercise can promote lymph fluid drainage through large muscle movement. Survivors should be instructed to perform physical exercise according to the general exercise guidelines^[31,32] (Table 2).

To facilitate effective lymphedema risk reduction, health care professionals can assist patients by presenting or reinforcing risk reduction information. Emphasis on self-protection rather than rigid rules fosters patient empowerment^[26]. An empowered patient assumes responsibility for reminding health care professionals to avoid use of the affected arm rather than expecting health care professionals to remember to do so.

MANAGEMENT OF BREAST CANCER-RELATED LYMPHEDEMA

Once breast cancer-related lymphedema is established, there is no cure. Management of lymphedema focuses on swelling reduction and symptom alleviation while minimizing exacerbations of swelling. Treatments include pharmacological therapy, surgery, complete decongestive physiotherapy (CDT), mechanical pneumatic pumps, and infection prevention and treatment^[29-44]. Emerging treatment such as low-dose laser needs more research to determine its efficacy.

Pharmacological management of lymphedema uses benzopyrones, flavonoids, diuretics, hyaluronidase, pantothenic acid, and selenium^[35]. Poor quality of existing trials on pharmacological agents makes it impossible to draw conclusions about the effectiveness of pharmacological approach for lymphedema among breast cancer survivors^[35].

Surgical treatment for lymphedema includes microsurgical lymphovenous or lympholymphatic anastomoses, debulking, and liposuction^[34]. Surgical procedures aiming at enhancing lymphatic function by removing excess fluid or tissue in the affected area have been shown to be only marginally effective^[34]. Surgery does not cure lymphedema, use of compression is necessary after surgery^[34]. Potential complications may occur with surgical management, such as recurrence of swelling, poor wound healing, and infection; thus surgical treatment should only be

Table 2 General exercise guidelines for breast cancer survivors

	Suitability	
	Survivors at-risk for Lymphedema	Survivors with Lymphedema
(1) Initiate exercise at lower intensity gradually increasing intensity as tolerated, monitoring the affected limb for signs and symptoms of lymphedema	Yes	Yes
(2) Walking, swimming, cycling and low impact aerobics are recommended.	Yes	Yes
(3) Modify physical exercise to reduce the risk of trauma and injury. Exercise to the extent that the affected body part is not sore or fatigued	Yes	Yes
(4) Flexibility exercises should be performed to maintain range of movement	Yes	Yes
(5) Appropriate warming up and cooling down should be implemented as part of exercise regime	Yes	Yes
(6) Compression garments should be worn during exercise	Not established	Yes

considered when other treatments fail, and with careful consideration of the benefits to risks ratio.

Chronic lymphedema leads to formation of excess subcutaneous adipose tissue secondary to slow or absent lymph flow^[36]. Liposuction can help to remove excess fat tissue^[36-38]. Liposuction increases skin capillary blood flow without further damaging already compromised lymph transport capacity in breast cancer survivors with lymphedema^[36-38]. Patients are able to maintain limb size reduction with the use of compression garments after liposuction. Liposuction does not correct inadequate lymph drainage and is contradictory when pitting edema is present.

Complete decongestive therapy (CDT) is the standard care for lymphedema in the United States, but it is time-consuming, expensive, and requires lifelong maintenance. This approach includes manual lymph drainage, multi-layer, short-stretch compression bandaging, gentle exercise, meticulous skin care, education in lymphedema self-management, and elastic compression garments^[39-41]. In the treatment phase, patients generally receive 2-h treatments 5 d a week for 3 to 8 wk. Once treatment phase is completed, the patient continues self-management phase at home with skin care and exercise, self-massage, and use of a compressive sleeve and glove during the day and/or arm bandaging at night^[40,41]. Studies have shown long-term volume reduction as high as 50%-63% in up to 79% mean volume reduction of patients who are 100% adherent^[39,40]. Lifelong adherence to prescribed treatment regimen is required to prevent progression of disease. Adherence to the prescribed management routine can be difficult because even the most customized garments or sleeves sometimes are uncomfortable, unsightly, and laborious to put on^[39-41]. A constellation of complex factors (*e.g.*, physical, financial, aesthetic, time) can influence survivors' adherence with management routines. From the patient's perspective, the complete decongestive therapy itself is a constant reminder of cancer experience that prevents her from living a normal life^[8].

Mechanical pneumatic pumps use electricity to inflate a single-chamber or multi-chamber sleeve that produces external limb compression. A decreased tissue capillary filtration rate facilitates tissue fluid reduction and, consequently, limb volume decrease^[42]. Lymph formation decreases, but lymph transport is not improved. Pneumatic

pumps can reduce swelling, but concern exists regarding the way in which the rapid displacement of fluid in the other areas of the body. The use of pumps does not eliminate the need for compression garments and may not provide more benefit than garments alone^[42]. Using pumps may cause complications, including lymphatic congestion and injury proximal to the pump sleeve, and increased swelling adjacent to the pump cuff in up to 18% of patients^[42].

Infection prevention and treatment is another important aspect of lymphedema management. Infection is the most common lymphedema complication^[43]. Lymph stasis, decreased local immune response, tissue congestion, and accumulated proteins and other debris foster infection^[43]. Patients and health care professionals should be vigilant about any signs and symptoms of infection, such as fever, malaise, lethargy, and nausea. Prompt oral antibiotics are the first line of treatment for acute infection to prevent the need for intravenous therapy and hospitalization^[29-30,44]. Preventive antibiotics have been highly effective for patients who experience repeated serious infections or inflammatory episodes^[43,44]. Skin care optimizes the condition of the skin and prevents cellulitis and infection^[43,44]. Lymphedema can cause skin dryness and irritation, increasing the risk of cellulitis and skin infection. Water-based and low pH moisturizers are recommended to discourage infection^[31].

CONCLUSION

Lymphedema is one of the most important factors that elicit daily stress in breast cancer survivors since there is no cure for this condition^[6-7]. In addition, breast cancer survivors face a life-long risk of developing lymphedema since there is no defined period of time after cancer treatment when the risk no longer exists^[3]. To reduce the risk of lymphedema and maintain optimal lymphedema management, patient self-care is ultimately necessary to promote lymph drainage and prevent inflammation-infection. Optimal self-care typically includes adherence to risk reduction behaviors, optimal weight management, use of compression garments, exercises, healthy lifestyle practices, and seeking assistance for lymphedema-related problems. Health care professionals should focus on empowering patients with skills and knowledge that helps

patients to reduce lymphedema risk and achieve optimal management and risk reduction. Empowering patients for optimal self-care is a great impetus to long-term success of lymphedema risk reduction and management.

Abstract

The estrogen receptor (ER) pathway plays a critical role in breast cancer development and progression. Endocrine therapy targeting estrogen action is the most important systemic therapy for ER positive breast cancer. However its efficacy is limited by intrinsic and acquired resistance. Mechanisms responsible for endocrine resistance include deregulation of the ER pathway itself, including loss of ER expression, post-translational modification of ER, deregulation of ER co-activators; increased receptor tyrosine kinase signaling leading to activation of various intracellular pathways involved in signal transduction, proliferation and cell survival, including growth factor receptor tyrosine kinases human epidermal growth factor receptor-2, epidermal growth factor receptor, PI3K/AKT/mammalian target of rapamycin (mTOR), Mitogen activated kinase (MAPK)/ERK, fibroblast growth factor receptor, insulin-like growth factor-1 receptor; alterations in cell cycle and apoptotic machinery; Epigenetic modification

including dysregulation of DNA methylation, histone modification, and nucleosome remodeling; and altered expression of specific microRNAs. Functional genomics has helped us identify a catalog of genetic and epigenetic alterations that may be exploited as potential therapeutic targets and biomarkers of response. New treatment combinations targeting ER and such oncogenic signaling pathways which block the crosstalk between these pathways have been proven effective in preclinical models. Results of recent clinical studies suggest that subsets of patients benefit from the combination of inhibitor targeting certain oncogenic signaling pathway with endocrine therapy. Especially, inhibition of the mTOR signaling pathway, a key component implicated in mediating multiple signaling cascades, offers a promising approach to restore sensitivity to endocrine therapy in breast cancer. We systematically reviewed important publications cited in PubMed, recent abstracts from ASCO annual meetings and San Antonio Breast Cancer Symposium, and relevant trials registered at ClinicalTrials.gov. We present the molecular mechanisms contributing to endocrine resistance, in particular focusing on the biological rationale for the clinical development of novel targeted agents in endocrine resistant breast cancer. We summarize clinical trials utilizing novel strategies to overcome therapeutic resistance, highlighting the need to better identify the appropriate patients whose diseases are most likely to benefit from these specific strategies.

Key words: Endocrine therapy; Endocrine resistance; Breast cancer; Therapeutic advances; Targeted therapy

Core tip: Endocrine therapy is the important systemic therapy for hormone receptor positive breast cancer. However, treatment resistance is common. Multiple mechanisms responsible for endocrine resistance have been identified over the past decade. New treatment

combinations targeting estrogen receptor and growth factor receptor signaling which block the crosstalk between these pathways are effective in preclinical models and clinical studies. In this review, we summarize the complex genomic and epigenetic regulatory pathways involved in endocrine resistance, in particular focusing on the clinical trials utilizing novel strategies to overcome therapeutic resistance.

INTRODUCTION

Estrogen receptor (ER) is expressed in about 75% of human breast cancers which is the one of the leading cause of death for women globally. The estrogen-bound ER functions through ligand-activated transcriptional regulation (genomic actions) and by acting as a component of signaling cascades outside of the nucleus (non-genomic actions)^[1-4]. Clinical observations and laboratory studies suggest ER signaling pathway is the major driver in promoting proliferation, survival and invasion of ER-positive breast cancer cells^[5]. Endocrine therapy is the mainstay of treatment for patients with ER-positive breast cancer, especially those with metastatic disease. Endocrine therapies include treatments which target ER by blocking receptor binding with an antagonist or by depriving the tumor of estrogen. The three broad groups of currently approved anti-estrogen therapies are selective estrogen receptor modulators (SERMs) such as tamoxifen, raloxifene and toremifene, which block activity of ER; selective estrogen receptor down regulators (SERDs) such as fulvestrant, which induce destabilization and degradation of ER; and aromatase inhibitors (AIs), including steroidal/irreversible (anastrozole and letrozole) and nonsteroidal/reversible (exemestane) inhibitors, which decrease estrogen production in peripheral tissues and within the tumors through inhibition of the enzyme aromatase^[5-11]. Endocrine therapy as the first targeted therapy in cancer treatment has successfully improved outcome of millions of breast cancer patients in the past 30 years^[5,12].

There is evidence that some breast tumors are more resistant to endocrine therapy than others, despite expressing ER. This is supported by stratification of ER positive tumors into luminal A and luminal B subtypes based on molecular profiling studies over the last decade. The luminal B subtype is more aggressive and less endocrine sensitive, while the luminal A subtype is more indolent and endocrine responsive^[13-15]. Recently The Cancer Genome Atlas (TCGA) data reinforces that luminal B cancers represent a unique subtype of breast cancer, with a distinctive biology from that of luminal A cancers. Multigene tests performed on the primary breast

tumor are increasingly utilized in clinical practice to assist in adjuvant therapy decision making and to distinguish which patients might benefit most from a combination of endocrine therapy plus chemotherapy, rather than endocrine therapy alone. For example, the 21-gene (OncotypeDx) and 70-gene (MammaPrint) assays can classify ER positive tumors according to their aggressiveness, risk of recurrence, and likelihood of benefitting from adjuvant endocrine or chemotherapy. PAM50 is a 50 gene expression assay to separate breast tumor samples into known intrinsic molecular subtypes (basal-like, HER-2 enriched, luminal A and luminal B) and correlate with risk of relapse. The progesterone receptor (PR) is expressed in half of patients with ER+ breast tumors^[16]. Clinical studies have shown that ER+/PR+ tumors are more responsive to endocrine therapy than ER+/PR- tumors^[17]. Furthermore, down-regulation of PR correlates with high growth factor activity, indicating that loss of PR in ER positive breast tumors could serve as a predictor of endocrine therapy outcome^[16,17]. However, no biomarkers that predict resistance to endocrine therapy with certainty are available currently. Therefore most patients with ER positive breast cancers are treated with endocrine therapy, in adjuvant and/or metastatic setting. Tamoxifen is the treatment of choice in premenopausal patients. And aromatase inhibitors (*e.g.*, letrozole and anastrozole) have become the treatment of choice as first-line therapy in postmenopausal patients. On disease progression, second-line treatment options include other classes of AIs (steroidal or nonsteroidal) and the ER antagonists, fulvestrant and tamoxifen^[18]. But the effectiveness of endocrine therapy is limited by high rates of *de novo* or intrinsic resistance (existing before any treatment is given) and acquired resistance during treatment (resistance that develops during a given therapy after an initial period of response). One third of patients will have recurrent disease within 15 years after being treated with tamoxifen for 5 years^[11]. About 50% of patients with metastatic disease do not respond to initial endocrine treatment^[8]. Inevitably the vast majority of patients with ER-positive advanced breast cancer will become refractory to endocrine therapy.

A plethora of mechanisms have been proposed to explain resistance to endocrine therapy, including deregulation of various components of the ER pathway itself^[11,14,19], activation of escape pathways that provide tumors with alternative cell proliferative and survival stimuli^[20-24], alterations in cell cycle and apoptotic machinery^[3,25], modulation in epigenetics and microRNA profile^[1,4,6,26]. In this review, we summarize the key mechanisms that have been implicated in the development of endocrine resistance in breast cancer. We give an overview of the completed and ongoing clinical trials with novel agents targeting these alternative mechanisms, with the goal to overcome endocrine resistance in breast cancer.

LITERATURE SEARCH

PubMed was searched for articles in English published between January, 2000 to February, 2014 using the terms

“breast cancer”, “endocrine resistance”, as well as the individual terms of the molecular components under molecular mechanism listed in this Review. Reference lists from key articles were searched for additional material. Abstracts from the ASCO annual meetings and the San Antonio Breast Cancer Symposium were considered (2010-2012). ClinicalTrials.gov was searched for relevant trials. Articles were identified on the basis of the authors’ knowledge of the advances in endocrine resistant breast cancer research.

MOLECULAR MECHANISM OF ENDOCRINE RESISTANCE

De novo resistance in breast cancer is characterized by loss of ER (the ER α isoform) expression and ER gene mutations such as deletion and point mutation. Patients carrying inactive alleles of cytochrome P4502D6 (CYP2D6) deficiency cannot convert tamoxifen to its active metabolite, endoxifen, therefore are resistant to tamoxifen^[27]. By contrast, multiple mechanisms have been detected to account for the acquired resistance to endocrine therapies. Although it is beyond the focus of this review to summarize all of the known mechanism of endocrine resistance in breast cancer, we can focus on the molecular changes in some of the key pathways involved and their clinical implications (Figure 1).

DEREGULATION OF CLASSIC ESTROGEN SIGNALING

The classic function of ER is its nuclear function, also known as genomic activity, to regulate the expression of genes important for normal and cancer cell proliferation and survival^[3]. The nuclear estrogen receptors (ER α and ER β) have similar structure, consisting of a central DNA-binding domain flanked by two autonomous transcriptional activation domains. In classic estrogen signaling, ligand-bound ER activates gene expression-either through direct binding of dimeric ER to specific DNA response elements in complexes including co-activators, or function as a coregulator through protein-protein interactions with other transcription factors, such as activation protein 1 (Ap1), specificity protein 1 (Sp1) and nuclear factor (NF- κ B) to facilitate binding to serum response elements and activation of transcription^[28-30].

Mechanisms of endocrine resistance include the loss of ER α expression which occurs in 15%-20% of resistant breast cancers, ER α mutations which present in < 1% of ER-positive tumors, the expression of ER splicing variants, specifically the truncated variant ER α 36, and estrogen related receptors (ERR)^[11,14,31-33]. Deregulation of ER co-regulators has been implicated in endocrine resistance as well. For example, increased Ap1 and NF- κ B transcriptional activity are associated with endocrine resistance. Overexpression of nuclear

receptor co-activator 3 (nCOA3, also known as AIB1 or SRC3), detected in two-thirds of all breast cancers, has been implicated in clinical and experimental tamoxifen resistance^[3,21,34].

Post-translational modifications (phosphorylation, methylation and ubiquitination) of ER and its co-regulators are regulated to influence ER activity, interactions with other proteins including cytoplasmic signaling molecules^[21,35,36]. Aberrant regulations at this post-translational level contribute to endocrine resistance as well^[3].

ACTIVATION OF GROWTH FACTOR RECEPTOR PATHWAYS

The ER can also be activated by ligand independent fashion, as a consequence of signaling events downstream of membrane receptor tyrosine kinases (RTKs). RTKs are the intracellular portions of a class of growth factor receptors including HER2 (ERBB2), epidermal growth factor receptor (EGFR) and insulin-like growth factor receptor (IGFR). The bidirectional crosstalk between the RTK signaling and ER pathways has been implicated in the development of resistance to endocrine therapy in preclinical studies. Many clinical trials have begun to test several attractive strategies, such as manipulation of growth factor signaling networks and the use of tyrosine kinase and multikinase inhibitors that may delay or even overcome the resistance of breast cancers to endocrine therapy.

HER2 pathway

HER2 (Human epidermal growth factor receptor 2/ERBB2) is a member of the HER receptor tyrosine kinase family, which plays an important role in promoting cell proliferation and malignant growth in breast cancer. Over-expression of HER2 occurs in approximately 30% of metastatic breast cancers (MBC) and is associated with aggressive disease course and poor outcome with reduced disease-free and overall survival rates. Both pre-clinical and clinical evidence suggested that HER2 over-expression confers resistance to anti-estrogen agents in ER positive tumors^[10]. Activation of the Her2 pathway, even without HER overexpression, confers tamoxifen resistance in ER positive cancer cells^[37]. Preclinical studies demonstrated that tamoxifen resistant cells have the ability to switch between HER2 and the ER pathway for cell growth and survival. Upregulation of HER2 signaling occurs in some tumors with disease progression during endocrine therapy. Recent studies show that HER2 gene expression is repressed by the PAX2-ER-tamoxifen complex in sensitive breast cancer cell lines; while in tamoxifen resistant cell lines, the ER coactivator AIB-1/SRC-3 competes with PAX2 for binding, leading to increased HER2 transcription^[38]. In addition, HER2 activation decreases ER level and increase ER phosphorylation, even in the absence of estrogen^[38-40]. HER2 signaling alters ER mediated transcription through disrupting the interac-

Figure 1 Estrogen receptor action at molecular level. A: Ligand dependent activation: in classic estrogen signaling, ligand-bound ER activates gene expression—either through direct binding of dimeric ER to specific DNA response elements in complexes including co-activators, or function as a coregulator through protein - protein interactions with other transcription factors to facilitate binding to serum response elements and activation of transcription; B: Ligand independent activation: the ER can also be activated by ligand independent fashion, as a consequence of signaling events downstream of membrane receptor tyrosine kinases (RTKs); C: Non-genomic mechanisms: signaling can be mediated through non-genomic mechanisms by ER that is localized at the cell membrane or in the cytoplasm. ER: Estrogen receptor; mTOR: Mammalian target of rapamycin; FGFR: Fibroblast growth factor receptor; IGF-1R: Insulin-like growth factor-1 receptor; EGFR: Epidermal growth factor receptor.

tion between ER and its coregulators (corepressors and coactivators). HER2 also activates downstream signaling pathways, such as the phosphoinositide 3-kinase (PI3K)/AKT pathway and mitogen activated kinase (MAPK) pathway, as discussed later^[3,15,19].

The interdependence of ER and HER2 pathways is highlighted by examples in which treatment with AIs or downregulation of ER with fulvestrant has inhibited the growth of HER2-positive tumors that had progressed with trastuzumab or lapatinib. In addition, HER2 inhibition with trastuzumab or lapatinib restores or upregulates ER levels or transcriptional activity in breast cancer cells^[24,41]. These data provide rationale for combined inhibition of ER and HER2 pathway, and clinical studies have demonstrated the benefit of targeting both the ER and HER2 in ER positive/HER2 positive breast cancer. In the phase III TAnDEM (Trastuzumab in Dual HER2 positive ER positive Metastatic Breast Cancer) trial, 207 postmenopausal women with HER2 positive ER positive MBC were randomized to anastrozole alone or anastrozole plus trastuzumab. The combination arm was clearly associated with a longer progression free survival (PFS) (4.8 mo *vs* 2.4 mo, $P = 0.0016$) and a higher clinical benefit rate (CBR) (42.7% *vs* 20.3%)^[42]. Similarly, in the randomized, double-blind phase III study of letrozole with or without lapatinib in MBC, PFS and clinical benefit

were superior in the combination arm compared with the AI-alone arm in 219 patients with ER positive/HER2 positive MBC^[43]. Both trials suggest that both HER2 and ER should be simultaneously targeted for maximal therapeutic efficacy.

EGFR pathway

Among the four HER family members (HER1-4), HER1 is better known as epidermal growth factor receptor (EGFR). Binding of EGF-related growth factors leads to receptor homo and/or heterodimerization (with HER2) and activation of downstream signaling cascades including PI3K/AKT and MARK pathways. In breast cancer, overexpression of EGFR and subsequently increased activity of MAPK and PI3K/AKT signaling pathways confer estrogen independency, resistance to endocrine therapy and poorer prognosis^[44-46]. For example, activation of ErbB3, EGFR and Erk is shown to be essential for growth of human breast cancer cell lines with acquired resistance to fulvestrant^[47]. In preclinical study, Gefitinib, a small molecule inhibitor of EGFR, effectively inhibited EGFR-HER2 heterodimerization, phosphorylation and downstream signaling in the tamoxifen resistant MCF-7 cell line^[48,49].

Lapatinib is a dual tyrosine kinase inhibitor blocking EGFR and HER2. In cell models of HER2 positive

breast cancer with acquired endocrine resistance, lapatinib restores hormone sensitivity^[50]. Johnston *et al.*^[51] reports in the randomized, double-blind phase III study, 1286 postmenopausal women with ER positive MBC, were randomized to receive letrozole with or without lapatinib. The benefit of combination therapy was observed in the ER positive, HER2 positive, but not in the ER positive, HER2 negative group. Letrozole plus lapatinib significantly increased PFS *vs* letrozole-placebo (8.2 mo *vs* 3.0 mo, HR = 0.71; 95%CI: 0.53-0.96; $P = 0.019$) in HER2 positive population^[46,51]. There was also a trend toward a prolonged PFS for the combination observed in patients who experienced relapse less than 6 mo since prior adjuvant tamoxifen discontinuation. These data suggest that there is benefit with the addition of an EGFR/HER2-targeted therapy to an AI in patients who experience relapse early during prior tamoxifen therapy which is consistent with preclinical models where EGFR activity is enhanced in association with endocrine resistance^[51].

Several selected EGFR inhibitors are being investigated as monotherapy or in combination with endocrine therapy in an attempt to overcome or prevent endocrine resistance. However, clinical trials that target EGFR in ER positive breast cancer have yielded mixed results. In the randomized placebo controlled phase II trial of tamoxifen with or without gefitinib, 290 patients were stratified into an endocrine naïve group who had not received endocrine therapy within one year prior to enrollment, and another group who had developed recurrence during or after AI therapy. PFS was not significantly prolonged in the endocrine naïve group (8.8 mo *vs* 10.9 mo, $P = 0.31$) or the group who had AI^[52]. Another small randomized placebo controlled phase II trial enrolled a total of 93 ER + metastatic breast cancer patients with or without prior endocrine therapy. In this study, combination of anastrozole with gefitinib showed a statistically significant increases in PFS compared to anastrozole plus placebo (14.7 mo *vs* 8.4 mo, HR = 0.55; 95%CI: 0.32-0.94). Similarly, subset analysis of PFS for patients who had received prior endocrine treatment compared with those who were endocrine therapy naïve showed a more pronounced benefit for patients that had not previously received endocrine therapy^[47]. These trials have suggested targeting EGFR could delay resistance to endocrine therapy in endocrine naïve patients.

Strategy of combined targeting the ER and EGFR was assessed in the neoadjuvant setting as well. Polychronis and colleague conducted the double-blind, placebo -controlled Phase II trial^[53]. 56 patients with ER and EGFR expressing breast cancer were randomized to receive gefitinib and placebo, or gefitinib plus anastrozole, for 4-6 wk prior to surgery. The combination arm showed a significant reduction in Ki67, which is the primary end point, than the monotherapy arm (5.6% difference, $P = 0.0054$). In contrast, Smith *et al.*^[54] reported a separate randomized phase II trial of neoadjuvant anastrozole alone or with gefitinib, in which 206 postmenopausal women with early stage ER positive breast

cancer were randomized to receive 16 wk of anastrozole monotherapy, 16 wk of anastrozole with 14 wk of gefitinib (preceded by two weeks of placebo) or 16 wk of gefitinib before surgery. There was no difference in proliferation index as measured by Ki67 for either gefitinib regimen when compared to anastrozole alone. Moreover, there was no difference in overall objective response (48% *vs* 61%, $P = 0.08$). The authors concluded that addition of gefitinib/EGFR inhibitor to neoadjuvant anastrozole did not improve clinical or biologic effect^[54]. The selection of EGFR overexpressing breast cancer cases in Polychronis *et al.*'s study might account for the difference in these trial results. One could postulate that the ideal setting for testing combination of endocrine therapy and EGFR inhibitors is in the patients with acquired resistance since it is associated with adaptive upregulation of growth factor receptor signaling. Further biomarker studies in patients who had prior endocrine therapy are clearly warranted to identify a phenotype that may predict relapse and subsequent benefit from combined endocrine therapy and EGFR inhibitors.

Mitogen activated kinase pathway

The mitogen activated kinase pathway (MAPK) pathway is stimulated by the RAF serine/threonine kinase, and signals to additional downstream cytoplasmic serine-threonine kinases that ultimately activate MAP kinases such as, ERKs, c-jun N-terminal kinases, and p38MAPKs with resultant downstream phosphorylation of transcription factors. As discussed earlier, the MAPK pathway is important in mediating HER2-and EGFR-induced endocrine resistance. In addition, studies show that ERK and p38 phosphorylate AIB1 and ER coactivators^[3,8]. Clinical trials targeting the MAPK pathway directly using MAPK inhibitors in combination with endocrine therapy are ongoing. Results on the randomized phase II trial, fulvestrant with or without AZD6244 (selumetinib, a MAPK Inhibitor) in advanced stage breast cancer progressing after aromatase inhibitor are awaited (NCT01160718).

The PI3K-AKT- mammalian target of rapamycin pathway

The PI3K-AKT (a serine/threonine kinase) pathway plays a central role in cell survival, proliferation and angiogenesis and is frequently deregulated in cancer^[45]. Phosphatidylinositol 3-kinase (PI3K) consists of a regulatory subunit (p85) and a catalytic subunit (p110). PI3K is activated by growth factor RTKs and G-protein-coupled receptors (GPCRs). PI3K phosphorylates phosphatidylinositol 4,5-bisphosphate (PIP2) to produce phosphatidylinositol 3,4,5- trisphosphate (PIP3). In turn, PIP3 recruits several adaptor proteins such as phosphatidylinositol-dependent kinase 1 (PDK1) and AKT (a serine/threonine kinase), which when activated, drive cell proliferation and survival. Through dephosphorylation of PIP3 and PIP2 respectively, PTEN and INPP4B provide negative regulation of this pathway. AKT activates the mammalian target of rapamycin (mTOR) -containing complex 1 (mTORC1), which regulates protein synthe-

sis^[25]. Activating mutations or genetic amplification of PI3K catalytic subunit, amplification of downstream targets such as *Akt*, amplification of upstream receptors such as *erbB2/HER2* and loss of negative regulators such as PTEN have all been described in breast cancer^[55-57]. The Cancer Genome Atlas (TCGA) analysis confirms the high mutation frequency of *PIK3CA* in luminal/ER-positive breast cancer. *PIK3CA* somatic mutation is present in approximately 32% of luminal B subgroup, 49% of luminal A, 42% of HER2-enriched, and only 7% of basal-like breast cancer. Within the same pathway, PTEN mutation/loss and *INPP4B* loss were observed in more luminal B (24%, 16% each) than luminal A subtype (13% and 9% respectively)^[14,58]. The PI3K-AKT pathway is widely viewed as an important therapeutic target and PI3K pathway inhibitors are being studied in clinical trials.

Preclinical studies have associated PI3K pathway activation with *de novo* and acquired resistance to endocrine therapy. Increased phosphorylation of mTOR substrates and AKT is observed in estradiol deprived breast cancer cell lines. Oncogene overexpression that activate PI3K/AKT signaling (*e.g.*, HER2, type 1 insulin-like growth factor receptor (IGF1R), activated mutant AKT1) and RNAi-mediated knockdown of PTEN lead to resistance to tamoxifen, fulvestrant, and estrogen deprivation in ER-positive breast cancer cells. Studies using long-term estrogen-deprived (LTED) ER-positive breast cancer cell lines have shown that endocrine resistance develops concomitantly with amplification of PI3K/AKT/mTOR signaling^[59]. Similar changes have been observed with chronic exposure of MCF-7 cells and xenografts to fulvestrant^[23].

Moreover, inhibition of PI3K has reversed antiestrogen resistance in experimental models. For example, treatment with the PI3K/mTOR inhibitor BEZ235 or the mTOR inhibitor everolimus prevents the growth of LTED cell lines in the absence of estrogen^[60]. Everolimus in combination with tamoxifen had an additive anti-tumor effect in breast cancer cells *in vitro*^[61]. In another study, the combination of temsirolimus with an ER antagonist synergistically inhibited the growth of breast cancer cells *in vitro* and growth in a xenograft model of breast cancer (mTOR)^[62]. In a separate study, high levels of AKT activity conferred resistance to letrozole and fulvestrant through alteration of the cell cycle and apoptotic response in an *in vitro* breast cancer cell model^[63]. Treatment with everolimus plus either letrozole or fulvestrant restored responsiveness in the resistant cells and results in synergistic inhibition of the proliferation and induction of apoptosis^[60].

These preclinical studies indicated the promise of drugs targeting PI3K network (PI3K, AKT, mTOR) in ER positive breast cancer resistant to endocrine therapy. Table 1 summarizes the randomized trials in which inhibitors of PI3K pathway have been combined with endocrine therapy. Neoadjuvant treatment with letrozole and the mTOR inhibitor everolimus more effectively

reduced tumor cell proliferation and improved clinical response compared with letrozole alone in patients with early-stage ER-positive breast cancer^[64]. Two studies (BOLERO-2 and TAMRAD trials) have demonstrated superior benefit of mTOR inhibition in combination with endocrine therapy in advanced resistant ER positive breast cancers. In the phase III randomized BOLERO-2 trial, 724 patients with ER positive metastatic breast cancer (MBC) who had recurrence or progression while receiving previous therapy with a nonsteroidal aromatase inhibitor (either letrozole or anastrozole) were randomly assigned to everolimus and exemestane *vs* exemestane and placebo. The median PFS was significantly longer in the combination arm (10.6 mo *vs* 4.1 mo, HR 0.36; 95%CI: 0.27-0.47; $P < 0.001$, according to central assessment)^[65]. The combination of exemestane and everolimus has been approved for ER positive advanced breast cancer in United States and Europe based on the magnitude of these positive results. TAMRAD is a randomized phase II trial of tamoxifen with or without everolimus in patients with aromatase inhibitor (AI)-resistant metastatic breast cancer. Patients in the combination arm showed an improved clinical benefit rate (61% *vs* 42%), time to progression (8.6 mo *vs* 4.5 mo), and overall survival compared with patients receiving tamoxifen alone. Notably patients with acquired endocrine resistance (relapse > 6 mo after AI treatment) derived the greatest benefit from the combination compared with those with primary resistance (relapse during adjuvant AI or within 6 mo of AI treatment in the metastatic setting) with an improvement in the median PFS of 12.4 mo *vs* 1.5 mo, respectively^[66].

In contrast, Wolff *et al*^[67] examined letrozole with or without temsirolimus as first line therapy for patients with ER positive MBC who had no prior endocrine therapy for advanced disease in a randomized phase III trial. The study was terminated early due to lack of efficacy in the combination arm. Differences in results between the temsirolimus trial and the everolimus trials are likely attributable to different dosing schedules and pharmacokinetics, as well as different patient populations. It is possible that by selecting the more resistant cases, the TAMRAD and BOLERO-2 trials were enhanced with breast cancers that are likely to be driven by PI3K-mTOR signaling. Studies to identify predictive biomarker that could be used to select patients who would likely benefit from the combined mTOR and ER targeting approach are needed. In addition to mTOR inhibitors, drugs targeting other components of the PI3K pathway are in clinical development. Furthermore, isozyme-specific PI3K inhibitors have been developed in the hope of increasing therapeutic benefit while decreasing toxicity. Pan-PI3K inhibitors BKM120 and XL-147, dual PI3K/mTOR inhibitors BEZ235 and XL-765, and AKT inhibitor MK2206 have entered phase I, or phase I / II trials in combination of endocrine therapy.

Hedgehog signaling

The hedgehog (Hh) signaling pathway is highly conserved

Table 1 Clinical trials of targeted agents in endocrine resistant breast cancer

Agent	Class	Type of study	Study design	Patient population	Status/Results	Ref.
Targeting receptor tyrosine kinases signaling pathway						
PI3K/AKT/mTOR						
Everolimus	mTOR inhibitor	Phase III randomized	Exemestane +/- everolimus	ER+/HER2- LABC/MBC pts failed previous therapy with a nonsteroidal AI	PFS: 10.6 vs 4.1 mo, HR 0.36; $P < 0.001$, favoring combination arm	[76]
Everolimus	mTOR inhibitor	Phase II randomized	Tamoxifen +/- everolimus	ER+/HER2- MBC pts after previous therapy with AI	CBR: 61% vs 42%; TTP: 8.5 vs 4.5 mo, $P = 0.008$, favoring combination arm	[77]
Temsirolimus	mTOR inhibitor	Phase III randomized	Letrozole +/- temsirolimus	First line therapy for patients with ER positive MBC	No difference in CBR, terminated early	[78]
Everolimus	mTOR inhibitor	Phase II randomized	Letrozole +/- everolimus	Neoadjuvant therapy in ER + breast cancer	RR (by U/S): 58% vs 47%; $P = 0.035$, favoring combination arm	[75]
Sirolimus	mTOR inhibitor	Phase I / II	Tamoxifen +/- sirolimus	Pts with ER+ MBC	$N = 400$, TAM + SIR: 193; TAM alone: 207, ORR: TAM + SIR 40%; TAM alone 4%; Time to progression: TAM + SIR: 11 mo TAM alone: 3 mo	Bhattacharyya <i>et al</i> Eur.J.Cancer 47, Abstract 16LBA (2011)
Bkm120	Pan-PI3K inhibitor	Phase III randomized	Fulvestrant + BMK120	ER+/HER2- LABC/MBC Postmenopausal pts, AI Treated, Progressed on or After mtor Inhibitor		NCT01633060
Bkm120	Pan-PI3K inhibitor	Phase I b	Fulvestrant + BMK120	Postmenopausal pts with ER+ MBC	Ongoing, to determine the maximum tolerated dose of BKM120	NCT01339442
Bez235	Dual PI3K-mTOR inhibitor	Phase I b	Letrozole + BEZ235	Postmenopausal pts with ER+ MBC		NCT01248494
BMK120 or BEZ235	Pan-PI3K inhibitor	Phase I b	Letrozole + BMK120 or BEZ235	Postmenopausal pts with ER+ MBC		NCT01248494
XL147 or XL765	Pan-PI3K inhibitors/ dual PI3K/mTOR inhibitor	Phase I / II	Letrozole + XL147 or XL765	ER+/HER2- MBC pts refractory to a previous AI therapy		NCT01082068
GDC-0941 or GDC-0980	dual PI3K/ mTOR inhibitor	Phase II randomized	Fulvestrant + GDC-0941 or GDC-0980	Part I : ER+/HER2- postmenopausal LABC/ MBC refractory to AI; part II : criteria plus pik3 camutation		NCT01437566
Gdc-0032	PI3K inhibitor	Phase I / II	GDC-0032 + fulvestrant	ER+/HER2- LABC/MBC Postmenopausal pts		NCT01296555
Byl719	PI3K- α inhibitor	Phase I	BYL719 + letrozole or exemestane	ER+/HER2- LABC/MBC pts		NCT01870505
Mk2206	AKT inhibitor	Phase I	Endocrine therapy + MK2206	Postmenopausal pts with ER+ MBC		NCT01344031
Mk2206	AKT inhibitor	Phase II	MK2206 monotherapy	LABC/LRBC/MBC with pik3ca mutation or AKT mutation or PTEN loss		NCT01277757
Azd5363	AKT inhibitor	Phase I / II	Paclitaxel +/- AZD5363	Parta: all MBC, partb: ER+ MBC, stratified by PIK3CA mutation		NCT01625286
Igf-1r Amg 479	IGF1R mAB	Phase II randomized	Addition of AMG 479 to either exemestane or fulvestrant	MBC or LABC pts who had progressed on prior endocrine therapy	No statistically significant difference in PFS (PFS: 3.9 vs 5.7 mo, favoring placebo arm, $P = 0.44$), OS or CBT between two arms	[87]
Bms-754807	dual IGF-1R/ insulin receptor kinase inhibitor	Phase II randomized	BMS-754807 +/- letrozole	MBC or LA BC pts who had progressed on prior nonsteroidal AI		NCT01225172
Dalotuzumab (MK-0646)	IGF1R mAB	Phase I / II	MK-0646 and fulvestrant and dasatinib	ER+/HER2- MBC pts without prior therapy in metastatic setting		NCT00903006

Cixutumumab	IGF1R mAB	Phase I / II	Cixutumumab and temsirolimus	MBC or LA BC pts progressed on one to two chemotherapy		NCT00699491
Ridaforolimus (mk-8669) with dalotuzumab (mk-0646)	mTOR inhibitor and IGF-1R mAB		Ridaforolimus and dalotuzumab <i>vs</i> standard care	Er + bc		NCT01234857
Fgf Dovitinib (TKI258)	TKI inhibits FGFR1-3, VEGFR and PDGFR	Phase II Phase I / II	Dovitinib monotherapy, stratified by FGF amplification	4 groups of MBC pts: (group 1: FGFR1+, HR+), (group 2: FGFR1+, HR-) (group 3: FGFR1-, HR+), (group 4: FGFR1-, HR-)	Dovitinib has activity in breast cancers with amplified FGF pathway	[94]
Dovitinib (TKI258)	TKI inhibits FGFR1-3, VEGFR and PDGFR		Dovitinib(TKI258) + AI	ER+/HER2- postmenopausal MBC resistant to AI with fgfr1 amplification status confirmed		NCT01484041
Dovitinib (TKI258)	TKI inhibits FGFR1-3, VEGFR and PDGFR	Phase II randomized	Fulvestrant +/- Dovitinib, stratified by FGF	Postmenopausal pts with HER2-/HR+ LA BC or MBC progressing within 12 mos of completion of adjuvant endocrine therapy or after \leq 1 prior endocrine therapy in the advanced setting		NCT01528345
Azd4547		Phase II	amplification	HER2-MBC with fgfr1 amplification		NCT01795768
Azd4547		Phase II	Fulvestrant +/- AZD4547	ER+ postmenopausal LABC or MBC with fgfr1 polysomy or gene amplification resistant to endocrine treatment (Adjuvant or First-line Metastatic)		NCT01202591
Targeting cell cycle regulators Pd 0332991	CDK4/6 inhibitor	Phase I / II randomized	Letrozole +/- PD 0332991	First line therapy for postmenopausal pts with ER+/HER2- MBC		[99]
Pd-0332991 (palbociclib)	CDK4/6 inhibitor	Phase III randomized	Letrozole +/- PD 0332991	First line therapy for postmenopausal pts with ER+/HER2- MBC		NCT01740427
Lee011		Phase I b/ II	LEE011 + exemestane +/-everolimus	Postmenopausal pts with ER+/HER2- LABC/MBC		NCT01857193
Epigenetic therapy Vorinostat	HDAC inhibitor	Phase II	Vorinostat + tamoxifen	ER+ MBC progressed on previous endocrine therapy	N = 43; 34 evaluable, 7 (21%) PR; 4 (29%) SD; ORR 19%, CBR 40%	[105]
Entinostat	HDAC inhibitor	phase II randomized	Exmestane +/- entinostat	MBC or LA BC pts who had progressed on prior nonsteroidal AI	N = 130; PFS: 4.3 <i>vs</i> 2.3 mo (HR 0.73, 95%CI: 0.50 to 1.07; P = 0.06); OS: 28.1 <i>vs</i> 19.8 mo (HR 0.59, CI, 0.36 to 0.97; P = .036), favoring combination	[106]
Panobinostat	HDAC inhibitor	Phase I / II	Panobinostat + letrozole	MBC, triple negative phase II portion		NCT01105312
Vorinostat	HDAC inhibitor	phase II	Vorinostat + AI	ER + MBC pts who previously derived benefit from AI		NCT01153672
Vorinostat		phase II	Vorinostat/placebo + nab-paclitaxel + carboplatin (n = 62)	Primary operable breast cancer, triple-negative or high grade ER-positive, HER2-negative	Ongoing	NCT00616967

MBC: Metastatic BC; LABC: Locally advanced BC; mAB: monoclonal antibody; ORR: Objective response rate; CBR: Clinical benefit rate response or stable disease >24 wk; PR: Partial response; SD: Stable disease; TKI: Tyrosine Kinase Inhibitor; PI3K/AKT/mTOR: PI3K-AKT- mammalian target of rapamycin (mTOR) pathway; IGF1R: Insulin-like growth factor-1 receptor pathway; FGF: Fibroblast growth factor. signaling.

and plays a critical role in embryonic development. The Hh pathway has been increasingly recognized as playing

a crucial role in carcinogenesis in the last decade. Three mammalian Hh ligands have been identified in humans, as denoted by the prefixes Sonic, Indian, and Desert (SHH, IHH, and DHH). They activate the Hh signaling pathway by binding to the cell surface receptor Patched (PTCH), which otherwise represses the activity of the transmembrane receptor like protein Smoothened (SMO). Release of SMO from PTCH-mediated repression subsequently leads to the modulation of GLI (glioma-associated oncogene homolog) transcription factors. There are three mammalian GLI proteins, GLI1, GLI2 and GLI3. GLI1 is a transcriptional activator; GLI2 can either activate or repress gene expression; GLI3 acts as a transcriptional repressor. Aberrant activation of the Hh pathway has been reported in several malignancies including breast cancer^[68,69].

Traditionally, four major mechanisms have been proposed account for aberrant activation of the Hh pathway: (1) Hh ligand-independent mechanism - Loss of function mutations in PTCH or gain of function mutations in SMO lead to constitutive activation of this pathway; (2) Autocrine signaling- tumor cells produce Hh ligand to activate the Hh signaling; (3) Paracrine signaling - Hh ligand produced by tumor cell stimulates stromal and endothelial cells that produce growth factors supporting tumor growth and survival; and (4) Reverse paracrine signaling-Hh ligand produced by stromal cells support tumor growth and survival. Upon the pathway activation, the GLI transcription factors activate or inhibit transcription by binding to their responsive genes and interacting with the transcriptional complex. A ligand-dependent autocrine model of activating the Hh signaling has been described in breast cancer^[69,70].

We recently show noncanonical Hh signaling as an alternative growth promoting mechanism that is activated in tamoxifen-resistant breast tumors. Importantly PI3K/AKT pathway plays a critical role in regulating Hh signaling by protecting key components of this pathway from proteasomal degradation. We showed that activation of Hh signaling correlated inversely with disease-free and overall survival in a cohort of 315 patients with breast cancer with poor disease outcome. Furthermore, we observed that among ER positive, node-positive patients, Hh activation in the primary tumors was an independent prognostic factor for worse disease-free survival. Add treatment of tamoxifen-resistant xenografts with anti-Hh compound GDC-0449 blocked tumor growth in mice. These promising preclinical results describe a signaling event linking PI3K/AKT pathway with Hh signaling that promotes endocrine resistance^[71]. Targeting Hh pathway alone or in combination with PI3K/AKT pathway could therefore be a novel therapeutic option in treating endocrine resistant breast cancer. We are currently planning a phase I / II clinical trial using GDC-0449 (vismodegib), an oral compound approved for the management advanced basal cell carcinomas in patients with ER positive MBC that are resistant to endocrine therapy. Interestingly, Hh signalling has been shown to condition the bone mi-

croenvironment for osteolytic metastasis of breast cancer^[45], therefore Hedgehog inhibitors are candidate drugs for the treatment of patients with bone metastases which is the most common site of metastasis in ER positive breast cancer.

Insulin-like growth factor-1 receptor pathway

Studies have shown that ligand activation of Insulin-like growth factor-1 receptor (IGF-1R) and its downstream pathways stimulate tumor growth by inhibition of apoptosis and promotion of transformation, metastasis and angiogenesis^[72]. IGF-1R is expressed in 90% to 95% of breast cancer and is often co-expressed with ER^[73]. The crosstalk between IGF-1R and ER pathway is critical for the development of IGF-1R -mediated endocrine resistance in breast cancer. For example, estrogen activates IGF1R pathway through genomic and nongenomic mechanism. IGF-1R plays a direct role in ER phosphorylation. In addition, activation of IGF-1R signaling is associated with loss of PR expression, which itself is associated with high proliferative ER positive breast cancer^[74]. IGF1R overexpression also renders resistance to tamoxifen and fulvestrant through activation of MAPK and PI3K pathway.

Multiple agents interrupting the IGF-1 signaling pathway are developed and tested in clinical trials. AMG 479, a humanized monoclonal antibody antagonist of IGF1R, is tested with exemestane or fulvestrant in postmenopausal women with ER positive locally advanced or metastatic breast cancer who had disease progression on prior endocrine therapy in a randomized phase II trial. No statistically significant difference in PFS (PFS: 3.9 mo *vs* 5.7 mo, favoring placebo arm, $P = 0.44$), OS or CBT between two arms in this study^[75]. Ongoing trials with IGF-1R inhibitors are listed in Table 1. Correlative studies of these trials will be critical to determine whether there is a benefit adding IGF-1R inhibition to anti-estrogen therapy in patient cases with aggressive features, such as increased proliferation.

Fibroblast growth factor signaling

Fibroblast growth factor receptor (FGFR) signaling system includes at least 18 FGF ligands and four transmembrane tyrosine kinase FGF receptors, and it is involved in cancer cell proliferation, migration, angiogenesis, and survival^[76]. Multiple studies indicate that deregulated FGFRs can function as driving oncogenes stimulating tumorigenesis in a variety of human malignancies in addition to its role as an escape mechanism of anti-VEGF (vascular endothelial growth factor) therapies^[76,77]. A variety of FGFR pathway alterations have been identified in cancer and include activating mutations; chromosomal translocations resulting in expression of FGFR-fusion proteins with constitutive FGFR kinase activity; aberrant splicing of *FGFR* and isoform switching which substantially alter ligand specificity; gene amplifications or receptor overexpression through post-transcriptional regulation. Subsequently, aberrant activation of downstream path-

ways results in mitogenic and antiapoptotic responses in cells^[78,79].

FGFR family members are frequently overexpressed in breast cancer^[28]. *FGFR1* is the most commonly amplified genes following *erb2/HER2* in breast cancer, present in about in 8%-15% of all breast cancer^[14,76]. Large series have shown that *FGFR1* amplification is associated with high proliferation as assessed by Ki-67 immunostaining, drives resistance to endocrine therapy and is an independent predictive factor of poor prognosis^[22].

Preclinical models of breast cancer cells with amplification of *FGFR1* or *FGFR2* have demonstrated sensitivity to inhibition of FGFR^[80]. Several antibodies and small molecule inhibitors of FGFR are currently in early-phase clinical trials. Dovitinib (TKI258) is a first generation oral tyrosine kinase inhibitor (TKI) which inhibits FGFR1-3, VEGFR and platelet-derived growth factor receptor (PDGFR). Dovitinib inhibits proliferation in *FGFR1*- and *FGFR2*- amplified, but not *FGFR*-normal, breast cancer cell lines. Dovitinib monotherapy was evaluated in the phase II trial selecting patients on the basis of hormone receptor (HR) status and *FGFR1* amplification status. The mean reduction in target lesions was 21.1% in patients with FGF pathway-amplified breast cancer based on qPCR assay, compared with a 12.0% increase in target lesions in patients who did not present with FGF pathway-amplified breast cancer. Therefore, preliminary results suggest Dovitinib has antitumor activity in advanced breast cancer with FGF pathway alterations and warrants further investigation^[81].

CELL CYCLE SIGNALING AND APOPTOSIS

Experimental model data and clinical correlations indicate anti-estrogen treatment leads to a G₁ phase-specific cell cycle arrest and reduction in growth rate. Several molecular consequences that result in apoptosis have been documented. Aberrant regulation of positive and negative regulators of the cell cycle has been shown to interrupt and inhibit the antiproliferative effects of endocrine therapy, leading to treatment resistance^[3]. For example, overexpression of the positive regulators MYC, cyclins E1 and D1 cause endocrine resistance either by activating cyclin-dependent kinases critical for G₁ phase or by relieving the inhibitory effects of the negative cell cycle regulators p21 and p27^[3,74]. Importantly, expression and activity of these negative cell cycle regulators are down-regulated by multiple growth factor receptors and their downstream signaling pathways by modulating specific transcription factors, microRNAs, or by interfering protein phosphorylation. Moreover, increased expression of anti-apoptotic molecules such as BCL-2 and BCL-XL and decreased expression of pro-apoptotic molecules such as BAK, BIK and caspase 9 lead to endocrine resistance as well^[82]. Of note, activation of growth factor receptor signaling *via* the PI3K/AKT pathway is critical modulators of many apoptotic/survival molecules^[83]. Cyclin D1 is a

well-studied ER target gene that is required for estrogen-induced cell proliferation. Cyclin D1 binds to and activates cell cycle-dependent protein kinases four and six (CDK4/6) essential for mediating RB-induced cell cycle progression at the G₁/S checkpoint^[53,74]. Cyclin D1 amplification and overexpression was a common oncogenic event in breast cancer and preferentially occurred within luminal tumors, and more specifically within luminal B subtype. In the Cancer Genome Atlas (TCGA) network studies, Cyclin D1 is amplified in 58% of luminal B breast cancers with CDK4 gain in 25% of this subtype. In comparison, only 29% of luminal A tumors has Cyclin D1 amplification with 14% has CDK4 gain^[14]. Furthermore, Wang *et al*^[84] report that the alternatively spliced message, cyclin D1b, is aberrantly regulated in response to therapeutic challenge and promotes resistance to estrogen antagonists. Recently, Thangavel *et al*^[85] noted that a unique gene signature indicative of RB protein loss of function could identify luminal B breast cancers most likely to be resistant to endocrine therapies. Therefore targeting cyclin D1 and its downstream mediators of ER action CDK4/6 may provide a viable strategy to treat endocrine resistant breast cancers.

A phase I / II clinical trial testing the efficacy of letrozole with or without PD-0332991 (an oral CDK4/6 inhibitor) was conducted as first-line treatment of ER-positive advanced breast cancer (NCT00721409). This trial excluded patients who have previously been treated for advanced breast cancer. Thus the patient population is not determined to be endocrine resistant. The preliminary results were very impressive and showed significant prolongation of median PFS with the combination when compared to letrozole alone (26.2 mo *vs* 7.5 mo; HR = 0.32, 95%CI: 0.19-0.56, *P* < 0.001)^[86]. The result of the randomized, multicenter, double-blind phase III study of palbociclib (PD-0332991), plus letrozole *vs* placebo plus letrozole for postmenopausal women with ER positive, HER2 negative MBC who have not received any prior systemic treatment for advanced disease is awaited (NCT01740427)^[87]. Trials using other CDK inhibitors (Novartis) are also underway.

EPIGENETICS AND ENDOCRINE RESISTANCE

Epigenetics is defined as reversible changes in gene expression without change in the DNA sequence. DNA methylation is mediated by the action of DNA methyltransferases (DNMTs). DNMTs directly interact with histone deacetylases (HDACs) and the methyl-CpG-binding domain (MBD) family of proteins at the promoter regions to form a repressive transcription complex. DNA methylation, histone modification, and nucleosome remodeling are the major epigenetic changes that are dysregulated in breast cancer. Several genes involved in proliferation, anti-apoptosis, invasion, and metastasis have been shown to undergo epigenetic changes in breast cancer^[88,89].

There is increasing evidence that epigenetic modification plays a potential role in the development of endocrine resistance in breast cancer. The epigenetic regulation of ER is mediated through the recruitment of multi-molecular complexes containing HDAC1, DNMT1 and other co-repressors to the promoter region. Methylation of the gene encoding ER- α is one of the mechanisms of loss of ER expression in ER negative breast cancer cell. The epigenetic silencing of ER target genes is crucial to the development of ER independent growth and endocrine treatment resistance. A number of preclinical studies have shown that epigenetic therapy can impact expression of ER. For example, inhibition of DNMTs in ER negative breast cancer cells leads to induction of ER expression^[90,91]. HDAC inhibitors can restore ER expression, either alone *via* chromatin remodeling or in combination with DNMT inhibitors^[89]. The TCGA study highlights the finding that breast cancer molecular subtypes harbor specific patterns of epigenetic hardwiring and further demonstrates luminal B is a distinct subtype from luminal A not only based on the mRNA-based assay but also at the methylation and protein levels^[14]. Five DNA methylation groups were identified from 802 patient samples. Interestingly, the hypermethylated group 3 was significantly related to Luminal B subtype. Comparison between DNA methylation status and mRNA expression profile of group 3 with other groups led to identification of over 4000 differentially methylated genes and almost 2000 differentially expressed genes^[14]. Collectively, these data provide basis for the biological rationale for combining endocrine therapy with epigenetic-targeted therapies.

A phase II study of vorinostat, a HDAC inhibitor, in combination with tamoxifen was conducted in MBC patients who had progressed on previous lines of hormone therapy^[92]. The overall response rate was 19% and CBR was 40% (defined as Complete Response, Partial Response or Stable Disease of > 6 mo in duration) in 43 patients treated. The results from the randomized double blind phase II study of exemestane with or without entinostat, a benzamide HDAC inhibitor, are promising for reversal of AI endocrine therapy resistance. 130 postmenopausal women with locally recurrent or metastatic ER-positive breast cancer progressing on treatment with a nonsteroidal AI were enrolled. In this study, PFS was 4.3 mo *vs* 2.3 mo (HR 0.73, 95%CI: 0.50-1.07, *P* = 0.055) and OS was 28.1 mo *vs* 19.8 mo (HR = 0.59, 95%CI: 0.36-0.97) for the group receiving combination therapy *vs*. exemestane alone^[93]. Trials combining letrozole and panobinostat, vorinostat and AI therapy in metastatic breast cancer, vorinostat and tamoxifen in early stage breast cancer, are ongoing. Based on the higher frequency of methylation observed in Luminal B tumors, it is possible that luminal B breast cancers may represent a better target for epigenetic therapy than other subtypes.

MICRO RNA

Micro RNA (miRNAs) is a class of small noncoding,

single-stranded, highly conserved RNAs (19-25 nucleotides) involved in essentially all aspects of physiological and pathological cellular processes, such as development, proliferation, differentiation and apoptosis. MiRNA can either cleave mature mRNA molecules or inhibit their translation through base-pairing within the 3'-UTR of protein coding genes. Research over the past decade has demonstrated that about one third of human genes appear to be targeted by miRNAs and each miRNA is thought to regulate multiple genes. Interestingly, specific miRNA signatures have been associated with different molecular subtypes of breast cancer. In the Cancer Genome Atlas network analysis, 7 breast cancer subtypes were identified on the basis of MiRNAs expression and correlated with molecular subgroups^[14]. We have explored the potential role of specific miRNAs in endocrine resistance, especially resistance to tamoxifen, in breast cancer. Studies from our and other groups showed miR-221, miR-222 and miR-181b are up-regulated, whereas miR-21, miR-342 and miRNA-489 are downregulated in the tamoxifen-resistant cells. Multiple mechanisms of these miRNAs in conferring resistance to tamoxifen have been published. Mir-221 and -222 target the cell cycle inhibitor, p27/Kip1 through posttranslational modification and sequestration of p27 protein, or through miRNA-mediated suppression. Mir-221 and -222 overexpression is known to suppress ER α expression at protein level which leads to tamoxifen resistance in ER positive breast cancer^[19]. We recently reported that TIMP3, a tissue metalloproteinase inhibitor, is down-regulated by miR-221, -222 and -181b. We showed miRNA-mediated regulation of TIMP3 level and inhibition of metalloproteases contribute to tamoxifen resistance in cell culture models, mouse xenograft models, as well as in primary breast tumors. Direct injection of antago miRNA-221/222 to tamoxifen resistant xenografts in mice caused decrease in miRNA-221/222 level and restoration sensitivity to tamoxifen^[94]. Other groups subsequently reported up-regulation of miR-221 and -222 is implicated in resistance to fulvestrant as well^[32].

Investigation during the last decade demonstrate emerging regulatory role of miRNAs in endocrine resistant breast cancer. Future studies evaluating miRNAs as prognostic and predictive markers, as well as novel therapeutic targets to overcome resistance are warranted.

CONCLUSION

Recent progress in the field of endocrine therapy has produced a significant number of active compounds. Patients with ER-positive advanced breast cancer are treated with different endocrine agents serially at tumor progression, often resulting in long periods of disease control with no significant toxicity. Inevitably, however, vast majority of patients will become refractory to endocrine therapy. Therefore resistance to endocrine therapy continues to be a subject of great importance. In this review, we have summarized the complex genomic and epigen-

etic regulatory pathways involved in endocrine resistance. A combination of ER-targeted and HER2- targeted therapies is our current standard-of-care therapy in ER positive, HER2 positive breast cancer. Early results from clinical trials suggest that subsets of patients may benefit from a combination of inhibitor targeting certain growth factor pathway with endocrine therapy. The combination of exemestane and mTOR inhibitor everolimus has been approved for ER positive advanced breast cancer in USA and Europe based on the magnitude of positive results in two randomized phase III trials. The use of epigenetic therapy or miRNA/antimiRNA-based therapy with existing endocrine therapy in breast cancer is a topic of active interest.

Many challenges still remain as we try to identify the subsets of patients most likely to benefit from these novel targeted agents. Efforts should be directed at defining biological markers that could predict the efficacy of a specific agent. The use of genome-wide approaches in detecting gene alterations that drive resistance to endocrine therapy will hopefully promote personalized cancer medicine in management of endocrine resistance breast cancer. Clearly, future clinical trials with prospective patient selection based on predictive biomarkers are needed.

Abstract

Breast cancer is the most common malignancy and the second leading cause of death in Western women. Breast cancer most commonly metastasizes to the bone and has a particular affinity with the spine, accounting for 2/3 of osseous metastases discovered. With significant improvements in cancer therapies, the number of patients at risk for symptomatic spinal metastases is likely to increase. Patients may suffer from intractable pain and neurological dysfunction, negatively influencing their quality of life. Timely diagnosis of patients is crucial and has been aided by several breakthrough advances in imaging techniques which aid in detection, staging, and follow-up of bone metastases. Breast metastases are usually responsive to hormonal therapy and pharmacologic interventions, but skeletal metastases often require surgical intervention. The treatments are palliative but goals include the preserving or restoring neurologic function, ensuring spinal stability, and relieving pain. Advances in surgical techniques and instrumentation have allowed more effective decompression

and stabilization of the spine, and with the support of recent evidence the trend has shifted towards using more advanced surgical options in appropriately selected patients. In this review, the clinical presentation, diagnosis, patient selection, and surgical management of breast cancer metastatic to the spine are discussed.

INTRODUCTION

Breast cancer is the most commonly diagnosed malignancy and is the second leading cause of cancer-related death in the western world^[1]. The incidence of breast cancer has continued to rise in the last several decades. In

the United States alone, there will be an estimated 230000 new cases of invasive breast cancer diagnosed in 2013^[2]. Fortunately, the prognosis of breast cancer has improved following advances in pharmacologic and surgical techniques in controlling regional disease. As a consequence, the prevalence of patients with a history of breast cancer is increasing as the rate of survival improves, making breast cancer in many aspects a chronic condition. According to recent statistics from the American Cancer Society, over 2.9 million United States women with a history of breast cancer are alive, highlighting the large and increasing population at risk for long-term complications of breast cancer^[3].

While medical advances have prolonged survival for patients with breast cancer, metastatic progression involving distal sites such as bone, lung, liver, and brain remains common^[4]. The bone is the most common site of metastasis, with osseous metastases developing in 8% of all patients with breast cancer and 69% of patients with advanced disease^[5]. Consequences of bony metastases include pathologic fracture, spinal cord compression, anemia, and hypercalcemia^[6]. Breast cancer has a particular affinity for the spine, accounting for approximately two-thirds of the osseous metastases discovered^[7]. Of these lesions to the spine about one-third become symptomatic, causing intractable pain, neurological deficits, mechanical instability, and ultimately disability and a severe deterioration in quality of life^[8,9]. Breast cancer metastases constitute the most common cause of symptomatic spine metastases, accounting for 9%-40% of reported clinical series of spinal epidural metastases in the literature^[10].

The management of patients with symptomatic spinal metastases from breast cancer is often complex and requires a multidisciplinary approach^[11]. The optimum treatment algorithm has not been definitively defined and varies per patient, with available options including pharmacologic management, radiotherapy, and surgery. Early management of metastatic spinal tumors traditionally emphasized treatment with radiotherapy over surgical decompression. Still, surgery continues to play a critical role in the treatment of metastatic spinal tumors. Advances in surgical techniques and instrumentation have allowed more effective decompression and stabilization of the spine, and with the support of recent evidence the trend has shifted towards using more advanced surgical options in appropriately selected patients^[11]. However, while management strategies are continually evolving and physicians now have the capability to treat more aggressively, all therapies for spinal metastases unfortunately remain palliative. This review will detail the presentation, diagnosis, and surgical management options for patients with symptomatic breast cancer metastatic to the spine.

TUMOR CHARACTERISTICS

Multiple malignancies such as breast, prostate, kidney, and lung show a remarkable affinity to metastasize to bone^[4]. Metastatic lesions can spread to the bone *via*

several mechanisms, but the method of dissemination most likely responsible for breast cancer involves hematogenous seeding *via* venous routes^[12]. Spread may be accomplished through the Batson plexus, a network of veins that connects the vertebral veins with other beds of venous drainage. This importantly includes the azygos vein, which receives blood draining from the breast *via* the intercostal veins. The venous plexus of Batson lacks valves to control the flow of blood, so changes in pressure within the body can lead to variable flow through the plexus, allowing retrograde or antegrade seeding of tumor cells^[13]. The exact mechanism of metastatic seeding of the bone is unclear. There exists a prominent disparity between the abundance of circulating tumor cells and the relative rarity of metastatic seeding, suggesting a complex environmental barrier to metastasis^[14]. Nevertheless, when metastatic events occur in the spine they most commonly occur within the vertebral body with or without extension into the posterior elements^[15].

The majority of bone lesions caused by breast cancer is generally accepted to be osteolytic^[6]. In reality, breast cancer metastases can cause osteolytic, osteoblastic, or most commonly mixed osteoblastic and osteolytic lesions in the bone^[6]. Studies show that resident metastatic breast cancer cells secrete a multitude of osteolytic factors that directly and indirectly activate osteoclasts^[15]. Indirect stimulation is mediated by up-regulation of RANK-RANKL signaling, either by osteoblast-mediated osteoclastogenesis or *via* stimulation of host immune cells by factors such as PTHrP^[16]. In addition, there is evidence to suggest that bone breakdown releases previously deposited growth factors and cytokines within the matrix. This has a proliferative effect on the metastatic cells, thus creating a vicious cycle of bone resorption^[17].

Thus, the overall local reaction caused by metastatic breast cells is predominantly increased osteolysis. On the other hand, there is often an osteoblastic component due to three mechanisms. The first is tumor cells may influence other cells in its microenvironment such as stromal cells, which can differentiate into osteoblasts^[16]. Alternatively, metastatic cells may simply secrete factors which directly stimulate osteoblast proliferation and bone formation^[15]. Finally, there is commonly a local bone response to increased bone lysis as a natural response to injury^[6]. Thus the resultant lesion may be quite variable, with these factors on a molecular level dictating the degree of overall bone distortion by the infiltrating metastatic tumor.

CLINICAL MANIFESTATIONS

Pain is the most common symptom and is the presenting complaint in nearly 90% of patients with spinal metastases from breast cancer^[18]. Pain symptoms vary in intensity but may be vague and nonspecific, and patients with metastatic spinal cord compression have been found to have a delay in diagnosis of about 2 mo from first presenting to a physician to the time of diagnosis^[19]. As

the neurological status of the patient at time of diagnosis correlates strongly to the patient's prognosis, a diagnosis before the onset of neurological compromise is essential^[11,20]. Accordingly, any patient with a known history of malignancy who presents with new-onset back or neck pain should be promptly and thoroughly evaluated with a high suspicion for metastatic disease involving the spine. Common degenerative disorders less commonly affect the thoracic spine than the cervical or lumbar spine, hence pain in the thoracic spine warrants a high clinical suspicion for metastatic disease^[11]. Likewise, patients with persistent nonmechanical pain should have a low threshold for evaluation of a neoplastic etiology^[21].

Eliciting the type of spinal pain is important as one may receive clues to the etiology, location, and severity of the tumor infiltration. The pain may be biological, radicular, or mechanical pain. Biological, or local, pain is commonly described as a persistent deep "aching" unrelated to activity that is worse at night^[22]. The mechanism is thought to be caused from local periosteal stretching from either tumor growth or tumor-induced inflammatory process^[11]. Percussion over the spinous process may elicit local tenderness^[13]. This type of pain usually responds to corticosteroids, anti-inflammatory medications, and tumoricidal treatments^[22]. Radicular pain results from tumor infiltration causing compression or irritation of individual nerve roots. This pain classically presents in a dermatomal distribution as a band-like, burning, or shooting pain. Effective treatments for radicular pain include surgical nerve root decompression, conventional or stereotactic radiotherapy, or even neuroleptic medications such as gabapentin and pregabalin^[22]. Finally, mechanical back pain results from spinal instability caused by the predominantly osteolytic metastatic breast lesion. This pain is aggravated with movement, activity, or activities that require axial loading of the spine, such as sitting or standing^[13]. Mechanical pain is important to recognize as patients generally cannot find relief with pharmacologic or radiation therapy, and often require bracing or surgical stabilization^[13].

Neurologic dysfunction is a feared consequence and is the second most common presenting symptom of metastatic cancer to the spine^[22]. Symptoms are caused by direct tumor growth or pathological fracture that leads to compression of the spinal cord, individual nerve roots, or the cauda equina. First, epidural spinal cord compression may lead to varying degrees of motor weakness, gait instability, autonomic dysfunction, and diminished sensation below the level of injury^[22]. Bladder dysfunction is the most common autonomic finding and commonly correlates well with the degree of motor impairment^[11]. Manifestations of myelopathy may be noted on detailed physical exam, such as hyperreflexia, clonus, or positive Hoffman or Babinski signs. Second, compression of individual nerve roots can cause radicular pain, as mentioned above, as well as weakness or paresthesia in the associated muscle groups^[22]. Thirdly, compression of the cauda equina may manifest as the characteristic constellation of

symptoms including back pain, saddle anesthesia, bladder and bowel dysfunction, and lower extremity weakness. Importantly, patients who present with motor weakness may have a variable rate of neurologic deterioration, but in the absence of intervention usually progress to complete paralysis in the absence of any treatment^[11].

IMAGING MODALITIES

The available imaging modalities to evaluate for suspected breast cancer metastatic to the spine include plain radiographs, skeletal scintigraphy (SS) (bone scan), computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography CT (PET-CT), and single photon emission CT (SPECT). These modalities carry varying sensitivities, degrees of information, and costs in evaluating for spinal metastases. Given the ability of metastatic breast cancer to present as osteoblastic, osteolytic, or mixed lesions in the bone, each imaging technique may play a valuable role in the evaluation of the at-risk patient depending on the clinical situation.

Plain radiographs are commonly the initial imaging study ordered in evaluating a patient presenting with back pain or neurological symptoms. Given its low cost and widespread availability, plain radiographs are a useful screening test to assess for lytic or sclerotic metastatic lesions, large masses, and pathological fractures. This imaging modality may detect the rare osteoblastic breast metastasis, but this would be more fruitful in a more osteoblastic lesion such as prostate cancer. Regarding osteolytic lesions, which is the predominant radiographic presentation of metastatic breast cancer, bone metastases only become visible on plain radiographs after 30%-50% of bone mineral loss has occurred^[23]. Thus, plain radiographs are fairly insensitive and does not provide a definitive diagnosis.

Skeletal scintigraphy (bone scan) is highly sensitive in the detection of osseous metastases, provides images of the entire skeleton, and has been suggested as the first imaging study in asymptomatic patients^[24]. This technique detects regions of remodeling within the skeletal system. Osteolytic lesions are accompanied by secondary formation of bone, which allows osteolytic bone metastases to be detected with skeletal scintigraphy several months before they appear on plain radiographs^[6]. However, remodeling may also be a result of inflammation, infection, or fractures^[22]. Thus, SS has limited specificity and findings need to be correlated by further imaging studies.

CT has become the preferred imaging modality for evaluation of the osseous structures of the spine. The ability of CT scanners to distinguish among materials of different densities allows it to show superior skeletal detail, including bone marrow^[25]. Using the bone window setting, CT can be useful in determining the extent of tumor extension, osteoblastic vs osteolytic lesions, and assessing spinal stability^[22]. CT is particularly better than plain radiographs and SS for evaluation of lesions in the spine, as these studies do not visualize the spine in suf-

ficient anatomic detail^[25]. CT also plays an essential role in preoperative planning and postoperative monitoring. CT myelography is a useful tool in imaging patients with prior spinal instrumentation, as the instrumentation artifact makes visualization with MRI difficult^[22].

MRI is the gold-standard diagnostic modality in the imaging of metastatic spinal tumors^[13]. This modality has superior sensitivity compared to standard radiographs, CT, and bone scans due to its superior resolution of soft-tissue structures of the spine. MRI is able to define important preoperative parameters such as the extent of epidural extension, degree of spinal cord compression, surrounding edema, and spinal root impingement. Further, evaluation of neighboring structures such as the ligaments, paraspinal muscles, and joints are able to be evaluated. Gadolinium contrast provides additional definition of soft-tissue infiltration and information regarding its vascularity^[26]. T1 and T2 weighted studies and fat suppression studies are frequently ordered.

PET is a nuclear medicine technique that detects cellular metabolism of a glucose analog, most commonly fluorodeoxyglucose^[24]. PET scans have limited resolutions, but fusion with CT (PET-CT) allows more precise localization of radiotracer uptake. While this modality is more sensitive and specific than SS, its role is controversial due to its increased radiation dose and high cost^[27]. Currently it is only recommended if plain radiography, CT, SS, and MRI do not provide adequate information for diagnosis or treatment planning^[24].

SPECT is similar to SS but acquires images in a cross-sectional fashion instead of a planar fashion^[24]. SPECT shows a greater sensitivity and specificity for detecting spinal metastases^[28]. Additionally, SPECT is able to differentiate tumors from inflammatory and infectious lesions, unlike SS^[22]. Modern scanners now allow SPECT, diagnostic-quality CT, and fused SPECT-CT images to be done within 1 h on the same machine, which further improves the diagnostic accuracy of the modality^[29].

Metastatic involvement of the spine can lead to emergent situations, such as spinal cord compression or pathologic fracture. In these patients, diagnosis in a timely manner is critical as the fragility of the spinal cord and nerve roots mandates urgent intervention. Failure to do so may result in vascular damage and spinal cord “stroke”, leading to irreversible neurological defect. Plain radiographs may be an initial study of choice to evaluate for compression fractures and overall spinal stability. An emergent MRI, which carries excellent soft-tissue contrast, is indicated in order to evaluate for the extent of tumor progression or retropulsed fracture fragments. A T1-weighted, fat saturated sequence after IV gadolinium contrast is optimum for imaging of spinal metastases as intramedullary and osseous lesions are best seen with this sequence^[24]. CT (using bone windows) can be helpful for preoperative assessment of extent of bone destruction and mechanical instability.

MANAGEMENT

The management of patients with metastatic breast can-

cer to the spine is complex and frequently requires a multidisciplinary approach, involving numerous medical specialties (oncology, radiation oncology, pain management, rehabilitation medicine), surgery subspecialties (neurosurgery, orthopedics, surgical oncology), as well as radiologists and interventional radiologists. Advances in the past few decades have improved the treatment of both systemic disease as well as localized tumor burden to the spine. Cytotoxic agents remain the mainstay of treatment of patients with breast cancer. Hormone therapies such as selective estrogen receptor modulators and aromatase inhibitors have been shown to be effective against breast cancer, and human epidermal growth factor receptor 2 (HER2) targeting agents have also been effective in treating metastatic patients^[30,31]. Moreover, bisphosphonates given with vitamin D and calcium, which inhibit tumor-related osteoclast activity, and corticosteroids, which may have oncolytic effects on breast cancer and decrease peritumor edema, give physicians an ever-growing array of tools to combat this disease. However, the treatment for symptomatic spinal metastases remains palliative and is not intended to prolong survival. The goals of treatment include restoration of and preservation of neurological function, maintaining spinal stability, and pain relief in an effort to achieve a better quality of life.

Treatment modality and tumor evaluation

A proposed algorithm for the treatment of patients with symptomatic spinal metastasis from breast cancer is shown in Figure 1. Treatment decision-making can be further aided by considering neurologic, oncologic, mechanical, and systemic parameters (NOMS)^[32,33]. Neurologic evaluation incorporates the degree of epidural tumor extension, as the presence of neurological deficits usually correlate with high-grade tumor extension. The Weinstein-Boriani-Biagini staging system was developed for primary spinal tumors in order to describe tumor involvement of vertebral body and adjacent tissues^[13]. Briefly, the vertebral body in the axial plane is divided into 12 sectors and 5 tissue layers, which allows a reliable inter-physician description of tumor involvement. More recently, the Spine Oncology Study Group (SOSG) validated a 6-point scale devised specifically for metastatic spinal tumors^[34]. Metastatic tumors are graded on a 3 point scale depending on tumor infiltration, with grade 0 representing no epidural extension and grade 3 representing spinal cord compression without CSF fluid around the cord. Grade 2 and 3 tumors are highly likely to result in neurologic deficits and generally require surgical decompression.

The oncologic parameter takes into account specific features of the primary tumor histology. When compared to other metastatic spinal tumors, patients with breast cancer have a relatively long life expectancy^[10,35]. Patients with breast cancer are also at higher risk for vertebral compression fractures because of age, osteoporosis, and the osteolytic nature of the tumor^[36]. Patients with breast cancer are at increased risk of losing ambulation as compared with patients with other primary histologies^[37,38].

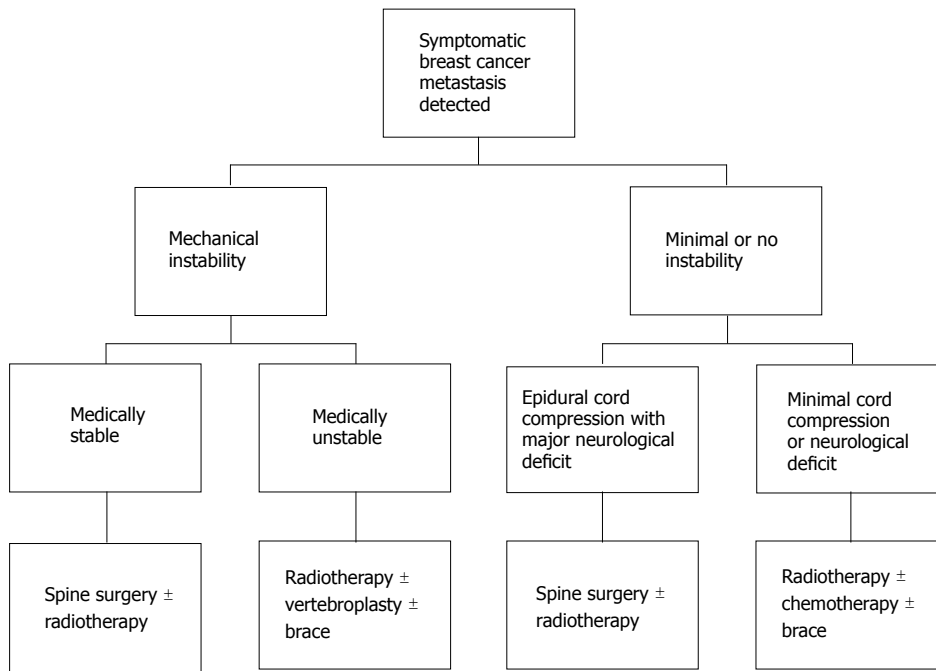

Figure 1 Proposed algorithm for treatment of patients with symptomatic spinal metastases from breast cancer.

For these reasons, patients with symptomatic spinal metastases from breast cancer may especially benefit from aggressive surgical intervention, in an attempt to achieve long-lasting symptom relief. Further, radiation response varies by tumor type and breast cancer metastases are generally more radiosensitive than other types of solid tumors^[22,35]. Thus, radiation therapy can be useful treatment consideration in this patient cohort, in addition to or independent of surgery.

Spinal instability in the setting of metastatic disease is caused by tumor invasion and distortion of the vertebral body and posterior elements. This results in movement-related pain, symptomatic or progressive deformity, or neural compromise under physiologic loads. The SOSG recently devised the first classification system to aid in predicting spine stability of neoplastic lesions, called the Spine Instability Neoplastic Score (SINS)^[39]. Briefly, the scoring system is a 6-point scale that takes into account location, pain, bone lesion type (lytic, blastic, or mixed), spinal alignment, extent of vertebral body collapse, and posterior element involvement. The SINS classification displays near-perfect intraobserver reliability and can be used to guide treatment decision-making, as unstable pathologies are likely to require surgical stabilization given that systemic or radiotherapy cannot restore spinal stability^[40].

Surgical management and patient selection

Patients with spinal metastases may be candidates for a wide range of surgical interventions, ranging from limited posterior decompression to radical tumor excision and reconstruction. Surgical advances in the last few decades have allowed improved and more aggressive spinal cord decompression and tumor resection with ac-

ceptably low morbidity. Although surgery may be palliative from an oncologic perspective, patients may benefit significantly given the appropriate surgical indications. In 2005, Patchell *et al.*^[41] reported the results from the first prospective and randomized controlled trial of direct decompressive surgery plus radiation compared to radiation therapy only. The patients in the surgical arm of the study demonstrated significantly superior postoperative functional improvement (ambulation, neurologic function, muscle strength, continence) and decreased analgesic requirements. Patients with spinal metastases from multiple primary lesions were enrolled, with breast cancer accounting for 11% of the patients in both arms of the study. However, postoperative results were not stratified by primary tumor type. Possible mechanisms underlying improvements following surgical resection and stabilization may include direct alleviation of neural compression by tumor-related spinal pathology, and reduction of mechanical pain caused by tumor-induced instability^[10].

The exact indications for surgery in patients with metastatic breast cancer to the spine are controversial, and evidence-based guidelines are not available due to the paucity of literature on this topic^[10]. Currently, it is generally agreed that aggressive surgical resection may be appropriate for patients with at least 3 mo expected survival who present with progressive neurological deficit, vertebral column instability, tumors that progress despite maximal radiotherapy, and medically intractable pain^[13,42,43]. The majority of the literature has studied metastatic spinal cord tumors as one large cohort, and there has been a recent effort to study histologic-specific spinal metastases. Surgical patients with various types of primary cancer have very different clinical characteristics, which can dictate a patient's surgical approach, prognosis,

and treatment options.

In 2007, Shehadi *et al*^[10] reported the largest retrospective cohort of breast cancer patients treated with aggressive resection of metastatic spinal disease. Eighty-seven patients were treated with aggressive decompression and instrumentation. Patients generally did well neurologically, with 53% of patients who presented with neurologic deficits improving and 85% of all patients maintaining or improving their neurologic function at 1 year. Further, postoperative pain levels were significantly reduced from a preoperative visual analog scale (VAS) of 6 to a median VAS of 2. In 2011, Tancioni *et al*^[35] reported on 23 breast cancer patients treated with more conservative decompressive surgery followed by radiotherapy. This retrospective study remarkably resulted in 96% complete remission of pain and 100% recovery of neurological defect with no major morbidity, which lasted until death or progression of disease at another site. Similarly, Chung *et al*^[44] reported on 15 breast cancer patients who underwent aggressive spinal cord decompression, with 56% of patients who presented with neurologic deficits improving and all patients maintaining or improving their neurological status after surgery.

Several scoring systems have been proposed to determine which patients with metastatic spinal disease would benefit most from decompressive surgery^[45]. Tokuhashi *et al*^[46] was the first to propose a scoring system designed to estimate patient prognosis, which guides excisional surgery (> 6 mo survival) *vs* nonoperative treatment or limited intralesional curettage (< 6 mo survival). Tomita *et al*^[47] also proposed a prognostic scoring system, recommending limited palliative decompression or supportive care *vs* total en bloc spondylectomy for long-term control. Both the Tomita and Tokuhashi scoring systems take into account the histology of the primary tumor as an important prognostic value, with breast cancer carrying the most favorable prognosis. However, both scores are based on a wide variety of tumor histopathologies with a limited number of breast cancer patients, multiple primary cancers are compiled into the same prognostic group, and medically intractable pain is not an indication for surgery. Therefore, these scores may not be entirely applicable for patients with metastatic breast cancer. Recent histopathologic-specific studies have reported potential prognostic variables, with estrogen receptor positivity, location of tumor, presence of other metastasis, and adjuvant radiotherapy potentially being important variables for patient risk stratification^[20,44,45]. However no same prognostic variable has been consistently reported and the studies are all retrospective with small sample sizes.

Surgical techniques

The surgical approach to metastatic tumors of the spine depend on the tumor location, extent of infiltration, and type of reconstruction needed. The approach can be anterior, posterior, lateral or a combination of the above depending on the tumor location. Lesions may also involve multiple levels and require multiple-level decompression

and excisions if the osteolytic lesions are extensive^[21]. Because the vertebral body is most commonly involved in metastatic disease, an anterior approach often represents the most direct route to the tumor^[22]. In the craniocervical region, access may be achieved with a transoral or transmandibular approach although these are associated with significant morbidity and are rarely used in the setting of metastatic disease. Recently, transnasal and transcervical approaches have been developed for improved access. The upper thoracic region (T1-T4) is difficult to access anteriorly due to obstruction by the great vessels and mediastinal organs^[48] and a transpedicular posterior or posterolateral approach is generally preferred^[13]. However, when necessary a manubriotomy, sternotomy, or trap-door approach may be used^[22].

The remaining thoracic region (T5-T11) may be accessed ventrally *via* a thoracotomy and L2-L5 may be accessed through a retroperitoneal approach^[49]. Care should be taken to screen patients who may have had previous radiation or surgery to the neck, thorax, or abdomen, as tissue planes may be disrupted and complicate ventral access. On the other hand, most spine surgeons have a greater familiarity with posterior approaches and thus this represents the most commonly used route for decompression and stabilization. Fortunately, T3-T12 nerve roots may generally be sacrificed without significant morbidity^[22]. Posterior stabilization involve multilevel pedicle instrumentation using titanium polyaxial screw-rod systems, which are indicated for resections at high-stress areas and multilevel vertebrectomies^[13,22]. Anterior reconstruction following a vertebrectomy is achieved using titanium or polyetheretherketone (PEEK) cages or with polymethyl-methacrylate (PMMA) cement and anterolateral plating. Newer surgical techniques such as minimally invasive surgery have shown efficacy in achieving neurological improvement and alleviating pain, while decreasing blood loss, operative time, and complication rates^[50].

Vertebroplasty and kyphoplasty

Less invasive operative techniques such as percutaneous vertebroplasty and kyphoplasty are cement formulations that can provide additional reinforcement to the vertebral body. Vertebroplasty, which involves PMMA injection into the vertebral body under fluoroscopic or CT guidance, stabilizes the anterior column and prevents further compression fractures. Kyphoplasty is a similar procedure in which an inflatable balloon is first inserted in order to provide a void to inject cement under low pressure, which restores vertebral body height and corrects kyphotic deformity^[22,51]. The analgesic properties are thought to be primarily secondary to mechanical stabilization, with potential contributions from thermoablation of nociceptive nerve endings and cytotoxic antitumor effects^[52]. Preliminary retrospective reports have demonstrated effective pain relief for metastatic breast cancer to the spine. For example, in 2008 Lee *et al*^[53] reported the results of vertebroplasty for patients with solitary metastases, 8 of whom had breast cancer. Following treatment, all breast

cancer patients experienced immediate pain improvement and reduction in analgesic requirement. Treatment strategies have also been proposed that combine percutaneous techniques with surgical resection as well as stereotactic radiosurgery^[54].

CONCLUSION

The prevalence of patients with a history of breast cancer is increasing as the rate of survival improves, highlighting the large population of patients at risk for symptomatic spinal metastases. The management of patients with metastatic breast cancer to the spine is often complex and requires a multidisciplinary approach. Precise diagnosis with history, physical, and imaging are imperative to initiate the appropriate treatment in a timely manner. The treatment for symptomatic spinal metastases remains palliative and is not intended to prolong survival. Surgical advances in the last few decades have allowed improved spinal cord decompression and tumor resection and continue to evolve. The goals of treatment include restoration of and preservation of neurological function, maintaining spinal stability, and pain relief in an effort to achieve a better quality of life. Further research should focus on pathology-specific whenever possible, given its implications for treatment selection and prognosis.

pharmacologic agents. Although breast cancer prognosis does not appear to be significantly impacted, weight gain has negative consequences on quality of life and overall health. Future studies should explore change in body composition, metabolism and insulin resistance. Avoiding weight gain in breast cancer survivors following initial diagnosis and treatment should be encouraged.

Key words: Breast cancer; Weight gain; Exercise; Survivorship; Insulin resistance

Core tip: Weight gain occurs in the majority of women following breast cancer treatment, especially those who are younger, closer to ideal body weight and who have been treated with chemotherapy. Although weight gain may be modest, changes are consistent with sarcopenic obesity. Women are unlikely to return to pre-diagnosis weight. Although the degree of weight gain does not appear to significantly alter prognosis, associated changes in metabolism and inactivity are of concern. Interventions should be promoted to avoid weight gain.

Abstract

Weight gain occurs in the majority of women following breast cancer treatment. An overview of studies describing weight gain amongst women treated with early to modern chemotherapy regimens is included. Populations at higher risk include women who are younger, closer to ideal body weight and who have been treated with chemotherapy. Weight gain ranges between 1 to 5 kg, and may be associated with change in body composition with gain in fat mass and loss in lean body mass. Women are unlikely to return to pre-diagnosis weight. Possible mechanisms including inactivity and metabolic changes are explored. Potential interventions are reviewed including exercise, dietary changes and

INTRODUCTION

Weight gain following a diagnosis of breast cancer has been reported consistently in women treated for breast cancer, but was an unexpected finding when first described in women undergoing adjuvant chemotherapy by

Dixon and colleagues in 1978^[1]. After subsequent reports confirmed this observation, weight gain was included as a known side effect of adjuvant chemotherapy^[2]. Despite this, most women appear to be inadequately informed about this possibility, as demonstrated by one study reporting concern about treatment-associated weight gain in only 27% of survivors prior to therapy^[3].

WHY IS POST-TREATMENT WEIGHT GAIN OF CONCERN?

Obesity is a global issue associated with increased risk of developing post-menopausal breast cancer^[4] and a worse prognosis at the time of diagnosis^[5]. However, the effect of weight gain following a diagnosis of breast cancer is less well understood. While weight gain following diagnosis does not necessarily lead to obesity or its consequences, any impact on breast cancer prognosis and overall health, patient self-image, or quality of life (QoL) would be an undesirable outcome. These outcomes may be interrelated: weight gain can influence other medical conditions such as diabetes, heart disease, hypertension and hypercholesterolemia that may impact overall survival. For example, Erickson *et al*^[6] found associations between weight change and the incidence of developing diabetes in breast cancer patients in the Women's Healthy Eating and Living (WHEL) study. Perhaps most concerning, patients appear rarely to return to pre diagnosis weight^[7,8] which might be coupled with already well-described body image concerns (in 70% of women under age 50 in one study^[9]). Weight gain and receipt of mastectomy with or without reconstruction are two significant factors impacting body image and quality of life; weight gain following reconstruction can result in asymmetry in the reconstructed breast (autologous tissue) or in the contralateral breast in women who had implant surgery^[10,11]. McInnes *et al*^[12], in an early descriptive study of 50 women receiving chemotherapy, found weight gain of more than 2.5 kg in 62.5% and proposed a relationship between weight gain and QoL, while Ganz and associates identified the influence of weight problems after modern chemotherapy on QoL^[13]. Patients unaware of the possibility of weight gain exhibited distress about this unanticipated outcome^[14]; consequently post-treatment related weight gain is a serious source of concern and needs to be better understood.

DOES IT OCCUR, HOW MUCH, AND IN WHOM?

Weight gain following treatment for early stage breast cancer is a global concern with the phenomena described by investigators spanning the continents. Table 1 provides an overview of studies describing weight gain following a diagnosis of early stage breast cancer selected based on a focus on factors impacting weight gain after diagnosis rather than obesity at diagnosis and includes reports from

a diverse selection of nations. Studies focusing on prognosis related to weight gain are discussed later in the text.

Weight gain after chemotherapy was reported in France, a country that has the lowest rates of obesity in Europe^[15]. Obesity is less prevalent in Asian countries also, yet here too weight gain has been reported following diagnosis^[16,17]. In developing countries, such as Malaysia, 63% of women reported weight gain with a mean weight change of 2.73 kg^[18]. In the United States, weight gain is seen in different ethnic groups. In an exploratory assessment of weight change in a group of 37 African American breast cancer survivors, 47% reported weight gain after treatment^[19]. Vance and colleagues, in their 2011 review, noted that 50%-96% of breast cancer survivors reported weight gain with gains in the range of 2.5-6.2 kg^[20].

Early reports: Pre-anthracycline era

Initial reports describing weight gain in the 1990s described changes of up to 8-10 kg^[21]. The chemotherapy regimens used at the time included longer duration treatments of non-anthracycline containing regimens such as cyclophosphamide, methotrexate, and fluorouracil (CMF) and often use of up to one year of prednisone prescribed as an anticancer agent. (More recent steroid use has been limited to dexamethasone employed to avoid chemotherapy-induced emesis.)

Levine *et al*^[22] followed 32 women over a two-year period and reported in 1991 that 63% gained weight with an average gain at two years was of 6 kg. Subsequently Goodwin and colleagues, studying 535 patients treated between 1989 and 1996, determined that adjuvant chemotherapy treatment and onset of menopause were factors predicting weight gain one year after diagnosis^[23]. Most women in this study were treated with mostly non-anthracycline based chemotherapy, however some received anthracycline-containing cyclophosphamide, epirubicin, and fluorouracil (CEF) delivered for the same duration as CMF. Overall, the total group gained a mean of 1.6 kg at one year-84% of patients had gained weight-with no accompanying alteration in waist-hip ratio (WHR); however those receiving any type of chemotherapy gained 2.5 kg (95%CI: 1.8-3.2 kg).

More recent reports: Modern chemotherapy regimens

In more recent reports, covering a period of time during which adjuvant chemotherapy regimens incorporated anthracyclines and/or taxanes, weight gain is reported but generally to a lesser degree than earlier studies. In a prospective study from Turkey, Basaran *et al*^[24] reviewed weight change in 176 women receiving adjuvant chemotherapy between 2003 and 2007, 98% of whom received an anthracycline-based regimen, with or without a taxane; 72% had gained weight (median weight change: 3 kg) at end of year one. Age, menopausal status and comorbidities impacted the degree amount of weight gain.

Makari-Judson and associates conducted a retrospective review of 185 patients with early stage breast

Table 1 Overview of studies describing weight gain in women following a diagnosis of breast cancer

Ref.	Patient numbers	Average weight gain	Study type	Comment
Levine <i>et al</i> ^[22] , 1991	32	6.03 kg at 2 yr	Prospective	63% of women receiving chemotherapy gained weight
Goodwin <i>et al</i> ^[23] , 1999	535	1.6 kg at 1 yr	Prospective	Weight gain associated with chemotherapy and onset of menopause
Demark-Wahnefried <i>et al</i> ^[31] , 2001	53	2.5 kg at 1 yr with chemo 1 kg local rx at 1 yr 2.1 kg at 1 yr with chemo	Prospective	Study group premenopausal only Weight gain associated with chemotherapy Change in body composition (sarcopenic obesity)
Makari-Judson <i>et al</i> ^[8] , 2007	185	2.2 kg at 1 yr	Retrospective	Weight gain associated with chemotherapy Younger women closer to ideal BMI gained most Most received anthracycline chemotherapy
Saquiab <i>et al</i> ^[25] , 2007	3088	Measured as relative weight gain > 5% on 65% of chemotherapy recipients	Prospective	Weight gain associated with chemotherapy Both anthracycline and non- anthracycline treatments similar
Heideman <i>et al</i> ^[26] , 2009	271	2 kg at one year	Retrospective	Younger, closer to ideal BMI more likely to gain Weight gain associated with chemotherapy and hormone therapy
Gu <i>et al</i> ^[16] , 2010	5014	2 kg at 18 mo	Prospective	Stage 0-III Weight gain associated with chemotherapy and younger, lower BMI, premenopausal women
Tredan <i>et al</i> ^[15] , 2010	272	3.9 kg at 1 yr	Prospective	All participants received chemotherapy Anthracycline 41%, anthracycline and taxane 58% Gained weight despite dietary counseling
Basaran <i>et al</i> ^[24] , 2011	176	3 kg at 1 yr	Prospective	Weight gain associated with chemotherapy Anthracycline/taxane chemotherapy
Chen <i>et al</i> ^[17] , 2011	4561	1.7 kg dx to 18 mo	Retrospective	Stage 0-IV, patient reported weights, Association of weight gain with younger age, premenopausal, and higher stage.
Nissen <i>et al</i> ^[27] , 2011	49	1.95 kg at 1 yr	Prospective	Obese more likely to lose weight All participants received chemotherapy
Yaw <i>et al</i> ^[18] , 2011	368	2.73 kg reported at study entry (treatment completion)	Retrospective	Weight gain associated with being closer to ideal BMI Overweight/obese women lost weight Patient reported weight gain one year prior to diagnosis and at study entry

BMI: Body mass index.

cancer and evaluated weight change at diagnosis, 1, 2 and 3 years^[8]. Ninety percent of this patient population received an anthracycline-containing regimen [most commonly doxorubicin and cyclophosphamide (AC) for four cycles]. Weight gain at 2 years was greater than one year, plateauing at year 3. Recursive partitioning analysis associated weight gain at year 1 with younger age, closer to ideal BMI and adjuvant chemotherapy. In fact, older and overweight patients receiving chemotherapy tended to lose weight, although these patients constituted a smaller subgroup. Length of chemotherapy, specific chemotherapy regimens, and hormonal therapy were not found to be significant predictors of weight gain. Of patients who had gained weight at year 1, only one in five had returned to baseline by year 3.

Similar results emerged from the WHEL study, which assessed the association between chemotherapy, and tamoxifen and weight gain in 2972 participants^[25]. Relative weight gain rather than an absolute number was reported because the authors considered it less likely to be confounded by initial body weight; a clinically meaningful gain was defined as a greater than 5% gain from baseline to year 1. Chemotherapy was significantly associated with weight gain while tamoxifen was not. Anthracycline *vs* non-anthracycline, or shorter duration of therapy (with

AC) compared with longer [six cycles of cyclophosphamide, doxorubicin and fluorouracil (CAF)] were not significant variables. Weight gain peaked at year 2, and then plateaued. After six years of follow up, only 10% returned to pre diagnosis weight.

Weight gain ranging from 1.95 kg to 4.5 kg has been described in the first year after chemotherapy. In a Dutch study of 271 women, the average gain at one year was 2 kg^[26]. Women who received both chemotherapy and hormonal treatments gained 4.5 kg at one year compared to 2 kg at five years. Nissen and co-investigators followed prospectively 49 chemotherapy-treated women ages 40-54 and found a mean gain of 1.95 kg accompanied by increased body fat; patients who were closer to ideal BMI at diagnosis experienced the greatest weight gains^[27]. In a prospective, observational study of 272 chemotherapy-treated women from France, weight change was reported at 6 and 12 mo post therapy^[15]. Approximately one third of the study population reported that they had experienced weight gain of unspecified amount in the year prior to diagnosis. At one year after diagnosis, 60% of women had gained weight (mean 3.9 kg) despite dietary counseling.

Gu *et al*^[16] reported findings from the Shanghai Breast Cancer Survival Study (SBCSS) of 5014 women with

stage 0-III breast cancer diagnosed between 2002 and 2006 and followed at 6, 18 and 36 mo after diagnosis and determined mean weight changes of 1, 2, and 1 kg respectively. Thirty-seven percent of survivors gained greater than 5% of their baseline body weight at 18 mo, a percentage similar to western studies despite the comparatively low obesity incidence in China. Younger age, premenopausal status, lower BMI at diagnosis, receipt of chemotherapy or radiation were significantly associated variables. In this study, women with co-morbidities and advanced stage were more likely to lose weight at 36 mo. In another report from SBCSS, Chen *et al*^[17] described 4561 women with stage 0-IV breast cancer, measuring weight, height, and waist and hip circumference at study entry and again at 18 mo. Compared to patient reports from one year prior to diagnosis, there was a gain reported in 61% with a mean gain of 1.7 kg at 18 mo post diagnosis. Thirty-seven percent gained more than 5% of body weight, however 27% lost weight. An association with chemotherapy was found in univariate but not multivariate analyses however, 91% of this cohort received chemotherapy; multivariate analysis identified socio-demographics and lifestyle factors as significant. The inclusion of Stage IV patients in this study is more difficult to interpret since these women may have more comorbidities and poorer performance status.

Anti-estrogen therapy effect

Hormonal treatments, such as tamoxifen and aromatase inhibitors, are less frequently associated with significant weight gain. Tamoxifen use in the P1 prevention trial did not lead to a significant weight gain when compared to placebo^[28]; similarly, in the Women's Healthy Eating and Living (WHEL) study (see above), tamoxifen did not lead to significant changes in weight^[25]. Additionally, aromatase inhibitor usage did not lead to weight changes when compared to tamoxifen in the ATAC trial^[29].

Treatment with radiation does not appear to be an independent factor contributing to weight gain^[8]. Neither treatment with corticosteroids or adjuvant therapy with anti-estrogens appears to be strongly associated. Thus, when taking into consideration all breast cancer treatments, weight gain is most strongly correlated with use of cytotoxic therapies.

Menopause and age effect

Several studies describe an increased tendency toward weight gain in premenopausal women compared to postmenopausal women^[16,23,26]. However, inconsistencies in defining menopause in retrospective studies and the issue of chemotherapy-related amenorrhea complicate the interpretation of this effect on weight gain. Goodwin and colleagues identified the greatest weight gains (mean of 2.65 kg) in premenopausal women who experienced chemotherapy-associated amenorrhea (receiving either CMF or CEF, each delivering 6 mo of cyclophosphamide) and became postmenopausal^[23].

When weight gain is assessed following the use of

regimens less likely to cause chemotherapy-induced amenorrhea, younger age rather than menopausal status appears as a significant risk factor. Makari-Judson *et al*^[8], employing recursive partitioning analysis found women younger than age 59 gained the most weight with no independent effect of menopausal status. Irwin and colleagues determined associations between weight gain and both younger age and postmenopausal status; this was further refined as younger post-menopausal women gaining significantly more than older post menopausal women and women who developed treatment-associated menopause after diagnosis^[30]. Tredan and associates found no influence of menopausal status on weight gain^[15].

Pre-treatment weight and BMI effect

Women of normal weight or women with closer to ideal BMI were found to be more likely to gain weight after diagnosis in several studies^[8,16,27]. Women with higher BMI ($> 30 \text{ kg/m}^2$) are less likely to gain weight, and some studies have demonstrated that these women are more likely to lose weight^[8,27]. Nissen *et al*^[27] found women who were close to ideal BMI gained an average of 2 kg while overweight patients lost 1.4 kg, and those who were obese lost 1.9 kg. It is not clear why obese women may be more likely to lose weight following chemotherapy; although it is possible that this is related to co-morbidities, no studies have demonstrated decrease in energy intake however increased walking was identified as a factor favoring weight loss in the Nissen study.

IMPACT OF TREATMENT-ASSOCIATED WEIGHT GAIN

Body composition

Several authors have identified a change in body composition as well as weight gain. Nissen and colleagues conducted a longitudinal, randomized observational study of a physical activity intervention *vs* zoledronic acid and calcium^[27]. While the primary endpoints related to bone density, body composition measurements were made. Forty-nine women aged 40-55 were studied, all within 24 mo of their last menstrual period and all receiving chemotherapy. Chemotherapy included AC in 39%, and AC-T (doxorubicin and cyclophosphamide followed by paclitaxel for a total of 8 cycles of therapy) in 57%. There was no difference in weight gain between those receiving 4 compared with 8 cycles. Only normal ($< 25 \text{ kg/m}^2$) BMI at baseline was predictive of weight gain, with those having normal BMI gaining the most. Women of normal weight had an increase in fat mass in the torso and arms while younger subjects appeared to gain fat mass in arms. Weight gain in this study and in the Demark study is consistent with sarcopenic obesity, namely loss of lean body mass and gain in fat mass^[31].

Freedman and colleagues performed a prospective study of weight and body composition in 20 women with Stage I-III breast cancer receiving modern chemotherapy^[32]. Weight change and measurements of body

composition were compared with age and BMI-matched controls at the start of treatment, immediately after completion of chemotherapy and 6 mo later. Mean pre-treatment BMI was 24.1 kg/m^2 . Six months after completion of chemotherapy, a statistically significant mean weight gain of $1.09 \pm 2.46 \text{ kg}$ was seen from the immediate post chemotherapy weight; however, this was not statistically significant when compared to the experience of controls. Strikingly, fat mass increased while lean body mass decreased in the women who received chemotherapy but not in the healthy controls. Using computed tomography, an unfavorable change of decrease in the ratio of visceral adipose tissue to subcutaneous fat was detected following chemotherapy. Although this small study did not demonstrate significant weight gain, the deleterious change in body composition is consistent with findings from others and raises concerns about metabolic function.

Cheney and associates, also using computerized tomography to measure changes in weight and abdominal and visceral subcutaneous adipose tissue, assessed 34 women prior to treatment and 6-12 mo later^[33]. Although the findings were not significant in terms of weight change, there was in this study similar to the Freedman study, a significant loss in lean body mass and gain in fat mass.

A small study by Campbell *et al*^[34] followed 10 women undergoing adjuvant chemotherapy and measured resting energy expenditure using dual energy x-ray absorptiometry across cycles of treatment. Although participants did not gain weight, and there was no change in resting energy expenditure, there was an increase in total fat mass. This was felt to be consistent with a decrease in physical activity.

Irwin *et al*^[30] reported results from the Health, Eating, Activity, and Lifestyle (HEAL) study concerning 514 women with stage 0-III breast cancers, almost half of whom used tamoxifen but only 27% received chemotherapy. Women, post treatment, increased their weight by a mean of 1.7 kg and their body fat by 2.1%. Weight increases were greatest for patients who were younger, postmenopausal, had a higher stage of disease, and who reported a decrease in their physical activity. Higher stage of disease may correspond to receipt of chemotherapy, longer duration of treatment and potential longer duration of de-conditioning.

Breast cancer prognosis

Speculation regarding the impact of treatment-related weight gain on breast cancer outcomes has been stimulated in part by the findings of increased incidence and poorer outcomes in patients with greater pretreatment weight or BMI^[35]. While minimizing weight gain is important, clarification of its impact on survival and recurrence outcomes is of critical importance.

The influence of weight gain on prognosis is inconsistent across studies. Camoriano and colleagues examined 646 lymph node-positive breast cancer patients treated prospectively in two clinical trials with extended non-anthracycline chemotherapy, chemo-hormonal

therapy, or observation, and found that premenopausal women who gained more than the median weight gain (of 5.9 kg) experienced significantly higher risk of death that persisted after controlling for other factors (multivariate hazard ratio 1.62); a similar trend in postmenopausal women (median weight gain for observed patients 1.8 kg, and for treated subjects 3.6 kg) was not statistically significant^[36]. Kroenke and associates, reporting results from the Nurses' Health Study (NHS), noted that patients with greater BMI before breast cancer diagnosis had a greater risk of breast cancer recurrence and death if a never-smoker or if premenopausal^[37]. In addition, patients who were never-smokers who gained weight after treatment had a higher risk of breast cancer recurrence and mortality, and all-cause mortality, than did never-smokers who had maintained their pre-treatment weight; significant covariates in the analysis included nodal status and tumor size (the effect of weight gain was more pronounced in patients with small tumors and negative lymph nodes) and baseline BMI [the effect on survival was seen in normal weight but not overweight ($\text{BMI} \geq 25 \text{ kg/m}^2$) subjects].

In contrast, Caan *et al*^[38] evaluated a prospective cohort of women [1692 with complete data in the Life after Cancer Epidemiology (LACE) study] drawn from the Kaiser Permanente Northern California and Utah Cancer Registries. While similar findings as to patient characteristics associated with weight gain and pretreatment weight associations with mortality were found, no impact of treatment-associated weight gain with mortality was discovered.

A pooled analysis of the LACE, WHEL, NHS, and SBCSS studies was subsequently performed, incorporating 12915 patients with breast cancer diagnosed between 1990 and 2006^[39]. The analysis contained a mixture of patient-reported and measured outcomes. Weight gain after treatment tended to impact all-cause mortality in US but not Shanghai patients; overall there was no impact on breast cancer-specific mortality. However, overall mortality was increased in women who were normal weight who had gained 10% or more (mean 10.5 kg) of their pre-treatment weight when compared to overweight patients. The authors concluded that while evidence for poorer survival associated with weight gain was found, the relative weight gain was substantial. A higher mortality rate was found for patients who lost $\geq 10\%$ of their pretreatment weight, particularly if they were smokers and were leaner prior to treatment. Similarly, Bradshaw and colleagues described a cohort of 1033 women from Long Island, NY, diagnosed with breast cancer between 1996 and 1997 for which complete data were available^[40]. Self-reported weights were employed at age 20, and one year prior to diagnosis, one year after, and at time of follow up questionnaire completion. Mortality-all cause and breast cancer-specific-was increased for women reporting a loss of $> 5\%$ or a gain of $> 10\%$ compared to pretreatment weight.

While the effect of weight gain on prognosis is vari-

able among studies, it appears to be significant in a subset of women. Investigations that linked obesity with metabolic outcomes and prognosis provide lessons and potential mechanisms. Goodwin and associates found that mean fasting insulin levels were higher in women diagnosed with breast cancer and that this negatively impacted prognosis in this subset^[41]. Similarly, Borugian *et al.*^[42] determined that higher fasting insulin levels were associated with poorer prognosis.

Though the amount of weight gain observed as a consequence of chemotherapy regimens is modest on average, it may be sentinel of a more dramatic shift in body composition. Adipose tissue produces a variety of inflammatory cytokines, which may be directly responsible for altering risk^[43,44]. Some of these factors can act directly on the breast epithelium to stimulate the development and expansion of cancer cells. In particular, IL-6 was shown to expand substantially the population of cancer stem cells raising the prospect of recurrences with features of triple negative breast cancers (that is devoid of estrogen and progesterone receptors and HER2/*neu* overexpression) that have, stage for stage, poorer prognoses and fewer effective treatment options when compared to most other breast cancers. These effects may be magnified in the minority of women who suffer substantial weight gain.

PROPOSED MECHANISMS OF WEIGHT GAIN AND CHANGE IN BODY COMPOSITION

Weight gain is ultimately a result of energy surplus due to either increased intake or decreased energy expenditure. It is important to identify possible mechanisms of weight gain in order to advise women on how best to avoid it. While diagnosis- and treatment-related depression may alter eating patterns, most studies have demonstrated that caloric intake actually tends to decrease over the first year after breast cancer diagnosis, suggesting that weight gain is not likely a result of overeating^[45,46].

Decreased energy expenditure was demonstrated by Demark-Wahnefried *et al.*^[31] in a study of 36 women receiving chemotherapy and 17 receiving only local treatment. Body composition, resting energy expenditure, dietary intake recalls and physical activity were recorded. Mean weight gain in the local treatment group was 1 kg compared to 2.1 kg in the chemotherapy group. Reduced activity and with no change in caloric intake was identified in the women who gained weight, who exhibited a body composition pattern consistent with sarcopenic obesity (loss of muscle mass and increase in body fat) that has also been suggested by other investigators^[27,47].

Decreased exercise and inactivity appeared to be linked to a higher risk of weight gain in the HEAL study^[48]. The activity levels of 812 patients were measured after diagnosis; chemotherapy patients' exercise time dropped by 3.6 h/wk compared to 1.6 h/wk for

surgery only patients. This was especially evident in patients with BMI > 30 kg/m² that lost 2.8 h of exercise compared to those with BMI < 25 kg/m² that lost only 1.7 h/wk. Women reported being less active 4-12 mo after diagnosis with an average 2-h drop in activity. A 50% reduction in activity level was noted in those treated with chemotherapy, surgery and radiation, compared to a drop of 24% in those treated with surgery alone. Broderick found weight gain and high levels of sedentary behavior in a study of 24 women at completion of chemotherapy with no improvement one year later^[49]. Patients may need encouragement to exercise since chemotherapy treatment may foster a more sedentary lifestyle.

In the study by Demark and colleagues, all of the women treated with chemotherapy experienced treatment-associated amenorrhea, leading to speculation about the role of hormones and menopause in a change of metabolism^[31]. Body composition and waist-hip ratio may change with the onset of menopause; as estrogen levels decrease, body composition changes and fat moves from hip to waist (*i.e.*, "pear-shaped" to "apple-shaped"). Weight gain was associated with increase in estrogen and insulin levels^[30]. Additionally, abdominal fat correlates with cortisol levels.

The results from Makari-Judson and colleagues suggest that insulin resistance may be a contributing factor^[50]. A prospective, observational study of 100 women receiving adjuvant therapy for early stage breast cancer measured BMI, waist hip ratio (WHR), fasting glucose and insulin at diagnosis, 6, 12 and 24 mo. Weight gain was associated with higher baseline WHR and homeostatic model assessment index (HOMA-IR), a measure of insulin resistance. In particular, women receiving chemotherapy had evidence of a deleterious effect on measures of insulin resistance at 6 mo and experienced weight gain. At 12 mo, although these measures had returned to baseline, participants continued to gain weight. By 24 mo, no further weight gain occurred and measures of insulin resistance were similar to baseline.

Even in the absence of weight gain, the change in metabolic profile may have negative implications. Increased adiposity in the abdominal region can be associated with insulin resistance; insulin and adiponectin may influence tumor growth pathways^[51]. Guinan *et al.*^[52] described development of metabolic syndrome and insulin resistance in a population of 61 non-diabetic women at surgery and completion of chemotherapy and/or radiation (87% received chemotherapy and 84% radiation therapy). Although there was not a statistically significant gain in weight, percent body fat increased. There was a significant increase in fasting insulin and HOMA-IR which correlated with development of metabolic syndrome. Bell *et al.*^[53] demonstrated impaired glucose metabolism in a small study of eight patients early on during chemotherapy and raised concerns about this when compared to non-malignant matched controls.

Genetic polymorphisms associated with obesity include the FTO, fat mass and obesity-associated protein.

These genetic predictors of weight gain were described by Reddy and colleagues in a retrospective analysis of 459 breast cancer patients^[54]. Blood samples were tested for single nucleotide polymorphisms in FTO and adiponectin pathway polymorphisms. In the general population, these genetic factors may contribute to weight gain: FTO decreases satiety and activity levels while adiponectin regulates insulin-like growth factor. The model was enhanced by incorporating environmental interactions demographic and clinical factors predictive for weight gain. Although limited by the fact that some of the weights were self-reported, this model is intriguing for combining genetic predisposition to obesity with the strongest clinical correlates for weight gain, namely, age and baseline BMI.

Weight gain may be a harbinger of more fundamental metabolic changes induced by chemotherapy. In addition to the direct DNA damage in tumor cells that are a result of chemotherapy agents such as anthracyclines, these drugs also interfere with mitochondrial function and ATP production which can have diverse effects^[55]. Cardiomyocytes derive as much as 90% of ATP from mitochondrial oxidative phosphorylation, and thus, are extremely sensitive to the effects of anthracyclines. In animal models, exercise has been shown to mitigate cardiotoxicity^[56] in part alleviating the effects on mitochondrial function^[57]. While overt toxicity may not be evident, other tissues may suffer from impairments. Insulin resistance could result from disruptions in glucose homeostasis in the muscle and liver providing a basis to propose a role for exercise in limiting weight gain.

POTENTIAL INTERVENTIONS TO AVOID WEIGHT GAIN

By identifying predictors of weight gain and populations at higher risk, we can target interventions specifically to those populations. Krogh-Madsen demonstrated in a general population that women who exercised regularly and then stopped for as little as two weeks, experienced a 7% increase in abdominal fat^[58]. There is consistent evidence that physical activity declines after diagnosis and that the reduced energy expenditure is associated with weight and fat gain. In addition to less energy expended for physical activity, more inactivity (*e.g.*, sitting) may contribute to a relative energy surplus and increased adiposity, even in the absence of higher energy intake. Paradoxically, the reduced energy intake observed in some prior studies also lowers daily energy expenditure due to less diet-induced thermogenesis (that is, the energy costs of digesting, absorbing and storing ingested nutrients). Finally, amenorrhea conserves energy output and can contribute to overall energy surplus and weight gain.

The “dose” of physical activity required to offset the deleterious effects of diagnosis and treatment on body weight and adiposity is not well characterized in cancer patients but evidence from the general population suggests it is not trivial. Women in the National Weight Con-

trol Registry^[59], a database of over 6000 people (mainly women who have lost weight and kept it off for more than 6 mo) report close to an hour of physical activity a day; an Institute of Medicine report generally concurred with that recommendation^[60]. A well-controlled study by Jakicic *et al.*^[61] demonstrated that women who performed less than 240 min of exercise per week slowly regained lost weight over the course of a year. An important consideration to prescribing an effective “dose” of exercise is the degree of compensatory behavior in terms of greater inactivity (hopefully minor) and increased energy intake.

Nissen and colleagues found that exercise was a stronger predictor of weight change during chemotherapy than energy intake^[27]. Goodwin and associates found that weight gain could be prevented in a group of 61 breast cancer patients with BMI of 20-35 kg/m² (OR 1.73 for each additional 30 min of exercise per week) however, weight loss required a combination of caloric reduction and exercise^[47].

Data from the SBCSS, demonstrated in a population of mostly normal BMI women at diagnosis (only 32% had BMI > 25 kg/m²) who exercised regularly, (65% reported exercise at baseline and 74% at 18 mo after diagnosis), that exercise did not prevent weight gain in the short run^[17]. The inability to identify a protective effect in this study may have been a consequence of the small numbers of non-exercisers, shorter follow up or because the exercise considered included such low to moderate intensity activities as walking and tai chi.

Exercise may improve metabolic profile and body composition without weight loss. Ligibel and co-investigators studied overweight (BMI > 25 kg/m²) but non-diabetic, breast cancer patients who were at least 3 mo beyond the completion of treatment^[62]. After 16 wk, fasting insulin levels decreased by 28% and hip circumference decreased in the exercise group compared to those receiving usual care, but there was not a significant decrease in WHR and no significant weight loss.

Kim and colleagues performed a meta-analysis of aerobic exercise on body composition in breast cancer patients and included ten trials of exercise interventions in women during (8 trials) or at completion (2 trials) of adjuvant treatment^[63]. The study groups participated in median of three sessions per week, 30-40 min each of moderate exercise and were found to have decreased percent body fat, without significant change in weight or lean body mass. De Backer carried out a review of twelve studies of resistance or resistance plus aerobic training. The studies had different endpoints: one study demonstrated a decrease in WHR, but of those that measured weight, BMI, or fat mass, there was no significant change^[64].

Loprinzi, in a narrative review, described the influence of physical activity, not only on weight gain, but also on other side effects of adjuvant treatment including fatigue, depression, and QoL^[65]. Participation in regular exercise contributed to weight loss and enhanced QoL, mood and energy level. In this review it was suggested, based on the

analyses by Kim and De Backer, that in order to decrease percent body fat, aerobic exercise would be favored over resistance training^[63,64].

Interventions for weight management or loss over the past twenty years were summarized by Demark-Wahnefried^[66]. Twelve studies were included consisting of exercise and dietary counseling. The interventions were not specifically directed towards women who had gained weight after treatment. The recommendation for weight to be an important outcome for overall health, functional status and quality of life was supported even if prognostic impact is inconclusive.

Regardless of whether or not exercise leads to avoiding weight gain after treatment, exercise improves breast cancer prognosis. Holmes found that 3 to 5 h walking per week at average pace (2-2.9 mph for one hour) reduced risk of death by 6% at ten years^[67]. Exercise has additional benefits on mood and QoL independent of weight loss and should be encouraged following recovery from surgery even in the midst of adjuvant treatment. A number of ongoing prospective, intervention trials will help further elucidate the contribution of physical activity to breast cancer prognosis.

In summary, breast cancer patients with a more normal BMI appear more likely to gain weight after treatment compared to overweight and obese survivors. This is in contrast to midlife women in the general population, in whom greater BMI is associated with weight gain^[68]. The weight gain and increase in waist circumference experienced over time in the general population may be prevented with increased participation in regular physical activity; similarly, evidence suggests that exercise has a role in avoiding weight gain in women after a diagnosis of breast cancer.

Obesity at the time of diagnosis is consistently correlated with a poorer prognosis^[5]. This same group of women appears to be more likely to experience unintentional weight loss following chemotherapy. It is not clear if intentional weight loss after a diagnosis of breast cancer affects prognosis. Interventions in addition to exercise may be necessary for obese women to reduce their BMI.

Patients frequently ask about diet alterations as a way of improving their cancer prognosis, but data are scant to make firm, evidence-based recommendations. The Women's Intervention Nutrition Study (WINS) study found that a low fat diet was associated with a 24% reduction in risk of relapse. Patients who were estrogen receptor-negative seemed to benefit more; this subgroup experienced a 42% reduction in relapse^[69]. However, some of this improved prognosis might be attributable to concurrent weight loss.

Goodwin *et al.*^[70] studied the impact of metformin in a group of non-diabetic breast cancer patients with fasting insulin levels at least 45 pmol/L and BMI at diagnosis of at least 28 kg/m². After treatment with metformin for 6 mo, fasting insulin levels decreased by 22%, insulin sensitivity improved by 25% and weight was reduced by

1.9 kg. Ongoing prospective trials are testing this further. Thus, in overweight and obese women, strategies to avoid weight gain may differ from those needed to achieve a healthy weight and may include diet, exercise and pharmacologic interventions.

CONCLUSION

Avoiding weight gain over time is challenging whether following a diagnosis of breast cancer or in the general population. Interventions during chemotherapy may prove especially difficult due to fatigue and other chemotherapy-associated symptoms, but may be necessary to avoid weight gain and improve QoL in both the short- and long-term and enhance prognosis. The two years after treatment may contain "teachable moments" when breast cancer survivors are open to lifestyle counseling. In their 2012 overview, Caan *et al.*^[39] conclude "prevention of weight gain appears to be an evidence based public health goal for breast cancer survivors."

Evidence suggests that following modern day chemotherapy, the modest weight gain experienced by breast cancer survivors does not impact on survival. However, a minority of breast cancer patients gains substantial weight, and further studies on the prognostic effect of change in body composition and measures of metabolism, including insulin resistance will be important. As the numbers of breast cancer survivors continue to grow, promoting strategies to avoid weight gain are supported by the literature and make sense to optimize overall health.

Abstract

Breast cancer is the most common cancer affecting women worldwide. Prediction models stratify a woman's risk for developing cancer and can guide screening recommendations based on the presence of known and quantifiable hormonal, environmental, personal, or genetic risk factors. Mammography remains the mainstay breast cancer screening and detection but magnetic resonance imaging and ultrasound have become useful diagnostic adjuncts in select patient populations. The management of breast cancer has seen much refinement with increased specialization and collaboration with multidisciplinary teams that include surgeons, oncologists, radiation oncologists, nurses, geneticist, reconstructive surgeons and patients. Evidence supports a less invasive surgical approach to the staging and management of the axilla in select patients. In the era of patient/tumor specific management, the advent of molecular and genomic profiling is a paradigm shift in the treatment of a biologically heterogeneous disease.

INTRODUCTION

Breast cancer is the most common cancer and also the leading cause of cancer mortality in women worldwide. Approximately 1.38 million new breast cancer cases were diagnosed in 2008 with almost half of all breast cancer cases and nearly 60% of deaths occurring in lower income countries^[1]. There is a large variation in breast cancer survival rates around the world, with an estimated 5-year survival of 80% in high income countries to below 40% for low income countries^[2].

Low and middle income countries face resource and infrastructure constraints that challenge the goal of improving breast cancer outcomes by early detection, diagnosis and treatment^[3]. In high income countries like the United States, approximately 232340 women will be diagnosed and 39620 will die of breast cancer in 2013^[4]. For an American woman, the lifetime risk of developing breast cancer is 12.38% or 1 in 8^[4]. The significant decrease in breast cancer-related mortality in the United

States from 1975 to 2000 is attributed to continued improvement in both screening mammography and treatment^[5,6]. According to the World Health Organization, improving breast cancer outcome and survival by early detection remains the cornerstone of breast cancer control.

RISK FACTORS AND RISK PREDICTION

Age, reproductive factors, personal or family history of breast disease, genetic pre-disposition and environmental factors have been associated with an increased risk for the development of female breast cancer.

Age

The risk of developing breast cancer increases with age. By using the Surveillance, Epidemiology, and End Results (SEER) database, the probability of a woman in the United States developing breast cancer is a lifetime risk of 1 in 8; 1 in 202 from birth to age 39 years of age, 1 in 26 from 40-59 years, and 1 in 28 from 60-69 years^[4].

Personal history

A personal history of breast cancer is also a significant risk factor for the development of a second ipsilateral or contralateral breast cancer. In fact, the most common cancer amongst breast cancer survivors is a metachronous contralateral breast cancer^[7]. Factors associated with an increased risk of a second breast cancer include an initial diagnosis of DCIS, stage IIB, hormone receptor negative cancers, and young age^[8].

Breast pathology

Proliferative breast disease is associated with an increased risk of breast cancer. Proliferative breast lesions without atypia, including usual ductal hyperplasia, intraductal papillomas, sclerosing adenosis and fibroadenomas confer only a small increased risk of breast cancer development, approximately 1.5-2 times that of the general population^[9]. Atypical hyperplasia including both ductal and lobular, usually incidentally found on screening mammography, confers a substantial increased risk of breast cancer. Women with atypia have an approximately 4.3 times greater risk of developing cancer compared to the general population^[9,10].

Family history

A woman's risk of breast cancer is increased if she has a family history of the disease. In the Nurses' Health Study follow-up, women with a mother diagnosed before age 50 had an adjusted relative risk of 1.69 and women with a mother diagnosed at 50 or older had a relative risk of 1.37 compared to women without a family history of breast cancer. A history of a sister with breast cancer also demonstrated an increased relative risk of 1.66 if the diagnosis was made prior to age 50 and a relative risk of 1.52 if diagnosed after age 50 compared to patients without a family history^[11]. The highest risk is associated with in-

creasing number of first degree relatives diagnosed with breast cancer at a young age (under age 50). Compared with women who had no affected relative, women who had one, two or three or more affected first degree relatives had risk ratios of 1.80, 2.93 and 3.90, respectively^[12].

Genetic predisposition

Approximately 20%-25% of breast cancer patients have a positive family history but only 5%-10% of breast cancer cases demonstrate an autosomal dominant inheritance^[13,14]. Genetic predisposition alleles have been described in terms of clinical significance^[15]. High-risk predisposition alleles conferring a 40%-85% lifetime risk of developing breast cancer include BRCA1 and BRCA2 mutations, mutations in TP53 gene resulting in Li-Fraumeni syndrome, PTEN resulting in Cowden syndrome, STK11 causing Peutz-Jegher's syndrome, Neurofibromatosis (NF1) and (CDH-1) E-Cadherin^[16]. Half of the breast cancer predisposition syndromes are associated with mutations in BRCA1 and BRCA2. Women with BRCA1 or BRCA2 deleterious mutations have a significantly higher risk of developing breast cancer. Lifetime breast cancer risk ranges from 65% to 81% for BRCA1 mutation carriers and 45% to 85% for BRCA2 carriers^[17-19]. Moderate risk genes including homozygous ataxia-telangiectasia (ATM) mutations^[20], somatic mutations in tumor suppressor gene CHEK2, and BRCA1 and BRCA2 modifier genes BRIP1^[21] and PALB2^[22] confer a 20%-40% lifetime risk of breast cancer. Numerous low-risk common alleles have been identified largely through genome-wide association studies^[15] and the clinical application in the presence of these mutations is yet to be determined.

ENDOGENOUS HORMONE EXPOSURE AND REPRODUCTIVE FACTORS

The cycles of endogenous estrogen levels throughout a woman's lifetime have implications for the development of or the protection against breast cancer.

Early menarche

Early age at menarche is a risk factor among both pre- and postmenopausal women for developing breast cancer. Delay in menarche by two years is associated with corresponding risk reduction of 10%^[23]. Within the European Prospective Investigation into Cancer and Nutrition cohort, women who had early menarche (≤ 13 years) demonstrated a nearly twofold increase in risk of hormone receptor positive tumors^[24].

Parity and age at first full term pregnancy

Nulliparous women are at an increased risk for the development of breast cancer compared to parous women. Young age at first birth has an overall protective effect, whereas relatively advanced age at first birth confers a relative risk of breast cancer greater than that of a nulliparous woman. Compared to nulliparous women the

cumulative incidence of breast cancer in women experiencing their first birth at age 20, 25, and 35 years was 20% lower, 10% lower and 5% higher, respectively^[25].

Breast feeding

Evidence suggests that breast feeding has a protective effect against the development of breast cancer. Breast feeding may delay return of regular ovulatory cycles and decrease endogenous sex hormone levels. It has been estimated that there is a 4.3% reduction for every one-year of breast feeding^[26].

Testosterone

High endogenous sex hormone levels increase the risk of breast cancer in both premenopausal and postmenopausal women. High levels of circulating testosterone in postmenopausal women have been linked to increased risk of developing breast cancer [relative risk (RR), 2.86-3.28]^[27].

Age at menopause

Later onset of menopause has also been associated with increased breast cancer risk. Every year delay in the onset of menopause confers a 3% increase in risk and every five year delay in the onset of menopause confers a 17% increase in risk of breast cancer^[23,28].

EXOGENOUS HORMONE EXPOSURE

Evidence suggests a relationship between the use of hormone replacement therapy (HRT) and breast cancer risk. Breast cancers related to HRT use are usually hormone receptor positive. When compared with patients who do not use HRT, breast cancer risk is higher in HRT users^[29]. An international meta-analysis examining the risk of breast cancer with HRT found that in women who did not use HRT, RR increased by a factor of 1.028 for each year older at menopause, comparable to the relative risk of 1.023 per year in women who use HRT or for those who ceased to use HRT up to four years previously^[30].

In the Woman's Health Initiative randomized control trial, combined estrogen plus progestin in postmenopausal women with an intact uterus significantly increased the risk of breast cancer, delayed breast cancer detection and diagnosis, and significantly increased breast cancer mortality. The study was terminated early because of increased mortality in the combined estrogen plus progestin group. By contrast, the use of estrogen alone by postmenopausal women without a uterus did not interfere with breast cancer detection and statistically significantly decreased the risk of breast cancer^[31]. Data from the Nurses' Health Study, however, suggest that women who use unopposed postmenopausal estrogen increase their risk of breast cancer by 23% at age 70^[32].

Timing and duration of HRT seem to be important factors associated with breast cancer risk as well. Breast cancer risk from exogenous hormone exposure is inversely associated with time from menopause. Women

initiating hormone therapy closer to menopause have a higher breast cancer risk^[33]. Long term (> 5 years) combined HRT use has been associated with the highest risk whereas short-term use of combined estrogen-progestin therapy does not appear to confer a significantly increased risk (RR = 1.023 per year)^[30].

LIFESTYLE FACTORS

Modifiable risk factors including the excessive use of alcohol, obesity and physical inactivity account for 21% of all breast cancer deaths worldwide^[34].

Alcohol consumption

Alcohol consumption has been associated with increased breast cancer risk that is statistically significant at levels as low as 5.0 to 9.9 g per day, equivalent to 3 to 6 drinks per week (RR = 1.15; 95%CI: 1.06-1.24; 333 cases/100000 person-years). Binge drinking, but not frequency of drinking, was associated with breast cancer risk after controlling for cumulative alcohol intake. Alcohol intake both earlier and later in adult life was independently associated with risk^[35].

Physical activity

Consistent physical activity has been shown to reduce the risk of breast cancer in a dose dependent manner, with modest activity conferring a 2% decrease in risk and vigorous activity a 5% decrease in risk^[36].

Obesity

Obesity, specifically in postmenopausal women, has also been shown to increase a woman's risk of breast cancer. In the EPIC multicenter prospective cohort study, postmenopausal women who did not use HRT had elevated breast cancer risk with increasing weight, body mass index (BMI) and hip circumference^[29]. In this cohort, multivariate relative risk was 1.28 for overweight women (BMI 25.0-29.9) and obese women (BMI > 30.0) compared to women in the normal weight range. Lean women on HRT are incongruously at an increased risk of breast cancer (RR = 2.04) compared to their overweight (1.93) and obese (1.39) counterparts^[29].

Insulin resistance and hyperinsulinemia have been studied as a risk factor for the comorbidities associated with obesity including cardiovascular disease and diabetes. Insulin has anabolic effects on cellular metabolism and insulin receptor overexpression has been demonstrated in human cancer cells^[37]. Hyperinsulinemia has been shown to be an independent risk factor for breast cancer in non-diabetic postmenopausal women and may help to explain the relationship between obesity and breast cancer^[38].

Radiation

Radiation exposure from various sources including medical treatment and nuclear explosion increases the risk of breast cancer. Radiation to the chest wall for treatment of childhood cancer increases the risk of breast cancer

linearly with chest radiation dose^[39]. Survivors of childhood cancers who received therapeutic radiation are at a dose dependent risk for the development of breast cancer, and those treated for Hodgkin's disease are at highest risk ($RR = 7$)^[40]. Radiation effects on the development of female breast cancer have also been demonstrated in Japan post nuclear attack on Hiroshima and Nagasaki^[41] and positively correlate with age younger than 35 years at time of exposure. The incidence of breast cancer has also increased in areas of Belarus and Ukraine. A significant two fold increase was seen in the most contaminated areas around Chernobyl following the nuclear accident and manifest in women who were younger at the time of the exposure^[42].

PREDICTION MODELS

Prediction models are used to better stratify a person's risk for developing cancer based on the presence of known and quantifiable risk factors. There is great value in identifying high risk individuals to better tailor timing of screening modalities or prompt referral to a geneticist for counseling and testing. The concordance statistic or "c-statistic" quantifies the ability to distinguish patients who will develop cancer from those who will not. A c-statistic of 0.5 indicates that the prediction model is no better at discriminating patients who are at risk from those who are not than flipping a coin.

Gail model

The most well-known and widely used screening tool is the Breast Cancer Risk Assessment Tool (BCRAT) or the Gail model, developed by Dr Mitchell Gail^[43,44] at the National Cancer Institute (NCI). The initial model used age, age at menarche, age at first live birth, number of previous biopsies, and number of first degree relatives with breast cancer, modified to include history of atypical ductal hyperplasia, lobular carcinoma *in situ*, and predicts a woman's 5-year and lifetime risk of developing invasive breast cancer. It was developed with data from the Breast Cancer Detection Demonstration Project (BCDDP) and included white and black women over age 35 only. Screening tools rely on incidence of disease and the Gail model is updated as necessary and is easily accessed at www.cancer.gov/bcrisktool. The NCI's BCRAT is widely available to clinicians and is best used for women without a strong family history. The c-statistic for the Gail model has reported to be between 0.55-0.67^[45]. The Gail model may under-predict women with a strong familial predisposition.

Models that emphasize family history

A commonly used risk prediction model with an emphasis on family history, including maternal and paternal family history and age of onset is the Claus model, engineered by Dr. Elizabeth Claus. The model, which predicted an autosomal dominant gene that led to an increased risk for developing breast cancer, was published the same

year as the BRCA1 gene was cloned^[46]. This model used data from the Cancer and Steroid Hormone study to assess breast cancer risk in women with a family history of breast cancer^[47]. The c-statistic for the Claus model is approximately 0.56^[48].

Mendelian models outperform epidemiologic models, owing to the high penetrance of BRCA gene mutations. BRCAPRO is a computer model developed by the University of Texas Southwestern Medical Center and Duke University that incorporates six unique predictive models to assess a woman's risk of developing breast cancer or carrying a deleterious BRCA gene mutation^[49,50]. The c-statistic for BRCAPRO is 0.76-0.92^[51,52] but when compared to experienced risk counselors, sensitivity for identifying BRCA gene mutation carriers were similar^[53].

The Tyrer-Cuzick model incorporates personal, familial and genetic risk factors in a comprehensive way to compare a woman's personal risk of developing breast cancer in 10 years with that of the population^[54]. The model accounts for BRCA genes, low penetrance genes, family history and personal risk factors such as age, age at menarche, age at first birth, menopausal state, body mass index and use of hormonal therapy. This model is considered to be one of the most accurate models in predicting a woman's risk for cancer with a c-statistic of 0.762, but may overestimate risk in patients with atypia^[55,56].

Most risk factors for breast cancer are fairly weak, ubiquitous or not yet known, making the prediction models that examine epidemiological risk factors inherently difficult. Advances in genomic sequencing, biomarker identification and genetic testing may improve the accuracy of these quantitative risk prediction models in the future.

SCREENING

Breast self- and clinical breast examination

Utility of the breast self-examination (BSE) is controversial as the benefit in terms of decreased mortality has not been demonstrated^[57]. Most clinicians encourage women to perform monthly BSE to become familiar with their normal anatomy and empower them with regards to their own healthcare^[58]. The 2013 NCCN guidelines recommend annual clinical breast examination (CBE) for women of average risk > 40 years of age as well as BSE to develop and exhibit breast self-awareness^[59].

Mammography

One of the most important advances in the treatment of breast cancer is early detection of non-palpable masses. In the 1960's, the first randomized control trials comparing periodic mammography screening *vs* clinical examination demonstrated a decreased mortality by approximately one third in the experimental group. However there is still controversy regarding mortality from breast cancer in the subset of women aged 40-49 years^[60-62]. Contemporary randomized control trials have demonstrated the benefits from screening mammography in women aged 40 to 70

years^[63-65]. A 2013 Cochrane Review suggests that mortality is an outcome biased toward screening, routine mammography leads to undue stress and uncertainty in the face of false-positive results with increase in total numbers of lumpectomies and mastectomies but no decrease in mortality^[66]. Controversy surrounding mammography is related to the inherent lead time and length time biases in screening for disease. Lead time bias is an overestimation of survival among screen detected cases compared to clinically detected cases when true survival time actually remains unchanged. Length bias is an overestimation of survival time among screening-detected cases, which is caused by those slowly progressing cases that may never be clinically relevant. The 2013 NCCN guidelines recommends annual screening mammography in women ≥ 40 years of average risk and annual mammography at age 25 or individualized based on onset of cancer in proband in patients who are high risk by prediction models, known history or genetic predisposition syndrome as well as the counseling and education of risks and benefits related to participating in cancer screening^[59].

Magnetic resonance imaging

Mammography remains the gold standard for breast imaging but magnetic resonance imaging (MRI) has become an important modality in the detection, assessment, staging, and management of breast cancer in selected patients. Screening MRI is more sensitive but less specific for the detection of cancer in high risk women. The sensitivity of MRI is 0.77-0.79 compared to mammographic sensitivity of 0.33-0.39. Specificity of MRI is 0.86-0.89 compared to mammographic specificity of 0.95^[67,68]. In a systematic review, MRI and mammography demonstrated a combined sensitivity and specificity of 0.94 and 0.77, respectively^[67]. The 2013 NCCN guidelines recommend patients who have increased ($> 20\%$) lifetime risk of developing breast cancer undergo annual mammography and MRI starting at age 25 or an age tailored to the risk of the patient on an individual basis. MRI is valuable in the screening of select high risk patients, patients in whom breast augmentation prevents effective screening mammography, or in patients with equivocal findings on other imaging modalities.

Ultrasound

There are several studies supporting the use of adjunctive screening ultrasound in high risk patients with dense breast tissue, which imparts a substantial but accepted number of false positives^[69]. No randomized controlled trials have been conducted to evaluate the impact of screening ultrasonography on breast cancer mortality rates. Whole breast ultrasound may allow the clinician to screen for breast cancers not detected by traditional mammography, especially in dense breasts where mammographic sensitivity is lower^[70]. Single center studies have shown that the incremental detection of breast cancer by ultrasound following screening mammogram offers only marginal added benefit in women of average

risk^[71].

DIAGNOSIS

History and physical examination

The clinical history is directed at assessing cancer risk and establishing the presence or absence of symptoms indicative of breast disease. It should include age at menarche, menopausal status, previous pregnancies and use of oral contraceptives or post-menopausal hormone replacements. A personal history of breast cancer and age at diagnosis, as well as a history of other cancers treated with radiation. In addition, a family history of breast cancer and/or ovarian cancer in a first-degree relative should be established. Any significant prior breast history should be elucidated including previous breast biopsies. After the estimated risk for breast cancer has been determined (see above), the patient should be assessed for specific symptoms like breast pain, nipple discharge, malaise, bony pain and weight loss.

Physical examination should include a careful visual inspection with the patient sitting upright. Nipple changes, asymmetry and obvious masses should be noted. The skin must be inspected for changes such as; dimpling, erythema, peau d'orange (associated with local advanced or inflammatory breast cancer). After careful inspection and with the patient in the sitting position the cervical, supraclavicular and axillary lymph node basins are palpated for adenopathy. When palpable the size, number and mobility should be ascertained. Palpation of the breast parenchyma itself is performed with the patient supine and the ipsilateral arm placed over the head. The subareolar (central quadrant) and each quadrant of both breasts is palpated systematically. Masses are noted with respect to their size, shape, location, consistency and mobility.

DIAGNOSTIC IMAGING

The initial choice of imaging should be individualized to each patient based on the age and characteristics of the lesions. Diagnostic imaging and image-guided needle biopsies play a central role in the diagnosis, treatment planning, and staging of patients with breast cancer.

Mammography

Mammography remains the mainstay in breast cancer detection^[72]. Diagnostic mammograms are performed in women who have a palpable mass or other symptom of breast disease, a history of breast cancer within the preceding 5 years, or have been recalled for additional imaging from an abnormal screening mammogram. Diagnostic mammograms include special views such as focal compression of one area of the breast tissue or magnification images. The breast imaging reporting and database system (BI-RADS) is the standardized method for reporting of mammographic findings^[73]. Carcinomas present as masses, asymmetries, and calcifications (Table 1). By definition, a mass is a space-occupying lesion seen in

Table 1 Breast imaging reporting and database system^[73]

Category	Assessment	Follow up
0	Need additional imaging evaluation	Additional imaging needed before a category can be assigned
1	Negative	Continue annual screening mammograms (women older than 40 yr)
2	Benign	Continue annual screening mammograms (women older than 40 yr)
3	Probably benign	Initial short term follow-up (usually six month) mammogram (< 2% chance of malignancy)
4	Suspicious abnormality	Biopsy should be considered (2%-95% chance of malignancy)
5	Highly suggestive of malignancy	Requires biopsy (> 95% chance of malignancy)
6	Known cancer	Biopsy-proven malignancy

two different planes. This is distinguished from a density, which is seen only in a single plane. The shape of masses is described as round, oval, lobular, or irregular, while the margins are identified as circumscribed (with well-defined margins), indistinct, and spiculated (with densities radiating from the margins). Calcifications associated with benign disease are generally larger than those seen with malignancy and typically are coarse (round, lucent centered, or “layering” on medial lateral or lateral medial images). Clustered amorphous, indistinct, pleomorphic (or heterogeneous), or fine, linear, or branching calcifications are more typical of carcinomas.

MRI

Breast MRI has become an integral part of breast cancer diagnosis and management in selected patients. Current indications for breast MRI include evaluation of patients in whom mammographic evaluation is limited by augmentation (including silicone and saline implants and silicone injections), determining the extent of disease at the time of initial diagnosis of breast cancer (including identification of invasion of the pectoralis major, serratus anterior, and intercostal muscles), evaluation of inconclusive findings on clinical examination, mammography, and/or ultrasonography, screening of the contralateral breast in selected patients with newly diagnosed breast carcinoma, and asymptomatic screening of patients at very high risk of breast carcinoma (in conjunction with routine mammography). Other uses of breast MRI include evaluation of response to neoadjuvant chemotherapy with imaging before, during, and/or after treatment, and identification of residual disease in patients with positive margins after lumpectomy.

Ultrasound

The current indications for breast ultrasonography include palpable findings (including as the initial imaging test of palpable findings in patients who are younger than 30 years, pregnant, or lactating), abnormalities or suspected abnormalities on mammography or MRI, problems with breast implants, suspected underlying mass in the setting of microcalcifications or architectural distortion on mammography, supplemental screening in women at high risk for breast cancer who are not candidates for or do not have easy access to MRI, and suspected axillary lymphadenopathy. Real-time imaging is also possible with ultrasonography, making it ideal for interventional pro-

cedures. Breast ultrasound imaging should be performed with a high-resolution real-time linear array transducer with a center frequency of at least 10 MHz, using the highest frequency with which adequate penetration of the tissue is feasible.

PROGNOSTIC INDICATORS

Estrogen receptor and progesterone receptor status

Estrogen receptor (ER) and progesterone receptor (PR) represent weak prognostic factors for patients with breast cancer, but these receptors are the strongest predictive factors for response to endocrine therapy. ER and PR assays should be performed on all invasive breast cancers^[74]. Both ER and PR are assessed by immunohistochemistry (IHC) on paraffin sections. IHC allows assessment of the expression specifically in either invasive or *in situ* cancer. Positive interpretation requires at least 1% of tumor cells showing positive nuclear staining of any intensity. Receptor negative is reported if less than 1% of tumor cells show staining of any intensity^[75]. The cutoff to define positivity is 1% because patients with even 1% ER/PR-positive tumors may benefit from hormonal therapy. About 70% of all breast cancers are ER-positive and 60% to 65% of all breast cancers are PR-positive. For the patients with a “weak positive” result an Allred score helps differentiate positive from negative receptor status. The Allred score categorizes the percentage of cells (scored from 0 to 5) with the intensity (scored from 0 to 3) and adds these two scores to give a numerical score from 0 to 8^[76]. A score of 0-2 was regarded as negative and 3-8 as positive.

HER2 protein expression and gene amplification

HER-2/neu is a proto-oncogene that encodes for a transmembrane tyrosine kinase growth receptor, and it is involved in several regulatory pathways in breast, involving proliferation, survival, cell motility, and invasion. HER2 is usually assessed by IHC. Fluorescence *in situ* hybridization (FISH) assay of HER2 expression is usually performed when the evaluation by IHC is equivocal. HER2 is a prognostic factor for outcome in both node-negative and node-positive patients and is a predictive factor for response to certain therapies that target the HER-2/neu receptor such as trastuzumab (Herceptin), a monoclonal antibody targeted to the HER2 protein, and other newer anti-HER2 agents.

Overexpression/amplification is reported in 10% to 34% of invasive breast cancers. Gene over expression and amplification and surface membrane protein expression are concordant in more than 90% of cases^[77,78].

Commercially available gene assays

OncotypeDX (Genomic Health, Inc, Redwood City, California) is a reverse transcription polymerase chain reaction-based assay that can be performed on paraffin sections. It is based on analysis of the expression of 21 genes and provides a “recurrence score” that correlates with outcome. Although it was initially used to assess prognosis in ER-positive, node-negative patients^[79], data have indicated that it is an equally valuable prognostic indicator in ER-positive, node-positive patients.

Another molecular profiling product is the Amsterdam 70-gene profile, Mammaprint (Agendia, Amsterdam, Netherlands), in which a microarray analysis of gene expression is used on breast cancer tissue. It is used to determine the prognosis of patients with breast cancer and can be used for all tumors, including node-positive, *HER-2 neu*-positive, and ER/PR-negative disease^[80].

MANAGEMENT

After a breast cancer has been diagnosed, the patient is clinically staged using the American Joint Commission on Cancer (AJCC) guidelines (Tables 2 and 3).

Several landmark trials with decades of follow-up form the foundation of contemporary breast surgery. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 trial compared radical mastectomy (RM) to total mastectomy (TM) with or without radiation therapy in a prospective randomized fashion. In the TM arm, axillary dissection was performed only if lymph nodes were positive. The investigators reported no difference in either group with regard to disease-free survival, relapse-free survival, distant-disease-free survival, or overall survival, confirming no advantage to RM. The NSABP B-06 trial prospectively randomized women with tumors less than 4 cm to mastectomy, lumpectomy, or lumpectomy with radiation. All women had an ALND regardless of treatment assignment or nodal status; negative margins, defined as no tumor at ink, were required. The 20-year follow-up data were published in 2002; the investigators found no difference in disease-free, distant-disease-free, or overall survival between any of the treatment arms^[81,82]. The data did demonstrate, however, a significant reduction in local recurrence (LR) after lumpectomy with the addition of radiation therapy (39.2% *vs* 14.3%, $P < 0.001$). The National Institutes of Health (NIH) issued a Consensus Conference statement in 1990 recommending BCT as the preferred surgical treatment of women with early stage breast cancer^[83].

Contraindications to BCT exist and are classified as absolute or relative. Absolute contraindications include multicentric disease (tumors in more than one quadrant of the breast), diffuse malignant-appearing calcifications,

inflammatory breast cancer, prior radiation to the chest or breast or inability to receive radiation, persistent positive margins despite appropriate attempts for breast-conserving surgery, and the need for radiation during pregnancy. Skin dimpling, nipple and areolar retraction, and tumor location are not contraindications to BCT, yet these should be considered in the preoperative assessment, specifically with respect to the ability to achieve negative margins.

Achieving negative surgical margins is a hallmark of successful BCT because this is associated with a lower rate of LR. However, what constitutes a negative margin remains a matter of considerable debate. The NSABP has long defined a negative margin as “no tumor at ink” regardless of the proximity of the nearest tumor cell. Historically, other series have argued that margins of more than 1 mm, more than 2 mm, more than 5 mm, or even more than 10 mm provide better local control. A recent meta-analysis reviewed 21 studies and 14571 patients undergoing BCT^[84]. Data demonstrate a significant increase in LR for positive margins with an odds ratio (OR) of 2.42 ($P < 0.001$) compared with negative margins. Direct comparison between different margin widths found no statistically significant improvement in local control. Although a weak trend was identified suggesting declining LR with increasing margin distance, this trend disappeared after adjustments for radiation boost treatment and endocrine therapy.

Neo-adjuvant chemotherapy increases eligibility for breast-conserving surgery, especially in patients presenting with locally advanced breast cancer or in borderline cases whereby the tumor-to-breast size ratio will not allow for excision and acceptable cosmetic results. NSABP B-1840 established the efficacy of neo-adjuvant therapy randomizing women with early stage breast cancer to 4 cycles of neo-adjuvant or adjuvant doxorubicin plus cyclophosphamide. An updated analysis with more than 16 years of follow-up demonstrates no difference in overall survival, disease-free survival, or event-free survival between the two arms^[85]. Women receiving neo-adjuvant therapy had a higher rate of pathologic negative axillary lymph nodes at surgery and a higher rate of BCT.

Radiation therapy plays a crucial role in successful BCT and has long been recognized to reduce LR risk by approximately 50%. The 2005 Early Breast Cancer Trialists' Collaborative Group's (EBCTCG) overview analyses demonstrated the influence of local control on long-term survival^[86]. With regard to BCT, the EBCTCG collectively analyzed data from 10 trials of 7300 women and found the risk of LR at 5 years to be significantly reduced from 26% after lumpectomy alone to 7% after lumpectomy with radiation therapy, an absolute reduction of 19%. The EBCTCG recently updated this data in 2011, expanding their analysis to 17 randomized trials of 10801 women undergoing breast-conserving surgery with and without radiotherapy. This meta-analysis again confirmed that radiation therapy resulted in an overall absolute reduction in LR of 15.7% at 10 years compared with those

Table 2 American Joint Commission on Cancer guidelines—tumor node metastasis classification

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i>
Tis (DCIS)	Ductal carcinoma <i>in situ</i>
Tis (LCIS)	Lobular carcinoma <i>in situ</i>
Tis (Paget's)	Paget's disease of the nipple
T1	Tumor ≤ 20 mm in greatest dimension
T1mi	Tumor ≤ 1 mm in greatest dimension
T1a	Tumor > 1 mm but ≤ 5 mm in greatest dimension
T1b	Tumor > 5 mm but ≤ 10 mm in greatest dimension
T1c	Tumor > 10 mm but ≤ 20 mm in greatest dimension
T2	Tumor > 20 mm but ≤ 50 mm in greatest dimension
T3	Tumor > 50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or skin nodules)
T4a	Extension to the chest wall, not including only pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed (for example, previously removed)
N0	No regional lymph node metastases
N1	Metastases to movable ipsilateral level I, II axillary lymph node(s)
N2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastases
N2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically detected ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastases
N3	Metastases in ipsilateral/intraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastases in ipsilateral/intraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph node(s)
Distant metastases (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i +)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

not receiving radiation (19.3% *vs* 35.0%, $P < 0.00001$, two-tailed); this translated into an absolute reduction in breast cancer death of 3.8% at 15 years^[87].

LR after BCT can be described as: (1) a true recurrence, one within the primary tumor bed; (2) a marginal miss, one within the same quadrant just outside of the tumor bed; and (3) an elsewhere recurrence, one in a separate quadrant of the breast. Generally, true recurrences and marginal misses account for 46% to 91% of all LRs and tend to occur earlier than elsewhere recurrences^[88]. The EBCTCG demonstrates that more than 75% of all recurrences occur within 5 years^[86]. Risk factors for LR include positive margins, young age, ER-negative receptor status, larger tumor size, positive nodes, and lymphovascular invasion^[89,90]. Systemic therapy, especially targeted therapy, reduces the risk of LR. For example, the adjuvant trastuzumab trials demonstrate that patients receiving trastuzumab had a 50% reduction in LR^[91].

Similarly, Mamounas and colleagues evaluated LR in estrogen receptor-positive patients enrolled in NSABP B-14 and NSABP B-20 according to the 21-gene recurrence score assay (Oncotype DX, Genomic Health, Redwood City, California, United States)^[92]. At 10 years, tamoxifen significantly reduced the risk of LR in the low-risk group from 10.8% to 4.3% ($P < 0.001$). The addition of chemotherapy further reduced LR to 1.6% in that group ($P = 5.028$).

LOCOREGIONAL TREATMENT OF CLINICAL STAGE I, II A, OR II B DISEASE OR T3, N1, M0

Lumpectomy with surgical axillary staging

Negative axillary nodes: Radiation therapy to whole breast with or without boost (by photons, brachytherapy,

or electron beam) to tumor bed or consideration of partial breast irradiation (PBI) in selected patients. Radiation therapy should follow chemotherapy when chemotherapy is indicated.

One-three positive axillary nodes: Radiation therapy to whole breast with or without boost (by photons, brachytherapy, or electron beam) to tumor bed following chemotherapy when chemotherapy is indicated. Strongly consider radiation therapy to infraclavicular region and supraclavicular area. Strongly consider radiation therapy to internal mammary nodes. Radiation therapy should follow chemotherapy when chemotherapy is indicated.

> Four positive axillary nodes: Radiation therapy to whole breast with or without boost (by photons, brachytherapy, or electron beam) to tumor bed, infraclavicular region and supraclavicular area. Strongly consider radiation therapy to internal mammary nodes. Radiation therapy should follow chemotherapy when chemotherapy is indicated.

Total mastectomy with surgical axillary staging ± reconstruction

No radiation therapy: Negative axillary nodes and tumor ≤ 5 cm and margins ≥ 1 mm.

Consider postchemotherapy radiation therapy to chest wall: Negative axillary nodes and tumor ≤ 5 cm and close margins (< 1 mm).

Strongly consider radiation therapy to internal mammary nodes: Negative axillary nodes and tumor > 5 cm or margins positive: Consider radiation therapy to chest wall \pm infraclavicular.

One-three positive axillary nodes: Strongly consider

postchemotherapy radiation therapy to chest wall + infraclavicular and supraclavicular areas; if radiation therapy is given, strongly consider internal mammary node radiation therapy.

\geq Four positive axillary nodes: Postchemotherapy radiation therapy to chest wall + infraclavicular and supraclavicular areas. Strongly consider radiation therapy to internal mammary nodes.

MASTECTOMY

Approximately 30% to 40% of breast cancer patients in the United States are candidates for mastectomy, either because they are not eligible for BCT or the patients choose mastectomy.

The types of mastectomy available are: TM or simple mastectomy: removal of the breast, overlying skin, and the nipple and areolar complex; SSM or skin-sparing: same as TM or simple mastectomy but sparing as much skin as possible and the infra-mammary fold for immediate or delayed reconstruction; MRM or modified radical mastectomy: same as TM but within continuity axillary lymph node dissection.

NSM: SSM technique also saving the areola and/or nipple; RM or radical mastectomy which includes removal of the pectoralis muscles and level III axillary nodes. Mastectomy is usually done in conjunction with sentinel node biopsy. Prophylactic mastectomy (PM) is a term that applies to mastectomy when there is no cancer in the breast.

MANAGEMENT OF THE AXILLA

The status of the axillary lymph nodes is one of the most important factors impacting overall prognosis and treatment decision-making for breast cancer. Complete axillary lymph node dissection (ALND), or removal of level I and II axillary nodes was the standard surgical approach to invasive breast cancer until recently. Now this operation is reserved for patients with clinically positive lymph nodes confirmed on needle biopsy at initial evaluation, or when a clinically negative axilla is evaluated by ultrasound, found to have a suspicious node and this is confirmed by needle biopsy. In patients with a clinically and radiologically negative axilla, a sentinel lymph node (SLN) biopsy can be performed safely at the time of mastectomy or lumpectomy, sparing patients the morbidity associated with ALND.

The sentinel node is based on the concept that breast cancers drain to a single node or nodes, the sentinel nodes, before draining to more distal nodes. One of the earliest randomized trials examining the use of SLN biopsy in breast cancer was reported by Veronesi *et al.*^[93] in 2003. They randomized 516 patients with breast cancer with tumors less than 2 cm in diameter to receive a SLN biopsy followed by routine ALND or SLN biopsy followed by an ALND only if the SLN contained metas-

tases. After 10 years of follow-up, no differences were observed between the groups for local axillary recurrence (0% in the SLN biopsy group *vs* 2% in the ALND group) or disease-free survival (89.9% *vs* 88.8%)^[94].

Recent research has questioned whether all patients with a positive SLN require a completion ALND. In patients with clinically node-negative disease, the SLN is the only involved node in 60% to 70% of patients, which raises the question as to whether ALND offers additional therapeutic benefit for all patients^[95].

This question was addressed prospectively in the ASOCOG Z0011 trial^[96]. Patients with T1 and T2 tumors undergoing lumpectomy who were found to have metastatic disease in the SLNs were randomized to undergo either ALND or no further treatment of the axilla. All patients were required to have negative margins in the breast excision, and went on to have whole-breast irradiation. Adjuvant treatment was per the primary team, with 96% receiving chemotherapy and 47% endocrine therapy. The trial closed early because of low accrual and events rates, reaching only 47% of its accrual goals (891 patients enrolled). Median follow-up for the evaluable patients was 6.3 years. At 5 years, the local recurrence rate was 1.6% in the SLN biopsy group compared with 3.1% in the ALND arm. There was also no difference in 5-year disease-free survival (89.9% *vs* 88.8%). The authors concluded that for select patients with node-positive breast cancer and low-volume axillary disease, a SLN biopsy alone does not result in inferior survival or inadequate local control.

ADJUVANT THERAPY

A multidisciplinary approach to the treatment of breast cancer has been fundamental for the recent advances in the management of this disease. A meta-analysis conducted by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG), which included randomized clinical trials conducted since adjuvant therapies became widely used in the 1990s, reported a decrease in annual relative risk of relapse and mortality of 23% and 17% respectively^[97]. The purpose of adjuvant systemic therapy is to improve the disease-free survival (DFS) and overall survival (OS) rates associated with treatment of BC by local therapies (surgery and/or radiation) alone. The high rates of recurrence are probably related to the presence of micrometastatic disease in 10%-30% of LN-negative and in 35%-90% of LN-positive patients at the time of diagnosis^[98,99]. Adjuvant chemotherapy helps eradicate residual local or distant residual microscopic metastatic disease. The addition of taxanes (paclitaxel and docetaxel) to the standard anthracycline based chemotherapy has been studied extensively and has shown a significant reduction of 17% in the risk of recurrence^[100,101]. A meta-analysis demonstrated that taxane-based regimens provide both DFS and OS benefit with an absolute 5-year risk reduction of 5% for DFS and 3% for OS when compared with standard anthracycline regimens irrespective of ER

status, LN status, and age. Additionally, the improvements in DFS and OS were similar for both paclitaxel and docetaxel^[102].

Current guidelines for adjuvant hormonal and chemotherapy after surgical treatment for invasive breast cancer vary depending on hormone receptor positivity or negativity and expression of HER-2/neu. Applicable practice guidelines are reproduced from the NCCN Breast Cancer Practice Guidelines below^[103].

Hormone receptor-positive

Her2-positive disease: pT1, pT2, or pT3; and pN0 or pN1mi (≤ 2 mm axillary node metastasis): (1) Tumor ≤ 0.5 cm or microinvasive (pN0, consider adjuvant endocrine therapy; pN1mi, adjuvant endocrine therapy or adjuvant chemotherapy with trastuzumab followed by endocrine therapy); (2) Tumor 0.6-1.0 cm, adjuvant endocrine therapy \pm adjuvant chemotherapy with trastuzumab; (3) Tumor > 1 cm, adjuvant endocrine therapy + adjuvant chemotherapy with trastuzumab; and (4) Node positive (one or more metastases > 2 mm to one or more ipsilateral axillary lymph nodes), adjuvant endocrine therapy + adjuvant chemotherapy with trastuzumab.

Her2-negative disease: pT1, pT2, or pT3; and pN0 or pN1mi (≤ 2 mm axillary node metastasis): (1) Tumor ≤ 0.5 cm or microinvasive (pN0, consider adjuvant endocrine therapy; pN1mi, adjuvant endocrine therapy or adjuvant chemotherapy with trastuzumab followed by endocrine therapy); (2) Tumor > 0.5 cm, consider 21-gene RT-PCR assay (not done, adjuvant endocrine therapy \pm adjuvant chemotherapy; low recurrence score (< 18); adjuvant endocrine therapy; intermediate recurrence score (18-30), adjuvant endocrine therapy \pm adjuvant chemotherapy; high recurrence score (≥ 31), adjuvant endocrine therapy + adjuvant chemotherapy; node positive (one or more metastases > 2 mm to one or more ipsilateral axillary lymph nodes), adjuvant endocrine therapy + adjuvant chemotherapy).

Hormone receptor-negative

Her2-positive disease: pT1, pT2, or pT3; and pN0 or pN1mi (≤ 2 mm axillary node metastasis): (1) Tumor ≤ 0.5 cm or microinvasive (pN0, no adjuvant therapy; pN1mi, consider adjuvant therapy with trastuzumab); (2) Tumor 0.6-1.0 cm, consider adjuvant chemotherapy with trastuzumab; and (3) Tumor > 1 cm, adjuvant chemotherapy with trastuzumab.

Her2-negative disease: pT1, pT2, or pT3; and pN0 or pN1mi (≤ 2 mm axillary node metastasis): (1) Tumor ≤ 0.5 cm or microinvasive (pN0, no adjuvant therapy; pN1mi, consider adjuvant chemotherapy); (2) Tumor 0.6-1.0 cm-Consider adjuvant chemotherapy; (3) Tumor > 1 cm-Adjuvant chemotherapy; and (4) Node positive (one or more metastases > 2 mm to one or more ipsilateral axillary lymph nodes), adjuvant chemotherapy.

More recently, the development of genomic profil-

ing techniques has identified gene expression patterns in breast tumors with distinct molecular profiles, pathologic features, and clinical outcomes^[104,105]. Expression patterns have defined 4 different subtypes: luminal A and B (estrogen-sensitive BC), HER2-enriched, and basal-like tumors (negative ER/PR and negative HER2). Luminal A tumors are classified by positive ER/PR, negative HER2, and low Ki-67, whereas luminal B tumors characteristically have positive ER/PR, negative HER2, and high Ki-67^[106,107]. The additive prognostic value of Ki-67, a cell proliferation marker, to steroid and HER2 receptors is accepted, as many significant genes in gene expression profiles are proliferation related. Ki-67 marks the difference between luminal A and B tumors; however, Ki-67 is not yet routinely available and standard cutoffs are not well defined.

Adjuvant hormone therapy is considered standard in all patients with endocrine-sensitive tumors defined by the expression of ER and PR by IHC. Approximately 70% of BCs have positive expression of the ER and are considered hormone sensitive. Treatment with tamoxifen for 5 years reduces the risk of recurrence by 41% and BC mortality by 34%^[97].

In postmenopausal women, an Aromatase Inhibitor may be substituted because of the proven efficacy and the low risk of for development of endometrial cancer with this drug. The arimidex, tamoxifen, alone or in combination (ATAC) trial, is a pivotal trial in adjuvant hormone therapy^[108]. The ATAC trial compared the adjuvant use of anastrozole plus tamoxifen either alone in postmenopausal women with early-stage BC. At 10 years, anastrozole as initial therapy showed increased DFS (HR 0.86, $P = 5.003$), time to local and distant recurrence (HR 0.79, $P = 5.0002$; HR 0.85, $P = 5.02$, respectively), and reduced indices of contralateral BC (HR 0.62, $P = 5.003$) compared with tamoxifen. However, there was no significant difference in overall mortality between the 2 groups^[109].

Approximately 15% to 20% of all BCs present with amplification of the HER2 gene^[110]. HER2 over-expression is reported to be an independent predictor of poor prognosis. This can be addressed by the incorporation of anti-HER2 therapy with trastuzumab, a monoclonal antibody targeting the extracellular domain of the HER2 protein, which in the adjuvant setting has shown significant improvement in clinical outcomes from adjuvant chemotherapy plus trastuzumab compared with chemotherapy alone. Based on results from randomized clinical trials, a trastuzumab-containing regimen for up to 1 year is now considered standard for all patients with HER2-positive tumors larger than 1 cm^[111,112].

There are rapid advances being made with respect to systemic therapy targeting specific molecular targets like phosphatidylinositol 3-kinase vascular endothelial growth factor receptor, epidermal growth factor receptor and poly polymerase.

performed by de Bock *et al.*^[113] identified that 40% of recurrent cancers are diagnosed in asymptomatic patients during routine visits. This data stresses the importance of follow up and surveillance. Clinical evaluation including history and physical exam is recommended every four to six months for five years, then every twelve months with annual mammography. Women on tamoxifen should undergo annual gynecologic assessment if the uterus is present. Women on an aromatase inhibitor or who experience ovarian failure secondary to treatment should have monitoring of bone health with a bone mineral density determination at baseline and periodically thereafter. Patients should also be instructed to augment modifiable risk factors such as decreasing alcohol consumption, increasing physical activity and decreasing BMI.

CONCLUSION

There is a greater refinement in breast cancer care with increased specialization and collaboration amongst surgeons, oncologists, radiation oncologists, nurses, geneticist, reconstructive surgeons and patients. The effectiveness and benefits of a multidisciplinary approach to the treatment of breast cancer has been empirically demonstrated^[114,115]. In the future, there will be great value in genomic sequencing and proto-identification of women at risk for developing breast cancer.

Abstract

There have been significant improvements in the detection and treatment of breast cancer in recent decades. However, there is still a need to develop more effective therapeutic techniques that are patient specific with reduced toxicity leading to further increases in patients' overall survival; the ongoing progress in understanding recurrence, resistant and spread also needs to be maintained. Better understanding of breast cancer pathology, molecular biology and progression as well as identification of some of the underlying factors involved in breast cancer tumourigenesis and metastasis has led to the identification of novel therapeutic targets. Over a number of years interest has risen in breast tumour kinase (Brk) also known as protein tyrosine kinase 6; the research field has grown and Brk has been described as a desirable therapeutic target in relation to tyrosine kinase inhibition as well as disruption of its kinase independent activity. This review will outline the current "state of play" with respect to targeted therapy for breast cancer, as well as discussing Brk's role in the processes underlying tumour development and metas-

tasis and its potential as a therapeutic target in breast cancer.

Key words: Breast tumour kinase; Protein tyrosine kinase 6; Breast neoplasms; Targeted molecular therapy; Intracellular signaling peptides and proteins; Protein kinase inhibitors

Core tip: Breast tumour kinase/protein tyrosine kinase 6 is overexpressed in up to 86% of invasive breast cancers. It plays a key role in regulating a number of cell processes that are involved in the metastatic process. As a kinase involved in both epidermal growth factor and insulin like growth factors signaling, inhibiting its activity could prove to be an effective way to enhance the effects of current targeted treatments. In addition, disrupting the protein-protein interactions central for the kinase-independent aspects of its function may generate an alternative mechanism for selective targeting of breast cancer cells.

INTRODUCTION

Exactly how breast cancer therapeutics has changed over the years is an intriguing aspect of the progress and evolution that has been made in research for cancer cures and treatments. Looking at the incidence and

mortality rates over the years in the United Kingdom and worldwide indicates the significant impact that continued improvements in detection and treatment of breast cancer have made. Statistically breast cancer incidence rates have been increasing since the 1970s^[1]. Approximately 75000 cases of breast cancer were diagnosed in 1975 compared to approximately 126000 in 2010^[1]. The increased frequency may be due to improved diagnostic techniques that contribute towards the rise in incidence; thus detecting cancers that may have remained unnoticed until much later. Breast cancer is the most common cancer in the United Kingdom with more than 48000 people being diagnosed each year^[1] and is the most recognized cause for the mortality rates of women aged between 33 and 55. This indicates room for improvement in relation to enhanced and effective therapeutic techniques that are patient specific, relatively non-toxic and contribute towards patients overall survival. Not only that, but there is ongoing progress needed towards understanding recurrence, resistant and spread^[2].

A closer look at breast cancer pathology, molecular biology and progression may lead to a better understanding of the underlying factors involved in breast cancer tumourigenesis and metastasis. A particular interest has risen in breast tumour kinase (Brk) also known as protein tyrosine kinase 6 (PTK6). Over a number of years the Brk research field has grown and Brk has been hinted at, as being a desirable therapeutic target in relation to tyrosine kinase inhibition as well as disruption of its kinase independent activity. Here, we outline Brk's role in the pathways essential for breast tumour development and discuss its potential as a therapeutic target in breast cancer.

BRK

Brk, also known as PTK6, was originally identified in a study involving human melanocytes and subsequently isolated from breast cancer cell lines in a study identifying novel kinases with therapeutic potential^[3]. The *ptk6* gene encodes the non-receptor tyrosine kinase, which consists of SH2, SH3 a linker region and catalytic domains. Total activity of Brk is significantly higher in malignancy than in normal mammary tissue, and over-expression of the protein has been noted in more than 80% of invasive ductal breast tumors^[4]. Brk expression so far has been detected in the majority of breast cancer cell lines with differing intensities^[5]. Gene sequencing indicated similarities with the SRC-family of protein tyrosine kinases, however there are distinct differences such as the lack of N-terminal extension and consensus sequences for fatty acylation and membrane association^[6]. Furthermore, its genomic structure is quite distinct from the SRC-family PTKs, which demonstrates an evolutionary divergence^[7]. Brk has also been shown to have a significant degree of similarity with the *Drosophila* src related gene known as Dsrc41, with six out of seven of Brk's exon boundaries

conserved with the Dsrc41 gene which has 9 exons. This could indicate Brk is likely to share a common ancestor with Dsrc41. The *ptk6* gene comprises 8 exons and encodes a 451 amino acid protein and FISH studies indicated localisation to chromosome 20q13.3^[6]. The protein product has a predicted molecular weight of 50 kDa, which generally resolves to around 48 kDa on an SDS-PAGE gel.

SH3 domains are small protein nodules made up of β -sheets. SH3 domains allow the assembly of specific protein complexes *via* proline-rich peptide binding, reviewed in^[8]. Brk's SH2 and SH3 domains are used for substrate recognition^[9,10]. The Brk SH3 domain has been known to undergo conformational changes due to pH fluctuations indicating that its structure could determine substrate and protein interaction, thus influencing its varied role in diverse cellular environments. The SH3 domain may have a role in enzyme regulation^[11]. The SH2 domain contains α/β folds and a phosphotyrosine binding surface with two α -helices opposite a central $\beta\alpha$ -sheet made up of four anti-parallel strands^[12]. This domain plays a role in protein-protein interactions and is important for regulation of catalytic activity^[10]. Due to the lack of myristoylation and a nuclear localization sequence, Brk's regulation is difficult to determine which allows for more flexibility with its subcellular localization, reviewed in^[13].

REASONS FOR NEW CANCER THERAPIES

Chemotherapy and radiotherapy have been recognised to target normal rapidly dividing cells such as bone marrow, gastrointestinal tract or hair follicles; the range and intensity of adverse effects reduces the specificity and increases toxicity of these therapies. Both these types of treatments therefore have a limited therapeutic index and can often be palliative in use as reviewed in^[14]. Hormonal therapies have also been in use; for example Tamoxifen, which has been used for early stage and metastatic breast cancer since its licence in 1972^[15]. Although proven to be effective against breast cancer, especially those that are oestrogen receptor positive, there are still many issues that need to be overcome for maximum effect of the drug to be achieved, whether by itself or as combination therapy. These include the diverse adverse toxicities such as thrombosis, strokes and development of secondary cancers. Other issues include resistance against Tamoxifen and subsequent recurrence in some patients. Furthermore, this drug is only effective against oestrogen or progesterone receptor positive breast cancers thus making it unsuitable for other types of breast cancer such as HER2 positive/ER/PR negative and triple negative breast cancers (reviewed in^[16]). However there are treatments available for HER2 positive cancers such as Herceptin, a monoclonal antibody that binds to HER2 thus negatively effecting receptor function, as well as a number of kinase inhibitors. Unfortunately the more advanced stages of

breast cancer do not always respond to Herceptin therapy and those that do, often progress in 12 mo from the start of the treatment^[17]. In addition resistance may occur due to the involvement of a number of signaling pathway molecules such as activation of the PI3K/AKT pathway, loss of PTEN and activation of PIK3CA, reviewed in^[18]. Brk is expressed in a wide range of cancer types and its expression appears to be independent of ER/PR/HER2 positivity, thus making it an ideal candidate for therapeutic intervention^[5,19].

TYROSINE KINASE INHIBITION

Targeted therapy is largely directed specifically towards tumour cells thus reducing many side effects and providing a wider therapeutic window. They can also be used in combination with traditional chemotherapy or radiotherapy to enhance anticancer effects. Further patient benefit includes convenience with oral consumption rather than intravenous administration as is the case for many chemotherapy drugs.

Tyrosine kinases have been implicated in a range of cancers; they are involved in cellular signalling and play an important role in growth factor signalling. In their active forms tyrosine kinases can promote tumour cell proliferation, growth and induce anti-apoptotic effects, as well as promote angiogenesis and tumour cell metastasis. Since most of these cellular events contribute to tumour progression and decreased patient prognosis, tyrosine kinases are considered ideal candidates for targeted therapy.

There are two main types of kinases; these can be categorized as receptor protein kinases that are generally membrane spanning, or non-receptor protein kinases that relay intracellular signals from the receptors and, of which, Brk is one. Briefly, when ligands bind to their cognate receptors, they stimulate receptor dimerization followed by autophosphorylation and activation of tyrosine kinase activity. As a result, multiple signalling pathways are activated and intracellular mediators in these pathways transduce signals from membrane receptors through the cytosol and into the nucleus which ultimately alters DNA synthesis and cell division as well as a wide range of biological processes as reviewed in^[14]. Protein tyrosine kinase activity within breast tumour tissues has been reported to be significantly higher in comparison with benign or normal breast tissues^[20]. For example, the tyrosine kinase activity of the product of c-src proto-oncogene has been found to be elevated in human breast tumors^[21], and several tyrosine kinase receptors have also been implicated in breast cancer development and progression.

These include members of the erbB Type 1 transmembrane receptor family such as epidermal growth factor receptor (EGFR) and HER2/neu transmembrane tyrosine kinase receptor, as well as receptors for insulin like growth factors (IGF) such as IGF-1R^[22,23]. Others include fibroblast growth factor receptor^[24] and met receptor tyrosine kinase^[25]. Of the substrates and proteins interacting with Brk^[13], many are linked to signalling from

these receptors, thus indicating a role for Brk in these signalling pathways.

EXAMPLES OF TYROSINE KINASE INHIBITORS IN BREAST CANCER- LAPATINIB, ERLOTINIB AND GETFINTIB

Gefitinib is an EGFR inhibitor, the first of its kind, that is also known to have an effect in HER2-overexpressing cell lines probably due to the reduction in phosphorylation of HER2/EGFR heterodimer^[26]. Gefitinib is especially effective in ER-positive and Tamoxifen resistant tumours indicating a target group of patients for this type of treatment^[27]. Erlotinib works in much the same way as Gefitinib, as a reversible EGFR inhibitor. It is clinically effective in locally advanced and metastatic non-small cell lung cancer^[28] but its benefit in breast is only recently becoming clearer, and there is some indication for Erlotinib in triple negative breast cancers^[29]. Erlotinib inhibits triple negative breast cancer as shown by Ueno and Zhang^[30] when they generated a SUM149 xenograft model by implanting luciferase expressing SUM149 cells into mammary pads of athymic nude mice. The results indicated significant inhibition of tumour growth at doses of 50 and 100 mg/kg.

There is a strong correlation between HER2 and EGFR in terms of dimerization, expression as well as activity^[31] since HER2 is EGFR's most common heterodimerization partner and HER2 potentiates EGFR signalling by enhancing EGF binding affinity^[32]. A dual inhibitor for HER2 and EGFR may therefore be of greater clinical benefit than individual therapies. When using an inhibitor with a single mode of action, therapeutic resistance can be increased whereas dual inhibition may reduce the chance of this happening^[32]. Other benefits of dual inhibition may include targeting a wider range of cancers since single inhibitors are, in some cases, specific for one particular type of cancer as well as a more effective inhibition in cancer cell growth overall^[33].

One such inhibitor already in use is Lapatinib, which reversibly inhibits the tyrosine kinase activity of both HER2 and EGFR, reviewed in^[32]. It is an orally available inhibitor that binds to EGFR in its inactive form in comparison to other EGFR inhibitors such as Erlotinib and Gefitinib, which bind EGFR in its active form. This allows for a greater duration of effect at the target site^[34]. So far Lapatinib has proven to be well tolerated with rare occurrences of high-grade toxicities. In relation to Brk, Lapatinib has been recognised to have reduced efficacy with increased levels of Brk in HER2-transfected mammary epithelial cells^[35]. This may suggest a role for Brk in acquired resistance against HER2 targeted therapy when both proteins are over-expressed. Targeting Brk alongside HER2 inhibition could overcome resistance as well as increase efficacy of HER2-targeted treatment.

Both Gefitinib and Erlotinib initially indicated no real

clinical benefit for metastatic breast cancer patients and had little efficacy in phase II studies^[27]. This indicates lack of correlation between EGFR expression level with response to treatment even though many breast cancer cells express EGFR^[36]. Previously there was strong evidence for combination therapy with tyrosine kinase inhibitors and hormone therapy^[32], thus allowing for a greater clinical benefit. However more recently, combination therapy using Gefitinib and anti-hormonal therapy (fulvestrant and anastrozole) demonstrated only a modest increase in clinical benefit compared to Gefitinib or hormonal therapy alone^[37].

Erlotinib resistance is linked to CDK2 activity; cell proliferation is induced in Erlotinib treated cells when CDK2 is expressed and, conversely, there is increased sensitivity to Erlotinib when CDK2 activity is suppressed. Erlotinib has also shown to upregulate p27 and nuclear translocation in association with cell growth inhibition in non-small cell lung cancer^[38]. Cyclin dependent kinases regulate cell cycle progression from quiescence to mitosis by activating the transcription factor E2F leading to activation of genes needed for progression from G₁ to S phase^[36]. Furthermore, in relation to breast cancer it has been shown that inhibition of the erbB2 pathway by EGFR inhibitors in erbB2-overexpressing breast cancer cell lines caused G₁ phase arrest with accumulation of p27 and reduced Cyclin D1^[39]. This is further verified by Nahta *et al.*^[40] who showed that downregulation of p27 in breast cancer cells was accompanied by an increased S-phase fraction and increased resistance to Herceptin therapy. The induction of p27 is therefore necessary in Erlotinib inhibition of cell growth.

Since cell cycle deregulation is implicated in development of neoplasia and may contribute towards development of breast cancer, as well as response to therapy the discovery that Brk is involved in cell cycle regulation was of importance^[41]. Brk deregulates cell cycle progression; an inverse correlation was shown between Brk expression levels and p27 expression levels. With increasing Brk expression there was reduced p27, and in cells lacking p27 and Fox03a, Brk induced a decreased level of cell proliferation indicating it may need the p27/Fox03a pathway to promote cell growth. This indicates the importance of Brk's role in cell cycle progression and suggests a role for Brk in mediating cell responses to EGFR/HER2 inhibitors through regulation of p27.

BRK AND HER2 INTERACTIONS

In cancer cells, alterations in HER receptors or in their downstream signalling components are known to occur; HER2 is a negative prognostic factor, the presence of which indicates aggressive phenotype and reduced overall survival rate as reviewed in^[42], although it should be noted that survival rates for HER2 positive cancers are improving due to the introduction of targeted therapies^[43].

HER2 is overexpressed in approximately 20%-30% of breast cancers^[44] and it has been suggested that Brk may be involved in regulation of signal transduction from HER tyrosine kinases. Several studies have shown a link between HER2/neu expression and Brk/PTK6^[35,45].

This is of interest because, as discussed above, HER2 targeted therapy although clinically proven to be effective does pose some restrictions such as lack of effect in some HER2/neu positive cancers as well as resistance. Therefore, Brk targeted therapy maybe of clinical benefit especially when used in combination with existing HER2/neu targeted therapy. Due to the strong correlation between PTK6 and HER2, there is evidence suggesting that it may also be linked with prognosis thus indicating a role for Brk as a prognostic factor in breast cancer. PTK6 expression studied in 426 breast cancer cases further supports its potential as a independent prognostic factor regardless of morphological and molecular markers such as lymph node involvement, tumour size and HER2 status^[46]. Co-expression of Brk and HER2 has been linked to co-amplification of both the *ErbB2* and *ptk6* genes^[35], although this is not a consistent finding in other patient studies. It is worth noting that although HER2 is over expressed in 20%-30% of breast cancers^[44], Brk is over expressed in upto 86% of breast cancers^[47], which indicates that in the majority of breast cancers Brk is over expressed independently of HER2 status.

At a protein level, Aubele and colleagues showed that PTK6 forms protein complexes with HER2 in paraffin tissues from invasive breast carcinomas^[48]. Recently, the effect of simultaneous knockdown of PTK6 and HER2 has been analysed in the herceptin-resistant cell line JIMT-1^[49]. The results indicated significant reduction in phosphorylation of important signalling intermediates, namely MAPK, ERK and p38MAPK and PTEN, which are involved in tumourgenesis. Furthermore there was reduced migration and invasion of JIMT-1 cells when expression of both proteins was suppressed. HER2 may also be involved in elevating Brk levels *via* upregulating calpastatin and inhibiting calpain-1 activity in breast cancer cells^[50].

These combined data further support the study of dual inhibition of Brk and HER2, firstly for a greater clinical effect and secondly to overcome anti-HER2 therapeutic resistance.

BRK AND EGFR INTERACTIONS

ErbB signalling in breast tumour progression has been extensively documented. EGFR tyrosine kinases have been involved in regulation of normal and abnormal cellular proliferation and survival (reviewed in^[51]). Both EGFR and HER2 are intrinsically linked; HER2 potentiates EGFR signalling by enhancing binding ability of EGF and reducing its degradation and studies have indicated that HER2 signalling is reduced *via* EGFR-specific inhibitors^[52].

The EGF receptor family are linked to the tumour-genic transformation of breast epithelial cells. When Brk Transfected mammary epithelial cell lines, MCF10A and Hb4a, were treated with human growth factors (EGF), mitogenic activity of Brk was observed. This reveals Brk's role in sensitizing human mammary epithelial cells to growth factors such as EGF^[53]. Furthermore, Brk association with the EGF receptor has also been detected, even in the absence of EGF, leading to proliferation of epithelial cells. EGFR expression also plays a role in keratinocyte differentiation^[54], a process in which Brk is involved^[55]. Inhibition of EGFR signalling during differentiation induces growth arrest, however Brk's promotion of EGFR signalling suggests that one of its roles may involve promoting cell survival during early differentiation.

EGF stimulation results in rapid phosphorylation of Brk indicating the involvement of Brk in the EGF signalling complex^[56]. EGF binding to its receptor, EGFR, not only induces its phosphorylation but also the phosphorylation of other EGFR family members (HER2, 3 and 4). The expression of Brk therefore not only increases phosphorylation of EGFR and HER2 but also of HER3 (erbB3) in breast cell lines^[56]. It may do this *via* direct interaction with an erbB3-containing complex in response to EGF stimulation. Brk's ability to enhance EGFR signalling could be mediated by inhibition of EGFR down-regulation^[57], which is achieved by phosphorylation of either ARAP-1^[58] or c-Cbl^[59], thereby prolonging EGFR signalling.

Expression of Brk enhances EGF-induced ErbB3 phosphorylation and recruitment of P13K to ErbB3 thus inducing P13K activity^[56]. Since the P13K pathway is implicated in breast cancer and is linked with resistance to HER2 targeted therapies, its interaction with Brk may give a wider overview of the mechanisms involved in developing resistance. P13K has been a desirable therapeutic target of its own and current therapies, as reviewed in^[60], focus on anti-mTOR agents, tyrosine kinase inhibitors and P13K inhibitors. However to create a greater clinical effect, combinations of these treatments including a potential Brk tyrosine kinase inhibitor maybe more useful and reduce the activation of compensatory feedback loops which could decrease efficacy of single agents. Since Akt is a known substrate of Brk, and Brk negatively regulates its phosphorylation in epithelial cells, the potential consequences of this therapy may need to be fully assessed^[61]. Nonetheless, due to most of the normal cells that express Brk being outside the proliferative areas of the tissues Brk targeted therapy may still be highly specific^[62].

Overall Brk has shown to prolong EGFR signalling, sensitise tumour cells to EGF stimulation, inhibit degradation of EGFR and reduce sensitivity of EGFR inhibitors in Brk overexpressing cells. This suggests Brk inhibition could reduce tumour proliferation and growth *via* reduced EGFR signalling and increase EGFR inhibitor sensitivity.

BRK AND IGF INTERACTIONS

Insulin receptor substrate 4 (IRS-4) is part of the insulin receptor substrate family, which also contains IRS-1, IRS-2 and IRS-3. Their function includes a variety of biological effects such as cell proliferation, growth, survival and differentiation downstream of insulin and insulin-like growth factor 1 (IGF-1) receptors^[63]. IRS-4, upon IGF-1 stimulation, is phosphorylated which leads it to binding to P13K activating the MAPK pathway. The link between insulin-like growth factor (IGF) and breast cancer has been well documented; the IGF-1 receptor is significantly overexpressed in tumour cell lines compared to normal breast cancer epithelial tissue and benign tumours^[64] and there is also a clear correlation between poor breast cancer prognosis and overexpression of IGF-1R^[65]. In the MCF-7 breast carcinoma cell line, IGF stimulation results in Akt activation leading to cell proliferation through phosphorylation of Raf kinase. Along with this, IGF stimulation leads to resistance to anoikis^[66], a process whereby epithelial cells undergo apoptosis due to loss of interaction with neighbouring cells and the basement membrane^[67]. Overexpression of IGF-1R is also implicated in resistance against breast cancer therapy, especially against Herceptin^[17].

Immunoprecipitation and mass spectrometry have shown IRS-4 substrate interaction with Brk in co-transfected HEK 293 cells^[68]. In addition to this interaction with IRS-4, Brk also co-precipitates with IRS-1 and IGF-IR^[66]. The interaction of Brk with IGF-IR as well as EGFR and HER2 gives an indication of the range of Brk activity in regulating signalling. EGFR, HER2 and IGF-1R are overexpressed in different subsets of breast cancers whereas Brk is overexpressed in majority of breast cancers and has a role in each of these signalling pathways, thus making it an attractive therapeutic target for disrupting signalling cross-talk. Since Brk interacts with IGF-1R, disrupting this association may also reduce the chance of developing resistance against current breast cancer therapies such as Herceptin, through HER2-IGF-R1 heterodimer formation resulting in phosphorylation and activation of HER2 as reviewed in^[69].

BRK AND ITS INTERACTION

ALTERNATIVELY SPLICED ISOFORM, ALT-PTK6

During the characterisation and chromosome mapping of Brk, an alternatively spliced short isoform was identified in T47D cells, which was originally called $\lambda m5$ and then later renamed to ALT-PTK6^[6,70]. ALT-PTK6 is 134 amino acids in size (15 kDa) and is expressed from an alternatively spliced transcript that has a 122 base pair deletion at the 3' end of the SH3 coding region; thus it lacks the SH2 and kinase domains and has an alternative C-terminal proline rich sequence (Figure 1). The protein

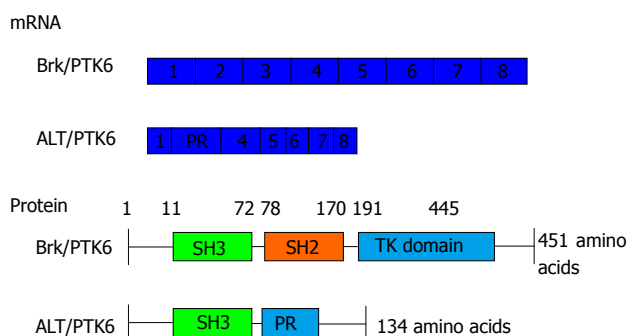

Figure 1 Breast tumour kinase domain structure. Full length Brk/PTK6 and short isoform ALT-PTK6 structure indicating the SH3 domain (green), SH2 domain (orange) and a tyrosine kinase domain or proline rich sequence (blue). Underneath is indicated the cDNA structure of both forms, with each box indicating each exon (total of 8 exons). ALT-PTK6 has deletion at exon 2 and lacks SH2 domain due to shift in open reading frame, which gives a proline rich sequence at exon 3 instead. PTK6: Protein tyrosine kinase 6; Brk: Breast tumour kinase.

level of ALT-PTK6 was lower than full length Brk in T47D breast cancer cells^[6]. There is still speculation of the role of ALT-PTK6 and the extent of its effect in the overall process of cancer pathology, however, there has been indication that the short isoform may act as a competitive inhibitor for the SH3 binding partners^[70] since both contain the SH3 domain^[6].

The Tyner laboratory were the first to describe a function of ALT-PTK6, albeit in prostate cancer cell lines^[70]. β -catenin has been identified as a direct substrate of Brk^[71] and ALT-PTK6 may influence Brk's ability to regulate β -catenin/TCF transcription^[70]. The Wnt/ β -catenin pathway promotes cancer cell growth and its deregulation is involved in pathogenesis of various cancers including breast cancer, reviewed by^[72]. ALT-PTK6 has also been shown to inhibit the phosphorylation of Brk to some extent, since the presence of ALT-PTK6 reduced PTK6 interaction with tyrosine-phosphorylated proteins in what appears to be a dose-dependent manner^[70].

Further to this, in co-transfection experiments, increased ALT-PTK6 expression resulted in an increase of constitutively active form of Brk in the nucleus with a decreased proportion at the membrane^[70]. There was also reduced proliferation in ALT-PTK6 expressing prostate tumour cells compared to those without this short isoform. These data therefore suggest that ALT-PTK6 may contribute towards limiting Brk localisation to the nucleus and acting as a competitive inhibitor thus reducing the ability of Brk to interact with its substrates that promote tumour cell growth.

The localisation of Brk therefore may play an important role in development of cancer since Brk's arrangement in the cellular environment may affect its role due to the variety of substrates available in nucleus and cytoplasm^[13]. Also Brk's role in various tissue types has shown to be dramatically different, for example, in normal tissues it is involved in regulation of differentiation process whereas in tumour cells it promotes cell proliferation and survival. Therefore, Brk's function may depend on the

tissue it is expressed in, its intracellular location and the substrate it interacts with^[70].

BRK'S ROLE IN CELL MIGRATION, TUMOUR FORMATION AND METASTASIS

To a large extent Brk is involved in breast cancer cell proliferation^[73], however it is also involved in cell migration. A reduced ability for T47D and JIMT-1 breast cancer cell migration was observed in response to Brk suppression^[49]. Paxillin is a multidomain protein that is recruited to edges of the cell once migration is initiated, as reviewed in^[74], and Brk has been recognised as a novel paxillin tyrosine kinase that binds to, as well as phosphorylates, paxillin^[75]. Brk also acts a mediator of EGF-induced paxillin phosphorylation, thus promoting activation of Rac1 and stimulating cell migration and invasion. KAP3A is a subunit of the kinesin-2 heterotrimeric complex and binds microtubule-based subunits KIF3A/3B to various cargo proteins, which enable membrane morphogenesis^[76]. KAP3A has also been identified as a substrate of Brk and is phosphorylated at its C-terminus, a process required for Brk-induced cell migration^[77]. Along with this, p190, another substrate of Brk, once phosphorylated is associated with p120 leading to Rho inactivation and Ras activation^[78]. Migratory effects of Brk are greatly impaired in cells lacking p190. These interactions indicate an important function of Brk in regulating tumour cell migration *via* various systems, thus a Brk-targeted therapy could potentially cause disruption in these processes.

STAT3 and STAT5 are also recognised as substrates of Brk and are involved in cellular processes leading to cell proliferation, migration and survival^[79-81]. STAT3 is regarded as an oncogene, with tyrosine phosphorylation of STAT3 connected to breast cancer development as discussed in^[79]. Activation of STAT3 by Brk may contribute towards cell transformation and uncontrolled growth in early stages of breast cancer. Brk also mediates STAT3 regulation in established tumours^[80], and constitutive activation of Brk accelerated cell migration and tumour growth *in vivo*^[82].

Angiogenesis has been recognised as an essential process in survival of cancerous cells *in vivo*; it is involved in tumour growth, progression and metastasis^[83]. One of the main pro-angiogenic factors involved in promoting tumour angiogenesis is vascular endothelial factor (VEGF)^[84]. Osteopontin is a secreted non-collagenous chemokine-like protein that regulates VEGF expression *via* a Brk/nuclear factor-kappaB (NF- κ B)/ATF-4 signalling cascade^[85]. Higher levels of expression of Brk, NF- κ B and ATF-4 correlated with higher tumour grades. As osteopontin is secreted from the bone and expressed in brain^[86,87], which are frequent sites for breast cancer metastasis^[88], this study provides a mechanism whereby Brk could be involved in the formation of metastases.

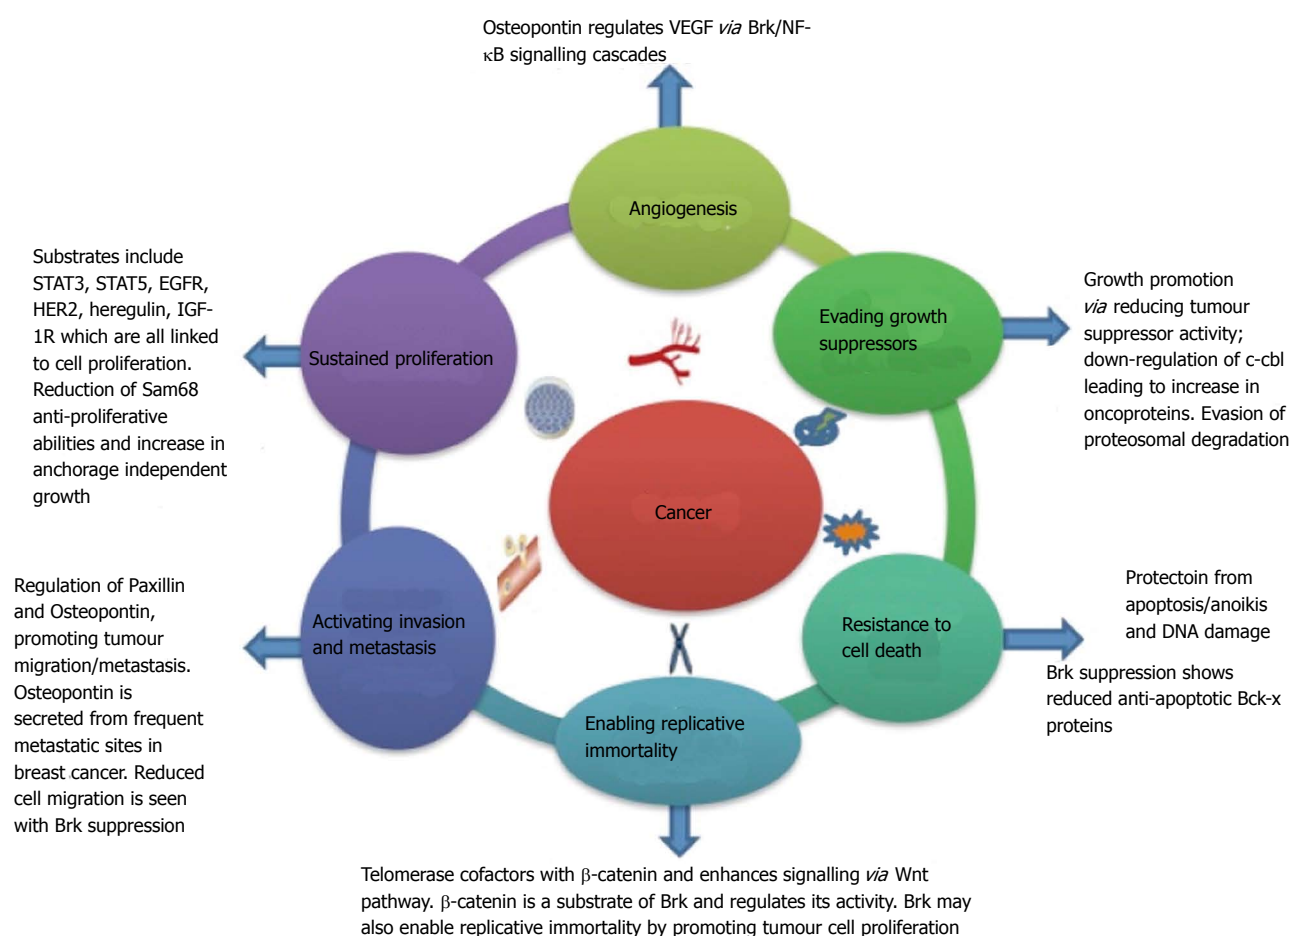

Figure 2 Breast tumour kinase and cancer hallmarks. Brk and cancer hallmarks. The original six cancer hallmarks described by Hannahan and Weinberg (2001)^[86] are illustrated along with a summary of Brk's role in their regulation. Brk: Breast tumour kinase.

BRK AND CELL DEATH

Brk's proliferative ability when coupled with its ability to protect cancerous cells from cell death promotes tumour cell survival. Brk has shown association with the P13-K/Akt pathway which is not only involved in cell proliferation but in apoptosis; thus activation of this pathway may reduce the ability of cells to undergo apoptosis^[56]. Furthermore, Brk can protect breast cancer cells from autophagy; reduced expression of Brk coupled with suspension of culture increased the number of dead cells compared to controls^[89]. Brk also increases phosphorylation of p38 MAPK which is associated with pro-survival cell phenotypes in breast cancer^[90]. Brk's ability to protect cancer cells from cell death is further enhanced due to its ability to protect cells from DNA damage-induced apoptosis in colon cancer cells. Knockdown of Brk in HCT116 cells led to increased apoptosis following γ -irradiation^[91]. In addition p53 was recognised as a possible positive regulator of Brk/PTK6 activity in response to DNA damage. Reduced expression of p21 and STAT3 were also noticed in Brk-suppressed cells, leading to increased apoptosis and decreased survival^[91]. This gives indication for PTK6 inhibitors reducing tumour cell growth and survival.

As discussed above, Brk also protected cells from anoikis *via* IGF-I signalling^[66]. Further to this, recently PTK6 was described to protect cells from anoikis *via* direct phosphorylation of focal adhesion kinase (FAK) and activating Akt^[92]. Knockdown of PTK6 in PC3 prostate cancer cell line disrupted FAK and Akt activation which in consequence promoted anoikis thus indicating important promotional role of Brk in anchorage independent survival.

Within a different cellular context such as non transformed rat fibroblasts, Brk has shown a role contradictory to that seen in breast cancer since it sensitises cells to apoptosis^[93]. Furthermore, it also promotes apoptosis in crypt epithelial cells in response to DNA damage^[94]. This may show a role for Brk as a damage sensor that promotes apoptosis in response to cellular stress. These differences in Brk's role may again depend on its cellular localisation, substrates and protein interaction as well as the tissue in which it is expressed^[74].

FUTURE PERSPECTIVES

Given that Brk's roles extend to regulation of several cancer hallmarks (Figure 2), Brk has promise as an ideal therapeutic target in breast cancer. Brk's therapeutic po-

tential could also extend to non-small cell lung cancer, prostate and colon cancer therapy^[70,91,95].

It was recognised as one of the tyrosine kinases expressed in breast cancer due to the immense interest in tyrosine kinase inhibitors^[23]. So far tyrosine kinase inhibitors have proven to be well tolerated with manageable side effects, selective and relatively effective in a range of cancers^[97]. PTK6-null mice have shown to grow relatively healthily into adulthood indicating potential tolerability to Brk inhibitors in breast cancer patients^[61]. These properties still make tyrosine kinase inhibition an attractive prospect despite Brk's kinase independent functions. Nonetheless, many of Brk's activities involve its kinase catalytic domain including EGFR signalling, cell migration and cell death^[13], thus targeting Brk's kinase activity may still prove to be effective. Furthermore, in comparison to HER2, EGFR, IGFR and p53 its expression is much higher in many types of breast cancer indicating targeting Brk may benefit a wider range of patients^[62].

Further study into the regulation of Brk may provide greater understanding in its therapeutic value. So far studies focusing on discovery of selective Brk inhibitors have shown effective inhibition with imidazo[1,2-a]pyrazin-8-amines^[98]. Recently, Brk's importance in anti-cancer therapy was uncovered in a study involving heat shock protein 90 (Hsp90) which has shown to regulate Brk since it is involved in folding and stability of many proteins^[99]. A potent Hsp90 inhibitor, geldanamycin decreased PTK6 expression in T47D and BT474 cell lines indicating the requirement of Brk's interaction with Hsp90 for stability. Further investigations in a clinical setting regarding these therapies may show their efficacy in treating subtypes of breast cancers including triple negative basal like breast cancer.

Brk has many substrates and protein interactions; some have been reported to require Brk's kinase domain whereas others may require protein-protein interactions and some through indirect association *via* a third party^[13]. Therefore, Brk kinase-independent activity does need consideration when looking at tyrosine kinase inhibitors. Interfering with Brk's protein-protein interactions by disrupting its conformational activation may also be therapeutically effective, including disruptions in the SH2 and SH3 domains^[62].

Additionally, ALT-PTK6 the short isoform of Brk may contribute towards its cellular localisation as increased ALT-PTK6 expression resulted in decreased Brk at the membrane and an increase in nuclear Brk^[70]. Normally Brk is active in differentiating, non-dividing epithelial cells in the small intestine where it is a negative regulator of growth, however, due to an external stimuli such as DNA damage by irradiation, it contributes towards apoptosis^[94]. This shows Brk's differing role within the same tissue but in different conditions. Thus Brk's functions may also depend on external stimuli and the short isoform ALT-PTK6. This needs further investigation and clarification within breast cancers.

Brk's role as a potential oncogene in relation to breast

cancer is further supported by a recent study, which indicated Brk catalytically phosphorylated c-Cbl, a E3 ubiquitin ligase that downregulates oncoproteins, resulting in c-Cbl degradation *via* auto-ubiquitination^[59]. Of the multiple signalling pathways that Brk is involved in, this is yet another pathway in which Brk plays a key role thereby enhancing tumour survival. Therefore Brk's involvement is extensive which suggests targeting Brk may allow targeting of a wider range of pathways that lead to tumour growth, survival and progression.

In the immediate future, most progress could probably be made in combination treatments. Brk's role in mediating cell responses to current EGFR/HER2 therapies is becoming known^[35,49]. Further work in this area could pave the way for improvement to these therapies. Investigations into Brk's role in tumour progression should allow for pre-clinical studies of breast cancer metastasis and determine whether any therapeutic intervention has potential clinical benefit.

CONCLUSION

Brk has been implicated in tumorigenesis, survival and progression as well as diagnosis and prognosis of breast cancer despite the fact there is no indication of expression of Brk in normal mammary tissue. Thus making it a viable target of breast cancer therapy and an interesting protein to investigate. Brk expression changes have not been associated with solely with an increase in *ptk6* gene copy number, which allows for study of alternative mechanisms by which Brk expression and breast cancer develops. Ongoing research may still reveal more associations of Brk with, as yet, uncharacterised substrates. A wider view of Brk's interacting proteins and substrates therefore will prove to be useful in developing anti-Brk therapies for breast cancers.

Abstract

Growing evidence suggests that breast cancer cell plasticity arises due to a partial reactivation of epithelial-mesenchymal transition (EMT) programs in order to give cells pluripotency, leading to a stemness-like phenotype. A complete EMT would be a dead end program that would render cells unable to fully metastasize to distant organs. Evoking the EMT-mesenchymal-to-epithelial transition (MET) cascade promotes successful colonization of distal target tissues. It is unlikely that direct reprogramming or trans-differentiation without passing through a pluripotent stage would be the

preferred mechanism during tumor progression. This review focuses on key EMT transcriptional regulators, EMT-transcription factors involved in EMT (TFs) and the miRNA pathway, which are deregulated in breast cancer, and discusses their implications in cancer cell plasticity. Cross-regulation between EMT-TFs and miRNAs, where miRNAs act as co-repressors or co-activators, appears to be a pivotal mechanism for breast cancer cells to acquire a stem cell-like state, which is implicated both in breast metastases and tumor recurrence. As a master regulator of miRNA biogenesis, the ribonuclease type III endonuclease Dicer plays a central role in EMT-TFs/miRNAs regulating networks. All these EMT-MET key regulators represent valuable new prognostic and predictive markers for breast cancer as well as promising new targets for drug-resistant breast cancers.

Key words: Embryonic transcription factors; Epithelial to mesenchymal transition; Breast cancer; MicroRNAs; Dicer; Feedback loop

Core tip: Epithelial-mesenchymal transition (EMT) and the reverse mesenchymal-epithelial transition (MET) are both involved in breast cancer plasticity. Embryonic transcription factors and miRNAs are key players regulating the balance between these two processes allowing cells that underwent EMT to transiently re-acquire epithelial phenotype. Here we highlighted the complex transcription factors/miRNAs regulation networks involved in EMT-MET during breast cancer progression and the central role played by Dicer, the key enzyme of miRNAs processing, in EMT process. These key regulators of EMT-MET may represent predictive markers and potential therapeutic targets for breast cancers.

EMT AND MET REPROGRAMMING DURING BREAST CANCER PROGRESSION

During embryonic development, a complex organism is formed from a single starting cell. Growth and differentiation are driven by large transcriptional changes, directed by the expression and activity of transcription factors (TFs). Cancer is often suggested to imperfectly resemble the development process by re-expressing certain embryonic TFs. Links between normal embryonic development and cancer biology have been postulated, but no defined genetic/epigenetic basis has been established. During normal development, cells divide, align themselves, and specialize to form discrete tissues and organs. For the body to develop properly, cells must coordinate their migratory patterns and the process by which they differentiate or evolve from less-specialized cells into more-specialized cell types. A lack of such coordination leads to disordered development and, in some cases, cancer.

The mammary gland is an organ that undergoes distinct and complex developmental stages after birth. Post-natally, mammary ducts elongate into the mammary fat pad. Terminal end buds, the highly proliferative structures found at the tips of the invading ducts, expand and increase greatly after birth. By puberty, the mammary ducts have invaded to the end of the mammary fat pad. At this point, the terminal end buds become less proliferative and decrease in size. Side branches form from the primary ducts and begin to fill the mammary fat pad. Ductal development decreases with the arrival of sexual maturity and undergoes estrous cycles. As a result of estrous cycling, the mammary gland undergoes dynamic changes where cells proliferate and then regress. During each estrus cycle, the density of ductal branches and alveolar buds increases. During pregnancy, the alveolar buds formed on the ductal tree give rise to large, lobulo-alveolar differentiated structures capable of milk production. Understanding how the mammary tissue develops and functions is of great importance in determining how its control mechanisms break down in breast cancer. The leucine-rich repeat containing G protein-coupled receptor 4 (*Lgr4*) has been implicated in mammary development and stem cell activity, with *Lgr4*^{-/-} mice showing delayed ductal development, fewer terminal end buds, and decreased side-branching mediated by the Wnt/ β -catenin/Lef1 pathway and Sox2^[1]. An article from the Breakthrough Breast Cancer Research Centre has recently compared an embryonic mammary epithelial signature with *Brca1*-deficient mouse mammary tumors and human breast cancer signatures. Specific subsets of embryonic mammary genes were found over-expressed both in mouse *Brca1*^{-/-} tumors and in human basal-like

cancers^[2]. Reactivation of a small network of embryonic mammary programs within differentiated tumor cells may elicit cell behavior associated with a stem-like, highly plastic state. The EMT-mesenchymal-to-epithelial transition (MET) cascade, although an intrinsic part of normal developmental processes during organogenesis, is also recognized as a critical event for metastasis of carcinomas^[3,4]. EMT allows tumor cells to de-differentiate and to acquire motility and invasive properties in order to spread into distant organs, and the MET program then reboots an epithelial program to establish new tumors at the sites of dissemination^[5]. It is not entirely known how and when EMT and MET programs, and the genes associated with these processes, are coordinated. The hallmark of EMT is the loss of adherent junctions through loss of E-cadherin (*CDH1*) expression. E-cadherin repressors fall into two groups, direct or indirect regulators, depending on whether or not they bind the *CDH1* promoter.

EMT INDUCERS

The powerful direct repressors of *CDH1*, playing a major role in EMT, originate from three distinct families: The Snail family comprises three members, Snai1, 2 and 3 (also termed Snail, Slug and Smuc), the Zeb family (*Zeb1/2*), which are zinc-finger transcription factors that recognize a consensus E-box type element, and the b-HLH family (*TWIST1/2*) which also bind to a consensus E-Box sequence, as homo- or heterodimers. These factors also repress the transcription of several other junctional proteins, including claudins and desmosomes. The other group of *CDH1* repressors (indirect regulators) comprises FoxC2, Goosecoid, TCF4, paired mesoderm homeobox protein 1 (*PRRX1*), and some Sox family members. FoxC2 is a winged helix/Forkhead domain transcription factor, which lies downstream of Twist, Snail and Goosecoid, and affects E-cadherin expression by promoting its cytoplasmic localization. They increase the invasiveness of epithelial cells (Table 1). The third member of the Snail family, (Smuc) does not play a major role during EMT, while Zeb1 is a strong motility driver. The Snail, Zeb and TWIST families operate within a complex regulatory network where they activate or repress each other. EMT inducers, such as EMT-TFs (*TWIST1*, Snail, Slug, and Zeb1), can also confer 'stemness' as demonstrated in several studies, where the induction of EMT enhances self-renewal and the acquisition of CSC (Cancer Stem Cell) characteristics^[6-8] (Table 1). In contrast, several studies show that tumor cells with an epithelial phenotype survive in the circulation and form distant metastases^[9-12]. It has been demonstrated that the mesenchymal phenotype does not facilitate metastatic progression; rather, most cancers invade and travel through lymphatic and blood vessels *via* cohesive epithelial migration, and do not undergo EMT-MET^[13]. Interestingly, Zvelebil *et al*^[2] showed that enrichment for the mammary mesenchymal gene signature (*TGF β 1*, *TWIST2*, *ZEB2*) was correlated with large tumor size, but no significant association with

Table 1 Involvement of epithelial-mesenchymal transition-transcription factors in breast carcinogenesis

EMT-TF	Transcription factor type	Deregulated in breast cancer	Association with biological and clinico-pathological features in breast cancer
SNAI1 (Snail)	Zinc finger	High levels ^[75]	Lymph node metastasis, effusion, distant metastasis, recurrence
SNAI2 (Slug)	Zinc finger	High levels ^[76]	Effusion, distant metastasis, recurrence, stemness capacities
TWIST1	Basic Helix-loop-Helix	Up-regulated ^[77]	Primary transformation, escape from failsafe programs, invasion, bone metastasis, angiogenesis, poor prognosis
ZEB1	Zinc finger E-box-binding homeobox 1	High levels ^[76,77]	Invasion, distant metastasis
ZEB2	Zinc finger E-box-binding homeobox 2	High levels ^[76,77]	Invasion, distant metastasis, stemness capacities
FoxC2	Forkhead-related protein FKHL14, FKHL-14, mesenchyme fork head protein 1	High levels ^[78]	Stemness capacities, distant metastasis
Oct3/4	Octamer-binding transcription factor 4, POU domain, class 5, transcription factor 1S homeodomain transcription factor of the POU family	Up-regulated ^[79]	Stemness capacities, invasion, migration
Sox2	Sex determining region Y-box 2 highly conserved DNA binding domains High-mobility group box domains	Up-regulated ^[80]	Tamoxifen-resistance, lymph node metastasis, stemness capacities
Prrx1	Paired related homeobox 1	High levels ^[15]	Metastasis, poor prognosis
TCF4	Basic Helix-loop-Helix immunoglobulin transcription factor 2	Up-regulated ^[81,82]	Metastasis, poorer prognosis in patients with high levels of osteopontin and better prognosis with low levels of osteopontin

EMT-TF: Epithelial-mesenchymal transition-transcription factors.

overall survival was observed in patients whose breast cancers showed activation of the embryonic mesenchymal signature. Four transcription factors (Bcl11a, Grhl3, Prox1, Sox11) activated in *Bra1*^{-/-} mouse tumors and basal-like human breast cancers were confirmed to be embryonic-enriched and highly expressed by some tumors. Increasingly, evidence points towards the transient involvement of an activated EMT program in the invasive front of tumors rather than in dissemination of cancer cells. The mesenchymal transcriptomic program is found associated with metaplastic breast carcinoma (MBC), a rare tumor with a carcinosarcoma-like aspect, with a larger tumor size, accounting for < 1% of all breast cancers. Histologic subtypes identified were chondroid (24%), spindle (20%), sarcomatoid (16%), squamous (11%) and mixed (29%), with the origin of the "mixed" subtype hypothesized to be from the "differentiation" of immature breast glandular epithelial cells into non-glandular mesenchymal tissue. In prostate cancer cell lines, subpopulations with a strong epithelial gene program were enriched in highly metastatic tumor-initiating cells (TICs), whereas mesenchymal subpopulations showed reduced TIC^[12]. Are epithelial cancer cells expressing EMT-TFs without experiencing a full EMT program the most prominent to metastasize? The answer is no for some factors, as it was recently shown that TWIST1 down-regulation and a subsequent re-differentiation (MET) at the distant site is necessary to allow colonization and macrometastasis^[14]. Intriguingly, the EMT-inducer Prrx1 suppresses stemness traits^[15] and a knockdown of Prrx1 and TWIST1 increased lung metastasis after tail vein injection.

The question of whether the MET is stable in the metastases or if these cells show ongoing phenotypic plasticity leading to a second EMT is also an open question. Collectively, these results illustrate the plasticity governing self-renewal and mesenchymal gene interactions

(Figure 1).

INVOLVEMENT OF DICER IN EMT

Genes central to gene regulatory networks (GRNs) may have a huge impact on cell plasticity. The ribonuclease type III endonuclease Dicer, involved in the RNA interference process, belongs to this gene category. RNA interference (RNAi) and microRNA (miRNA) pathways are conserved, post-transcriptional gene silencing mechanisms in which single-stranded guide RNAs bind to cognate mRNAs and direct their endonucleolytic cleavage or translational repression by RNA-induced silencing complexes (RISCs). An important function of Dicer is to process miRNA precursors into approximately 22-nucleotide non-coding small RNAs. As a master regulator of miRNA biogenesis, Dicer is involved in EMT, cancer cell plasticity and tumor progression. We have found that Dicer mRNA expression was variable in breast carcinoma samples and that lower levels were more frequent in patients with metastatic relapse, indicating that Dicer mRNA levels are clinically relevant as reported by Grelier *et al*^[16]. In accordance with other studies, we have found a global decrease of miRNA expression in correlation with the decrease of Dicer expression^[17]. Levels of Dicer are tightly controlled to maintain the homeostasis of miRNA production, largely at the post-transcriptional level. Dicer is a highly conserved protein that is found in almost all eukaryotic organisms. Some organisms contain multiple *Dicer* homologues, whereby different Dicer isoforms have distinct roles, for instance *D. melanogaster* Dicer-1 is required for miRNA biogenesis, whereas Dicer-2 functions in siRNA production. Contrary to other organisms, mammals have a single *Dicer* gene, but its expression is a highly regulated process with spliced Dicer mRNAs putatively encoding both spliced and full-length pro-

Figure 1 Epithelial to mesenchymal transition and mesenchymal to epithelial transition during breast tumor progression. During tumor progression, cancer cells undergo apithelial to mesenchymal transition (EMT) to acquire invasive, dissemination, chemoresistance and stem cell properties. Thus, an *in situ* carcinoma progresses to an invasive carcinoma and cells disseminate throughout the entire body via the blood and the lymphatic vessels. After dissemination, cells must undergo an mesenchymal to epithelial transition (MET) to colonize distant organs.

teins. In humans, there are 3 full-length isoforms showing considerable differences in their 3'UTR sequence. Only two variants exhibit a long 3'UTR sequence, while the third variant exhibits a very short 3'UTR lacking all predicted miRNA target sites^[18,19]. Moreover, we identified two splice variants which were highly expressed in some breast cancer cell lines, yet totally absent in others. Theoretically, these isoforms may be functional as they both contain the ribonuclease III domain and the dsRNA binding domain, while one isoform contains only a PAZ domain^[18]. We have shown that the full-length Dicer protein decreased during the EMT process^[16]. The presence of spliced forms was correlated with epithelial/mesenchymal phenotype. Indeed, in almost all cell lines that exhibit a complete or partial mesenchymal phenotype, these truncated isoforms were not detectable by western blot as shown by Hinkal *et al.*^[18]. Conversely, epithelial cells expressed easily-detectable levels of the two variants. Furthermore, we have found decreased expression of these variants during EMT using immortalized human epithelial mammary cells transfected by RAS. These data imply an integral role for internal site miRNA regulation of Dicer isoforms, but the physiological relevance of these data remains to be clarified. Thomas Duchaine's group has shown the presence of a truncated form of Dicer in *C. elegans*, corresponding to a C-terminal fragment (sDCR-1). They demonstrated that sDCR-1 operates independently of full-length Dicer in two distinct RNAi pathways; it enhances exogenous RNAi (exoR-

NAi) and concurrently acts as a negative regulator of microRNA (miRNA) biogenesis^[20]. Interestingly, one of the spliced form variants we identified in epithelial breast cancer cell lines encodes a protein sharing the same domains as sDCR-1. By ectopically expressing this isoform in HEK293T cells, they have found that, similar to the function of sDCR-1, there was a decrease in accumulation of mature-to-precursor forms for some miRNA but not all, showing that this function is miRNA-specific^[20]. Deciphering the role of the highly conserved Dicer variants is of great importance since Dicer acts as a tumor suppressor in specific cancers^[16,21,22]. As a miRNA target, full-length Dicer was also shown to be directly repressed by miR-103/107 and this repression enhanced breast cancer metastasis^[23], whereas transcriptional induction of Dicer by Tap63 suppressed metastasis^[24].

The nearly global decrease in miRNAs observed across a range of human tumors suggests that Dicer loss could be necessary for tumor progression. To better understand how cancer cells respond to loss of miRNA expression, Philip Sharp and collaborators^[25] have characterized the effects of homozygous deletions of *Dicer1*-conditional alleles on the tumorigenicity of murine sarcoma cells and on the cellular phenotype of immortalized murine mesenchymal stem cells (MSCs). *Dicer1*^{-/-} cells survived and proliferated without recovery of miRNA processing. Interestingly, their two models are mesenchymal, corroborating our results that show a repression of Dicer during the EMT process. Inactivation of p53,

a common feature in both the sarcoma and MSC models, may facilitate, or be indispensable for, viability in the absence of Dicer. p53 loss was shown to allow primary MEFs to bypass an immediate senescence phenotype induced by *Dicer1* loss^[26].

miRNAS AND BREAST CANCER PLASTICITY

As a consequence of Dicer loss, tumors of epithelial origin should express more miRNAs than mesenchymal tumors. If we compare development and cancer progression, a parallel can be drawn between miRNA biogenesis during embryogenesis with repression of miRNAs synthesis in stem cells, and global miRNA loss during acquisition of cancer cell stemness. In embryonic zebrafish development, most miRNAs were expressed in a highly tissue-specific manner during segmentation and later stages, but not early in development. This suggests that they do not play a role in tissue fate establishment, but rather in differentiation or maintenance of tissue identity^[27]. The link between deregulated miRNA expression and cancer has been well established, with miRNA profiling studies revealing distinct expression profiles in various cancers that could help in the diagnosis of these malignancies^[28-30]. Only a small subset of specific oncogenic miRNAs has been found to be upregulated in cancer.

Different miRNA signatures have been identified in the different breast cancer subtypes. Do these signatures reflect cell lineage of origin? miRNAs have been implicated in the development of murine mammary gland, which showed seven distinct temporal clusters during mammaryogenesis^[10,31]. Among them, miRNAs clusters over-expressed during puberty and gestation in normal tissue of mammary gland, for example the miR-17-92 cluster, have been shown to play a crucial role in breast cell proliferation and have also been found in aggressive cancers, such as the basal-like subtype^[32]. As it has been found for other types of cancer, miR-21 appeared to predominantly act as an oncogene and its expression is inversely correlated with the tumor suppressor PTEN (Phosphatase and TENSin homolog) expression^[33]. Another potent miRNA oncogene, miR-191 was positively regulated by estrogen and was shown to promote proliferation and invasion^[34]. miR-155 was also categorized as an oncomiR, as it was implicated in TGF- β -induced EMT, cell migration and invasion. Let-7 was the diametric opposite of miR-21, acting as a general tumor suppressor, and was found down-regulated in breast cancers. Let-7 has been described as a regulator of self-renewal and a pro-differentiation miRNA of breast cancer cells repressed by the Wnt- β -catenin pathway^[35], targeting oncogenes including RAS, HMGA2 and MYC. miR-21, miR-155 and let-7 are involved early in tumorigenesis and were found deregulated in benign breast tumors^[36]. In contrast to miR-191, miR-206 was negatively regulated by estrogens and decreased miR-206 levels are associated with breast cancer of advanced clinical stage and shorter overall survival. Different studies

have profiled the expression of miRNAs as a function of intrinsic breast cancer subtype. A clear miRNAs signature was identified in luminal breast cancer, with over-expression of miR-191 and miR-26 and down-regulation of miR-206. Interestingly, based on miRNAs signatures, the tumors can be easily classified as luminal A, luminal B, normal-like, HER²⁺ and basal-like^[32].

EMT-TFs signatures were more often found in Triple Negative Breast cancer (TNBC), a very aggressive cancer subtype representing, however, a very heterogeneous group of breast cancers with the only common phenotype being ER-, PR- and HER2-negative. Further transcriptomic studies allowed the sub-classification of TNBC by identifying additional entities such as the Claudin-low subtype, characterized by low expression of claudin proteins, proliferation genes and luminal markers, and high expression of EMT markers and CSC-like features^[37]. Interestingly, as previously mentioned for epithelial-mesenchymal dichotomy of miRNA expression, the highly undifferentiated nature of TNBC is correlated with a global down-regulation of microRNAs^[38]. However some miRNA are readily expressed in stem cells, such as the miR-302 cluster, "stemness miRNA cluster," in ES cells which decreases upon cell differentiation, and is undetectable in somatic cells. An Oct4/Sox2-miR-302-cyclin D1 regulatory network governing ES cell pluripotency and self-renewal properties has been proposed^[39]. miR-302 over-expression converts cancer cells into ES-like pluripotent stem cells associated with high expression of Oct3/4, SSEA-3, SSEA-4, Sox2, and Nanog^[40]. The group of Carlos Caldas also identified miR-301a as a hub of pluripotency in breast cancers, and demonstrated that mRNA relationships altered in miR-301a high/low tumors showed a link between immune and EMT pathways, illustrated by the immunoglobulin superfamily member ALCAM, the EMT-TF ZEB2 and Claudin-3. miR-301a directly targeted and suppressed the tumor suppressor PTEN, one negative regulator of the Wnt/ β -catenin signaling cascade, which promotes breast cancer invasion and metastasis. In the Claudin-low subtype, while the global decreased miRNAs expression can be assigned to a repression of Dicer expression, the down-regulation of miRNAs targeting transcription factors implicated in EMT and cancer stem cells may result from a transcriptional repression of their promoters. The miRNAs targets can directly drive this repression (Figure 2).

FEEDBACK LOOPS INVOLVING miRNAS DURING EMT-MET

EMT is driven both by transcriptional and post-transcriptional changes. Because of the reversible nature of EMT, miRNAs functioning as co-repressors or co-activators are key players in this plasticity, specifically involved in regulation networks with EMT-TFs. miRNAs are categorized as either EMT-inducers or EMT-repressors, inversely involved in MET.

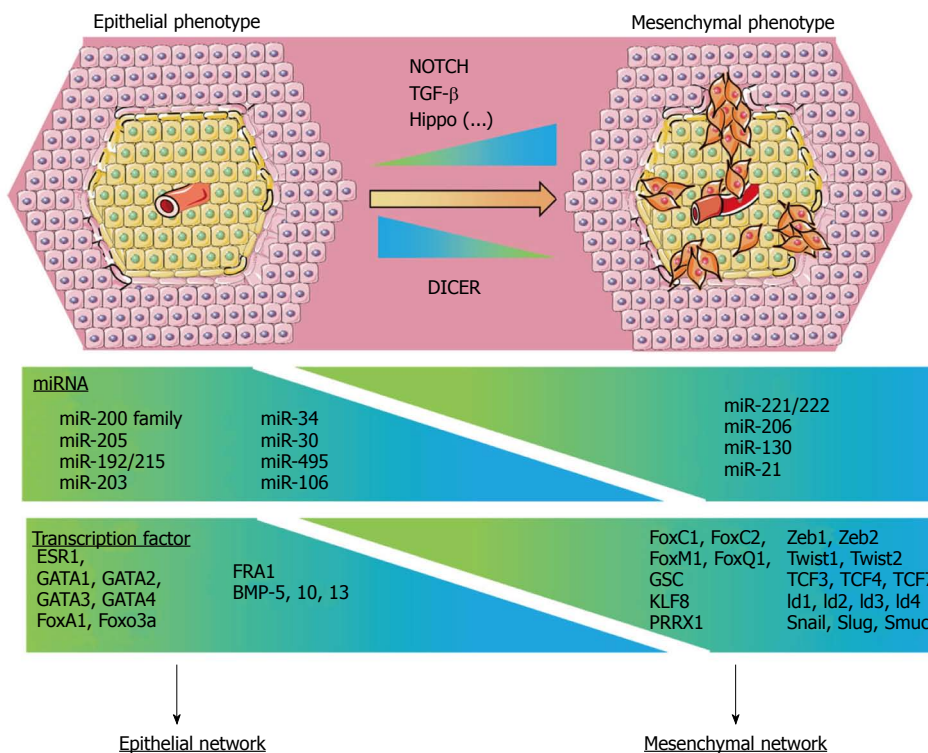

Figure 2 Transcription factors and miRNA epithelial and mesenchymal expression networks in breast cancer. Through activation of different signaling pathways such as TGF- β , Notch or Hippo pathways and the down-regulation of Dicer, epithelial cells undergo the epithelial to mesenchymal transition. Transcription factors and miRNAs act together to be the "plastic surgeons" of the epithelial or mesenchymal phenotype. Regulation networks between these two main actors drive cells to plasticity.

miRNAs with EMT inducer activities

The well-known oncomiR miR-21 was identified as an EMT-inducer, similarly to miR-103/107 which represses Dicer and PTEN expression during breast tumor initiation. PTEN is a major miR-21 target that negatively regulates EMT and CSC phenotypes. miR-10b was also identified as a positive regulator of EMT as it was demonstrated to be a positive effector of TWIST. It was shown to induce migration and invasion capacities in breast cancer cells *via* the direct targeting of the HOXD10 transcript. HOXD10 is a known repressor of genes involved in cell migration and extracellular matrix remodeling, including RHOC, α 3 integrin, matrix metalloproteinase-14 and urokinase-type plasminogen activator receptor^[41].

The oncomiR miR-206 expressed in aggressive breast tumors is involved in a double-negative feedback loop with ER α and participates in EGFR-mediated abrogation of estrogenic responses in MCF-7 cells, thus contributing to a Luminal-A- to Basal-like phenotypic switch^[42]. ER α is also involved in a simple negative feedback with the miR-18a (17-92 cluster), where ER α induced the expression of the miR-17-92 which in turn targets ER α with miR-18a. miR-17-92, an miRNA polycistron also known as oncomir-1, is among the most potent oncogenic miRNAs. Genomic amplification and elevated expression of miR-17-92 was found in several types of tumor, including mammary. miR-17-92 carries out pleiotropic functions during both normal development and malig-

nant transformation, as it acts to promote proliferation, inhibit differentiation, increase angiogenesis, and sustain cell survival^[43]. ER α functions in a forward positive feedback loop with miR-375. Inhibiting miR-375 in ER α -positive MCF-7 cells resulted in reduced ER α activation and cell proliferation. Researchers have identified RASD1 (Dexamethasone-induced Ras-related protein 1), a small G protein of the Ras family, as a potential miR-375 target. Mechanistic investigations revealed that miR-375 regulates RASD1 by targeting the RASD1 3'UTR and RASD1 negatively regulates ER α expression^[44]. miR-206, which contributes to a Luminal-A- to Basal-like switch, targets KLF4 (Kruppel-like factor 4) a pivotal transcription factor that is associated with both tumor suppression and oncogenesis. In untransformed cells, KLF4 likely acts as a potent inhibitor of proliferation. Conversely, in transformed cells, KLF4 suppresses the expression of p53 by directly acting on its promoter; consistently, KLF4 depletion from breast cancer cells restores p53 levels and causes p53-dependent apoptosis^[45]. To further complicate the function of KLF4, it was shown that a co-operative binding of KLF4 and p53 to the DNA binding sites of some p53 targets, contributes to p53 target selectivity^[46]. miR-206 levels were KLF4-dependent in breast cancer cells, and a KLF4-miR-206 feedback pathway was identified that negatively regulates protein translation in normal cells and cancer cells^[47]. Very recently, KLF4 was evoked in a feedback loop involving p21. The tumor suppressor p21 has been shown to regulate gene expression by func-

tioning as a transcription co-repressor. Li and collaborators^[48], have identified p21-regulated miRNAs, among them, the miR-200 family and the miR-183-96-182 cluster, that were down-regulated in p21-deficient cells.

miRNAs with EMT repressor activities

miR-200 family members were identified as the guardians of the epithelial phenotype in many types of cancers, including breast cancers^[49-51]. The miR-200 family activates the Sec23a-mediated tumor cell secretome which leads to secretion of metastasis-suppressive proteins. Predictably, loss of miRNA-200a is frequently observed in breast cancers, especially tumors with high-grade histology, but this loss does not predict tumor recurrence or patient survival^[52]. miR-200 family members (miR-200a, miR-200b, miR-200c, miR-141 and miR-429) encoded from two clusters, directly target the mRNAs of the E-cadherin transcriptional repressors ZEB1 and ZEB2. Interestingly, Thomas Brabletz' group and others^[50,53] have shown that both promoter regions are repressed in mesenchymal cells by ZEB1 and ZEB2 through their binding to a conserved pair of ZEB-type E-box elements, located proximal to the transcription start site. These findings establish a double-negative feedback loop controlling ZEB1-ZEB2 and miR-200 family expression. During EMT induced by TGF- β , miR200s are inhibited mainly by ZEB1^[50]. The induction and maintenance of a stable mesenchymal phenotype requires the establishment of autocrine transforming growth factor- β (TGF- β) signaling to drive sustained ZEB expression. Prolonged autocrine TGF- β signaling induced reversible DNA methylation of the miR-200 loci, demonstrating the existence of an autocrine TGF- β /ZEB/miR-200 signaling network that regulates cancer cell plasticity^[54]. But the activity of this miRNA family is a doubled edged sword during cancer progression, as it has been shown to promote MET through E-cadherin up-regulation, allowing migrating cancer cells to colonize distant tissues. Intriguing, the role of the miR-200 family during metastatic colonization can be partly elucidated by the oncogene c-Myb, which was shown to activate the expression of all five members of the miR-200 family. The transcriptional activation of miR-200 by c-Myb occurs through binding to myb binding sites located in the promoter regions of miR-200 genes on human chromosomes 1 and 12. Furthermore, when c-Myb and the transcriptional repressor ZEB1 are co-expressed, such as at the onset of EMT, the repression by ZEB1 prevails over the activation by c-Myb, and miR-200s are repressed. Researchers have also shown a positive correlation between the expression of c-Myb and miR-200 members in a dataset of breast cancer patients^[55].

Interestingly, another EMT-TF, Slug (SNAI2, Snail2) is transcriptionally regulated by c-Myb and induces vimentin, fibronectin, and N-cadherin expression and membrane ruffling *via* actin polymerization, consistent with the acquisition of partial but not complete mesenchymal-like phenotype^[56]. Both expression of c-myb

and miR-200 members lead to simultaneous expression of vimentin, N and E-cadherin. These data support the concept that, during distinct phases of tumor progression, the role of the genes involved in the EMT process may change in relation to the expression of other regulators and to epigenetic changes. Are both mesenchymal and epithelial traits required for metastatic progression at distant sites? The complex relationship between miR-200 and ZEB during tumor progression was also investigated in a xenograft orthotopic model of breast cancer metastasis, where ectopic expression of members of the miR-200b/200c/429, but not the miR-141/200a, limits tumor cell invasion and metastasis. Despite modulation of the ZEB1-E-cadherin axis, restoration of ZEB1 in miR-200b-expressing cells was not sufficient to alter metastatic potential, suggesting that other targets contribute to this process^[48].

Other feedback loops between EMT-TFs and miRNAs were identified during breast tumor progression. miR-183 and miR-96 repressed common targets, including Slug, ZEB1, and KLF4. Re-introduction of miR-200, miR-183 or miR-96 into p21-/- cells inhibited EMT, cell migration and invasion. p21 forms a complex with ZEB1 at the miR-183-96-182 cluster promoter to inhibit transcriptional repression of this cluster by ZEB1, suggesting a reciprocal feedback loop. ZEB1 and ZEB2 are also involved in a negative feedback loop with miR-205 through the E-box motifs present in the miR-205 promoter sequences^[57]. During Snail-induced EMT in MCF7 breast cancer cells, miR-203 and miR-200 family members were repressed in a correlated manner. Importantly, miR-203 repressed endogenous Snail, forming a double negative miR-203/Snail feedback loop^[58]. miR-203 is also able to target Slug (SNAI2). In parallel with the TGF- β /ZEB/miR-200 negative loop, TGF- β induced Slug to promote EMT by repressing the miR-203 promoter to inhibit its transcription. SNAI2 and miR-203 thus form a double negative feedback loop. It was found that miR-203 was significantly down-regulated in highly metastatic breast cancer cells, and the restoration of miR-203 in these cells inhibited tumor cell invasion *in vitro* and lung metastatic colonization *in vivo* by repressing Slug^[59].

The miR-34 family is one of the most studied tumor suppressor miRNAs and comprises miR-34a, miR-34b and miR-34c. miR-34 is implicated in the inhibition of EMT mediated by p53. It was reported that activation of p53 down-regulates the EMT-inducing transcription factor Snail *via* induction of the miR-34a/b/c genes. Suppression of miR-34a/b/c caused up-regulation of Snail and EMT markers, and enhanced migration and invasion. Ectopic miR-34a induced MET and down-regulation of Snail. miR-34a also down-regulated Slug and ZEB1, as well as the stemness factors BMI1, CD44, CD133, OLFM4 and c-MYC. Conversely, the transcription factors Snail and ZEB1 bind to E-boxes in the miR-34a/b/c promoters, thereby repressing miR-34a/b/c expression. miR-34a prevents TGF- β -induced EMT, and the repression of miR-34 genes by Snail and related factors is part

of the EMT program^[60]. miR-34 and SNAIL represent a double-negative feedback loop controlling cellular plasticity, governed by p53.

Transcription factors/miRNAs regulating networks

What are the targets of miRNAs during EMT/MET and what is the mode of TF-miRNA co-operation during pluripotency reprogramming? Sass *et al.*^[61] demonstrated that miRNAs which target the same protein complexes are frequently co-expressed. They experimentally verified that the miR141-200c cluster simultaneously targets several protein components of the CtBP (C-Term binding proteins)/ZEB complex (CtBP are conserved transcriptional co-repressors), implying an efficient regulation of a protein complex by a cluster of miRNAs. There is also evidence of functional redundancy among miRNAs resulting, in part, from miRNAs existing in large families sharing common seed sequences that can be co-expressed in the same cell. Redundancy also occurs at the level of co-targeting, where multiple distinct miRNAs with different sequences commonly target a single transcript through non-overlapping sites^[62]. The miRNA-regulated protein complexes are mainly involved in regulation of transcription and chromatin modification. Conversely, house-keeping functions, such as translational elongation, are under-represented, meaning that miRNAs are "regulators of regulators"^[61].

An important goal is to elucidate how complex TFs/miRNAs networks evolve in cancer. TFs and miRNAs are the two largest families of trans-acting, gene regulatory molecules in multicellular organisms, and they share a common regulatory logic. TFs generally do not work in isolation, but instead, together with co-regulators, they form large networks of co-operating and interacting transcription factors. The term "motif" was used to describe a small group that illustrates the regulation patterns of an miRNA, a TF, and their target genes. Common motifs, such as feedforward loops (FFLs) and feedback loops (FBLs) have been found to play crucial roles in cancer, such as the miR-17 cluster, E2F1, and c-Myc that modulate cellular proliferation^[63]. However, the miRNA-TF synergistic effect may not be limited only to the FFLs or FBLs. Non-loop forms, such as the cascaded form, which have helped in understanding the regulatory mechanism, are also candidates^[48]. miRNAs can also antagonize the function of other miRNAs, for example, miR-22 can suppress the expression of miR-200 *via* direct targeting of chromatin remodeling enzymes such as TET family members, which leads to the hypermethylation of the miR-200 promoter^[64].

How can we decipher miRNA-regulating networks composed of proteins with opposite functions? For example, let-7 acts as a protective miRNA that inhibits RAS and transcriptional factors thus leading to cell commitment during development, but paradoxically Dicer, the master regulator of miRNA maturation is a hub for let-7 targeting. A recent finding may help us to understand this paradox; ZEB2 transcript was shown to function as

a competitive endogenous RNA (ceRNA) for PTEN miRNAs. ZEB2 loss during MET can lead to repression of PTEN^[65] and this regulation, that may appear counter-intuitive at first glance, may explain how MET could be intricately linked to stemness acquisition (Figure 3).

EMT, miRNAS AND CHEMORESISTANCE

Chemotherapeutics and radiotherapy effectively reduce tumor bulk but have little effect on cancer stem cells (CSC) that stimulate tumor recurrence, emphasizing the importance of identifying CSC-specific pathways that may be exploited to selectively target these resistant cells. Induction of EMT can activate some CSC state-specific signaling transcriptomic networks and the therapeutic resistance associated with CSCs. It was shown that EMT could be induced by chemotherapeutic agents and patients receiving neo-adjuvant therapy were more likely to express EMT-TFs in their circulating tumor cells (CTCs)^[66]. Adriamycin treatment has been seen to induce EMT in a Twist-dependent manner in breast cancer cells. Additionally, irradiation, a common treatment modality in breast cancer, can increase EMT and CSC characteristics^[67]. Tam and colleagues^[68] found that EMT stimulated a switch between two main kinase pathways, through the protein kinase C α (PKC α). PKC α was activated following EMT by a shift from EGF receptor (EGFR) signaling, which predominated in non-CSCs, to autocrine platelet-derived growth factor receptor (PDGFR) signaling in mesenchymal stem-like cells and basal breast cancer cell lines. Up-regulation of PKC α resulted in induction of the transcription factor FRA1 (FOS-like antigen 1), which was required for CSC viability and FRA1 expression was directly induced by the EMT transcription factors TWIST and Snail in triple-negative breast cancer (TNBC).

The mechanism of action of miRNAs in drug-induced EMT remains mainly unknown. miR-21 up-regulation has been associated with taxol resistance in breast cancer cells^[69] and suppression of the oncogenic miR-21 sensitizes cancer cells to chemotherapy. Results by Li and collaborators^[70] reported that miR-448 is the most strongly down-regulated miRNA following chemotherapy. Suppression of miR-448 correlated with EMT induction in breast cancer *in vitro* and *in vivo*. miR-448 suppression induces increasing epidermal growth factor receptor (EGFR)-mediated TWIST1 expression, as well as nuclear factor κ B (NF- κ B) activation. The authors have also demonstrated that the adriamycin-activated NF- κ B directly binds the miR-448 promoter, suppressing its expression, suggesting a positive feedback loop between NF- κ B and miR-448. It was shown that the loss of miRNA-200c correlated with the acquired resistance of breast cancer cells to adriamycin^[71]. In breast CSC, the Wnt- β -catenin pathway suppresses mature let-7 miRNAs by up-regulating Lin28, a negative let-7 biogenesis regulator. Loss of function of Lin28 impairs Wnt- β -catenin-pathway-mediated let-7 inhibition and breast cancer stem

Figure 3 Feedback and feedforward loops existing between transcription factors and miRNA during breast cancer progression. Epithelial and mesenchymal regulators modulate their own expression creating regulatory feedback and feedforward loops.

cell expansion; enforced expression of let-7 blocks the Wnt- β -catenin pathway-stimulated breast CSC phenotype. Another study has shown that Lin28 expression was dramatically increased in tumor tissues after neoadjuvant chemotherapy, in local relapse and in metastatic breast cancer tissues^[72].

CONCLUSION

Due to their implication in tumor development and metastasis, miRNAs represent potential therapeutics tools. Several studies either inhibiting or re-introducing miRNAs involved in EMT and CSCs regulation, are currently ongoing. Cai *et al.*^[35] have delivered a let-7a agomir into the pre-malignant mammary tissues of MMTV-wnt-1 mice and shown that it resulted in a complete rescue of the stem cell phenotype driven by the Wnt- β -catenin pathway. An interesting approach to neutralize miRNAs is to saturate them with target mRNAs. These artificial targets are called "miRNA sponges", expressing an mRNA containing multiple tandem binding sites for an endogenous miRNA and thus prevent the association of the miRNA with its endogenous targets^[73]. We can hypothesize that introducing a ZEB2 miRNA sponge transcript in metastatic breast cancer cells may lead to a de-repression of PTEN transcripts.

In order to better evaluate the TFs--miRNAs regulatory relationships during mammary cancer progression, the next step is to identify specific combinations of epithelial and mesenchymal TFs--miRNAs networks co-existing in metastatic and stem-like cells in breast cancers. It is crucial to discriminate between the aberrant

dynamics of epithelial-mesenchymal transitions during tumorigenesis and normal programs of embryonic development and wound healing. Interestingly, a synthetic analysis has shown that a core regulatory unit composed of two highly interconnected modules, the miR-34/SNAIL and the miR-200/ZEB double negative feedback loops, participate in the regulation of stemness, genome stability, cell-cell communication, and cellular motility. The authors have shown that the miR-200/ZEB loop exhibits tristability (the existence of three distinct stable states: epithelial, hybrid and mesenchymal) and that the miR-34/Snail circuit exhibits monostability (existence of a single stable state)^[74]. Regarding breast tumorigenesis, the miR-200/ZEB circuit is likely involved in cell plasticity and the miR-34/Snail in the stabilization of metastatic phenotype.

Manipulation of the EMT-TF-miRNAs feedforward and/or feedback loops may provide new therapeutic targets for breast cancers.

Abstract

The control of the half-life of mRNA plays a central role in normal development and in disease progression. Several pathological conditions, such as breast cancer, correlate with deregulation of the half-life of mRNA encoding growth factors, oncogenes, cell cycle regulators and inflammatory cytokines that participate in cancer. Substantial stability means that a mRNA will be available for translation for a longer time, resulting in high levels of protein gene products, which may lead to prolonged responses that subsequently result in over-production of cellular mediators that participate in cancer. The stability of these mRNA is regulated at the 3'UTR level by different mechanisms involving mRNA binding proteins, micro-RNA, long non-coding RNA and alternative polyadenylation. All these events are tightly interconnected to each other and lead to steady state levels of target mRNAs. Compelling evidence also suggests that both mRNA binding proteins and regulatory RNAs

which participate to mRNA half-life regulation may be useful prognostic markers in breast cancers, pointing to a potential therapeutic approach to treatment of patients with these tumors. In this review, we summarize the main mechanisms involved in the regulation of mRNA decay and discuss the possibility of its implication in breast cancer aggressiveness and the efficacy of targeted therapy.

Key words: mRNA stability; Breast cancer; RNA binding proteins; MicroRNA; Alternative polyadenylation

Core tip: This review article is dedicated to the understanding of the mechanisms involved in the regulation of mRNA half-life. mRNA relative stability is an important way to rapidly increase or decrease the level of a given gene. This process is a much more rapid mechanism compare to transcriptional regulation. Since many genes implicated in cancerous processes are regulated at the level of their half-life, the proteins and/or small non coding RNA implicated in this regulation may serve as relevant prognosis markers or predictive markers of the efficacy of chemotherapeutic agents.

GENERAL INTRODUCTION TO mRNA STABILITY

In the last few decades, our knowledge of the complexity of the regulation of gene expression in eukaryotes has expanded considerably. Control of regulation is exerted through several mechanisms that take place in

the nucleus or in the cytoplasm. In the past, the majority of studies focused on transcription, but modulation of post-transcriptional events has gaining a lot of interest and represents a rapid and plastic way of regulating gene expression. In particular, regulation of mRNA stability determines the spatial and temporal expression of many genes and plays a fundamental role in determining the outcome of gene expression^[1,2].

Most mRNA regulatory elements involved in this process are situated within the 5' and 3'untranslated regions (UTRs), where they act as platforms for the assembly of protein complexes and other regulatory factors. Whereas the 5'UTR is primarily involved in controlling mRNA translation^[3], the 3'UTR regulates multiple aspects of mRNA metabolism, including nuclear export, cytoplasmic localization, translational efficiency and mRNA stability^[4].

Tight regulation of mRNA stability is essential for cells to perform their normal functions. Substantial stability means that a mRNA will be available for translation for a longer time, resulting in high levels of protein gene products. The lengths and structures of the 3'UTR vary substantially and more than half of the mammalian genes produced by alternative splicing and alternative polyadenylation (APA) multiple the number of mRNA isoforms that differ in their 3' UTRs and therefore in regulatory sequences within their 3' UTRs^[5-7].

Modulation of the mRNA half-life plays a central role in inflammatory diseases and various cancers^[8-17]. Aberrant stabilization of mRNAs may lead to prolonged responses that subsequently result in undesirable states, including over-production of growth factors, oncogenes and other mediators that participate in cancer. The steady state levels of mRNA-binding proteins and regulatory RNAs are often associated with invasion and aggressiveness^[18,19].

We are only beginning to define the mechanisms coordinating the mRNA half-life and to understand its involvement in tumorigenesis. The fate of a transcript is determined by the complex interplay of *cis*-acting sequences within the 3'UTR of the mRNA and *trans*-acting factors, such as RNA binding proteins (RBPs) and regulatory RNAs (microRNA (miRNA) and long non coding RNA (lncRNA)) that bind directly or indirectly to the *cis*-acting elements and promote the deadenylation and degradation of the mRNA.

In this review we will discuss the role played by all these factors on mRNA stability, focusing on breast cancer and the recent advances made in evaluating cancer aggressiveness and the efficacy of targeted therapy. We will focus on the effect of these key factors on only the mRNA half-life and not on the efficiency of protein translation (for more comprehensive studies see^[20-22]). We will also briefly discuss new topics such as shortening of 3' UTR by alternative polyadenylation.

A BRIEF OVERVIEW OF THE MECHANISMS INVOLVED IN THE REGULATION OF THE mRNA HALF-LIFE

The stability of common RNAs is regulated by a variety of signals acting on specific sequences within the RNA, which are recognized by *trans*-acting factors such as mRNA binding proteins, miRNA and lncRNA. All these factors are post-transcriptional gene regulators that bind mRNA and can regulate both mRNA stability and translation.

AU-rich sequences and mRNA binding proteins

The most conspicuous among the different *cis*-acting destabilizing elements identified so far are the AU-rich elements (AREs), located in the 3'UTR of a variety of short-lived mRNAs such as those for cytokines and proto-oncogenes^[23,24]. Estimated to represent approximately 7% of all transcripts, ARE-mRNAs (see public database at: <http://rna.tbi.univie.ac.at/AREsite>) encode a functionally diverse group of proteins involved in the inflammatory and immune response, transcription, cell proliferation, RNA metabolism, development, and signaling^[25,26]. This functional enrichment of ARE-genes correlates with the observed rapid patterns of mRNA decay, particularly of those involved in transcription and signaling^[27]. These elements are recognized by *trans*-acting factors, such as mRNA-binding proteins that bind directly or indirectly to the *cis*-acting elements and promote the deadenylation and degradation of the mRNA. These proteins may have opposite effects on mRNA stability. Some of them, such as AU-rich element RNA-binding protein 1 (AUF1), tristetraprolin (TTP) and KH-type splicing regulatory protein (KSRP), promote mRNA degradation, while others such as embryonic lethal abnormal vision (ELAV)-like protein 1 (HuR) and polyadenylate-binding protein-interacting protein 2 (PAIP2) act as mRNA stabilizing proteins^[10,28,29].

Briefly, AUF1 binds with high affinity to RNA that contain ARE sequences such as *MYC*, *FOS* and *GM-CSF* mRNAs. In contrast, it does not bind with high affinity to RNA sequences that lack a ARE^[30]. Over-expression of AUF1 correlates with rapid degradation of ARE-containing mRNAs^[31-33].

TTP (also named *ZFP36*) is characterized by two tandem repeat zinc finger motifs through which it binds to AREs and mediates mRNA decay^[34,35]. Some of the well-established targets of TTP include TNF alpha mRNA^[36], granulocyte/macrophage colony-stimulating factor (GM-CSF)^[37], cyclooxygenase 2^[38], vascular endothelial growth factor (VEGF)^[39], interleukin-1^[40], interleukin-8^[41,42] and the hypoxia-inducible factor-1 (HIF-1)^[43]. HuR is a member of the ELAV family of proteins found in mammalian cells. HuR selectively binds and stabilizes ARE-containing mRNAs of proto-oncogenes, cell cycle regulators, cytokines and other early-response genes^[44,45]. For a more

comprehensive review and detailed description of RNA binding proteins see^[10,28,30,46,47].

Regulatory non-coding RNA

RNAs have long been considered as an intermediate between DNA sequences and proteins that execute cellular functions. However, recent genome-wide analyses suggest that protein-coding genes represent only 2% of the human genome while there are at least thousands of non-coding RNAs (ncRNAs) transcribed from mammalian genomes. For many of them, a clear role in regulation of gene expression has been demonstrated^[48,49].

There are two major classes of ncRNAs; the small ncRNA, such as miRNAs and lncRNAs. miRNA act by pairing to the mRNAs of protein-coding genes to direct their repression, while lncRNAs show different mechanism of action, varying from chromatin remodeling, transcriptional responses and RNA processing^[50,51].

miRNAs, a small class of ncRNAs approximately 18-25 nucleotides in length, are able to regulate gene expression at the post-transcriptional level, by binding to partially homologous sequences to the 3'UTR of target mRNAs, and thereby causing a block in translation and/or mRNA degradation^[52]. Although miRNAs were first identified in the early 1990s, it is only during the past decade that their potential has been more widely explored. Several studies have demonstrated that miRNAs are highly specific for developmental stages and that they play important roles in essential processes, such as differentiation, cell proliferation, stress response and cell death^[53,54]. Gene regulation by miRNAs is important for the onset and progression of several human cancers^[55-57].

Recent profiling studies have identified miRNAs that are aberrantly expressed in human cancers and miRNAs are now widely believed to play an essential role in many malignancies, acting as either tumor suppressors or oncogenes. This classification is based on repression of their target genes, which means that certain miRNA will be tumor suppressive if its target gene is an oncogene or a tumor suppressor^[58,59]. miRNA usually act by pairing to complementary sequences in their 3'UTR and promoting mRNA deadenylation or a translational block^[20,60].

lncRNA are a new class of ncRNA, with a length ranging from 200 bp to 100 kbp, which have recently caught a lot of attention. The latest GENCODE project has annotated 14880 lncRNAs from 9277 loci^[61], but only a few of them have been characterized. Studies demonstrated that lncRNAs play major biological roles in embryonic stem cell biology and cellular development and show developmental and tissue specific expression patterns^[62-65]. lncRNA are involved in numerous biological roles such as imprinting^[66,67], epigenetic regulation^[68], apoptosis and cell cycle control^[69], transcription^[49] and post-transcriptional regulation, splicing^[70] and aging^[71].

Therefore, aberrant lncRNA expression can cause various human diseases including cancer^[69,72]. Currently, dozens of lncRNAs have been identified to play critical roles in the development and progression of cancer, act-

ing as potential onco- or tumor-suppressor RNAs^[73,74]. The mechanisms of action of lncRNAs are varied and include the creation of secondary RNA structures, binding to DNA and RNA binding proteins, or hybridization with complementary sequences of RNAs^[75,76].

Accumulating evidence of deregulated lncRNA expression in numerous cancer types suggests that this type of regulation may open new avenues to identification of therapeutic targets for cancer^[73,77]. For more a detail discussion on short and long RNA see also^[59,78-80].

Alternative polyadenylation

Alternative polyadenylation (APA) is emerging as a widespread mechanism used to control gene expression but the mechanisms/steps governing both global and gene-specific APA are only starting to be deciphered.

APA consist of two steps, cleavage and polyadenylation of RNAs, which are maturation events that cut and add an oligo(dA) tail to the 3' end of the nascent transcript. This processing protects mRNAs from degradation and increases their stability. The specific cleavage position and the efficiency of the process depend on the interaction between *trans*-acting polyadenylation factors and *cis*-elements present in the pre-mRNAs, such as the central sequence motif AAUAAA, identified in the mid 1970s and subsequently shown to require flanking, auxiliary elements for both 3'cleavage and polyadenylation pre-mRNA^[2,81-83]. Previous studies have indicated that more than half of the human genes possess multiple polyadenylation sites^[84], called APA, which may produce mRNA isoforms with different protein-coding regions or 3'UTRs of variable length (when APA occurs in the last exon). The differential recognition of polyadenylation signals leads to long or short 3'UTR of the transcripts. Usage of alternative poly(A) sites influences the fate of mRNAs in several ways, for example, by altering the availability of RNA binding protein sites and miRNA binding sites. Usage of APA and alterations in polyadenylation are beginning to be discovered and studied in human diseases^[85,86] and it is now clear that APA has several functional consequences in cancerogenesis.

INTERACTIONS BETWEEN THESE MECHANISMS

Our knowledge of the complexity of post-transcriptional regulation has expanded continuously and it is now clear that there is a strict connection between all the mechanisms involved in determining mRNA half-life. Evidence collected so far show a growing number of connections between miRNAs and RNA-binding proteins, underlying a new level of complexity of regulation of gene expression^[87,88]. As described above, miRNAs and RBPs are post-transcriptional gene regulators that bind mRNA and can regulate both mRNA stability and translation.

Bioinformatic analyses showed that ARE motifs, normally recognized by RBPs, are over-represented in

miRNA target sites of transcripts and might antagonize or cooperate with miRNA-dependent gene regulation^[89]. This *in silico* analysis provides support for other studies in which close interactions between ARE-BPs and miRNAs were found^[88,90]. In fact, recent studies demonstrated co-operative interactions between miRNA and ARE-BPs in the modulation of gene expression. TTP and miR16, a miRNA containing a UAAAUAUU sequence that is complementary to the ARE sequence, were shown to depend on each other to efficiently suppress the mRNA of TNF alpha^[88]. In other cases, ARE-BPs and miRNA compete for a binding site on the mRNA, thereby counteracting the functions of each other. The binding of HuR to the 3'UTR of the cationic amino acid transporter 1 (CAT1) mRNA prevents miR122-mediated repression of CAT-1 expression, thereby resulting in enhanced expression of the CAT-1 gene^[91]. Other studies revealed that HuR sites are enriched near predicted miRNA sites in mRNAs and frequently overlap with them^[92,93].

There are also other examples, miRNAs can regulate the expression of RBPs, or the converse, where an RNA-binding protein specifically regulates the expression of a specific miRNA, and some of them have been described in detail in a recent review^[94].

Recently an interaction between the two major classes of regulatory RNAs has been demonstrated: miRNA and lncRNA. It has long been assumed that miRNAs can only target protein-coding mRNAs in the cytoplasm. However, recent studies have revealed that miRNAs are also transported from the cytoplasm to the nucleus, where they function in a non-canonical manner to regulate lncRNAs^[95]. These results suggest that certain miRNAs might affect the expression level of many genes through modulating the biogenesis and function of lncRNAs^[96]. Recently, a dynamic interplay between alternative polyadenylation and miRNA regulation has also been reported. Since APA often results in mRNA isoforms with different 3'UTRs lengths, these isoforms of an mRNA are differentially regulated by miRNAs^[97].

The connection between all the mechanisms involved in determining mRNA half-life underlies the great potential of fine-tuning post-transcriptional control of gene expression. A careful revision of the literature has made us realize that alterations and dysfunction in all these mechanisms may be involved in breast cancer.

BREAST CANCER

Breast cancer is the leading cause of cancer-related deaths among women and its incidence is increasing worldwide. This neoplasia is a multi-factorial disease in which several factors contribute to initiation of the disease such as a genetic predisposition, chronic inflammation, exposure to toxic compounds, abundant stress factors, and others. The cumulative effects lead to a high incidence of breast cancer in populations worldwide^[98]. In the last few years post-transcriptional regulation has been demonstrated to play a major role in breast cancer. Below, we will provide

an overview and update of the dysfunction or alteration involved in the control of the mRNA half-life. Therefore, a better understanding of these mechanisms may help exploit the full potential of mRNA stability with respect to cancer diagnosis, treatment, and therapeutics.

RBPS IN BREAST CANCER

Modulation of the mRNA half-life plays a central role in breast cancer. Evidence collected so far has demonstrated the important role for RNA binding proteins in regulation of the mRNA half-life of several genes involved in cancer progression such as oncogenes, cytokines, and growth factors that are often involved in tumorigenesis^[10,99,100]. In particular, TTP and HuR have often been shown to be deregulated in breast cancer and can be proposed as prognostic markers.

Several studies performed on breast cancer cell lines showed that TTP is deficient in breast cancer cells when compared with normal cell types, suggesting the involvement of TTP as a tumor suppressor in breast cancer^[101,102]. Similar results were confirmed by analysis of samples from breast cancer patients.

In 2009, a gene array data set of 251 breast tumors, showed a negative correlation between TTP mRNA levels and tumor grade, with more advanced tumors typically showing the weakest TTP expression^[103]. Moreover, patients with intermediate or low tumor TTP mRNA levels were 2- to 3-fold more likely to die from recurrent breast cancer than patients whose tumors strongly expressed TTP, suggesting that suppressed TTP expression may represent a negative prognostic indicator in breast cancer. The same findings were confirmed by other studies, which also found that TTP expression is higher in normal breast tissue and benign lesions than in infiltrating carcinomas. Moreover a strong positive association of TTP expression and mammary differentiation was identified in normal and tumor cells, with mammary differentiation inducing expression of TTP^[104]. Loss of TTP also enhances infiltration of monocytes/macrophages into the tumors, which is typically associated with poor prognosis in breast cancer^[105]. Recently, TTP has been showed to be involved in mammary differentiation both in normal and tumor cells, suggesting that this protein might play specific and relevant roles in the normal physiology of the gland^[104]. Regarding HuR, a lot of evidence showed a direct role in breast carcinogenesis. HuR seems to enhance breast cancer cell growth and invasion^[106], even though the same group showed that breast cancer patients expressing high levels of HuR had a favorable prognosis^[107]. This finding contradicts two recent studies showing that cytoplasmic HuR expression is elevated in ductal *in situ* carcinomas, when associated with a high tumor grade^[108], and a negative prognostic indicator for survival in patients with breast cancer^[109]. Moreover, in breast cancer cell lines HuR specifically regulates the Forkhead box O (FoxO) transcription factor FOXO1, an important tumor suppressor involved in apoptosis,

the cell cycle, DNA damage repair and oxidative stress. Recently, it was demonstrated that cytoplasmic HuR is associated with reduced survival in invasive breast cancer and can be used as an independent prognostic marker in breast cancer patients undergoing chemotherapy^[110].

REGULATORY RNA IN BREAST CANCER

As described above, regulatory RNAs include miRNAs and lncRNA that play important gene-regulatory roles. While lncRNAs show different mechanisms of action, miRNA act by pairing to the mRNAs of protein-coding genes to direct their repression. In this way, they can decrease the translational efficiency and/or decreased mRNA levels of gene targets^[50]. Even though most of miRNA act by lowering mRNA levels^[20], after reviewing the vast amount of literature on miRNAs, we found that most of the published articles do not investigate the mechanisms by which the miRNA act. Most of them reported the binding of the miRNA to the 3'UTR of the gene or the effect obtained with a luciferase assay, without clarifying if the miRNA affect the mRNA stability or efficiency of translation of the target gene. Since the effect on the efficiency of translation goes beyond this review, we will focus here on miRNA that affect the mRNA half-life and not the global number of miRNA involved in breast cancer. This topic has been extensively covered by other reviews^[111-114]. We will briefly discuss some examples of miRNA demonstrated to directly affect mRNA stability. By acting on mRNA stability, miR125a and miR125b decrease the expression of HER2 and HER3, two genes crucial in breast carcinogenesis and c-RAF, another gene that plays a crucial role in cancer^[115-117]. Another important miRNA is miR206, which targets ER alpha and represses both ER alpha mRNA and protein expression^[118,119]. miR200 regulates epithelial-mesenchymal transition (EMT) targeting Zfhx1b mRNA probably by mRNA deadenylation and destabilization^[120] while miR506 is always involved in EMT by increasing the levels of E-cadherin (CDH1)^[121]. miR34 suppresses invasion and metastatic potential of breast cancer cells by directly targeting Fos related antigen 1 (Fra1) by reducing both the mRNA and protein level^[122]. miR31 decreases the mRNA levels of many genes involved in breast cancer metastasis^[123], while miR203 plays a crucial role in triple negative breast cancer by targeting baculoviral IAP repeat-containing protein 5 (BIRC5) and Lim and SH3 domain protein 1 (LASP1) at the RNA level^[124]. miR21 is another miRNA that affects mRNA stability and is involved in decreasing mRNA levels of Programmed cell death 4 (PDCD4)^[125], while miR26b decreases *Prostaglandin-endoperoxide synthase-2 (PTGS2)* levels in breast cancer^[126] and miR124 affects the cd151 mRNA level^[127].

It is interesting to note that some miRNA affect the mRNA half-life of target genes by perturbing the levels of RNA binding proteins. In 2009, miR29a was reported to suppress TTP in cancer cell lines^[128]. The same miRNA is abundant in invasive breast cancer cells, where it

increases stabilization and subsequent over-expression of HuR. In this way the TTP: HuR ratio was perturbed and associated with cancer invasion^[129]. Moreover, other miRNAs bind to AREs and, thus, interact with ARE-binding proteins (ARE-BPs) to regulate transcript levels. miR3134 mediates an up to 4-8-fold increase in the levels of SOX9, VEGFA, and EGFR, which contain ARE in their 3'UTR, and are also regulated by HuR. Both miR3134 and HuR act together in a general mechanism of regulation of gene expression, which enhances transcript stability^[130].

Another example of interactions is the one between miR125 and HuR. Guo *et al.*^[115] observed that the expression of miR125a inversely correlated with HuR in several different breast carcinoma cell lines. They demonstrated that HuR was translationally repressed by miR125a. This result suggested that miR125a may function as a tumor suppressor for breast cancer, with HuR as a direct and functional target.

To date, the emerging literature on lncRNA includes only one example of regulatory RNA that effect mRNA stability in breast cancer. Two studies reported the effect of a lncRNA on the half-life of the HIF-1 mRNA. HIF-1 is a heterodimeric transcription factor that regulates the expression of genes associated with adaptation to reduced oxygen pressure. HIF-1 is considered to be a reliable prognostic and diagnostic marker for an increasing number of cancers from various origins, including breast cancer^[131]. A natural antisense of HIF-1 transcript (aHIF) that is complementary to the 3'untranslated region of the HIF-1 mRNA has been described in breast and renal carcinoma. The mechanism of action is not clear but it seems that aHIF could expose AU rich elements present in the 3' untranslated region of the HIF-1 mRNA and thus increase the rate of degradation of the HIF-1 mRNA^[132]. aHIF has been proposed as a marker of poor prognosis^[133], but further studies are clearly necessary.

ALTERNATIVE POLYADENYLATION IN BREAST CANCER

APA gives rise to mRNA isoforms with 3'UTR of variable length. There are few examples of the usage of alternative poly(A) in breast cancer in control of gene expression. One of the best examples is the shortening of the 3'UTR, which has been reported by Lembo *et al.*^[134] to correlate with poor prognosis. These authors showed that shorter 3'UTR can contain less regulatory elements that are normally involved in mRNA decay, such as miRNA binding sites or ARE sequences. In this way, miRNA and RBPs may increase the degradation rate of long isoforms of the gene, altering the ratio between the long and short isoforms and causing a shift from the normal to cancerous state^[134,135]. Recently, it has been reported that estrogens, which play a major role in breast cancer initiation and progression, can induce APA

Figure 1 The regulation of the mRNA half-life and targeted therapy in breast cancer. Modulation of mRNA half-life depends on the interaction and balance between RNA binding proteins, regulatory RNAs (miRNA and lncRNA) and alternative polyadenylation in the 3'UTR of genes.

in breast cancer cells. In particular, estradiol up-regulates the 3'UTR shortening of CDC6, an essential regulator of DNA replication^[136]. Further investigations are necessary to establish if the expression ratio of alternative 3'UTR can be a predictor of survival in breast cancer patients.

PROGNOSTIC FACTORS AND TARGETED THERAPEUTICS

In the last few years several studies have proposed evaluating post-transcriptional regulation as a prognostic factor for breast cancer aggressiveness and for development of targeted therapy.

Regarding miRNA, Iorio and coauthors identified several miRNA associated with breast cancer, which points to their role in the development of this neoplasia and to the impact on putative innovative therapeutic approaches^[113]. Among the miRNA that have a direct impact on mRNA half-life of genes involved in breast cancer, miR206 and miR125a and 125b are surely of great interest. These miRNA are involved in specific networks, such as in the HER family-driven or ER-mediated signaling, and could likely influence the response to chemotherapy or to targeted therapies, such as trastuzumab, the monoclonal antibody directed against HER2, or anti-estrogens, such as tamoxifen. Recently Hong L and coauthors investigated the role of miR210 in predicting survival. A total of 511 cases of breast cancer were examined in a global meta-analysis that showed that high expression levels of miR210 predicted poor survival in patients with breast cancer^[137], confirming previous results obtained with miR210^[138].

Several miRNA involved in the regulation of the mRNA half-life in breast cancer, such as miR200, miR26b, miR21, miR34a are also modulated by estradiol^[139], which plays a major role in a hormone-dependent cancers such

as breast cancer.

Regarding RBPs, it is now generally assumed that loss of TTP and gain of HuR expression represent useful negative prognostic indicators in breast cancer. Monitoring mRNA or protein levels of these RBPs is being discussed, but it seems that at least for TTP, monitoring protein levels would provide a better negative correlation with breast cancer invasiveness than quantifying transcript levels^[101,104]. Recently, it has been suggested that the ratio between TTP and HuR be evaluated, since it is perturbed in invasive breast cancer patients, and to correlate it with cancer invasion^[108,109,129,140,141]. Due to the pivotal role played by TTP and HuR in stabilizing mRNA of key factors and cytokines involved in carcinogenesis and subsequent cancer progression, their clinical implication and therapeutic potential in cancer have been thoroughly investigated and recently reviewed by Ross *et al.*^[46], Eberhardt *et al.*^[142], Srikantan *et al.*^[47] and Abdelmohsen *et al.*^[143].

Recently, Wang *et al.*^[110] investigated the predictive and prognostic value of HuR expression in women with breast cancer who underwent neo-adjuvant chemotherapy followed by surgical resection. They evaluated the relationship between the HuR expression level and pathologic complete response (pCR), and found that cytoplasmic expression of HuR was an independent prognostic marker in breast cancer patients undergoing chemotherapy^[110].

Promising data have been obtained from the study of regulatory lncRNA or alternative polyadenylation, but need further investigation and large-scale studies on cohorts of breast cancer patients.

It is of interest to point out the genetic polymorphisms in TTP and HuR, which may represent prognostic factors for breast cancer. Since the two RBPs play a central role in post-transcriptional control of genes involved in breast cancer, some studies analyzed the frequency of germline polymorphisms in breast cancer patients compared to healthy controls. A synonymous polymorphism in the TTP gene showed a statistically significant association with a lack of response to Herceptin/trastuzumab in HER2-positive breast cancer patients^[101]. This polymorphism was associated with a decrease in translational efficiency. Moreover, another genetic variation in the promoter of the gene drastically reduced the amount of TTP mRNA and was significantly associated with poor prognosis. No association between polymorphisms of the HuR gene and breast cancer have been found^[144].

Several polymorphisms in miRNA have been described but meta-analysis has shown that they can be used for prediction of breast cancer risk in healthy population but not as prognostic markers in breast cancer patients^[145-148].

FINAL REMARKS

In recent years the importance of post-transcriptional control in breast cancer has become recognized. This process involves several steps including mRNA degrada-

Table 1 mRNA half-life modulators in breast cancer

mRNA half-life modulators	Main target	Prognostic factor	Ref.
RBP			
TTP	GM-CSF, cox2, VEGF, IL8, HIF1a, TNF- α	Yes	Griseri and Pagès
HuR	GM-CSF, cox2, VEGF, IL8, TGFB, TNF- α	Yes	Griseri and Pagès
microRNA			
miR125a, miR125b	HER2, HER3, cRAF, HuR	Possible	[115-117]
miR206	ER	Unknown	[118,119]
miR200	Zfhx1b	Yes	[120,137,138]
miR506	cdh1	Unknown	[121]
miR34	Fra1	Unknown	[122]
miR31	Fzd3, ITGA5, MMP16, RDX, RhoA	Unknown	[123]
miR203	BIRC5, LASP1	Unknown	[124]
miR21	PDC4	Unknown	[125]
miR26b	PTGS2	Unknown	[126]
miR124	cd151	Unknown	[127]
miR29a	TTP	Unknown	[128]
miR3134	SOX9, VEGFA, EGFR	Unknown	[130]
miR125	HuR	Unknown	[115]
lncRNA			
aHIF		Possible	[132,133]

tion and translation. Here we have focused on the regulation of the RNA half-life in breast cancer, focusing on several mechanisms that control this process, all involving the 3'UTR of genes: mRNA binding proteins, regulatory RNA such as short and long RNAs, alternative polyadenylation. All these mechanisms lead to a broad range of rates in gene decay. A diagram summarizing the involvement of different proteins in regulating the balance between stabilization and degradation of mRNA is given in Figure 1. In this review, we have discussed how alteration of mRNA stability mediated by all these mechanisms can contribute to the development of breast cancer. The goal is to elucidate the molecular mechanisms involved in breast cancer and to identify molecules that are useful as bio-markers of diagnosis or prognosis.

Full knowledge of this process may help to develop potential diagnostic and therapeutic strategies against tumor progression. The available data strongly suggest the use of RBPs or miRNAs as markers of diagnosis and prognosis, and eventually as new targets or tools in specific therapy. Table 1 shows the key players involved in control of mRNA half-life in breast cancer as discussed in this review, documenting the functional importance in defining the aggressiveness of breast cancer cells. A better understanding of the pathways they modulate and how this dictates pathological processes will surely help to obtain a better understanding of the pathogenesis of breast cancer and will in the future open doors for better classification, prognosis and direct treatment.

Key words: Breast cancer; Bone metastasis; Targeted therapy; Osteoclasts

Core tip: Breast cancer cells preferentially colonize bone sites during their metastatic diffusion. Bone microenvironment and tumor cells operate a reciprocal selective pressure that results in the formation of osteolytic lesion and tumor progression. Targeting the molecular factors involved in this interaction has been demonstrated to be an effective strategy in preventing the clinical morbidity associated with bone metastases. In this review, we summarize physiopathologic aspects of bone metastases from breast cancer and discuss the most promising therapeutic targets for their future clinical management.

Abstract

Metastatic occurrence is the principal cause of death in breast cancer patients. The high osteotropism makes breast cancer the most common primary tumor type associated with metastatic bone disease. The peculiar clinical aspects associated with metastases limited to the skeletal system suggest considering these cases as a distinctive subset of metastatic patients with a better prognosis. Because bone is frequently the first metastatic site in disease relapse, it is feasible that the next improvement in therapeutic options for bone metastatic disease could be associated with an improvement of survival expectation and quality of life in breast cancer patients. Study of the molecular basis of bone remodeling and breast cancer osteotropism has allowed identification of several therapeutic candidates involved in formation and progression of bone metastases. These targets are frequently the determinants of positive feedback between the tumor and bone cells whose clinical outcome is osteolytic lesions. In this review, we discuss the physiopathologic features underlying targeted therapeutic strategies aimed at interfering with the aberrant bone remodeling associated with breast cancer metastases.

Rucci N, Sanità P, Delle Monache S, Alesse E, Angelucci A. Molecular pathogenesis of bone metastases in breast cancer: Proven and emerging therapeutic targets. *World J Clin Oncol* 2014; 5(3): 335-347 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i3/335.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i3.335>

CLINICAL ASPECTS

Progress in the diagnosis and treatment of primary breast carcinoma (BrCa) has not led to an overall improvement in survival. The main reason is that residual disease always generates distant metastases, eventually leading to a substantial reduction in life expectancy. As revealed by autopsy studies, undiagnosed metastases in BrCa patients are more frequent than expected, and without an effective strategy aimed at reducing the spread of cancer cells, clinically relevant metastases are estimated to remain the main cause of death associated with BrCa. Although

the presence of metastasis at diagnosis is uncommon in BrCa, the risk for this complication increases considerably within a few years after first treatment. Metastases involving multiple organs, mainly the lung, liver, and bone, are the most frequent situation, while the incidence of isolated metastasis is thought to be lower than 5%^[1].

Large autopsy series have demonstrated that bone metastases are present in 54%-73% of BrCa patients who died of the cancer^[2]. In addition, the high incidence of latent bone metastases at autopsy and the frequent detection of disseminated tumor cells in the bone marrow by sensitive methods suggest that bone colonization by BrCa cells is commonly associated with an indolent disease course and clinical dormancy^[3]. For this reason, study of the molecular determinants associated with predominance of dormancy over aggressive metastatic growth will have an important impact on clinical management of BrCa patients.

Although BrCa is the most common primary tumor type associated with metastatic bone disease, bone-only metastasis is infrequent and about 2% of these patients are diagnosed at the time of initial treatment^[4,5]. Also, according to autopsy records the chance of having bone-restricted metastasis is very low. Patients with disease confined to bone are more likely to be older at diagnosis and to have well differentiated tumors. Bone metastases are frequently associated with lung and/or liver metastases, and the cases with bone-only metastases are about 5%^[1]. In a distinctive way, patients with bone metastasis are more likely to have metastases in the central nervous system (CNS, about 27%) with respect to patients without bone metastasis (about 10%)^[6], and 18% of patients with CNS disease have bone as the initial site^[7]. In addition, lung and liver metastases are frequently found in more widespread disease with respect to bone metastasis^[6].

The predilection of BrCa cells for bone is confirmed by the fact that in more than 50% of BrCa patients, bone is the first site of distant relapse^[5,8]. The median period from BrCa diagnosis to the development of first metastatic bone lesion is about 3 years. However, 49% of these relapsing patients tend to develop extraosseous metastases, and 56% of patients with solitary bone metastasis tend to develop multiple metastatic bone lesions.

Also, for BrCa patients with bone-only disease the presence of multiple bone metastases at first diagnosis is common (59%), and the more frequent (> 50%) anatomical sites are thoracic and lumbar spine, the sternum, and pelvis. The sternum was described as the site of solitary metastasis in a significant percentage of BrCa patients at the time of diagnosis and this could be explained by anatomical proximity with the primary tumor^[5,9].

The median survival after the first recurrence of BrCa in bone is markedly higher with respect to the survival of those with first recurrence of cancer in extraosseous sites (20 mo *vs* 3 mo)^[8]. Although bone-only metastasis demonstrates a relative good prognosis, skeletal involvement is frequently associated with considerable morbidity. This

includes hypercalcemia, fractures, impaired mobility, and spinal cord compression and pain, which require higher and higher doses of analgesics.

According to the histological and clinical features, bone metastases can be classified as osteolytic, osteosclerotic, or mixed, the latter when both features coexist in the same metastatic district^[10]. BrCa bone metastases are quite exclusively osteolytic, characterized by bone destruction due to an exacerbated activity of osteoclasts, the bone cells physiologically devoted to resorb bone matrix. Indeed, the first theories speculated that the osteolytic lesion was the result of physical pressure of the tumor on the bone or bone resorption activity of the tumor cells themselves. It has also been highlighted that cancer cells induce lymphocytes to produce factors such as prostaglandins, which in turn could stimulate destruction of the bone^[11]. To date, more and more evidence has conclusively shown that cancer cells are not able to directly destroy the bone, but they release factors that directly or indirectly activate the formation and activity of osteoclasts^[10].

Due to the prevalent osteolytic nature of BrCa bone metastasis, skeletal progression of the disease can be monitored by the measurement of specific biochemical markers derived from the breakdown of type I collagen^[12]. These peptides include crosslinked C-terminal telopeptide isomers (CTX) and crosslinked N-terminal telopeptide (NTX), which can be measured in serum and urine.

MOLECULAR BASES

The high osteotropism of BrCa cells has been widely demonstrated in preclinical studies. The predilection of tumor cells for bone tissue could not be explained simply by anatomical features, and the so-called "seed and soil" theory, postulated by Steven Paget more than 100 years ago, is still valid today^[13]. This theory emphasizes that the process of colonization requires an interaction between tumor cells, which represent the seed, and the bone microenvironment, a deposit of calcium and growth factors released in response to bone resorption that provides the fertile "soil" in which cancer cells can proliferate.

These considerations have supported an intense investigation of the molecular determinants of osteotropism. However, the frequent widespread presentation of metastases in BrCa patients indicates that the pure osteotropic signature is restricted to a limited number of bone-only cases. Today, histologic analysis of BrCa subtypes drives prognosis, and in many cases permit prediction of the metastatic propensity of the primary tumor^[14]. Although much effort has been made to find a link between molecular profiles and metastatic site, this has not been fully established. In addition, molecular subtyping of the primary tumor is often not repeated in the metastases and the assumption that the metastatic tumor has identical marker expression as the primary tumor is currently debated^[15]. Moreover, it has to be considered that the bone microenvironment, with its peculiar characteristics,

may exert strong selective pressure on tumor cells, thus influencing the resulting phenotype of clinically relevant metastases. For example, parathyroid hormone-related protein (PTHrP), which was previously considered an effective predictor for identifying patients who are at high risk of developing bone metastases and which is expressed in the large majority of BrCa bone metastases and in 60% of primary BrCa, is thought to be stimulated in BrCa cells in response to transforming growth factor- β (TGF- β) released in the bone^[16].

Estrogen receptor (ER) expression represents the best consolidated marker associated with the risk for bone metastasis^[17]. ER+ breast tumors relapse preferentially to the bones over a delayed period^[18]. However, because there is significant loss of ER expression at many metastatic sites including bone, the role of ER in driving pathogenesis of bone metastasis needs to be verified^[6].

THERAPEUTIC OPTIONS

Bone-only metastatic cases have attracted clinical attention due to their good response to treatment and their association with extended patient survival. This aspect suggests considering patients diagnosed with metastases limited to the skeletal system as a distinctive subset of metastatic BrCa patients. The median survival of patients with metastatic BrCa involving extraskelatal sites is significantly shorter with respect to that of patients with bone-only metastasis, independent of the number of sites of skeletal involvement^[19]. Over the past two decades, bisphosphonates have emerged as a safe and effective component of treatment of bone metastatic disease from different cancers. The use of bisphosphonates in managing bone metastases had a profound beneficial effect on the frequency and severity of skeletal morbidity, resulting in improvement of quality of life^[20]. Bisphosphonates are potent inhibitors of osteoclast function that are recommended for long-term treatment^[21]. These compounds bind to exposed bone mineral and then are internalized by bone-resorbing osteoclasts, inhibiting bone resorption with different modes of action. Nitrogen-containing bisphosphonates (*e.g.*, zoledronic acid and pamidronate) act by inhibiting farnesyl diphosphate synthase, while other bisphosphonates are involved in the formation of cytotoxic metabolites in osteoclasts^[22,23]. In addition, recent studies have suggested that bisphosphonates may directly affect tumor cell invasion and survival^[24] and inhibit tumor-induced angiogenesis^[25].

Beyond the use of bisphosphonates, considered the most effective treatment for cancer-induced skeletal complications, other therapy choices include orthopedic intervention, radiation therapy, and cyclooxygenase-2 inhibitors or nonsteroidal anti-inflammatory drugs for reducing bone pain^[26]. Novel agents in clinical development are bone-seeking radionuclides that have been demonstrated to be safe and potentially useful in combination therapy with bisphosphonates or radiosensitizing drugs^[27].

PHYSIOLOGY OF BONE REMODELING

Understanding the molecular mechanisms leading to cancer-induced bone metastases requires knowledge of the physiology of bone tissue which, in contrast to its “hard” feature, is extremely dynamic and undergoes continuous renewal throughout the life of each individual, through a process known as bone remodeling^[28]. In particular, it has been estimated that about 10% of the bone is renewed every year^[29]. This phenomenon guarantees the following crucial functions: (1) Regulation of calcium homeostasis; (2) Renewal of old bone; (3) Substitution of primary infantile bone with mechanically competent bone; and (4) Repair of ischemic and microfractured bone.

Bone remodeling is the result of a perfect balance between the function of bone resorption performed by osteoclasts and osteogenesis accomplished by osteoblasts. Both cell types are the principal cells of bone tissue. This balance is crucial for maintenance of a proper bone mass and the lack of synchrony between the two functions is the starting point for skeletal diseases. As described in Figure 1, bone remodeling takes place according to the following phases:

Activation phase

This phase is so called because the lining cells, which are quiescent osteoblasts, respond to different stimuli (*i.e.*, growth factors, alteration of mechanical loading, and micro fractures) by increasing the expression of factors that stimulate osteoclast differentiation.

Resorption phase

Mature osteoclasts polarize on the bone surface, adhere to it and, by a process of acidification and subsequent release of proteolytic enzymes, such as the cathepsin K and the metalloproteinase (MMP)-9, degrade the bone matrix^[30]. Once they have accomplished their function, osteoclasts undergo apoptosis, a physiologic consequence necessary to avoid exacerbated bone resorption.

Reverse phase

This phase is so called because of the presence of reverse cells, macrophage-like cells that are likely responsible for removing the debris produced during bone matrix degradation.

Formation phase

The players of this phase are osteoblasts, recruited by the growth factors that are usually stored in the bone matrix but that are released after its degradation by osteoclasts. Once recruited, osteoblasts produce a new bone matrix, initially not calcified (osteoid), and then they provide mineralization, thus completing the bone remodeling process.

PLAYERS IN BONE REMODELING

The principal cells of the bone involved in bone remodeling

Figure 1 Phases of bone remodeling. Starting from the quiescence phase, bone remodeling is triggered by different stimuli that lead to activation of lining cells, which increase surface expression of receptor activator of nuclear factor kappa-B ligand (RANKL). This cytokine, by binding to its receptor RANK, promotes osteoclast differentiation (activation phase). Next, mature osteoclasts resorb bone (resorption phase), thus allowing the release of factors usually stored in the bone matrix (BMPs, TGF- β and FGFs) that recruit osteoblasts in the reabsorbed area. Once recruited, osteoblasts form the bone matrix and ensure its mineralization (formation phase), completing the bone remodeling process. BMPs: Bone morphogenetic proteins; TGF- β : Transforming growth factor- β ; FGFs: Fibroblast growth factor; OCL: osteoclast; OBL: osteoblast.

eling, osteoblasts and osteoclasts, also play a key role in the development of bone metastases.

Osteoclast formation and function

Osteoclasts arise from the monocyte/macrophage lineage^[31] and are multinucleated cells formed by the fusion of mononuclear precursors^[30]. Starting from a pluripotent hematopoietic stem cell, the transcription factor PU.1, along with macrophage colony stimulating factor (M-CSF), drives the commitment of a common progenitor for macrophages and osteoclasts. In particular, M-CSF stimulates proliferation of osteoclast precursors and upregulates receptor activator of nuclear factor kappa-B (RANK) expression, while PU.1 positively regulates the expression of c-Fms, the M-CSF receptor^[32]. With the appearance of c-Fms and RANK receptors, the precursors become fully committed to an osteoclast lineage. The RANK/receptor activator of nuclear factor kappa-B ligand (RANKL) pathway is mandatory for osteoclast differentiation and function, although it is not the only player in correct osteoclastogenesis.

Once differentiated, multinucleated osteoclasts need to adhere to the bone matrix and polarize in order to resorb bone. The first step of resorption requires the dissolution of the inorganic component of the matrix, which is hydroxyapatite. This can be achieved by the release of hydrochloric acid into the area to be resorbed, called resorption lacuna^[33], and also requires sealing of the underlined bone matrix, which is achieved through a cytoskeletal rearrangement and subsequent formation of an actin

ring. This is a circumferential structure formed by several dynamic and dot-like structures called podosomes, each of which consists of an actin core surrounded by the $\alpha_v\beta_3$ integrin and associated cytoskeletal proteins^[34].

Dissolution of mineral crystals allows digestion of the bone matrix organic component, which is performed by MMPs and lysosomal cathepsins. Among the latter, cathepsin K has a crucial role, as its deletion in mice leads to several skeletal diseases^[35]. Regarding the MMPs, osteoclasts mainly produce the MMP-9 isoform and, to a lesser extent, MMP-14^[36].

Osteoblasts

They arise from a mesenchymal stem cell (MSC) lineage consisting of pluripotent cells following a specific program of gene expression that may give rise to different tissue-specific cells including osteoblasts, chondrocytes, fibroblasts, myocytes, and adipocytes^[37]. The initial step of osteoblastogenesis is the commitment of MSCs towards an osteo/chondro-progenitor, which relies on the activation of two principal pathways: the Wntless-int (Wnt) pathway and the pathway triggered by bone morphogenetic proteins (BMPs). One of the earliest factors mandatory for osteoblast differentiation is Runt-related transcription factor 2 (RUNX2), along with osterix (OSX), which is downstream of RUNX2^[38]. Committed pre-osteoblasts are identifiable because they express alkaline phosphatase (ALP), one of the earliest markers of the osteoblast phenotype. As the pre-osteoblasts cease to proliferate, a key signaling event occurs for development of the large cuboidal differentiated osteoblasts. The active osteoblast is highly enriched in ALP and secretes bone matrix proteins such as collagen I and several non-collagenous proteins including osteocalcin, osteopontin, osteonectin, and bone sialoprotein II.

REGULATION OF BONE REMODELING

Several factors, systemic as well as local, regulate bone remodeling. Moreover, it is well known that the two principal players of bone remodeling talk to each other to reciprocally regulate their functions. In particular, osteoblasts produce RANKL mainly in the transmembrane form and, to a lesser extent, as soluble cytokine, which interacts with its receptor RANK, expressed by osteoclast precursors, eventually activating the intracellular pathway that stimulates osteoclast differentiation^[39]. Osteoblasts also produce osteoprotegerin (OPG), a soluble protein with the same extracellular structure as RANK but lacking the transmembrane domain. This allows it to act as a decoy receptor, since it binds RANKL, thus preventing its interaction with RANK and inhibiting osteoclastogenesis. Therefore, osteoclast differentiation relies on a proper RANKL/OPG ratio^[40].

BONE REMODELING PERTURBATION AND THE ONSET OF THE VICIOUS CYCLE

The physiology of bone remodeling is drastically dis-

Figure 2 Schematic representation of the vicious cycle. Under physiologic conditions, osteoblasts produce factors that regulate osteoclastogenesis (RANKL/OPG). Mature osteoclasts erode the bone matrix, allowing the release of factors (IGF-1, BMPs, TGF- β , PDGF, and FGFs). Tumor cells perturb this homeostasis by producing factors (PTHrP, IL-6, TNF- α , M-CSF, and PGE2) that favor osteoclastogenesis, with subsequent bone resorption and release of the growth factors stored in the bone matrix, which in turn enhance tumor growth. BMPs: Bone morphogenetic proteins; TGF- β : Transforming growth factor- β ; FGFs: Fibroblast growth factor; IGFs: Insulin-like growth factors; PDGF: Platelet-derived growth factor; M-CSF: Macrophage colony stimulating factor; PGE2: Prostaglandin E2; OCL: osteoclast; OBL: osteoblast.

rupted by tumor cells once they colonize the bone milieu, eventually leading to the so-called vicious cycle (Figure 2). Indeed, tumor cells produce factors that, directly or indirectly through osteoblasts, induce exacerbated osteoclastogenesis, which in turn increases bone resorption and osteolysis. This means that tumor cells are not able to destroy bone *per se*, but they constrain resident cells to support their growth by creating new spaces inside the bone and allowing the release of several growth factors stored herein, such TGF- β , VEGF, insulin-like growth factors, platelet-derived growth factor, and BMPs. Thus, synergy between osteoclasts and tumor cells is created that fuels the vicious cycle, with an inexorable increase in both bone destruction and tumor growth^[10].

The ability of tumor cells to release in the bone microenvironment osteoclastogenic factors, usually produced by osteoblasts, further feeds the vicious cycle. Among the osteoclastogenic factors is PTHrP, produced by tumor cells under the stimulation of TGF- β , which in turn elicits RANKL expression and inhibits OPG production by bone marrow stromal cells and osteoblasts. Evidence for a role of PTHrP in this context arose some years ago from studies by Theresa Guise showing, in a mouse model of bone metastasis, that treatment with PTHrP-blocking antibody reduced BrCa cell-induced osteolysis as well as cancer growth. Moreover, tumor cells also produce M-CSF and prostaglandin E2, as well as several pro-inflammatory cytokines such as interleukin (IL)-1 β , IL-6, IL-11, and tumor necrosis factor α (TNF α),

which directly stimulate osteoclast formation and function^[41]. Finally, evidence from the vicious cycle tells us that, in order to fight it, we could act on two fronts: interfering with the release of specific factors by tumor cells or inhibiting aberrant osteoclastogenesis, and these two phenomena are strictly related.

THERAPEUTIC TARGETS

RANK/RANKL pathway

Given the crucial role of this pathway in osteoclast differentiation, it is not surprising that it has been considered one of the most promising therapeutic targets, leading to the development of denosumab, a human monoclonal antibody directed against membrane-bound and soluble RANKL. Denosumab prevents the binding of RANKL to its receptor, eventually leading to the inhibition of osteoclastogenesis. This drug is currently in clinical trials for the treatment of post-menopausal osteoporosis and bone metastases. In particular, denosumab administered subcutaneously every 4 wk at a dose of 120 mg showed a higher efficiency compared with zoledronic acid in delaying the onset of skeletal-related events in patients with BrCa and in reducing the levels of the bone resorption marker NTX^[42]. However, there was no difference between the two drugs in terms of the effect on patient survival. With regard to the potential side effects, we should not forget the role played by RANKL in the immunologic contest. A few cases of osteonecrosis of the jaw^[43] as well as frequent occurrence of hypocalcaemia^[44] have been reported.

Cathepsin K

Cathepsins are a family of cysteine proteases with 11 members in humans (cathepsin B, C, H, F, K, L, O, S, V, W, and X/Z) with different functions, such as antigen presentation, apoptosis, and autophagy. In the pathological context, cathepsin has been positively correlated with tumor invasion and angiogenesis^[45]. Indeed, B and L cathepsins are prognostic markers of different cancers, among them breast, where their increased expression is associated with a poor prognosis^[46].

Among the different cathepsins, the K isoform has been identified as a good therapeutic target in bone metastasis treatment, due to its pivotal role in bone resorption. Recently, inhibition of cathepsin B was also proven to be effective at inhibiting bone and lung metastases in a mouse model of BrCa^[47]. The crucial role of cathepsin K in osteoclast functions has been clarified by the evidence that a human mutant form of this gene determines a rare genetic disease called pycnodysostosis, characterized by an impairment of bone resorption. Preclinical data from animal models of BrCa bone metastases showed the ability of the cathepsin K inhibitor AFG-495 to reduce osteolytic lesions as well as local tumor growth^[48]. Another recent compound is odanacatib (MK-0822), a promising drug already used for osteoporosis treatment. A phase II clinical trial involving BrCa patients with bone metastases showed a reduction of bone resorption markers after

4 wk of treatment^[49].

Metalloproteases

Due to their function of degrading extracellular matrix, MMPs are obviously involved in the general process of invasion and metastasis. Indeed, some of them play a specific role in the onset of bone metastases, such as MMP-7, which is able to cut membrane-bound RANKL, thus increasing its local activity and favoring bone metastasis development^[50]. MMP-1, along with a disintegrin-like and metalloproteinase with thrombospondin motifs 1 (ADAMTS1), promotes proteolytic cleavage of epidermal growth factors (EGFs), which in turn inhibit osteoblast production of OPG, thus favoring osteoclastogenesis^[51]. Nannuru *et al.*^[52] showed that treatment of mice with Cl66 mammary tumors with MMP13 antisense oligonucleotides led to a significant reduction in bone destruction and in the number of activated osteoclasts at the tumor-bone interface, likely by reducing MMP-9 and RANKL expression.

Vascular cell adhesion proteins

This family is also mainly involved in carcinogenesis and metastasis. Among them, vascular cell adhesion proteins (VCAMs) seem to give a specific contribution to the development of bone metastases, as demonstrated by a recent study. Indeed, by interacting with its integrin receptor $\alpha 4 \beta 1$, VCAM-1 promotes the recruitment of osteoclast precursors. Moreover, treatment of metastatic mice with VCAM-1-blocking antibody significantly reduced bone and lung metastases^[53].

Mammalian target of rapamycin

Rapamycin is an immunosuppressive and antitumoral drug previously used to prevent graft rejection. Rapamycin inhibits mammalian target of rapamycin (mTOR), which is a serine-threonine kinase that stimulates cell survival and proliferation and whose deregulation is associated with the development of several tumors. What makes rapamycin an interesting target for bone metastases treatment is the evidence that the signal triggered by mTOR is important for the survival of osteoclasts^[54]. Moreover, a recent study showed that treatment with rapamycin reduced both the incidence and the area of the osteolytic lesion, through the inhibition of osteoclast formation^[55].

Integrins

Integrins include a large family of surface receptors that mediate cell-extracellular matrix interactions. Osteoclasts mainly express $\alpha v \beta 3$ integrin, which plays a crucial role in osteoclast adhesion, a process that is mandatory for correct bone resorption^[56]. Preclinical evidence shows that $\alpha v \beta 3$ inhibition blocks osteolysis and tumor growth in animal models of bone metastases. These studies were the starting point for ongoing clinical trials that are testing the effectiveness of various $\alpha v \beta 3$ antagonists in different bone metastatic cancers^[57].

Erythroblastic leukemia viral oncogene homolog (ErbB) receptors

The ErbB family of receptor tyrosine kinases represents an attractive therapeutic target in carcinomas. In fact, ErbB kinases are frequently overexpressed in these cancers and regulate important aspects of cancer progression by activating several key intracellular signaling intermediates, including PhosphoInositide 3 Kinase (PI3K), Ras-Raf Mitogen Activated Protein Kinase (MAPK), c-Jun N-terminal Kinase (JNK) and PhosphoLipase C (PLC)^[58]. The ErbB family comprises four members: ErbB1 [alias epidermal growth factor receptor (EGFR) and HER1]; ErbB2 (alias HER2 and Neu); ErbB3 (alias HER3); and ErbB4 (alias HER4). For EGFR and HER2, sufficient data have been collected to support their use as two of the five protein surrogate markers for assessing BrCa subtypes [ER, progesterone receptor (PgR), HER2, EGFR, and cytokeratin-5 (CK5)]^[59]. The role of the other ErbB kinases in BrCa progression remains controversial. In addition, only HER2 is found to be amplified in about 25% of primary BrCa cases. Although the data indicate that EGFR is not overexpressed in primary BrCa with respect to the normal breast epithelia^[60], recent studies have suggested a significant association of EGFR expression with the aggressive basal-type BrCa^[61] and with circulating BrCa cells^[62,63].

Current evidence does not support the hypothesis that EGFR or HER2 expression can predict bone metastasis^[17]. In contrast, ErbB-expressing BrCa shows the predilection to metastasize to visceral sites, including the brain, liver, and lung^[64]. Nevertheless, numerous preclinical studies have proposed a leading role for ErbB kinases in the progression of bone metastases^[65]. In particular, ErbB receptors may participate in the positive feedback underlying the vicious cycle. In fact, EGFR ligands present in the bone microenvironment are able to directly stimulate bone cells and osteolysis. Among the recognised ligands of the ErbB family, EGF, TGF- β , and amphiregulin (AREG) have been proposed as the main players in the bone microenvironment. EGF and TGF- β stimulation of osteoclastogenesis and bone resorption is accompanied by decreased OPG expression and sustained production of RANKL by bone stromal cells^[56,66]. In addition, EGFR is expressed by osteoblasts, and its activation stimulates osteoblast proliferation and decreases mineralization^[67]. EGFR ligands may also function by an autocrine loop, stimulating the release of cytokines by BrCa cells that directly influence osteoclastogenesis or indirectly stimulating EGFR signaling within bone cells. The key cytokine produced by BrCa cells in this way is PTHrP, which is able to stimulate RANKL expression and inhibit OPG expression in cells of the osteoblast lineage^[68]. In addition, PTHrP induces the expression and shedding of AREG and TGF- β , increasing the availability of ErbB ligands in the bone microenvironment. In turn, osteoblasts release EGFR ligands and perpetuate the cycle of osteoclast activation *via* RANKL and thus bone destruction^[65].

Src

In the last few years, Src, a nonreceptor tyrosine kinase, has attracted increasing interest due to its involvement in both tumorigenesis and bone metabolism. Src activity appears to be significantly associated with the development of bone metastases and late-onset relapse to bone. Using a bioinformatics approach, it was demonstrated that the role of Src was independent of the distinct molecular subtypes of human BrCa and also ER status^[69].

In BrCa cells, Src is frequently overexpressed and overactivated, allowing the transduction of signaling pathways associated with proliferation, adhesion, invasion, and angiogenesis^[70]. In particular, Src is a key mediator for several cell surface receptors, including EGFR and HER2^[71]. Src-overexpressing tumors may have a specific survival advantage in the bone microenvironment. In fact, activated Src is required for Chemokine (C-X-C) motif Ligand 12 (CXCL12)/Stromal cell-Derived Factor (SDF)-mediated cell survival and abrogates TNF-Related Apoptosis-Inducing Ligand (TRAIL)-mediated apoptosis^[69]. Preclinical studies confirmed that treatment with Src inhibitors effectively reduced BrCa growth compared with untreated cells^[72]. In several mouse models of BrCa, inhibition of Src activity decreased metastases and improved survival^[73,74]. Other *in vivo* studies have found inhibition of bone metastasis but not of metastases at visceral sites, confirming the specific role for Src in bone turnover^[69]. Moreover, Src activity has been linked to resistance to anti-hormonal therapy^[75]. That BrCa bone metastases are more frequent in ER+ than ER- tumors suggests the possibility that Src inhibition could overcome resistance to endocrine therapy and block metastatic growth. The results from a clinical trial recruiting ER+ and HER2+ BrCa seemed to confirm a better potential activity of an inhibitor of Src in ER+ tumors with respect to HER2+ cases^[76].

At the same time, Src is a key signaling molecule in the physiology of bone, since osteoclast function appears to be dependent on the activation of Src^[77]. Indeed, src-deficient mice develop osteopetrosis, with a significant reduction of bone resorption, although the number of osteoclasts was equal to that of wild-type (WT) littermates, thus indicating that Src is mandatory for osteoclast activity^[78]. Significantly, when Src inhibitors were used in *in vivo* models of BrCa bone metastasis, it was reported that bone resorption as well as BrCa growth at the metastatic site were significantly inhibited^[74]. There are currently several Src inhibitors in preclinical development or in clinical trials for the treatment of solid tumors^[79]. One of these compounds, dasatinib, a dual Src/Abl inhibitor, approved for the treatment of leukemia, was successfully investigated in phase I / II clinical trials in patients with prostate and BrCa bone metastases. Dasatinib treatment was associated with a substantial decrease in bone resorption markers and with a lack of disease progression in a significant percentage of breast and prostate cancer patients^[80,81]. However, although recent data of the Randomized Study Comparing Docetaxel Plus Dasatinib to

Docetaxel Plus Placebo in Castration Resistant Prostate Cancer (READY) trial confirmed the reduction in bone resorption, they showed no overall survival improvement, suggesting the need for appropriate predictive biomarkers^[82].

Chemokines

Chemokines constitute a family of small secreted cytokines. Their name comes from their ability to induce chemotaxis in adjacent responsive cells. Chemokines are generally divided into four classes according to the number and position of cysteine residues: CC, in which the residues are adjacent; CXC, in which the residues are separated by one amino acid; the family XC, which has only one cysteine residue; and CX₃C, in which the cysteine residues are separated by three amino acids^[83]. Some chemokines are pro-inflammatory, being able to induce an immune response consisting of attraction of immune cells at the site of infection, while others are involved in homeostasis, controlling the process of cell migration. These proteins exert their effect by interacting with specific transmembrane receptors called chemokine receptors, present on many different cell types^[84]. The chemokine receptors belong to the family of G protein-coupled receptors (GPCRs), which have an extracellular region that binds to chemokines, seven transmembrane α -helices, and a cytoplasmic side associated with a G protein. Several studies highlighted the importance of CXCL12 (SDF-1) and CXCR4 in BrCa. The first studies on the role of CXCR4 in BrCa date back to 2001^[85], and its specific involvement in the migration of BrCa cells from the primary site through the basement membrane was reported by Yagi *et al.*^[86] in 2011. Mutation at the COOH-terminal domain of CXCR4 also plays a role in receptor regulation during the process of epithelial-to-mesenchymal transition^[87]. It has also been shown that CXCR4 levels are high in bone metastasis, suggesting that the CXCL12/CXCR4 axis plays an important role in its pathogenesis. CXCL12 is a homeostatic chemokine constitutively expressed also in those organs that are the most common metastatic sites of BrCa, including bone marrow, but its secretion by damaged tissues is particularly abundant. CXCR4 expression is low or absent in normal breast tissue, while it is upregulated in neoplastic tissue; moreover, CXCR4 levels are related to the degree of tumor malignancy. However, additional studies are needed to confirm that the increase of CXCR4 expression can be a predictive marker for metastatic diffusion. Shim *et al.*^[88] showed that, in cultured cells, the binding of CXCL12 to CXCR4 induced CXCR4 translocation from the cytoplasm to the nucleus. After its translocation to the nucleus, CXCR4 works as a transcription factor^[89], leading to upregulation of cytokines such as MCP-1 and IL-8 and metalloproteases such as MMP-2 and MMP-9. The importance of CXCR4 in BrCa progression was confirmed by the use of anti-CXCR4 antibody or specific siRNA, *in vitro* and *in vivo*, showing its ability to block the formation and the dissemination of metastasis.

Given the involvement of chemokines and chemokine receptors in tumor progression, many molecules have been developed to counteract their biological activity. These molecules belong to two categories: peptides and small molecules. Bicyclams are low-molecular-weight agents that have been shown to act as potent and selective CXCR4 antagonists. Bicyclam AMD 3100 (Plerixafor) is currently being investigated in clinical trials alone or in combination with bisphosphonates^[83]. The 14-residue polypeptide 4F-benzoyl-TN14003 (BKT140) is a highly selective and unique CXCR4 antagonist^[90]. Besides its ability to inhibit BrCa metastases by impairing migration, it could also be used as a diagnostic tool to identify CXCR4 receptor-positive tumor cells in culture as well as in paraffin-embedded clinical tumor samples^[91]. Finally, *in vivo* studies have demonstrated that the synthetic peptide antagonist CTCE-9908 is able to reduce the incidence and extent of bone metastases. Unfortunately, results from the first clinical trials conducted in patients with advanced metastatic disease showed good tolerance but low response^[92].

Transcription factors

The osteolytic phenotype is associated with the activity of a specific pattern of transcription factors, including glioma-associated oncogene family zinc finger 2 (GLI2), RUNX2, and hypoxia-inducible factor-1 (HIF-1). In particular, GLI2 stimulates PTHrP expression by tumor cells and is mainly involved in the development of melanoma-induced bone metastases^[93,94]. With regard to RUNX2, it has been demonstrated that inactivating mutations of its gene in BrCa cells significantly inhibit bone metastasis development in animal models^[95]. Finally, HIF-1, besides its pivotal role in hypoxia-associated tumor progression, also stimulates tumor-driven osteolysis (Figure 3). Transcriptional activity of HIF-1 is induced by the reduction in oxygen (O₂) availability. HIF-1 is a heterodimeric protein composed of an O₂-regulated HIF-1 α subunit and a constitutively expressed HIF-1 β subunit^[96]. HIF proteins, when stabilized, trigger the transcription of numerous target genes involved in tumor growth and in promoting the feed-forward of the metastatic cycle^[97]. Hypoxia is a frequent consequence of the growth of solid tumors. It is well known that many hypoxia-response genes regulated by HIF-1 α are genes involved in controlling energy metabolism. These include VEGF, which permits increased O₂ delivery to cells by stimulating angiogenesis, and glycolytic enzymes, which allow cells to survive O₂ deprivation^[98]. Paradoxically, therapeutic inhibition of tumor-induced angiogenesis could stimulate autocrine growth factor secretion downstream of HIF-1, thus producing a more aggressive phenotype in BrCa cell lines^[99].

Concerning the role of hypoxia in pre-metastatic niche formation, clinical studies have shown that expression levels of HIF-1 α in BrCa patients increase proportionally with the severity of the pathologic stage^[100]. As reported by Le *et al*^[101] in 13 different types of human cancers, HIF-1 α was overexpressed in two-thirds of the

all regional lymph nodes and bone metastasis examined. Furthermore, increased levels of HIF-1 α were associated with a poor prognosis^[102,103]. Several data have indicated that factors stimulated by HIF-1 α are associated with bone metastasis through their capacity to modify extracellular bone matrix and stimulate metastatic homing of cancer cells^[85,104,105].

Some of the most well-known target genes of hypoxia, which are able to promote metastatic progression, include lysyl oxidase (LOX), LOX-like (LOXL) family proteins such as LOXL2 and LOXL4, TGF- β , MMP2, MMP9, CXCR4, SDF-1, and VEGF^[106]. It was demonstrated that HIF-1, in hypoxic BrCa cells, could promote BrCa metastasis by inducing the expression of LOX proteins. This phenomenon is probably due to increased VEGF secretion by endothelial cells (ECs) and the modification of collagen molecules in the extracellular matrix (ECM)^[107]. While the role of LOX in metastases was initially attributed to its capacity to remodel the ECM in the proximity of the primary tumor, subsequent studies revealed that LOX could remodel the ECM at distant sites and recruit bone marrow-derived cells to the metastatic niche^[108].

In the bone microenvironment, overactivated HIF-1 α can increase the development of osteolytic bone metastases *via* dysregulation of factors involved in the vicious cycle. Several findings have suggested that acidosis, which is caused by glycolytic metabolism of hypoxic cancer cells, has a negative effect on osteoblast differentiation as well as on osteoblast functions^[109,110]. In contrast to the effect on osteoblast differentiation, hypoxia seems to stimulate osteoclast-like cell formation. Frick *et al*^[111] demonstrated higher RANKL mRNA expression in bone cells caused by metabolic acidosis with respect to control. In addition, osteoblasts express components of the HIF-1 pathway, and hypoxia can upregulate the expression of VEGF-A, the major inducer of tumor angiogenesis^[112].

Although HIF-1 is an attractive therapeutic target and several different strategies have been developed to directly target HIF-1, none of these inhibitors have been translated to the clinical setting. However, different chemical compounds and chemotherapeutic drugs that indirectly target HIF-1 α , such as EGFR inhibitors, digoxin and other cardiac glycosides, anthracyclines, geldanamycin and other heat shock protein 90 (HSP90) inhibitors and, recently, topotecan and topoisomerase I inhibitors, have been shown to counteract primary cancer progression, angiogenesis, and metastasis in mouse models^[113-117]. Among these inhibitors, promising results were obtained with the HIF-1 α inhibitor 2-methoxyestradiol (2ME2), which was able to decrease osteolytic lesion area and tumor burden in an *in vivo* model of bone metastasis^[118,119].

CONCLUSION

Bone represents a peculiar distant site for dissemination of BrCa cells: it is actively colonized and frequently becomes a fertile “soil” for tumor growth after the develop-

Figure 3 Potential pro-metastatic role of hypoxia in bone. Hypoxia stimulates targeting of cancer cells to bone and facilitates their survival within the bone microenvironment. The presence of a hypoxic environment, further sustained by cancer growth, induces the secretion of hypoxia-inducible factors by cancer cells. These factors, in conjunction with parallel acidification of the microenvironment, are associated with osteoclastogenesis. TGF- β : Transforming growth factor- β .

ment of self-reinforcing crosstalk between tumor and bone cells. This interaction determines osteolysis and the consequent extensive morbidity, but it is also fundamental for cancer progression. Several preclinical and clinical data have demonstrated that the therapeutic strategy directed at interrupting the crosstalk between cancer and bone cells is effective in ameliorating prognosis. Therefore, understanding the effects of the factors implicated in physiopathology of bone remodeling may help to identify future targets for a curative therapy of bone metastasis.

WJCO 5th Anniversary Special Issues (2): Breast cancer**Effects of psoralens as anti-tumoral agents in breast cancer cells**

Maria Luisa Panno, Francesca Giordano

Maria Luisa Panno, Francesca Giordano, Department of Pharmacy, Health and Nutritional Sciences, University of Calabria, Arcavacata di Rende, CS 87036, Italy

Author contributions: Both authors contributed to designing the scientific paper; Panno ML wrote most of the paper and studied a great deal of the literature that was also shared with the other author; Giordano F developed the introductory part, provided additional comments and ordered the references; Panno ML and Giordano F approved the final version.

Abstract

This review examines the biological properties of coumarins, widely distributed at the highest levels in the fruit, followed by the roots, stems and leaves, by considering their beneficial effects in the prevention of some diseases and as anti-cancer agents. These compounds are well known photosensitizing drugs which have been used as pharmaceuticals for a broad number of therapeutic applications requiring cell division inhibitors. Despite this, even in the absence of ultraviolet rays they are active. The current paper mainly focuses on the effects of psoralens on human breast cancer as they are able to influence many aspects of cell behavior, such as cell growth, survival and apoptosis. In addition, analytical and pharmacological data have demonstrated that psoralens antagonize some metabolizing enzymes, affect estrogen receptor stability and counteract cell invasiveness as well as cancer drug resistance. The scientific findings summarized highlight the pleiotropic functions of phytochemical drugs, given that recently their target signals and how these are modified in the

cells have been identified. The encouraging results in this field suggest that multiple modulating strategies based on coumarin drugs in combination with canonical chemotherapeutic agents or radiotherapy could be a useful approach to address the treatment of many types of cancer.

Key words: Psoralens; Breast tumor; Bergapten; Growth factors; Estrogens

Core tip: This review examines the biological properties of coumarins by considering their beneficial effects in the prevention of some diseases and as anti-cancer agents. The attention is mainly focused on the effects of psoralens on human breast cancer as they are able to influence many aspects of cell behavior. More recently, it has been reported that these drugs in breast cancer cells are capable of antagonizing some metabolizing enzymes, to affect estrogen receptor stability and to counteract cell invasiveness as well as cancer drug resistance.

INTRODUCTION

Coumarins are classified as members of the benzopyrone family of compounds, all which consist of a benzene ring joined to a pyrone ring^[1]. There are four main coumarin sub-types: the simple coumarins (*e.g.*, coumarin, 7-hydroxycoumarin and 6,7-dihydroxycoumarin); the furanocoumarins (*e.g.*, psoralen, angelicin) that consist of a five-

Figure 1 Interaction between psoralen and DNA. Upon absorption of ultra-violet radiation A (UVA) photons, the psoralen excited state can react with a thymine and covalently attach the DNA. The initial photoadduct can absorb a second UVA photon and react with a second thymine on the opposing strand of DNA helix to crosslink the two strands.

membered furan ring attached to the coumarin nucleus, divided into linear or angular types with substituents at one or both of the remaining benzoid positions; the pyranocoumarins that are analogous to the furanocoumarins but contain a six-membered ring (*e.g.*, seselin, xanthyletin); and the coumarins substituted in the pyrone ring, often at 3-C or 4-C positions (*e.g.*, warfarin)^[2].

Coumarins comprise a very large class of compounds found throughout the plant kingdom^[3-5]. They are present in fruit, roots, stems and leaves, but some essential oils, particularly cinnamon bark, lavender oil and cassia leaf oil, are also a good source. Coumarin members have also been isolated from microorganisms. For example, coumarin group antibiotics, such as novobiocin, coumermycin A1 and clorobiocin, come from various *Streptomyces* species. These antibiotics are potent inhibitors of DNA gyrase^[6,7]. Aflatoxins, isolated from the *Aspergillus* species, are a group of highly toxic fungal metabolites.

In the 1970s, furanocoumarins attracted scientific attention when they were introduced in clinical practice^[8]. Two of the most important and well known furanocoumarins are psoralen and angelicin, which have been demonstrated to influence cell division and differentiation. In addition, anticancer^[9,10], immunomodulatory^[11], antibacterial^[12], antioxidant^[13] and neuroprotective functions^[14] have also been shown.

Psoralens, extremely toxic to a wide variety of prokaryotic and eukaryotic organisms, are mainly extracted from the ripe fruit of *Psoralea corylifolia* (Leguminosae), an erect annual herb widely used in Ayurvedic medicine and traditional Chinese medicine. 8-methoxypsoralen (8-MOP) and 5-methoxypsoralen (5-MOP), or bergapten, are the psoralen compounds that occur in nature but several analogues have also been described^[15-20].

These molecules cause cell damage by covalent binding to DNA after ultraviolet radiation A (UVA) irradiation. They have a planar tricyclic structure with two pho-

toactive sites (3,4-pyrone and 4,5-furan double bonds). The initial intercalation and interaction with double-stranded DNA occur after absorption of a photon of UVA and afterwards a pyrimidine residue of the DNA covalently binds to the first photoreactive site with a 5,6-double bond. The psoralen monoadducts formed in the DNA can further react photochemically with a pyrimidine base on the complementary strand of the DNA. In fact, it is precisely the planar structure of psoralens which allows them to intercalate between DNA bases^[21], thus preventing cell mitosis (Figure 1). This feature is clinically relevant and the combination of psoralen and UVA irradiation (PUVA therapy) has been employed in autoimmune or hyper-proliferative skin diseases, including psoriasis and vitiligo^[8]. However, extensive studies have pointed to other biological and clinical applications.

PSORALENS IN NORMAL AND TRANSFORMED CELL PHENOTYPES

Effects on normal cells

Diets rich in fruit and vegetables are often a predominant source of phytochemical compounds with defensive health effects. Initially, natural products were used as concentrated herbal extracts. However, the identification of the biological activity of each single component became a very complex matter due to a mixture of other constituents. In fact, herbal drugs or extracts contain a combination of active constituents, which are well known in popular medicine for the treatment of various kinds of disorders, such as asthma, coughs, nephritis, vitiligo, cavities and gastroenteric diseases. In Asian countries such as Mongolia, when people were infected with *Helicobacter pylori*, an alternative non-antibiotic method based on green tea catechins was found to strongly inhibit *H. pylori* urease activity *in vitro* and to suppress the bacterial-induced gastritis^[22]. A few years later, in a cohort study of gastric carcinomas after screening a total of 25 food phytochemicals, bergamottin was designed as the most promising agent^[12]. Grapefruit and grapefruit-based products are rich in flavonoids, coumarins and carotenoids, which in the long run have been shown to have anti-inflammatory^[23], anticarcinogenic^[9,10,24], antibacterial^[12] activities and significant protective effects on cardiovascular diseases^[9,13]. Furthermore, these bioactive compounds possess antioxidant properties because they act as free radical scavengers, therefore protecting cellular structures and functions in many stressful conditions.

A rich source of coumarins and coumarin containing compounds are the *Psoralea corylifolia* L. seeds, well known in traditional Chinese medicine as "Buguzhi". The plant has long been used for its *magical effects* to cure various skin diseases but, over the years, many other properties have been discovered^[3,10]. The first historical notes on the biological effects of furanocoumarins are related to their photoactivation ability. As previously mentioned, PUVA has been suggested as a potential therapeutic to treat psoriatic lesions and other dermatological condi-

tions^[25,26]. Studies reproduced in the 1980-90s on PUVA therapy for psoriasis have reported the comparison of oral and bathwater delivery of 8-MOP^[27]. Compared with systemic administration, selectively bathing the epidermis with concentrated psoralen leads to a more complete reversal of the pathological epidermal alterations^[11].

Psoriatic keratinocytes inappropriately synthesize a number of immune-related molecules and express a higher amount of epidermal growth factor receptors and insulin-like growth factor receptors that can well support the cellular hyperplasia of the psoriatic lesions. In fact, one of the first studies on PUVA demonstrated how this therapy strongly suppressed the mitogenic stimuli on keratinocytes^[11].

A number of conditions with an autoimmune basis other than psoriasis, such as vitiligo, cutaneous T-cell lymphoma, pemphigus vulgaris, systemic sclerosis and rheumatoid arthritis, have benefited from the above treatment^[28-30].

The compounds best known and widely used for these applications are 4,5',8-trimethylpsoralen (TMP), 8-MOP and 5-MOP. All these assessed in human cell line cultures *in vitro* as well as in *in vivo* studies showed anti-proliferative activity and apoptotic effects. Along with other derivatives, two angular furanocoumarins angelicin and 4,6,4'-trimethyl angelin (TMA) in human keratinocytes photoinduce cellular death and cell cycle arrest in G1 phase. The molecular responses involve up-regulation of p21^{waf/Cip} and p53 activation, with mitochondrial-induced cytochrome *c* release and the consequent apoptotic reaction^[31].

Effects on tumoral cells

In addition to these uses, coumarins display anticancer activities. Interest in this field stemmed from reports by Thornes who evidenced the immunomodulatory activity of coumarin and its utility in malignant melanoma^[32]. The photoactivated coumarins are effective in preventing proliferation of bladder^[33] and mucoepidermoid carcinoma^[34], mammary cancer cell^[35] and human melanoma cell line^[36], with potential for their use in clinical treatments. Despite their photoactivity even in the absence of UV radiation, they have biological properties.

In fact, the native coumarins have been shown to affect adhesion and motility of neoplastic cells. This aspect was well elucidated in the highly invasive murine melanoma cell line B16-F10 by Velasco-Velazquez MA (2003).

In the latter cell type, compared to the non-malignant fibroblastic cells, the authors reported that 4-hydroxycoumarin (4-HC) was able to affect the assembly of actin filaments, thus decreasing the cellular adhesion to extracellular matrix proteins and motility only in the tumoral cell type.

Since adhesion of tumor cells to extracellular matrix is required during the metastatic process, 4-HC might be useful to prevent metastasis and could be used as an adjuvant therapy for melanoma^[37].

The chemopreventive role of coumarin 5-MOP, in

the absence of photoactivation, was investigated in human hepatocellular carcinoma (HCC) cell line by studying apoptotic and cytotoxic responses^[38].

This study suggested that the suppressive effect of 5-MOP includes at least three modes of action: (1) it first kills cells directly; (2) induces apoptosis by arresting cells at the G₂/M phase of cell cycle; and (3) induces apoptosis through an independent pathway with cell-cycle arrest. The authors concluded that the inhibition of cyclin B1 by 5-MOP may play an important role in mitotic arrest and provide an additional way to prevent cells from entering the M phase and undergoing apoptosis.

Antitumoral activity of the methanolic seed extract of *P. corylifolia* L was evaluated in two human cancer cell lines: oral carcinoma cell line and erythroleukemia cells and their corresponding multidrug-resistant cell lines. Both psoralen and isopsoralen constituents were able to inhibit the growth of these cells in a dose-dependent manner. They can also inhibit the growth of normal human primary cells but the IC₅₀ values were higher than those of tumoral cells, suggesting that these two active components had potential selective cytotoxicity^[10].

The resistance aspect of cancer cells to chemotherapeutic agents is one of the major obstacles in achieving an effective treatment for cancer. This results from a variety of factors, including individual variations in patients and somatic genetic differences in tumors. The most common reason for cancer drug resistance involves overexpression of membrane drug efflux pumps, such as P-glycoprotein, but other mechanisms might be implicated. Various Chinese herbal drugs have been evaluated for their specific actions against multi drug resistant (MDR) cancer cells. In an experimental study by Wu JYC of the University of Hong Kong^[39], a bioassay-guided fractionation of extracts from *Radix Peucedani* (also known as "Baihua Qianhu" in Chinese medicine) led to the isolation of the pyranocoumarin compounds, (±)-3'-angeloyl-4'-acetoxy-cis-khellactone, a good candidate as a MDR reversing agent for tumoral cells. Strong synergistic interactions were demonstrated when pyranocoumarins were combined with common anti-tumor drugs, including doxorubicin, paclitaxel, puromycin or vincristine, in multidrug resistant human oral epidermoid carcinoma cell line (MDR KB-V1) compared to its drug-sensitive cell line, KB-3-1. Pyranocoumarins increased doxorubicin accumulation in KB-V1 cells and the same treatment down-regulated the expression of P-glycoprotein.

BREAST CANCER CELLS

Estrogen receptor status and estrogen/antiestrogen responsiveness

Estrogenic hormones are essential for mammary gland development but the same microenvironment plays a pivotal role in the initiation and progression of breast tumorigenesis. In addition, the weight of genetic factors that contribute to the development of breast cancer must be also taken into account.

Estrogen signaling pathways are mediated by two nuclear estrogen receptor (ER) proteins, ER-alpha and ER-beta, with different roles. ER-alpha transduces proliferative responses, thus determining cellular growth and tumor progression, while ER-beta has inhibitory actions^[40-43].

Besides these nuclear receptors, the GPR30/GPER, a member of the seven-transmembrane G protein-coupled receptor family, has been implicated in mediating the effects of estrogens in various normal and cancer cells. In particular, GPER is able to trigger gene expression and proliferative responses induced by estrogens and even ER antagonists in hormone-sensitive tumor cells^[44,45].

Indeed, a whole series of intracellular events, such as the rapid phosphorylation of mitogen-activated protein kinases (MAPK) ERK1/2, the activation of PI3-kinase (PI3K) and phospholipase C (PLC), the increase in cAMP concentrations and intracellular calcium mobilization, was shown to follow GPER activation by both estrogens and anti-estrogens^[45].

Approximately 70% of breast cancers are ER-alpha positive and estrogen-dependent. However, the majority of these tumors will transit from an estrogen-dependent to an estrogen independent state that is usually associated with an aggressive form of the disease. During the initial stages of the disease, depletion of ER-alpha from breast cancer cells is a potent approach to prevent estrogen-dependent growth. For this reason, an anti-estrogen such as tamoxifen, acting as a competitive inhibitor of the receptor, has been implemented in the therapeutical protocols for breast cancer. However, the anti-hormonal long-term use of tamoxifen for most treated women leads to the development of drug resistance and an increase of endometrial cell proliferation with risk of endometrial carcinogenesis^[46-48].

Therefore, the goal of minimizing the negative side effects of estrogens on breast tumor has stimulated the search for a new molecule able to block the agonistic effects of both estrogen and tamoxifen. The pure anti-estrogen, Fulvestrant (ICI 182780), which competes with estrogen for binding to ER with a higher affinity, fulfils these properties very well. This drug is particularly effective as a second-line treatment when tumor cells develop resistance to tamoxifen^[49].

In addition to blocking ER activity, scientific research has recently focused attention on the possible use of the aromatase inhibitors (AIs) since breast cancer cell growth is closely supported by estrogen production. Steroidal (exemestane) and non-steroidal (anastrozole, letrozole) aromatase inhibitors are an additional strategy to counteract estrogen function and signaling. These compounds either bind and inactivate aromatase or compete with endogenous substrates to reduce estrogen synthesis. They are approved for use in endocrine treatment of postmenopausal breast cancer and have demonstrated efficacy in patients that develop resistance to anti-hormonal therapy^[50-52].

Several models have been proposed to explain the

transition of breast tumor from an estrogen-dependent to an estrogen-independent status, including expression of variant or mutated ER-alpha, altered expression of co-factors or downstream estrogen target genes, post-receptor and pharmacological alterations^[53] as well as ligand-independent activation of ER-alpha by other signaling pathways.

ER and growth factors

Accumulated evidence has indicated that a constitutive expression of growth factor or growth factor receptors in breast cancer cells plays an important role in pharmacological resistance. In many cases, an over-production of polypeptide growth factor with an increased activation of the corresponding signaling pathways can bypass the requirement of mitogenic estrogen signaling during progression of breast cancer^[54].

Intricate interactions between ER-alpha and polypeptide growth factors, such as IGF-I, epidermal growth factor (EGF), transforming growth factor (TGF)-alpha and TGF-beta, are involved in the maintenance of proliferation and survival signals. In ER positive breast cancer cells, estrogens increase the mitogenic potential of IGF-I, sensitizing the cells to IGF-I action through the amplification of IGF-I signal^[55-59].

The mechanisms of ER-alpha/IGF-I crosstalk is bidirectional and includes the ligand-independent activation of ER-alpha by IGF-I as well as the regulation of the IGF-I system by ER-alpha^[60,61]. Other than this type of interaction, the crosstalk between ER-alpha and members of the EGFR family is well known. This receptor was found to be amplified in a human breast cancer cell line and named human epidermal growth factor receptor 2 (HER2)^[62].

Amplification of HER2 in human mammary epithelial cells induces proliferative advantages, transformed characteristics, tumorigenic growth and in 3D models induces proliferative and anti-apoptotic changes that mimic early stages of epithelial cell transformation^[63,64]. Overexpression of the HER2 protein, either through gene amplification or transcriptional deregulation, is seen in approximately 25%-30% of breast and ovarian cancers and confers worse biological behavior^[65].

Patients with these characteristics have lower ER levels and are modestly less responsive to anti-estrogens; therefore, they develop the hormone-resistant phenotype. Moreover, high levels of HER-2/*neu* expression constitutively activate survival signals involving PI3K/Akt, which is closely related to MAPK hyperactivity^[62,66].

Tyrosine kinase associated receptors control most of the fundamental cellular processes, including cell proliferation, differentiation, metabolism, migration and survival. The over-expression of these signals facilitates the emergence of anti-hormone resistance in breast cancer. In such cases, potential interventions with anti-growth factor agents, either alone or in combination with anti-estrogen agents, have been reported and have shown promising results^[67].

Figure 2 Estrogens and growth factor signaling in breast cancer. Mitogenic signals from estrogens and growth factors activate PI3K/AKT-Ras-Erk pathway to target estrogen receptor (ER). The phosphorylation cascade promotes ER activation. The receptor is recruited to a transcription factor (TF) that binds to responsive elements on DNA for the corresponding transcriptional responses. Antagonistic actions of tamoxifen on ER are shown. Psoralens may act by inhibiting aromatase enzyme, metalloproteinases (MMPs) and CYP enzymes. They address antagonistic effects on PI3K/AKT survival signals and apoptotic response with the involvement of p53 and p21 waf. Estrogens also bind the GPER, a member of the seven-transmembrane G protein-coupled receptor family, to trigger proliferative responses.

Targeting multiple pathways simultaneously may help to kill cancer cells and onset of slow drug resistance. In addition, the association of chemotherapy or radiotherapy with pure or synthetic analogs of phytochemical drugs may take advantage of the synergic effects of the combined protocols, resulting in the possibility of lower doses, consequently reducing toxicity. An overall view of the main signal transductions active in breast cancer is shown in Figure 2.

PSORALENS AND BREAST CANCER

Breast cancer signals and psoralen influence

A large number of epidemiological studies suggest that a daily intake of phytochemicals can reduce the incidence of several types of cancers, including breast tumors^[68-71]. Moreover, genetic variation in pathways affecting absorption, metabolism and distribution of these natural substances can influence exposure at the tissue level, thus modifying disease risk in individuals^[72,73].

The increasing research on this has revealed that the antiproliferative action of psoralens in many tumoral cells, as well as in breast carcinoma, is not only due to

their photoactivation, but that these molecules exert their responses even in the absence of radiation. The biological activities in target tissues have been related to the binding of psoralens with specific receptor proteins identified in cytoplasmic and membrane fractions of responsive cells. Binding of psoralens to these proteins is of high affinity and reversible^[74]. Coumarins and coumarin-related compounds have been reported to possess significant growth inhibitory activities in *in vivo* models and against a panel of breast cancer cell lines, in which the structure-activity relationships has also been evaluated^[75-77].

Until a few years ago, the transductional pathways activated by psoralens in target cells were not well known; however, the growing interest on this aspect led to the identification of main signals by which the anti-tumoral action is exerted. Moreover, in our first study^[78] it was demonstrated that bergapten "*per se*" without photoactivation was able to influence transductional pathways mainly involved in the regulation of cell survival in two hormone-dependent and hormone-independent human mammary tumoral cell lines, expression of the two biological variants of breast cancer respectively, MCF-7 and SKBR-3. The psoralen induced growth inhibition and

Figure 3 Bergapten affects estrogen receptor stability in breast cancer cells. Mechanism through bergapten (B) in breast cancer cells induces the polyubiquitination (Ub) of estrogen receptor (ER) with the involvement of transforming growth factor- β /SMAD4 protein. Immunoprecipitation assay performed in MCF-7 cells revealed that ER/SMAD4 and polyubiquitin are co-associated. The psoralen enhances the amount of SMAD4 and Poly-Ub complexed to ER, thereby regulating breast cancer cell progression^[87].

apoptosis through the up-regulation of the cyclin inhibitor p21 waf and p53 mRNA and proteins. The molecular study addressed how bergapten transactivated p53 gene promoter through the involvement of the NF- κ B transcriptional factor and the p38 MAPK activation.

Besides this, in hormone-dependent MCF-7 cells, the psoralen counteracted the stimulatory effects of two important mitogenic factors, estradiol and IGF-I on the PI3 kinase/Akt survival pathway.

Similarly, in the presence of photoactivation, bergapten preferentially addressed apoptosis at lower doses than those reported in the previous paper, as revealed by the increase of p53, caspase activation and DNA ladder, while in the absence of UV, the psoralen significantly reduced the p-Akt survival signal^[79]. In estrogen-receptor positive breast cancer cells, as previously mentioned, estradiol exerts its main role supporting the proliferation and growth of mammary tissue.

Aromatase is the enzyme responsible for the conversion of androgens into estrogens and synthetic aromatase inhibitors, such as letrozole, anastrozole and exemestane, have proven to be effective in endocrine regimens for ER-positive breast cancer. Together with these molecules, several flavones have also been demonstrated to be effective inhibitors of aromatase and NADPH-quinone reduc-

tase 1 and 2 both play an important role on breast carcinogenesis. Among the coumarin-derived compounds, the 4-benzyl-3-(4'-chlorophenyl)-7-methoxycoumarin has been shown to be a potent aromatase inhibitor. The structure-activity studies have evidenced that the three functional groups of the coumarin [the 3-(4'-chlorophenyl), 4-benzyl, and 7-methoxyl groups] are important for its ability to inhibit aromatase^[72,80] and not only this (Figure 2). The realization that, in addition to the formation of estrogens by the aromatase pathway, steroids with estrogenic properties could also be formed *via* a sulfatase route has stimulated the interest of other authors in developing potent steroid sulfatase (STS) inhibitors. The furanocoumarins have proved to be successful steroid sulfatase inhibitors once tested in breast cancer cells and for this they may be useful in suppressing estrogen-dependent breast tumors^[72,81,82]. The development and testing of both aromatase and sulfatase inhibitors are in progress and should resolve the question as to whether inhibition of only aromatase or sulfatase is superior to inhibition of only aromatase or STS activity when used for the treatment of hormone-dependent breast cancer.

Several observations have also documented the interplay between E2/ER and growth factor signals such as the TGF- β -dependent pathway. Indeed, it has been

evidenced that ER- α is able to physically interact with components of the latter pathway, SMAD2, SMAD3 and SMAD4, and to abrogate TGF- β signaling cascade^[83,84]. On the other hand, while TGF- β signaling has been demonstrated to stimulate ER- α transcriptional activity, the complex of SMAD3 and SMAD4 inhibits its activity^[85,86]. Analogously, treatment of breast cancer-sensitive and tamoxifen-resistant cells with bergapten induced a depletion of ER protein through a degradative process that sees the involvement of the SMAD4 protein^[87] (Figure 3).

This study once again draws attention to the anti-tumoral properties of psoralen and highlights a new molecular mechanism through which bergapten may prevent the crosstalk between the receptor and growth factor mitogenic signaling by affecting ER- α stability in breast cancer tamoxifen-sensitive and resistant cells. However, in a recent paper^[88], it was demonstrated well that psoralen can also affect the Erb2 receptor tyrosine kinase whose over-expression, as previously reported, characterizes the most aggressive forms of breast cancer.

Independently of interstrand DNA crosslinks, the photo-activated 8-MOP interacts with the Erb2 catalytic autokinase domain, blocking its activity, and furthermore, it can reverse therapeutic resistance by triggering tumor cell apoptosis.

Psoralen action on pro-metastatic and detoxification enzymes

A further negative aspect of estrogens is to promote the migration and motility of breast cancer cells, as demonstrated in an “*in vitro*” assay, and in fact, they increase the closure of wounded confluent culture. This phenomenon is dependent on the expression of ER, because antiestrogens completely abolish the migratory potency of estrogens^[89]. A number of proteolytic enzymes participate in the degradation of environmental barriers, such as the cell-extracellular matrix (ECM) and basement membrane. Matrix metalloproteinases (MMPs), a family of zinc-dependent endopeptidases, play an important role in the proteolysis of ECM components, thus supporting metastatic and angiogenetic processes^[90-92].

Agents able to suppress MMP signaling are useful to target cancer metastasis. Some natural products have been demonstrated to play a remarkable role in inhibiting MMP enzymes in breast and other type of cancers^[93-97].

The antimetastatic activity of furanocoumarin bergamottin has been described in human fibrosarcoma HT-1080 cells and in MCF-7 breast cancer cells where the compound suppresses MMP-9 gene expression by repressing the transcriptional activation in the MMP-9 promoter. The results obtained in this study evidenced that the furanocoumarin inhibited PMA or TNF- α -induced activation of MMP-9 by suppressing NF- κ B activation in tumoral cells^[98].

Considering that psoralen influences bone metabolism and that breast cancer frequently metastasizes to the skeleton, one study^[99] investigated whether it can affect this process *in vivo*. Histological, molecular, biological

and imaging analyses revealed that psoralen inhibits bone metastasis; in fact, it regulated the function of osteoblasts and osteoclasts in tumor-bearing mice. Accordingly, the authors suggest the possible therapeutic role of the drug for metastatic breast cancer.

In addition to the above mentioned effects, the furanocoumarin bergamottin has also been described to inhibit members of the family of CYP enzymes (cytochrome P450s) involved in the metabolism of many xenobiotics and drugs. It is well established that tumorigenesis is closely linked to the metabolism of pro-carcinogenic substances, which when subjected to biotransformation into the cells become dangerous for the body. Certain linear furanocoumarins (*e.g.*, bergamottin, imperatorin, isopimpinellin) and a simple coumarin (osthuthin) were found to inhibit cytochrome P450 and to reduce the formation of DNA adducts induced by benzo[a]pyrene and 7,12-dimethylbenz[a]anthracene^[24,100-103]. This evidence has encouraged more studies in which five new tetracyclic benzofurocoumarins were synthesized and then tested in three different human tumor cell lines: MDA MB 231 (breast adenocarcinoma), HeLa (cervix adenocarcinoma) and TCC-SUP (bladder transitional cell carcinoma). All of them significantly inhibited cell proliferation and this was mainly linked with the inhibition of CYP2A6 enzyme, belonging to the family of CYPs. The effectiveness of the drugs is related to the chelation of the oxygen from the furan ring with the iron from the heme, possibly resulting in the inactivation of the enzyme, and this might be one of the main causes that preclude tumor cell proliferation^[104].

CONCLUSION

Currently, there is a great scientific interest towards natural anticancer drugs due to their multiple target activities on tumoral cells. As reported here, from the early studies on the activity of psoralens, much has now been documented, especially with regards to their mechanism of action at the molecular level.

The anti-tumoral activity of these molecules against breast cancer has been the main point reported in this review. Many intracellular signals that maintain high survival of breast cancer cells are selectively affected by these drugs. Starting from the latest experimental investigations, it appears that even the most aggressive and resistant cell phenotypes are responsive to psoralens since they antagonize metabolic pathways, protease enzymes, cell cycle progression and even interfere in the crosstalk between receptors and growth factor mitogenic signaling. The combination of natural products with the traditional chemotherapeutic agents, with the purpose of using low doses, can be well addressed and may be a new opportunity for the treatment of breast tumors, thereby decreasing the side effects at the systemic level.
