Abstract

Phytoestrogens have multiple actions within target cells, including the epigenome, which could be beneficial to the development and progression of breast cancer. In this brief review the action of phytoestrogens on oestrogen receptors, cell signalling pathways, regulation of the cell cycle, apoptosis, steroid synthesis and epigenetic events in relation to breast cancer are discussed. Phytoestrogens can bind weakly to oestrogen receptors (ERs) and some have a preferential affinity for ER β which can inhibit the transcriptional growth-promoting activity of ER α . However only saturating doses of phytoestrogens, stimulating both ER α and β , exert growth inhibitory effects. Such effects on growth may be through phytoestrogens inhibiting cell signalling pathways. Phytoestrogens have also been shown to inhibit cyclin D1 expression but increase the expression of cyclin-dependent kinase inhibitors (p21 and p27) and the tumour suppressor gene p53. Again these effects are only observed at high (> 10) μ mol/L doses of phytoestrogens. Finally the effects of phytoestrogens on breast cancer may be mediated by their ability to

inhibit local oestrogen synthesis and induce epigenetic changes. There are, though, difficulties in reconciling epidemiological and experimental data due to the fact experimental doses, both *in vivo* and *in vitro*, far exceed the circulating concentrations of "free" unbound phytoestrogens measured in women on a high phytoestrogen diet or those taking phytoestrogen supplements.

INTRODUCTION

Phytoestrogens are naturally occurring plant compounds which are structurally similar to oestrogens and can have weak oestrogenic actions. There are six major classes

Table 1 Major classes of phytoestrogens and their common dietary sources

Flavonoids	Isoflavonoids	Lignans	Coumestans	Stilbenes
Apigenin Quercetin Narigenin Catechins Red/yellow fruits and vegetables, tea	Genistein Biochanin A Daidzein → equol Soy beans, soy foods, vegetables	Enterodiol Enterolactone Flaxseed, whole grains, fruit, vegetables	Coumesterol Peas, beans, alfafa, sunflower seeds	Resveratrol Red wine

of phytoestrogens, all of which have distinct common dietary sources (Table 1) but the most intensively investigated phytoestrogens are the isoflavones and the stilbene, resveratrol. The link between breast cancer and phytoestrogens arose from the early epidemiological evidence showing that the incidence of breast cancer is lower in Asian populations who consume high dietary concentrations of soy products which have a high isoflavonone content^[1,2]. This fuelled the widespread belief that consumption of soy foods reduces the risk of breast cancer and other hormone dependent cancers and led to further research on the protective effects of many other phytoestrogens^[3,4].

However reconciling experimental evidence, mainly based on high supraphysiological doses of single phytoestrogens, coupled with the limited bioavailability of orally consumed phytoestrogens has raised questions and concerns about the validity of promoting the health benefits of diets rich in phytoestrogens and/or taking dietary supplements^[5-7]. Furthermore phytoestrogens exert a plethora of actions beyond weak oestrogenic effects (Figure 1) and these include antagonist effects oestrogen receptors (ERs), modulation of cell signalling pathways, regulation of the cell cycle, enzyme inhibition, anti-oxidant properties, angiogenesis and epigenetic alterations^[8]. This review will focus on the action of phytoestrogens on oestrogen receptors and cell signalling pathways, their regulation of the cell cycle and apoptosis, inhibition of steroidogenic enzymes and induced epigenetic changes.

DIETARY INTAKE, METABOLISM AND BIOAVAILABILITY OF PHYTOESTROGENS

In foods phytoestrogens are present as mixtures and are usually found as biologically inactive glycoside conjugates containing glucose or carbohydrate moieties. Blood levels can vary widely between individuals depending both on dietary preferences as well the phytoestrogen content of a particular food product resulting from local and/or seasonal variations^[9]. For example Asian diets can result in isoflavone consumption as high as 50 mg/d compared with 1-3 mg/d for individuals eating a typical Western diet although a vegetarian diet or use of supplements can increase dietary intake to levels of an Asian diet^[10-12] and references therein.

In the gut phytoestrogens are broken down by glucosidases to their respective aglycones allowing more effi-

cient absorption, although intestinal bacteria may further metabolise these products. For example the phytoestrogens genistein and daidzein, can be further metabolised to *p*-ethyl phenol and to equol and/or *O*-desmethyldanglensin (*O*-DMA) respectively though it should be noted that only 30%-50% of the population can produce equol and approximately 80%-90% *O*-DMA^[10,13]. Thus not only will dietary factors contribute to phytoestrogen intake but also individual variations in metabolism.

Once absorbed the aglycone phytoestrogens are rapidly conjugated to glucuronic acid and to a lesser extent sulphuric acid in the hepatic circulation. They are then de-conjugated prior to excretion with urinary concentrations increasing in parallel to consumption^[14]. There is generally very low levels of biologically active 'free' unconjugated phytoestrogens in the circulation (< 3% of the total) and blood levels are in the ng/mL range or lower^[10,15]. One may then argue what is the relevance of *in vitro* studies showing that only high micromolar doses of unconjugated phytoestrogens can inhibit the growth the breast cancer cells, inhibit oestrogen-dependent gene transcription or inhibit cell signalling pathways?^[16,17]. Similarly *in vivo* studies have only shown that dietary supplements far in excess of those consumed with an Asian diet had any effect on inhibiting experimentally-induced tumour growth and even this data is conflicting^[16,18,19] and references therein.

PHYTOESTROGENS, OESTROGEN RECEPTORS AND CELL SIGNALLING PATHWAYS

Two major oestrogen receptors (ERs) have been identified, ER α and ER β , which are encoded by separate genes and have different tissue distributions and roles in gene regulation^[20]. They also have differential effects in oestrogen-sensitive tissue and in breast tissue ER α activation can stimulate proliferation whilst ER β activation can counteract this proliferative effect. This is thought to be mediated by dimerization of ER β with ER α ^[20,21]. In breast tumours the ratio of ER α to ER β is raised and tumour aggressiveness is increased in those that are ER β negative^[21].

The relative binding affinity (RBA) of phytoestrogens to ERs is weak and are in the order of 1000-10000 times less than that of oestradiol although some phytoestrogens

Figure 1 Multiple targets for the action of phytoestrogens.

such as genistein, coumestrol and apigenin have a higher affinity for ER's and their RBAs are in the order of only 10-100 times that of oestradiol^[22]. Interestingly several phytoestrogens such as genistein, daidzein and apigenin have a 9-10 fold increased affinity for ER β than ER α ^[22] and a more recent study showed that after dietary supplementation total genistein and daidzein concentrations were 20-40 fold higher than oestradiol equivalents in breast adipose/glandular tissue^[23]. Thus their ability to preferentially activate ER β and their ability to accumulate in breast tissue may have some clinical significance. That said, the concentrations required to induce apoptosis or at least inhibit cell growth arrest are induced only by over-saturating doses ($\geq 10 \mu\text{mol/L}$) doses of phytoestrogens^[16].

However, phytoestrogens can also act on cell surface oestrogen receptors or interact with growth factor and cytokine signalling pathways (Figure 2). Thus phytoestrogens can modulate the responses to growth factors or activate/inhibit kinases which may alter ligand-independent transcriptional activity of oestrogen receptors or other transcription factors such as AP-1 and NF- κ B^[24]. For example genistein is a tyrosine kinase inhibitor and has been shown to alter the activity/expression of both extracellular regulated kinase (ERK) and the PI-3/Akt pathway as have other phytoestrogens including resveratrol^[25,26]. Long-term treatment of breast cancer cells with dietary levels of genistein (10^{-8} mol/L) have also been shown to down-regulate the expression of Akt^[27]. In context of the growth-repressing effect of ER β and cell signalling, a recent study showed that activation of the MEK 1/2 and PI-3K/Akt pathways inhibited the ER β growth-mediated repression in breast cancer cells^[28]. Thus down regulation of these pathways by long-term dietary phytoestrogens could promote the effectiveness of ER β activation and inhibit proliferation.

PHYTOESTROGENS AS REGULATORS OF THE CELL CYCLE AND APOPTOSIS

Recently much attention has focussed on the action of

phytoestrogens in regulating the expression of proteins regulating the cell cycle and apoptosis (Figure 2). Cyclins are a family of proteins which regulate transition of the cell cycle through the G₁, S, G₂ and metaphase (M) phases and, through coalescing with cyclin-dependent kinases (CDKs), they initiate gene transcription controlling regulation of the cell cycle. Cyclin D1, which regulates the G₁ to S phase of the cell cycle, is the most widely investigated being established as an oncogene and over-expressed in more than 50% breast cancers^[29]. The majority of studies have shown that high concentrations of phytoestrogens ($\geq 10 \mu\text{mol/L}$ range) inhibit the expression of cyclin D1^[30-32] although another study reported a transient increase mimicking the effects of oestradiol^[33] and other studies reported no effects^[34,35].

The activity of cyclin/CDK complexes is regulated by CDK inhibitors (CDIs) and thus these proteins can inhibit the cell cycle^[36,37]. The two most widely investigated CDIs are p21^(CIP1/WAF1) and p27^(Kip1) and the expression of p21 is controlled by the tumour suppressor gene p53^[38] which has many other actions as a tumour suppressor including inducing apoptosis^[39]. High doses of phytoestrogens have been shown to increase the expression/activity of p21, p27 and p53^[33,35,40-43] which parallel changes in the reduction of cyclin D1. Such effects have been seen with high doses of phytoestrogens but a microarray analysis showed that low levels of genistein (1 and 5 $\mu\text{mol/L}$) that stimulated growth of MCF-7 cells had no effect on the expression of p53 target genes such as p21^(CIP1/WAF1) and only at a higher pharmacological dose of genistein (25 $\mu\text{mol/L}$) cell growth was inhibited and increased the expression of p53 target genes. This would result in increased apoptosis and decreased proliferation^[44].

The pro-apoptotic protein, Bax, is regulated positively by p53 whilst the anti-apoptotic protein, Bcl-2, is negatively regulated by p53^[45]. Both *in vivo*^[46-48] and *in vitro* studies^[33,49-52] have shown that phytoestrogens can stimulate apoptosis and increase the Bax/Bcl-2 ratio but evidence as to whether this effect is due to increased or decreased activity of ERK1/2 is controversial^[49-52].

Figure 2 Different ways in which phytoestrogens may alter gene transcription. (1) Acting as an oestrogen agonist/antagonist and the transcriptional activity of oestrogen receptors; (2) Modulating cell signalling pathways which can be activated by cell surface oestrogen receptors or growth factor receptors and ultimately activate gene transcription by activating oestrogen receptors or other transcription factors (TF); (3) Inhibiting/stimulating transcription of genes regulating apoptosis and the cell cycle; and (4) Epigenetic alterations in DNA, histone proteins and RNA to alter transcription/translation of proteins.

PHYTOESTROGENS AS INHIBITORS OF OESTROGEN SYNTHESIS

Low doses of phytoestrogens are generally found to stimulate growth of breast cancer cells with only high supraphysiological doses inhibiting growth and with evidence that they regulate the expression of proteins involved in controlling the cell cycle and apoptosis as opposed to their action as weak oestrogen agonists/antagonists at ER α and ER β . There is, however, evidence that phytoestrogens can also inhibit steroid synthesis and this may be particularly significant in relation to the local production of oestrogens in breast tissue^[53] and references therein. Fatty tissues are a major storage site for phytoestrogens^[13] and the most abundant cells surrounding breast cancer cells are mature adipocytes and progenitors which may be a key component of breast cancer progression by locally affecting breast cancer cell behaviour^[54].

Approximately 60%-70% breast cancers express oestrogen receptors and these are considered to promote tumour growth. Hence initial treatments are directed towards reducing oestrogenic effects by inhibitors of oestrogen receptors and inhibitors of aromatase which converts androgens to active oestrogens^[55]. The incidence of breast cancer increases with age despite the loss of ovarian hormones in post-menopausal women. Peripheral tissue can convert circulating androgens (dehydroepiandrosterone/DHEA) and oestrone sulphate into 17 β -oestradiol (E₂) and in post-menopausal women with breast cancer concentrations of E₂ in the tumour is at least 20-fold higher than in the circulation^[56].

Flavones and isoflavones are the most potent phytoestrogens that inhibit aromatase and the IC₅₀ values are in

the order of 0.1-10 μ mol/L which is more than 100 times higher than the IC₅₀ value for the steroidal inhibitor, 4-hydroxyandrostendione^[53,57]. Isoflavones are generally weak inhibitors of aromatase but like other phytoestrogens can inhibit 17 β -hydroxysteroid dehydrogenase (HSD) type 1 which reduces oestrone (E₁) to E₂ and 17 β -HSD type 5 that converts androstenedione to testosterone, which can subsequently be converted to E₂ by aromatase^[53] and references therein. More recently certain phytoestrogens have been shown to alter the activation of breast cancer-associated aromatase promoters^[58]. Overall, however, the inhibition of these enzymes by unconjugated phytoestrogens are in the order of 1-10 μ mol/L whilst total circulating phytoestrogens are in the low nanomolar range except in vegetarians or those eating a high soy diet where concentrations of 100 nM to 1 μ mol/L may be achieved^[59]. Thus there is another discrepancy between experimental results and levels of phytoestrogens achieved by dietary means. However our study on human granulosa cells showed that low dose mixtures of three isoflavones in the nM range inhibited expression and activity of aromatase though a similar inhibition was only achieved with a single phytoestrogen at 100 times the dosage^[60]. Further studies are required to investigate mixtures of phytoestrogens as occurs through dietary means.

EPIGENETIC MODULATION BY PHYTOESTROGENS

Over the last decade there has been an explosion in the number of studies concerning epigenetic changes and the development and progression of breast cancer^[61] and not surprisingly these have included studies on the ability

of phytoestrogens to alter the epigenome which could be useful in the prevention of cancer^[61-63]. In fact studies have indicated that early childhood exposure to phytoestrogens could protect against breast cancer in later life^[62] and references therein and this could involve epigenetic events (Figure 2). Epigenetic changes are defined as heritable changes in gene expression which do not involve mutations of DNA nucleotide sequences. They include DNA methylation, histone acetylation and microRNAs (miRNAs).

DNA methylation occurs on cytosine in the cytosine-phosphate-guanine (CpG) dinucleotide sequence of genomic DNA, a reaction catalysed by DNA methyl transferases (DNMTs). CpG dinucleotide rich regions (known as CpG islands) are found in the promoter region of approximately 60% of all human genes and, whilst most CpG islands are unmethylated in normal cells, they become hypermethylated in cancerous cells leading to gene suppression, including the tumour-suppressing genes^[61]. Along with DNMTs are the methyl-CpG-binding domain family of proteins which bind to a methylated gene and can inhibit transcriptional activity by altering chromatin structure. Chromatin structure can also be modified by histone acetylation which is catalysed by histone acetylase (HAT) and results in a more open structure of chromatin allowing access for transcription factors to DNA. The reverse occurs when histone proteins become deacetylated and this reaction is catalysed by histone deacetylases (HDACs). Histones may also be methylated by histone methyl transferases (HMT's) and generally methylation causes gene transcription to be switched off. The most recent participant of the epigenetic field are the miRNAs, small non-coding RNAs that inhibit protein expression of target genes by binding to the 3'-untranslated region of mRNA causing degradation or inhibition of mRNA of the target gene^[61,62] and references therein.

The most widely studied dietary components in relation to epigenetic changes are the tea polyphenols, epicatechins and epigallocatechins (EGCCs), the isoflavones, genistein and diadzein, resveratrol and curcumin and all have been well reviewed recently^[63-66]. Relatively few studies have been directed towards epigenetic changes in breast cancer models and results have been inconclusive^[61,62].

Recent studies have shown that 20-40 µmol/L genistein stimulated expression of the tumour suppressing genes, *p21^{WAF1}* and *p16^{INK4a}*, in breast cancer cells and that this was associated with a small reduction in the activity of HDACs but a large increase in the activity of HMTs^[67]. The same group also showed that genistein can reactivate ERα expression in ER^{ve} breast cancer cells and that this effect was associated with increased markers of histone acetylation in the ERα promoter region and decreased activity of HDAC and DNMT^[68]. Another study showed that µmol/L doses of genistein and diadzein "might reverse" DNA hypermethylation in breast cancer cells thus restoring expression of the oncosuppressor genes BRCA1 and BRCA2^[69]. In biopsies of human

breast tissue specific DNMT transcripts were increased in cells taken from the tumourous tissue compared to adjacent normal breast tissue and parallel studies showed that treatment of breast cancer cells lines with genistein, resveratrol, curcumin and EGCC also reduced the mRNA of the same DNMTs^[70]. Whilst all these studies have been performed acutely with high doses of single phytoestrogens, we showed that long-term treatment with 10 nmol/L genistein down-regulated the expression of acetylated histone3, cyclin D1 and procaspase 9 and reduced the growth promoting effects of E2 and epidermal growth factor^[71].

It is clear that both nutrition and exposure to phytoestrogens and other phytochemicals can have dramatic effects on epigenetic events and that these may become heritable through transgenerational mechanisms. Thus their impact on both disease and the health of future generations needs to be carefully considered.

CONCLUSION

Phytoestrogens have multiple targets within cells and whilst acute studies with supraphysiological doses of these compounds indicate that they may inhibit the development and progression of breast cancer, lower doses have been shown to promote the growth of breast cancer cells *in vitro* and experimentally induced tumours *in vivo*. More studies utilizing long-term exposure to lower doses and mixtures of phytoestrogens are required to demonstrate unequivocally that dietary supplements do have beneficial rather than detrimental effects on breast cancer. However their multiple targets in breast cancer cells and their ability to modulate epigenetic events associated with breast cancer and prevention may lead to new, non-toxic therapeutic approaches through development of highly specific and long-acting analogues of phytoestrogens.

Abstract

Alcohol consumption is associated with an increased risk of breast cancer, increasing linearly even with a moderate consumption and irrespectively of the type of alcoholic beverage. It shows no dependency from other risk factors like menopausal status, oral contraceptives, hormone replacement therapy, or genetic history of breast cancer. The precise mechanism for the effect of drinking alcohol in mammary cancer promotion is still far from being established. Studies by our laboratory suggest that acetaldehyde produced *in situ* and accumulated in mammary tissue because of poor detoxicating mechanisms might play a role in mutational and promotional events. Additional studies indicated the production of reactive oxygen species accompanied of decreases in vitamin E and GSH contents and of glutathione transferase activity. The resulting oxidative stress might also play a relevant role in several stages of the carcinogenic process. There are reported in literature studies showing that plasmatic levels of

estrogens significantly increased after alcohol drinking and that the breast cancer risk is higher in receptor ER-positive individuals. Estrogens are known that they may produce breast cancer by actions on ER and also as chemical carcinogens, as a consequence of their oxidation leading to reactive metabolites. In this review we introduce our working hypothesis integrating the acetaldehyde and the oxidative stress effects with those involving increased estrogen levels. We also analyze potential preventive actions that might be accessible. There remains the fact that alcohol drinking is just one of the avoidable causes of breast cancer and that, at present, the suggested acceptable dose for prevention of this risk is of one drink per day.

Key words: Alcohol; Ethanol; Acetaldehyde; Free radicals; Mammary cancer; Oxidative stress; Estrogens; Polyphenols

Core tip: Excessive alcohol drinking of any type of alcoholic beverage is known to linearly increase the risk of breast cancer. The precise mechanism involved to produce this effect is still far from being established. In this review we introduce our present working hypothesis integrating the participation in cancer initiation and promotion of: *in situ* accumulation of the acetaldehyde metabolite, the local promotion of oxidative stress and the effects of the increased levels of estrogen occurring during alcohol drinking. Some potential preventive alternatives were also analyzed.

EPIDEMIOLOGY OF ALCOHOL DRINKING INDUCED BREAST CANCER

Alcohol drinking is causally related to an increased risk of cancer of the upper aero-digestive tract, liver, colorectum, and female breast^[1-4]. Of particular concern is the case of breast cancer promotion by chronic alcohol consumption. In effect, breast cancer is an extremely relevant cause of disease and death in women and alcohol intake is one of the few modifiable risk factors for breast cancer. The International Agency for Research on Cancer recently reported that by 2010 more than 100 epidemiological studies have evaluated the association between the consumption of alcoholic beverages and the risk of breast cancer^[4]. Further, combined analysis of data from 53 studies around the world showed a clear dose-response relationship between alcohol consumption and increased risk of breast cancer^[2]. This study showed 9% increase in risk per 10 g intake of alcohol per day. In fact, other recently epidemiological studies in a total of 1280296 middle-aged women in the United Kingdom reported that even drinking women consuming an average in only 10 g of alcohol (one drink) per day showed 12% increased risk of breast cancer^[1]. In addition, a detailed prospective study in 254870 women, made in eight European countries, reported that 5% of the female breast cancer was attributable to alcohol consumption^[5].

Unfortunately, there is limited information regarding a possible mechanism for this effect and about positive modulatory effects of dietary factors if alcohol drinking is not avoided. That issue was of particular interest in the studies made by our laboratory and by other workers^[6-9]. In this review we are going to describe our working hypothesis on the pathogenesis of alcohol drinking induced mammary cancer and its potential prevention.

ACETALDEHYDE FORMATION, ACCUMULATION AND EFFECTS

Despite the relevance of the problem, the mechanism for ethanol-increased risk of breast cancer remains unknown.

Several lines of evidence indicate that acetaldehyde, a product of alcohol metabolism, might play a role in alcohol-related carcinogenic effects in different target tissues^[10,11]. Animal experiments have clearly shown that acetaldehyde is an established mutagenic and carcinogenic chemical^[12-14]. In addition, other factors such as oxidative stress, altered methyl transfer, abnormal metabolism of vitamin A and retinoic acid and perturbed levels of hormones might be of particular relevance according to the target tissue involved^[3,8].

Concerning the specific case of mammary tissue, the knowledge of the acetaldehyde concentrations was of particular interest to our laboratory. In general terms, the concentration of acetaldehyde in any tissue, and also in the mammary, depends of its ability to produce it *in situ*, plus the additional arriving to the organ *via* blood supply

and in the capacity of the given organ to degrade it^[15].

The ability of mammary tissue to produce acetaldehyde *in situ* was studied in our laboratory. The available information was scarce to null at that time. Two different pathways of bioactivation of ethanol to acetaldehyde were reported by our laboratory to be present in the rat mammary tissue. One is in the cytosolic fraction and the other is in microsomes^[16,17]. Both were preliminary characterized and showed to be susceptible to inhibitory effects by chemicals present in food (this last subject will be analyzed ahead when discussing the preventive potential of findings).

The enzyme involved in the cytosolic pathway was evidenced to be xanthine oxidoreductase (XOR) because of its susceptibility to inhibitory effects of allopurinol and by the ability of the process to occur only when the presence of NAD⁺ was accompanied by substrates of the XOR form of the enzyme such as hypoxanthine, xanthine, caffeine, theobromine, theophylline or 1,7-dimethylxanthine^[16].

Moreover, it is also known that during acute alcohol intoxication, there is an increased purine degradation and hyperuricemia^[18,19]. The enhanced supply of purines resulting from this process could also provide an extra amount of cofactors for the XOR-mediated pathway of metabolism of ethanol to acetaldehyde (and also free radicals) in the mammary tissue.

The presence of XOR in mammary tissue is well known^[20,21], and past studies from our laboratory evidenced their presence in high amounts in the rat mammary tissue epithelial cells^[22]. Interestingly, the activity of this cytosolic pathway significantly increased after repetitive alcohol drinking through a Lieber and De Carli diet for 28 d^[22].

The contribution of enzymes present in cytosolic fraction of mammary tissue, other than XOR, to the activation of ethanol to acetaldehyde, for example, alcohol dehydrogenase (ADH) may be more limited. On one hand, previous studies^[23] showed that no ADH activity was found in homogenates of rat mammary tissue. More recently, our laboratory reported traces of ADH activity in the cytosolic fraction of mammary tissue that was about 16 times smaller than in the liver^[15]. By the other hand, Triano *et al.*^[24] reported that human mammary tissue contains a class of ADH having a limited potential to transform alcohol to acetaldehyde.

In addition to the mammary tissue cytosolic pathway of ethanol oxidation to acetaldehyde described above, our laboratory reported the presence of another one occurring in the microsomal fraction of that tissue^[17].

In our earlier studies of that pathway it was established that the enzymatic transformation involved was oxygen and NADPH-dependent, but that the cytochrome P450 was not involved because it was not inhibited by CO:O₂ (80:20 v/v) or by SFK525A^[17].

Interestingly, this microsomal transformation of alcohol to acetaldehyde was strongly inhibited by diphenyleneiodonium (DPI), sodium diethyldithiocarbamate, sodi-

Figure 1 Cooperative mechanism between NADPH oxidase and lipoxygenase in the oxidation of ethanol to acetaldehyde in microsomes.

um azide, nordihydroguaiaretic acid but not by dapsone, aminotriazole or indomethacin. Those results suggested us the potential participation in this biotransformation of an oxidase or a peroxidase but not of lactoperoxidase or cyclooxygenase^[17]. We were unable to detect the formation of either hydroxyl or 1-hydroxyethyl radicals in those studies. In the course of following studies performed at the opportunity in rats exposed to a standard Lieber and De Carli diet for 28 d, we observed the induction not only of XOR cytosolic activation pathways but also of the microsomal one^[22].

That was of particular significance, since we showed in the course of additional recent work that the enhancing effect is not due to the participation of CYP2E1 after chronic alcohol drinking as it is known for the liver microsomal fraction^[25].

Further, acetone, another inducer of microsomal CYP2E1-mediated alcohol metabolism in liver microsomes, failed to enhance ethanol bioactivation and CYP2E1 enzymatic activity in the microsomal rat mammary tissue^[25]. To ensure that CYP2E1 enzymatic activity in the microsomal rat mammary tissue was not present or was very low, we also included in those studies determination of chlorzoxazone hydroxylase activity. This activity was considered in literature as having a significant response to the presence of CYP2E1 in a given tissue^[25]. We were not able to detect CYP2E1-mediated metabolism of chlorzoxazone in the mammary tissue microsomal fraction despite the fact we employed a particularly sensitive procedure developed in our laboratory, where the formation of 6-hydroxychlorzoxazone metabolite could be determined by HPLC with coulometric detection^[25]. That further excluded the participation of CYP2E1 in this microsomal pathway of alcohol metabolism in the mammary tissue and encouraged us to challenge the possibility that a peroxidase or a lipoxygenase was involved in that process instead. That hypothesis was originally coined because of the potent inhibitory effect of nordihydroguaiaretic acid. This polyphenol is a known inhibitor of lipoxygenases^[26,27]. We also envisaged the possibility that the potent inhibitory effect of DPI could be suggesting the additional participation of a NADPH oxidase enzyme as a supplier of hydrogen peroxide. Under this view, the role of NADPH oxidase would be the generation of the necessary co-substrate required by lipoxygenase to exert its activity against xenobiotics^[8]. On behalf of this hypothesis is the fact that the specific inhibitory effect of DPI on NADPH oxidase is well established^[28]. That hypothesis visualizes the overall process of microsomal ethanol oxidation to acetaldehyde in rat mammary tissue as a cooperative mechanism between NADPH oxidase and lipoxygenase (Figure 1).

The concentration of acetaldehyde in different tissues

depends on the production and degradation of acetaldehyde and on the amount of it arriving to the given tissue *via* blood supply. In a detailed study from our laboratory, we attempted to evaluate how much acetaldehyde accumulates in mammary tissue after single doses of ethanol and also the levels of it arriving *via* blood at different periods of time. The studies were performed at three different dose levels (high, medium and low). Values were compared with the equivalent occurring in liver^[15].

The levels of acetaldehyde in mammary tissue were higher than in plasma and lower than in liver for at least 15 h for the higher dose tested or six hours for the medium dose or two hours for the case of the lower one. The shape of the curve concentration of acetaldehyde in mammary tissue *vs* time after p.o. administration always mimicked that observed in liver. But, more important, the levels of acetaldehyde in plasma were similar for the three ethanol doses given^[15]. These results suggest that acetaldehyde present in the mammary tissue (and in the liver) reflects the balance between the ability of these tissues to generate acetaldehyde and the one to metabolize and excretes it. The liver is able to get rid of the acetaldehyde formed with the participation of aldehyde dehydrogenase (ALDH) and glutathione transferase (GST)^[19]. In the case of mammary tissue the situation appears to be different. On one hand, ADH activity is about 16 times smaller than in the liver, but perhaps more important, ALDH activity present in three subcellular fractions tested in our study were in all of them at least ten times smaller than in the liver^[15].

The overall conclusion of those results was that acetaldehyde is able to accumulate during significantly relevant periods of time in mammary tissue mainly as result of its ability to oxidize ethanol to acetaldehyde *in situ* and to a less important extent to the arrival of it *via* blood and produced elsewhere (for example, in the liver)^[15].

Which might be the expected consequences of acetaldehyde accumulation in a given tissue for long lasting periods of time?

It is important to point out that acetaldehyde is a reactive chemical that proved to be toxic, mutagenic and carcinogenic and able to interact with many cellular constituents, including DNA, proteins (nuclear proteins), lipids (including nuclear lipids), glutathione and others^[19,29,30].

The reactions of acetaldehyde with DNA are of particular concern because they clearly suggest that it acts as a tumor initiator and mutagenic compound. Structures of the identified DNA adducts of acetaldehyde were recently reviewed in literature^[31-33]. Representative structures are shown in Figure 2.

DNA adducts may cause polymerase errors and induce mutations in critical genes. Furthermore, they may lead to mutations that activate proto-oncogenes and inactivate tumor suppressor genes in replicating cells^[34,35].

Notwithstanding, there are known DNA repair enzymes that can modify DNA damage caused by acetaldehyde, removing its adducts from DNA. The relation between adducts formation and their repair would be relevant to molecular epidemiology of cancer, particularly

Figure 2 Structures of some of acetaldehyde-guanine adducts.

in replicating cells^[35].

It is of particular interest in this respect that studies by Freudenheim *et al.*^[36] reported results that were consistent with an increased likelihood of tumors with p53 mutations for pre-menopausal breast cancer with increased alcohol intake 10 or 20 years previous. For intakes of 16 or more drinks per month in the period of 20 years before the interview compared with non drinkers, the OR was 5.25 (95%, 1.48-18.58)^[36].

Acetaldehyde is also known to bind to proteins and amino acids and the subject might also be relevant to potential carcinogenic effects of alcohol drinking in different organs.

However, non specific studies related to breast cancer and alcohol drinking and the potential participation of acetaldehyde protein binding are available at present in literature. Notwithstanding, it is well known that acetaldehyde binds to reactive lysine residues, to some aromatic amino acids, cysteine, or to free alpha-amino groups, such as the terminal valine of hemoglobin. The subject was thoroughly reviewed by Niemela^[37], who also pointed the relevance of those interactions in different pathologies occurring in several tissues other than the breast.

In this respect, it might be relevant to take in consideration that acetaldehyde was shown to bind covalently to liver nuclear proteins^[30]. In the case of liver, the biotransformation of ethanol to acetaldehyde may occur not only in the cytoplasm or in the endoplasmic reticulum but also in the nearby outer nuclear membrane^[30,38]. Acetaldehyde, despite being a reactive molecule, does not have the equivalent reactivity to the one of a low molecular weight free radical (for example, trichloromethyl or 1-hydroxyethyl). This allows it to travel from cellular distant sites (cytoplasm or endoplasmic reticulum) to the nucleus and interact with DNA and nuclear proteins or lipids when acetaldehyde accumulates for long periods of time as those observed to occur in mammary tissue after alcohol drinking.

In the case of other liver carcinogenic chemicals, like carbon tetrachloride, a good correlation was observed between the covalent binding of its reactive metabolites to nuclear proteins and carcinogenicity. The interaction involved histone and non-histone proteins. Acidic and residual nuclear proteins were the favorite targets of that interaction and showed a good correlation between those

covalent interactions and carcinogenicity^[39].

In addition, is important to take in mind that ethanol is a well known inducer of CYP2E1-mediated metabolisms^[19] and that this enhancing effect was observed in the outer nuclear membrane of the liver^[40,41].

Far reaching consequences may also be expected from alterations in nuclear proteins resulting from an attack by acetaldehyde. In effect, it is known that nuclear proteins are critical for cell division, growth, differentiation and apoptosis^[42-44]. A clear example of relevant nuclear proteins is the one of those involved in the cell cycle clock. They include cyclins, cyclin-dependent kinases; protein coded by proto-oncogenes and tumor suppressor genes (such as the myc and Bcl proteins or the pRB or p53 and others); enzymes required for DNA synthesis and for DNA repair^[45,46].

Critical evidence that some of these activities may be affected by acetaldehyde produced during ethanol consumption was provided by several authors, who showed that chronic ethanol consumption results in inhibition of the DNA alkylation repair by O⁶-methylguanine transferase (O⁶-MeGT), which removes alkyl groups from the O⁶-position of guanine. Acetaldehyde has been shown to inhibit O⁶-MeGT^[10,47-49]. Further, exposure to ethanol was reported in recent studies to interfere with the cell division machinery by perturbing the key G2 cycling protein^[50].

Concerning the covalent binding to nuclear lipids, it should be noted that all lipid fractions were involved in our studies performed in the case of liver. Part of the covalent binding was acid labile, but a significant part was not. The labile portion might be attributable to the presence of Schiff base adducts of acetaldehyde with amino groups from phospholipids^[30]. In effect, previous studies from other laboratories reported that amino-containing phospholipids like phosphatidylserine and phosphatidylethanolamine formed Schiff base adducts^[51,52].

The fraction of covalent binding resistant to acid hydrolysis might be attributed in part to addition reactions of 1-hydroxyethyl on unsaturated fatty acid double bonds or on cholesterol moieties and on nitrogen-containing phospholipids. That behavior was previously reported for the case of other carbon-centered free radicals, for example the trichloromethyl radicals^[53,54].

Another part of the covalent binding to lipids resistant to mild acid media might also be attributed to the

formation of ethyl esters of fatty acids. It is known that liver microsomes and cytosol contain enzyme systems able to esterify free fatty acids or transesterify other esters to ethyl esters^[55-57]. Whether nuclear preparations from mammary tissue have similar ability remains to be established. Irrespectively of the present lack of knowledge about the structure of the reaction products formed, it is not unexpected to envisage that the alteration of nuclear membranes by their reaction with either acetaldehyde or 1-hydroxyethyl or resulting from ester formation with ethanol, might lead to profound alterations in liver nuclear functions. It is well established that ethanol also strikingly alters other liver membranes and their fluidity^[58]. It is known that nuclear lipids may be part of an intracellular signaling system modulating protein kinase C, an enzyme involved in phosphorylation of nuclear proteins^[59]. The covalent binding to nuclear phospholipids deserves special interest since they have a known ability to regulate gene function, nucleosome structure, RNA synthesis and activation of DNA polymerase alpha^[59-65]. Past studies from the laboratory reported correlations between alterations in nuclear lipids resulting from a free radical attack and the different response of the rat strains employed to the carcinogenic effects of CCl₄^[54].

FREE RADICALS, OXIDATIVE STRESS AND EFFECTS

Oxidative stress was also considered to be a potential factor involved in the alcohol drinking promoted carcinogenic effect on mammary tissue. Notwithstanding this, no evidence of its occurrence in mammary tissue were reported until our recent studies where we showed that oxidative stress can be observed in this tissue after an experimental protocol of 28 d of alcohol drinking through the Lieber and De Carli diet^[15,22,25]. It is relevant at this point to have present what "oxidative stress" is all about. Oxidative stress has been defined as an imbalance between oxidants and antioxidants in favor of the former, resulting in an overall increase in cellular levels of reactive oxygen species (ROS). Many pathways play a role in how ethanol induces oxidative stress in the liver (the issue has exercised the interest of numerous researches for years) and is reviewed in Cederbaum *et al.*^[66]. Ethanol-induced oxidative stress in the liver included the ability to generate free radicals able to initiate the process (for example, 1-hydroxyethyl and hydroxyl radicals) and formation of hydroperoxides, peroxides, superoxide, H₂O₂ and other. In the case of liver exposed to alcohol, the evidence included the formation of products derived from the attack of ROS to relevant target molecules (for example, DNA, proteins or lipids) like 8-oxodeoxyguanosine, protein carbonyls, decreases in protein sulfhydryls, lipid hydroperoxides and other products such as malondialdehyde or 4-hydroxy-2-nonenal (4HNE)^[66].

The evidence that cellular antioxidant defenses were overwhelmed might include determinations of the variety of enzymatic and non-enzymatic mechanisms that have

evolved to protect cells against ROS such as superoxide dismutase, catalase, glutathione peroxidase, GST and other enzymes. Also are relevant low molecular weight antioxidants, such as glutathione itself, vitamin E, ascorbate, vitamin A and others. In summary, toxicity induced by ROS reflects the balance between the rates of production of ROS compared to the rates of removal of ROS plus repair of damage to cellular macromolecules^[66].

After these introductory remarks learnt from free radical cell injury and from the effects of alcohol on liver, let us to introduce what kind of evidence we obtained for the case of mammary tissue.

Initially we began to consider the possibility that during alcohol drinking an oxidative stress process occurred in mammary tissue because in our hands repetitive alcohol drinking exposure led to increased XOR and lipoxygenase activities in the rat mammary tissue^[22]. In effect, increased XOR and lipoxygenase activities by themselves would lead to not only higher generation of ROS, but also when occurring in the presence of ethanol, to increased generation of free radicals. The formation of hydroxyl radicals was detected during XOR mediated cytosolic alcohol metabolism^[16].

Other reason leading to a similar potential effect was derived from our observation that acetaldehyde accumulates in mammary tissue during repetitive alcohol drinking^[15]. It is well known that the generation of increased level of acetaldehyde may provoke decreases in GSH as it was respectively observed in liver^[66]. Further, GSH and GSH-dependent enzymes such as glutathione peroxidase, glutathione reductase and glutathione transferase are a vital first line defense against oxidative stressful conditions^[66].

The initial observation indicating that alcohol drinking could provoke oxidative stress that we obtained was derived from our studies in the *t*-butylhydroperoxide-induced chemiluminescence in mammary tissue homogenates from rats exposed to repetitive alcohol drinking when compared to those from control animals^[15].

The samples from alcohol treated animals had a completely different response to the *t*-butylhydroperoxide challenge and the shape of their response curve compared to that observed in the control samples clearly suggested that animals exposed to alcohol have diminished defenses against *t*-butylhydroperoxide challenge^[15]. However, that experiment did not give indication about the nature of the defensive process that was compromised. Further, it did not show which target molecule involved the potential oxidative process that was occurring.

To answer those questions, other studies were performed and we found that after repetitive alcohol drinking, the levels of lipid hydroperoxides in mammary tissue were significantly increased. Further, the protein sulfhydryl and vitamin E content in the alcohol-treated animals decreased. However, in those experiments we did not observe protein carbonyl enhancement or increased formation of 8-hydroxyguanine^[22]. One reason to explain that different response to alcohol drinking-provoked oxidative stress might be that much longer periods of

Figure 3 Structures of adducts formed between DNA bases and (A) malondialdehyde or (B) 4-hydroxy-2-nonenal.

expose to alcohol could be necessary. That is in our work we were detecting early manifestations of alcohol drinking induced oxidative stress in mammary tissue.

If that was the case, after more prolonged periods of alcohol drinking, other relevant effects might occur derived from generation of harmful reactive aldehydes produced from lipid peroxidation such as malondialdehyde and 4HNE. They are able to react with proteins, lipids and with sulfhydryl-containing molecules of low molecular weight^[33,66]. See Figure 3 for their structures.

The reaction with sulfhydryl groups that we observed might be of significance considering that many sulfhydryl-containing enzymes play a key role in cell functioning and also in cell signaling processes^[67-70].

Free radicals not only are relevant in relation to the carcinogenesis initiation step. The progress of human breast cancer to the metastasis stage was linked to hydroxyl radical-induced DNA damage^[71].

These findings should be of some significance in light of the well established correlation between oxidative stress and tumor promotion and cancer^[72-74].

INCREASED LEVELS OF ESTROGENS AND CONSEQUENCES

Increased plasmatic levels of estrogen by alcohol drinking have been clearly demonstrated in controlled feed-

ing studies in human female volunteers^[75-84]. Further, the hypothesis about the role of estrogens in alcohol drinking-induced breast cancer is strongly supported by the fact that their higher risk was related to estrogen receptor ER-positive rather than to ER-negative mammary tumors^[85-88]. However, estrogens may exert their carcinogenic effects in mammary tissue not only *via* ER, but also by direct damage to DNA^[89]. Metabolic activation of estrogens to catechol-3,4-quinones is an example. These reactive metabolites are able to interact with DNA to give mutational events^[90-93]. Those increased levels of estrogen after alcohol drinking would arise because alcohol increases aromatase activity and that leads to enhanced conversion of testosterone to estrogen, resulting in decreased testosterone and increased estrogen level^[94].

These considerations might be of particular relevance, since there are available in literature clear evidences that high levels of estrogen in blood are associated with an increased risk of breast cancer^[94].

One major mechanism of action of estrogens is that by which estrogen stimulates cell proliferation through nuclear ER-mediated signaling pathways, thus resulting in an increased risk of genomic mutations during DNA replications^[95-97].

Another pathway involves estrogen metabolism that is mediated by cytochrome P450 1B1, which generates 2- and 4-catechol estrogens that easily autoxidize to the respective quinones, even without the need for enzymatic or metal ion catalysis^[98]. At this point it is particularly relevant to do mention that alcohol consumption was reported to significantly increase the rate of NADPH-dependent oxidative metabolism of estrogens to quinones in females. CYP1B1 had a distinct, selective activity for the 4-hydroxylation of estradiol and estrone^[99]. This inductive effect of alcohol drinking might increase chances of participation of cytochrome-mediated pathway in relation to other related to direct interactions of the estrogens with ER.

It is our idea that, under conditions where oxidative stress or peroxidizing conditions occur (like those reported by our laboratory to occur during exposure of mammary tissue to alcohol), the transformation of one to the other might be even further facilitated.

In addition, o-quinones are also potent redox-active compounds^[98,100]. For example, these quinones can be reductively detoxified by a quinone reductase in a two-electron transfer process^[101]. However, they can also undergo redox cycling with the semiquinone form of P450 reductase (a one-electron process) and generate superoxide radicals, that in the presence of iron or other transition metal give hydroxyl radicals^[100] (Figure 4).

By the other hand, the estrogen quinones can directly damage DNA leading to genotoxic effects^[102,103]. DNA adducts of estrogen quinones have been detected in the mammary glands of ACI rats treated with 4-hydroxyestradiol or its quinones^[103]. Further, recently developed highly sensitive LC/MS-MS procedures were used to analyze DNA from human breast tumors and their

Figure 4 Estrogen oxidation to reactive metabolites that bind to DNA to generate depurinating adducts.

adjacent tissue and the DNA adducts formed from estrogen quinones were detected^[104].

All these results suggest that these mechanisms might be relevant for the carcinogenic effects of estrogens by themselves. However, there is not available in literature evidence of their formation in mammary tissue from alcohol drinking animals or humans at present.

As part of our present working hypothesis about the contribution of estrogens in the alcohol drinking effects in mammary tissue, we assumed that these estrogen quinones might be formed (Figure 4). The reasons for that hypothesis are going to be described ahead and are related to some of our results.

It is relevant to understand our “views” about the cooperative effects between alcohol metabolism to acetaldehyde, its ability to promote oxidative stress and the participation of induced levels of estrogen in carcinogenic effects in mammary tissue to describe what happens with the catechol estrogens and the estrogen quinones after their formation.

The catechol estrogens may be further metabolized by O-methylation, by reaction with glutathione, and also by glucuronidation and sulfation^[105,106].

Interestingly, catechol estrogen metabolites display a less intense ER-mediated estrogenic activity, implying that catechol estrogens are attributed to have both, direct genotoxic effects as well as ER-mediated tumor promoter actions^[107]. Further, sulfate and glucuronide conjugates seem to play a role for free estrogens and, in general, it is at present a controversy about conjugation metabolism, if they may mitigate the catechol estrogen-mediated carcinogenic properties^[107].

Notwithstanding, being the conjugated estrogens more water-soluble they seemed to be more readily excreted than the lipophilic parent estrogens^[107]. These suggest that the conjugation pathway is considered as a protection mechanism against damage caused by reactive metabolites of estrogens^[105].

An important aspect of the mechanism of generation of estrogen quinones from catechol estrogens concerns the resulting formation of ROS during the process. In effect, ROS are generated *via* the redox cycling between cat-

echol estrogens and their quinone analogs^[108-110] (Figure 4).

Catechol estrogens can be oxidized by any oxidative enzyme or metal ions such as Cu^{2+} or Fe^{3+} to give rise to semiquinones and o-quinones^[108-110]. Is our hypothesis that it might very well be that this activating pathway of the catechol estrogens was stimulated during alcohol drinking by the inductive effect of alcohol on mammary tissue XOR and lipoxygenase or even more likely, by the alcohol drinking promoted oxidative stress that was observed^[15,22,25].

The reduction of o-quinones back to semiquinones and catechols by P450 reductase provides an opportunity to generate ROS, including superoxide and hydroxyl radicals^[107].

In our experiments on the effect of alcohol drinking on rat mammary tissue we were able to detect the formation of hydroxyl radicals and lipid hydroperoxides during the metabolism of ethanol in this tissue^[16,22].

In those studies we also reported that repetitive alcohol drinking provoked the depletion of defenses against oxidative stress insult due to significantly reduced levels of glutathione, α -tocopherol and defensive enzymes such as glutathione transferase and glutathione reductase^[25]. Besides the consequences that those effects have on the oxidative stress process itself and in the promotion of the carcinogenic process^[73], this might have additional relevant consequences for the contribution of estrogens to the mammary carcinogenic process. In effect, glutathione is also able to react with the estrogen quinones and semiquinones to give glutathione conjugates in a reaction catalyzed by glutathione transferase^[107]. Further, the lowered levels of glutathione would also decrease the capacity of mammary tissue to destroy hydroperoxides since it is the necessary cofactor for glutathione peroxidase to operate even when the levels of this enzyme were not decreased^[25].

Decreased levels of two critical antioxidants like vitamin E and glutathione that we observed in mammary tissue after alcohol drinking might be not only of relevance for the promotion of oxidative stress^[25], but also to understand that their depletion might be a potential factor of the genotoxic effect of estrogens, *via* their oxidative

Figure 5 Pathways for catechol-estrogen methylation by carboxymethyl transferase.

metabolism that might be enhanced^[107] (Figure 4).

The increased generation of ROS produced by alcohol toxicity^[66] and the effects of estrogen^[107] might explain the decreased levels of α -tocopherol observed^[25].

In addition, the significantly decreased levels of GST observed in our experiments on the effect of alcohol drinking on mammary tissue might also be explained as attributable to the potent inhibitory effects that specific glutathione-estrogen metabolites have on the GST molecule^[111-113]; of course that remain to be proved. It might of particular relevance in light of previous observations reported by Zheng *et al.*^[114] in epidemiological studies, that alcohol consumption increased breast cancer risk in women among those who carry susceptible GST genotypes.

Not only the GSH/GST detoxicating pathway of the estrogen metabolites could be negatively modulated by alcohol drinking. Other might be the carboxymethyl transferase (COMT) pathway of catechol estrogens methylation (Figure 5). Several points of the cycle depicted in that process are already known that might be altered during alcohol drinking. For example, the S-adenosylmethionine (SAM) involved in the methyltransferase step of catechol estrogens methylation is known to be diminished because of SAM decreased hepatic biosynthesis. In alcoholic liver disease methionine adenosyltransferase capacity is affected. In fact, chronic alcoholics have hypermethioninemia and impaired methionine clearance^[115]. That leads to decreased SAM biosynthesis and in turn to impact on methylation capacity of the cell and decreased antioxidant defenses^[115].

Further, chronic exposure to ethanol has been shown not only to decrease hepatic SAM levels, but also to increase hepatic concentrations of S-adenosylhomocysteine and decrease plasma concentrations of folate in animals and humans^[115,116]. In turn, homocysteine may exert pathogenic effects largely through metabolic accumulation of SAH, which is a strong non-competitive inhibitor of

COMT-mediated methylation metabolisms of various catechol substrates, including those arising from estrogens^[117].

In addition to depleting folate concentrations, chronic ethanol exposure decreases the activity of methionine synthase, which is required to catalyze the transfer of a methyl group from folate to homocysteine to form methionine^[116,118,119].

All these facts might decrease the ability of COMT to methylate harmful catechol estrogens during chronic alcohol drinking as we describe in our working hypothesis about the concerted action of alcohol drinking, the formation of deleterious acetaldehyde, free radicals, oxidative stress and increased levels of estrogens.

WORKING HYPOTHESIS ABOUT HOW ALCOHOL DRINKING MIGHT PROMOTE CARCINOGENIC EFFECTS IN MAMMARY TISSUE

Considering the growing evidence about the relevance of acetaldehyde participation in the alcohol drinking-carcinogenic effects in target organs (for example, the aerodigestive tract) we consider that its *in situ* formation and accumulation in mammary tissue should play a role. Contribution of acetaldehyde arriving *via* blood supply should play some but a minor role.

Taking into account that oxidative stress promotion was observed and that free radical generation systems are present in mammary tissue exposed to ethanol during alcohol drinking we felt that it was relevant to consider oxidative stress as a relevant participant in the alcohol drinking promoted carcinogenic effects on mammary tissue. It is well known that it plays a role in promotion and initiation of tumors induced by other chemicals acting in other tissues as well as in mammary tissue.

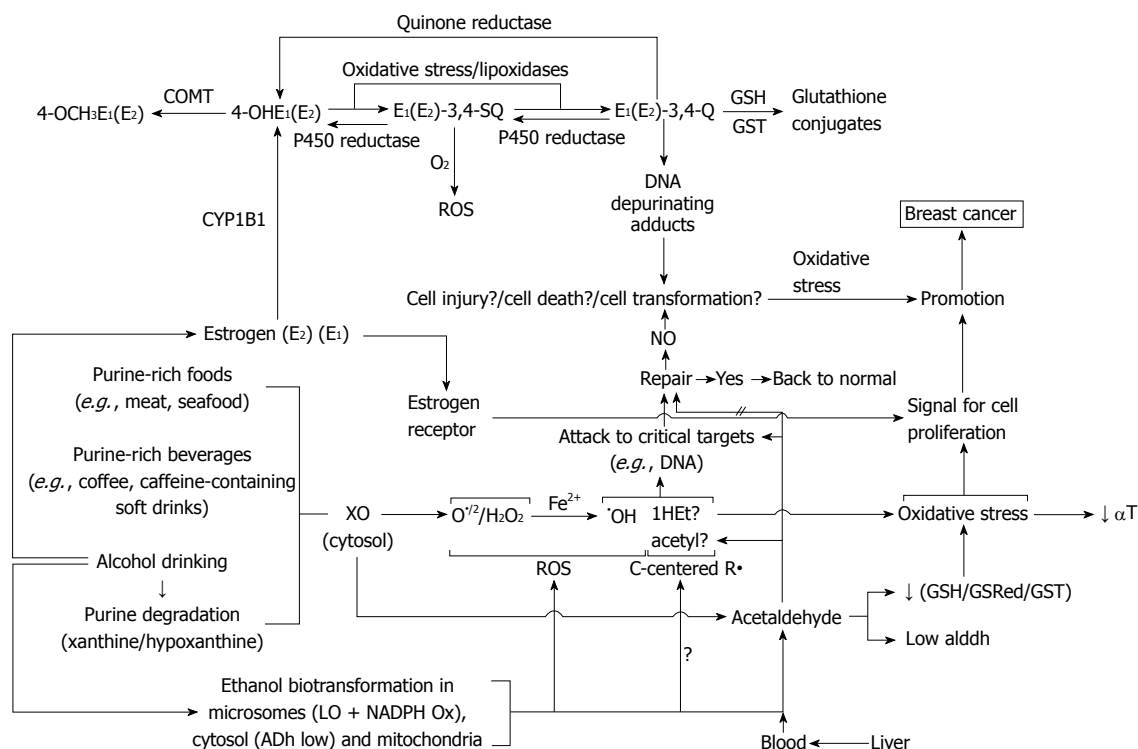

Figure 6 Working hypothesis about the mechanism of the promotion of mammary cancer by alcohol drinking.

Finally, alcohol drinking is also known to increase estrogen blood levels in animals and human beings and it is an established carcinogen for mammary tissue^[95,120]. In women, Eriksson *et al.*^[121] observed an estrogen associated acetaldehyde elevation after alcohol intake.

Alcohol is able also to provoke even on culture studies proliferative and cell transforming effects, not only *via* estrogen receptors but also as a “chemical carcinogen”, mediated by products of their oxidative metabolism^[87,122,123].

In light of the remarkable susceptibility of mammary tissue to alcohol drinking, clearly evidenced in epidemiological studies, we coined the working hypothesis that the resulting deleterious carcinogenic effects might arise from a sort of collaborative participation of these three components, making some of them more susceptible to the effect of the other. Some of those possibilities are going to be described at the time of proposing potential preventive treatments that we postulate based on existing linked literature.

Only the challenge of the hypothesis will tell whether is valid or not. Lack of hypothesis does lead to new experiments. New experiments may show the need of a new one. The present one in our hands is shown in Figure 6.

POTENTIAL PREVENTIVE TREATMENTS AGAINST ALCOHOL DRINKING DELETERIOUS EFFECTS IN MAMMARY TISSUE

The first point to mention is that being alcohol drinking one of the few causes of breast cancer promotion a

wise suggestion might be not to drink. Notwithstanding we feel that epidemiology shows that the real success of that advice may not be easily achievable. The present suggested tolerance for alcohol drinking by women is of one daily drink^[4]. The analysis of the potential preventive strategies for women deciding to moderately exceed that suggested tolerated levels will be analyzed in light of the existing knowledge and of our working hypothesis.

The preventive alternatives to be analyzed include: (1) Blockade of acetaldehyde generation and accumulation in mammary tissue; (2) Prevention of alcohol and estrogen-induced oxidative stress in mammary tissue by antioxidants; (3) Treatments increasing defenses against estrogen provoked effects; and (4) Treatments able to be preventive in different aspects of the problem.

Inhibitory effects on acetaldehyde generating enzymes present in mammary tissue

Considering that most of the acetaldehyde accumulating in mammary tissue was generated *in situ*^[15], we considered of particular interest to pay attention to inhibitors of the two pathways already evidenced by our laboratory, one present in cytosolic fraction and mediated by XOR and other, located at the microsomal fraction being linked to a lipoxygenase activity^[8,16,17,124-126].

It was of our especial interest the search for compounds present in food or drinks or available as dietary supplements, having low toxicity, potent inhibitory effects and ideally acting on both, the cytosolic plus microsomal pathways of ethanol metabolism to acetaldehyde^[127,128].

Several phytochemicals of polyphenolic nature tested appeared as potential candidates exhibiting those interest-

Figure 7 Structures of some of the compounds with the most powerful ability to inhibit the oxidation of ethanol to acetaldehyde in rat mammary tissue microsomal and cytosolic fractions.

ing characteristics and deserve our future attention. The most potent inhibitors among those polyphenols were flavonols quercetin, myricetin and kaempferol; also the flavones apigenin, luteolin and the polyphenols nordihydroguaiaretic acid and ellagic acid. Their structures are shown in Figure 7.

It might be important to consider at this point that several polyphenols were found to be inhibitory of carcinogenesis in laboratory investigations^[129-131].

The case of ellagic acid particularly attracted our interest because it is present in several fruit sources^[132]. This compound was able to diminish estrogen-mediated mammary tumorigenesis in ACI rats^[133]. Other authors reported anti-proliferative activities *in vitro* with several cell types^[134]. And more, it also exhibited beneficial anti-cancer effects based in a chemical study in male prostate cancer patients^[135,136].

We also found that folic acid behaved a highly potent inhibitor of acetaldehyde formation in the cytosolic fraction of mammary tissue^[124]. That suggests a preventive effect mediated not only by acetaldehyde depletion but also because it is a critical component of the overall methylation processes. Folate was found to be relevant in the prevention of breast cancer^[137].

Removal of acetaldehyde accumulated in mammary tissue

Past studies from our laboratory evidenced that acetaldehyde accumulates in mammary tissue during long periods

of time, even after single doses of ethanol given orally^[15].

Removal of acetaldehyde from mammary tissue appears far more difficult than in liver. In effect, the ALDH activity in mammary tissue subcellular fractions (cytosol, mitochondria and microsomes) was at least ten times lower than in the liver^[15]. In addition, the relevant mitochondrial ALDH activity might become irreversibly inhibited by the lipid peroxidation byproduct 4HNE, which is a potent inhibitor as well as a substrate for ALDH^[138,139]. Lipid peroxidation might occur during the oxidative stress produced by ethanol acting on mammary tissue^[22]. Further, the other potential GSH/GST system able to get rid of acetaldehyde is significantly decreased in mammary tissue after repetitive alcohol drinking^[25].

Other alternative to eliminate acetaldehyde accumulation in mammary tissue might arise from cysteine administration. Cysteine is able to ameliorate the toxicity of acetaldehyde by forming a stable adduct, the 2-methylthiazolidine-4-carboxylic acid^[140] (Figure 8). Its efficiency to lower the acetaldehyde accumulation in mammary tissue remains to be established. This alternative was suitably employed to prevent acetaldehyde accumulation in the oral cavity during alcohol drinking^[141,142].

In the case of mammary tissue, we consider N-acetylcysteine (NAC) as having more likely potential preventive action. NAC might be less effective than cysteine in extracellular environment (*e.g.*, saliva), but can be given at higher doses and during longer periods of time than cysteine because of its lower toxicity and because it is also

Figure 8 Reaction between acetaldehyde and cysteine to form the adduct 2-methylthiazolidine-4-carboxylic acid.

a precursor of cysteine and glutathione^[143]. In a number of studies since 1984, NAC also proved to have the potential to prevent cancer and other mutation-related diseases^[143].

Prevention of estrogen oxidation or enhancement of detoxication of estrogen reactive metabolites

The invoking hypothesis displayed in Figure 6 assumes that a significant component in the alcohol drinking promotion of mammary cancer involves de formation of catechol estrogens that might be oxidized to their quinones, which can react with DNA.

The contribution of alcohol drinking to this deleterious pathway might involve the inductive effect on CYP1B1 and provision of relevant oxidizing conditions for the generation of the estrogen reactive metabolites and the decreased detoxication of those reactive moieties.

The contribution of antioxidants if that hypothesis was likely appears attractive to prevent this factor of the alcohol-drinking *via* the oxidative estrogen metabolism component. Recent studies^[144] evidenced that the antioxidant N-acetylcysteine, a precursor of cysteine and of intracellular GSH^[145] is able to block the initial step in the genotoxicity caused by estrogen quinones.

The authors concluded that N-acetylcysteine preventive action included multiple protective mechanisms, including nucleophilicity, antioxidant activity and inhibition of DNA adduct formation^[146]. Preventive properties were also observed in human breast epithelial cells and mouse mammary epithelial cells^[147].

Further, GSH, an ubiquitous antioxidant is able to react non-enzymatically with the catechol estrogen quinones or more efficiently, with the catalytic activation of GST^[101,148].

Resveratrol, a natural antioxidant present in grapes and different plant products^[149,150] was also effective in inhibiting the formation of estrogen-DNA adducts^[146] and is also known to exert diverse anticarcinogenic effects *in vitro* and *in vivo*^[149,151].

Dihydrolipoic acid, which is formed *in vivo* when lipoic acid is administered, can also inhibit the formation of depurinating estrogen-DNA adducts^[146]. Resveratrol achieved the highest level of inhibitory effect and NAC or dihydrolipoic acid a moderate action^[146].

Interestingly, our laboratory reported that alcohol-drinking decreased levels of GSH and α -tocopherol, and GST in mammary tissue and enhanced oxidative stress in mammary tissue^[25].

These alcohol drinking-induced deleterious effects should decrease the detoxicating pathway of glutathione conjugates formation and give to the estrogen 3,4-quinones more opportunity to react with DNA to produce depurinating adducts.

Other harmful effect of alcohol drinking may also occur at the level of the COMT detoxicating pathway operating at the level of the catechol estrogens, especially the 4-hydroxylated metabolite of 17 β -estradiol. In effect, the COMT pathway to proceed requires the participation of SAM, folic acid, vitamins B6 and B12 (Figure 5).

The SAM requiring methyl transferase then methylates the 4-OH group of the catechol estrogens to give the 4-OCH₃ derivative having less toxic effects^[98,107]. In the SAM-mediated transmethylation process, S-adenosylhomocysteine (SAH) is generated as a product and is hydrolyzed afterwards by SAH hydrolase to form homocysteine and adenosine. SAH is a potent competitive inhibitor of the methylation reaction and it is important to remove adenosine and homocysteine to prevent accumulation of SAH. Re-methylation of homocysteine requires folic acid and vitamin B12. Homocysteine can also form cysteine *via* enzymatic processes requiring vitamin B6. Cysteine is, in turn, the rate determining precursor for GSH synthesis *via* a two step enzymatic process. All these processes are better reviewed by several authors^[115,116,119,152]. See Figure 5 for a summary of the SAM-mediated methylation process of catechol estrogens.

The reason for briefly introducing this matter is that this COMT detoxicating process also offers possibilities of preventive treatments.

First it is important to summarize which are the effects of alcohol drinking on the components of the above described participating molecules of the transmethylation process.

For example, it has been shown that chronic ethanol exposure decrease hepatic concentration of SAM, increasing plasma concentration of homocysteine, increase hepatic concentration of SAH and decrease plasma concentration of folate, in animal and human studies^[116].

Conversely, exogenous administration of SAM has been shown to attenuate deleterious effects of alcohol drinking in animals. SAM administration is known to restore hepatic concentrations of GSH depleted by alcohol drinking^[116].

That is, SAM treatment might also be of help to prevent alcohol drinking effects on mammary induced cancer by improving the COMT pathway of detoxication.

CONCLUSION

Our reviewed considerations about the pathogenesis of alcohol-drinking induced mammary cancer led to the working hypothesis that: acetaldehyde accumulation and its harmful effects, induced generation of ROS and oxidative deleterious effects on increased estrogen levels might cooperatively be involved in cancer promotion. That remains to be proved.

If assumptions were even partially correct, some

useful preventive alternatives might be available: inhibition of acetaldehyde forming metabolic pathways, destruction of accumulated acetaldehyde, treatments with powerful and safe antioxidants and also enhancement of estrogen quinones detoxicating pathways. Further, cocktails having mixtures of components from each type might be envisaged.

Notwithstanding, it is always important to consider that alcohol drinking induced mammary cancer is one of the very few avoidable causes of cancer and it might be possible to avoid alcohol drinking at all or more probably acceptable to drink just one drink per day (12 g of ethanol per day only).

Abstract

Cancer initiation and development engage extremely complicated pathological processes which involve alterations of a large number of cell signaling cascades and functional networks in temporal and spatial orders. During last decades, microRNAs (miRNAs), a class of non-coding RNAs, have emerged as critical players in cancer pathogenesis and progression by modulating many pathological aspects related to tumor development, growth, metastasis, and drug resistance. The major function of miRNAs is to post-transcriptionally regulate gene expression depending on recognition of complementary sequence residing in target mRNAs. Commonly, a particular miRNA recognition sequence could be found in a number of genes, which allows a single miRNA to regulate multiple functionally connected genes simultaneously and/or chronologically. Furthermore, a single gene can be targeted and regulated by multiple miRNAs. However, previous studies have demonstrated that miRNA functions are highly context-dependent,

which leads to distinct pathological outcomes in different types of cancer as well as at different stages by alteration of the same miRNA. Here we summarize recent progress in studies on miRNA function in cancer initiation, metastasis and therapeutic response, focusing on breast cancer. The varying functions of miRNAs and potential application of using miRNAs as biomarkers as well as therapeutic approaches are further discussed in the context of different cancers.

Key words: MicroRNA; Breast cancer; Therapeutic response; Biomarker

Core tip: MicroRNAs (miRNAs) have been shown to play critical roles in cancer pathogenesis and progression by modulating tumor initiation, growth, metastasis, and therapeutic resistance. In this review, we discuss the recent progress in understanding miRNA function in cancer development and therapeutic response, especially in breast cancer, as well as the potential application of using miRNA signatures as biomarkers for predicting therapeutic response and for personalizing anti-cancer regimens.

INTRODUCTION

In the human genome, protein coding genes (around 20000) only represent approximately 1.5% of entire DNA sequences^[1]. Since little discernible function was known about the majority of non-coding sequences, they were called “junk DNA”. However, recent data provided by ENCODE project and other research progress

have revealed that a large portion of “junk DNA” may pertain to important biological functions, such as host regulatory DNA sequences, long interspersed elements, short interspersed elements and non-coding RNA genes. Non-coding RNA (ncRNA) comprises several classes of functional RNA transcripts, including ribosomal RNA (rRNA), transfer RNA (tRNA), small nuclear RNA (snRNA), small nucleolar RNA (snoRNA), long non-coding RNA (lincRNA), small interfering RNA (siRNA) and microRNA (miRNA), which have been shown to exert critical roles such as regulating transcription, stability and translation of protein-coding genes^[2,3]. The most studied ncRNAs to date are miRNAs, owing to their crucial functions in control of varying biological and pathological processes, such as development, cell proliferation, differentiation, programmed cell death and stress response. Most miRNAs are highly conserved across different species, while exhibiting high specificity to tissue/cell types and developmental stages. The involvement of miRNAs in cancer initiation and progression was first reported in chronic lymphocytic leukemia^[4]. Later studies further revealed that miRNAs may serve as either tumor suppressors or oncogenes (also known as oncomiRs) in a variety of cancers, depending on which genes or pathways were regulated/dysregulated by particular miRNA in a specific cancer type^[5,6]. Meanwhile, an individual gene could be regulated by multiple miRNAs, which further underscored that the potential pathological impact of specific miRNA or miRNA cluster may vary in different types of cancer^[5,7,8]. High throughput analyses using expression microarrays or next-generation sequencing have revealed that miRNAs are dysregulated in most types of human cancer^[9,10]. Moreover, the aberrant expression signatures of miRNAs have been suggested to have diagnostic, prognostic, predictive and therapeutic values^[11-14].

As many outstanding reviews have comprehensively described the current understanding of the pathophysiological functions of miRNAs and their involvement in cancer initiation, progression and metastasis^[3,5,6,14,15], here we only summarize the recent progress in these research areas and focus on miRNA function in cancer therapeutic response, especially in breast cancer. The potential application of using miRNA signatures as predictive biomarkers for cancer therapeutic response and how these insights can be used for the development of novel anti-cancer regimens targeting miRNAs are further discussed.

MIRNA GENERATION AND FUNCTION

MiRNAs are a family of single-strand RNAs ranging from 19 to 24 nucleotides, which are predominantly transcribed from the genome as primary miRNAs by RNA polymerase II^[16,17]. The primary transcripts then undergo a multi-step process to generate precursor and mature form of miRNAs. The initial transcription of miRNA genes yields long, capped and polyadenylated primary miRNA transcripts, varying from several hundreds to several thousands of nucleotides. These primary tran-

scripts are subsequently processed by a nuclear microprocessor complex consisting of ribonuclease (RNase) III Drosha and DGCR8 (DiGeorge syndrome critical region 8, also known as Pasha), yielding precursor miRNAs (Pre-miRs)^[18]. Besides the core components of the Drosha microprocessor, several additional proteins, including the DEAD-box helicase proteins p68/DDX17, NF90 and NF45, have been shown to interact with Drosha and facilitate the processing of nearly one-third of pri-miRNAs. Alternatively, pre-miRNAs can also be generated by RNA splicing when the miRNA sequence resides in intron of a protein-coding gene and is co-transcribed with the mRNA of the host gene. Precursor miRNAs form a complex with exportin 5 (XPO5) and Ran-GTP, which is then transported into the cytoplasm. The hairpin structure of pre-miRNAs can be recognized by cytoplasmic type III RNase Dicer which further cleaves pre-miRNAs into double-stranded miRNAs. Then, the miRNA double strands are separated, and the mature miRNA can be loaded into the RNA-induced silencing complex (RISC) along with its target mRNAs, leading to posttranscriptional gene silencing^[19-21] (Figure 1).

In general, miRNAs post-transcriptionally decrease gene expression by inhibiting ribosome-dependent translation and/or destabilizing mRNAs of target genes. Typically, mature miRNAs recognize their target genes through sequence-complementarity within the 3'-untranslated region (3'-UTR) of mRNA to the miRNA seed region (nt. 2-7). However, several lines of evidence indicated that miRNAs can also bind to 5'-UTRs or open reading frames (ORFs) of a target mRNA and repress its expression^[22,23]. By comparison, ORF targeting appears less frequent and less effective than 3'-UTR targeting but still much more frequent than 5'-UTR targeting based on the computational and experimental genome-wide analyses.

The overall function of miRNAs is believed to negatively regulate gene expression. However, recent evidence suggested that certain miRNAs, such as miR-369, can enhance the translation *via* binding to the AU-rich elements of the target gene mRNA^[24]. Moreover, miR-328 was found to indirectly increase the protein output by promoting release of translation-inhibiting hnRNP E2 from the target gene mRNA, thereby de-repressing translation^[25]. In addition, miR-373 was shown to induce expression of genes with complementary promoter sequences, while miR-10a can bind to the 5'-UTR of ribosomal protein gene transcripts and augments their translation^[26]. Nevertheless, in contrast to the well-studied consensus mechanism of miRNA-dependent gene silencing, much remains to be learned about how miRNA up-regulate gene expression.

In addition to intracellular functions, abundant miRNAs are detected in the serum and other biological fluids. Circulating miRNAs are released from source cells into extracellular milieu and can be taken up by recipient cells *via* endocytosis. This process may be mediated by as yet unidentified miRNA-binding membrane receptors on

Figure 1 Biogenesis and function of microRNAs.

the recipient cells^[27]. The circulating miRNAs can act on neighboring cells as well as at remote sites in a paracrine and endocrine fashion, suggesting their roles in mediating both short- and long-range intercellular communication^[28,29]. The uptaken miRNA could regulate target gene expression *via* RISC in recipient cells, or induce pro-metastatic inflammatory response by binding to intracellular Toll-like receptors (TLRs)^[28].

MIRNAS IN CANCER DEVELOPMENT

MiRNAs have been shown to play pivotal roles in cancer initiation and progression. It was found that miRNA genes were frequently located within cancer-associated genomic regions, either amplified or deleted, and miRNAs can act either as oncogenes or tumor suppressors, depending on regulated genes and cancer types^[30]. Furthermore, a particular miRNA can exploit both tumor-suppressive and oncogenic functions depending on the cellular context of its target genes in different cancers.

The first evidence that miRNAs may be involved in human cancer pathogenesis was derived from a study aiming to identify tumor suppressors within the 13q14 region which is frequently deleted in chronic lymphocytic leukemia (CLL)^[4]. It was found that, in 69% of CLL patients analyzed, polycistronic miR-15a and miR-16-1 were deleted or downregulated by epigenetic inhibition. Since downregulation of miR-15a/16 is observed in the majority of indolent CLLs, loss of miR-15a and miR-16-1 is likely among the initiating events in the pathogenesis

of this disease^[4]. Subsequent studies revealed additional tumor suppressor miRNAs including the let-7 family and miR-34 family^[15]. These tumor suppressor miRNAs were shown to target varying protein-coding oncogenes for translation inhibition or mRNA decay^[5]. For example, miR-15a and miR-16-1 inhibit the expression of anti-apoptotic gene *BCL2* (B cell lymphoma 2) and *MCL1* (myeloid cell leukemia 1), both of which are well-established oncogenes in hematopoietic cancers.

The tumor suppressive effects of let-7 have been attributed to inhibition of a list of oncogenes, such as *KRAS*, *CCND1*, *CDK6*, *HOXA9*, *TLR4* and *MYC*^[31-33]. Let-7 was also found to negatively regulate self-renewal and tumorigenicity of breast cancer initiating cells through repressing cell proliferation and growth as well as inducing cell cycle exit and terminal differentiation. It has been proposed that cancer stem-like cells or tumor initiating cells may play important roles in breast cancer incidence. Consistently, ectopic expression of miRNAs from the let-7 family was shown to suppress mammary tumor development in mouse models^[33]. Furthermore, by comparing miRNAs in normal stem cells from the mammary gland and cancer stem-like cells from DCIS tumors, miR-140 was found to be significantly decreased in cancer stem-like cells but not in normal stem cells, indicating that miR-140 may play a critical role in preventing malignant transformation of mammary stem cells. The downregulation of miR-140 may be associated with DNA hypermethylation in breast cancer cells. Further investigation found that expression of stem cell marker

SOX9 and ALDH1, which are significantly upregulated in DCIS stem-like cells, are repressed by miR-140. Accordingly, overexpression of miR-140 decreased expression of SOX9 and ALDH1 in ER α -basal-like DCIS mammospheres, and reduced tumor growth *in vivo*^[34]. These studies indicated that tumor suppressive miRNAs may antagonize tumor formation by reducing cancer initiating cell population.

Tumor suppressive miRNAs may also work downstream of coding tumor suppressor genes, which may directly regulate miRNA expression. For instance, tumor suppressive miR-205 can be directly transactivated by the tumor suppressor p53^[35]. Moreover, a study evaluating miR-205 expression in a panel of highly aggressive triple-negative breast cancer cell lines demonstrated that miR-205 is substantially downregulated compared with normal cells. Accordingly, reconstitution of miR-205 expression strongly reduced cancer cell proliferation and tumorigenic potential in cell culture models and inhibited tumor growth in animal models. The miR-205-dependent tumor suppression is attributed, at least in part, to repressing E2F1 and LAMC1, resulting in blockade of cell cycle progression as well as reduced cell adhesion and migration^[35].

Similarly, oncogenes may also promote tumor growth by inhibiting tumor suppressor miRNAs. It was found that estrogen downregulated miR-34b in ER α -positive/p53 wild-type breast cancer cells, as well as in ovarian and endometrial cells, but not in ER α -negative or p53 mutant breast cancer cells^[36]. The negative association between ER α and miR-34b expression levels has also been validated in ER α -positive breast cancer patients. miR-34b was found to inhibit expression of cyclin D1 and Jagged-1 (JAG1) in breast cancer cells. It may also mediate tumor suppressor p53 signaling by repressing oncogenes such as cyclin-dependent kinase 4 (CDK4), MYC and MET^[37]. In addition, overexpression of miR-34b could inhibit tumor growth in an orthotopic xenograft mouse model transplanted with ER α -positive breast cancer cells, but not with ER α -negative or p53 mutant breast cancer cells^[36]. These results suggest that downregulation of miR-34b may play an important role in ER α -driven breast cancer tumorigenesis.

In contrast to the anti-tumorigenic functions described above, oncogenic miRNAs, such as miR-21, miR-17-92 cluster and miR-155, exhibit strong cancer-promoting activity in various human malignancies. As a well-characterized oncomiR, miR-21 was found to be upregulated in almost all cancer types^[38]. *In vivo* studies revealed that cancer cells showed strong addiction to miR-21, whereas inactivation of miR-21 induced complete tumor regression in a pre-B-cell lymphoma model^[39]. In breast cancer, repression of the tumor suppressors such as PTEN, PDCD4 and TPM1 by miR-21 was demonstrated to mediate cancer cell survival and proliferation. A strong correlation between the high expression level of miR-21 and advanced clinical stage, lymph node metastasis and poor prognosis has also been found in

breast cancer patients^[40-42]. It was found that the increased ratio between miR-21 and PDCD4 level in bone marrow of breast cancer patients showed a significant correlation with shortened disease-free survival (DFS) and overall survival (OS)^[43]. Meanwhile, the expression of miR-17-92 cluster, another well-studied oncomiR located within 13q22, was found to be frequently increased in a variety of cancers such as breast cancer, lung cancer, colon cancer and lymphoma, through gene amplification or transcriptional activation^[38]. Interestingly, this miRNA cluster was found to be a direct downstream target of the MYC oncogene, and the increased expression of miR-17-92 could attenuate apoptosis induced by MYC amplification, thereby promoting B cell lymphoma development in a mouse model^[44,45]. These findings suggest that up-regulating miR-17-92 may contribute significantly to the oncogenicity of MYC. In contrast, blockade of miR-17 decreased the breast cancer cell invasion/ migration *in vitro* and metastasis *in vivo*^[46]. Moreover, a series of studies have shown that miR-17-92 cluster acts as an oncogenic gene to promote breast cancer cell invasion and migration through diverse signaling cascades such as Wnt/ β -catenin pathway and miR-17-92/ZBTB4/Sp axis^[46-51]. Likewise, miR-27a was also found to play oncogenic roles through ZBTB/Sp cascade in breast cancer cells. Upregulation of miR-27a has been shown to repress ZBTB10 and Myt-1 expression in breast cancer cells, which promoted cancer cell proliferation^[52]. Inhibiting miR-27a by miR-27a antagmir or anti-cancer drugs, such as betulinic acid, resulted in increased ZBTB10 and decreased Sp family of transcription factors expression in breast cancer cells, thereby leading to consequent growth suppression^[52-54].

Recent studies also demonstrated that differentially expressed miRNAs correlated to specific pathological features in breast cancer, such as tumor grade, disease stage, proliferation index and vascular invasion^[55]. Moreover, a panel of differentially expressed miRNAs have been identified between ER⁺ and ER⁻ breast cancer patients. In this panel, miR-191 and miR-26 are the most significantly upregulated miRNAs, while miR-206 was at the opposite end of spectrum^[54]. In another study, miR-7, miR-128a, miR-210, and miR-516-3p were identified to be significantly associated with ER⁺ luminal signature and breast cancer aggressiveness^[56]. All these studies support the potential application of miRNA profiling in cancer diagnosis and subtype characterization.

MIRNAS IN CANCER METASTASIS

It has been demonstrated that miRNAs also play critical roles in tumor metastasis by regulating the migration and invasion of cancer cells^[57,58]. A pair of basal-like subtype breast cancer-specific miRNAs, miR-221 and miR-222, could promote epithelial-to-mesenchymal transition (EMT), a phenotype strongly associated with cancer invasion and metastasis, by repressing epithelial genes while enhancing mesenchymal gene expression^[59-61]. The transcription of miR-221/222 can be directly upregulated

by FOSL1 (also known as Fra-1), a RAS-activated FOS family transcription factor, and the level of miR-221/222 decreased when MEK (mitogen-activated or extracellular signal-regulated protein kinase) was inhibited, which suggest that miR-221/222 cluster is a transcription target of the oncogenic RAS-RAF-MEK signaling pathway. The miR-221/222-mediated decrease of the mesenchymal signature gene E-cadherin is dependent on repression of trichorhinophalangeal syndrome type 1 (TRPS1), which is a miR-221/222 target and a transcriptional repressor belonging to GATA family. Decrease of TRPS1 could enhance the transcription of zinc finger E-box-binding homeobox 2 (ZEB2), thereby inhibiting E-Cadherin expression while up-regulating Vimentin^[60]. Besides, miR-9 was found to directly repress E-Cadherin expression in breast cancer cells, resulting EMT transition as well as activation of β -Catenin signaling^[62]. The activated β -Catenin promotes VEGF (vascular endothelial growth factor) transcription, which in turn enhances angiogenesis during the secondary tumor formation. Therefore, these data strongly support the hypothesis that miRNAs may contribute to the aggressiveness of breast cancer by promoting EMT.

In contrast, miR-126 decreases the ability of breast cancer cells to remodel the metastatic niche by recruiting endothelial cells from the tumor microenvironment, leading to reduced metastatic colonization^[63]. Meanwhile, miR-335 was found to target the stemness transcription factor SOX4 and extracellular matrix protein tenascin C, resulting in suppression of breast cancer cell metastasis and migration. Consistently, decrease of miR-335 was found in the majority of primary tumors from breast cancer patients who eventually relapsed, which was also associated with poor DMFS^[64]. Interestingly, it was found that treatment with 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and selective AHR modulator 6-methyl-1,3,7-trichlorodibenzofuran (MCDF) could induce miR-335 expression and SOX4 downregulation in several breast cancer cell lines, which inhibited cancer cell growth and lung metastasis *in vivo*^[65,66]. In addition, it was found that significant decrease of miR-34a/c was associated with breast cancer metastasis and lymph node invasion. Overexpression of miR-34a/c leads to decreased breast cancer cell motility and invasiveness as well as reduced distal lung metastasis in animal models. Additional studies found that Fra-1 mRNA and protein levels were decreased by miR-34a/c upregulation, indicating that FOSL1 is a downstream target of miR-34a/c. Furthermore, significant decrease of miR-34a in breast cancer metastases inversely correlates with Fra-1 expression, confirming the critical role of miR-34a-Fra-1 axis in regulating metastasis^[67]. As we discussed above, FOSL1/Fra-1-dependent upregulation of miR-221/222 has been linked with aggressiveness of breast cancer^[60], and miR-221/222 may serve as indirect downstream target of miR-34a/c for its anti-metastatic activity. The similar crosstalk between miRNAs and their critical roles in cancer progression have been further supported by other studies. A recent

study showed that miR-22 may suppress expression of anti-metastatic miR-200, which increased the population of breast cancer stem-like cells and promote metastasis in mice. It was found that miR-22 directly targets the TET (Ten eleven translocation) family of methylcytosine dioxygenases, which promotes DNA demethylation of the miR-200 promoter and its transcriptional activation. The negative correlation between miR-22 and TET-miR-200 axis was also confirmed in metastatic breast cancer patients, supporting the clinical relevance of miRNA crosstalk in breast cancer progression^[68].

Some miRNAs can promote oncogenesis in one cancer type while suppressing tumor development in the other. For instance, although the miR-221 has critical roles in antagonizing breast cancer metastasis and aggressive behaviors, overexpression of miR-221 in liver cancer promoted tumor initiation by inhibiting the expression of the tumor suppressor phosphatase and tensin homolog (PTEN)^[69]. On the contrary, miR-221 acts again as a tumor suppressor in erythroblastic leukemia by reducing the expression of the KIT oncogene^[70]. The complex interactions between miRNAs and protein-coding genes in various cancers indicate that therapies targeting both miRNA and protein-coding genes may be required for effectively controlling cancer progression. However, when miRNAs are considered as emerging therapeutic targets, the selection of miRNA may be highly cancer type- and even stage-specific.

MIRNAS IN CANCER THERAPEUTIC RESISTANCE

Therapeutic resistance is the major obstacle of effective cancer treatment, and plays paramount roles in cancer relapse and cancer-related deaths. Previous studies have demonstrated that drug resistance of cancer cells can be mediated by a variety of mechanisms including the removal or detoxification of the drug, upregulation of anti-apoptotic processes, or alteration of drug transporters such that the therapeutic agent cannot gain entry into the target cells or is immediately exported. Recently, dysregulation of miRNAs was found to not only affect cellular processes involved in carcinogenesis, but also have a direct impact on the cancer therapeutic response. A number of oncogenic miRNAs (*e.g.*, miR-9, -155, -21) have been shown to induce chemoresistance *in vitro* by modulating expression of key resistance-associated genes^[5,71-73]. In breast cancer, miRNAs have been implicated to affect the response to different types of treatments, including anti-endocrine therapies, targeted therapies, chemotherapy, and radiotherapy, *via* treatment-specific or shared mechanisms.

Chemotherapy

The importance of ATP-binding cassette (ABC) transporter proteins, including multidrug resistance protein 1 (MDR1/P-glycoprotein/ABCB1), breast cancer resistance protein (BRCP/ABCG2) and multidrug

Table 1 miRNAs involved in chemotherapy response regulation in breast cancer

miRNA	Drug	Target(s)	Ref.
miR-328	Mitoxantrone	BRCP/ABCG2	[75]
miR-21	Doxorubicin	MDR1, PDCD4	[81]
miR-451	Doxorubicin	MDR1	[76]
miR-130/107	Cisplatin	RAD51D	[125]
miR-345	Cisplatin	MDR1	[77]
miR-326	VP16/Doxorubicin	MRP1	[78]
miR-128	Doxorubicin	BMI1, ABCC5	[79]
miR-34a	Docetaxel	BCL-2, CCND1	[83]
miR-125b	Doxorubicin	BAK1	[84]
	Paclitaxel	E2F3	[85]
miR-200b/c	Doxorubicin	ZEB1, PTEN	[86,87]

resistance-associated proteins 1/2 (MRP1/ABCC1, MRP2/ABCC2), in the development of chemoresistance has been well-established^[74]. Recently, miRNAs were reported as key regulators of drug transporter gene expression in cancer cells. For example, miR-328 was shown to negatively regulate BRCP by directly targeting 3'-UTR of ABCG2 and consequently influence drug disposition in breast cancer cells. miR-328-directed downregulation of ABCG2 expression significantly improved response to the chemotherapeutic agent mitoxantrone in a cell culture model^[75]. Besides, several other miRNAs have been found to target MDR1, including miR-451^[76], miR-7, miR-345^[77], and miR-326^[78], all of which increased cancer cell sensitivity to numerous chemotherapeutic agents. In addition, miR-128-dependent repression of BMI1 and ABCC5 (MRP5) has been implicated in the improved response to doxorubicin treatment, both *in vitro* and in breast cancer patients^[79]. Reduction of miR-128 leads to upregulation of Bmi-1 and ABCC5 in breast tumor initiating cells, which contributes to chemotherapeutic resistance in breast cancer. Ectopic expression of miR-128 sensitizes breast tumor initiating cells to the pro-apoptotic and DNA-damaging effects of doxorubicin, indicating the potential therapeutic value of miR-128 in reducing drug resistance. Moreover, miRNAs may indirectly repress drug resistance gene expression by repressing their upstream activators. It was reported that miR-137 was significantly decreased in cancer cells resistant to doxorubicin. Further investigation revealed that miR-137 can directly repress the expression of constitutive androstane receptor, a nuclear receptor promoting MDR1 gene transcription, thereby downregulating MDR1 expression^[80]. In contrast, miR-21 may upregulate MDR1 expression through repressing PDCD4, a miR-21 target gene, leading to reduced apoptosis and chemotherapeutic resistance^[81]. The increase of MDR1 may be associated with decreased interaction between PDCD4 and eIF4A, resulting in enhanced protein translation.

It has been recognized that one miRNA could simultaneously target multiple genes sharing the same miRNA-recognition sequence, and these genes could be involved in a specific signaling network and play additive or synergistic roles in regulating cellular processes, such as

apoptosis, proliferation or cell survival processes. For instance, chemotherapeutic drugs could upregulate miR-21 expression in breast cancer cells, which in turn inhibits chemodrug-induced apoptosis and promotes therapeutic resistance. Both PTEN and PDCD4 were identified as miR-21 target genes in this experimental setting, whose downregulation could promote cancer cell survival and proliferation^[82]. Moreover, miR-34a was found to regulate human breast cancer cell response to docetaxel through targeting BCL-2 and CCND1^[83]. Furthermore, miR-125b was found to inhibit pro-apoptotic BCL-2 antagonist killer 1 (BAK1) expression. Upregulation of miR-125b in breast cancer cells could markedly inhibit taxol-induced cytotoxicity and apoptosis, and consequently increase the resistance to taxol^[84]. In parallel, miR-125b directly targets the E2F3 gene, which regulates cell proliferation and apoptosis^[85]. Interestingly, circulating miR-125b in breast cancer patient serum may also serve as a biomarker predicting chemoresistance. Tumor samples from breast cancer patients with high levels of circulating miR-125b showed increased cancer cell proliferation and decreased apoptosis. Accordingly, ectopic miR-125b expression correlated with increased resistance to anticancer drugs, whereas suppressing miR-125b level improved breast cancer cell sensitivity to chemotherapy^[85]. Additional studies also revealed that inhibition of miR-21 and miR-200b enhanced sensitivity to doxorubicin in breast cancer cells, which may be mediated by repression of PDCD4 and PTEN, as well as upregulation of pro-apoptotic genes due to ZEB1 inhibition, respectively^[81,86,87].

All these findings indicate that miRNAs may regulate cancer cell response to chemotherapeutic drugs by targeting multiple genes, simultaneously or in parallel, which lead to complex changes in varying cellular processes, such as proliferation and apoptosis. A list of miRNAs involved in sensitivity to chemotherapy in breast cancer can be found in Table 1.

Anti-endocrine therapy

Anti-estrogen therapy is prescribed as standard treatment for ER-positive breast cancer and tamoxifen has been shown to reduce mortality in these patients by 31%^[88]. However, many patients subsequently display resistance and clinical progression, and the involved mechanisms have not been fully understood. Multiple miRNAs have been implicated in mediating anti-estrogen therapy resistance by modulating ER α expression, receptor tyrosine kinase signaling, cell survival signaling, and apoptosis^[89,90]. MiR-221/222 were shown to be key regulators of anti-endocrine resistance *in vitro*, and the resistance could be achieved by downregulation of cell-cycle inhibitor p27/Kip1 and ER α ^[91,92]. Overexpression of miR-221/222 promoted resistance to tamoxifen in MCF-7 cells. Moreover, knockdown of miR-221/222 sensitized ER⁺ breast cancer cells to tamoxifen-induced cell growth arrest and apoptosis. The protein level of p27/Kip1, which has been demonstrated as a direct target of miR-221/222, decreased along with miR-221/222 overexpression in

Table 2 miRNAs involved in antiendocrine therapy response in breast cancer

miRNA	Drug	Target(s)	Ref.
miR-221/222	Tamoxifen	P27Kip1 ER α	[91]
	Fulvestrant	TGF- β	[93]
miR-181b	Tamoxifen	TIMP3	[94]
miR-30c	Tamoxifen		[96,97]
miR-342	Tamoxifen	cyclin B1	[126]
miR-451	Tamoxifen	14-3-3 ζ	[127]
Let-7	Tamoxifen	ER- α 36	[128]
miR-128a	Letrozole	TGF α R1	[129]

MCF-7 cells. Additionally, ectopic p27/Kip1 increased cell death in the endocrine resistant cells exposed to tamoxifen. In parallel, overexpression of miR-221/222 in MCF-7 and T47D cells decreased ER α protein, but not mRNA, level, while miR-221/222 depletion partially rescued ER α downregulation in these cells^[92]. Besides, the miR-221/222-mediated resistance to fulvestrant, a drug inducing ER α degradation, was also attributed, at least in part, to the activation of β -catenin and estrogen-independent growth of breast cancer cells^[93]. In an *in vivo* study using miRNAs as therapeutic targets, it was found that when anti-miR222 and -181b were directly delivered into mammary tumor xenografts, the growth of tamoxifen-resistant xenografts was suppressed^[94]. The authors subsequently found that miR-221, -222, and -181b all target TIMP3 directly, and knockdown of TIMP3 in MCF7 cells enabling tumors to grow in the presence of tamoxifen. A significant association was found between the expression level of miR-221 and hormone receptor (HR) status in breast cancer patients. High plasma miR-221 level was associated with HR-negative genotype as well as poorer overall response rate to neoadjuvant chemotherapy and shorter overall survival. Additional studies also found that plasma miR-221 may have predictive value in assessing chemoresistance in patients with breast cancer who received neoadjuvant chemotherapy^[95].

In contrast, miR-30c was shown to be associated with a better response to endocrine therapy in advanced ER+ breast cancer. Higher expression level of miR-30c was found in patients with longer progression-free survival (PFS) after tamoxifen treatment, which may be attributed to inhibited HER and RAC1 signaling pathways^[96]. It was also found that miR-301 was upregulated in mammary tumor *vs* normal tissue. Moreover, miR-301 expression increased again in patients that relapsed following tamoxifen treatment, but not in those who remained relapse-free^[97]. Consistently, downregulation of miR-301 in tamoxifen-resistant cells restored the sensitivity to the drug. A summary of miRNAs involved in sensitivity to antiendocrine therapy in breast cancer can be seen in Table 2.

Targeted therapy

Targeted therapy has brought great success in treating

selected subtypes of breast cancer, but the subsequent drug resistance is not rare. Compared with chemotherapy and endocrine therapy, much less was known about the mechanisms involved in resistance to targeted therapies. It has been shown that hyperactivation of the PI3K-Akt pathway played a critical role in HER2⁺ breast cancer resistance to trastuzumab (a therapeutic antibody targeting HER2/ERBB2)^[98], and miR-21-mediated PTEN repression may contribute to the increased Akt activation in trastuzumab-resistant breast cancer cells^[99]. Resistant cells can be re-sensitized to the trastuzumab treatment by blocking miR-21 with antisense oligonucleotides, which leads to proliferation inhibition and G₁-S cell cycle arrest. Consistent resensitizing effect of miR-21 inhibitor can be also observed in breast cancer xenograft models, while miR-21 mimics promoted resistance to trastuzumab. Importantly, upregulation of miR-21 was found in tumor biopsies obtained from patients receiving trastuzumab treatment, which associated with poor therapeutic response, indicating a potential role of miR-21 level in predicting trastuzumab response. On the contrary, restoration of miR-205 expression, which is downregulated in breast tumors, was found to sensitize breast cancer cells to gefitinib and lapatinib, two tyrosine kinase inhibitors targeting downstream signaling of HER2^[100]. The authors further identified HER3 as a direct target of miR-205 in breast cancer cells. HER3 is a critical partner of HER2 to activate downstream tumorigenic signaling pathways, and HER3 upregulation has been implicated as a potential mechanism in breast cancer resistance to HER2-targeting therapies^[101-103]. Therefore, reintroduction of miR-205 likely could improve the response to HER2-targeted therapy by silencing HER3^[100]. Moreover, plasma miR-210 has been found to correlate with sensitivity to trastuzumab, tumor presence, and lymph node metastases in breast cancer patients. High baseline circulating miR-210 level in patients before receiving neoadjuvant chemotherapy combined with trastuzumab significantly correlated with pathologic complete response, suggesting that miR-210 may serve as a predictive marker for better response to regimens combining trastuzumab^[104].

PARP1 [poly (ADP-ribose) polymerase] inhibitors hold high promise as a novel targeted therapy for treating cancers harboring BRCA1/2 mutation, such as breast and ovarian cancers^[105]. Recent studies have demonstrated that inhibiting PARP1 results in synthetic lethality in cancers with defect in DNA repair due to BRCA1/2 mutation, which highly overlap with basal-like triple negative breast cancer (TNBC)^[106]. Interestingly, miR-182 has been shown to sensitize breast cancer cells to both radiotherapy and to PARP1 inhibitors by repressing BRCA1 expression and inhibiting DNA repair^[107]. Antagonizing miR-182 in breast cancer cells increases BRCA1 protein level, leading to reduction of IR-induced cell death and resistance to PARP1 inhibitors. These results suggested that inhibiting miR-182 may further enhance the therapeutic efficiency of PARP1 inhibitors in combination with genotoxic therapies.

Radiotherapy

Besides targeted therapy and chemotherapy, miRNAs may also modulate cancer cell response to radiotherapy. For example, inhibition of miR-155 was shown to sensitize breast cancer cells to ionizing radiation^[108]. Likewise, anti-miR-21 treatment decreased breast cancer cell survival after irradiation, which was associated with failed G₂/M checkpoint upon DNA damage^[109]. Cell cycle arrest at the G₂/M checkpoint is essential for DNA repair machinery after DNA damage, whose failure likely will increase apoptosis upon genotoxic stress. It was found that miR-21 expression was transiently increased after irradiation in T47D cells and MDA-MB-361 cells, which was required for proper cell cycle arrest in these cells after irradiation. These observations indicated that miR-21 may contribute to radiation resistance in breast cancer cells through enhancing cell cycle checkpoint and subsequent DNA repair^[109]. Similarly, increased miR-34a has been linked to poor response to radiotherapy in breast cancer cells^[110]. It appeared that miR-34 promotes apoptosis while antagonizes non-apoptotic cell death in nematodes upon radiation, which was also confirmed in human breast cancer cell lines. Moreover, it has been shown that miR-34 is a target gene of p53 and can be upregulated in response to radiation^[111]. Thus, inhibiting miR-34 with antagonist may be of potential therapeutic utility for sensitizing p53-mutant breast cancer to radiotherapy.

MIRNA AS CANCER THERAPEUTICS

miRNA therapeutics can be devised to downregulate or block the function of pathogenic miRNAs as well as to upregulate the expression of disease-defensive miRNAs. For instance, miravirsin is a locked nucleic acid-modified DNA phosphorothioate antisense oligonucleotide that forms a highly stable heteroduplex with mature miR-122, resulting in its inactivation. It is one of the earliest miRNA-targeting therapeutics approved for clinical trials and has recently shown positive results in treating hepatitis C infection in a phase II trial^[112]. In chronic HCV infection patients, miravirsin treatment reduced HCV RNA level in blood samples in a dose-dependent manner without obvious viral resistance.

Since the pathogenesis of cancer involves a number of gene mutations, amplifications and deletions, usually an effective cancer therapeutic regimen needs to target multiple genes involved in same and/or parallel functional networks as well as several signaling cascades. A significant advantage of using miRNAs as therapeutic targets lies in that one miRNA generally has multiple coding genes or non-coding RNAs as targets, which may be involved in a single pathway or in parallel pathways regulating cancer progression^[6]. Compared with the strategy using siRNAs, which are usually aiming to repress one specific target gene, miRNA therapeutics appear to be superior to a mixture of siRNAs. For example, several genes associated with the epidermal growth factor recep-

tor (EGFR) signaling pathway, such as p38 mitogen-activated protein kinase (p38), signal transducer and activator of transcription 3 (STAT3) and AKT2, are miR-124 targets^[113]. As aberrant activation of EGFR signaling has been found in a number of human malignancies, such as lung and breast cancers^[114], it is plausible that enhancing miR-124 expression may concurrently repress the expression of p38, STAT3 and AKT2, thereby effectively inactivating the EGFR signaling pathway.

Antagomirs are synthetic RNAs with a 2' -O-methyl linkage and phosphorothioate modification and conjugated to cholesterol. They can be used as miRNA antagonizers by complementarily binding to the targeted miRNA, thereby deblocking other endogenous miRNA target gene expression. It was found that miR-10b antagomirs remarkably reduced the lung metastasis formation in a breast cancer xenograft model. Further investigation demonstrated that silencing of miR-10b with antagomirs significantly decreased miR-10b levels and enhanced expression of Hoxd10, a miR-10b target gene playing critical roles in breast cancer metastasis^[115]. Another type of miRNA inhibitors, miRNA sponges, are RNA traps that are constructed with tandem binding sites complementary to the seed sequence of the miRNA of interest. It was shown that a single sponge inhibitor can block an entire miRNA family sharing the identical seed sequence. In a study using miRNA sponges targeting miR-9, it was found that sponge-dependent miR-9 inhibition dramatically reduced mouse breast cancer cell lung metastasis, potentially by alleviating miR-9-modulated E-Cadherin downregulation and inhibiting EMT^[62].

Although the preclinical studies implied high promise of using miRNA therapeutics in cancer treatment, there are also significant challenges remaining to be overcome before practical clinical applications of miRNA-targeted therapy^[6]. First of all, miRNA activity highly depends on the cellular context and cancer types. Different target genes may be repressed by the same miRNA in different cell types and consequently opposite biological effects may occur within the same organism. Consequently, targeting a specific miRNA may be beneficial in one cell type but harmful in another. Thus, selective delivery of miRNA therapeutics to target tissues is a major obstacle for effective miRNA-based therapy and minimal side effects. A specific and efficient delivery system that targets only cancer cells has yet to be developed. Moreover, double-stranded RNAs (≥ 21 base pairs) can elicit a sequence-independent interferon response^[116]. Since macrophages and monocytes were found to remove complexed RNAs from extracellular spaces, systemically delivered miRNAs or RNA-based miRNA inhibitors might trigger and be eliminated by the host immune response^[117]. Nevertheless, the recent advance of using antibody-conjugated nanoparticles to encapsulate miRNA agents may represent a promising future of cancer cell-selective delivery approach with minimal adverse immune response in patients^[118].

Beyond being directly delivered as pharmacologi-

cal intervention, miRNAs may also serve as mediators for carrying out tumoricidal effect of other anti-cancer agents. For instance, Enoxacin, an antibacterial compound, was found to inhibit cancer growth through upregulating tumor suppressive miRNA production^[119]. Similarly, curcumin analogue CDF was shown to inhibit pancreatic tumor growth *in vitro* and in xenograft models, which involved CDF-induced EZH2 downregulation and consequent activation of tumor suppressor miRNAs, such as let-7, miR-26a, and miR-101^[120]. It is worth noting that induction of miRNAs may lead to complicated pathological responses in cancer cells, which can be exemplified by the observation that retinoid (ATRA)-induced miR-21 upregulation in MCF-7 cells reduced cell motility but promoted cell proliferation^[121]. Meanwhile, general inhibition of miRNA biogenesis and function by small molecules was shown to reverse tumorigenesis^[122]. Therefore, the pharmacological effects of conventional drug-induced miRNAs in cancer treatment are highly drug- and cancer type-specific.

As combination therapies have been proved to be more effective than single agents in various cancer regimens, it is not surprising that combinations of varying miRNA agents as well as along with conventional cytotoxic drugs or molecularly targeted agents have been studied in treating cancers. It was shown that overexpression of miR-30c, which is a favorable prognostic marker in breast cancer, sensitized TNBC cells to doxorubicin treatment in an animal model. The chemo-sensitizing effect of miR-30c was attributed to the downregulation of miR-30c target gene, twinfilin 1, which promotes EMT and induces drug resistance by upregulating IL11^[123]. Similarly, adenoviral delivery of miR-145 along with 5-fluorouracil achieved greater tumor reduction than using 5-fluorouracil alone in breast cancer models^[124]. These preclinical studies suggest that selective miRNA therapeutics may be applicable as sensitizing agents in clinic when used in combination with conventional therapies.

CONCLUSION

Dysregulated miRNAs in breast cancer play critical roles in the cancer initiation and progression. However, the signatures of miRNA alteration may also help to stratify patients into different risk groups as well as to predict therapeutic response. Accumulating evidence support the notion that miRNAs may serve as both therapeutic targets and tools in anticancer therapy. We envision that novel miRNA therapeutic approaches will be developed and approved for clinical application in the near future, which are combined with chemotherapy, anti-endocrine therapy or radiotherapy, based on small RNAs regulated pathway. To this end, better understanding of the regulatory mechanisms involved in miRNA biogenesis and function is pivotal for developing successful application of miRNA therapeutics. Although there are still big challenges in developing miRNA-based therapy, such as the effective delivery with high selectivity and safety evaluation,

miRNAs have emerged with great potential as diagnostic/prognostic biomarkers as well as promising therapeutic targets in cancer treatment.

Abstract

Cervical cancer is the third most common cause of cancer in women in the world. During the past few decades tremendous strides have been made toward decreasing the incidence and mortality of cervical cancer with the implementation of various prevention and screening strategies. The causative agent linked to cervical cancer development and its precursors is the human papillomavirus (HPV). Prevention and screening measures for cervical cancer are paramount because the ability to identify and treat the illness at its premature stage often disrupts the process of neoplasia. Cervical carcinogenesis can be the result of infections from multiple high-risk HPV types that act synergistically. This imposes a level of complexity to identifying and vaccinating against the actual causative agent. Additionally, most HPV infections spontaneously clear. Therefore, screening strategies should optimally weigh the benefits and risks of screening to avoid the discovery and needless treatment of transient HPV infections.

This article provides an update of the preventative and screening methods for cervical cancer, mainly HPV vaccination, screening with Pap smear cytology, and HPV testing. It also provides a discussion of the newest United States 2012 guidelines for cervical cancer screening, which changed the age to begin and end screening and lengthened the screening intervals.

Key words: Cervical cancer; Cancer screening; Pap smear; Human papillomavirus; Papillomavirus vaccines

Core tip: Screening is the best method to prevent cervical cancer. Screening strategies should weigh the benefits and risks of screening to avoid discovery and needless treatment of transient human papillomavirus (HPV) infections. Current United States guidelines recommend Pap smear screening with conventional or liquid-based method no frequent than every 3 years, or every 5 years in women greater than age of 30 if done in conjunction with HPV testing. Screening is not recommend in females younger than 21 years, regardless of age at initiation of sex. In this population, options for prevention include HPV vaccination and decreasing other risk factors associated with HPV infection.

INTRODUCTION

The World Health Organization estimates that yearly, about 530000 women worldwide are identified with cervical cancer and 275000 women die from the disease^[1]. Cervical cancer is heralded as being the third most common cause of cancer among women in the world and

the second most common form of cancer in women in the developing world^[2]. Cervical cancer is responsible for the largest cause of mortality in women due to cancer in most developing countries.

There has been a large decline in the incidence and death rate of cervical cancer in industrialized countries observed during the past few decades. This unfortunately, has not been mirrored by a similar decline in developing nations. An example of this is illustrated by the 70% decrease in mortality caused by cervical cancer in the United States from 1955 to 1992. Each year this initial decline in death caused by cervical cancer has been sustained at a rate of a 3% decrease in the incidence of cervical cancer^[2]. Similarly, in the United Kingdom there has been a 70% decline in the mortality caused by cervical cancer recorded in 2008 than was reported 30 years prior^[2]. In industrialized nations the age-adjusted incidence of cervical cancer is 10 out of 100000 per year; however in developing nations the incidence of the disease can be as high as 40 out of 100000. By 2030, it is expected that cervical cancer will be responsible for the death of 474000 women annually with over 95% of these deaths anticipated to occur in low- and middle-income countries (LMICs)^[3].

HPV infection and cervical cancer

Infection with HPV is the main causative agent in cervical cancer. The latest estimation of the number of genotypes of HPV was 200 with 18 genotypes that are directly related to cervical cancer^[4,5]. The fifteen HPV types that have a strong oncogenic potential include HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82. These high-risk HPV types account for 95% of all cervical cancer.

It has been found that greater than one HPV type can exist in pre-invasive and invasive cervical cancer^[6]. This imposes a level of complexity in identifying which one is the actual causative agent, with various genotypes depending on geographical regions. While high-risk HPV 16 and 18 are accountable for around 90% of all cervical cancer^[7], there is greater than average presence of subtypes 31 and 45 detected in the developing world^[8]. There is also a prominent presence of HPV 58 associated with pre-invasive lesions in women in various countries, including Thailand, Uganda, Zambia and Cameroon^[9-12].

The most carcinogenic HPV genotype is HPV 16, which mostly causes squamous cell carcinoma. HPV 18 mostly causes adenocarcinoma, a cancer that is less frequently found but more aggressive, resulting from the endocervical glandular^[13]. However, cervical carcinogenesis may arise from infections with many high-risk types that act synergistically^[14]. The Bethesda classification encompasses the biological behavior of cervical squamous intraepithelial lesions (SILs)^[8]. The classification system partitions abnormal squamous epithelial cells into four categories: (1) atypical squamous cells of undetermined significance (ASCUS); (2) low grade squamous intraepithelial lesions (LSILs), including light dysplasia/cervical intraepithelial neoplasia (CIN) 1 in addition to HPV associated cell changes; (3) high-grade squamous intraepithelial le-

sions (HSIL), encompassing moderate dysplasia/CIN 2, severe dysplasia, and carcinoma *in situ*/CIN 3; and (4) squamous cell carcinoma^[8]. Almost 90% of infections with HPV clear on its own within 1-2 years^[15]. High-grade cervical intraepithelial lesions that are classified as CIN 2 have a 40% chance of regression. High-grade cervical intraepithelial lesions that do not regress are categorized as CIN 3. These lesions have a 30% probability of progression to invasive cervical cancer^[16]. HPV 16 is the most persistent infection and the type that is most likely to progress to CIN 3, carcinoma *in situ*, and invasive cervical cancer. HPV negative cervical cancer is extremely rare, but it has been found. This form of cervical cancer is believed to be due to an artifact caused by limitations in the current detection methods or perhaps due to the loss of HPV DNA during the progression to cancer.

Risk factors for cervical cancer

Sexually transmitted infection with HPV is the strongest risk factor for development of cervical cancer. There are multiple risk factors that have been connected with the acquisition of HPV infection and cervical cancer (Table 1). HPV acquisition is most dependent on genital contact. This prominent risk increases with higher number of sexual partners of a woman or her partner^[17-19]. Other sexual and reproductive risk factors associated with HPV infection and cervical cancer include: initiation of sexual activity at an early age (≤ 18 years), earlier age at first full-term pregnancy (< 18 years), high parity (4 or greater vaginal deliveries), use of combined hormonal oral contraceptives for longer than 5 years, and a history of other sexually transmitted infections [e.g., chlamydia, human immunodeficiency virus (HIV), herpes simplex 2]^[18,19]. The use of tobacco, both current and past, increases the risk of squamous cell cervical carcinoma, and the risk rises with quantity of cigarettes smoked per day and number of years smoked^[19]. Infection with HIV is strongly associated with incidence and persistence of HPV infection, and advancement to invasive cervical cancer from squamous intraepithelial lesions^[19]. In fact, cervical cancer is one of the acquired immunodeficiency syndrome (AIDS)-defining illness, *i.e.*, a person with HIV who develops cervical cancer is considered to have AIDS. The acquisition of HPV is most dependent on contact with the genital skin and condom use is associated with reduced cervical cancer risk^[19]. However, condom use is only 70% effective in averting the transmission of HPV since there is remaining contact with genital skin that is not covered by the surface of the condom^[17]. In summary, counseling for tobacco cessation, delaying initiation of sexual intercourse, using condoms, and decreasing number of sexual partners may prevent HPV infection and help to reduce the risk of cervical cancer.

CERVICAL CANCER PREVENTION WITH HPV VACCINATION

Another potential way to prevent cervical cancer is the

Table 1 Cervical cancer risk factors

Cervical cancer risk factors ^[17-19]
Genital Infection with high risk human papillomavirus
HIV infection
Smoking
Younger age at first sexual intercourse
Greater number of sexual partners
Oral contraceptives use greater than 5 yr
Having 4 or greater full-term pregnancies
History of sexual transmitted diseases

HIV: Human immunodeficiency virus.

use of HPV vaccination to prevent high risk HPV infection and subsequent cervical carcinogenesis. The Food and Drug Administration (FDA) approved in 2006, Gardasil, a recombinant quadrivalent HPV vaccine. This vaccine has the capability of preventing infection with HPV 16 and 18 in addition to HPV 6 and 11, and it is targeted for use in females 9-26 years of age^[20]. It has been marketed as having the ability to prevent genital warts as well as cervical cancer when given in three vaccinations, at months 0, 1 to 2, and 6^[21]. Gardasil also has the capability to convey protection against vulvar, vaginal cancer and intraepithelial neoplasia, and recently, for the deterrence of genital warts in males age 9-26 years^[6]. Short to medium clinical studies show the capability of Gardasil to protective against HPV-16 and 18 infections and its associated precancerous lesions for up to 5 years post vaccination^[6,8,13].

In 2008, a second vaccine, Cervarix, the HPV bivalent vaccine targeting HPV 16 and 18 was approved^[22]. Cervarix is indicated for use in females aged 10 to 25 years when given in three vaccinations at months 0, 1 to 2, and 6^[23]. Cervarix is effective against anogenital warts caused by HPV, precancerous lesions, and cervical cancer^[6]. Short to medium clinical studies show Cervarix conveys protection against HPV-16/18 and its associated precancerous lesions for 6.4 years post vaccination^[2,10,15,20].

The two HPV vaccines, Gardasil and Cervarix, are currently approved in over 100 countries. In their individual trials, the efficacy of Cervarix in protecting against cervical cytologic abnormalities in HPV-naïve women is slightly higher than Gardasil^[19]. Cervarix also seems to have higher cross-protection against other nonvaccine HPV types, as evidenced by its higher reduction in excisional treatments for CIN 2/3 disease compared to Gardasil, and its efficacy in decreasing incidence of genital warts caused by HPV 6, 11, and 74^[19]. However, clinically significant differences in efficacy of Gardasil *vs* Cervarix is difficult to discern and will not be apparent for many years. Researchers believe that the differences will be revealed with longer-term evaluations of women that were vaccinated in countries with population-based registries that can track HPV associated cervical lesions^[8].

There are a cluster of symptoms that have been reported most frequently in correlation to administration

of the HPV vaccines including pain where injected (78%), ecchymosis (17%), fainting (15%), and swelling (14%). These side effects have been reported most commonly in younger than older girls^[24].

Routine HPV vaccination of girls is recommended by the Centers for Disease Control and Prevention's Advisory Committee on Immunization Practices (ACIP) at 11 to 12 years of age with catch-up vaccinations at 13 to 26 years of age^[25] (Table 2). However, the American Cancer Society has not found enough research evidence to recommend for or against routine vaccination of females age 19 to 26 years^[24]. Young women are the targeted group because immunological response is greatest in girls aged 10-15 years, and the vaccine has greatest efficacy in girls who haven't initiated sex^[26]. Estimations have been made that only 7% of students in United States high schools report having started sexual intercourse prior to 13 years of age^[26]. In the developing world there is a much variation in the prevalence of virginity and the age which women marry. Therefore, international vaccination programs may have to change according to their country's conditions and traditions^[27].

Barriers to implementation of HPV vaccine

The acquisition of immunity of the entire population or herd immunity has been met by a great deal of challenges. Advocates for the vaccine estimate that approximately 70%-80% of girls that are pre-pubertal are required to be vaccinated to obtain herd immunity. This level of immunity will be hard to reach in light of the fact that many conservatives in the US have described the drug as "the promiscuity vaccine" and have imposed their fears that inoculating preteen girls will disrupt their message of abstinence from pre-marital sexual intercourse *via* what they have called the "disinhibition effects"^[28]. All of this political rhetoric has resulted in a shift in public opinion of the vaccine and resulted in a decline in the percentages of parents that are in favor of the vaccine. Interestingly, the intention to vaccinate with HPV is greatest when the vaccine is depicted that it is free or cheaply available and that it prevents cancer, rather than preventing an infection that is sexually transmitted^[25]. Studies show that there are still realist barriers in place as it pertains to the cost of the vaccine as well as the stigma that is attached to it^[27].

Advocates for the HPV vaccination also believe that herd immunity will only authentically be obtained when there is the existence of a gender-inclusive vaccination policy^[28]. There is a belief that men play a pivotal role as carriers of HPV. However, there has been a limited amount of clinical trials that have been carried out on boys as it pertains to HPV vaccinations. This fact is even reflected in the lack of attention given to administering HPV vaccines to boys and men in United States newspapers^[29]. Positive strides have been made with regards to boys and men immunization when the ACIP approved the non-routine vaccination of Gardasil in boys age nine to 18 years for the purpose of preventing genital warts^[29]. While it is known that males represent a reservoir for fe-

Table 2 Recommendations for human papillomavirus vaccination by the Advisory Committee on Immunization Practices

Population	Recommendation for HPV vaccination
Females 11-12 yr of age	Routine vaccination with 3 doses at 0, 1-2, and 6 mo of either HPV2 or HPV4. Can be initiated as early as age 9 and be given up to age 26
Females 13-26 yr of age	Catch up immunization with 3 doses at 0, 1-2, and 6 mo of either HPV2 or HPV4
Males age 11-12 yr	Routine vaccination with HPV4 with 3 doses at 0, 1-2, and 6 mo. Can be initiated as young as age 9 and be given up to age 26
Female or males with inadequate dose of HPV vaccine	Minimum time between 1 st and 2 nd vaccine doses is 1 mo. Minimum time between the 2 nd and 3 rd vaccine doses is 3 mo. Insufficient receipt of HPV vaccine due to shorter than the recommended dosing interval should be re-administered
Females or males with interrupted vaccine schedule	HPV vaccination does not need to be restarted. The 2 nd dose should be administered as quick as possible if delayed after the 1 st dose. The 2 nd and 3 rd dose should be separated by 3 mo. If just the 3 rd dose is late, it should be given as soon as possible

HPV: Human papillomavirus vaccine; HPV2: Bivalent human papillomavirus vaccine (Cervarix); HPV4: Quadrivalent human papillomavirus vaccine (Gardasil).

male HPV infections, HPV vaccination in boys is controversial because there is no proof that it is cost-effective^[29].

While the controversy over the cost-effectiveness of the vaccine in males as well as the debate surrounding the use of the vaccine in young girls continue, some question the true effectiveness of the HPV vaccine. The Females United to Unilaterally Reduce Endo/Ectocervical Disease (FUTURE) trials that validated the effectiveness of the vaccine were only conducted over a three-year timeline^[21]. However, the average time from carcinogenic HPV infection to invasive cervical cancer, if it happens, is at least 25-30 years^[22,30]. Furthermore, it takes approximately five to seven years from acquisition of HPV infection and the first incidence of a pre-invasive cervical lesion^[22]. As a result of this reasoning, some argue that to declare that the vaccine averted the occurrence of cervical lesions after only a few years of follow-up has the potential to be misleading.

Another factor that concerns the international community is the presence of serotypes that are not targeted by the two HPV vaccines^[31,32]. For example, the quadrivalent vaccine prevents infection from HPV 16, 18, 6 and 11, and the bivalent vaccine targets HPV 16 and 18, however, there are other genotypes of HPV that are prevalent in other geographical regions. Consequently, a daunting question is imposed on the effectiveness of the current vaccines in these other regions.

CERVICAL CANCER SCREENING

The ultimate objective of cervical cancer screening is to find high-grade cancer precursor lesions and early asymptomatic invasive cervical cancer, while avoiding the discovery and needless treatment of fleeting HPV infection and its resultant benign lesions. Since the majority of HPV infections and many CIN 1 and CIN 2 cases are transient, there is a large margin for harm that is associated with discovering these fleeting lesions, including mental stress, physical discomfort incurred from extra diagnostic and treatment measures (*e.g.*, vaginal pain, bleeding, infection), and a higher risk of maternity complications such as preterm delivery after treatment^[33,34].

The systemic screening with the Papanicolaou cy-

tological test (Pap smear) to find pre-invasive cervical lesions and early stage cancer has drastically reduced the incidence and death from cervical cancer in the United States and other industrialized nations^[34]. However, cervical cancer still produces much morbidity and mortality in certain sub-populations. In the United States, approximately one-half of cervical cancer is diagnosed in women who were never screened. Groups of the population that participate least frequently in Pap smear include: women who are less educated, older, uninsured, or homeless; migrant workers who face language barriers; and lesbians^[24]. The segment of the United States population at highest risk for cervical cancer is Hispanic and African American women. Fortunately, these populations have benefited from community-based awareness raising programs, which have successfully resulted in a decline in their prevalence of cervical cancer^[35]. It is then practical to reason that programs similar to the ones implemented on Hispanic and African-American women should be applied to the various groups of the population where the women are at greater risk to having cervical cancer due to their lack of compliance with Pap smear screening.

Cervical cytology tests

There are two forms of Pap smears, conventional and liquid-based cytology. In the conventional method cells are obtained from the neck of the cervix and then the cells are spread on a glass slide. In the liquid-based cytology method, the cells are obtained from the neck of the cervix, but instead of being spread on a glass slide, they are placed in a small glass vial that contains preserving fluid. There has been much debate with regards to which form is superior. Current evidence indicates that no clinically important differences in sensitivity or specificity exists when comparing liquid-based and conventional cytology^[36]. The United States Preventive Services Task Force (USPSTF) considers both of these methods to be of substantial net benefit when they are administered in the appropriate age groups at the recommended interval^[37].

HPV testing

Although the Pap test has proven to be a greatly effec-

tive tool for screening in countries that have the capacity to implement it to the majority of its population, one problem with the test is its high rate of false positive cytology^[38]. The higher understanding of the correlation between HPV and cervical cancer led to the development of molecular tests for HPV with greater sensitivity (approximately 90 percent)^[39]. However, it has slightly reduced specificity for CIN2 and CIN3 when compared with cytology. The currently available DNA test detects only the high-risk HPV types, and has greater reproducibility than cytology. The HPV test is a solution hybridization that has the capacity to amplify the DNA signal in the assays of the 13 HPV high-risk types^[14]. The HPV test should be performed only in women age 30 years or more because women less than 30 years have a high prevalence of transient infection and a low prevalence of underlying high-grade lesions^[37]. Therefore, HPV DNA testing in women under the age of 30 can lead to unneeded evaluation and overtreatment^[37].

At the present time HPV DNA testing has the highest sensitivity, which can additionally be used with Pap smears (co-testing) for optimizing diagnosis of high-grade cervical intraepithelial neoplasia^[39]. In women with mild or borderline abnormal Pap results, a Pap-plus-HPV test may be better, since a negative HPV DNA test has the potential to assure women that their Pap smear result is probably untrue; whereas treatment for a positive HPV DNA test may begin quicker in these women due to the high sensitivity of this test^[40].

Visual inspection with acetic acid

Low-and-middle-income countries (LMICs) are faced with a lack of critical resources for health in general and often an even larger deficit for preventative health initiatives for women. To combat this, LMICs pursue screening options that work within the various societal confounds faced by women in their countries. The majority of these LMICs do not have the current capacity to sustain cytology-based cervical cancer prevention programs^[41]. In these societies, the Pap test is hindered by numerous operational factors that inhibit quality, including the follow-up challenges of multiple visits for screening and later post-diagnosis therapy, inefficient recall and referral systems, inadequate resources for screening and treatment, and competing priorities in the healthcare systems^[41]. A viable alternative to the Pap test has been developed due its low cost and ability to “see-and-treat” in one visit. This screening method, known as visual inspection with acetic acid (VIA), partnered with cryotherapy-based treatment of VIA-positive lesions is a testing method that has been readily mastered by non-physician providers and has been extensively studied as a viable alternative to the Pap smear^[41,42]. A method of screening that is gaining increasing popularity in LMICs is the combination of VIA-based “see-and-treat” platforms with HPV DNA testing, given that they have the benefit of same-visit benefit of triage by VIA-based screening^[43-45]. This opportunity is made possible with the

ongoing development of low-cost, rapid molecular-assay technologies for HPV that may function optimally in the field^[46,47].

CURRENT GUIDELINES FOR CERVICAL CANCER SCREENING

In the United States, there has recently been a shift in the way that screening for cervical cancer is being conducted with recognition that yearly screening was unnecessary and caused higher rate of harms. This is due to greater understanding of the pathological development of cervical cancer and the discovery of the HPV DNA test and HPV vaccines that have occurred in the last decade. Consequently, screening guidelines have evolved rapidly, and many of the organizations that develop screening guidelines now agree on the screening recommendations^[27,48,49]. The American Cancer Society (ACS), American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society of Clinical Pathology (ASCP) all tasked expert panels within the past five years to review the available evidence on cervical cancer screening and jointly produce a new cervical cancer screening guideline. At the same time, the United States Preventive Services Task Force (USPSTF) developed an updated systematic review of cervical cancer screening. On March 14, 2012, The ACS/ASCCP/ASCP group^[33] and the USPSTF^[36] released their updated guidelines. The American Congress of Obstetrics and Gynecologist (ACOG) issued their updated guidelines for cervical cancer screening shortly thereafter in November 2012^[50]. The consensus of recommendations made by these organizations, as it pertains to cervical cancer screening, are for the general population only. The guidelines are not for women that are at a high risk, as they may need more frequent screenings, including women with a history of cervical cancer, who are immunocompromised, or were exposed in utero to diethylstilbestrol^[50].

Table 3 presents the current guidelines for specific age groups. These differ from previous recommendations most notably in when to begin screening and the screening intervals. Women before the age of 21 years should not have Pap smears, irrespective of the age when they initiated sexual activity^[37,48,49]. The previous guidelines by the ACS in 2002 and 2003 stated that Pap smears should start 3 years following the initiation of sexual intercourse^[37,51]. There has been a call for lengthening the screening intervals in two of the age classifications. The updated ACS/ASCCP/ASCP and ACOG guidelines^[51,52] have increased the time between Pap smears to 3 years in females between ages 21 to 29. Their previous guidelines recommended screening be done every 2 years. The reason behind this change in the guidelines is because 2-3 year screening of women before age 30 carry similar predicted lifetime risk of cervical cancer mortality (0.05 per 1000 women); however screening women every 2 years increases the risk of colposcopies by 40% compared with screening every 3 years^[49]. Hence, 3 year screening in

Table 3 Comparison of cervical cancer screening guidelines

Population	Current Guidelines ACS/ACOG/USPSTF 2012	Prior ACS guideline 2002/2003	Prior ACOG guideline 2009	Prior USPSTF guideline 2003
Females younger than 21 yr of age	Begin screening at age 21	Begin 3 yr following the onset of vaginal intercourse, but no later than 21 yr	Begin 3 yr following the onset of vaginal intercourse, but no later than 21 yr	Begin within 3 yr of onset of sexual activity or age 21, whichever is earliest
Females age 21–29 yr	Conventional Pap or liquid based cytology alone every 3 yr	Conventional Pap: Annually; every 2–3 yr for females ≥ 30 with 3 negative cytology tests Liquid-based cytology: Every 2 yr; every 2–3 yr for females ≥ 30 yr with 3 negative cytology tests If HPV testing used: Every 3 yr if HPV negative and cytology negative	Cytology every 2 yr	Conventional Pap: At least every 3 yr Liquid-based cytology: Insufficient evidence If HPV testing used: Insufficient evidence
Females age 30–65 yr	HPV and Pap smear co-testing every 5 yr or Pap smear alone every 3 yr. Do not use HPV testing alone.		HPV and cytology co-testing every 3 yr	
Women older than 65	Stop screening if adequate prior negative screening result and women not at high risk	Stop screening in Women ≥ 70 yr with 3 or more recent, consecutive negative tests and no abnormal tests in previous 10 yr	Stop between 65 and 70 yr of age after > 3 consecutive negative cytology tests over the past 10 yr	No screening if adequate prior negative screening result and women not at high risk
Women after hysterectomy	No screening if removal of cervix and no prior high grade pre-cancer or cervical cancer	Discontinue if hysterectomy for benign reasons and no previous high-grade CIN	Stop screening	Discontinue if hysterectomy done for benign reasons
Women who were immunized with HPV	Same as non-immunized women	No vaccines recommended for use at this time period	Same as non-immunized women	No vaccines recommended for use at this time period

women younger than age 30 years has the optimal benefit to risk ratio. In women 30 to 65 years of age, screening can be done every 5 years if the woman's result on co-testing with Pap smear and HPV testing are negative, since co-testing increases the sensitivity of screening, and co-testing every 5 years results in fewer colposcopies and comparable cancer risk than Pap smear screening every 3 years^[52,53]. Cytology testing only at 3-year intervals is also satisfactory in this patient population. The new guidelines also recommend a decrease in the age that screening is stopped, from 70 to 65 years^[49,50,54]. The reason for this is that studies show in women age 65 or older, new high-risk HPV infection is associated with a extremely low absolute risk of HPV persistence and progression to CIN3^[55,56].

There are some special circumstances that require specific recommendations in the screening guidelines. The new guidelines maintain previous recommendations to not screen women that have received hysterectomies with excision of the cervix for a benign cause and who do not have prior history of cervical cytology higher than CIN2^[37,48,49]. This recommendation has been made in part based on evidence produced by a large study of 5330 screening Pap smears in women with previous hysterectomy where there was just one person found with dysplasia and none with cervical cancer^[56]. Another unique circumstance that has arisen since 2006 was the advent

of the HPV vaccine. Current guidelines recommend the same screening strategy in individuals that have received the vaccine as in individuals that have not had the vaccine because it will be another decade or more before modeling studies predicting the effectiveness of the vaccine will be available^[57]. The guidelines also address the situation when women have a negative Pap smear but a positive HPV test. The ACS/ASCCP/ASCP and ACOG recommend genotyping of HPV 16/18 and if positive, immediate colposcopy^[49]. However, evidence for HPV 16/18 genotyping is sparse; therefore, an acceptable alternative option is to perform the combined HPV and cytology testing again within 12 mo^[49,58]. These recommendations are based on results found in large cohort studies showing that the risk of CIN 3 approximates 10% over 1 to 4 years when a woman's test is evident for HPV 16, and over 2 to 5 years if the woman's test shows HPV 18^[59,60].

DISCUSSION AND FUTURE PERSPECTIVE ON CERVICAL CANCER PREVENTION AND SCREENING

With the advent of the HPV vaccine and the limitless screening possibilities that have been afforded by the growing understanding of HPV and the role that it plays in the evolution of cervical cancer, there is a real possibil-

ity that cervical cancer can be eliminated in the future. However, for that vision to become a reality there are numerous complexities that have to be resolved with regards to prevention as well as to screening for cervical cancer. The innovative strides that have been made at the present time must be met by global efforts that are tailored to various societal confines.

In the United States there has been a push by health care providers for immunization with HPV vaccine routinely in young women. This effort has not only been met by opposition created from those challenging the morality and questioning the effectiveness of the vaccine; it has also been met by exclusion of male counterparts in the dissemination of this vaccine, as well as the ever present lack of access of certain populations to adequate health care. Individuals that are at higher risk of acquiring cervical cancer are those that demonstrate less knowledge of HPV and the HPV vaccine. Therefore, educational outreach and program funding is needed that are targeted at reaching the subgroups of the population with low health care literacy and who are at risk of succumbing to the morbidity and mortality of this preventable cancer.

The call to local and governmental officials to enhance the educational outreach and program funding as a means to decrease the incidence of morbidity and deaths due to cervical cancer is also at the frontline of the dialogue in LMICs. Immunization of women with HPV vaccine to potentially prevent cervical cancer in these regions may take a back seat to other health care issues in light of the cost and the unique blend of genotypes that are present based on the geographical region. Fortunately, officials in these regions are becoming more knowledgeable of the advantages of implementing innovative cervical cancer see-and-treat programs. There is a continued need for industrialized nations to lend aid to these countries. This aid should not only be sent in the form of the monetary contributions that have been made by vaccine manufactures; they should continue sending aid via providing the service of individuals that can train their non-physician workforce who do a great deal to treat the masses of women in their countries.

In both LMICs and developed countries, the advent of HPV DNA testing has had a tremendous impact on the way that screening for cervical cancer is conducted. Affordable versions of this test are being developed, non-physician providers can perform it independently, and the results can be obtained the same day. More research needs to be done to see if testing with this technology should be conducted as the primary testing method, especially in hard to reach populations, since compared to cytology, it offers extended safety after a negative result. Some experts argue that because testing for HPV has greater sensitivity than Pap smear, while Pap smear screening has greater specificity, HPV testing should be performed initially and then obtain Pap smear screening for patients testing positive for HPV. The potential advantage to this was seen in a Canadian trial that found that HPV testing followed by Pap smear caused lower re-

ferrals for colposcopy than did either alone (1.1% *vs* 2.9% with only Pap smear or 6.1% with just HPV testing)^[59].

The greatest effect on mortality rates from cervical cancer is on women that are unscreened or under screened. There is a huge need to continue with the innovative strides that have been made to overcome the health care barriers crippling this population. If this population is able to benefit from low-cost screening and vaccinations subsidized by the government and continued efforts that are being made possible by the growing dialogue surrounding cervical cancer, it is possible that women in future generations will no longer succumb to cancer of the cervix.

and transforming growth factor (TGF)- β 1 to produce a local immunosuppressive environment, which, along with altered tumor surface antigens, forms an immunosuppressive network that inhibits the antitumor immune response. In this review we analyzed the available data on several deregulated cellular immune functions in patients with NIC I, NIC II and NIC III and cervical cancer. The effects of immunosuppressive cytokines on innate immune response, T-cell activation and cellular factors that promote tumor cell proliferation in cervical cancer patients are summarized. We discuss the functional consequences of HPV E2, E6, and E7 protein interactions with IL-10 and TGF- β 1 promoters in the induction of these cytokines and postulate its effect on the cellular immune response in squamous intraepithelial cervical lesions and cervical cancer patients. This review provides a comprehensive picture of the immunological functions of IL-10 and TGF- β 1 in response to HPV in humans.

Abstract

Cervical cancer is a worldwide disease that constitutes a significant public health problem, especially in developing countries, not only due to its high incidence but also because the most affected population comprises women who belong to marginalized socio-economic classes. Clinical and molecular research has identified immunological impairment in squamous intraepithelial cervical lesions and cervical cancer patients. Human Papillomavirus (HPV) has several mechanisms for avoiding the immune system: it down-regulates the expression of interferon and upregulates interleukin (IL)-10

Core tip: Human Papillomavirus (HPV) persistence is a key event for cervical cancer development. HPV proteins E2, E6 and E7 induce the transcription of immunosuppressive cytokines as a means of evading HPV the host immune system. We postulate that interleukin-10 and transforming growth factor- β 1 induce HPV immune system evasion through an immunosuppressive state in the local microenvironment of the cervix in HPV-infected women. These findings allow us to gain insight in our understanding of how HPV persist in the cervix and favor cervical lesions and cancer development, with potentially strong impact on vaccine development and the

design of new targeted immunotherapies for women with cervical neoplasia.

Role of IL-10 and TGF- β 1 in local immunosuppression in HPV-associated cervical neoplasia. *World J Clin Oncol* 2014; 5(4): 753-763 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i4/753.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i4.753>

INTRODUCTION

Cervical cancer is the second most common cancer in women worldwide^[1]. Cervical cancer and its precursor, squamous intraepithelial lesion (SIL), arise as a result of an uncontrolled and persistent infection with a high-risk human Papillomavirus (HPV)^[2]. Based on molecular epidemiological studies that provide risk estimates of specific HPV types in cases and controls, as well as the evidence of the oncogenic potential of the different HPV types, 13 high-risk HPV types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, and 58, 68, 82) have been identified, with three considered probable (26, 53, 66). Ten types were classified as low-risk (6, 11, 40, 42, 43, 44, 54, 61, 72, 81CP6 108) and three of indeterminate risk (34, 57, and 83)^[3]. The most prevalent high-risk viral types in the general population are 16 and 18. These two types are responsible for approximately 70% of all cervical cancer cases^[4].

Most of the HPV infections are of a transient and intermittent nature, especially among women under 30 years of age^[5]. Around 70% of infections disappear within approximately one year. After two years 90% of the infections will have disappeared. Only 10% of the women studied remained infected and developed cervical epithelium alterations and eventually cervical cancer^[5,6]. The majority of women clear HPV infections spontaneously through the antiviral host immune response. The mechanistic explanation for HPV clearance is by specific immunological reactions, which require competent humoral and cell-mediated immune mediators^[7,8]. Among the factors influencing viral persistence are host factors (genetic or acquired, such as age, immunosuppression, oral contraception, smoking) and viral factors (genotype, variants, viral load and viral integration)^[6,9].

In this review we discuss the mechanisms that allow HPV and human cervical cancer cells to evade immune surveillance through soluble immunosuppressive factors produced in the tumor microenvironment, such as interleukin (IL)-10 and transforming growth factor (TGF)- β 1, and we dissect the molecular events underlying tumor immune escape.

NATURAL HISTORY OF CERVICAL CANCER

The natural history of cervical cancer has been well

established by a large number of prospective cohort studies. Figure 1 summarizes the molecular events and changes at tissue level related to HPV infection and cancer establishment.

The development of a precancerous lesion and cancer involves several events. Exposure to high-risk HPV causes an initial infection of squamous epithelium in the transformation zone. This is followed by persistent infection, viral genome integration into the host cell genome, genomic alterations, immortalization and transformation of epithelial cells (Figure 1)^[10].

As the understanding of the natural history of the disease has improved, the classification of these lesions has received different names [PAP I to V; moderate dysplasia, carcinoma *in situ* and severe, cervical intraepithelial neoplasia (CIN) I, II, III; low squamous intraepithelial lesions (LSIL) that include CIN I or mild dysplasia, condyloma and koilocytosis and high squamous intraepithelial lesions (HSIL) that include CIN II and CIN III or moderate or severe dysplasia and carcinoma *in situ*], as shown in Figure 1. The development of cervical cancer is preceded by a series of cellular abnormalities characterized by cytological and histological maturation variations and irregularities in nuclear cytoplasm^[5]. LSIL have a diploid DNA content or polyploid. This is correlated with their tendency to revert. In contrast, HSIL type CIN III is often aneuploid, have a greater degree of cellular atypia and are more likely to persist and progress^[6].

The immune system plays a key role during HPV-carcinogenesis since the majority of high-risk HPV infections (90%), as well as most of low-grade lesions (75%), regress. Upon infection, on average 2-3 years are necessary to develop CIN 1/2 and/or high-grade intraepithelial lesion (CIN3) and nearly one third of untreated HSIL may progress to cancer in about ten years^[5,6].

HPV enters the mitotically active basal cells through micro abrasions in the epithelium of the cervix. After infection, early HPV genes E1, E2, E4, E5, E6 and E7 are expressed in infected cells and the viral genome is maintained episomally. The virus can lie latent until the negative regulation of viral transcription in these cells by cellular factors is released. The viral genome is replicated with greater intensity and late genes L1 and L2 are expressed in the upper layers of the epithelium. Capsid ruptures allow the release of the viral genome, the formation of new virions and the start of a new infection^[11,12].

The long latency period between initial infections and the emergence of cancer suggests that HPV can evade recognition by the immune system. Indeed, the infection cycle of HPV is characterized by the absence of viraemia, very low expression levels of viral protein, no inflammation and no danger signal to alert the immune system^[13-15]. Host immune responses to HPV are generally low-level because the virus, being confined to basal epithelial cells, is shielded from the circulating immune cells during initial stages of infection. In this location there is only a limited expression of viral proteins. Other factors contributing to the low level of host immunity are that HPV infection

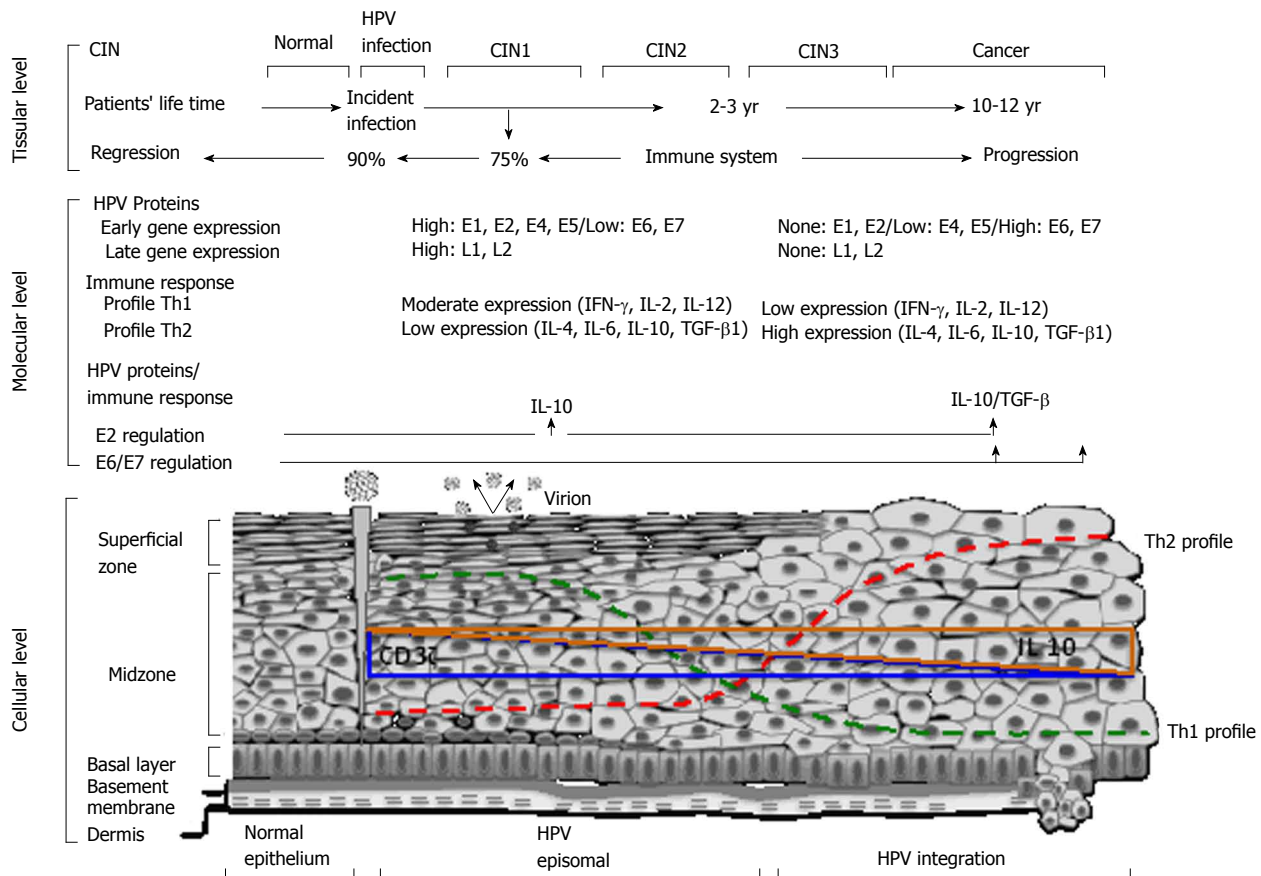

Figure 1 Systematic representation for cervical human Papillomavirus-carcinogenesis: Role of immune response. The main event is the human Papillomavirus (HPV) infection of epithelial cells in the basal membrane. HPV can turn into episomal bodies, which will be in charge of, on one part, producing infective virions and, on the other, integrating into the genome of epithelial cells. Upon infection, an average of 2-3 yr are necessary to develop of CIN 1/2 and/or high-grade (CIN3), often characterized by the integration of the viral genome, one key event for disease progression as this frequently triggers the deregulation of the E6 and E7 oncogenes, major chromosomal alterations and cellular immortalization^[10]. The immune system plays a key role during HPV-carcinogenesis since the majority of high-risk HPV infections (90%), as well as most of low-grade lesions (75%) regress^[5,6]. Due to this, and the long periods of time between viral infection and the progression to invasive disease, the fail of immune response is necessary to cancer development. Since the beginning of HPV infection, there are augment in the immunosuppressive cytokine IL-10 at the cervical level, and this increased according with the grade of lesion, being the highest concentration at cancer stage^[25]. A shift to Th2-type cytokines in the course of development of cervical cancer is reflected with an increased serum concentration of Th2-type cytokines^[22,23]. Inversely, the presence of CD3zeta chain in the tumor infiltrating T-lymphocytes, decreases as the grade of lesion progress, this is due to a reduction of Th1-type cytokines at the late stages of the disease^[24]. These are key elements for the impairment of immune responses that allows HPV-persistence, viral integration into the genome epithelial cells, and cellular transformation and immortalization.

is non-lytic; that a functionally active immune response is generated only at later stages of HPV infection; and that only in suprabasal keratinocytes has the HPV DNA been sufficiently amplified to be detected by the host immune-surveillance cells^[16].

Although most HPV infections are transient and sub-clinical, progression is strongly associated with HPV persistence. This process often leads to disruption of viral E1/E2 regions and integration in the genome of the host cell. E2 rupture releases E6/E7 viral promoters and increases expression of these oncogenes, as show in Figure 1^[10-12,17]. Infection with one high-risk HPV acts as a trigger for the cascade of events in which the mechanisms of repair or correction of cell replication, mediated by p53 and pRb, are altered. Thus, the cell cycle is controlled by the virus, which triggers cellular changes that culminate in the transformation and immortalization of epithelial cells, in consequence establishing conditions for the onset

of cancer^[18-20].

During cancer progression, the pattern of changes in expression of viral oncoproteins changes; in CIN I, the order of events is similar to that observed in productive lesions. In CIN II and III, however, the event occurrence is delayed and virions production is restricted to smaller areas near the epithelial surface. Integration of HPV sequences in the genome of the host cell may accompany these changes and may lead to a further deregulation of the expression of E7 (and the loss of replication proteins E1 and E2). In cervical cancer, the production stages of the viral cycle are not permanent and the viral episomes are lost^[11,12].

A predominance of the Th2 cytokine profile, in association with a diminished Th1 profile, has been demonstrated in patients with cervical cancer^[21]. A shift to Th2-type cytokines in the course of development of cervical cancer is reflected by an increased serum concentration

of Th2-type cytokines^[22,23]. Inversely, the presence of CD3zeta chains in the tumor-infiltrating T-lymphocytes decreases as the grade of lesion progresses. This is due to a reduction of Th1-type cytokines in the late stages of the disease^[24]. This shift from Th1 to Th2 might be responsible for facilitating tumor progression by subverting various cellular immune surveillance mechanisms.

In addition, an impaired cellular immune response induced by immune suppressor cytokines, such as interleukin (IL)-10 and transforming growth factor beta (TGF- β 1), has been involved in high risk HPV persistence and cervical cancer development^[21]. Since the beginning of HPV infection there are increases in the immunosuppressive cytokine IL-10 at the cervical level. The increase is proportional to the grade of lesion, with the highest concentration occurring at the cancer stage^[25]. These are key elements for the impairment of immune responses that enable HPV-persistence, viral integration into the genome epithelial cells, and cellular transformation and immortalization.

IMMUNE EVASION IN HPV INFECTION, SIL AND CERVICAL CANCER

Innate immune response, which involves macrophages, natural killer (NK) cells, and natural killer T cells, plays a critical role as the first line of defense against HPV infection^[26]. However, effective evasion of innate immune recognition seems to be the hallmark of HPV infections^[27]. Several alterations of natural immunity have been documented in HPV infection. The interferon (IFN) response, a key antiviral defense mechanism^[28], is actively suppressed by the E6 and E7 proteins of high-risk HPVs, which inhibit the interferon receptor signaling pathways and prevent activation of the interferon response genes^[29,31]. Macrophages are activated by binding to viral components, such as single-stranded DNA, and by cytokines, which can kill HPV-infected cells via tumor necrosis factor α (TNF- α) secretion. HPV16 E6 and E7 proteins inhibit the translocation of macrophages to the site of HPV infection^[32].

Likewise, NK cells are a subset of lymphocytes that kill virally infected cells or tumor cells lacking the surface expression of major histocompatibility complex (MHC) class-I molecules. Low NK cell receptor expression and reduced cytotoxic activity of NK cells were recently observed in cervical cancer and precursor lesions. A previous study suggests that NKp30, NKp46 and NKG2D down-regulation represents an evasion mechanism associated with low NK cell activity, HPV-16 infection and cervical cancer progression^[26,33]. Recent studies have demonstrated that CD1d on the surfaces of cells infected with HPV6 or 16 is down-regulated by E5 protein, and that this may be a mechanism for immune evasion^[34]. Additionally, augmented serum level of major histocompatibility complex class I-related chain A (MICA) protein and reduced NKG2D expression on NK and T cells in patients with cervical cancer and precursor lesions have

been reported^[35,36].

Similarly, Toll-like receptors (TLRs) play a key role in the innate immune system against HPV infection. The activation of the TLR9 pathway by CpG motives is impaired severely in human keratinocytes expressing HPV16 E6 and E7 oncoproteins. This event is due to the ability of the viral oncoproteins to down-regulate TLR9 mRNA. This phenomenon has been observed in HPV16-positive cancer-derived cell lines and in primary cervical cancers. TLR9 promoter down-regulation is less significant for high-risk HPV 18 compared with HPV 16 and is completely absent in cells expressing E6 and E7 from the low-risk HPV 6. Thus, the efficiency of HPV16 in persisting appears to correlate with its ability to down-regulate the transcription of TLR9^[37].

In high-risk HPV-infected women there is a decrease in the levels of Langerhans DCs in the human female genital tract (reduction of E-cadherin by E6)^[38]. CD4 regulatory T cells (Treg) subsets act as major mediators of peripheral immune tolerance by regulating Th1 and Th2 immune responses^[39,40]. Treg cells contribute to the induction of peripheral tolerance via expression of inhibitory cell-surface molecules (CD4⁺/CD25⁺ T cells) or production of IL-10 and TGF- β 1. IL-10 produced by Treg cells can impair TAA cross-presentation by DCs, thus potentially preventing T cells from mounting an effective immune response against malignant cells. IL-10 hinders the antigen-presenting properties of DCs by reducing their expression of *human leukocyte antigen* (HLA) class II molecules, inter-cellular adhesion molecules (*e.g.*, ICAM-1), co-stimulatory molecules (*i.e.*, B7-1/CD80 and B7-2/CD86), and Th1 cytokines (*e.g.*, IL-12), which correlates with the ability of IL-10 to impair primary alloantigen-specific T cell responses^[41]. IL-10 inhibits the host inflammatory response and favors tumor development. Thus, the predominant secretion of Th2 cytokines in innate immunity attenuates the antitumoral response^[42].

In addition, HPV effectively evades the innate immune response to delay the activation of adaptive immunity in patients with SIL^[43,45]. HPV16 E5-mediated immune evasion also involves suppressing the expression of MHC class I and Ag processing via the TAP pathway, reflecting the lack of Ag presentation to cytotoxic T lymphocytes (CTLs)^[13,46]. Immune function alterations that have been described in HPV infection further include impairment of CD4⁺ T-cell-mediated immunity and cytokine dysregulation in the blood of women with precancerous lesions or cervical cancer^[22,44]. At the systemic level, there is a report that shows a dysregulated CD28 and CTLA-4 expression in peripheral blood T cells of cervical cancer patients, which may lead to impaired function of these lymphocytes and a systemic immunosuppression related to disease progression^[47]. A lack of dendritic cells^[48,49] and a decrease in helper T cell type 1 immune infiltrates have been described in the presence of HPV-associated lesions^[50,51]. Therefore, all these findings provide solid evidence that altered immune responses are a crucial step involved in the carcinogenic events medi-

ated by HPV.

IL-10 and TGF- β 1 cytokine expression in SIL and cervical cancer: Evidence for the generation of local immunosuppression

It is well known that antiviral and anti-tumor immunity in cervical cancer is activated by Th1 cytokines and inhibited by Th2 cytokines. The transformation zone of the cervix, the region most sensitive to SIL and cancer development, is associated with above-average levels of type II cytokines (IL-4/IL-6) or immunosuppressive cytokines (IL-10 and TGF- β 1) produced by various types of cells, including macrophages, dendritic cells and keratinocytes^[52]. Since both cytokines have the ability to interfere with the efficient induction of a type I response by antigen-presenting cells (APC), these cytokines may contribute to the predisposition of this region to cervical carcinogenesis^[52].

We hypothesize that the changes in the immune response observed during different stages of the HPV infection can support the idea that development of immunosuppressive environment in cervix correlates with the progression of lesions into more aggressive neoplasia. IL-10 (UniprotKB/Swiss-Prot: P22301) is a Th2 anti-inflammatory cytokine that participates in the regulation of the immune response at several levels and can have pleiotropic effects on cell mediators of adaptive and innate immunity^[53]. Human IL-10 is produced by CD4⁺ T cells, activated CD8⁺ T cells, Epstein-Barr virus-transformed lymphoblastoid cell lines, fibroblasts and monocytes. It has potent inhibitory effects on T cell proliferation and inflammation. IL-10 also depresses the production of a number of Th1 cytokines normally synthesized by activated macrophages and mononuclear cells^[53]. More recent studies have clarified that IL-10's immunosuppressive effect on T cells is mainly indirect and is mediated by two other immune cell types: DCs and Treg cells^[54]. Additional evidence supports the hypothesis that DCs are the major target of IL-10's immunosuppressive effect. It has been shown that IL-10 reduces the expression of antigen-presenting and costimulatory molecules and interferes with the maturation of monocytes to DCs^[55]. These properties support the role of IL-10 as a strong immunosuppressive cytokine and a potent negative regulator of immunoproliferative and inflammatory responses.

A previous study reported a high tendency of IL-10 expression associated with the frequency of HPV types and the severity of the disease^[25]. Additionally, Arany *et al.*^[56] described a mechanism by which IL-10 might enhance persistence and progression of HPV-related lesions under certain conditions (*e.g.*, dysplastic progression, HIV infection) when the cytokine expression in the cervical microenvironment changes. It has been shown that peripheral blood mononuclear cells (PBMC) from patients with both SIL and cervical cancer produce decreased amounts of IL-2 and IFN- γ and higher levels of IL-4 and IL-10 following mitogenic stimulation, compared

with the control group^[57]. High levels of IL-10 have been detected in serum and at the cervical level of patients at early stages of the disease^[58-60]. The systemic IL-10 mRNA expression level and the IL-10 protein level in serum are significantly higher in SIL compared to women without lesions. The IL-10 expression level is determined by whether a person is a carrier of the allele A of the SNP at -592 nt of the human IL-10 gene^[23]. Therefore, the presence of IL-10 appears to be an important factor in the progressive development of the impaired immune response against cervical lesions.

Most cervical tumors expressed IL-4 and IL-10 mRNA and, most importantly, all of them expressed TGF- β 1 and IFN- γ mRNA^[21,22,61]. IL-10 has been identified by immuno-histochemical analysis in tumor cells and koilocytic cells, but not in tumor-infiltrating lymphocytes, suggesting that the IL-10-producing cells are those transformed by HPV. Similarly, a correlation between immunostaining for IL-10 protein and the level of IL-10 mRNA expression has been reported and supernatant from HPV-transformed cell lines has been found to contain IL-10 and TGF- β 1. These findings show a predominant expression of immunosuppressive cytokines, which help down-regulate tumor-specific immune responses in the tumor microenvironment^[21,22,61].

A recent study examined T cell functions of PBMC and tumor infiltrating T lymphocytes (TIL) from women with SIL or cervical cancer, including proliferation, cytokine mRNA expression (IL-2, IFN- γ , IL-4, IL-10, TGF- β 1), and CD3 ζ expression^[24]. The distribution of T cells in the epithelium and stroma of biopsies from women with SIL and from women with microinvasive carcinoma of the cervix was determined by immuno-histochemical analysis. There were more TIL in the stroma than in epithelium in advanced stages of the disease where CD8⁺ T cells prevailed. Consistent with other reports^[62], it was found that CD8⁺ T cells predominate but lack activity compared with CD4⁺ T cells in women with cervical cancer^[24]. To better understand T cell behavior during the course of cervical cancer disease, the proliferation of PBMC and TIL from patients with SIL or cervical cancer with phytohemagglutinin (PHA) or immobilized anti-CD3 was examined and compared to those of healthy donors. For PHA, PBMC from cervical cancer patients proliferated less than those from SIL patients and healthy women, although the differences between SIL patients and healthy women were not significantly different^[24]. Moreover, a significant difference was found in anti-CD3-stimulated PBMC between cervical cancer patients and healthy donors. When the proliferation of PBMC *vs* TIL was compared in women with cervical cancer, only PBMC proliferation was statistically higher than that of PHA-stimulated TIL. Thus, women with cervical cancer have a deficient PBMC proliferative response, with no response observed for TIL^[24].

Additionally, it has been suggested that reduced T cell function may be associated with alterations in CD3 ζ protein expression in cervical cancer patients^[63]. A previ-

ous study demonstrated that *in vivo* suppression of CD3 ζ chains in patients with CIN can occur as the result of a circulating factor^[64]. This circulating factor is composed of IL-10 and TGF- β 1, which reduce CD3 ζ expression *in vitro*, as show in Figure 1^[24]. We therefore propose that IL-10 and TGF- β 1 play an important role in generating an immunosuppressive state in the tumor microenvironment which allows the tumor to evade the host cellular immune responses in cervical cancer^[24]. A significant correlation between low T cell proliferation and decreased CD3 ζ mRNA expression by anti-CD3 stimulated T cells has been reported^[24]. Thus, decreased T cell function appears to correlate with cervical cancer progression, which corresponds to a decreased T cell proliferation in cervical cancer patients^[24,62,64]. Similarly, a significant positive association between CD3 ζ /IL-2 and CD3 ζ /IFN- γ expression has been found, indicating that an optimal expression of CD3 ζ is associated with the expression of IL-2 and IFN- γ ^[24,64].

A separate role in immune response escape may be played by TGF- β 1 (UniprotKB/Swiss-Prot: P36897), a multifunctional cytokine that prevents cellular immune responses by inhibiting T cell proliferation and differentiation into cytotoxic T cells and helper T lymphocytes. It achieves this by inhibiting stimulatory functions induced by APC. An additional T cell subset, known as Th3, secretes TGF- β 1, which can suppress cytotoxic T cell function. Animal and human models suggest that TGF- β 1 can promote tumor progression by facilitating extracellular matrix invasion and angiogenesis and by inhibiting immune surveillance^[65]. Direct inhibitions of the proliferation and effector functions of CTLs are the immunosuppressive functions of TGF- β 1. TGF- β 1 may polarize APC activity to favor a Th2 type immune response. In animal models, neutralization of TGF- β 1 with monoclonal antibodies or antisense oligonucleotides results in tumor regression or decreased invasiveness^[66,67].

After HPV infection of basal epithelia cervical cells, E6 and E7 oncoproteins are expressed (Figure 1), and induce cytokine expression of TGF- β 1 throughout the Sp1 transcription factor. The E6-Sp1 and E7-Sp1 complex formation can migrate into the nucleus and induce the TGF- β 1 gene expression^[68]. TGF- β 1 down-regulates IL-2 receptor signaling in T cells and IL-12 expression by APC and induces the expression of IL-10 by macrophages, contributing to immunosuppression during cervical carcinogenesis^[68]. Reports have shown increased TGF- β 1 expression by cervical cancer, consistent with previous reports of TGF- β 1 expression in 94.1% of the stroma surrounding invasive cancer^[69]. TGF- β 1 gene expression is normally constitutive; however, during tumor progression there is an upregulation of TGF- β 1 gene expression, which induces favorable conditions for tumor development^[70].

Finally, the presence of IL-10 and TGF- β 1 in supernatants from human cervical carcinoma cell lines HeLa and SiHa after 24 h of incubation without FBS has been reported. HPV-positive cervical cell lines produce higher

quantities of both cytokines than the HPV-negative C-33A cell line^[24]. It was found that the inhibitory effect of rhTGF- β 1 is totally counteracted with neutralizing anti-rhTGF- β 1 whereas the inhibitory effect of rhIL10 is blocked with neutralizing α -rhIL-10. Thus, both cytokines independently produce a profound inhibitory effect on T cell proliferation^[24]. Furthermore, loss of the inhibitory effect of TGF- β 1 plays a role in the transformation of normal cervical epithelial cells to dysplastic and malignant cells. Following development of malignancy the TGF- β 1 acts to facilitate aggressiveness and tumor progression^[71].

Expression of IL-10 and TGF- β 1 may be induced by HPV

We hypothesize that the expression of some cytokines, such as IL-10 and TGF- β 1, may be induced by HPV, and that IL-10 and TGF- β 1 cytokines may be produced by the transformed cell as a mechanism to escape the immune response. Several human heterologous promoters are regulated by HPV proteins. Particularly, HPV-16 E5, E6, and E7 oncoproteins, *trans*-activate a large variety of viral and cellular gene promoters^[72]. On the other hand, the presence of HPV E2 regulatory recognition site was reported in the position from -2203 nt to -2191 nt in the IL-10 gene regulatory region^[73]. HPV E2 protein is a sequence-specific DNA-binding protein that recognizes the specific sequence ACCN₆GGT present in the viral long control region (LCR) of all HPV genomes^[73].

To understand the potential trans-activation ability of HPV E2 protein on the human IL-10 gene expression in cervical cancer, the effects of HPV E2 protein on the promoter activity of human IL-10 gene were evaluated in cervical tumor cell lines, using the luciferase gene reporter assay^[74]. The human IL-10 gene regulatory region was obtained by PCR and several construct plasmids that contain different fragments of the IL-10 promoter region were generated in order to transfect HPV-negative C-33A cells. C-33A cells were transfected with the constructs containing the IL-10 regulatory region alone and co-transfected with pCMV16E2 expression plasmid, which expresses HPV E2 protein. For comparison, a plasmid containing the IL-10 complete promoter (pGIL10VB1 plasmid from -2534 nt to +132 nt) and the HPV E2 recognition site was used. The reporter IL-10 gene activity was detected as relative promoter activity, in cells that were transfected with IL-10 complete promoter. This promoter activity increased 6-fold when the cells were co-transfected with pCMV16E2. Similar promoter activity to that of the IL-10 complete promoter was found when the cells were transfected with plasmid that did not contain the HPV E2 recognition site. Thus, we concluded that HPV E2 is able to transactivate human IL-10 gene expression throughout the HPV E2 recognition site into the IL-10 promoter^[74].

A synthetic DNA probe containing the HPV E2 recognition sequences present in the IL-10 promoter was designed, and the ability of HPV E2 protein to interact with the E2-binding site was determined using an EMSA assay, to corroborate the effects of the HPV E2 protein

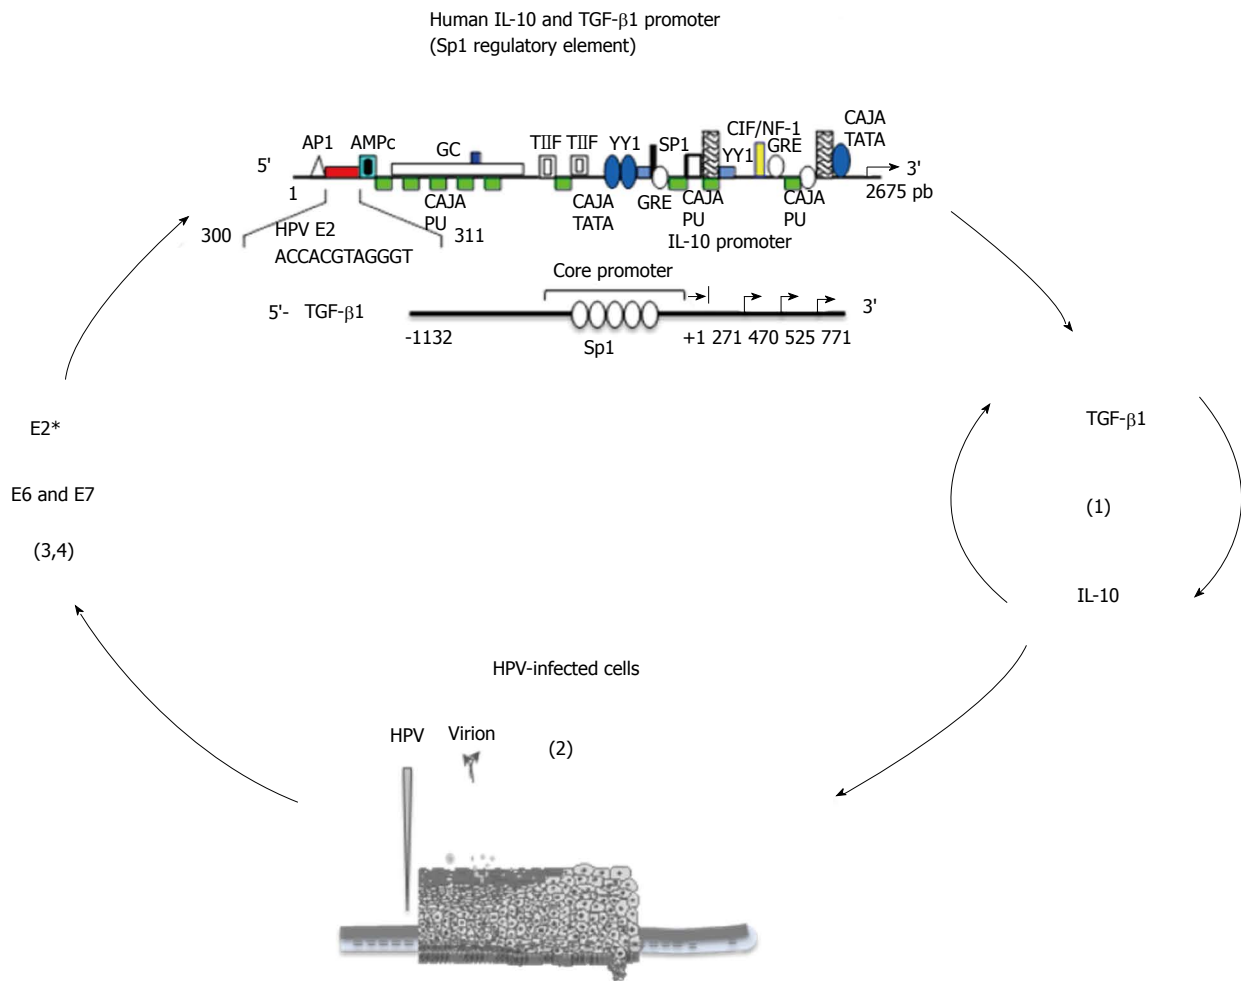

Figure 2 Vicious cycle between Interleukin-10, transforming growth factor- β 1, and human papillomavirus. (1) IL-10 enhances TGF- β 1 expression and vice-versa^[76]; (2) IL-10 induces transcription of HPV-16 E6 and E7^[56]; (3) HPV E6 and E7 proteins induce activation of TGF- β 1 promoter through Sp1 recognition sequence^[21]; (4) Human gene IL-10 regulatory regions possess Sp1 regulatory elements, which suggests that HPV E6 and E7 proteins may bind to IL-10 regulatory region to activate IL-10 gene transcription, just as HPV E2* protein does^[74], and may induce IL-10 expression in HPV-transformed cervical cells. HPV can enhance the expression of cytokines TGF- β 1 or IL-10, which inhibit T cell functions and augment viral proteins, contributing to the persistence of HPV infection and progression of HPV-related cervix lesions to cervical cancer. The production and activity of these two cytokines, IL-10 and TGF- β 1, are interrelated and likely involve a positive feedback loop in which IL-10 enhances the expression of TGF- β 1 and vice-versa^[76]. In fact, IL-10 not only enhances the production of TGF- β 1 but also controls the ability of target cells to respond to TGF- β 1. This involves the IL-10-mediated restoration of the expression of TGF- β 1 receptor 2 in recently activated T cells, which usually down-regulate this receptor and become desensitized to the inhibitory effects of TGF- β 1. Conversely, TGF- β 1 can promote the production of IL-10^[76]. IL-10: Interleukin-10; TGF- β 1: Transforming growth factor- β 1; HPV: Human papillomavirus.

on the transactivation mechanism of the IL-10 promoter and the importance of physical interaction with the HPV E2 recognition site. HPV E2 protein is able to bind to the IL-10 gene promoter, particularly with in the HPV E2 recognition site. The evaluation of IL-10 gene expression in HPV E2 transfected cells, measuring IL-10 mRNA by semiquantitative RT-PCR analysis, demonstrated that HPV E2 is able to induce IL-10 gene expression. This evidence contributes to the knowledge of the IL-10 gene expression molecular mechanism induced by HPV E2 protein, and is crucial to understanding the role of IL-10 in the process of HPV cervical carcinogenesis^[74].

These results lead us to propose a novel molecular pathway through which HPV E2 protein may stimulate IL-10 gene expression. This finding suggests a potential mechanism through which HPV proteins regulate IL-10

gene expression during cervical cancer development, which may represent an immune response regulation strategy mediated by HPV proteins^[74]. Additionally, it has been demonstrated that IL-10 induces transcription of the E7 early promoter, through the segment of the upstream regulatory region^[56]. Also, cervical keratinocytes express IL-10 receptor mRNA, which may explain IL-10's autocrine activity on tumour cells and HPV transcription in a dose-dependent manner. IL-10 expression by cervical cells after HPV infection is associated with enhanced viral persistence and progression of HPV- lesions to cancer^[75].

To gain insight into the potential TGF- β 1 gene regulation mechanism produced by the high-risk HPV E6 and E7 oncoproteins, the TGF- β 1 promoter activity induced by these oncoproteins was analyzed. When the TGF- β 1

core promoter in HPV E6- and E7-expressed tumor cells was evaluated, an increase in the reporter gene expression was found, compared with E6 and E7 non-expressed tumor cells. The TGF- β 1 promoter *trans*-activation was slightly elevated in E7 compared to E6 expression cells. These findings support the notion that the TGF- β 1 promoter activation by HPV-16 E6 and E7 could be physiologically relevant, particularly in cell transformation and immortalization^[68].

A cluster of five DNA binding motifs 100% homologous to Sp1 recognition sites was found in the TGF- β 1 core promoter sequence (-650 nt to +36 nt). DNase Footprinting assays *in vitro* were used to examine the profile of DNA-protein interaction at the TGF- β 1 core promoter to identify the target sequences responsible for TGF- β 1 promoter *trans*-activation by HPV-16 E6 and E7 oncoproteins. A differential protection pattern in the TGF- β 1 core promoter was found which suggests that HPV-16 E6 and E7 oncoproteins may induce varied interactions in tumor cells and may favor the recruitment of co-activators and/or transcription factors. This finding indicates that HPV-16 E6 and E7 oncoproteins expression may induce the formation of novel molecular transcription complexes throughout Sp1 recognition sites in tumor cells during cervical cancer development^[68].

In addition, the *trans*-activation caused by E6 and E7 can be abolished by mutation in the Sp1e (-108 to -102) recognition site. The data shows that HPV-16 E6 and E7 oncoproteins bind first to the Sp1 transcription factor and then the Sp1-E6 or Sp1-E7 complex binds to the TGF- β 1 regulatory element site (GGGGCGG). They do not bind directly to DNA^[68]. The physical interactions and functional cooperation between HPV E6 and E7 oncoproteins and cellular regulatory elements at the TGF- β 1 promoter explain the contribution of HPV-16 to TGF- β 1 gene expression in cervical cancer^[68]. Similarly, human gene IL-10 regulatory region possesses this Sp1 regulatory element (GGGGCGG). This suggests that HPV E6 and E7 proteins may bind to the IL-10 regulatory region to activate IL-10 gene transcription, just as the HPV E2 protein does, which may induce IL-10 expression in cervical HPV-transformed cells, as shown Figure 2.

CONCLUSION

The presence of IL-10 and TGF- β 1 in high-risk HPV cervical infections and patients with SIL may constitute an early event that promotes a microenvironment in the lesion with negative effects on the cellular immune response. Such a microenvironment could favor virus persistence and progression to cervical cancer. These cytokines have been detected in serum and cervical tissues from patients with high-risk HPV infection, with low grade SIL, high grade SIL, and cervical cancer. Their levels increase in correlation with the severity of the lesions^[23]. Results discussed in this review suggest that cervical cancer is characterized by local immunosuppression

dependent on Th2/Th3 cytokines. This data is in agreement with findings in cervical biopsies in which there is a pattern of Th2/Th3 cytokine expression present in cervical cancer but absent in normal cervix, suggesting that HPV infection induces the transcription of immunosuppressive cytokines as a means of evading the host immune system^[21,22,61].

IL-10 is a potent immunosuppressive cytokine that induces and is induced by TGF- β 1 expression. It also induces the HPV-16 E6 and E7 proteins, which induce TGF- β 1 transcription activation and IL-10 gene expression to create a vicious cycle. IL-10 and TGF- β 1 also down regulate CD3 ζ expression, which plays a crucial role in T-cell activation. Finally, IL-10 and TGF- β 1 induce the recruitment of Treg cells, which produce a profound peripheral tolerance. In summary, we postulate that IL-10 and TGF- β 1 induce immune system evasion through an immunosuppressive state in the environment of the cervix in women infected with HPV. This information is highly relevant in the areas of HPV vaccine generation and the design of new targeted immunotherapies for women with LGSIL, HGSIL, and cervical cancer^[77].

The future of research on the immune system in the context of HPV-associated cervical cancer has more questions than answers. Since it has been demonstrated that T-lymphocytes from patients with cervical lesions and cervical cancer are partially activated and had reduced expression of several signal transduction molecules which are involved in the complete activation of T-lymphocyte, it is of great interest to investigate whether the expression of these molecules can be reversed by type Th1 cytokines and whether they can turn these HPV-specific T-lymphocytes fully functional.

ACKNOWLEDGEMENTS

The authors wish to thank Juraj Lord and Jessica Deas for manuscript assistance. This work was submitted in partial fulfillment of the requirements for the PhD degree of Torres-Poveda KJ from the Doctoral Program in Public Health Sciences of the School of Public Health of Mexico. Torres-Poveda thanks the Ministry of Foreign Affairs of Mexico for the PhD fellowship.

Abstract

Brachytherapy forms an integral part of the radiation therapy in cancer cervix. The dose prescription for intracavitary brachytherapy (ICBT) in cancer cervix is based on Tod and Meredith's point A and has been in practice since 1938. This was proposed at a time when accessibility to imaging technology and dose computation facilities was limited. The concept has been in practice worldwide for more than half a century and has been the fulcrum of all ICBT treatments, strategies and outcome measures. The method is simple and can be adapted by all centres practicing ICBT in cancer cervix. However, with the widespread availability of imaging techniques, clinical use of different dose-rates, availability of a host of applicators fabricated with image compatible materials, radiobiological implications of dose equivalence and its impact on tumour and organs at risk; more and more weight is being laid down on individualised image based brachytherapy. Thus, computed tomography, magnetic-resonance imaging and even positron emission computerized tomography

along with brachytherapy treatment planning system are being increasingly adopted with promising outcomes. The present article reviews the evolution of dose prescription concepts in ICBT in cancer cervix and brings forward the need for image based brachytherapy to evaluate clinical outcomes. As is evident, a gradual transition from "point" based brachytherapy to "profile" based image guided brachytherapy is gaining widespread acceptance for dose prescription, reporting and outcome evaluation in the clinical practice of ICBT in cancer cervix.

Key words: Cancer cervix; Intracavitary brachytherapy; Point A; Image guided brachytherapy; Computed tomography-guided brachytherapy; Magnetic resonance imaging-guided brachytherapy; Ultrasound guided brachytherapy

Core tip: Traditionally, intracavitary brachytherapy in cancer cervix is based on dose prescription at point A. However, with the availability of computed tomography-magnetic resonance imaging compatible applicators, various imaging techniques, treatment planning systems for dose computations and evaluation, there is a gradual shift towards image based brachytherapy. The article reviews the evolution of dose prescription concepts from "point" to "image" based brachytherapy in the current clinical practice of intracavitary brachytherapy of cancer cervix. This could enable prescribing doses to conform the target and avoid normal structures based on individualized applicator geometry, tumour architecture and anatomy of the organs at risk, thereby improving the therapeutic outcome.

INTRODUCTION

Radical treatment of cancer cervix with radiotherapy is incomplete without the use of brachytherapy. The present standard of care for treatment of locally advanced cancer cervix is concurrent chemoradiation followed by brachytherapy. The probability of local control and development of normal tissue toxicity is related to the dose of radiation delivered. Since brachytherapy delivers a significant proportion of the dose, it is imperative to properly estimate the tumour extension and place the applicators optimally to decrease normal tissue toxicity and improve local controls.

The practice of external beam radiotherapy (EBRT) has seen radical changes with the advances in the field of imaging, radiation treatment planning and treatment delivery. Standard fields bounded by just “four lines” have given way to treatment portals encompassing the tumour in all its “four dimensions”. Thus individualized target delineation, dose computation and dose delivery dose has become the routine for any EBRT treatments.

However, practice of brachytherapy has not changed much and continues to be based on systems that were developed in early 20th century. Brachytherapy practices in cancer cervix had perhaps lesser scope for development, given the relatively fixed configuration of the applicators, poor visualisation of the standard applicators on computed tomography (CT) scans and the limited scope of dose optimisation with a single uterine tandem. With the advent of CT/magnetic resonance imaging (MRI) compatible applicators, availability of three-dimension (3D) cross sectional imaging and brachytherapy treatment planning software, it is time to explore the arena of cervical brachytherapy beyond the “point” based dose prescriptions.

This article summarises the evolution of brachytherapy in cancer cervix, focusing specifically on the intracavitary brachytherapy (ICBT), an integral component of radiotherapeutic management in cancer cervix. It analyses the problems inherent with the traditional point A based prescriptions and evaluates the present day scenario to explore the future approaches and possibilities that could provide a definitive dose prescription and reporting parameters on an individualized basis.

POINT A: THE TRADITIONAL BASIS OF INTRACAVITARY BRACHYTHERAPY

Use of radium sources in ICBT of cancer cervix started in 1903 and dose prescription at that time was largely empirical or subjective, on account of lack of data regarding biological effects of radiation on tumour and the surrounding normal tissues. To surmount this problem, dosimetric systems were formulated that provided guidelines regarding loading, arrangement and duration

of treatment with a set of specific radioisotopes in a designated manner to deliver the desired dose. The three dosimetric systems in use were-Paris system, Stockholm system and the Manchester system. With ICBT prescriptions being specified in terms of mg-hours, only the amount of radium required and the time duration were specified; doses to the normal tissues were neither calculated nor quantified.

To overcome these issues, Tod *et al*^[1,2] formulated the Manchester system in 1938 and they subsequently modified it in 1953. Within this system, they attempted to define the treatment in terms of dose to a point, which they believed to be representative of the target itself and was reproducible from patient to patient. To better define the actual dose that was delivered with specific “mg-hr systems”, Tod and Meredith calculated the dose (in Röntgen) at multiple points in the pelvis. They showed that the initial lesion of radiation necrosis was due to the high dose effects in the area at the medial edge of the broad ligament, within the pyramidal shaped area (paracervical triangle), where the uterine vessels cross the ureter. Keeping this triangle in mind as the dose limiting region, the authors defined point A, lying within the paracervical triangle that was 2 cm lateral to the center of the uterine canal and 2 cm superior to the mucosa of the lateral fornix, in the plane of the uterus. Additionally, applicator design, loading and arrangements were specified so as to deliver the same dose-rate at point A, regardless of the combination of applicators used for treatment.

The strong point of Manchester system point A prescription was the constancy of dose rate at the point A, irrespective of the combination of tandems and ovoids used. Point A prescription was easily taken up into clinical practice on account of its simplicity and was most suitable at that time with limited imaging modalities available (*i.e.*, orthogonal radiographs). As the originally defined point A could not be visualised on a radiograph, it was modified and redefined in relation to the applicator itself that could be visualized on radiographs. As per the new definition, point A was defined as a point 2 cm above the external os of uterus and 2 cm lateral to the uterine tandem in the plane of the uterus^[2].

HOW WELL DOES BRACHYTHERAPY POINT A REPRESENT THE ANATOMICAL POINT A?

The point A, defined in the paracervical triangle was based on the assumption that the region represented the tolerance limits due to crossing of the uterine artery and ureter. Wang *et al*^[3] correlated the anatomical point A and the brachytherapy point A in 11 patients undergoing ICBT. The anatomical point As-both right and left, were marked with radio-opaque clips and their positions compared with the brachytherapy point A. During the 64 brachytherapy applications, it was observed that the mean distances between the brachytherapy point A and anatomical point A were 5.2 cm (SD: ± 1.0) on right and 5.4

cm (SD: ± 1.1) on left. Furthermore, the dose received to the anatomical point A on right and left were 35.2% and 30% of the doses prescribed to the right and left brachytherapy point as respectively. This, questions the basic assumption of point A (the so called crossing point of the uterine artery and ureter) as being the dose limiting point. Lewis *et al*^[4] too, have demonstrated that the location of point A was far from the ureter in 93% of their observations and at a distance of 0.8 cm or more.

INTERNATIONAL COMMISSION ON RADIATION UNITS AND MEASUREMENTS REPORT 38 RECOMMENDATIONS AND ITS IMPLICATIONS

To provide an uniformity in the reporting of ICBT of cancer cervix practiced at different centres, International Commission on Radiation Units and Measurements (ICRU) proposed reporting guidelines in 1985 in its ICRU Report 38^[5]. As per the report, the type of source, the applicator, total reference air kerma (TRAK), dimensions of the reference volume (60 Gy or other dose equivalent volume), description of the dose distribution, dose rate and/or treatment time, absorbed dose at reference points and regional structures and organs at risk (OAR) were to be reported when using the 2D method of treatment planning.

Pötter *et al*^[6] reported their outcomes in 189 patients of cancer cervix stages I a to IVb treated between 1993-1997 in Vienna using the ICRU Report 38. They used a combination of a box technique for EBRT and a high-dose-rate ICBT using ring-tandem applicator. Small tumours were treated with 50 Gy of EBRT (25 Gy in brachytherapy reference volume) and 5-6 fractions of 7 Gy at point A (isoeffective at 76-86 Gy at point A) while the larger tumours received 3-4 fractions of 7 Gy after 50 Gy EBRT with open fields, (isoeffective to 82-92 Gy at point A). The 60 Gy ICRU volumes for the irradiation of small tumors ranged from 240 to 407 cm³ (mean: 337 cm³) and for larger tumors from 452 to 785 cm³ (mean: 607 cm³). At a mean follow-up of 34 mo, depending on the disease stage, their actuarial pelvic control and disease-specific survival rates varied from 52.7% to 100% and 52.1% to 100% respectively. The actuarial late grades 3 and 4 complication rate (LENT/SOMA) was 2.9% for the bladder, 4.0% for the bowel, 6.1% for the rectum and 30.6% for the vagina (shortening and obliteration). The authors felt that, in future the outcomes could be further improved using image based ICBT for a highly individualized treatment planning based on the topography of the actual tumour and OARs.

DOSE PRESCRIPTIONS IN HDR ERA USING POINT A AND ICRU REPORT 38

Over the years, the practice of ICBT has changed from

low-dose-rate (LDR) to high-dose-rate (HDR), taking into considerations several logistics and technical advantages of HDR over LDR. The use of HDR brachytherapy has increased substantially in the last decade all over the world. As per the recent Quality Research in Radiation Oncology (formerly Patterns of Care) survey (2007-2009), 62% facilities in United States were using HDR as compared to 13% in the 1996-1999 survey^[7]. During a recent global survey, HDR was found to be practiced by 85% of the respondents^[8].

Three randomized controlled trials have proved HDR brachytherapy to be comparable to LDR brachytherapy in terms of loco-regional control and complication rates^[9-11]. A meta-analysis showed that there were no significant difference in terms of outcomes between LDR and HDR^[12].

However, depending on the institutional protocols HDR ICBT requires multiple applications. This could lead to a variation in the applicator geometry and its spatial position in relation to the pelvic organs, pelvic bony anatomy and the organs at risk^[13-17]. These have been reported in terms of changes in the uterine axis, uterine length, slippage of tandem, colpostat separation and vaginal packing, resulting in fluctuations in spatial location of the applicator in craniocaudal axis, lateral and antero-posterior rotation as well as variation in coronal, transverse and saggital planes (Figure 1)^[18]. This has been attributed to mainly patient movement, vaginal packings and tumour regression during the interval between multiple fractions of HDR ICBT.

The variation in the applicator position in successive brachytherapy sessions, results in varying location of point A, as it is primarily defined in relation to the applicator itself^[14,19,20]. Multiple HDR applications, thus result in different set of point As for both right and left sides, each set corresponding to each application. Thus, the resultant of multiple ICBT in HDR brachytherapy could lead to multiple point As on right and left side, each corresponding to a particular application. This eventually results in loss of the geometrical definition of a point (a dimensionless entity), as multiple points would result in a volume encompassed by these multiple points on both sides of the intrauterine tandem (Figure 2)^[21]. Multiple point As, thus tend to change into "volume A" for multiple HDR applications in a single patient.

As a consequence to the above, in a given patient, multiple HDR ICBT could result in multiple ICRU volumes, with different volumes of common intersections depending on the variability of the applicator positions during these multiple ICBT applications (Figure 3)^[21]. All these could result in variation in the doses to various ICRU Report 38 reporting parameters-OARs, ICRU volumes, total reference air kerma in the same patient during the course of multiple HDR ICBT^[14,18,19].

Continuing to report dose to point A or ICRU Report 38 parameters, is therefore fraught with uncertainty. Apart from the ease of defining these points based on orthogonal radiographs, it is quite imperative that the extent of tumour coverage within the prescribed dose would still

most workers, although point A still continued to be the most common reporting parameter.

A NEED TOWARDS IMAGE GUIDED BRACHYTHERAPY: CT BASED INTRACAVITARY BRACHYTHERAPY

The limitations of orthogonal radiographs and dose prescriptions based on point A has mandated exploration of brachytherapy based on the actual position of the tumour and OARs in relation to the applicator. In the 90's, changes in brachytherapy practice started owing to the availability of CT scans and applicators that were CT/MRI compatible^[24]. Major changes in the design of the applicators were incorporated in keeping with the requirements of the tumour volume to be treated, *viz* a combined intracavitary/interstitial approach using Vienna ring applicator^[25] or Utrecht ovoid applicator^[26]. Shin *et al*^[27] performed CT based intracavitary brachytherapy and compared them with conventional point A based treatment plans. For CT based plans, dose was prescribed to the outermost point that covered all CTVs. In 30 treatment plans with HDR ICBT, the mean target volume coverage index, conformal index, significantly improved with CT based treatment plans. However, the mean values of bladder and rectal point doses and volume fractions receiving 50%, 80% and 100% of the reference dose did not differ between the plans based on CT or point A.

In another study, reported by Datta *et al*^[28], patients underwent an ICRT application and thereafter underwent a CECT scan with the CT compatible applicator *in situ*. On the scans, the target was delineated by including the entire cervix mass along with any parametrial or intrauterine or vaginal extension. The plans were generated with doses prescribed at point A and the tumour coverage within the prescribed isodose was evaluated on the axial CT images. It was observed that in FIGO stages II and III, when prescribing doses at point A, the mean percent-

Figure 3 Fusion of three 6 Gy International Commission on Radiation Units and Measurements 38 dose distribution in a given patient with respect to the cervical os depicted in antero-posterior and lateral projections. Reproduced with permission^[21].

remain ambiguous. Moreover, the outcomes in cancer cervix have not been found to correlate with the point A doses. Katz *et al*^[22], evaluated the outcomes for tumour control and bladder and rectal morbidity in 808 applications in 396 patients with respect to the dose at point A and also the ICRU Report 38 rectal and bladder points. They reported a lack of correlation between the reference doses and outcomes^[22]. Thus, point A as a panacea of reporting or dose prescription for ICBT is questionable.

Although ICRU Report 38 recommended reporting of the 60 Gy reference isodose dimensions and other parameters including the ICRU reference volumes and doses to OARs, a survey by Pötter *et al*^[23] showed that these guidelines are usually not followed, nor are they reported by most centres in clinical practice or in the literature related to HDR ICBT. The variations in the ICRU Report 38 reference volumes with multiple HDR applications could have further added complexity to the reporting parameters and therefore might not have been favoured by

Figure 4 Scatter-plot for tumour volume vs percentage of tumour enclosed within the 6 Gy isodose lines. Reproduced with permission^[28].

Figure 5 Tumour well covered within 6 Gy isodose volume (A) and tumour lying outside the 6 Gy isodose volume (B). Reproduced with permission^[28].

age tumour volume encompassed within the prescribed isodose (of 600 cGy) ranged from 60.8% to 100% with a mean \pm SD) of 88.8% (\pm 9.2). The extent of target coverage was inversely correlated with the target volume delineated at the time of brachytherapy (Figures 4 and 5)^[28]. Apart from this, the true maximal doses to bladder and rectum were underestimated when compared to the ICRU Report 38 reference points for these OARs and represented the 90th and 95th percentile of the maximum doses to these organs respectively.

Impact of use of 3D image based (mainly CT based) brachytherapy on outcomes was reported by Charra-Brunaud *et al.*^[29]. For the radical radiotherapy treatment arm, the local relapse free survival at 24 mo was 73.9% and 78.5% while the grade 3-4 toxicity rate was 22.7% and 2.6% in 2D *vs* 3D plans, respectively. Clearly improved outcomes both in terms of local control rates and toxicity rates have been demonstrated with use of image based brachytherapy planning.

Soft tissue imaging is best done with MRI. However, CT scans are widely available in most of the radiation oncology departments and could be used more frequently for logistic reasons. It has been shown that although CT scans are adequate for contouring the OARs, the CT based contours could significantly overestimate the tumour width^[30]. The results of the CT contouring could

be improved by contrast enhanced images for both bladder and rectum. Intravenous contrast could enhance the central areas of the cervix more than the peripheral areas and may also help to identify the uterine artery, thereby assisting the delineation of the upper border of cervix. The guidelines using CT scans for ICBT have been detailed using a comparative study with MRI^[30].

CT GUIDED INTERSTITIAL BRACHYTHERAPY

Apart from intracavitary brachytherapy, availability of CT compatible interstitial needles, permits CT guided interstitial brachytherapy. This approach could facilitate a better assessment of the target volumes and its delineation and dose adaptation leading to improved outcomes. Wang *et al.*^[31] reported the use of CT guided HDR interstitial implantation in 20 patients and had achieved a median 90% dose of 45 Gy for high risk clinical target volume by brachytherapy alone. Together with external radiotherapy, the median 90% dose reached to 94 Gy. At a median follow-up of 15 mo, only 2 patients experienced local failure. In a similar report, by Lee *et al.*^[32], 68 patients with both primary and recurrent disease were treated with CT guided interstitial brachytherapy. A median cumulative equivalent dose of 78.4 Gy was delivered by interstitial brachytherapy. At a median follow-up of 17 mo, the actuarial local control reported was 86% with grade 3 late toxicities in nine patients.

MRI BASED IMAGE GUIDED BRACHYTHERAPY AND GUIDELINES

MRI with its superior soft tissue contrast and visualization is able to detect subtle abnormalities that may not be appreciated on CT. It has been found to accurately estimate tumour size to within \pm 5 mm and correctly identify the parametrial invasion in 88% of cases^[33]. In contrast to CT which is needed for EBRT treatment planning as it requires tissue electron density data for computation, brachytherapy calculations rely on the inverse square law. Thus, MRI based treatment planning represents the current state of the art in ICBT of cancer cervix.

The Groupe Européen de Curiethérapie-European Society for Therapeutic Radiology and Oncology (GEC-ESTRO) published their detailed guidelines in 2005 and 2006 on the 3D image-based treatment planning in ICBT for cancer cervix^[34,35]. Recently, the American Brachytherapy Society (ABS) has also framed their recommendations and adopted the GEC-ESTRO guidelines for contouring, image-based treatment planning, and dose reporting^[24,36]. The guidelines provides clear recommendations for tumour delineation-gross target volume (GTV), high risk (HR) clinical target volume (CTV), intermediate risk (IR) CTV and OARs (rectum, bladder, sigmoid colon, and any adjacent bowel loops). The GTV, HR-CTV and IR-CTV represent a declining tumour cell density and thus are expected to have different radiotherapy dose

requirements. As per the recommendations, parameters for reporting are based on 3D image based dosimetric evaluation of ICBT and these include the reference volume, TRAK, prescribed dose, point A dose, D90 CTV (dose in 90% of CTV), D100 CTV (minimum target dose), D100 GTV (minimum dose in GTV), V100 CTV (CTV volume receiving > 100% of the prescribed dose) and dose volume parameters for OAR's. The recently published ABS guidelines provides dose limits for target and OARs for ICBT based on both radiographs and image based brachytherapy. The guidelines also suggests doses for template based interstitial HDR brachytherapy following 45-50.4 Gy of EBRT^[24].

The transition from 2D to 3D CT to 3D MRI based brachytherapy has been rapid. Radiation oncologists need to get accustomed to correctly interpreting the MRI data before delineation of the GTV and the high risk CTV. There is a learning curve involved and interobserver variations with MRI have been found to be lesser as compared to CT scans^[37,38]. GEC-ESTRO recommends to start with the standard method of prescription and then adjust the loading pattern and dwell times for optimisation. So, the starting point could either be point A prescription or the 60 Gy reference volume. The ABS recommends cautious use of optimisation based exclusively on dose volume histogram parameters as changes in spatial dose distribution may be significant and if not carefully analysed there may be unfavourable results^[24,36]. Using the response adapted CTV defined at the time of brachytherapy, there is an option of using dose escalation and delivering much higher dose than is feasible with EBRT^[39].

Apart from usual T2 images used for MRI based ICBT, diffusion weighted imaging (DWI) and the derived apparent diffusion coefficient (ADC) values, could also add additional biological information on tumour cell density. Haack *et al*^[40] have demonstrated significant differences in ADC values for the three GEC-ESTRO target. The mean ADC values were lowest for the IR-CTV, followed by HR-CTV and highest for GTV of the GEC-ESTRO target volumes.

The GEC-ESTRO working group recently issued guidelines for the MRI for 3D image guided cervical cancer brachytherapy^[41]. They recommended pelvic MRI scanning prior to radiotherapy and at the time of ICBT with one MR image. Multiplanar (transversal, sagittal, coronal and oblique image orientation) T2-weighted images with pelvic surface coils have been considered as the golden standard for delineating the topography of the tumour and the critical organs, while the use of complementary MRI sequences (*e.g.*, contrast-enhanced T1-weighted or 3D isotropic MRI sequences) was considered as optional.

Beriwal *et al*^[42] investigated the dosimetric consequences of brachytherapy planning using individualized MRI/CT based 3D-treatment plans for each ICBT application *vs* plans based on a single scan for all fractions. They observed that a single-plan procedure achieved

acceptable dosimetry in most patients but individualized planning at each application improved dosimetry as it took into account the variation in the applicator geometry and position of critical organs during each HDR ICBT.

Nesvacil *et al*^[43] evaluated the feasibility of adaptive 3D image based ICBT using a combination of MRI for the first BT application and planning the subsequent fractions on CT. They reported that such an approach is feasible, especially in small tumours for HR CTV coverage and OARs. However, for larger tumours, MRI based ICBT was preferred for all BT applications. This could be required in departments with limited access to MRI.

Tanderup *et al*^[44] in 72 consecutive patients compared the point doses to 3D dose volume parameters for tumour and OARs. They reported that the HR CTV90 was highly variable in standard plans with point A dose prescriptions. Although for small tumours (< 31cc), HR-CTV were well covered by standard plans in 94% patients, the OAR constraints exceeded in 72% of the cases. This was improved by MRI based optimization. On the contrary, optimization resulted in full coverage of the HR-CTV90 in 72% of the patients as compared to 25% with standard plans. The authors, concluded that point A was a poor surrogate of HR-CTV doses and MRI based image guided adaptive brachytherapy could improve target coverage and OAR doses.

OUTCOMES WITH MRI BASED IMAGE GUIDED ADAPTIVE BRACHYTHERAPY

The practice of image guided adaptive brachytherapy (IGABT) is gradually gaining momentum and the number of centres opting for IGABT is increasing. In United Kingdom, 71% of the centres in 2011 had embarked on IGABT compared to just 26% in 2008^[45]. In Canada, although point A is still the most common dose prescription point, but 73% of the centres have expressed their desire to change to 3D IGABT^[46]. Most of these centres are either using 3D imaging and planning or are in transition towards 3D IGABT.

The data on outcomes with MR based treatment planning is emerging gradually^[47-49]. Lindegaard *et al*^[48] have demonstrated that a point A based non-optimised plan will result in discrepancy to the target doses ranging from 50% to 150%. The ICRU Report 38 bladder reference point underestimated the 2 cm³ bladder dose by 75%-300%, while it overestimated the rectal dose in 75% patients. 3D MRI based planning, improved the optimization to the various dose-volume parameters^[48]. Pötter *et al*^[50] have reported excellent local control rates of 95%-100% at 3 years in limited/favourable tumours (stage I B1/ II B proximal, less than 4-5 cm) and 85%-90% in larger tumours (stage II B-IV) with acceptable treatment related morbidity (< 5%). Pelvic recurrences in this series had decreased by 65%-70%, as compared to historical series. They attributed this to the practice of MRI guided dose volume adaptation that enabled dose escalation in larger tumours (prescribed D90 > 85 Gy) often with in-

Figure 6 Positron emission tomography-computed tomography explore for brachytherapy planning in cervical cancers. A and B: Positron emission tomography-computed tomography with the Vienna applicator; C and D: Depiction of the 6 Gy isodose volume. The tumour in relation to the applicator is visualized within the 6 Gy volume.

terstitial needles as used in Vienna applicators.

In the Nordic study, Lindegaard *et al.*^[51] reported comparative results of outcome of cohort of patients treated at 2 different time periods with orthogonal radiograph based point A dose prescription (99 patients in NOCECA study, between 1994-2000) and those with MRI based IGABT (140 consecutive patients, 2005-2011). With IGABT, the actuarial local control reported was 91% at 3 years. MRI based IGABT significantly improved both overall and cancer specific survivals by 16% ($P < 0.005$) and 19% ($P < 0.001$) at three years, respectively. The improved survival was also seen in stage II B to IV stages ($P = 0.01$). Additionally, significant reduction in moderate gastrointestinal and vaginal morbidity was reported with MRI based plans ($P < 0.001$). There were also few patients who reported severe morbidity and grade 3 urological and gastrointestinal morbidities were reduced by more than 50% with MRI based IGABT over point A dose prescription brachytherapy ($P = 0.02$). This study further highlights the improved outcomes both in terms of local control, survival and reduced toxicities with MRI based IGABT in comparison to point A based conventional brachytherapy.

Studies from Vienna explored feasibility of dose escalation with CT based *vs* MRI based treatment planning^[52]. They found that compared to conventional radiograph based treatment planning, it was possible to escalate the dose to 95% of the target volume by a mean factor of 1.2 (range 1-1.7). The doses to the OARs, rectum and bladder could be maintained within the prescribed tolerance limits of 71% of the prescribed dose. Further, in a subgroup of 10 patients, MRI based ICBT permitted a dose escalation to 138% compared to 124% by CT based planning.

Using 3D IGABT with MRI, Tharavichitkul *et al.*^[53] reported their intermediate term results in 47 patients of locally advanced cancer cervix. Patients received a combination of 45-46 Gy EBRT followed by 6.5-7 Gy of 4 fractions of HDR IGABT. At 26 mo, the local control, disease free survival and overall survival were reported to be 97.9%, 85.1% and 95.6% respectively. The grade 3-4 bladder and rectum morbidity was 2.1% for each of these

OARs.

Results of a retrospective analysis of 46 patients using MR based 3D IGABT along with chemoradiation was reported from University Medical Centre, Utrecht, The Netherlands^[54]. At a median follow up of 41 mo, 3 year local control, progression free survival and overall survival was 93%, 71% and 65% respectively. Late grade 3-4 gastrointestinal and vaginal toxicities were observed in 4 patients (9.5%).

A multi-centric collaborative study, (intErnational study on MRI guided BRACHytherapy in locally advanced Cervical cancer) was launched in 2008 to validate these results prospectively^[55]. The study attempts to use MRI based IGABT in locally advanced cervical cancers in a multi-centric setting to establish benchmark for local control, overall survival, morbidity and quality of life. It also would correlate local control with GEC-ESTRO dose volume parameters for GTV, HR CTV, and IR CTV as well as late morbidity and dose volume parameters for OARs. With an expected sample size of more than 600 patients and a proposed long term follow up of 3-6 years, the outcomes from this study are keenly awaited to reconfirm the utility and efficacy of MRI based IGABT.

POSITRON EMISSION TOMOGRAPHY-CT BASED IMAGE GUIDED ADAPTIVE BRACHYTHERAPY

Positron emission tomography-CT (PET-CT) has been used increasingly for initial tumour evaluation and also during follow up in cancer cervix. PET-CT has also been explored for brachytherapy planning in cervical cancers (Figure 6). PET-CT is superior to other modalities for ruling out any positive regional lymph node or distant metastasis. The additional information could also be used to assess the target volumes for image based brachytherapy^[56,57]. Olsen *et al.*^[58] recently reported on a comparative evaluation of PET-CT and MRI. They compared the ADC maps on DWI MRI to evaluate the concordance of two functional imaging techniques and observed a good correlation of functional imaging between FDG-PET

and DWI for cervical cancer. Tumor subvolumes with increased metabolic activity on FDG-PET also were found to have greater cell density by DWI. With the availability of PET-MRI in clinics, it could be expected that in near future the IGABT could be based not just on anatomic imaging as evident on MRI or CT, but on an anato-metabolic-imaging using PET- CT/MRI.

FUTURE CONSIDERATIONS AND PRACTICAL ISSUES FOR CLINICAL ADAPTION OF IGABT

Even though GEC-ESTRO recommends 3D MRI image-based treatment planning, point A continues to be used as a starting point of optimisation and dose to point A is still reported as a bridge between the 2D and 3D treatment planning. The superiority of MRI based treatment planning has been documented in several publications. Without contesting the superiority of MRI based planning at each brachytherapy application, there is much trepidation in accepting it in routine clinical practice worldwide, especially in resource constraint settings on account of the additional cost, extra manpower and infrastructural requirement. Recently several publications have explored alternative techniques to acquire 3D image data without escalating the cost of the treatment^[59-62].

Trans-rectal ultrasound and MRI have been demonstrated by Schmid *et al*^[59] as having high correlation in accurately measuring the target width and thickness at the time of brachytherapy, when the target itself was defined as the complete macroscopic tumour mass and the remaining cervix. Trans-abdominal ultrasound too has been used to delineate the uterus, cervix and the central disease and has been demonstrated to have a fairly strong correlation with MRI^[60].

In absence of MRI, CT scans alone when used for brachytherapy planning can ensure OAR doses to be kept within acceptable limits. However, CT based target volumes have been overestimated as compared to MRI volumes^[30,63]. In limited resource setting, MRI based pre-planning at the first brachytherapy application and consecutive CT/MRI data fusion has been demonstrated to be safe and feasible with acceptable inaccuracy of soft tissue registration by Dolezel *et al*^[64].

Incorporation of successive clinical examination to CT based delineation has been explored by Hegazy *et al*^[65]. The study concluded that target delineation accuracy can systematically improve through incorporation of additional information from comprehensive 3D documentation of repetitive gynaecological examinations and can improve accuracy of dose optimization in settings with limited imaging facilities. With availability of CT images alone, a minimum two-third uterine height may be a good surrogate for height of HR CTV.

Considering the practical logistic issues, that could arise during practice of IGABT, one may have to judiciously select the patient population who may benefit

with MRI based IGABT vs CT based technique. For early and favourable disease cases, excellent local control rates have been reported with CT based planning^[45]. For these cases, dose escalation may not be required and may not need MRI based IGABT. For locally advanced diseases, the standard point A based prescriptions can result in under dosage or geographic misses as has been documented on CT images^[28].

The best way forward will be to perform a 3D cross sectional imaging prior to brachytherapy to correctly estimate the residual disease and thereafter proceed either with CT based or preferably MRI based planning^[34,35,63,64]. An alternate in form of an ultrasound based planning as evident from some of the recent studies could also be explored^[61,62,66]. It would still need some more time till we can integrate PET-CT/MRI into IGABT in cervical cancers.

CONCLUSION

Continuing to use point A dose prescriptions in ICBT at a time when the practice of EBRT has moved away from point prescriptions towards biological target based planning, amounts to an inequality in the fundamental approaches to planning for EBRT and ICBT. This is neither acceptable nor desirable. Point A prescription has for long served as the workhorse of intracavitary brachytherapy. Now, it may be time to honour it with a well-deserved place in the archives of ICBT of cancer cervix and move ahead and adapt image based intracavitary brachytherapy for an individualized and evidence based adaptive brachytherapy.

Abstract

Cervical cancer prevention requires a multipronged approach involving primary, secondary and tertiary prevention. The key element under primary prevention is human papilloma virus (HPV) vaccination. So far, only prophylactic HPV vaccines which prevent HPV infection by one or more subtypes are commercially available. Therapeutic HPV vaccines which aid in clearing established infection are still under trial. Secondary prevention entails early detection of precancerous lesions and its success is determined by the population coverage and the efficacy of the screening technique. A number of techniques are in use, including cytology, visual inspection (using the naked eye, magnivisualizer, acetic acid and Lugol's iodine), HPV testing and a combination of these methods. Updated screening guidelines have been advocated by the American Cancer Society in light of the role of HPV on cervical carcinogenesis. Recent research has also focussed on novel biomarkers that can predict progression to cancer in screen positive women and help to differentiate those who need treatment from those who can be left for follow-up. Last but not the least, effective treatment of precancerous lesions can help to reduce the incidence of invasive cervical cancer and this constitutes tertiary prevention.

A combination of these approaches can help to prevent the burden of cervical cancer and its antecedent morbidity and mortality, but all of these are not feasible in all settings due to resource and allocation constraints. Thus, all countries, especially low and middle income ones, have to determine their own cocktail of approaches that work before we can say with certainty that yes, cervical cancer can be prevented.

Key words: Cervical cancer; Prevention; Screening; Human papilloma virus; Pap smear

Core tip: While cervical cancer is not new, approaches to prevent the burden of this deadly disease are constantly being re-invented, be it human papilloma virus (HPV) testing or screening strategies. Novel biomarkers than can predict which HPV positive lesions will progress into cancer are the need of the hour. Along with early diagnosis of pre-invasive lesions, the other preventive aspect includes prophylactic vaccines which have flooded the scene, but their true impact remains to be gauged as the precancerous phase of cervical cancer is longer than the vaccine has been around. Only time can answer the question: can we truly prevent cervical cancer?

INTRODUCTION

Cervical cancer is the most common cause of deaths due to any cancer in developing countries and the number of these is ten times that in developed countries. It is the third most common cancer in women after breast and

Table 1 Risk factors for cervical cancer

Causal agent	Relative risk
Low socio-economic class	1.5
Low educational level	2-3
Early age at first coitus	2-4
Multiple sexual partners	2-5
Early age at first pregnancy	2-4
Multiparity	2-4
Long term use of oral contraceptives	1.5-2
History of sexually transmitted infections	4-10
History of genital warts	18
Cigarette smoking	2-4
Diet low in folates, carotene and vitamin C	2-3
Lack of routine cytological screening or prior abnormal smears	2-6
HIV	2.5
Immunosuppression	5.7

HIV: Human immunodeficiency virus.

colorectal cancer, with more than 530000 cases in 2008, 85% of these in developing countries. The mortality: incidence ratio is 52% and there were 275000 deaths in 2008, 88% of them in developing countries^[1,2].

The case for prevention of cervical cancer is thus a strong one that would serve to prevent mortality in many women and morbidity in many others. We know that cervical cancer is preventable, but the bigger question is, can it be prevented?

Prevention of any condition is described in terms of primary, secondary and tertiary prevention. While primary prevention deals with modification of risk factors to prevent disease occurrence, secondary prevention essentially signifies early diagnosis and treatment, while tertiary prevention seeks to limit the disability caused by the condition^[3]. Cervical cancer is particularly amenable to prevention as it has a long pre-clinical phase and the natural history of cervical carcinogenesis is well researched. In addition, treatment of pre-invasive lesions has been shown to reduce the incidence of invasive cervical cancer.

PRIMARY PREVENTION

In terms of cervical cancer, primary prevention involves education about safe sexual practices and *human papilloma virus* (HPV) vaccination^[4]. This is because HPV is known to be a necessary cause of cervical cancer and it is the persistence of this infection over decades which can lead to precancerous changes in the cervix and eventually cancer. The first vaccine licensed was Gardasil (Merck, Pennsylvania) in 2006 which protects against HPV 6, 11, 16 and 18, while Cervarix (Glaxo Smith Klein, Belgium) which was licensed in 2009 protects against HPV 16 and 18. Both of these are prophylactic vaccines which have now been introduced in over 80 countries. Short term data indicates that they are safe, immunogenic and efficacious in preventing HPV infection and hence precancerous lesions by the respective HPV types. There is

also some evidence of cross-protection against closely related HPV types. They are less effective in established infection. The best evidence of HPV vaccination success comes from Australia, where introduction of nationwide HPV vaccination resulted in a decrease in the incidence of high grade cervical abnormalities within 3 years after vaccination^[5]. Recent data indicates that two doses of vaccine may be as protective as three doses^[6] and this has implications for use where the utilization is limited by costs.

There is another kind of vaccine, the therapeutic vaccines which help in the clearance of HPV infections by generating T-cell mediated immunity against the HPV E6 and E7 antigens. These have been shown to be efficacious under trial conditions^[7].

However, although HPV infection is the most common, it is not the only causal agent of cervical cancer. As understood by the model for cervical carcinogenesis, there are various other behavioral and demographic risk factors that increase the relative risk of developing cervical cancer. These are given in Table 1.

Others factors like older age, racial factors and genetic predisposition are non-modifiable risk factors^[8]. There is some data to indicate that consumption of high amounts of whole fruits and vegetables, fish and nuts which provide a rich source of antioxidants like vitamin C, E, carotene, lutein and lycopene, and vitamin A, calcium and poly-unsaturated fatty acids can significantly reduce the risk of CIN^[9]. The mechanism of action is purported to be by enhancing HPV clearance while still in the transient phase, inhibiting the expression of E6 and E7, preventing DNA damage and reducing immunosuppression^[9].

SECONDARY PREVENTION

Secondary prevention involves screening asymptomatic patients or carrying out definitive tests in symptomatic or screen positive patients to pick up precancerous lesions before they turn into cancer. A number of methods are available for cervical cancer screening. Observational studies have shown that introduction of any regular cervical cancer screening program results in a fall in the incidence of invasive cervical cancer and cancer deaths. The Nordic countries are a prime example where introduction of organized cervical screening reduced the incidence of cancer deaths between 10%-80%.

Various modalities employed for screening preinvasive disease are: (1) cervical cytology - both conventional and liquid-based; (2) direct visual inspection (DVI); (3) visual inspection using 3%-5% acetic acid (VIA); (4) visual inspection using 3%-5% acetic acid and magnification (VIAM); (5) visual inspection using Lugol's iodine (VILI); (6) HPV DNA testing; (7) speculscopy; and (8) polar probes. Other modalities like colposcopy, cervicography and microcolpohysteroscopy can be used for further evaluation of abnormal results.

Cervical cytology is the globally preferred screening method and has been shown to reduce the incidence

Table 2 American College of Obstetricians and Gynecologists guidelines for cervical cancer screening

Commence	Frequency of smears (Pap or LBC) and HPV testing	Discontinue	HPV DNA
21 yr	1 3 yearly smears for < 30 yr 2 3 yearly smears or 5 yearly co-testing for > 30 yr (if 2 previous smears normal) 3 3 yearly smears or 5 yearly co-testing for those previously treated for CIN2/3 or cancer (up to 20 yr)	1 > 65 yr 2 After hysterectomy for benign disease with no history of CIN	For women > 30 yr, two options to manage Positive test: Repeat co-testing at 12 mo; Test for HPV 16/18 and colposcopy if positive

HPV vaccination does not change these guidelines. HPV: Human papilloma virus; LBC: Liquid based cytology.

of invasive cervical cancer by up to 80%^[10], while other methods of screening have generally been used in project settings. However, the fall in incidence with Pap smear based screening is directly linked to the frequency of screening and the proportion of population covered by screening. The conventional Papanicolaou test is done to examine exfoliated cells from the ectocervix and the endocervix using a wooden Ayre spatula and cytobrush. The smear is prepared and fixed with 95% ethylene glycol. Slides are stained using the Papanicolaou method and graded according to the revised Bethesda system. Although cytology has a high specificity of 95%-99%, pooled data has shown the sensitivity of a single Pap smear to be as low as 51%^[11]. For liquid based cytology (LBC), the method involves using a cytobrush which is rotated by 360 degrees five times around the cervix and the exfoliated cells are stirred in a proprietary solution. This reduces specimen inadequacy (which can cause false negative smear results) by 80% but adds to the cost. In addition, a single specimen may be used for HPV, chlamydia and gonorrhea testing. Screening guidelines have been advocated by various societies.

The latest screening guidelines^[12] by the American College of Obstetricians and Gynecologists (ACOG) published in 2012 are given in Table 2.

Where resources are limited, the World Health Organization recommends that the highest priority group for screening is those aged 35 or over and that screening every 5 years for a total of 3 tests in a lifetime will achieve a major impact. In low resource settings, screening using HPV as a primary test followed by further triaging for treatment using cytology or VIA of HPV positive women can cut costs while maximising benefits of screening.

Direct (unaided) visual inspection (DVI) is advocated in low resource settings where no other method is available as the incidence of CIN in a clinically unhealthy cervix may be as high as 9% compared to 0.9% in a healthy cervix^[13]. DVI can detect cancer early and improve survival rates and thus should be done in all patients, even if pregnant.

Aided visual inspection methods which include VIA, VIAM and VILI are simple, low tech approaches that are minimally reliant on infrastructure, assuming that basic facilities for performing a speculum examination are available. Non-physicians can perform the procedure if they receive adequate and ongoing training. Furthermore, results of the procedure are available immediately, making

it possible, in principle, to provide treatment during the same visit (screen-and-treat or single-visit approach). VIA involves swabbing the cervix with 5% acetic acid and inspecting the cervix in good light after 1 min to look for acetowhite lesions. For VIAM, the cervix is inspected as before but by using a self-illuminated hand held device. The disadvantages are low specificity compared to cytology, potential for over-diagnosis and over-treatment, observer dependency and usefulness in detecting ectocervical disease only. Our own institutional data (including over 1200 patients) found the sensitivity and specificity of VIA to be between 91%-96% and 31%-82% respectively^[13,14]. The large variation in specificity indicates that several variables affect the test characteristics of VIA, including light source, observer training, criteria for test positivity and the presence of co-existing infection, inflammation and metaplasia. VIAM offers the advantage of 4 × magnification using a hand held battery powered device and improved the specificity over VIA from our data^[14]. It can supplement VIA in doubtful cases where colposcopy is not available as a secondary triage. In low resource settings, primary screening by VIA/VIAM is more cost effective compared to universal Pap smear and can be used to take a guided biopsy and endocervical curettage.

HPV DNA testing

Two types of tests for HPV DNA are currently in use; one is a nucleic acid hybridization assay with signal amplification for the qualitative detection of high risk HPV types in cervical specimens (Digene Hybrid Capture 2 High Risk HPV DNA TestTM; Cervista HPV HR TestTM); the other is a polymerase chain reaction based assay (HPV DNA Nested Polymerase Chain Reaction Detection KitTM). Detection of high risk HPV DNA increases the sensitivity of detection for both squamous and glandular abnormalities; however, it does not have the analytical specificity that can help to decide which lesions need treatment and those that will regress on follow-up.

A new test for HPV E6/E7 mRNA (PreTect HPV-ProoferTM assay and APTIMATM assay) is under research and is based on the fact that mRNA levels are directly correlated to the severity of the lesion and can predict progression to cancer with higher specificity than HPV DNA testing alone. This can be used to stratify high risk HPV positive women that need treatment. The reported sensitivity and specificity range from 0.41-0.86

and 0.63-0.97 respectively for PreTect based on pooled data^[15]. FDA approval is awaited.

In both triage (investigation of minor abnormalities detected by cytology) and screening studies (when both cytology and HPV testing are jointly performed) the cross-sectional sensitivity of HPV test is high and so is the negative predictive value ($> 97\%$). The combination of the high sensitivity of HPV DNA testing and the high specificity of cytology can increase the screening interval for testing in women negative by both methods. Such a combined test was approved by the FDA in 2003 for primary screening of low risk women aged ≥ 30 years^[16]. In low and middle income countries, integrating the highly accurate HPV testing with the triaging capacity of VIA in “screen and treat” protocols can offer the dual benefits of maximizing detection using HPV and then using VIA to triage them for treatment^[17]. Despite the high cost of HPV testing compared to VIA alone, this can turn out to be cost effective in the longer run due to the costs saved on diagnosis and treatment of cancer. The advantages of HPV DNA testing are the objectivity of the test, possibility of complete automation, built in quality control, opportunities for self sampling and high sensitivity. Its disadvantages are cost, dependence on a single manufacturer (so far only HC2 is FDA approved and validated), requirement of a molecular diagnostic lab, low specificity in younger women and populations with significant HIV seropositivity, and follow up visits for test results and treatment.

Speculoscopy refers to direct observation of the cervix under 4-6 \times magnification using a blue-white chemiluminescent light source to enhance visualization of abnormal tissue after acetic acid application. This is a variant of the VIA designed to increase its specificity but it is marginally more expensive.

Polar probe is a pen-sized device (which is moved across the cervix) of electro-optical systems to identify cancer or pre-cancerous cells in cervical tissue by measuring the response of cervical tissue to light together with tissue capacitance of epithelial, basal and stromal layers. In a multicentric study, it was found to be as sensitive as a top quality Pap smear. It also has a high accuracy with instant report which prevents loss to follow up. Due to the objective, self-checking digital system, there is no subjective error of interpretation or the need for trained personnel to read the smear.

Colposcopy provides a magnified (up to 40 \times) stereoscopic view of the cervix and vagina and is a sensitive method for diagnosing CIN and invasive cancers. It helps in localizing abnormal areas from where a biopsy can be taken and accurate grading and conservative management of CIN is possible. It can supplement cytology and also triage cases that are a doubtful positive on VIA/VIAM. Its disadvantages are bulky and costly equipment and the need for experienced personnel.

Cervicography is a technique that attempts to reproduce colposcopy photographically. A photograph of the cervix (cervigram slide) is taken with a specially designed

camera (cerviscope) after the application of acetic acid and sent to an expert for interpretation. Cervicography has a better sensitivity than cytology (89% *vs* 52%), with similar specificity (94% *vs* 92%)^[18]. Cervicography is a highly sensitive tool for evaluating the ectocervical transformation zone but is unable to evaluate the endocervical canal. The expense of the instrument and the costs of photographs make it unlikely to be used for population screening, although it can be used in combination with a Pap smear to facilitate the selection of therapy for patients with an abnormal Pap test.

Microcolpohysteroscopy permits a naked eye view of the endocervix to evaluate the cervical canal *in situ*, thus obviating the need for a cone biopsy. It focuses on cells that have not been desquamated within their topographic and architectural context. A magnification of 20 \times gives visualization comparable to colposcopy, while 150 \times gives visualization comparable to cytology.

Recent research has centered on identifying the host genes up regulated in association with HPV infection, determining their suitability as “surrogate markers” for HPV infection, and using them to identify HPV-associated epithelial lesions in tissue or cytological specimens^[19]. These can help to increase diagnostic accuracy of cervical tissue specimens and provide information on risk of progression. These are given in Table 3.

Other newer technologies like optical imaging, spectroscopy and high-resolution imaging methods provide *in vivo* diagnosis with high sensitivity and specificity and are anticipated to improve conventional cervical cancer screening. They are based on the concept of morphological and biochemical alteration in the properties of cervical tissue in response to malignant transformation. In addition, contrast agents that target against specific neoplastic biomarkers can enhance the effectiveness of this new technology^[20].

The cycle of testing (using a sensitive test at regular intervals), diagnosis (using a highly specific test), treatment (with effective methods and by trained staff) and follow-up (as a part of an organized program with high population coverage) should be completed to ensure the success of screening.

TERTIARY PREVENTION

Tertiary prevention seeks to limit disability and promote rehabilitation. As cervical cancer has a long history in the form of precancerous lesions, diagnosis in the early phase and proper management (by cryotherapy or large loop excision of the transformation zone (LLETZ)) will prevent the progression to invasive cancer. Both can be done in the outpatient setting. While cryotherapy is useful for lesions involving maximum 1-2 contiguous quadrants of the cervix and no endocervical involvement, LLETZ can treat the entire transformation zone as well as a lesion extending not more than 1 cm into the endocervical canal. It also has the advantage of removing the specimen for histological analysis^[21]. Complication rate is less

Table 3 Biomarkers in cervical dysplasia

Biomarker	Significance
L1 capsid protein	Represents approximately 90% of the total protein on the virus surface and is generally detectable during the reproductive phase of HPV infection. The L1 protein is abundant in productive infections (CIN 1), found only in rare cases of CIN2/3, and not produced in carcinomas
p16INK4a (CINtec™)	Surrogate marker of HPV E7-mediated pRb catabolism, providing evidence of transformation of the cervical mucosa. On immunohistochemistry, diffuse staining for p16INK4a is present in almost all cases of CIN2, CIN3, squamous cell carcinoma and endocervical glandular neoplasia; however, it is rarely detected in benign squamous mucosa or CIN 1 lesions caused by low risk HPV types
Ki-67	Proliferation marker confined to the parabasal cell layer of normal stratified squamous mucosa but shows expression in the stratified squamous epithelium in CIN lesions in correlation with the extent of disordered maturation, but cannot discriminate HPV-mediated dysplasia from proliferating cells in benign reactive processes
DNA Aneuploidy	HPV infection leads to DNA hypermethylation, disruption of the normal cell cycle, and chromosomal aberrations, all of which may lead to changes in DNA content. Aneuploidy increases progressively from CIN1 to CIN3
MCMs (ProExC test™)	MCMs are required for the origination of DNA replication and are overexpressed in cervical high-grade dysplasia and carcinoma, but can also be seen in some benign cycling squamous and glandular cells
FISH technology	One of the most consistent chromosomal abnormalities in cervical carcinoma is gain of chromosome arm 3q (in about 70%), which can be detected by FISH. TERC gene in this region is amplified in progression to CIN3

FISH: Fluorescent *in situ* hybridization; MCAs: Minichromosome maintenance proteins; TERC: Telomerase RNA component.

Table 4 Management of preinvasive cancer (American Society for Colposcopy and Cervical Pathology 2012 guidelines)

Lesion on biopsy	Other features	Management
CIN 1	Preceding cytology of ASC-US, ASC-H, LSIL	Follow up with cytology (6, 12 mo) and HPV testing (12 mo)
CIN 1	Preceding cytology of HSIL, AGC-NOS	Either of these: Diagnostic excisional procedure or review of findings or observation with HPV and cytology (12 and 24 mo) (only if colposcopy satisfactory and ECC negative)
CIN 1	Adolescent (< 20 yr)	Follow up with cytology (12 mo)
CIN 1	21-24 yr	Follow up with cytology and colposcopy (6 monthly, up to 2 yr)
CIN 2/3	Satisfactory colposcopy	Either excision or ablation of transformation zone
CIN 2/3	Unsatisfactory colposcopy or recurrence or endocervical disease	Diagnostic excisional procedure
CIN 2/3	Adolescent (< 20 yr) and young women (21-24 yr)	Observation with cytology and colposcopy (only if colposcopy satisfactory) or treatment using excision or ablation of transformation zone
Adenocarcinoma <i>in situ</i>	Specimen from diagnostic excisional procedure	Hysterectomy preferred (rarely conservative management if margins negative and future fertility desired)

HPV: Human papilloma virus. CIN: Cervical intraepithelial neoplasia, ASC-US: Atypical squamous cells - undetermined significance; ASC-H: Atypical squamous cells - cannot exclude; LSIL: Low-grade squamous intraepithelial lesion; HSIL: High-grade squamous intraepithelial lesion; ECC: Endocervical curettage.

with cryotherapy and includes watery discharge for 3-4 wk, cervical stenosis (< 1%) and vaginal bleeding (very rare). It has no adverse effects on fertility and pregnancy and can be carried out by the average gynecologist. LLETZ on the other hand, requires more technical skill, a ready supply of electricity and is associated with severe perioperative bleeding (< 2%), cramping abdominal pain and effects on future fertility (infertility, preterm labor, cervical stenosis and dystocia).

The American Society of Colposcopy and Cervical Pathology has issued guidance for management of preinvasive cervical lesions diagnosed on biopsy^[22]. These are given in Table 4. Similar guidelines are also in place for a diagnosis based on Pap smear.

Pregnancy constitutes a special situation where the only indication for treatment is suspected invasive cancer. Both CIN 1 and CIN 2/3 require follow up during pregnancy (no more frequently than 12 wk) as the risk of progression to invasive cervical cancer is minimal and the rate of spontaneous regression postpartum is relatively high. Re-evalua-

tion is recommended no sooner than 6 wk postpartum.

Thus, prevention of cervical cancer involves a multi-pronged approach of education, creating awareness, advocacy, public-private partnerships for HPV vaccination, screening and early treatment of precancerous lesions before they develop into cancer. The extent of focus on each of these measures may vary between communities and countries based on the availability of resources and healthcare commitments. A holistic approach to prevention involving locally effective measures and treatment protocols and evaluating their adherence and success over time can help to tailor programs and policies to maximize the benefits for cervical cancer prevention.

Cervical cancer is preventable. Cervical cancer can be prevented. The extent to which we achieve this goal depends on us.

Abstract

Head and neck cancer (HNC) arises from the skull base to the clavicles and is the fifth most common cancer in the world by incidence. Historically, in the developed world HNC was associated with tobacco use and alcohol consumption, and the combination of the two produced a synergistic increase in risk. However, beginning in 1983, investigators have found a significant and growing proportion of HNC patients with human papillomavirus-positive (HPV) tumors who neither drank nor used tobacco. Since that time, there has been increased interest in the molecular biology of HPV-positive HNC. Multiple studies now show that HPV has shifted the epidemiological landscape and prognosis of head and neck squamous cell carcinoma (HNSCC). These studies provide strong evidence for improved survival outcomes in patients with HPV-positive HNSCC compared to those with HPV-negative HNSCC. In many reports, HPV status is the strongest predictor of locoregional control, disease specific survival and overall survival. In response to these findings, there has been significant interest in the best management of HPV-positive disease. Discussions within major cooperative groups consider new trials designed to maintain the current strong survival outcomes while reducing the long-term treatment-re-

lated toxicities. This review will highlight the epidemiological, clinical and molecular discoveries surrounding HPV-related HNSCC over the recent decades and we conclude by suggesting how these findings may guide future treatment approaches.

INTRODUCTION

Head and neck cancer (HNC) describes a broad range of tumors that arise from the skull base to the clavicles. Worldwide, the incidence of HNC exceeds half a million

annually, making it the fifth most common cancer in the world^[1]. In the year 2013, it is estimated that there will be 53640 new cases of HNC and 11520 deaths attributed to this disease in the United States alone^[2]. Anatomic sites of the head and neck include: the sinuses, orbits, nasopharynx, oropharynx, oral cavity, hypopharynx, and larynx. The primary risk factors for HNC include tobacco, alcohol, human papillomavirus (HPV) infection (for oropharyngeal cancer) and Epstein-Barr virus (EBV) infection (for nasopharyngeal carcinoma). The relative prevalence of these risk factors contributes to the various distributions of disease in different areas of the world.

Over the past 20 years there have been marked improvements in the diagnosis and treatment of HNC. Three-dimensional imaging including computed tomography (CT scans), positron emission tomography (PET), and magnetic resonance imaging (MRI) has allowed for better staging, target localization, and treatment planning. Advances in microsurgery and radiation therapy techniques have decreased treatment related morbidity and long term toxicities, while maintaining locoregional control (LRC)^[3].

Historically, in the developed world head and neck squamous cell carcinoma (HNSCC) was associated with tobacco use and alcohol consumption, and the combination of the two produced a synergistic increase in risk^[4]. However, a significant minority of patients (15%-20%) did not smoke or drink, indicating a different etiology existed. In 1983 investigators found immunohistochemical evidence of human papillomavirus (HPV) infection in tissue samples from 6 oral SCC^[5]. Since that time, there has been increased interest in the molecular biology of HPV-positive HNSCC. Multiple studies now show that HPV has clearly shifted the epidemiology and prognosis of head and neck squamous cell carcinoma (HNSCC). These studies provide strong evidence for improved survival outcomes in patients with HPV-positive HNSCC compared to those with HPV-negative HNSCC. In many reports, HPV status is the strongest predictor of locoregional control (LRC), disease specific survival (DSS) and overall survival (OS)^[6-8].

In response to these findings, there has been significant interest in the best management of HPV-positive disease. Discussions within major cooperative groups including the Radiation Therapy Oncology Group (RTOG) and the Eastern Cooperative Oncology Group (ECOG) have considered new trial designs based on HPV-status including: induction chemotherapy with response adapted radiation; alternatives to concurrent cisplatin chemotherapy, de-escalation of radiation dose, and the integration of minimally invasive surgery into the treatment algorithm. The primary objective of these approaches is to maintain the current strong survival outcomes while reducing the long-term treatment toxicities. A detailed analysis and comparison of these techniques and results is beyond the scope of this review, but may be found elsewhere^[8]. There have been a number of reviews that have addressed HPV in HNSCC^[9,10]. Here we review the

discoveries and observations (including clinical retrospective reviews, clinical prospective trials, and basic science research) that showed how HPV dramatically changed the epidemiologic, clinical, pathological and molecular landscape of head and neck cancer. In addition, we present hypotheses for the causes of these changes, and how they may guide future clinical trial design.

EPIDEMIOLOGIC CHANGES

Retrospective analyses have shown a clear change in the epidemiology of HNSCC in the United States over the last 4 decades. A review of 60 published studies using PCR-based methods to detect and genotype HNSCC biopsies demonstrate a higher prevalence of HPV-positivity in oropharyngeal SCC (OPSCC) *vs* oral or laryngeal SCCs (35.6% *vs* 23.5% *vs* 24.0%). HPV-16 was found in 86.7% of the HPV-positive OPSCCs, while the second most prevalent high risk type HPV-18 was found in only 2.8% of HPV-positive OPSCCs^[11]. A Surveillance, Epidemiology, and End Results (SEER) study of HNC cases between 1973-2003 showed a 1.85% annual reduction in smoking-related HNSCC, while HPV-related HNSCC had increased by 0.8% per year^[12]. HPV-related sites were defined as oropharyngeal, while smoking-related sites were defined as oral cavity, nasopharynx and larynx. The decrease in smoking-related HNSCC correlated with a decrease in smoking in the United States during that time^[13]. In addition, the age at diagnosis for HPV-related HNSCC decreased by 1.5 years while the age at diagnosis for HPV-unrelated HNSCC increased. Analysis of tissue from 271 cases in the SEER database between 1984 and 2004 revealed that HPV prevalence in OPSCC tumors increased from 16.3% during the 1980s to 72.7% during the 2000s^[14]. Table 1 shows the estimated number of HPV-positive and HPV-negative HNC cases in the United States in 2011 by site. Similar increases were shown in Swedish, Australian, and Canadian populations^[15-17].

Changes in sexual practices are potential causes for the observed increase in HPV-related HNSCC. HPV transmission occurs primarily through direct sexual contact, most often during vaginal or anal intercourse, but may also occur during oral sex or other forms of mucosal contact. As a general trend, Americans are reporting their first sexual encounter at a younger age, they are having more sexual partners, and are performing more oral sex^[18-20]. In particular, a French study showed the lifetime prevalence of oral sex increased from roughly 50% in 1970 to 90% in 2006^[19]. Two cross-sectional studies conducted in the United States confirmed that increased sexual promiscuity, such as lifetime number oral sex partners, was associated with an increased risk of oral HPV-16 infection^[21,22]. Additional epidemiologic studies have shown that exposure to HPV increases the risk of developing HNSCC, and HPV-16 seropositivity predates cancer development by 9 years^[23,24]. Finally, a case-control study by D'Souza *et al*^[25] revealed that the number of vaginal and oral sexual partners [odds ratios (OR), 3.1 and

3.4] and HPV-16 seropositivity (OR, 32.2) correlated with an increased risk of developing OPSCC. Notably, alcohol and tobacco increased the risk of developing OPSCC primarily in those patients without HPV-16 exposure. Similar results have been substantiated in other studies of HNSCC^[26-28].

CLINICAL CHANGES

The changing epidemiology of HNSCC, particularly HPV-positive OPSCC, created a new patient profile in the clinic. Patients began presenting at a much younger age without a strong alcohol or tobacco history and with more advanced disease in the neck^[29]. The natural history of HPV-positive HNSCC began to unfold following several small retrospective studies reported in the late 1990s and early 2000s. In an analysis of 42 patients treated between 1975-1987, HPV-positive SCC of the tonsil showed improved survival compared to HPV-negative SCC^[30]. Furthermore, an incidental finding in a 1998 German study of 208 HNSCC samples (11 of 36 tonsil primaries tested positive for HPV DNA) revealed a better prognosis despite more adverse pathologic features for the HPV-positive samples^[31]. In a Swedish review of 60 patients treated with radiation with or without surgery between 1986-1996, HPV-positive OPSCC cases had better 5-year OS (53.5% *vs* 31.5%) and decreased risk of recurrence (OR, 4.1) regardless of age, stage or gender^[32]. These findings were supported by a Swiss study of 98 patients with OPSCC who received definitive radiation therapy from 1991-1997, which also showed that HPV-positive tumors (14% of the total) had better LRC and OS [risk ratios (RR), 0.33 and 0.35]^[33]. A meta-analysis of 37 studies examining HPV and HNSCC from 2007 showed that HPV-positive OPSCC in particular had a 28% reduced risk of death [meta hazard ratio (HR) 0.72] and a 49% lower risk of disease-failure (HR, 0.51) than HPV-negative OPSCC. The prognostic benefits of HPV-positive tumors was not significant for other sites^[34].

These smaller studies led to larger retrospective analyses of prospective trials. The phase III TAX324 trial comparing two different induction chemotherapy regimens was retrospectively reviewed and included 111 OPSCC patients. HPV-positive patients had OS and locore-

gional failure (LRF) rates of 79% and 13% compared to 31% and 42% for HPV-negative patients^[35]. In the phase II ECOG 2399 trial involving induction chemotherapy followed by chemoradiation, HPV-positive patients (38 of 96) had a better response to induction chemotherapy (82% *vs* 55%) and chemoradiation treatment (84% *vs* 57%)^[8]. Moreover, the HPV-positive OPSCC patients had a 62% lower risk of progression (HR, 0.38) and a 61% lower risk of death (HR, 0.39) when compared to those with HPV-negative OPSCC^[6]. Around the time of ECOG 2399, the Danish DAHANCA 5 phase III clinical trial prospectively collected samples from 156 patients who underwent conventional radiation therapy for OPSCC or supraglottic SCC from 1986-1990. Of the 74 OPSCC samples, 24 were p16-positive (a surrogate marker for HPV-driven disease) and showed a LRC benefit (OR, 5.1) compared to those that were p16-negative^[36]. A phase II prospective trial of OPSCC from 2000-2002 using induction chemotherapy to stratify definitive treatment paths correlated HPV-16 to response and survival. Pre-treatment biopsies of 42 patients were analyzed and 67% were HPV-positive. HPV titer was associated with significantly improved response to induction chemotherapy ($P = 0.001$), improved response to chemoradiation therapy ($P = 0.005$), improved OS ($P = 0.007$), and improved DSS ($P = 0.008$)^[37]. When the Trans-Tasman Radiation Oncology Group (TROG) 20.02 trial comparing cisplatin-based chemoradiation with or without tirapazamine was retrospectively reviewed for HPV and p16 status, 57% of 185 patients with OPSCC were p16-positive. The p16-positive tumors showed better 2-year OS (91% *vs* 74%; HR, 0.36; $P = 0.004$) and failure-free survival (87% *vs* 72%; HR, 0.39; $P = 0.003$). Table 2 summarizes select studies that examined HPV status and prognosis for HNSCC.

It was evident that patients with HPV-positive HNSCC experienced improved OS compared to HPV-negative disease, but whether this was secondary to improved treatment sensitivity, locoregional control or distant metastasis was unclear. Princess Margaret Hospital reviewed the rates of distant metastases (DM) in HPV-positive OPSCC following radiation or chemoradiation therapy. They included 457 HPV-positive and 167 HPV-negative OPSCC cases, and while DM rates were similar at 3 years, 24 of 25 HPV-positive cases of DM occurred within 2 years while 7 of 54 HPV-negative cases were detected 3 years after treatment. The authors found that the post-DM survival rates were 11% *vs* 4% at 2-years in favor of the HPV-positive cases and interestingly, 5 of 6 HPV-positive patients with lung oligo-metastases had stable disease 2-years after salvage procedures, which included chemotherapy, resection, or radiation^[38]. Additional recent retrospective reviews, have shown similar unique patterns of distant metastatic spread including to bone, brain, and multiple organs, and increased post-DM OS for HPV-positive patients^[38-42]. The trend of better post-DM OS was not seen when analyzing data from the SPECTRUM trial of metastatic or recurrent HNSCC.

Of 443 patients, 99 were p16-positive, and no significant difference was observed in OS for these patients when compared to p16-negative patients^[43]. Additionally, when Rischin *et al*^[44] analyzed the TROG 20.02 trial there was no difference in DM rates between HPV-positive and HPV-negative OPSCC patients.

As previously discussed, HPV-positive HNSCC generally presents in younger healthier patients with small primary tumors and advanced lymph node (LN) metastases. The analysis of the TAX324 trial confirmed the association with smaller primaries and improved performance status. The authors found that HPV-positive patients were more likely to have T1 or T2 tumors (49% *vs* 20%) and an ECOG performance status of 0 (77% *vs* 49%)^[35]. Similar results were found when the TROG 02.02 Phase III trial data was retrospectively reviewed; p16-positive tumors were more likely to have a lower T stage ($P = 0.001$), higher N stage ($P = 0.001$), and better performance status ($P = 0.002$)^[44]. The ECOG 2399 data showed that although nodal status and overall AJCC TNM stage did not differ by HPV status, HPV-positive tumors were more likely to have a tumor stage of T2 *vs* T3 or T4, and an ECOG performance status of 0 (66% *vs* 33%)^[6]. An analysis of cystic lymph node metastases (20 of 100) from neck dissections from 2002-2004 showed a strong association with HPV-positive SCC of the tonsil^[45]. Princess Margaret Hospital reviewed data from 493 N2-3 HNSCC patients between 2003-2009 and found that HPV-positive LNs (257) were larger (2.9 *vs* 2.5cm), were more likely to be cystic (38% *vs* 6%), regressed more often post treatment (36% *vs* 41% of initial size), and were more likely to resolve after 36 wk (90% *vs* 70%), when compared to LNs of HPV-negative patients^[46]. The etiology of these differences in clinical presentation is unknown, and do not seem to be prognostic when controlling for HPV status.

Microscopic pathologic differences have also been observed between HPV-driven HNSCC and tobacco and alcohol-related HNSCC. HPV-positive tumors are more likely than HPV-negative tumors to be poorly differentiated and to have basaloid features, though the relevance of this difference is still undetermined^[6,47]. The improved LRC observed in HPV-positive HNSCC may be due to a lack of field cancerization historically observed in smoking-related HNSCC causing a higher risk of both recurrence and development of a second primary tumor^[48-50]. A Germany study of 25 HPV-16 positive HNSCCs in 2001 showed that HPV-16 was more likely to localize to the tonsil and HPV DNA did not appear outside of the tumor, suggesting that HPV-positive patients may not have entire mucosal fields predisposed to tumor development^[51].

MOLECULAR DIFFERENCES

The molecular biology of high risk HPV-driven tumorigenesis has been thoroughly studied in cervical cancer. HPV is a small, nonenveloped double-stranded DNA virus that infects keratinocytes and promotes transformation by altering cell cycle control primarily through expression of the nuclear proteins E6 and E7. Normally, p53 levels increase in response to DNA damage and prevent entry into S phase at the G1 checkpoint. E6 prevents accumulation of p53 and p53-mediated cell cycle arrest by causing the ubiquitination and subsequent degradation of p53^[52-54]. E6 likely promotes immortalization through other mechanisms including increasing telomerase activity^[55].

E2F is a transcription factor necessary for DNA synthesis, and is inhibited by hypophosphorylated retinoblastoma protein (pRb). Mitogenic signals cause an increase in cyclin-dependent kinases (CDKs), which promote phosphorylation of pRb leading to the release of E2F allowing entry into S phase. E7 preferentially binds to hypophosphorylated pRb causing its degradation and uncoupling the G1 checkpoint from CDK control^[56-58]. The CDK inhibitor p16 is normally suppressed by pRb and E7-mediated pRb degradation causes p16 upregulation^[59]. However, E7 stimulates the S-phase cyclins E and A, which bypass the normal p16 cell cycle inhibitory effects^[60]. E7 also binds to another DNA damage checkpoint protein p21, a p53-induced CDK inhibitor, driving the cell cycle into S phase^[61].

Molecular investigations of HNSCC initially did not differentiate between HPV-positive and HPV-negative samples because they were conducted in the era when HPV-negative tumors were more prevalent. Studies showed that the *TP53* gene was mutated in 45% of HNSCC and *TP16* gene inactivation by either mutation, deletion, or promoter hypermethylation occurred in 80% of HNSCC^[62-65]. To determine the prognostic significance of *TP53* mutations, a large scale prospective study of 560 patients with HNSCC who were treated with primary surgery with curative intent was performed. Disruptive *TP53* mutations were found in 53% of patients and predicted for decreased OS (HR, 1.7)^[66]. The epidermal growth factor receptor (EGFR) pathway has been extensively studied in various cancers and several trials have shown clear clinical efficacy of a targeted EGFR blockade. In regards to HNSCC, EGFR is overexpressed in approximately 80% of cases, and EGFR overexpression and copy number both correlate with a poorer prognosis^[67-70].

A German study from 1998 examined the status of the retinoblastoma (Rb) pathway in 208 HNSCC that were treated surgically. The investigators found that 11%

of the tumors had no or dramatically reduced levels of the pRb without genetic disruption of the *Rb1* gene, and these samples localized to the tonsil. They also overexpressed p16 and had wild type *p53*. The authors detected high risk HPV DNA in 11 of the 12 pRb-deficient tumors strongly suggesting that the E7 viral protein inactivated the Rb pathway. These tumors had poorer differentiation and they were all metastatic at the time of resection, yet they had better clinical outcomes post treatment compared to the rest of the cohort^[31]. Although this study had a very small number of HPV-positive patients, several additional studies examining HPV status and cell cycle regulators followed. A study in 2000 including 253 patients with HNSCC tested archived samples for HPV-status and *TP53* mutations. HPV was detected in 25% of the samples, and HPV-positive tumors were less likely to harbor *TP53* mutations (OR, 0.06)^[47]. A Dutch group investigating the relationship between HPV-status and *p53* mutational status examined 47 HNSCC in 2003 and found 10 were HPV-positive with 8 of those being OPSCC. All 10 HPV-positive cases overexpressed p16, while 8 of the 10 overexpressed *p53*, yet none harbored mutations in *p53*. They also noted an inverse relationship between smoking and HPV-positivity^[71]. The interest in EGFR prompted an examination of EGFR and p16 expression in 106 OPSCC patients, which showed a significantly higher 5-year disease-free survival (DFS) and OS for patients who overexpressed p16, but not EGFR when compared to those with tumors overexpressing EGFR, but not p16^[72]. Further analysis of a phase II trial for OPSCC showing HPV copy number correlated with prognosis, revealed that HPV copy number was associated with p16 expression ($P < 0.0001$), and p16 overexpressing tumors had a better response to therapy ($P = 0.009$) and OS ($P = 0.001$). In addition, EGFR expression correlated with worse OS ($P = 0.001$) and DSS ($P = 0.002$), and was inversely associated with HPV copy number and p16 expression^[73].

In 2005 investigators attempted to use gene expression analysis to accurately predict LN metastasis in oral and OPSCC. They included 45 tumors from patients who were N+ postoperatively or who subsequently developed LN metastasis and 37 tumors from individuals who were N0 postoperatively and remained metastasis-free. The 102 predictor genes outperformed the current clinical diagnosis when independently validated^[74]. Gene expression profiles for 8 HPV-positive and 28 HPV-negative HNSCC were generated and published in 2006. Statistical analysis based on HPV status identified 91 differentially expressed genes, which included HPV-related overexpression of *p16*, *p18*, and *CDC7*, and a significant proportion of the HPV-positive genes localized to 3q24^[75]. Recently, multi-institutional groups conducted whole-exome sequencing of 74 HNSCC tumor-normal pairs (14% HPV-positive) and of 32 HNSCC samples. The results identified previously known HNSCC genes (*TP53*, *CDKN2A*, *PTEN*, *PIK3CA*, and *HRAS*), and found mutations in genes that regulate squamous differentiation (*NOTCH1*,

IRF6, and *TP63*). Compared with traditional tobacco-induced HNSCC, HPV-positive samples had one half the mutation rate ($P = 0.004$) and an inverse relationship with *TP53* mutations ($P = 0.001$)^[76,77]. These studies have not resulted in dramatic breakthroughs yet, but form an important foundation for elucidating critical pathways in HNSCC.

Molecular characterization and environmental history has allowed stratification of patients with OPSCC into risk categories. In 2006, the HPV and p16 status of 79 OPSCC patients with long term follow-up were determined leading to a three-class model based on p16 expression and the presence of HPV DNA. The class that was HPV-positive and overexpressed p16 had better OS (79% *vs* 20% and 18%; $P = 0.0095$), DFS (75% *vs* 15% and 13% ($P = 0.0025$), 5-year local recurrence (14% *vs* 45% and 74%; $P = 0.03$), and lower *p53* and pRb expression ($P = 0.017$ and 0.001)^[78]. Ang *et al*^[7] retrospectively reviewed 323 OPSCC patients from the phase III prospective trial RTOG 0129 comparing standard and accelerated fractionation for HPV status. They found that 63.8% of patients had HPV-positive tumors and these patients had better 3-year OS (82.4% *vs* 57.1%, $P < 0.001$). In addition, the risk of death significantly increased with each additional pack-year of tobacco smoking. Using recursive-partitioning analysis for HPV-status, pack-years of tobacco smoking (≤ 10 *vs* > 10), tumor stage (T2-T3 *vs* T4), and nodal stage (N0-N2a *vs* N2b-N3), patients were classified as having a low (3-year OS 93.0%), intermediate (3-year OS 70.8%), or high risk (3-year OS 46.2%) of death^[7].

One explanation for the improved LRC seen in HPV-driven HNSCC is an increased sensitivity to chemoradiation^[79]. E6-related degradation of *p53* in HPV-positive cancers may be functionally inequivalent to HPV-negative *p53* mutations, and therefore, HPV-positive tumors may have an intact apoptotic response to radiation and chemotherapy. However, enforced expression of E6 and/or E7 in cell lines did not cause radiosensitization *in vitro*^[80,81]. Interestingly, *p53* overexpression has been found in HPV-positive tumors, which indicates that another mechanism unrelated to E6 may be involved^[71]. Moreover, survival for patients with HPV-positive oropharyngeal cancers was improved relative to HPV-negative patients both with and without *p53* mutations in their tumors and in patients treated with and without radiation therapy^[82].

Pre-clinical studies show that successful chemoradiation depends on innate and adaptive antitumor immune responses, and the increased immunogenicity of HPV-infected tumor cells may contribute to their robust treatment response^[83,84]. As part of a prospective phase II trial for OPSCC, 47 patients had baseline immune cell counts in addition to assessment of EGFR and HPV status. The authors found that improved survival was associated with an elevated percentage of CD8 cells ($P = 0.04$), a low CD4:CD8 ratio ($P = 0.01$), low EGFR expression ($P = 0.002$), and HPV status ($P = 0.02$). The percentage of CD8 cells was significantly higher ($P = 0.04$) and

the CD4:CD8 ratio was significantly lower ($P = 0.02$) in HPV-positive patients. A higher percentage of CD8 cells was associated with response to induction chemotherapy ($P = 0.02$) and complete tumor response after chemoradiotherapy ($P = 0.045$)^[85]. These associations were studied at a basic level in HPV-positive and HPV-negative OPSCC cell lines. *In vitro*, there was a decreased response to either cisplatin or radiation for the HPV-positive cell line. However, *in vivo*, there was an increased response to both cisplatin and radiation. The authors found this only to be true in immunocompetent mice and immune-deficient mice that had been injected with competent immune cells, suggesting more of an immunologic mechanism for HPV-driven disease response to therapy^[86].

FUTURE DIRECTIONS

There are clear clinical, epidemiologic and molecular differences between tobacco-driven tumorigenesis in the oropharynx and HPV-driven OPSCC. However, these complex interactions are inadequately described, and clinically, it appears that some OPSCCs are caused by a combination of both tobacco and HPV infection. While the relationship between HPV-induced oncogenesis, tumor sensitivity and improved clinical outcomes is still being investigated, we now know that approximately 50%-80% of OPSCCs are associated with HPV-positivity. With these trends, it is estimated that HPV will eventually become the primary etiology for head and neck cancer in the United States.

Induction chemotherapy, alternative systemic regimens to cisplatin and other approaches have been investigated prior to the era of HPV-positive disease. The retrospective analyses of these trials, which we have discussed above, created the overwhelming body of evidence for the better prognosis of HPV-positive OPSCC. In response to the improved survival outcomes, several collaborative groups have considered dose reduction in patients with HPV-positive HNSCC. Patients receiving lower doses of radiation and/or chemotherapy should experience less acute and long-term toxicities. Because patients with HPV-positive HNC are typically younger and demonstrate excellent LRC and OS, the value of limiting long-term toxicities such as lymphedema, swallowing dysfunction, and xerostomia is particularly important. ECOG 1308, a phase II trial, recently reported excellent early outcomes in patients where radiation dose reduction was based on a complete response to chemotherapy^[87]. Several groups have initiated clinical trials investigating other forms of treatment de-intensification such as using less toxic radiosensitizers. For example, the RTOG 1016 phase III trial plans to compare concurrent cisplatin and radiotherapy *vs* concurrent cetuximab and radiotherapy for HPV-positive OPSCC. Three additional randomized trials investigating patients with HPV-positive disease are currently pending enrollment or underway in the United States^[88].

Molecular markers are being collected prospectively in

these trials, and continued research will offer new insight into the oncogenic pathways that influence clinical outcomes. Many questions remain including: why do HPV-driven tumors present with smaller primary tumors and more advanced nodal involvement; why do HPV-driven OPSCCs respond better to locoregional chemoradiation and induction chemotherapy, but have similar distant metastasis rates; and would the molecular analysis of distant metastatic disease show similar differences in HPV- *vs* tobacco-driven OPSCC?

Perhaps HPV-driven tumors are more localized to the tonsillar crypts and the lack of mucosal field changes influences the size of the primary tumor. The lack of field cancerization may also contribute to the improved LRC, although it would not fully explain improvements seen in response to both induction and chemoradiation. Another possibility is that HPV-driven tumors are more immunogenic and are tempered by an active immune response. Perhaps the molecular characteristics of HPV-driven tumors predispose malignant cells to metastasize to LNs, and once HPV-driven disease enters the LNs it creates a more robust immune response. This response may be due to intracellular characteristics or cell surface markers on HPV-positive cells, such as E7.

Since metastasis rates are similar for HPV-positive and -negative tumors, it is possible that once an OPSCC cell becomes metastatic, it dedifferentiates to a particular molecular state regardless of HPV-status. However, recent reports point towards increased time to DM, and improved OS after DM for HPV-positive disease, which appears to contradict previous evidence of a comparable response to salvage/palliative chemotherapy. Both pre-clinical and correlative studies suggest that immunogenicity is an important component to HPV-driven disease response. Perhaps differences in clinical outcomes will be due to differential immune responses. HPV vaccines in adolescents promise to reduce the incidence in HPV-driven OPSCC in decades to come, but to date they have not shown efficacy as therapy for these tumors after they develop. We may discover clinical benefits using immunomodulators in HNSCC, just as we do with current trials in malignant melanoma and non-small cell lung cancer.

APPENDIX I-V Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Clinical Oncology*, Masahiko Nishiyama, MD, PhD, Professor, Department of Molecular Pharmacology and Oncology, Gunma University Graduate School of Medicine, 3-39-22 Showa-Machi, Maebashi, Gunma 371-8511, Japan

AIM AND SCOPE *World Journal of Clinical Oncology* (*World J Clin Oncol*, *WJCO*, online ISSN 2218-4333, DOI: 10.5306) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJCO covers a variety of clinical medical topics, including etiology, epidemiology, evidence-based medicine, informatics, diagnostic imaging, endoscopy, tumor recurrence and metastasis, tumor stem cells, radiotherapy, chemotherapy, interventional radiology, palliative therapy, clinical chemotherapy, biological therapy, minimally invasive therapy, physiotherapy, psycho-oncology, comprehensive therapy, and oncology-related nursing. Priority publication will be given to articles concerning diagnosis and treatment of oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJCO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING *World Journal of Clinical Oncology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

The sentinel lymph node biopsy (SLNB) was initially pioneered for staging melanoma in 1994 and it has been subsequently validated by several trials, and has become the new standard of care for patients with clinically node negative invasive breast cancer. The focussed examination of fewer lymph nodes in addition to improvements in histopathological and molecular analysis has increased the rate at which micrometastases and isolated tumour cells are identified. In this article we review the literature regarding the optimal management of the axilla when the SLNB is positive for metastatic disease based on level 1 evidence derived from randomised clinical trials.

INTRODUCTION

Sentinel lymph node biopsy (SLNB) was pioneered for the staging of melanoma in 1994^[1]. Shortly thereafter, Giuliano *et al*^[2] demonstrated the feasibility of SLNB for breast cancer. Over the subsequent two decades, the SLNB has been validated by several trials, and has become the new standard of care for patients with clinically node negative invasive breast cancer. Since the SLNB is positive in approximately 30% of patients undergoing surgical treatment of clinically node negative breast cancer, therefore, 70% of women are now able to avoid radical surgery, in the form of complete axillary node dissection (ALND), which is known to be associated with a higher incidence of morbidity and longer hospitalisation, with impairment of quality of life^[3].

The SLNB technique formally utilises a radioactive isotope tracer in addition to a blue dye. When both modalities are used, the procedure has been reported to be 96% accurate when performed by an experienced operator^[4]. It was noted in early studies that there was not any identifiable advantage of lymphoscintigraphy mapping even for surgeons learning the techniques. Intra-operative frozen section analysis of the sentinel node has been shown to be accurate for the evaluation of metastatic disease with high sensitivity and excellent specificity^[5].

Figure 1 Evidence-based algorithm for the management of the axilla in clinically node negative women with T1-T2 breast cancer undergoing breast conserving.

Since the sixth edition of the AJCC/UICC TNM classification, the extent of metastatic disease in the sentinel node has been classified into three categories: isolated tumour cells (ITCs; < 2 microns); micrometastatic disease (MM; 2 microns-2 mm); and macrometastatic disease (> 2 mm). In addition, the sixth edition also mentions real-time polymerase chain reaction (RT-PCR) as a possible means of detecting cancerous cells in sentinel nodes^[6].

MANAGEMENT OF ITCs AND MM

ITCs and MM have become more common findings due to the increased use of immunohistochemistry (IHC). In the current seventh edition of the TNM staging, the trends noted in the previous edition have become the norm in most major centres^[7]. Similarly, new refinements in RT-PCR, such as One-Stop Nodal Analysis, have been recently introduced for intra-operative evaluation, and have been demonstrated to be even more sensitive for detecting metastatic deposits than IHC^[8].

The clinical implications of these findings was unclear, with little progress towards a consensus until very recently due to non-availability of suitable level evidence^[9-11]. Although the presence of ITCs in the sentinel nodes has a prognostic significance, however, there is a consensus that it does not represent an indication for further treatment of the axilla^[11]. The presence of micrometastatic disease in the sentinel node was, until recently, considered an absolute indication for a complete axillary node dissection. However, more recent evidence is highly suggestive that a more conservative approach to such micro-deposits would be more appropriate despite modest upstaging of the disease^[9]. A recent randomised controlled trial (RCT) confirmed the oncological safety of omitting complete ALND for MM positive SLNB (IBCSG 23-01)^[12].

MANAGEMENT OF MACRO-METASTASES

Until recently the presence of macrometastases in the sentinel nodes has been considered a routine indication of complete ALND, however, a recent randomised controlled trial carried out by the American College of Surgeons Oncology Group (Z0011) showed that in women undergoing breast conserving surgery (BCS) for clinically node negative T1/T2 invasive breast cancer, complete axillary node dissection is not required if only 1-2 sentinel nodes were found to be involved by malignancy. The five year disease-free survival and overall survival were similar in the axillary node dissection group *vs* no axillary node dissection group. There was no significant difference between the two groups in relation to the primary tumour characteristics and the use of adjuvant systemic therapy. All the patients received adjuvant radiotherapy following breast conserving surgery^[13]. Therefore, patients who fulfil the criteria for this mature trial can avoid complete ALND, which is associated with a higher incidence of complications. The presence or absence of extra-capsular extension (ECE) was not analysed in this trial. A recent retrospective study showed that the presence of an ECE greater than 2 mm in the sentinel nodes was associated with significant tumour burden in non-sentinel nodes during ALND and therefore this feature can be added to the eligibility criteria for omitting ALND when the SNB is positive (*i.e.*, ECE < 2 mm)^[14].

Complete axillary node dissection is still indicated in women undergoing breast conserving surgery, who are found to have metastatic disease involving three or more lymph nodes and those undergoing total mastectomy with positive sentinel node biopsy involving any lymph nodes.

In a further shift towards less radical surgery to the axilla, the recent EORTC ARAMOS randomised controlled trial showed that axillary radiotherapy was as effective as complete axillary node dissection in terms of five year overall and disease-free survivals. Furthermore, radiotherapy (50Gy in 25 fractions) was associated with a lower incidence of lymphedema of the arm, in the short and long terms. The authors, however, observed non-significant trend towards impairment in the shoulder movement in women undergoing radiotherapy to the axilla in the short term. Earlier analysis of the trial data showed that the lack of knowledge of the pathological status of the non-sentinel nodes did not influence the treatment decisions in relation to adjuvant systemic therapy^[14]. Moreover, oncologists are increasingly basing their systemic treatment recommendations on the use of multigene molecular signatures of the primary tumour, such as Mammaprint[®], Oncotype DX[®], and Endopredict[®].

The American Society of Clinical Oncology (ASCO) has recently updated its guidelines to reflect the results of these trials^[15]. The adoption of these guidelines worldwide will spare thousands of women radical surgery to the axilla, which is associated with a higher incidence of complications and longer hospitalisation without compromising their clinical outcome. Needless to say that the final treatment recommendations are made in the context of multidisciplinary discussion. The findings of these trials are consistent with the biological behaviour of breast cancer and the longstanding perception that axillary surgery aims to provide staging and prognostic information to guide systemic treatment and radiotherapy recommendations rather than achieving mechanical eradication of the disease. Evidence-based medicine means that we should embrace the results of these RCTs and introduce the new ASCO recommendations into our clinical practice in order to improve the quality of life of our patients. The proposed management of a positive SLNB in patients undergoing BCS for T1-T2 breast cancer has been summarised in the algorithm shown in Figure 1.

Abstract

Breast cancer remains a major cause of neoplastic disease in much of the developed world. The majority of cases are diagnosed with oestrogen receptor (ER)-positive and human epidermal growth factor receptor-2 negative invasive ductal carcinoma and are treated predominantly by surgery which includes sentinel node biopsy and adjuvant endocrine therapy \pm adjuvant radiotherapy. It is believed that an indeterminate subset of the patient population is needlessly incurring chemotherapy related morbidity without attaining any increase in survival due to therapy. Furthermore in the era of extended adjuvant endocrine therapy it is important to identify those patients who can be safely treated with 5 years rather than 10 years of endocrine therapy thus optimising the benefit-risk balance. This perception has propelled the development of more personalised prognostic tools for newly diagnosed cases of ER-positive breast cancer. In this article, we shall review the evidence regarding the currently available gene assays for human breast cancer.

Key words: Personalised medicine; Breast cancer; Prognosis; Polymerase chain reaction

Core tip: Recurrence score, Prosigna and EndoPredict (EP) currently have the most convincing evidence available, of which Prosigna and EP have a significant degree of external validation. In terms of cost and turnover, EP has an advantage over its competitors, being designed to be performed at a local laboratory rather than at a central facility. The results of the MINDACT and TailorX trials are awaited.

Wazir U, Mokbel K. Emerging gene-based prognostic tools in early breast cancer: First steps to personalised medicine. *World J Clin Oncol* 2014; 5(5): 795-799 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/795.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.795>

INTRODUCTION

Breast cancer remains a major cause of neoplastic disease in much of the developed world, comprising of 30.7% of cancers diagnosed in 2011. The 41523 cases were registered during that year^[1]. The majority of cases are diagnosed with oestrogen receptor (ER) positive and human epidermal growth factor receptor-2 (HER2) negative invasive ductal carcinoma, which predominantly undergo surgery and staging, including sentinel node biopsy (SNB)^[2]. Subsequent decisions by the multi-disciplinary team regarding the use of chemotherapy, radiotherapy and endocrine therapy are determined by the perceived risk of recurrence. Conventionally, the risk of recurrence is estimated based on histology, receptor status and the result of the SNB, or by composite prognostic tools, such as the Nottingham Prognostic Index^[3], and Adjuvant! Online (Adjuvant, Inc., San Antonio, TX)^[4].

However, it is believed that an indeterminate subset of the patient population is needlessly incurring chemotherapy related morbidity without attaining any increase

in survival due to therapy. This perception has propelled the development of more personalised prognostic tools for newly diagnosed cases of breast cancer^[3]. Furthermore, the results of the ATLAS randomised trial suggests that the survival benefit of continuing adjuvant tamoxifen for 10 years may be superior to stopping at 5 years after diagnosis of ER positive breast cancer. This finding has necessitated the development of new tools that could identify the subset of women who would not benefit from extended adjuvant endocrine therapy beyond 5 years^[5].

Central to these developments was the identification of sub-types of breast cancer based on so-called “molecular patterns” or “signatures”. These classifications are now referred to as intrinsic sub-types, and have a broad if imperfect concordance with breast cancer classifications based on histology and receptor status. Initially, breast cancers were typed as luminal, HER2 enriched and basal. Luminal are further sub-typed into luminal-A and -B^[6]. The intrinsic typing of breast cancers continues to be an area of continuous research. As of the time of writing, 7 intrinsic types have been identified thus far. Luminal-A is characterised as strongly ER positive, while luminal-B is less so, with a greater preponderance of proliferative genes. Broadly speaking, luminal-A corresponds with ER positive and HER2 negative tumours, which are characterised as relatively low risk for recurrence^[7].

With a suitable prognostic test, it may be possible to treat a portion of luminal-A patient with post-resection endocrine therapy rather than chemotherapy with endocrine therapy. This subset of patient has been the target of the majority of the extant prognostic and predictive assays.

The major gene-based prognostic assays for breast cancer have been discussed below (Table 1).

MAMMAPRINT

This the oldest test available, developed by Agendia BV (Netherlands). This is a 70 gene DNA microarray test performed on frozen or formalin-fixed tissue by a central reference laboratory, which returns a score which stratify patients into a high and low risk categories^[8].

The assay was developed in a non-randomised cohort of 78 patients treated at the Netherlands Cancer Institute, in which the median age was 55^[9]. Subsequent internal studies characterised this assay to be an independent prognostic assay in the primary target group, outperforming clinical parameters^[10].

However, it is yet to be validated externally. The studies pertaining to this assay were performed in only one market. Furthermore, owing to the lack of randomisation, the cited studies do not qualify as level 1 evidence. In addition, the population in which it was used is considerably younger than that seen in many countries where this assay may potentially be utilised^[11]. Furthermore, the test seems to be a reliable predictor of recurrence occurring in the early follow up period. In meta-analysis of

published studies, a high MammaPrint score was found to predict a 12% distant disease-free survival benefit from the addition of chemotherapy^[12]. Prospective validation is awaited with the results of the ongoing MINDACT (Microarray In Node negative and 1-3 positive lymph node Disease may Avoid ChemoTherapy) trial^[13].

ONCOTYPE-DX

Oncotype-DX (Genomic Health Inc., CA, United States) is currently the most widely available prognostic assay for breast cancer. It is a 21-gene assay in which quantitative real-time polymerase chain reaction (qRT-PCR) is performed on formalin-fixed breast cancer tissue samples taken during initial surgical resection and processed in a central laboratory, which returns a recurrence score (RS) out of a maximum score of 100. It is quoted to have a turnaround time of 7-10 d. It is primarily advised in early ER positive and HER2 negative disease with negative SLN^[14]. In addition, it is also recommended in ER positive and HER2 negative disease in elderly patients with positive SNB^[15].

The RS score was formulated and validated in patients enrolled in the National Surgical Adjuvant Breast and Bowel Project (NSABB) trials. Specifically, the predictive value of the score was initially validated by the NSABB trial B14, in which patients were randomly allocated into placebo and tamoxifen groups^[16]. This was followed up by the NSABB trial B20, in which patients on tamoxifen alone were compared with patients receiving tamoxifen with chemotherapy^[17]. A subsequent retrospective study is cited for validation of Oncotype-DX for predicting prognosis in relatively elderly patients treated with tamoxifen with SNB positive disease^[18].

These initial studies stratified RS scores into low, intermediate and high risk groups, with RS score below 18 being labelled as low risk of recurrence (< 5% risk), and 31 and above as high risk (39.5%)^[16]. Since the beginning, the clinical implications of an intermediate score has been ambiguous. Furthermore, the thresholds have been revised downwards to 11 and 25. Validation for the new thresholds is less clear^[8]. The results of the Trial Assigning Individualized Options for Treatment (TAILORx) are awaited to help clarify the recommendations for the intermediate group^[19].

There have been several studies suggesting that Oncotype-DX is cost effective as a prognostic test^[20]. Furthermore, this assay has been recommended by a number of regulatory bodies^[11,21]. However, the cost and turnover time of the test are not insignificant primarily due to test centralization. Although the Oncotype-DX was validated by randomised controlled trials, it must be emphasised that these studies were supported by funding from industry, and are regarded as internal trials by regulatory bodies^[11]. It should be also highlighted that only 26% and 29% of patients (some of whom had HER2 positive tumours) in the B-14 and B-20 trials respectively were available for analysis thus reducing the effect of randomi-

Table 1 Comparison of gene-based prognostic assays for early oestrogen receptor + breast cancer

Prognostic assay	Manufacturer	Underlying technology	No. of genes	Test induction	Output/score	Comments
MammaPrint	Agendia BV, The Netherlands	DNA microarrays	70	Reference lab	Risk category for recurrence (low risk vs high risk)	Prospective validation is awaited with the results of the ongoing MINDACT trial
Oncotype-DX	Genomic Health Inc., CA, United States	qRT-PCR	21	Reference lab	RS scores (1-100) stratified into low, intermediate and high-risk groups for recurrence	Oncotype-DX has been included in several guidelines, and has been validated by internal industrial studies (NSABB trial B14). The characterisation of intermediate risk group awaits the results of the TAILORx trial
PAM50/ Prosigna	NanoString Technologies, Inc., WA, United States	DNA microarrays and qRT-PCR using nCounter technology	50	Reference lab	ROR scores (1-100) stratified into low, intermediate and high risk groups	The assay was been validated in studies based on the ATAC and ABCSG-8 trials
EndoPredict	Sividon Diagnostics GmbH, Köln, Germany	qRT-PCR	8	Local lab	Low or high risk groups on the basis of EP or EPclin scores	EndoPredict has been validated in ABCSG-6 and ABCSG-8 trials, and has been included in German guidelines. Potentially shorter turnover at lower cost, as there is no need for dispatching samples to a reference laboratory

qRT-PCR: Quantitative real-time polymerase chain reaction; ROR: Risk of recurrence.

sation. This significantly weakens the evidence regarding the predictive role of Oncotype-DX in adjuvant chemotherapy, so much so that the evidence does not reach level 1 as per the Marker Utility Grading System^[22]. Moreover, the Oncotype-DX is not specific to HER2 negative disease and does not incorporate any clinicopathological features which could improve its prognostic ability of longer term clinical outcome. Although the test has not been validated externally for reproducibility and reliability due to industrial centralization, the internal industry reports suggest that the test is reliable.

PAM50

Parker *et al.*^[23] developed a risk of recurrence (ROR) score (also called Prosigna) which is applicable to all tumour types including those that are ER positive. The score is derived by analysing of the expression levels of a set of 50 genes using qRT-PCR and DNA microarrays. The ROR score was developed as a prognostic tool in a cohort of 761 patients^[23]. The DNA microarray cluster partitioning and analysis was done using the partitioning around medoid or microarray (PAM) methodology^[24]. In addition, a related test was developed primarily as an intrinsic sub-type classifier for breast cancer. This test was termed PAM50 (NanoString Technologies, Inc., WA, United States)^[25].

Currently, the ROR score and PAM50 test are performed on formalin fixed samples by a central laboratory utilising proprietary nCounter technology^[26,27]. Like Oncotype-DX, ROR scores (1-100) are stratified into low, intermediate and high risk groups. The ROR score has predictive value in the neoadjuvant setting, as well as in the case of newly diagnosed patients with node negative disease^[23]. The assay was validated in studies based on the ATAC^[28] and ABCSG-8 trials^[29]. In addition, a recent study validated the Prosigna assay for use at local labora-

tories^[26]. Dowsett *et al.*^[28] found Prosigna to be superior to immunohistochemistry and RS in ER positive node negative patients receiving endocrine therapy.

ENDOPREDICT

EndoPredict (EP) is a relatively new assay developed by Sividon Diagnostics GmbH (Köln, Germany), which until recently was largely limited to German-speaking markets. It is an 8-gene qRT-PCR assay performed on formalin fixed breast tissue, design in the first instance to be performed at a local laboratory. Remarkably, whilst these genes are related to proliferation and hormone receptor activity, the assay does not include ER, PR, or HER2 status^[30]. It was validated on 1702 samples taken from two randomised control trials, ABCSG-6 and ABCSG-8^[31].

There is a level Ib evidence showing that EP is an independent prognostic parameter in patients with ER-positive, HER2 negative breast cancer. Patients with a low EP score can be safely treated with endocrine therapy as the only adjuvant systemic treatment, therefore, they can be spared chemotherapy^[32]. The level of evidence regarding its independent prognostic role is similar to that of Oncotype-DX^[33]. Furthermore, a hybrid score incorporating clinical parameters (EpClin) has been shown to be superior to purely clinical assessment tools^[32]. In addition, Muller *et al.*^[34] found that use of EP resulted in change in clinical decision in 37.7% of patients when applied to a cohort of 167 patients. The effects of the change in therapy are to be assessed.

A further consideration is the inherent costs and logistics such a test may incur. In this regard, EP has an advantage over other similar test, being designed to be performed at a local laboratory rather than at a central facility. Proponents of this assay cite the fact that EndoPredict can be performed on-site resulting in a faster result at a lower cost. In addition, it also has the advantage of

dividing tumours into two categories: low and high thus avoiding the immediate group or grey zone of characterisation, which can create anxiety and dilemma to both the oncologist and the patient. EP has achieved CE certification, and has been included in German guidelines^[35]. In addition to reliably identifying patients who can be safely treated with adjuvant endocrine therapy only, EP has other potential applications including further stratification of tumours with intermediate RS (18-31) in order to make final recommendations regarding the need for chemotherapy and selection of patients for 5 years *vs* 10 of adjuvant endocrine therapy. Finally, the hybrid score EpClin is applicable to patients with node positive ER-positive breast cancer.

However, owing to its relative novelty, other regulatory bodies are yet to consider EP in their recommendations.

CONCLUSION

The recent developments in our understanding of intrinsic sub-types within breast cancer, and the explosion in the use of PCR and DNA microarrays have resulted in a growing number of promising prognostic tools for human breast cancer. OncoType-DX, Prosigna and EP currently have the most convincing evidence available, of which Prosigna and EP have a significant degree of external validation. EpClin is the only tool available that combines molecular signature with important clinico-pathological parameters with the potential advantage of superior prognostication regarding the longer term clinical outcome. The RS is the only assay that has been investigated in a randomised trial population as a predictive tool of chemotherapy benefit. However the evidence in this context is considered to be of low quality^[22].

Whilst some products are more mature than others, the results of several ongoing trials, such as MINDACT and TailorX, can be expected to have profound implications for the selection of the optimal test.

Abstract

Endometriosis is the leading cause of morbidity among premenopausal women and the complex pathogenesis of this disease remains controversial despite extensive research. This disease represents one of the most common gynecological problems. It is generally believed that this disease is due primarily to retrograde menstruation or transplantation of shed endometrium. Based on overwhelming data, ovarian endometrioma is considered a neoplastic process, since most endometriosis-associated ovarian carcinoma occur in the presence of atypical ovarian endometriosis. A study comparing patients with typical epithelial ovarian cancer with endometriosis-associated ovarian cancer demonstrated that the patients with the latter disease strongly differ in both biological and histological characteristics. The prevalence of this disease is not completely established, but approximately 15 percent of women suffer from this disease. In addition, we know about the possible links between endometriosis and cancer for almost 100 years. Despite clear evidence revealing that endometriosis increases ovarian

cancer risks, it is possible that it may not affect disease progression after the appearance of ovarian cancer. However, despite clear evidence revealing that endometriosis increases ovarian cancer risk, our knowledge of the risk factors is far from established. In our review, we focused on the most recent approaches including possible biomarkers and genetic approaches.

Key words: Endometriosis; Ovarian cancer; Biomarkers; Cancer; Histology

Core tip: Endometriosis is a multifactorial disease, which, despite intensive research in the last decades, is still not fully explained. In addition, many questions remain to be answered as to the exact events leading from cysts to endometriosis-associated ovarian cancer. Surprisingly, having endometriosis might be less risky than undergoing *in vitro* fertilization, which can increase the risk of ovarian cancer. Our review summarizes current hypothesis on probable mechanisms and attributing factors such as longstanding estrogen stimulation, repeated heavy menstruation and early events on the molecular level. Thus far, however, no single one can be used for diagnosis or treatment.

INTRODUCTION

Endometriosis is a common gynecologic disorder usually defined as presence and/or growth of endometrial tissue outside the uterine cavity. Although the prevalence of this disease is not clear, approximately 7%-15% of women of reproductive age^[1] have endometriosis, but significantly increases in cases of infertility^[2]. Despite the fact that this

disorder was first described in 1860^[3], the definite cause of endometriosis is still unclear and this disease remains to be one of the most enigmatic female diseases. Probably the most accepted mechanism is the adhesion and subsequent growth of endometrial fragments occurring in the peritoneum by retrograde menstruation. Another possibility is the occurrence of anatomical abnormalities. The repeated events of hemorrhage can also contribute to carcinogenesis and further cancer progression^[4]. Lately, the hereditary aspect gained traction, with *CYP11A1* m1 polymorphism (particularly *CYP10* variable number of tandem repeats allele) and *GSTM1* null deletion playing an important role^[5]. A detailed summary of possible theories is reviewed by Baldi *et al.*^[6] and Yuan *et al.*^[7]. In addition, at least three theories supporting the concept of *in situ* development exist, including a Mullerian and Wolffian rest theory, coelomic metaplasia theory and metaplasia following endometrial stimulation theory (for review see Thomas *et al.*^[8]). However, none of these theories explain all the different types of endometriosis^[9]. Based on overwhelming data, ovarian endometrioma can be viewed as a neoplastic process.

RELATION BETWEEN ENDOMETRIOSIS AND OVARIAN CANCER

The possibility of transformation of endometriotic tissue into malignant ovarian cancer has been recognized for almost 100 years^[10]. In 1925, Sampson^[10] first described malignant changes in endometriosis and proposed the following criteria for diagnosing the carcinomatous development in endometriosis: (1) coexistence of carcinoma and endometriosis within the same ovary, (2) a similar histological pattern and (3) exclusion of a second malignant tumor elsewhere. Later, in 1953, Scott^[11] postulated that in addition to the criteria by Sampson, morphological changes demonstrated by benign endometriosis that are contiguous with malignant tissue is a prerequisite for adjudication of a malignancy originating from endometriosis. Histopathological studies have assumed atypical endometriosis to be a transition between benign endometriosis and cancer^[12] suggesting the possibility that endometriosis is in fact a premalignant condition. This is supported by the fact that between 60% to 80% of endometriosis-associated ovarian carcinoma occur in the presence of atypical ovarian endometriosis^[13].

A summary of more recent cohort studies showed a standardized incidence ratio around 2^[14]. Tumors arising from the transformed endometriomas are predominantly of the clear cell and endometrioid types^[15]. A study of operated ovarian cancer patients showed that full 10% of patients had coexisting ovarian endometriosis. This number increased to 36.8% in patients with clear cell ovarian cancer^[16]. These types of studies led to the definition of “endometriosis-associated ovarian carcinoma” (EAOC), which describes ovarian cancer having both cancer cells and endometriosis in the same ovary, presence of cancer in one ovary and endometriosis in second ovary or the

presence of ovarian cancer and pelvic endometriosis. Histological evaluations showed significant clinical differences between patients with EAOC and non-endometriosis-associated ovarian cancer^[17]. Some studies found that the risk is increased up to 8-fold^[18], but the actual increases fluctuate widely among individual studies^[19]. For a review of ovarian cancer etiology and risk factors see Hunn *et al.*^[20].

However, despite clear evidence revealing that endometriosis increases ovarian cancer risk, the results from meta-analysis suggested that it may not affect disease progression after the appearance of ovarian cancer^[21]. In addition, some studies even suggested that the association with endometriosis might have a survival benefit^[22]. No associations were observed for common benign gynecologic disorders such as uterine myoma, adenomyosis or endometrial polyps^[23]. On the other hand, Brinton *et al.*^[24] showed an increased risk of extra-pelvic carcinomas (including breast cancer) in patients with endometriosis. The newest results are less clear since the outcome of studies examining the association between endometriosis and breast cancer are often contradictory^[14] and the newest population-based cohort studies show no overall association^[25]. A study evaluating possible risk factors revealed only one-ovarian endometriomas of 9 cm or more in diameter was a strong predictor of development of ovarian cancer^[26].

An interesting observation was the measurement of the incidence of ovarian cancer confined to endometrial polyps, which can reach between 0.5% to almost 5% depending on the diagnostic methods^[27]. These polyps can be found with increased frequency in women with endometriosis, but the retrospective analysis did not reach clear conclusions^[28].

Despite the extensive research, the exact mechanisms leading to malignant transformation of endometrial tissue are not established. In endometriosis-associated cancer, the benign-appearing ovarian masses can be detected several years before cancer diagnosis^[29].

Ovarian cancer resulting from endometriosis has some special characteristics such as having endometrioid or clear cell histology, being diagnosed earlier than other types of ovarian cancer and have a better prognosis^[30]. However, the question of endometriosis being a prognostic factor for cancer survival is not clear. On one hand, some studies found no definitive association between the presence of endometriosis and survival^[31]. On the other hand, a large Swedish study found significantly better survival in women with endometriosis than for all malignancies combined. In the cases of breast and ovarian cancer, this survival was even more pronounced^[32]. The protective effect for both one-sided oophorectomy and radical excision of all visible endometriosis was described^[33]. The most recent meta-analysis of risks and prognosis of ovarian cancer confirmed that endometriosis is strongly associated with the increased risk of ovarian cancer and these cancers show favorable characteristics including low grades and specific histology^[21].

Both diseases are progressive and estrogen dependent, often associated with late menopause and infertility. In addition, tubal ligation, hysterectomy and progesterone treatment can decrease the incidence of both diseases^[34].

HORMONE THERAPY

Despite the fact that postmenopausal endometriosis is rare, there is a risk in patients taking hormone therapy^[35]. Hormone therapy, particularly estrogen therapy, is often supposed to stimulate the growth of endometriosis, with additional increase in the risk of ovarian cancer development, which is particularly dangerous in postmenopausal endometriosis, where estrogen therapy should be used only in combination with progesterone^[35]. Estrogen-induced triggering is the same in endometriosis and estrogen-dependent cancer. The quantification of estrogen derivatives was even suggested to be a prognostic factor in ovarian cancer development^[36]. *In vitro* experiments using ovarian cancer cell lines showed similarly increased expression of ER- α receptors as in active endometriosis^[37] which was connected with the pathogenesis of endometriosis. Implants of endometriosis contain estrogen, progesterone and androgen receptors, but the effects of these hormones are opposite-estrogen stimulates proliferation and androgens cause atrophy and regression. The findings show that the basalis has approximately five times as many lymphatic vessels as the functionalis, but it cannot be currently explained^[38].

STEM CELLS

Since several theories about the causes of endometriosis failed to explain all types of lesions and suggest the possibility of combined mechanisms, recent hypothesis include the likelihood that endometriotic lesions arise from ectopic endometrial stem cell progenitors (for review see Maruyama *et al.*^[39]). The origin of oocytes in adult ovaries has been disputed for a long time. Some of the recent studies suggested the possibility that newly implantation of persistent fetal stem cells might play role in tissue regeneration and/or growth. A finding that several *HOX* genes controlling lineage infidelity in ovarian cancer^[40] are expressed in primitive hematopoietic cells suggested a role in early hematopoietic differentiation. Some studies even suggested that *HOX* genes expressed in ovarian epithelial cells might regulate cancer stem cells. At the same time, stem cell transformation can be underlying cause of ovarian cancer^[41,42].

BIOMARKERS

The main risk factor is clearly the age at endometrioma diagnosis. As independent prognostic factors, endometrioma of a diameter above 9 cm and postmenopausal status were established^[26]. There is some evidence that drugs employed in *in vitro* fertilization might increase the risk of ovarian cancer^[43]. However, some studies found

opposite results, so at present, no clear conclusion can be reached.

An effort to determine the potential association between endometriosis and ovarian cancer led to the study evaluating the expression of possible biomarkers which have been previously shown to participate in the pathogenesis of these diseases. The results revealed that endometriosis and epithelial ovarian cancer cells manifested significantly higher levels of mRNAs of transforming growth factor- β 1, cyclooxygenase-2, vascular endothelial growth factor, ER-1 α , aromatase and androgen receptors, whereas the mRNA levels of progesterone receptors were much lower^[44]. The clinical importance of this report is somewhat limited due to the low number of patients; however, its conclusion deserves further investigation.

An additional possible biochemical marker might be cancer antigen CA125^[13], which is commonly used for the monitoring of epithelial ovarian cancer. Since endometriosis is also often associated with a high level of this antigen, it cannot be used for differential diagnosis. A detailed study suggested that a CA72-4 antigen can serve in this role as a biomarker useful to confirm the benign nature of endometriomas in patients with high CA125 levels^[45].

An immunohistochemistry study of ovarian cancers arising from endometriosis confirmed that the estrogen-dependent cancers are substantially more associated with endometrioid adenocarcinoma than clear cell carcinomas. The positive hepatocyte nuclear factor-1 beta was common in clear cell carcinomas, but rare in endometrioid adenocarcinoma, which correlated with *p53* staining, but reversely correlated with estrogen receptor presence^[46].

Suryawanshi *et al.*^[47] focused on plasma microRNAs as a novel biomarker. Using a reverse transcriptase quantitative polymerase chain reaction, the authors identified 23 microRNAs which are differentially expressed in healthy people and patients with either endometriosis or EAO. These microRNAs were subsequently further evaluated in a larger cohort. The results showed that plasma microRNA expressing patterns might serve as specific and reliable diagnostic biomarkers^[47] resulting in some authors suggesting that microRNA studies will lead to changes in current treatment of both endometriosis and ovarian cancer^[48].

GENETIC APPROACHES

A wide variety of molecular alterations have been reported to be involved in the malignant transformation of endometriosis, some of which are common in both endometriosis and ovarian cancer, whereas the others are universal among various tumors. Only a very few were suggested to specifically refer to the malignancies of endometriosis.

Many hypothesize that changes in the expression of tumor suppressor genes and oncogenes occurring in the eutopic endometrium might lead to overgrowth of endometrial foci outside the uterus^[49,50].

Microsatellite analysis showed that loss of heterozygosity on p16 (Ink4), gut-associated lymphatic tissue (GALT), and *p53* occurs in endometriosis. Similarly, activation of mutated *K-ras* gene is an important step in both genesis and progression of ovarian cancer. Alteration of *p53* gene caused aberrant regulation of the H-ras protooncogene^[51]. Using a murine model of mutationally activated *K-ras* gene, it was demonstrated that these animals develop both endometrial lesions and the ovarian tissue. The following mutation blocking the expression of *PTEN* caused ovarian cancer^[52]. *K-ras* mutation may promote carcinogenesis of endometriosis leading to ovarian clear cell carcinoma^[53].

Mutations in *ARID1A* and *PIK3CA* were first described in numerous cases of ovarian clear cell carcinoma, but later also in precursor endometriosis tissues. In addition, *PTEN-PIK3CA-mTOR* pathway was strongly implicated by finding *PIK3CA* mutation in up to 46% clear cell ovarian cancer^[54]. *PIK3CA* mutation is considered to be an early event in the development of endometriosis-associated ovarian clear cell adenocarcinoma. For a better understanding of the effects of these two mutations, functional studies evaluating effects of individual mutations separately and in both normal endometrium and endometriotic epithelium are necessary. The sequence of events leading from normal eutopic endometrium to endometriosis and subsequent ovarian cancer is still hypothetical^[55].

Some studies suggested that a histologically normal endometrium may bear genetic damage caused by iron-dependent oxidative stress^[56]. Some authors suggested that suppression of pre-apoptotic gene Bax and/or up-regulation of anti-apoptotic gene Bcl-2 can be involved in endometriosis and malignancies^[57].

Genetic instability might lead to both endometriosis and ovarian cancer. It can include deactivation of some tumor-suppressing genes, changes in activity of enzymes involved in DNA repairs or mutations in genes such as GALT and GSTM. Similarly, mutations in tumor suppressive gene *PTEN* was often found both in endometrial and cancer tissues^[58]. In addition, *c-erbB-2* and *p53* genes have been found to associate with endometriosis-related ovarian cancer^[59]. The recent study showed that endometriotic lesions have mutations in cancer-related genes such as *PTEN*, *KRAS*, *p53*, and *ARID1A*^[48,60].

In addition, both endometriosis and EAOCs share some of the mediators implicated in inflammatory angiogenesis. They exhibit genetic polymorphisms of several genes including intercellular cell adhesion molecule-1, interleukin (IL)-6 and IL-10 promoters, tumor necrosis factor- α , and nuclear transcription factor- κ B^[61]. Further genetic factors such as loss of heterozygosity, *K-ras*, *P53*, and *PTEN* mutations or hepatocyte nuclear factor-1 β were suggested and tested (for review see Kobayashi *et al.*^[4]). Genome-wide association studies and as well as transcriptome sequencing have shown that genes from the 1p36 region might be important in both endometriosis and endometriosis-associated cancer development^[62].

In a recent study, the endometriosis-associated ovarian carcinogenesis has been linked to oxidative stress-induced increased genomic instability, aberrant methylation, and aberrant chromatin remodeling, as well as mutations of tumor suppressor genes^[63]. For a summary of the molecular biology aspects of ovarian cancer in endometriosis, see Mandai *et al.*^[64].

CONCLUSION

Endometriosis is a multifactorial disease and despite intensive research in the last several decades, many questions remain to be answered as to the exact events leading from endometriotic cysts to endometriosis-associated ovarian cancer. The probable mechanisms and attributing factors include longstanding estrogen stimulation, repeated heavy menstruation resulting in tissue damage and early events on the molecular level were repeatedly shown. Numerous markers have been proven to correspond with this type of cancer. Thus far, however, no single one can be used for diagnosis, not to mention treatment. Despite the fact that the links between endometriosis and ovarian cancer appear to be clear, we have to keep in mind that having endometriosis might be less risky than undergoing *in vitro* fertilization, which can increase the risk of ovarian cancer three times^[65]. The exact mechanisms of the endometriosis-ovarian cancer conversion are still not fully established and the need for new approaches in the understanding and treatment of endometriosis is urgent.

Abstract

Epidermal growth factor receptor (EGFR) controls a wide range of cellular processes, and aberrant EGFR signaling as a result of receptor overexpression and/or mutation occurs in many types of cancer. Tumor cells in non-small cell lung cancer (NSCLC) patients that harbor EGFR kinase domain mutations exhibit oncogene addiction to mutant EGFR, which confers high sensitivity to tyrosine kinase inhibitors (TKIs). As patients invariably develop resistance to TKIs, it is important to delineate the cell biological basis of mutant EGFR-induced cellular transformation since components of these pathways can serve as alternate therapeutic targets to preempt or overcome resistance. NSCLC-associated EGFR mutants are constitutively-active and induce ligand-independent transformation in nonmalignant cell lines. Emerging data suggest that a number of factors are critical for the mutant EGFR-dependent tumorigenicity, and bypassing the effects of TKIs on these pathways promotes drug resistance. For example, activation of downstream pathways such as Akt, Erk, STAT3 and Src is critical for mutant EGFR-mediated biological processes. It is now well-established that the potency and spatiotemporal features of cellular signaling by receptor tyrosine kinases such as EGFR, as well as the specific pathways activated, is determined by the nature of endocytic traffic pathways through which the active receptors traverse. Recent evidence indicates that NSCLC-associated mutant EGFRs exhibit altered endocytic trafficking and they exhibit reduced Cbl ubiquitin ligase-mediated lysosomal downregulation. More recent work has shown that mutant EGFRs undergo ligand-independent traffic into the endocytic recycling compartment, a behavior that plays a key role in Src pathway activation and oncogenesis. These studies are beginning to delineate the close nexus between signaling and endocytic traffic of EGFR mutants as a key driver of oncogenic

processes. Therefore, in this review, we will discuss the links between mutant EGFR signaling and endocytic properties, and introduce potential mechanisms by which altered endocytic properties of mutant EGFRs may alter signaling and vice versa as well as their implications for NSCLC therapy.

Core tip: Since their discovery ten years ago, much work has revealed the signaling properties of non-small cell lung cancer-associated mutant epidermal growth factor receptors (EGFRs). While therapeutic options for patients harboring mutants have emerged, these are beset with rapid development of resistance, making it critical that mutant EGFR biology be better understood to design more effective therapies. Emerging data suggests that mutant EGFRs exhibit altered endocytic trafficking, a process critical for the regulation of EGFR signaling. Deregulated endocytic traffic appears to enable mutant EGFRs to activate oncogenic signaling pathways. This review highlights the signaling and endocytic trafficking of mutant EGFR and the intimate link between the two processes.

INTRODUCTION

Epidermal growth factor receptor (EGFR) is a member of the ErbB (avian erythroblastic leukemia virus oncogene homolog) or human EGF receptor (HER) family of receptor tyrosine kinases (RTKs). The ErbB family comprises of EGFR (also known as ErbB-1/HER1), ErbB-2 (neu, HER2), ErbB-3 (HER3) and ErbB-4 (HER4). Studies of EGFR as a model RTK and prototypic oncogene have provided much of our understanding of cellular and molecular mechanisms of RTK function and regulation^[1-4]. EGFR is a transmembrane glycoprotein with extracellular domains that bind to ligands such as EGF and transforming growth factor α (TGF α) to promote receptor dimerization and activation of a cytoplasmic tyrosine kinase domain. The resulting phosphorylation of the receptor and downstream signaling proteins mediate the various biological responses downstream^[1,5]. In particular, EGFR is known to play crucial roles in cellular proliferation, survival, migration, and differentiation. Indeed, impaired epithelial development in several organs

as well as perinatal lethality among *EGFR* knockout animal models illustrates the essential nature of EGFR in cellular functions^[6,7]. Furthermore, oncogenic viruses exploit the EGFR signaling network in many different ways, altering both receptor tyrosine kinase activity and gene expression^[8].

The role of aberrant EGFR signaling in oncogenesis has been investigated for many years. A major mechanism for aberrant signaling involves the overexpression of EGFR, found in various epithelial tumors^[3]. The cancers where overexpression of EGFR is found include breast cancer, glioblastomas, head-and-neck cancer, non-small cell lung cancer (NSCLC), renal cancer, ovarian cancer, and colon cancer^[1,9]. Transgenic studies^[10] and *in vitro* studies, using NIH 3T3 mouse fibroblasts^[11], demonstrate that high-level expression of EGFR and EGF ligands can transform cells. Recent studies using genetic deletion of *EGFR* illustrate the essential role of this receptor in oncogenesis in a pancreatic cancer model^[12]. In addition, EGFR activation initiates cytoprotective signaling, enabling tumor cells to become resistant to radiation and chemotherapy^[13,14]. Increased expression of EGFR is associated with poorer survival, and EGFR serves as a strong prognostic indicator in many cancer types^[15].

In addition to overexpression, recent studies have demonstrated a key oncogenic role of mutant forms of EGFR in driving oncogenesis. EGFR overexpression in glioblastomas is associated with an alternatively-spliced variant, EGFRvIII, lacking the extracellular sequences encoded by exon 2-7 as a result of an 804 base pair in-frame deletion that corresponds to the removal of N-terminal amino acid residues from 6-273^[16]. EGFRvIII is expressed in approximately 25% of glioblastomas^[17] and in a higher percentage of patients with *EGFR* amplification^[18,19]. This mutant initiates ligand-independent signaling and is transforming in animal models of glioblastoma^[20]. Missense point mutations or small in-frame deletions in the kinase domain have been identified in NSCLC and shown to be constitutively active and oncogenic^[21-23]. Notably, NSCLC-associated somatic *EGFR* mutations impart a higher sensitivity to EGFR-directed TKIs such as gefitinib (Iressa) or erlotinib (Tarceva)^[3,22]. Because the NSCLC-associated EGFR mutants are constitutively-active and capable of transforming cells, they present fascinating models to study signaling pathways and defects in negative regulatory mechanisms. Therefore, this review will discuss our current understanding of NSCLC-associated mutant EGF receptors and their signaling properties, and the critical links between the endocytic and signaling pathways of mutant EGF receptors.

EGFR MUTATIONS IN NSCLC

Lung cancer is the leading cause of cancer deaths in both men and women in the United States, and NSCLC accounts for about 85% of lung cancers^[24]. Studies in gastrointestinal stromal tumors showed that activating

mutations of *c-KIT* gene were associated with clinical responses to small molecule TKI imatinib, and fueled interest to search for similar mutations in *EGFR* in NSCLC patients that responded favorably to gefitinib and erlotinib^[25]. Indeed, in 2004, *EGFR* mutations associated with gefitinib sensitivity were identified in NSCLC^[21,23].

Somatic mutations in the *EGFR* kinase domain are found in about 10% of NSCLC patients from the United States and about 25% of those from East Asia^[26,27]. In-frame deletions in exon 19 (*EGFR* Δ746-750) and an arginine to leucine mutation at position 858 (*EGFR* L858R) account for about 90% of these mutations^[26]. The mutations confer constitutive activity by disrupting the inactive conformation of the kinase domain of *EGFR*, and a 20-fold increased TKI binding accounts for their hypersensitivity to TKIs^[28]. *EGFR* mutations in NSCLC have been correlated with gene amplification^[29]. Somatic mutations of the *ErbB2* kinase domain in NSCLC (in-frame insertions in exon 20) have also been identified in a subset (1.6%) of patients with a similar profile as those that harbor *EGFR* mutations: never smoker, East Asian ethnicity, and female gender^[30]. More recent studies of breast cancer patients identified nine additional somatic mutations among *EGFR* family members that represent potential TKI therapeutic targets^[31].

Multiple factors modify the sensitivity of NSCLC patients with *EGFR* mutations to *EGFR* TKIs. For instance, in-frame deletion in exon 19 is more sensitive to erlotinib inhibition than the L858R mutant^[32]. Similarly, patients with an in-frame deletion mutant showed better response and longer overall survival with gefitinib or erlotinib treatment than did patients with the L858R mutant^[33]. High *EGFR* gene copy number identified by fluorescence *in situ* hybridization (FISH) was proposed to be an effective molecular predictor of gefitinib efficacy in advanced NSCLC^[34]. However, a meta-analysis has found that *EGFR* overexpression is not associated with overall survival in NSCLC patients^[35]. Increased *ErbB2* expression is also associated with increased sensitivity to gefitinib both in the presence^[36] and absence of *EGFR* mutations^[37], although phosphorylated-*ErbB2* along with total *ErbB3* levels have been associated with resistance to gefitinib in head and neck squamous cell carcinoma^[38].

Despite their success in a subset of patients, the overall effectiveness of *EGFR* inhibitor treatment for cancer therapy remains elusive. While erlotinib can be effective for the initial treatment of those with sensitizing *EGFR* mutations, overall median survival of patients treated with erlotinib *vs* placebo is only 6.7 mo *vs* 4.7 mo^[24]. Together with the fact that patients with erlotinib reported severe side effects including rash and diarrhea^[39], it is vital that alternative and improved regimens be developed to better treat NSCLC.

Further complicating TKI treatment efficacy, patients with drug-sensitive *EGFR* mutations develop acquired resistance after about 12 mo, and up to 50% of resistant cases can be attributed to a secondary mutation at position 790 (*EGFR* T790M)^[26,40,41]. It is thought that the

T790M mutation leads to steric hindrance for erlotinib binding due to the bulky methionine side chain in the ATP-binding pocket^[42]. However, another study revealed that the T790M mutation causes drug resistance simply by increasing the affinity for ATP^[43].

Amplification of the hepatocyte growth factor receptor tyrosine kinase (MET) has been implicated in drug resistance, presumably by driving *ErbB3*-dependent activation of phosphoinositide-3 kinase (PI3-K)^[44]. MET amplification was reported in about 20% of TKI-resistant patients, sometimes concomitantly with *EGFR* T790M^[44]. In addition, insulin-like growth factor I receptor reportedly interferes with anti-*EGFR* directed therapies^[45], and a block in apoptosis is implicated as one of the mechanisms of TKI resistance^[46].

A multigene signature indicative of an epithelial to mesenchymal transition (EMT) was also identified as a determinant of insensitivity to erlotinib^[47]. Cells expressing the epithelial cell junction protein E-cadherin show greater sensitivity to *EGFR* inhibition, whereas cells that have undergone EMT, expressing vimentin or fibronectin, are insensitive^[48]. Src-mediated cell signaling has been proposed to be another mechanism for anti-*EGFR* directed therapy resistance, by bypassing the dependency on *EGFR* for cell growth and survival^[49]. *KRAS* mutational status also predicts resistance to anti-*EGFR* directed therapies apparently as cancer cells may no longer need *EGFR* for survival^[50-52].

To circumvent the problem of TKI resistance and to enhance the efficacy of *EGFR*-directed therapies, alternative strategies are being utilized to enhance the survival rate of cancer patients, albeit with mixed results. Because erlotinib has a lower IC₅₀ than gefitinib against wild-type *EGFR*, it has been suggested that gefitinib-resistant patients be treated with erlotinib, but such studies have not had much success as erlotinib could not overcome the resistance conferred by the T790M mutation^[53]. Phase II clinical trial data also showed that patients with activating *EGFR* mutations do not respond to monoclonal antibody-based therapy with cetuximab even though they respond to a TKI^[54]. However, a different study showed cetuximab to be effective against cells expressing either TKI-sensitive or resistant NSCLC *EGFR* mutations^[55].

Promising results were observed in an animal model using a combination of cetuximab and TKI, which yielded enhanced tumor regression^[56]. Cells expressing mutant *EGFR* also show sensitivity towards an inhibitor of vascular endothelial growth factor receptor-2 (VEGFR-2), ZD6474, indicating that VEGFR-2 may be critically involved in mutant *EGFR*-mediated cell survival^[57]. An irreversible pan-*ErbB* inhibitor PF00299804 is also a potent inhibitor of gefitinib-resistant *EGFR* and *ErbB2* mutations^[58].

It is evident from the current directions of the anti-*EGFR* directed therapy that it is critical to identify key partners and pathways of *EGFR*-mediated tumorigenicity and co-target these factors simultaneously. This approach will not only benefit NSCLC, but other cancer

types in which EGFR may play a critical role.

MUTANT EGFR SIGNALING

Early studies using NSCLC tumor cell lines indicated that mutant EGFRs are constitutively-active^[22,28,59], transform nonmalignant cell lines in a ligand-independent manner^[60], and enhance tumor growth in xenograft models^[60]. Furthermore, cells harboring mutant EGFRs undergo “oncogene addiction” and require the mutant receptor activity for survival^[61]. In transgenic mouse models, reduction in the expression of mutant EGFR or inhibition of its kinase activity caused rapid tumor regression, demonstrating that mutant EGFR is required for tumor maintenance^[62].

It is becoming increasingly evident that in addition to oncogene addiction, cells also depend on non-driver oncogenic pathways for survival^[63]. It has been found that downstream signaling pathways that are key to mutant EGFR function include Akt, Erk1/2, and STAT3^[23,34,64-67]. Sensitivity to growth inhibition by gefitinib is associated with signaling molecules downstream of activated EGFR such as Akt and Erk^[68,69], and gefitinib effectively blocked Akt and Erk phosphorylation in gefitinib-sensitive NSCLC cell lines^[66].

Transfection studies using the EGFR exon 19 in-frame deletion mutant revealed highly phosphorylated Akt and STAT3 compared to transfection of wild-type EGFR (wtEGFR)^[70]. In fact, continued activation of PI3-Kinase signaling by a *PIK3CA* (PI3-K, catalytic, alpha polypeptide) oncogenic mutant is sufficient to abrogate gefitinib-induced apoptosis in NSCLC-associated EGFR mutant-expressing cells^[71]. PI3-K was found to exclusively associate with ErbB3 in gefitinib-sensitive NSCLC cell lines, and, interestingly, the gefitinib-sensitive wtEGFR-expressing NSCLC cell lines showed greater ErbB3 expression than gefitinib-insensitive cell lines^[72]. In addition, the expression of NSCLC-associated EGFR mutants correlates with constitutive activation of mammalian target of rapamycin (mTOR) and Erk5 as well as enhanced expression of cyclin D1 and EGR1^[73-76].

Subsequent studies have also identified Src to be critical for cell proliferation, survival and migration of mutant EGFR-expressing cells. In contrast to mutant EGFRs, overexpression of wtEGFR in primary cells is not oncogenic. High levels of exogenous ligands^[77] and/or cooperating oncogenic partners are required for the wtEGFR to transform cells. In this regard, Src has been established to cooperate with EGFR and to be an important determinant of EGFR-mediated oncogenesis^[78,79]. EGFR and Src overexpression in fibroblast systems led to synergistic increases in EGF-induced DNA synthesis, soft agar colony formation, and tumor formation in nude mice^[80]. This cooperativity has also been demonstrated in a model of epithelial cell transformation: loss of polarity in three-dimensional cultures of nonmalignant human mammary epithelial cells as well as their anchorage-independent growth were only seen when both EGFR

and Src were co-overexpressed^[81]. Consistent with these studies, EGFR and Src are often co-overexpressed in human cancers^[82], and enhanced Src activity was observed in NSCLC tissue compared to normal lung tissues^[83].

Importantly, mutant EGFR-expressing NSCLC cell lines exhibit increased Src phosphorylation^[64], and more Src is associated with mutant EGFR compared to wtEGFR^[84,85]. Mutant EGFR-expressing cells were sensitive to Src inhibitors such as Dasatinib, PP1, or SKI-606^[64,65], and Src-dependent phosphorylation on EGFR Y845 was required for full phosphorylation of mutant EGFR and downstream signaling molecules such as Akt, Erk and STAT3^[85,86]. Interfering with Src-dependent phosphorylation on EGFR Y845 resulted in decreased mutant EGFR-mediated biological processes such as cell transformation and migration^[85]. Further studies are needed to identify additional factors and processes critical to mutant EGFR-mediated oncogenic signaling and biological outcomes.

ENDOCYTIC TRAFFIC OF EGFR

In normal cells, EGFR signaling is tightly regulated by endocytic traffic. The ligand-induced EGFR dimerization and activation are associated with rapid internalization from the cell surface into endosomes followed by further traffic into lysosomes, or alternatively into an endocytic recycling compartment from which the receptor returns back to the cell surface (Figure 1). The pathways of endocytic traffic to the lysosome and their functional impact have been substantially elucidated in recent years. Activated EGFR undergoes ubiquitination, which provides a signal for sorting of internalized EGFR into lysosomes for degradation^[2,87], a mechanism for signal termination^[88,89]. In this context, endocytosed EGFR migrates down a system of heterogeneous compartments that have generally been characterized as “early” or “late” endosomes based on their morphology, kinetics of labeling with endocytic cargo as well as compartment-specific markers^[90]. While punctate early endosomes are primarily located towards the cell periphery, the late endosomes are larger and more spherical, and often positioned closer to the nucleus^[90]. Furthermore, some late endosomes have a multivesicular appearance by ultrastructure and are referred to as multivesicular bodies (MVBs). The ubiquitinated cargo, such as EGFR, at the outer limiting membrane of MVBs is recognized by a series of protein complexes called the endosomal complex required for transport (ESCRT) 1 to 3, and selectively sorted into invaginating vesicles that bud off to form the internal vesicles of MVB^[91]. The MVB subsequently matures and/or fuses into the lysosome where the receptor is degraded by lysosomal hydrolases^[91]. Under conditions where EGFR does not undergo ubiquitination, or if ubiquitin chains are cleaved by deubiquitinases^[92], the receptor is alternatively sorted into vesicles that traffic along the endocytic recycling pathway back to the cell surface for additional rounds of ligand binding and signaling^[93]. Endocytic recycling can

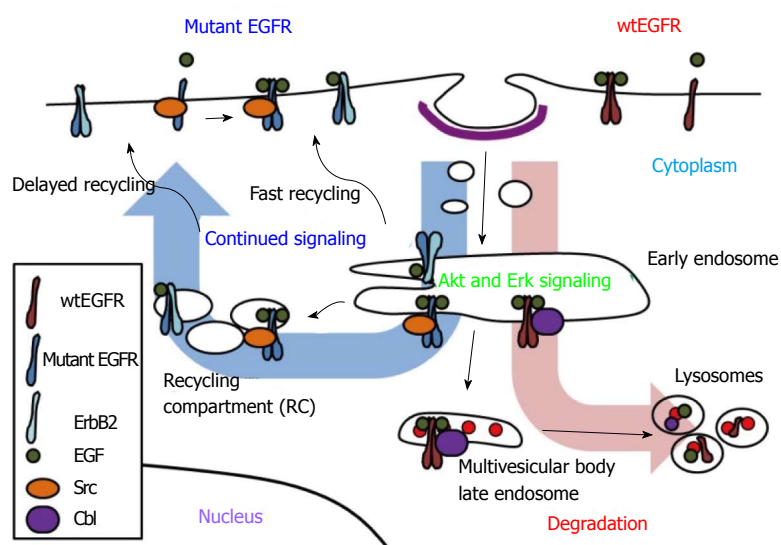

Figure 1 Model of mutant epidermal growth factor receptor endocytic trafficking. Upon ligand binding, activated wtEGFR becomes internalized and localized to endosomes. Internalized EGFR has been linked to Erk and Akt activation. Depending on type of ligand bound, ligand concentration, dimerization partner, mutational statuses and/or availability of other regulators, wtEGFR may recycle to cell surface or be sorted to lysosomes. EGFR bound to EGF is mostly targeted for lysosomes, where it becomes degraded. Sorting of ligand-induced wtEGFR to lysosome is mediated by E3 ubiquitin ligase Cbl which remains attached to receptor throughout endocytosis. Mutant EGFR, however, escapes ligand-induced downregulation through decreased interaction with Cbl, enhanced dimerization with ErbB2, which prefers recycling pathway, and/or constitutive interaction with Src, which antagonizes Cbl. EGFR: Epidermal growth factor receptor.

take place *via* the fast/direct recycling from the early endosomes back to the plasma membrane, or *via* a delayed recycling pathway that involves the perinuclear endocytic recycling compartments (Figure 1)^[93,94]. Members of Rab-family of small GTPases play key roles in facilitating alternate sorting itineraries. The delayed recycling pathway utilizes Rab11 as well as Arf6 small GTPase^[94]. Notably, members of a family of dynamin-like ATP-binding and EPS15-homology domain-containing (EHD) proteins have been identified as key regulators of the delayed endocytic recycling compartments^[95,96].

The endocytic trafficking fates of EGFR are regulated by a complex, and still incompletely understood, molecular machinery. First, the nature of the ligand bound to EGFR can dictate alternate fates of the ligand-receptor complex. In particular, EGF, which forms a more stable complex with EGFR in the low pH environment of endosomes, primarily targets the receptor for ubiquitination and lysosomal degradation; in contrast, other ligands such as TGF α and amphiregulin form less stable complexes with EGFR, induce lower levels of ubiquitination, and promote recycling of the receptor accompanied by more sustained signaling responses^[88,97]. The concentration or the availability of ligands is another factor that determines the fate of EGFR degradation as low concentrations of EGF induce clathrin-mediated endocytosis of EGFR for recycling while higher concentrations induce internalization *via* lipid rafts for degradation^[98,99]. The dimerization partner may also affect the regulation of EGFR; for example, overexpression of ErbB2 has been shown to reduce EGFR downregulation by increasing its recycling or decreasing internalization^[100,101].

The Cbl (Casitas B-lineage Lymphoma proto-oncogene) family of ubiquitin ligases plays an essential role in promoting ubiquitination and lysosomal degradation of EGFR^[102]. Cbl proteins selectively associate with activated EGFR, *via* phosphorylated tyrosine 1045 (number corresponding to human EGFR) and facilitate the juxtaposition of Cbl-bound ubiquitin conjugating

enzymes to facilitate EGFR ubiquitination^[102,103]. Once bound, Cbl remains associated with the activated EGFR throughout its endosomal transport to lysosomes^[103]. Ubiquitination mediated by the association of Cbl proteins is essential for EGFR sorting into lysosomes (Figure 1). It has also been suggested that Cbl can function as an adaptor protein to recruit Cbl-interacting protein of 85 kDa (CIN85) together with its partner Endophilin A to promote initial internalization of EGFR^[104]. However, a more recent study suggested that CIN85 is dispensable for EGFR internalization^[105]. Grb2, which interacts with the proline-rich region of Cbl and phosphotyrosine-containing motifs on EGFR, may also mediate EGFR-Cbl complex formation and initiate EGFR internalization by promoting delivery into clathrin-coated pits^[104,106,107]. Disruption of Grb2 interactions with EGFR or Grb2 knockdown using a small interfering RNA significantly inhibited the receptor internalization^[108,109]. A recent study also demonstrated that the cooperative recruitment of Cbl, in complex with Grb2, to EGFR determines the threshold of ubiquitination of EGFR^[110]. Other factors are also known to affect EGFR endocytosis and down-regulation. For example, Sprouty2 or activated Cdc42^[111], which appear to block Cbl function, as well as suppressor of T-cell receptor signaling (Sts-1/Sts-2), and Cortactin, inhibit efficient EGFR trafficking to the lysosome and block receptor downregulation^[107,112,113]. In addition, SNX1, stimulatory G protein subunit (G α s), and factors important in mediating or regulating ESCRT complex function, such as Hrs (hepatocyte growth factor-regulated tyrosine kinase substrate), signal-transducing adaptor molecule (STAM), tumor susceptibility gene product 101 (TSG101), and other components of ESCRT complexes, are required for the MVB sorting of EGFR and efficient receptor degradation^[7,114]. Interfering with Cbl-dependent negative regulatory process prolongs the EGFR activity and enhances the EGFR-mediated cell transformation^[87]. Thus, it is clear that endocytic traffic of EGFR plays a critical role in controlling its signaling and regulating its

oncogenicity.

ENDOCYTIC TRAFFIC OF MUTANT EGFRS

Mutant EGFRs function as oncogenic drivers in NSCLC and other cancers including glioblastomas. To understand the biological basis of how mutant receptors drive oncogenesis, it is important to gain insights into how the regulatory mechanisms that control EGFR operate in the context of mutant receptors. A key component of EGFR regulation involves the ligand-induced receptor endocytosis which leads to degradation of the receptor and termination of signaling, or to receptor recycling for continued signaling. Because of the radically different outcomes of the alternate endocytic fates, elucidating mechanisms of mutant EGFR endocytic trafficking is fundamentally important to understanding mutant EGFR-driven signaling and oncogenesis, with a potential to improve the EGFR-directed therapies.

Since mutant EGFR exhibits constitutive signaling, it is likely that this is associated with altered endocytic trafficking. Indeed, multiple lines of evidence suggest that mutant EGFRs undergo altered endocytic trafficking compared to the wild-type receptor^[115-118]. In this section, we will describe mutant EGFR endocytic trafficking in terms of basal receptor localization, as well as ligand-induced internalization and degradation.

MUTANT EGFR LOCALIZATION AND LIGAND-INDUCED INTERNALIZATION

Mature wtEGFR is primarily localized at the cell surface prior to ligand binding, but becomes internalized upon ligand binding. There are conflicting reports in regards to ligand-induced mutant EGFR internalization compared to that of wtEGFR. It has been reported that EGF-induced internalization of gefitinib-sensitive mutant EGFR expressed on PC9 cell line was faster than that of wtEGFR on gefitinib-insensitive cell lines A549 and QG56^[68,119]. Another study, however, reported that mutant EGFR-expressing NSCLC cell lines H1975 and H1650 showed delayed internalization of labeled EGF in comparison to a wtEGFR-expressing cell line H358^[116]. Yet another study found that rhodamine-conjugated EGF uptake was comparable between H1299 cell lines permanently transfected with mutant EGFRs or wtEGFR, suggesting that NSCLC EGFR mutation did not affect ligand-induced receptor internalization^[120]. Differences in EGF-induced mutant EGFR internalization may be attributed to cell lines used to compare wtEGFR and mutant EGFRs, and underscore the need for more comprehensive and concurrent studies using multiple assays to fully understand if and how the NSCLC-associated mutations of EGFR affect its ligand-induced EGFR internalization.

Compared to the uncertainty of the impact of NSCLC-

associated EGFR mutations on ligand-induced internalization, emerging evidence suggests that mutant EGFRs are constitutively internalized. Mutant EGFR ectopically overexpressed in a murine pro-B cell line model was shown to undergo EGF-independent internalization, whereas wtEGFR was primarily localized to the cell surface in the absence of ligand^[121]. Another study showed that mutant EGFR in PC9 cell line, but not the wtEGFR, in QG56 cell line was distributed inside the cell^[119]. These data suggest that mutant EGFRs may undergo enhanced constitutive internalization compared to wtEGFR. Indeed, unlike wtEGFR, mutants EGFRs showed constitutively intracellular localization and colocalized with endosomal markers^[118]. Inhibition of endocytic recycling pathway using monensin resulted in the accumulation of mutant EGFRs in perinuclear vesicles, and mutant EGFRs showed colocalization with various recycling endosomal markers, suggesting that mutant EGFRs undergo altered endocytic trafficking through recycling pathway^[118]. Importantly, recycling inhibition delayed the ligand-mediated mutant EGFR degradation and enhanced the mutant EGFR association and colocalization with Src (Figure 1)^[118]. These findings support the notion that enhanced endocytic trafficking of mutant EGFRs *via* the recycling pathway provides a potential compartment where mutant EGFR may engage in preferential interaction with Src and sustained oncogenic signaling.

As for the cellular localization and internalization of EGFRvIII, there remains much confusion. Earlier work has suggested that EGFRvIII expressed in a glioma cell line remains on the plasma membrane even after EGF stimulation, whereas wtEGFR was removed from the cell surface and appeared in perinuclear vesicles corresponding to endosomes and lysosomes^[122]. Similarly, EGFRvIII, when transfected into a small cell lung cancer cell line, localizes predominantly at the cell surface^[123]. However, confocal microscopic analyses on biopsy samples of human gliomas showed that the subcellular localization of EGFRvIII was identical to that described for wtEGFR; predominant cell membrane expression, with some perinuclear distribution^[124]. Future studies will need to delineate the exact subcellular localization and endocytosis of EGFRvIII.

The mechanisms underlying the tendency of NSCLC-associated EGFR mutants to remain constitutively internalized are currently unclear. As mutant EGFRs are constitutively-active, a role for kinase activity in promoting ligand-independent internalization appears plausible. Published studies on the role of kinase activity for internalization of wtEGFR have arrived at opposite conclusions, suggesting either a requirement for or dispensability of the kinase activity for internalization^[125-127]. In fact, ligand-induced internalization of EGFR in the presence of TKIs was previously employed by investigators to initiate signaling directly from the endosomes^[128]. Rather than the kinase activity *per se*, it may be the conformational changes associated with activation that expose endocytic motifs in EGFR and permit its internalization^[43,60]. Fur-

thermore, activated EGFR recruits adapter proteins such as Epsin and Grb2 that have been shown to promote internalization^[129,130]. Given the constitutive activity of mutant EGFRs, these mechanisms may mediate enhanced internalization of mutant compared to wtEGFR. Notably, gefitinib inhibits the ligand-induced internalization of mutant EGFR in gefitinib-sensitive PC9 cell line but does not affect internalization of wtEGFR in gefitinib-insensitive QG56 cell line^[119]. Therefore, kinase activity might play a more critical role in the internalization of mutant EGFR compared to wtEGFR. Other studies have shown that EGFR dimerization is critical for wtEGFR internalization^[125]. Given that mutant EGFR has been found to be constitutively dimerized^[131], dimerization may indeed be critically involved in the constitutive internalization of mutant EGFRs.

Some studies also suggest sensitivity to TKI to play a role in ligand-induced EGFR internalization. For example, it has been reported that a H1650 NSCLC cell line rendered gefitinib-resistant showed increased ligand-induced mutant EGFR internalization when compared to the parental gefitinib-sensitive cell line^[132]. In contrast, the reverse was true for wtEGFR, as others showed that ligand-induced internalization of wtEGFR in erlotinib-sensitive H292 cells was greater than that in erlotinib-insensitive H1703 cells^[133]. Quantification also showed that inhibition of EGF-induced EGFR internalization by erlotinib was greater in sensitive cell line compared to that in the insensitive cells^[133]. Further studies are needed to more clearly delineate key determinants of ligand-induced and constitutive mutant EGFR internalization as well as the relationship of these processes with TKI sensitivity *vs* resistance.

ALTERED LIGAND-INDUCED DEGRADATION OF MUTANT EGFRS

As mentioned in the introduction, lysosomal degradation of EGFR is critically dependent on ubiquitination promoted by Cbl-family ubiquitin ligases. Upon ligand activation and phosphorylation of EGFR, Cbl associates with the phosphorylated (active) receptor and facilitates its ubiquitination^[102,134-137]. The Cbl-EGFR association has been shown to persist throughout the endosomal pathway and Cbl-family proteins are essential for the lysosomal sorting step of activated EGFR downregulation^[103,134,138]; accordingly, ubiquitin ligase activity-defective Cbl mutants enhance the EGFR recycling^[135]. Ubiquitin ligase activity-deficient Cbl itself can become oncogenic due to loss of negative regulatory control on receptor signals^[135,139-141]. Depletion of Cbl proteins or expression of mutant forms has clearly shown that lack of Cbl function deregulates EGFR traffic, elevates downstream signaling and promotes epithelial cell migration^[134,137,142]. As NSCLC mutant EGFRs appear defective in Cbl-dependent downregulation, it is quite likely that the ensuing recycling and endosomal signaling contribute to the

oncogenicity of mutant EGFRs^[115-117] (Figure 2).

Several studies have examined the association of NSCLC EGFR mutants with Cbl, but have provided conflicting results. Reduced ligand-induced association of mutant EGFR with Cbl, as compared to that of wtEGFR, was reported in NSCLC cell lines H1975 and PC-9 expressing EGFR L858R/T790M or Δ 746-750 mutants respectively, as well as in human embryonic kidney and normal lung bronchial epithelial cells made to overexpress EGFR L858R or Δ 746-750^[116,117,143,144]. However, another study using TGF α as a ligand showed intact and constitutive mutant EGFR-Cbl association in NSCLC cell lines^[115].

Similar to conflicting reports on mutant EGFR-Cbl association, the phosphorylation status of the Cbl binding site, EGFR-Y1045, on mutant EGFRs remains unclear^[87]. Reverse-phase protein microarray was used to quantify levels of phosphorylation of various EGFR phosphorylation sites on pure tumor cell populations isolated by laser capture microdissection from human lung tumor biopsy specimens^[145]. The group found that phosphorylation of EGFR-Y1045 was reduced across patient samples that expressed all classes of mutant EGFRs (inframe deletion mutant, EGFR L858R and H773L/V774M) compared with wtEGFR^[145]. Similarly, EGFR L858R and EGFR Δ 747-753 mutants expressed in a mouse fibroblast cell line or COS-7 cells showed lower levels of EGFR-Y1045 phosphorylation when compared to wtEGFR, while EGFR Δ 746-750 showed hypoubiquitination, delayed downregulation, and increased surface retention upon ligand stimulation^[146]. Another study, however, showed that when mutant EGFRs were stably expressed in a NSCLC cell line H1299, the mutant EGFRs showed higher basal phosphorylation levels at all tyrosine residues, including Y1045^[120]. Intact ligand-induced Y1045 phosphorylation has been observed in other mutant EGFR cell systems, including L858R mutant-expressing and in-frame deletion mutant-expressing non-transformed mouse mammary epithelial cells^[23], SF9 insect cells^[147], and murine hematopoietic cells^[121]. Similarly, endogenous EGFR Δ 746-750 or L858R/T790M expressed in NSCLC cell lines H1650 or H1975, respectively showed robust phosphorylation on EGFR Y1045 compared to that in wtEGFR-expressing NSCLC cell line H358^[116]. Interestingly, human embryonic kidney 293 cells transfected with EGFR L858R showed intact ligand-induced Y1045 phosphorylation and association with Cbl, whereas EGFR Δ 747-753 showed decreased Y1045 phosphorylation and EGFR-Cbl association^[55]. The discrepancies among reported results are likely to be due to the difference in EGFR mutation type, different cell type used, and/or the types of cells used as controls to make comparisons. Nonetheless, a consistent picture on Cbl-mutant EGFR association has not emerged, and the role of other Cbl family members remains unclear.

In contrast to a lack of consensus on Y1045 phosphorylation of mutant EGFRs and their association with Cbl, different studies have consistently noted an impair-

Figure 2 Mutant epidermal growth factor receptor vs wt-epidermal growth factor receptor signaling. While wtEGFR signaling to Akt and Erk is subjected to Cbl-mediated degradation, mutant EGFR cooperates with Src to exaggerate signaling through downstream effectors. EGFR: Epidermal growth factor receptor.

ment of ligand-induced ubiquitination and downregulation of mutant EGFRs. It was reported that mutant EGFRs undergo reduced ubiquitination and delayed downregulation upon ligand stimulation in NSCLC cell lines H1650 and H1975, expressing endogenous mutant EGFRs, and in human embryonic kidney cells ectopically overexpressing mutant EGFR^[116,143]. Decreased ligand-induced ubiquitination and delayed downregulation were also observed in various NSCLC cell lines expressing endogenous EGFR Δ 746-750 or L858R (HCC827 and H3255, respectively), and in normal human bronchial epithelial cells stably expressing EGFR Δ 746-750 or L858R^[117].

Interestingly, even under conditions that permitted mutant EGFR-Cbl association, mutant EGFR showed decreased ligand-induced ubiquitination and impaired degradation; this correlated with constitutive association of mutant EGFR with the molecular chaperone Hsp90^[115]. Constitutive association of mutant EGFR with Hsp90^[115,148] may provide a mechanism to impair Cbl-dependent mutant EGFR downregulation. However, Cbl overexpression in HCC827 cell line resulted in enhanced mutant EGFR downregulation, suggesting that mutant EGFRs retain the ability to undergo Cbl-dependent downregulation but the process is less efficient^[117]. Among the ErbB family receptors, ErbB2 is known to be stably associated with Hsp90 while EGFR-Hsp90 interaction is transient^[149]. It is therefore noteworthy, that heterodimerization with ErbB2 has been identified as a mechanism for the ability of EGFR L858R or EGFR L858R/T790M to avoid ligand-induced downregulation^[116] (Figure 1). Previous studies in breast cancer and other models have established that ErbB2 is impaired in downregulation, and its co-overexpression with EGFR inhibits the downregulation of EGFR by increasing the recycling rate of EGFR and/or inhibiting internalization^[100,101,150,151]. Indeed, treatment of gefitinib-resistant EGFR L858R/T790M-expressing NSCLC cells with a EGFR/ErbB2 dual TKI, lapatinib, decreased STAT3 activation and this was associated with reduced mutant EGFR-ErbB2 heterodimerization^[56]. Combining lapatinib and cetuximab treatment resulted in enhanced cytotoxicity against gefitinib-resistant EGFR L858R/T790M-expressing cells *in vitro* and in xenograft models *in vivo*^[56].

However, EGFR mutants expressed in Chinese hamster ovary cells were less sensitive to lapatinib, indicated by the levels of autophosphorylation, than wtEGFR^[152]. Therefore, the impact of ErbB2 co-expression based on the effects of lapatinib must be considered in the context of the genetic makeup of the cell system used, including the levels of ErbB2 expression. It has also been shown that certain stimuli activate EGFR and promote its internalization but do not induce efficient downregulation. Such stimuli include specific EGFR ligands, such as amphiregulin and TGF α , and exposure to certain chemicals including H₂O₂ or cigarette smoke^[97,153] and the role of such factors in inefficient downregulation of mutant EGFRs in NSCLC needs to be considered.

A number of interacting proteins are thought to affect Cbl-dependent lysosomal trafficking of EGFR. Cbl interacting proteins CD2AP and CIN85 are thought to cooperate with Cbl to promote EGFR endocytosis^[113,154], whereas Cool-1, Sprouty and Sts-1/Sts-2 interfere with EGFR downregulation^[107,112,113,155]. Therefore, alterations of these components may account for defective Cbl-dependent downregulation of mutant EGFRs even though EGFR Y1045 phosphorylation and association with Cbl remain intact^[23,115,116,120].

In addition, there are other factors to be considered for the altered endocytic trafficking of mutant EGFRs. Cdc42-associated tyrosine kinase 1 associates with activated EGFR and is involved in ligand-induced clathrin-coated vesicle-mediated EGFR endocytosis and degradation^[156-158]. Rab5 controls endosome fusion and enhances lysosomal degradation of EGFR^[159,160], and Rab5 exchange factor GAPex-5 mediates EGFR ubiquitination, lysosomal trafficking and degradation^[161]. Alternatively, TBC1D3 enhances EGFR internalization but suppresses Cbl-dependent EGFR ubiquitination and degradation^[162]. In addition, STAM1/2, Hrs, Rin1 and ESCRT proteins also regulate EGFR endocytic traffic at various stages^[91,163]. Verifying expression levels of proteins critical to Cbl-dependent EGFR downregulation, and/or RNAi-mediated knock-down of proteins implicated in interfering with EGFR downregulation may identify those critical to mutant EGFR endocytic trafficking and provide mechanism of altered endocytic traffic of mutant EGFRs. Given the biological consequences of inefficient mutant

EGFR downregulation, elucidation of cell biological and biochemical mechanisms responsible represent a fertile area of future research.

ENDOSOMAL SIGNALING BY EGFR

Aside from the importance of endocytosis as a necessary step in lysosomal downregulation of ligand-activated EGFR, endocytosis has emerged as a requirement for efficient activation of specific downstream signaling pathways. For example, inhibition of the internalization machinery demonstrated that activation of PLC γ 1 upon EGF stimulation occurs primarily at the cell surface while activation of Erk and Akt signaling occurs primarily post-internalization^[164]. Therefore, oncogenic signaling from mutant EGFRs may result from or be sustained by altered receptor endocytic trafficking. It is now well-established that internalized receptor tyrosine kinases, including EGFR, continue to be active unless degraded, providing a mechanism for persistent signaling as well as activation of distinct pathways through the formation of spatially-distinct signaling complexes^[165]. Many studies have shown that Erk activation upon EGF stimulation critically depends on endosomal localization of EGFR; activated EGFR in endosomal compartments participate in the activation of Ras, the upstream activator of Erk signaling^[166]. A relationship between accumulation of EGFR in endosomes and enhanced Erk activation is provided by studies in which overexpression of SEF (for similar expression to FGF) enhances EGF-induced EGFR internalization but delays its targeting to lysosome, and results in sustained Erk activation and differentiation in the PC12 rat pheochromocytoma cell model^[167]. Knockdown of Cbl in 293 cells^[168], or lack of Cbl in Cbl-knockout mouse embryonic fibroblasts^[134], delayed exit of ligand-stimulated EGFR out of early endosomes towards lysosomes, and resulted in prolonged Erk activation. Combined knockdown of Cbl and Cbl-b had a similar impact on EGFR traffic and Erk signaling in human mammary epithelial cells^[132].

Endosomal localization of not just EGFR but also of Ras signaling cascade proteins is required for Erk activation. Dynamin-regulated endocytosis of activated MEK is required for Erk activation^[169]. Analysis of endosomal localization of MEK2-GFP suggests that endosomal localization of MEK2 requires clathrin-dependent endocytosis, the presence of an upstream kinase, RAF, and the catalytic activity of MEK^[170]. Erk activation mediated by beta 2-adrenergic receptor transactivation of EGFR is sensitive to clathrin-dependent endocytosis in transfected COS-7 cells^[171], although it has been recently reported that clathrin-dependent endocytosis is not required for Erk activation in HeLa cells^[170]. MAP kinase signaling may itself affect EGFR endocytic traffic, as activation of p38 MAP kinase induced the internalization of EGFR, suggesting that p38 may provide an important feedback regulatory loop in the regulation of EGFR trafficking and signaling^[172]. Recently, it was shown that activated

Akt promotes early endosome to lysosome transition and degradation of EGFR by activating PIKfyve (FYVE-containing phosphatidylinositol 3-phosphate 5-kinase)^[173]. By utilizing reversible kinase inhibitors to promote ligand-induced internalization into endosomes followed by inhibitor removal, it was established that endosomal EGFR signaling is sufficient to activate major signaling pathways leading to cell survival and proliferation^[128,174]. Thus, it is easy to visualize how constitutive internalization into endosomes together with impaired lysosomal downregulation of NSCLC-associated EGFRs can promote endosomal signaling-dependent oncogenic cascades, as further discussed below.

MUTANT EGFR TRAFFIC AND SIGNALING

As discussed above, studies of mutant EGFR signaling pathways have identified Akt, Erk, STATs and Src as critical downstream molecular players. Our studies established that preferential trafficking of mutant EGFRs *vs* wtEGFR into the endocytic recycling compartment promotes association of mutant EGFRs with their oncogenic partner Src (Figure 1)^[118]. The requirement of the major Src phosphorylation site of the mutant EGFRs (Y845) for their ability to transform NIH 3T3 cells supports a role for Src signaling within the endosome in mutant EGFR oncogenic activity^[85] (Figure 2). This is consistent with the impact of Src inhibitors on NSCLC *in vitro* and in animal models^[85,175]. Further studies are needed to directly assess if Src-dependent signaling by mutant EGFRs takes place primarily within the endosomal compartments or if endocytic recycling is required to traffic Src to its site of action. In this regard it is notable that inactive Src is primarily localized on lysosomal membranes and an endocytic traffic pathway orchestrated by the ESCRT machinery is required for its traffic to focal adhesions/invadopodia, where Src activity is essential for cell migration and invasion^[176,177]. Notably, lysosomal regulatory small GTPase Rab7 and ESCRT1 component TSG101 were shown to be required for unoccupied wtEGFR to enter into the endocytic recycling compartment and to recycle back to the cell surface^[178]. It will be of considerable interest in the future to determine if NSCLC-associated mutant EGFRs and c-Src co-traffic through a lysosomal/MVB compartment to enter the endocytic recycling compartment.

Notably, endocytic traffic-dependent EGFR signaling is also critical for cell migration. The developmentally regulated border cell migration in drosophila requires localized EGFR signaling, and deletion of proteins involved in endocytic traffic of EGFR (Cbl and Rab5 guanine nucleotide exchange factor) disrupted border cell migration^[142]. In this system, receptor endocytosis is necessary to help establish ligand gradients and localized RTK signaling, preserving spatial information that is critical to guide migrating cells in a directional manner^[142]. Recently, it was shown that TGF α -induced cell migration in mammalian corneal epithelial cells required endocytic

recycling of EGFR^[1179]. Thus, it is plausible that endocytic recycling and endosomal signaling may contribute to cell migration, invasion and metastatic behavior of mutant EGFR-expressing NSCLCs.

NSCLC-associated EGFR mutants exhibit constitutive internalization^[118,119,121]. Since hyperactive Erk signaling is a prominent feature of mutant EGFRs in NSCLC^[23,66], enhanced endosomal localization of mutant EGFR may provide one of the mechanisms contributing to enhanced Erk activation. Indeed, the upstream activators of Erk signaling pathway have been shown to be associated with endosomal EGFR. Analysis of rat livers following administration of EGF, internalization of EGFR coincided with recruitment of the adaptor protein Shc, and its association with GRB2 and the Ras guanine nucleotide exchange factor, mSOS, and the complex of tyrosine phosphorylated Shc, Grb2 and mSOS was largely present in the endosomal fraction^[180]. FRET measurements also indicated that activated EGFR-CFP interacted with YFP-Shc and Grb2-YFP in endosomes^[181]. Similarly, inhibition of EGFR internalization through knockdown of Grb2 by RNA interference or use of a dynamin mutant resulted in inhibition of EGF-induced MAPK and Erk activities^[106,164].

Akt activation has also been linked to endosome-localized EGFR. Inhibiting internalization through clathrin heavy chain or AP-2 knockdown reduced EGFR-mediated Akt as well as MAPK activation^[99]. Initiation of EGFR signaling directly from the endosomes, by allowing EGFR endocytosis in the presence of a washable inhibitor, demonstrated that endosomal signaling of EGFR is sufficient for activating signaling pathways including Erk and Akt, as well as cell survival and proliferation^[128,174]. Likewise, ligand-induced trafficking of internalized EGFR from early endosomes to lysosomes was severely delayed in cells lacking presenilin 1 and resulted in prolonged EGFR, Akt and Erk activation^[182]. A similar impact of depletion of Cbl proteins has been demonstrated on EGFR-induced Erk and Akt activation^[134,137]. Therefore, similar to Erk, Akt activation may also be dependent on EGFR localization in endosomes. Interestingly, some studies indicate that endosomal EGFR does not recruit and activate PI3-K^[183,184], suggesting that EGFR-dependent Akt activation may involve additional factors and/or mechanisms. Clathrin-dependent EGFR internalization has also been shown to be essential for STAT3 nuclear translocation and Stat3-dependent gene regulation, and Stat3 co-localizes with labeled EGF in endocytic vesicles^[185]. These studies, done on wtEGFR, support the likelihood that constitutively endosome localized mutant EGFRs promote enhanced Map kinase and potentially PI3-kinase and STAT signaling through endosomal signaling. Future investigations targeting this key question are urgently needed.

ROLE OF SRC IN EGFR ENDOCYTOSIS

In addition to its critical involvement in EGFR-mediated oncogenesis^[85], Src plays a role in EGFR endocytosis.

Active Src has been shown to phosphorylate clathrin heavy chain^[186], and overexpression of Src was shown to accelerate clathrin-mediated internalization of EGFR without increasing EGFR degradation in fibroblasts. Interestingly, Src co-overexpression with EGFR in human mammary epithelial cells led to reduction in surface EGFR levels without a decrease in total EGFR levels, together with EGFR hyperactivation, suggesting that overexpressed Src promotes the traffic of surface EGFR into a non-degradative and likely signaling endosomal compartment^[187]. Src-mediated tyrosine phosphorylation has been shown to be required for dynamin function in ligand-induced EGFR internalization^[188]. Src is also critical for proper ubiquitination and degradation of EGFR; Src activity antagonizes the function of Cbl by mediating its phosphorylation and degradation^[189]. In the presence of a Src inhibitor, EGF-induced phosphorylation of Cbl and ubiquitination of EGFR were blocked^[190]. Similarly, mouse embryonic fibroblasts with deletion of Src-negative regulator C-terminal Src kinase results in hyperactive Src; suppression of Src family kinases in these cells resulted in delayed EGFR degradation and prolonged EGF-induced activation of Erk1/2^[191]. Src-mediated phosphorylation was also shown to antagonize the function ALG-2 interacting protein X (Alix) in receptor tyrosine kinase internalization^[192]. A study using Src-GFP fusion protein showed that upon EGF stimulation, Src traffics into endosomal compartments with activated EGFR, and that Src expression and kinase activity prolong the EGFR activation^[193]. Src overexpression also induced activation of EGFR and of EGFR-mediated downstream signaling targets Erk and Shc^[193]. At a biological level, Src overexpression was found to promote the ability of EGFR overexpression to transform rodent fibroblasts^[194], and promote a transformed phenotype in three-dimensional cultures of human mammary epithelial cells^[81]. Therefore, constitutive interaction between mutant EGFR and Src^[84,85,118] suggests that, in addition to activating EGFR signaling, the hyperactivity of Src in NSCLC may provide a mechanism for delayed ligand-induced association of Cbl with EGFR, and reduced EGFR ubiquitination and/or downregulation^[116,117,143,146] (Figure 2). In this scenario, the preferential trafficking of mutant EGFRs to the endocytic recycling compartment^[118] may be due, in part, to their constitutive interaction with Src. Future studies are needed to establish if this mechanism can indeed explain the altered trafficking and signaling of mutant EGFRs.

CONCLUSION

Much insight has been gained on naturally occurring NSCLC-associated mutant EGFRs, thanks in large part to studies instigated by their clinical relevance which resulted in targeted therapies with TKIs. However, acquired resistance and other drug interfering mechanisms limit the efficacy of EGFR-directed therapies in NSCLC patients with EGFR mutations. Mutant EGFR biology remains poorly understood, and as yet their biologically-

linked and essential traits of signaling and endocytic traffic have not been integrated for mutant EGFRs. The current review summarizes our current understanding of mutant EGFR signaling and traffic and areas where we lack a clear picture, and points to a need for further understanding and integration. It is clear that mutant EGFRs, in addition to attaining constitutive activity, exhibit deregulated endocytic traffic that appears to promote the ability of mutant receptors to signal into oncogenic pathways. Increased understanding of mechanisms that underlie defects in mutant EGFR endocytic traffic could help define novel approaches to refine EGFR-directed therapies by intercepting at key endocytic traffic nodes.

Abstract

In lung cancer, tumor hypoxia is a characteristic feature, which is associated with a poor prognosis and resistance to both radiation therapy and chemotherapy. As the development of tumor hypoxia is associated with decreased perfusion, perfusion measurements provide more insight into the relation between hypoxia and perfusion in malignant tumors. Positron emission tomography (PET) is a highly sensitive nuclear imaging technique that is suited for non-invasive *in vivo* monitoring of dynamic processes including hypoxia and its associated parameter perfusion. The PET technique enables quantitative assessment of hypoxia and perfusion in tumors. To this end, consecutive PET scans can be performed in one scan session. Using different hypoxia tracers, PET imaging may provide insight into the prognostic significance of hypoxia and perfusion in lung cancer. In addition, PET studies may play an important role in various stages of personalized medicine, as these may help to select patients for specific

treatments including radiation therapy, hypoxia modifying therapies, and antiangiogenic strategies. In addition, specific PET tracers can be applied for monitoring therapy. The present review provides an overview of the clinical applications of PET to measure hypoxia and perfusion in lung cancer. Available PET tracers and their characteristics as well as the applications of combined hypoxia and perfusion PET imaging are discussed.

Key words: Molecular imaging; Positron emission tomography; Hypoxia; Perfusion; Quantification; Lung cancer

Core tip: This review provides an overview of the current applications of positron emission tomography for hypoxia and perfusion imaging in lung cancer. Available PET tracers are discussed and the benefits of combined hypoxia and perfusion PET imaging are clarified. Hypoxia imaging could aid in selecting patients for hypoxia-specific treatment strategies. To achieve this, consensus about the optimal imaging protocol and quantification method is essential. Large clinical trials are needed to confirm the value of hypoxia imaging for improving patient care.

INTRODUCTION

Worldwide, lung cancer is the most common cause of cancer related death among men and women^[1]. Every year, approximately 1.2 million new cases of lung cancer

are diagnosed globally and 1.1 million patients die of this disease^[2]. Non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC) are the main histological types and represent approximately 85% and 15% of the lung cancer cases, respectively^[3,4]. The prognosis of both NSCLC and SCLC is poor and depends on the stage of the disease^[5,6]. For example, the 5-year overall survival is approximately 1% and 2% for stage IV NSCLC and extensive stage SCLC, respectively. Treatment of lung cancer depends on histological type, stage and performance status. The available treatment options include surgery, radiation therapy and chemotherapy, or a combination of these modalities. Systemic therapy of lung cancer consists mainly of a platinum-based doublet, such as cisplatin or carboplatin, in combination with a third generation cytotoxic drug such as gemcitabine, pemetrexed, paclitaxel or docetaxel^[7,8]. In addition, targeted agents, including gefitinib, erlotinib, bevacizumab and crizotinib, have been introduced for the treatment of advanced NSCLC^[9-16]. For the last decades, several tumor characteristics have been under investigation in order to further understand the biology of lung cancer and enhance the efficacy of the several treatment modalities.

In lung cancer, tumor hypoxia is a characteristic feature^[17], which is associated with a poor prognosis^[18-20] and resistance to both radiation therapy^[21] and chemotherapy^[22]. Hypoxia is a reduced O₂ tension in tissue and is defined between normoxia (pO₂ levels of 40-60 mmHg) and anoxia (0 mmHg)^[23]. In clinical practice, no consensus has been achieved for hypoxic thresholds in tumors, but tumors with pO₂ values below 10 mmHg are usually considered hypoxic^[23]. Tumor hypoxia is the result of an imbalance between oxygen supply and consumption and can be caused by the following mechanisms^[23]: (1) the structurally and functionally abnormal tumor vasculature leads to a perfusion-limited delivery of oxygen^[24], thereby inducing “acute” hypoxia; (2) tumor proliferation increases the distance between tumor cells and blood vessels that provide nutrients and oxygen to tumor cells. Consequently, the distances to blood vessels can become larger than the diffusion distance of oxygen (> 70 µm), locally causing diffusion-limited hypoxia (referred to as “chronic” hypoxia); (3) tumor hypoxia is also associated with a systemic decrease in oxygen supply, *i.e.*, anemia, which can be caused by tumor-related factors as well as anticancer therapy.

To promote cell survival in hypoxic conditions hypoxia inducible factor-1 (HIF-1) is upregulated, which in turn activates a number of processes including growth factor signaling, angiogenesis, proliferation, glycolysis, tissue invasion, and finally metastasis^[25]. As a result, markers of the HIF signaling cascade such as HIF-1α, glucose transporter-1, and vascular endothelial growth factor (VEGF), have been investigated as surrogate markers for tumor hypoxia in lung cancer^[18,19,26,27]. Alternatively, immunohistochemical staining using injectable exogenous bioreductive markers like pimonidazole and 2-(2-nitro-1-[H]-imidazol-1-yl)-N-(2,2,3,3,3-pentafluoropropyl)-

acetamide (EF5) can be applied^[28]. However, immunohistochemistry requires tissue samples and represents an indirect measurement of tumor hypoxia. Alternatively, pO₂ levels in tumors can be directly assessed using Eppendorf polarographic electrodes. This an invasive technique that can be applied in tumors that are easily accessible^[29]. In lung cancer, this technique is not feasible^[17], as these tumors are usually deeply seated within in de body. Positron emission tomography (PET) may be useful, as PET enables direct assessment of tumor hypoxia in patients non-invasively^[30].

As the development of tumor hypoxia is associated with decreased perfusion, perfusion PET imaging may provide more insight into the relation between hypoxia and perfusion in malignant tumors. PET scans may not only reveal the prognostic significance of hypoxia and perfusion in lung cancer, but may also help to select patients for specific treatments including radiation therapy, hypoxia modifying therapies, and antiangiogenic drugs^[31,32]. This review provides an overview of the clinical applications of PET to measure hypoxia and perfusion in lung cancer.

PET PRINCIPLES

PET enables non-invasive 3D imaging of dynamic processes *in vivo*. To this end, molecules of interest are radiolabeled with positron emitting radionuclides. For PET imaging, commonly used radionuclides are oxygen-15 (¹⁵O), carbon-11 (¹¹C) and fluorine-18 (¹⁸F). These radionuclides are isotopes of elements that are often naturally present in organic molecules as well as in chemically produced molecules, *e.g.*, anticancer drugs. After replacing one of the molecules' atoms by its radioactive isotope, the molecular structure is unchanged, leaving chemical properties unaffected. After intravenous injection of a PET tracer, the radiolabeled molecules can be located within the body by detecting the emitted photons. Since only a small amount of radiotracer is required for PET imaging, it is assumed that the radiotracer does not affect the dynamic process under study.

PET is based on the detection of positron emission. During radioactive decay, the radionuclide, *e.g.*, ¹⁸F, emits a positron which, after traveling a short distance (few mm) in tissue, annihilates with a nearby electron to emit two 511 keV photons in opposite directions. These two “annihilation” photons are registered by the PET scanner using a coincidence detection circuitry, providing 3D information of the tracer distribution with high sensitivity and resolution. To achieve quantitative accuracy, imaging data needs to be corrected for attenuation: when emitted from tissues deeper in the body, photons are more likely to be absorbed than from superficial structures. As a result, 3D images would falsely show low tracer concentrations in deeper structures compared to superficial structures. In PET, the attenuation perceived by the annihilation photon pairs, traveling in opposite directions over a line through the body, is mathematically equivalent

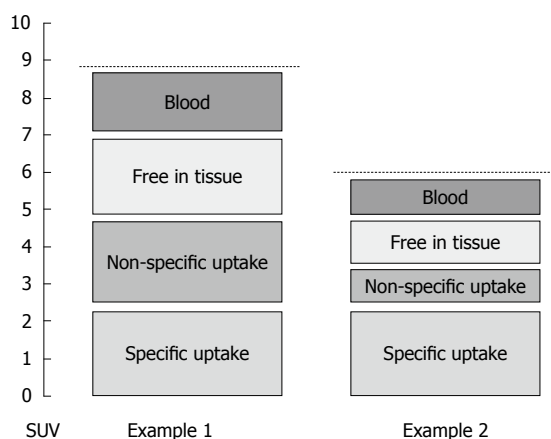

Figure 1 Graphical representation of the different components that determine the total positron emission tomography signal. Examples 1 and 2 can represent either different patients, different lesions in one patient or different scans of one patient, for example before and after therapy. In both examples the contributions of specific uptake (the uptake of interest) are equal, but the total signal is different due to differences in contribution of other (non-relevant) signals. Measured standardized uptake value (SUV) values are reflected by the dashed lines. As SUV does not only reflect the specific signal, its use should be validated before it is used in a clinical setting, *i.e.*, it is required to assess if contributions from non-specific signals affect SUV values in a non-predictable way. For the purpose of illustration, the Y-axis represents SUV values on an arbitrarily chosen scale.

to the attenuation perceived by one photon transmitted through the body over that same line. Therefore, accurate attenuation correction can be achieved using a transmission source, *e.g.*, computed tomography (CT). In addition, PET/CT systems can correct for false detections due to random coincidence detection or scattered annihilation photons. As a result, PET provides radioactivity measurements with high quantitative accuracy^[33].

Quantification of tracer uptake, however, remains challenging. First, the measured radioactivity concentration in tissue depends on the tracer concentration in blood over time, which, in turn, depends on the injected dose and distribution volume. The standardized uptake value (SUV) takes this variability into account, as the radioactivity concentration in tissue is normalized by the ratio of the injected dose to patient weight. Second, the PET signal does not necessarily reflect specific uptake, *e.g.*, trapping of the tracer by the process of interest. A tracer could also be free in tissue, trapped by a different process or reside in blood vessels within the region of interest, *e.g.*, tumor (Figure 1). Pharmacokinetic modeling can be applied to distinguish between the various kinetic processes and separates the total signal into these components^[34].

In addition to spatial information, temporal information of the tracers' distribution is used in pharmacokinetic modeling. To obtain information on the changes in tracer activity concentrations over time (time activity curves or TAC), sequential PET images are acquired over the same body area. In addition, accurate temporal data on tracer concentration in plasma is obtained from arterial blood sampling and dedicated lab analysis. Mathematical models ("compartment models") are then used

to extract measures of the relevant components of the tracers' kinetics, such as specific uptake or binding. As absolute quantification by kinetic modeling can be challenging and cumbersome in the clinic, alternatives have been introduced to measure tracer uptake. Before clinical implementation, these "simplified parameters" (such as SUV) should be validated and correlated with parameters from pharmacokinetic modeling.

To date, 2-deoxy-2-[¹⁸F]fluoro-D-glucose ([¹⁸F]FDG) is the most commonly used PET tracer. As [¹⁸F]FDG is a glucose analogue, it accumulates in malignant tumors with high glucose consumption. As a result, [¹⁸F]FDG PET is extensively used for diagnosis, staging and response monitoring of cancer. Currently, [¹⁸F]FDG PET is routinely performed for initial staging^[35] and pre-operative staging^[36,37] of patients with NSCLC. As tumor hypoxia is associated with increased glycolysis, it is conceivable that hypoxia is associated with increased [¹⁸F]FDG uptake. However, results on [¹⁸F]FDG to assess tumor hypoxia have been conflicting^[38], indicating that [¹⁸F]FDG is not specific enough to identify hypoxia. Therefore, other PET tracers have been developed to measure hypoxia and perfusion in tumors more specifically. In the following paragraphs, these PET tracers will be discussed.

TUMOR HYPOXIA IMAGING

Clinical relevance

Tumor hypoxia is associated with resistance to both radiation therapy^[21] and chemotherapy^[22]. Radiation therapy requires oxygen to induce DNA damage and hypoxic cancer cells are three times less sensitive to radiation therapy than normoxic cancer cells^[39,40]. In addition, the resistance to anticancer drugs is attributed to the lack of O₂ available for drug activation, the increased genetic instability, the antiproliferative effects of hypoxia, and the increased gene transcription induced by HIF-1^[41,42]. Currently, drugs that selectively target tumor hypoxia and its increased gene transcription are still under study and have entered the first clinical trials^[43-45]. Since tumor hypoxia may affect clinical outcome, hypoxia imaging may be useful to determine prognosis and tumor response in lung cancer patients. Furthermore, hypoxia assessment may help to optimize treatment strategies in individual patients.

In particular, the efficacy of radiation therapy may be increased by several interventions. First, the systemic oxygenation level can be increased by hyperbaric chamber treatment^[46], carbogen breathing^[47] and improved oxygen transport by hemoglobin. For the latter, blood transfusions and erythropoietin injections are available^[48]. Oxygen transport can be further improved by agents that improve perfusion and affect vascular permeability^[49]. Second, the apparent oxygenation level in tumors can be increased using radiosensitizers, which are usually based on a nitroimidazole-group and specifically target hypoxic tumor cells (pO₂ < 10 mmHg). Once incorporated in hypoxic tumor cells, radiosensitizers mimic oxygen, thereby

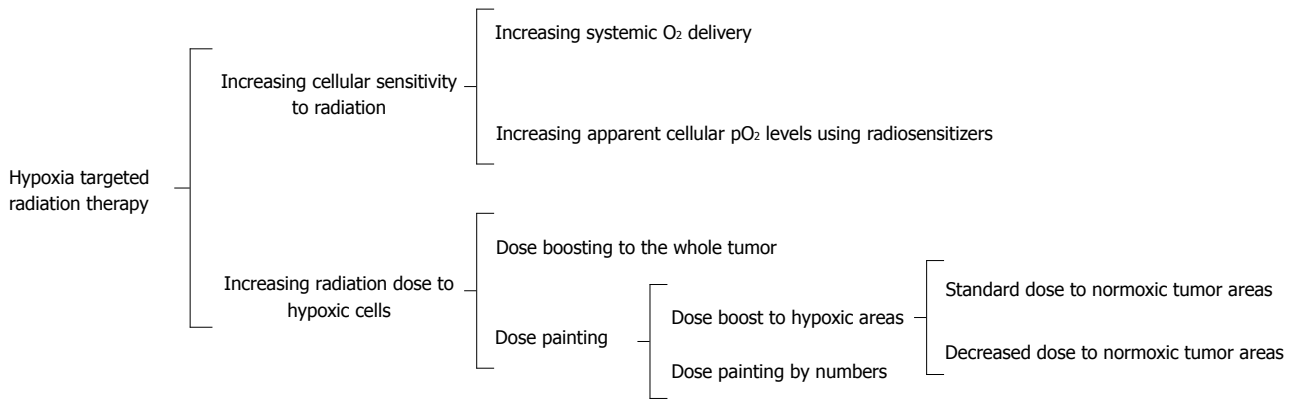

Figure 2 Radiation therapy treatment strategies for tumor hypoxia.

increasing the efficacy of radiation therapy^[50]. Third, the radiation therapy plan can be adjusted to increase the dose administered to hypoxic tumor tissue. This can be achieved by dose boosting to the whole tumor, dose painting, or dose painting by numbers^[51]. For dose boosting, an increased dose is administered to hypoxic areas, thereby increasing the radiation dose to normal tissue and, potentially, its associated side effects. For dose painting, the dose to a specific area (*e.g.*, hypoxic area) is increased, whereas the radiation to the remaining part of the tumor can be either maintained or decreased. In the latter case the total dose level can be maintained. Dose painting can be further refined when it is directly based on the voxel-by-voxel values of a PET image (referred to as “dose painting by numbers”). For successful implementation of the previous mentioned radiation therapy strategies, hypoxia imaging may help to identify hypoxic tumors, prevent unnecessary side effects in patients with normoxic tumors, and reveal heterogeneous distribution of hypoxia within tumors. Figure 2 summarizes the potential applications of hypoxia imaging for radiation therapy.

Characteristics of a hypoxia PET tracer

The ideal hypoxia tracer would freely and rapidly diffuse to tissue, including remote areas. For optimal contrast of the PET image, accumulation of the tracer should be high in hypoxic cells, whereas no binding should occur in normoxic cells. To achieve the best image quality, an optimal balance between tracer half-life, accumulation rates and clearance rates is required: the tracers’ half-life should be long enough to obtain a high signal-to-noise ratio whilst allowing the tracer enough time to diffuse and bind to hypoxic cells and clear from normoxic tissues and blood. Accumulation and clearance rates are influenced by the tracers’ octanol/water partition coefficient. More lipophilic compounds may more readily pass through the cell membrane. On the other hand, more hydrophilic compounds may more easily diffuse across tissues and show faster clearance from blood and normoxic tumors through the urinary pathway^[30,52]. Besides these hypoxia specific characteristics, the tracer should be metabolically

inert, since the formation of radiolabeled metabolites results in a decreased amount of the original tracer available for hypoxia specific uptake, poor image contrast and inaccurate tracer quantification.

For clinical implementation, hypoxia tracers require fast kinetics, allowing for rapid accumulation in hypoxic tissues, thereby limiting the time between tracer injection and imaging. In addition, simplified and reproducible methods (*e.g.*, SUV) are needed to quantify tracer uptake.

Hypoxia tracers for PET

Over the last decades, several PET tracers have been developed to measure tumor hypoxia. To identify all relevant hypoxia tracers in lung cancer, a literature search was conducted in PubMed to identify studies published before 1 January 2014. To this end, PET specific search terms (PET, positron emission tomography) were combined with hypoxia specific search terms (hypoxia, anoxia), and/or lung cancer specific search terms (lung cancer, lung neoplasms, non-small cell lung cancer, small cell lung cancer), and/or kinetic modeling specific search terms (kinetic modeling, modeling), and/or radiation therapy specific search terms (radiation therapy, radiation). For these search terms, the corresponding Mesh terms were included. Thereafter, the obtained English abstracts were evaluated for relevance. Based on the obtained publications, a specific search strategy was subsequently performed for each identified hypoxia PET tracer. Additional publications were identified by cross-referencing. Brain studies were excluded since the blood-brain barrier may affect tracer kinetics. Figure 3 and Table 1 give an overview of the identified hypoxia tracers that have been evaluated in oncology. The tracer names and abbreviations are displayed in Table 2. These hypoxia tracers can be subdivided in nitroimidazole-based and thiosemicarbazone-based tracers. In the following paragraphs, these tracers and their potential applications in lung cancer patients will be discussed.

Nitroimidazole-based tracers: Originally, nitroimidazoles have been developed as radiosensitizers. Already in 1984, Chapman^[53] have proposed nitroimidazoles for

Figure 3 Timeline for development and evaluation of hypoxia specific tracers that have been evaluated by preclinical or clinical positron emission tomography. Development and *in-vitro* analysis (blank), preclinical positron emission tomography (PET) evaluation (grey), and clinical PET evaluation (black). The number of published clinical studies in oncology is indicated (excluding brain studies). See Table 2 for full names.

hypoxia imaging. Upon entering the cell, nitroimidazole undergoes electron reduction, thereby becoming a radical. In normoxic cells, this reaction is reversed by O_2 . In hypoxic cells, the radical can react with an intracellular macromolecule instead and remains trapped. As the latter process occurs at $pO_2 < 10$ mmHg, an oxygenation level associated with increased radiation therapy resistance, nitroimidazoles are able to detect clinically relevant hypoxia^[54].

Among the developed hypoxia tracers for PET (see Figure 3), [^{18}F]FMISO has been investigated most extensively. Although [^{18}F]FMISO showed rapid metabolism in mice studies, it appeared to be a robust hypoxia tracer in humans, with parent fractions up to 96% at 90 min after injection^[55]. Since [^{18}F]FMISO is rather lipophilic with a partition coefficient ($\log P$) of 0.4, clearance from blood and normoxic tissues is slow. Therefore, the required time intervals between injection and imaging are long, at least 3 h^[56]. Efforts have been made to develop hypoxia tracers with more favorable characteristics. Being the most evaluated and validated hypoxia tracer to date, the performance of new hypoxia tracers is often compared with [^{18}F]FMISO (see Table 1). Among these tracers, [^{18}F]FAZA has been introduced in the clinic. [^{18}F]FAZA ($\log P = 0.04$) is more hydrophilic than [^{18}F]FMISO and shows faster clearance from blood and normoxic tis-

sues^[57]. This allows for a shorter time interval between injection and imaging^[58]. In addition, [^{18}F]FAZA has a high parent fraction during imaging, accounting for a parent fraction of 90% at 70 min after injection^[59]. Other more hydrophilic nitroimidazole tracers include [^{18}F]FETNIM and [^{18}F]HX4, which have a partition coefficient ($\log P$) of 0.17^[60] and -0.69^[61], respectively. An example of a more lipophilic tracer is [^{18}F]EF5, which is the ^{18}F -labelled version of exogenous hypoxia marker EF5, with a partition coefficient ($\log P$) of 0.6.

Thiosemicarbazone-based tracers: Thiosemicarbazone-based tracers represent another subgroup of hypoxia tracers for PET. Thiosemicarbazones possess a strong antitumor activity, particularly when coupled with a metal ion like copper (Cu)^[62]. [Cu]ATSM is a therapeutic agent which, by replacing the Cu atom with a suitable radioactive Cu isotope, can be used for hypoxia PET imaging^[63]. In nuclear medicine, Cu is of particular interest for its favorable radiochemical properties. First, Cu is relatively easy to incorporate in molecules and has multiple radioactive isotopes suitable for PET imaging. Second, with half lives ranging from 24 min to 13h for ^{60}Cu and ^{64}Cu , respectively, Cu has several potential applications. The short-lived radionuclides can be used for sequential measurements, whereas radionuclides with longer half lives do

[¹²⁴ I]IAZG	[¹²⁴ I]iodazomycin galactoside

not require a cyclotron on-site and are more suitable for the clinical setting. Remarkably, ⁶⁴Cu can also be applied as radiation therapy agent, since it also emits a β⁻ particle (40% yield)^[64,65]. In oncology, [Cu]ATSM has been evaluated both preclinically and clinically. This tracer shows favorable kinetics with rapid uptake in hypoxic tissue and fast clearance from normoxic tissues, enabling imaging within 30 min after injection^[66,67]. However, the exact uptake mechanism of [Cu]ATSM is still under debate^[63,68,69] and several preclinical studies have shown that [Cu]ATSM uptake depends on tumor type and other characteristics than hypoxia alone^[70-76].

Clinical evaluation of hypoxia PET tracers in lung cancer

Hypoxia PET imaging is in development and most clinical studies have been focused on notoriously hypoxic cancer types such as cervical cancer and head and neck cancer. Nevertheless, several clinical PET studies have evaluated hypoxia imaging in lung cancer (Table 3). In the following paragraphs, data acquisition, quantification and clinical observations of these hypoxia tracers will be discussed.

Data acquisition and analysis: Nitroimidazole based tracers require relatively long time intervals for accumulation in hypoxic cells and clearance from normoxic cells. In concordance, most studies used images > 2 h after injection for hypoxia assessment. The length of the time interval between injection and imaging may affect the tracers' distribution pattern in tumors. For example, it has been shown that the distribution of [¹⁸F]FMISO at 2 h is significantly different from the distribution at 4 h, whereas only the 4 h data are predictive of tumor recurrence^[77]. In contrast, the distribution of [¹⁸F]HX4 was similar at 2 h and 4 h^[78]. Compared to nitroimidazole based tracers, [Cu]ATSM shows fast kinetics and images were acquired after time intervals as short as 10 min after injection^[67,79-81].

Quantification of hypoxia: To identify hypoxia in tumor tissue, several simplified parameters have been used, including tumor-to-blood ratio, tumor-to-background ratio, tumor-to-muscle ratio, tumor-to-mediastinum ratio, and SUV. In addition, several studies have used dynamic PET scans to investigate the tracers' kinetics in more

detail, for example by using pharmacokinetic modeling for quantification^[59]. Furthermore, consecutive imaging using multiple tracers has been performed to facilitate the identification and quantification of hypoxia. For example, consecutive PET scans have been performed with hypoxia tracer [Cu]ATSM and perfusion tracer copper-pyruvaldehyde-bis(N4-methylthiosemicarbazone ([Cu]PTSM). Here, the ratio of [Cu]ATSM SUV to [Cu]PTSM SUV has been used as a measure of hypoxia^[81].

To date, it is not known which measure and threshold accurately reflects pO₂ levels in tumors. As repeated measurements with a polarographic electrode are not feasible in lung cancer, a more pragmatic approach is required. The clinical relevance of a threshold can be determined by clinical parameters like tumor response, progression-free survival and overall survival.

Determination of clinically relevant hypoxia: Among the clinical studies on hypoxia PET tracers in lung cancer, most studies have only evaluated tumor hypoxia prior to treatment. For [¹⁸F]FMISO, a pretreatment threshold of > 2 for tumor-to-mediastinum ratio was associated with poor outcome after radiation therapy. However, the shape of the time activity curve appeared to be a better predictor of response^[77]. In contrast to these results, other authors did not find a predictive value for [¹⁸F]FMISO after chemoradiation^[82,83]. In other patients treated with chemoradiation, a threshold of tumor-to-blood ratio > 1.9 for [¹⁸F]FETNIM^[84,85] and > 3.0 for [Cu]ATSM^[86] was associated with poor overall survival and tumor response, respectively. In addition, a number of studies have evaluated the changes in hypoxia tracer uptake during therapy. While hypoxic cells are considered to be more resistant to radiation therapy, most studies in lung cancer reported a decrease in hypoxia tracer uptake after radiation therapy^[58,82,87].

PET FOR TUMOR PERFUSION MEASUREMENTS

Tumor angiogenesis

Blood flow is not only required for the delivery of PET tracers and anticancer drugs to tumors, but also for the

transport of nutrients, *e.g.*, glucose, and oxygen. Under hypoxic conditions in tumors, the HIF protein is usually up-regulated. Activated HIF translocates to the nucleus of tumor cells and results in transcription of a large repertoire of genes including VEGF^[88,89]. VEGF is a potent protein and plays a key role in tumor angiogenesis, which is the formation of new blood vessels. This tumor angiogenesis is essential for tumor growth, metastatic spread and survival of tumor cells. As a result, VEGF signaling has become an important therapeutic target for the treatment of malignant tumors. To date, several antiangiogenic drugs have been developed including monoclonal antibodies that bind circulating VEGF (*e.g.*, bevacizumab^[90]) and tyrosine kinase inhibitors that target the intracellular domain of the VEGF receptors (*e.g.*, sunitinib and sorafenib^[91]). Among the currently available antiangiogenic drugs, bevacizumab has been registered for the treatment of patients with NSCLC. In combination with paclitaxel and carboplatin, bevacizumab has been approved for first-line treatment of non-squamous NSCLC^[15]. As tumor vascularization is an important factor in the biology of malignant tumors, and antiangiogenic strategies have been introduced for the treatment of lung cancer, imaging techniques are increasingly used for perfusion measurements in lung cancer.

Imaging of tumor perfusion

PET is a sensitive technique to quantify tumor perfusion^[92]. To this end, perfusion tracers like rubidium-82 (⁸²Rb^[93]), radioactive ammonia ([¹³N]NH₃^[94]), radioactive water ([¹⁵O]H₂O^[95-101]) can be administered. Other PET tracers such as [⁶⁸Ga]transferrin^[102] and [¹¹C]methylalbumin^[103] are available to assess vascular permeability. Currently, experience with perfusion PET tracers is rather limited in oncology, except for [¹⁵O]H₂O. In particular, previous PET studies have shown that quantification of tumor perfusion using [¹⁵O]H₂O is feasible in patients with lung cancer^[97,104,105].

[¹⁵O]H₂O PET

As [¹⁵O]H₂O is a freely diffusible tracer with near 100% extraction over a wide perfusion range (0-6 mL/min per mL), its kinetics directly reflect tumor perfusion. As a result, [¹⁵O]H₂O is an ideal tracer for quantitative perfusion imaging. The short half-life of ¹⁵O, which is 2.03 min, enables sequential PET scans using both [¹⁵O]H₂O and another tracer, *e.g.*, [¹⁸F]FDG^[97] or a hypoxia tracer^[106]. However, it requires the presence of a nearby cyclotron. Because [¹⁵O]H₂O is metabolically inert and is not retained in cells, quantification using SUV, which is a parameter for quantification of irreversible uptake, is not

possible. Instead, pharmacokinetic modeling, using short (< 10 min) dynamic PET scans, is required to quantify tumor perfusion.

Monitoring tumor perfusion during treatment

Currently, [^{15}O]H $_2\text{O}$ PET scans are increasingly used to assess response of the tumor vasculature to antiangiogenic therapy^[107-110]. As [^{15}O]H $_2\text{O}$ PET has shown high reproducibility in lung cancer^[105], it can be applied for response monitoring during treatment. de Langen *et al.*^[111] have investigated changes in tumor perfusion in 44 NSCLC patients who were treated with bevacizumab and erlotinib. Three weeks after the start of treatment, a mean decrease of 11% in tumor perfusion was measured using [^{15}O]H $_2\text{O}$ PET^[111]. A significant reduction in tumor perfusion was measured in patients with a partial response according to the response evaluation criteria in solid tumors (RECIST^[112]). More importantly, patients with > 20% reduction in tumor perfusion had an improved progression-free survival as compared to other patients (12.5 mo *vs* 2.9 mo). The latter findings indicate that [^{15}O]H $_2\text{O}$ PET may have predictive value in lung cancer patients who are treated with antiangiogenic drugs. For early prediction of tumor response, early perfusion measurements may be useful, as the effects of antiangiogenic can be very rapid^[113].

Tumor perfusion and drug delivery

As the short half-life of ^{15}O enables sequential PET scans using both [^{15}O]H $_2\text{O}$ and an additional tracer, [^{15}O]H $_2\text{O}$ PET is a useful tool to investigate drug delivery of radiolabeled anticancer agents by correlating uptake of radiolabeled drugs with [^{15}O]H $_2\text{O}$ perfusion data^[114,115]. Apparently, it has been shown that tumor perfusion is an important determinant of drug tumor exposure, as indicated by several PET studies on [^{18}F]5-fluorouracil(FU)^[116-118], [^{11}C]DACA^[119], and [^{11}C]docetaxel^[120,121]. Consequently, tumor perfusion may be predictive of tumor response to the above mentioned anticancer drugs. These findings advocate further studies investigating the predictive value of tumor perfusion for tumor response to chemotherapy. As tumor perfusion is the key factor for the uptake of several anticancer drugs in tumors^[122], antiangiogenic drugs may affect drug exposure in tumors. To investigate this concept, a PET study has been performed in NSCLC patients using both [^{15}O]H $_2\text{O}$ and the radiolabeled taxane [^{11}C]docetaxel^[113]. In that study, bevacizumab reduced both perfusion and net influx rate of [^{11}C]docetaxel within 5 h. These rapid effects persisted after 4 d and were not associated with significant changes in tumor heterogeneity. The mentioned studies indicate that [^{15}O]H $_2\text{O}$ PET may reveal the role of perfusion in drug delivery and antiangiogenic therapy in malignant tumors^[123].

IMAGING HYPOXIA AND PERFUSION

It is conceivable that the development of tumor hypoxia is associated with a decrease in tumor perfusion. This may complicate PET imaging, as tracer delivery will be

reduced in these areas. Although the uptake of the ideal hypoxia tracer is not directly related to perfusion, lack of perfusion will limit tracer delivery.

Diffusion-limited hypoxia is present in tumor cells located away from capillaries, *i.e.*, further than the diffusion distance of oxygen. As perfusion is relatively low in these areas, tracer delivery may be limited and this may, in turn, affect uptake of hypoxia tracers. In addition, low perfused areas can become necrotic. The PET signal will be decreased in areas containing necrosis even though these areas may also contain highly hypoxic cells. In Figure 4, these hypothetical considerations are summarized. The figure also illustrates the limitations of using a predefined threshold to delineate hypoxic areas on a PET image, as areas likely to contain the most severely hypoxic cells will be missed. The mentioned considerations may explain the conflicting results between the uptake of hypoxia tracers and the direct assessment of tissue oxygenation using polarographic electrodes^[124-127]. [^{15}O]H $_2\text{O}$ PET may help to understand these conflicting results and may identify the remote, low perfused areas. An example of images obtained from consecutive perfusion and hypoxia PET imaging is displayed in Figure 5.

Acute hypoxia is directly caused by a (temporary) lack of tumor perfusion. Since acute hypoxia is presumed to be transient or even cycling^[128], hypoxia tracer uptake may not accurately reflect this type of hypoxia. [^{15}O]H $_2\text{O}$ PET may help to study the effect of acute hypoxia and its relation with hypoxia tracer uptake.

Besides the previous considerations for combining [^{15}O]H $_2\text{O}$ perfusion PET imaging with hypoxia tracer PET imaging, the combination may provide further insight into the effects of treatment. Jain has previously proposed that antiangiogenic therapy may normalize the abnormal tumor vasculature, thereby decreasing tumor hypoxia and improving drug delivery of cytotoxic agents^[129,130]. This is underscored by the fact that a decrease in [^{18}F]FMISO uptake has been measured in renal cell cancer after treatment with sunitinib^[131]. On the other hand, an increase in [^{18}F]FMISO uptake after sorafenib^[132] and a rapid decrease in tumor perfusion after bevacizumab have been reported as well^[113]. The latter findings suggest that antiangiogenic therapy may decrease tumor perfusion and subsequently the delivery of hypoxia tracers to tumors. To further clarify these findings, future PET studies need to combine hypoxia tracers with [^{15}O]H $_2\text{O}$ at different time points after drug administration.

FUTURE PERSPECTIVES

In the present review, the currently available tracers for PET imaging of hypoxia and perfusion in lung cancer patients were discussed. Considering the currently available studies, PET seems feasible to assess hypoxia and perfusion in lung cancer. In contrast to traditional probe measurements, PET hypoxia imaging is non-invasive and provides information on the heterogeneous distribution

Figure 4 Representation of hypothetical considerations on the link between perfusion and the hypoxia signal as measured by imaging positron emission tomography. The continuous curve represents hypothetical level of hypoxia in tissue for increasing levels of perfusion (i.e., closer to the capillaries). The dotted line represents the positron emission tomography signal obtained from hypoxia imaging using an optimal imaging protocol. The horizontal line represents a threshold used for delineation of hypoxic areas.

Figure 5 Example of consecutive perfusion and hypoxia positron emission tomography in a patient with non-small cell lung cancer. A: Low dose computed tomography; B: Perfusion image (averaged image acquired over time interval 30-120 s after injection of 370 MBq [^{15}O]H $_2$ O); C: Hypoxia image (averaged image over time interval 40-70 min after injection of 185 MBq [^{18}F]FAZA).

of hypoxia in tumors. In addition, whole body PET scans using a hypoxia tracer can reveal hypoxic areas not only in primary tumors, but in metastases as well. To date, several tracers have been developed to measure tumor hypoxia, whereas tumor perfusion has been mostly quantified using [^{15}O]H $_2$ O. While acquisition and quantification of [^{15}O]H $_2$ O data is rather straightforward, several challenges remain for PET hypoxia tracers.

Although several hypoxia tracers have been developed and evaluated in the clinical setting, no consensus has yet been reached on the most feasible tracer, the optimal timing of acquisition, and the most accurate quantification method. In lung cancer, the studies on hypoxia PET tracers are preliminary and include a limited number of patients. Ideally, the clinical impact of hypoxia imaging would be evaluated in large clinical trials validating hypoxia tracers for prediction of tumor response and survival. In addition, clinical trials are needed to reveal the clinical value of hypoxia tracers for advanced radiation therapy strategies such as dose painting. In NSCLC, several trials are currently recruiting patients for [^{18}F]FMISO based (NCT01576796) and [^{18}F]FDG based (NCT01024829) dose boosting.

In patients with lung cancer, quantification of tracer uptake can be challenging due to tumor movement during respiration. As PET acquisition usually takes 10min

to 1 h, patient motion during PET imaging is unavoidable and the acquired image of the lung tumor will be blurred, which complicates accurate delineation of hypoxic areas. As a result, these images are less suitable for dose painting techniques, especially for dose painting by numbers. For PET imaging, respiratory gated imaging (4D imaging) is currently under study. In respiratory gated imaging, patient motion is continuously monitored during acquisition. As a result, PET data can either be corrected for the registered motion or PET data from a specific interval of the respiratory cycle can be used for reconstruction. As similar techniques are also under study for radiation therapy, dose painting strategies may be further improved by combining 4D PET hypoxia imaging with 4D radiation therapy.

Since the introduction of antiangiogenic drugs, perfusion measurements have been increasingly applied in the clinic. [^{15}O]H $_2$ O PET provides quantification of tumor perfusion and may be useful for response monitoring during antiangiogenic therapy. Further studies are needed to evaluate the predictive value of tumor perfusion for tumor response to anti-cancer drugs. In addition, tumor perfusion may not only affect the delivery of drugs to tumors, but also the delivery of PET tracers such as hypoxia tracers.

In conclusion, PET using both [^{15}O]H $_2$ O and a hy-

poxia tracer is a promising method to further understand the development of hypoxia in lung cancer. As previously mentioned, these PET scans are promising for response monitoring of radiation therapy and antiangiogenic drugs. In addition, hypoxia tracers may be useful to select patients for treatment with radiosensitizers (*e.g.*, nimorazole, NCT01733823) and realize a more precise radiation plan including dose boosting and dose painting. As the available PET studies on hypoxia and perfusion are rather preliminary in patients with lung cancer, further studies are needed for validation and clinical implementation in this patient population.

Abstract

To review current recommendations for palliative radiotherapy for bone metastases secondary to lung cancer, and to analyze surveys to examine whether global practice is evidence-based, English language publications related to best practice palliative external beam radiotherapy (EBRT) for bone metastases (BM) from lung cancer were sought *via* literature search (2003-2013). Additional clinical practice guidelines and consensus documents were obtained from the online Standards and Guidelines Evidence Directory. Eligible survey studies contained hypothetical case scenarios which required participants to declare whether or not they would administer palliative EBRT and if so, to specify what dose fractionation schedule they would use. There is no convincing evidence of differential outcomes based on histology or for spine *vs* non-spine uncomplicated BM. For uncomplicated BM, 8Gy/1 is widely recommended as current best practice; this schedule would be used by up to 39.6% of respondents to treat a painful spinal lesion. Either 8Gy/1 or 20Gy/5 could be considered standard palliative RT for BM-related neuropathic pain; 0%-13.2% would use the former and 5.8%-52.8% of respondents the latter (range 3Gy/1-45Gy/18). A multifraction schedule is the approach of choice for irradiation of impending

pathologic fracture or spinal cord compression and 54% would use either 20Gy/5 or 30Gy/10. Survey results regarding management of complicated and uncomplicated BM secondary to lung cancer continue to show a large discrepancy between published literature and patterns of practice.

Key words: Bone metastases; Lung cancer; Survey; Evidence-based practice; Radiotherapy

Core tip: Palliative radiotherapy (PRT) remains the gold standard for treatment of painful bone metastases from lung cancer. While PRT should be appropriately customized to patients, prescription should also be based on robust evidence. Depending on the clinical scenario, between 4%-66% of survey respondents would use dose-fractionation schedules considered congruent with best available current evidence. These results show a large discrepancy between treatment guidelines and international patterns of practice. It is not completely clear why level 1 data supporting specific dose schedules continues to be overlooked, although reasons for reticence in following these recommendations are reviewed.

Fairchild A. Palliative radiotherapy for bone metastases from lung cancer: Evidence-based medicine? *World J Clin Oncol* 2014; 5(5): 845-857 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/845.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.845>

INTRODUCTION

Lung cancer causes bone metastases (BM) in a large proportion of patients, up to 40%-80%^[1]. With improvements

in systemic therapy, median survival of patients with advanced lung cancer is now approximately 12 mo; as such, the prevalence of BM has significantly increased. BM can be described as complicated or uncomplicated, where uncomplicated generally refers to the absence of: impending or established pathological fracture (PF), surgical fixation, impending or established spinal cord compression (SCC), impending or established cauda equina or nerve root compression, neuropathic pain, previous RT, or associated soft tissue mass.

By definition, all patients with lung cancer and BM have stage IV disease and treatment is palliative. Goals for the treatment of BM are pain relief, preservation of mobility and function, prevention of future complications, optimized quality of life (QoL), maintenance of skeletal integrity, and minimization of hospitalization. About half of all patients with stage IV non-small cell lung cancer (NSCLC) receive at least one course of palliative external beam radiotherapy (EBRT) within 15 mo of diagnosis^[2].

A prospective observational multicenter study recently documented treatment costs of BM in patients with pathologically-proven lung cancer during the first year after BM diagnosis^[3]. Five hundred and fifty-four patients with radiologically-proven BM were enrolled. A mean monthly cost was calculated using a Markov approach, taking into account direct costs only (hospitalization, drug purchases, medical and transport costs). Indirect costs such as lost income and intangible costs such as pain and suffering were not assessed. 76.5% were male, with a mean age of 62 years, 9% with small cell lung cancer, 69.3% with PS 0-1, and 64.6% had metastases other than to bone. At some point during follow-up, 89.9% had analgesic treatment (77.7% with opioids) and 42.1% had RT. Median survival was 5.8 mo and 1 year OS was 22%. Factors predictive of better OS were adenocarcinoma, performance status (PS) 0-1, and female. Monthly costs for asymptomatic and symptomatic BM were €190 and €374 respectively. Mean disease management costs during the first year after BM diagnosis were €3999 +/- €4135 (95% confidence interval €374-15886)^[3].

EBRT remains the gold standard for treatment of BM^[4], and comprises the largest single component of palliative RT practice^[5], approximately 40%^[6]. The number of lung cancer patients requiring palliative EBRT for BM is continuing to grow, increasing pressure on clinicians, simulators, and treatment units, in addition to health care costs.

Both the limited survival of most patients with advanced lung cancer and a requirement for the judicious use of resources argue for use of the shortest dose fractionation schedule which is effective^[7]. Single fraction (SF) EBRT for palliation of painful BM has many advantages: the risk of acute side effects is minimized which increases patient QoL and acceptance of treatment; RT can be delivered over as little as one day, which decreases transportation and hospital admission requirements; it is more convenient; decreased discomfort with positioning

and travel increases tolerance for those with poor PS; and it frees resources for others. SFRT is cost-effective, and is easier to schedule amongst systemic therapy and other appointments, resulting in increased accessibility and decreased waiting times^[7-17].

Previous patterns of practice surveys focusing on EBRT for BM, including a large international study from 2009, have suggested that considerable controversy over the optimal treatment schedule still exists^[9]. The objectives of this review were to (1) examine the literature supporting current treatment recommendations for BM secondary to lung cancer, to determine for which clinical scenarios SFRT is appropriate; and (2) analyze published surveys to examine evolution in practice and degree to which it can be considered evidence-based.

LITERATURE SEARCH

Publications related to best practice palliative EBRT for complicated and uncomplicated BM from lung cancer were sought *via* literature search (Table 1). Medline and Embase were searched for English language articles published in full between 2003 and 2013. Eligible studies were also identified from reference lists of retrieved papers and review articles. Additional clinical practice guidelines and consensus documents were obtained from searching the online SAGE (Standards and Guidelines Evidence) Directory compiled by the Canadian Partnership Against Cancer (www.cancerview.ca). Eligible survey studies contained hypothetical case scenarios which required participants to declare whether or not they would administer palliative EBRT and if so, to specify what dose fractionation schedule they would use. Retrospective reviews and practice audits which did not include hypothetical patient cases^[18-25] as well as surveys which did not include lung cancer cases^[26-31] were excluded.

RESEARCH

Evidence summary-uncomplicated bone metastases

Four meta-analyses of more than 20 randomized controlled trials [level I evidence, according to the Oxford Centre for Evidence-Based Medicine (www.cebm.net)] have shown that for uncomplicated bone lesions, there is no advantage in degree of pain relief, analgesic use, time to first improvement in pain, time to complete pain relief, time to pain progression, duration of response, rates of PF or SCC, acute toxicity, QoL, or overall survival from protracted fractionation *vs* SFRT above 4Gy^[8,12,13,15]. The randomized trials accrued patients with various histologies; selected studies published since 2000 included up to 26% of patients with lung cancer. The most recent meta-analysis evaluated 25 studies comprising 2818 randomizations to SF and 2799 to MF arms, respectively^[8]. On an intent-to-treat basis, the overall response rate to SF RT was 60%, and complete response (CR) rate was 23%, which was not significantly different from the 61% and 24% rates of patients randomized to MF RT. The overall

pain response proportion increases by about 10% if per-protocol patients only are analyzed^[15]. Median time to onset of pain relief is 1-4 wk and median duration of response is 12-24 wk. After SF, 3.3% of patients fractured *vs* 3.0% after MF ($P = 0.72$). Two point eight percent of patients receiving SF and 1.9% of patients receiving MF experienced SCC ($n = 6$ trials; $P = 0.13$). There were significantly more retreatment episodes in the SF arms (20%) *vs* MF arms (8%) ($P < 0.00001$). Re-analysis of assessable patients did not alter conclusions. There is a trend for greater acute toxicity after MF which is not statistically significant, and which was not a primary endpoint for any of the source trials^[8].

In view of mounting evidence, 8Gy/1 has been repeatedly recommended as standard of care for uncomplicated BM in the practice guidelines of many international bodies, including specifically for lung cancer (see Table 2 for references; level 5 evidence). A secondary analysis of the Dutch trial reported that in patients with spine BM, SF and MF EBRT result in equivalent pain relief (level 1 evidence)^[32]. In general, neither anatomic location treated nor RT dose is predictive of degree of functional improvement after RT (level 4 evidence)^[33,34]. No subgroups of patients with uncomplicated painful BM have been identified that clearly benefit from a higher total dose (level 5 evidence)^[11]. Additionally, it is not standard practice to prophylactically irradiate an asymptomatic uncomplicated BM (to avoid toxicity).

Evidence summary - does histology influence outcome?

The most detailed data on outcomes in relation to histology were reported in a secondary analysis of the Dutch Bone Metastases trial related to reirradiation (level 1 evidence)^[35]. In the original trial, between 03/1996 and 09/1998, 1157 Dutch patients with painful BM were randomized between 8Gy/1 ($n = 579$) and 24Gy/6 ($n = 578$); 287 lung patients were accrued^[16]. Patients had a minimum pain score of 2/10. Eligibility criteria included BM treatable in one RT target volume, no previous RT, no fracture or impending PF needing surgery, no SCC, and no BM within the cervical spine. Participants completed weekly questionnaires \times 13 wk, then monthly to

a maximum of 2 years, reporting maximum pain at the treated site, analgesic use and acute side effects. No major differences were reported between SF and MF in overall response rates, duration of response or progression rates^[16].

267/287 lung patients were assessable for response to initial EBRT: 107 (39.8%) were non-responders and 162 (60.2%) were responders^[35]. Fifty-eight percent responded after initial SF and 62% after initial MF. Mean time to initial response was 3 wk and mean duration of remission was 11 wk. Overall there was no correlation between histology and initial response ($P = 0.69$). Of the 267, 78 experienced pain progression (29.2%).

Within the first year after randomization, 49 patients with lung cancer were retreated. Of initial nonresponders, 22% were retreated at a mean time of 10 wk and mean pain score of 7.7/10. Of initial responders, 7% were retreated at a mean time of 11 wk and mean pain score of 3.8/10. Of those who had progressed, 19% were retreated at a mean time of 5 wk and mean pain score of 7.2/10. Progressive patients with lung cancer were retreated most often and earliest after randomization of any histology^[35].

Response to retreatment could be ascertained for 40/49^[35]. Of those who did not respond to initial RT, 50% (8/16) responded to repeat treatment at a mean time to response of 7 wk. Of those responding to initial treatment, 67% (16/24) also responded to repeat treatment at a mean time of 5 wk. After progression, 12/14 (86%) responded to a second course of RT at a mean time of 4 wk. The mean duration of response in initial non-responders, responders and those with progressive pain was 8 wk, 12 wk and 6 wk, respectively. Including the effects of retreatment, overall response rates in lung cancer patients receiving SF increased from 58% to 62%, but did not change post-MF. This is likely because SF patients were retreated earlier than were MF patients. Almost three times more lung patients were retreated than breast patients (HR = 2.6; 95%CI: 1.7-3.8; $P < 0.001$), probably because they were less likely to both respond to initial RT and to receive systemic therapy. In multivariate analysis corrected for early death, primary tumour, PS and randomization arm remained predictive for retreat-

Table 2 Evidence supporting recommended dose-fractionation schedules

RT: Radiotherapy; SCC: Spinal cord compression.

ment ($P = 0.01$, $P = 0.001$ and $P < 0.001$ respectively)^[35].

Results of other studies are contradictory: in one, lung cancer patients were less likely to experience an early pain response to EBRT [only 27% had responded by month two, *vs* 70% of breast and prostate cancer patients (level 4 evidence)^[34]], and in another, lung cancer patients had the highest response rate (level 4 evidence)^[36] (see below). Overall there is no convincing evidence that outcomes differ based on primary site as reported in the dose-finding randomized trials [reviewed by reference 6 (level 4 evidence)]. Similarly, none of the meta-analyses separated out treatment effects by histology (level 1 evidence)^[8,12,13,15].

Evidence summary - complicated bone metastases

Although neuropathic pain secondary to BM is not as predictively responsive to standard analgesics^[37], it does respond to RT^[38]. Roos *et al*^[38] compared a single 8 Gy *vs* 20 Gy/5 for 245 per-protocol patients with any primary site with BM causing neuropathic pain; 31% had lung cancer (level 1 evidence). Eligible patients had no other metastases along the distribution of the neuropathic pain, no cauda equina or SCC. Pain relief was seen in 53% of SF and 61% of MF patients (intent-to-treat) with 26%-27% experiencing CR at two months. Median time to treatment failure was longer in the fractionated arm (3.7 mo *vs* 2.4 mo), but, like the response rates, the difference did not reach statistical significance within the confidence limits set by this non-inferiority trial. Rates of SCC, PF and reirradiation were not significantly different. Therefore, for BM causing neuropathic pain, either 8Gy/1 or 20Gy/5 may be considered standard. The authors recommended the latter; however, patients with decreased PS, shorter expected survival or comorbidities, who would not be amenable to multiple hospital visits should receive SF^[38] (Table 2).

The treatment of an asymptomatic BM may be deferred unless the patient has a serious impending condition such as SCC or PF. Diagnosis of impending SCC requires radiologic evidence of indentation of the thecal sac at the level of local or radicular pain, without associated neurologic signs or symptoms^[39]. RT may prevent neurologic dysfunction in impending SCC^[40] although these patients were excluded from the vast majority of the clinical trials investigating RT doses for uncomplicated BM. There is insufficient evidence at present to

guide practice on the optimal dose schedule, although definitive EBRT for epidural tumour without neurological impairment, mechanical pain, or spinal instability should be fractionated (level 5 evidence)^[41]. Based on data from established SCC, MFRT may have advantages in terms of local control and/or in-field recurrence (level 1 evidence)^[8,42,43], and there is likely no advantage in offering more than 30Gy/10 (level 1 evidence)^[42] (Table 2).

An impending PF is defined as a BM that has a significant likelihood of fracture under normal physiological loads. In patients with lung cancer who have a painful BM affecting a weight-bearing bone, especially a solitary lytic lesion involving > 50% of the cortex circumferentially, an expected survival > 4 wk, and satisfactory health otherwise, surgical fixation is recommended (level 5 evidence)^[39]. Although at least one group has reported a marked increase in surgical involvement for metastatic bone lesions in recent years (level 4 evidence)^[44], a proportion of patients will not be candidates for operative intervention, or will decline. In that circumstance, multifraction RT should be delivered (level 1 evidence)^[45] (Table 2).

Harada *et al*^[36] reviewed results from a single institution to clarify the outcomes of RT for femoral BM (level 4 evidence). 72 consecutive patients (20.8% with a lung primary) with 84 femoral lesions (77/84 symptomatic) were treated (2002-2005). 39/84 lesions were lytic and 43/84 were considered impending PF. Median RT dose was 30Gy/10 (range 20-40Gy/5-20) and peri-RT systemic therapy was allowed. No reirradiation was performed. Median follow-up was five months (range 1-28 mo). Overall post-RT, 8 lesions achieved a radiological CR and 27 a radiological partial response (PR) on plain X-ray assessed independently by a radiologist and orthopedic oncologist. The best overall response rate (CR + PR) was 42% (35/84), with 30 lesions considered stable and 19 showing progressive disease. Of impending PF lesions, 15/43 showed a radiological response. Median interval from the start of RT to radiologic CR/PR was 3 mo and median duration was 10 mo. Administration of chemotherapy, hormone therapy or bisphosphonates significantly correlated with a favourable radiological response; RT dose and impending PF status did not. Response rates differed significantly based on primary site: lung cancer had the highest (65%) in comparison to breast (47%), prostate (42%) and other (28%) ($P =$

0.03). Eleven lesions eventually required surgery at a median of 3 mo of which 8 had actually fractured; seven of these had been classified initially as impending PF. Eventual fracture rate in the impending PF group (7/43; 16%) was significantly higher than in the no impending PF group (1/41; 2%) ($P = 0.03$). In the 77 symptomatic lesions at baseline, pain was classified as improved in 36, stable in 36 and as progressive in 5. There was no correlation between radiological response and pain relief ($P = 0.17$). Overall median survival was 7 mo (95%CI: 4-9 mo)^[36].

Results of survey studies

Since 1998, 12 hypothetical cases involving patients with lung cancer and BM have been reported in one abstract and five full publications^[6,9,46-49] (Table 3). Case histories included patients of both genders, ranging in age from 45-78 years, PS 1-2, previously treated with radical surgery +/- adjuvant chemotherapy or curative chemoRT, or metastatic at diagnosis. Histologic subtype of lung cancer was usually unspecified. Investigations diagnosing BM varied as did extent of non-osseous metastases. One publication described current pain score and response to analgesics^[47]. Overall, eight cases were of uncomplicated BM (one non-spine, seven spine), and four were complicated (three neuropathic pain, one impending SCC and impending PF). Fairchild Case 3 and Chow Case 2 were identical except for the patient's age, while Chow Case 2 and Hartsell Case 2 are presumed identical given that the Chow survey was designed based on Hartsell's questionnaire. Overall response rates ranged from 15.7% to 63.3% ($n = 5$ studies); response rate of the Nakamura survey was provided as a proportion of institutions rather than practitioners (Table 3).

Radiation Oncologists living in Japan, Italy, the United States, Canada, Australia, and New Zealand along with members of the American, Canadian, Australian and New Zealand Radiation Oncology professional groups were surveyed by mail^[48,49], internet^[9,46] or during attendance at national meetings^[6,47]. Responses to three surveys were anonymous^[6,9,47]. Trainees were included in the sampling frame^[6,47], excluded^[9], or not specified but likely excluded^[46,48,49]. A prespecified list of dose fractionation schedules was provided only by De Bari. Factors influencing dose prescribed were sought on the basis of case^[6,46,47], overall^[9], or not explored^[48,49].

Table 4 indicates the proportion of respondents who would deliver EBRT in each case and the specified dose fractionations, with shading indicating practice that would currently be considered evidence-based. For uncomplicated bone BM, 8Gy/1 would be used by 13.7% of Japanese respondents to treat a right shoulder, and between 5.9% and 39.6% of respondents internationally to treat a painful spinal lesion. Range of doses suggested for an uncomplicated spine metastasis was 3Gy/1 to 55Gy/22 with up to 78.4% using 30Gy/10; this was also the most common dose suggested by respondents in Hartsell and in the Nakamura survey. For a BM associated with neu-

ropathic pain, 0%-13.2% would use 8Gy/1 and 5.8% to 52.8% would use 20Gy/5 (range 3Gy/1-45Gy/18). Finally, for the patient with impending SCC and PF, 54% would use a multifraction schedule of either 20Gy/5 or 30Gy/10; the respondents using a dose in the 'other' category could also be considered to have evidence-based practice although the specific additional proportion cannot be differentiated from missing values.

In the four publications which explored factors influencing choice of dose fractionation based on direct questioning of respondents, the most commonly cited factors impacting treatment decisions were wish to minimize risk of neurologic progression/SCC, prognosis, literature results and wish to minimize the chance of recurrent pain. Among those factors impacting treatment decisions the least were waiting list, personal habits and financial aspects (Table 5). In the only study to explore it, 36.4% (uncomplicated BM) and 30.6% (complicated BM) of respondents were influenced in their decision to deliver RT by analgesic response^[47].

Statistical predictors of characteristics of respondents likely to use SF schedules were reported by Fairchild, Chow, and Roos; Hartsell reported predictors of use of <30 Gy (Table 6). For use of SF in uncomplicated spinal BM, time in practice was associated with use of < 30 Gy by Hartsell but not associated in the Chow or Roos publications. University/academic practice was associated with use of SF^[9,49], and private practice with less use of SF^[9], while no differences were found by Roos. Fairchild *et al*^[9] found that those trained in the United States tended to use SF less often while Chow found no correlation. Radiation Oncologists practicing in the Southwest United States, New Zealand and Australia tended to use lower doses more often^[49], with no differences between Australia and New Zealand or between Australian states^[6]. No trends were observed for treatment of neuropathic pain in the two surveys reporting statistical predictors (Table 6).

DISCUSSION

Treatment decisions regarding palliative EBRT for BM should be based on individualized considerations of symptom burden, extent of disease, life expectancy, PS, comorbidities, toxicity, prior treatment and patient wishes. A retrospective study of 33 patients dying within 30 d of hospital admission, 39.4% of whom had lung cancer and 94% with metastatic disease, reported planned *vs* actual EBRT treatment; sites were not specified^[50]. 90% were planned for ≥ 30 Gy but only 58.1% completed it; almost 25% died during treatment. Half of patients spent > 60% of their remaining life on therapy with the median treatment time equivalent to the cohort's median survival (15 d)^[50]. However, while palliative EBRT should be appropriately customized to patients, the choice of dose schedule should have a robust evidence base.

Despite multiple randomized trials and four meta-analyses showing efficacy of SF irradiation for uncom-

Table 3 Hypothetical cases utilized by previous surveys

Ref.	Case history	Methodology	Response rate
Nakamura <i>et al</i> ^[46] Case 1 (Japan, 2012)	A 65 yr old man was diagnosed with squamous cell lung cancer one year earlier and was treated by radical surgery. He now has pain in his right shoulder. Radiologic examinations detected osteolytic bone metastasis at the right scapula and multiple lung metastases. ECOG 1	Radiation Oncologist members of JROSG completed an internet-based survey Presumed trainees were excluded Not anonymous	NR
Nakamura <i>et al</i> ^[46] Case 2 (Japan, 2012)	A 65 yr old man was diagnosed with squamous cell lung cancer one year earlier and was treated by radical surgery. He now has back pain. Radiologic examinations detected osteolytic bone metastasis at L1 and multiple lung metastases. There is no evidence of vertebral collapse or spinal or thecal sac compression. ECOG 1		
Nakamura <i>et al</i> ^[46] Case 3 (Japan, 2012)	Same setting as in case 2 with the addition of paresthesias in a distribution consistent with the L1 dermatome, compatible with neuropathic pain		
De Bari <i>et al</i> ^[47] Case 2 ¹ (Italy, 2011)	68yo woman ECOG 1, right lung cancer in 2005, pT2N1M0 underwent lobectomy -> adjuvant chemotherapy. No previous RT. Negative F/U to today. Lumbar pain (L2-L3) underwent bone scan and spinal MRI, total body CT and CT brain. 3 new liver lesions. Bone scan: multiple sites of pathological uptake. MRI: multiple osteolytic spinal metastases including at symptomatic sites. No clinical or radiologic evidence of SCC and no risk of immediate fracture. VAS: 8 without analgesics, 3 after regular weak opioids	Questionnaires given to ROs attending the national congress at the time of registration and collected at the end of the congress Trainees included Anonymous Prespecified list of dose fractionation schedules provided as answer choices, or 'other'	122/300 (40.6%) ³
De Bari <i>et al</i> ^[47] Case 4 ¹ (Italy, 2011)	78yo man ECOG 2, left lung cancer in 2007, pT3NOM0 post left pneumonectomy -> adjuvant chemo x6. Negative f/u until today. Sudden thoracic (D5/D6, D10) and lumbar (L4) pain. No clinical signs of cord compression. No other symptomatic sites. MRI spine: multiple spinal secondary lytic lesions. Radiological signs of D10 spinal cord compression. Risk of pathologic fracture at C3. CT body: multiple liver and lung metastases. VAS: 9 without analgesics, 3 after regular opioids analgesics (transdermal fentanyl 50 ug) and prn NSAIDs	Factors influencing dose were sought for each case	
Fairchild <i>et al</i> ^[9] Case 3 (Intl, 2009)	A 55-year-old male was diagnosed with stage IIIA (T3N2) non-small cell lung cancer one year ago, and was treated radically with chemotherapy and thoracic radiotherapy. He now has pain in the lower back, and a bone scan shows a lesion at L3. His pain localizes to an area consistent with L3, and motor and sensory exams are unremarkable. There is a lytic lesion present and evidence of mild vertebral collapse, but no cauda equina or thecal sac compression on MRI scan	Web-based survey distributed to Radiation Oncologist members of ASTRO, CARO and RANZCR Anonymous Trainees, retirees excluded No prespecified list of dose fractionation schedules provided	962/6110 (15.7%)
Fairchild <i>et al</i> ^[9] Case 4 (Intl, 2009)	Same setting as in case above, with the addition of paresthesias in a distribution consistent with the L3 dermatome, compatible with neuropathic pain	General factors influencing dose were sought (not case-by-case) Bonferroni used	
Chow <i>et al</i> ^[48] Case 2 (Canada, 2000)	A 45 yr old male was diagnosed with stage IIIA (T3N2) large cell carcinoma of the lung one year ago, and was treated with chemotherapy and thoracic irradiation. He now has pain in his lower back, and a bone scan shows a lesion in the third lumbar vertebra. His pain localizes to an area consistent with L3, and does not radiate. Motor and sensory examinations are unremarkable. A CT scan of this area shows a lytic lesion, but no evidence of compression of the cauda equina or thecal sac	Survey mailed to all ROs in active practice in Canada Excluded retirees or those practicing outside of Canada No mention of including trainees Did not specify whether anonymous No prespecified list of dose fractionation schedules provided	172/300 (57.3%)
Chow <i>et al</i> ^[48] Case 3 (Canada, 2000)	Same setting as above, but instead of L3, the lesion is at L1 with no evidence of cord compression. Assume the external beam irradiation to the painful site in L1 would not overlap the previous radiation field	Factors influencing dose not explored	
Roos <i>et al</i> ^[6] Case 3 (Aust/NZ, 2000)	Male, age 63 with disseminated large cell lung cancer and bone scan positive L1-L3, several ribs and skull. There is pain in the upper lumbar spine only and no neurologic dysfunction	Survey distributed to delegates at 1998 Royal ANZ College of Radiologists Annual Scientific Meeting and returned before a presentation on bone pain Anonymous Trainees included Presumed no prespecified list of dose fractionation schedules were provided since cases were designed based on previous surveys Factors influencing dose sought for each case Used Bonferroni correction	53/114 (46.5%) ³
Roos <i>et al</i> ^[6] Case 4 (Aust/NZ, 2000)	Male, age 63 with disseminated large cell lung cancer and bone scan positive L1-L3, several ribs and skull. There is pain in the upper lumbar spine as well as pain and tingling in the right L2 distribution consistent with neuropathic pain		

Hartsell <i>et al</i> ^[49] Case 2 ² (United States, 1998)	A 45 yr old male was diagnosed with stage IIIA (T3N2) large cell carcinoma of the lung one year ago, and was treated with chemotherapy and thoracic irradiation. He now has pain in his lower back, and a bone scan shows a lesion in the third lumbar vertebra. His pain localizes to an area consistent with L3, and does not radiate. Motor and sensory examinations are unremarkable. A CT scan of this area shows a lytic lesion, but no evidence of compression of the cauda equina or thecal sac	Survey mailed to randomly selected radiation oncologists in United States (63.3%) Factors influencing dose not reported Did not specify whether prespecified list of doses was given Presumed trainees excluded Did not report whether anonymized

¹41 specialists/12 trainees; ²Takes into account multiple dose fractionation schemes listed per respondent; ³Includes unknown/missing responses; €: Extrapolated from data reported or from figure. EBRT: External beam radiotherapy; Intl: International; NR: Not reported.

plicated BM and BM associated with neuropathic pain in patients with lung cancer, its use as reported by respondents to hypothetical case scenarios remains low. Most common practice internationally and over time continues to be a 30Gy/10 schedule, representing significant divergence from multiple clinical practice recommendations and consensus guidelines (Table 2). The consequences in terms of increased departmental workload, health care costs and patient burden are significant^[6].

For a complicated BM presentation where the literature is less robust but supports fractionation, a higher proportion of respondents' dose schedules are evidence-based. For a patient with good PS, a truly solitary BM and no visceral disease, multifractionated highly conformal treatment may be a reasonable option. In that circumstance, long term tumour control may be important^[7].

However most patients with lung cancer and complicated BM do not meet these criteria and palliation, not tumour control, is the goal^[7]. Additionally, patients who are not likely to benefit from irradiation, especially those who are not likely to complete the prescribed course, should not be offered treatment. Those with extensive metastatic disease, a short life expectancy or very poor PS should be considered for SF radiotherapy regardless

of type of BM lesion, if they are treated at all^[42]. Settings in which RT should be omitted entirely in favour of best supportive care are reviewed by Lutz *et al*^[51].

It is not completely clear why the results of literature confirming the equivalence of single to MF continue to be overlooked, although studies suggest that trial evidence is just one of the factors physicians use in determining dose fractionation schedules^[9]. Patient-, institution- and training-related factors, along with individual physician beliefs, also play a role (Table 7).

Patient-related

The number of respondents employing SF for neuropathic pain, which in fact decreased after the publication of the TROG trial in 2005, may be due to the risk of occult spinal cord/cauda equina compression, the belief that tumour shrinkage is required to alleviate pressure on nerves or the general exclusion of these patients from trials examining efficacy of SF EBRT^[6,38]. Half of respondents to Nakamura Case 2 were concerned about the possibility of SCC^[46]. Concerns over toxicity and other QOL issues have not emerged as major factors^[6,9], likely because acute toxicity is typically mild and long term toxicity uncommon^[7,8]. As many as 85% of respondents who

Table 5 Factors influencing choice of dose fractionation scheme based on direct questioning of respondents

Case	Most impact	Least impact

recommended MFRT for Nakamura Case 2 regarded it as superior based on time until first increase in pain; participants in the Roos survey also cited this factor, which is not supported by level 1 evidence.

Physician-related

Some international guidelines still recommend multifraction schedules for uncomplicated BM. NCCN suggests, but does not provide supporting evidence for, the range of 8-30Gy/1-20 for an uncomplicated BM secondary to NSCLC^[52]. Japanese radiation oncologists prefer to learn from US resources resulting in similar patterns of practice^[46]. Despite evidence to the contrary, radiation oncologists may continue to believe that higher total doses, which can now be delivered with minimal toxicity *via* highly conformal techniques, are preferred^[2,53]. However, the mechanism of pain relief may be related to changes in the local microenvironment rather than direct tumour kill^[7]. Suboptimal quality of early studies (heterogeneity of patients, differences in endpoint selection, inconsis-

tent follow-up practices) may have contributed to lack of confidence in their results^[48].

Institution-related

SF is most frequently prescribed in university or government (*vs* private) centres and in large treatment facilities^[6,7,9,26,49].

Health Care System-related

Reimbursement system is one part of the wider cultural and bureaucratic context of location of practice/institutional structure^[24]. SF is more commonly used in countries using a budget or case-payment system (*e.g.*, Canada) compared to those with fee-for-service reimbursement, such as Japan^[7,46]. In a survey of 23/25 Belgian RT centres after changes in the Belgian reimbursement system in 2001 from fee-for-service to case payment, there was an increase in use of SF in 86% of centres^[11]. In Canada, where SF are used more often, the majority of departments are funded mostly by government while university

Table 6 Statistical predictors of use of single fraction schedules

and other funds make up < 10% support^[28].

A recently published patterns of care study characterized palliative RT dose and fractionation in a large US cohort of metastatic NSCLC patients (stage IV at baseline or metastatic at recurrence) and explored factors influencing RT delivery^[2]. The Cancer Care Outcomes Research and Surveillance Consortium prospectively enrolled 1574 patients (2003-2005) who participated in phone surveys and whose medical records were reviewed. 65% were male with a median age of 68. Eighty-seven point two percent had metastatic disease at diagnosis and the remainder was diagnosed with a distant first recurrence within 15 mo. Among 194 patients who received palliative EBRT to bone (218 courses), 50% received 6-10 fractions, 20% five fractions or fewer and 6% received SF. Among 206 patients with known dose, 49% received 21-30Gy. Patients younger than age 55, who had had surgery to a metastatic site and those receiving chemotherapy were more likely to receive RT to any site. Type of insurance was not predictive. Patients receiving RT to BM treated in integrated networks (HMOs, Veterans Administration) received on average 3.4 fewer fractions ($P = 0.001$) and 4Gy less dose ($P = 0.049$), although had similar rates of RT delivery^[2]. No information was provided about whether BM were complicated or uncomplicated. The authors concluded that a substantial proportion of patients received higher doses and more fractions than clinical trial data supports, despite the fact that this cohort had a short median survival. Patients treated in integrated networks received lower total doses and fewer fractions suggesting that provider characteristics, organizational structures and processes or financial incentives influenced clinical practice^[2].

However, arguments against SF have been almost entirely refuted by recent data, including multiple second-

ary analyses of the 1999 Dutch trial which randomized between 8Gy/1 and 24Gy/6, reporting no difference in outcomes^[16]. In terms of reirradiation, although SF and MF patients experienced equivalent response and progression rates, SF patients were retreated more frequently, at an earlier time during follow-up and at a lower pain score. This was interpreted by the authors as evidence that the differences resulted from practitioner bias rather than true differences in efficacy^[35].

Several economic analyses have compared different schedules of EBRT. A cost-utility analysis was conducted prospectively within the Dutch trial^[14]. SF RT provided an additional 1.7 quality-adjusted weeks and cost USD\$873 less than MF, including the effects of retreatment. When considering total societal including non-medical costs, the estimated savings was larger (USD\$1753) but not statistically significant^[14]. In a cost-effectiveness analysis of the TROG neuropathic bone pain study^[38] incorporating data to three months post-RT, although larger retreatment costs were associated with the SF arm, these were offset by savings in medication and hospital admission costs, as well as by the lower cost of initial RT^[54]. Through the use of a Markov model, Konski estimated that SF RT was more cost-effective for painful BM than either multifraction RT, chemotherapy (mitoxantrone and prednisone) or analgesics (oxycontin with senokot bowel routine). MF RT had only slightly more quality-adjusted life months than SF but cost USD\$1300 more^[55].

van der Linden *et al*^[56] compared patients with any histology accrued to the Dutch trial surviving > 52 wk from randomization. Responses were 87% after 8Gy and 85% after 24Gy, again including effects of retreatment ($P = \text{NS}$). Duration of response, time to response, and progression rates were also similar, indicating that patients do not outlive the benefits of SF.

Type of centre	[9]
Health care system-related	
Retreatment more often required	[35]
Increased costs due to retreatment	[14]
Reimbursement system	[24]

Two studies have examined the effect of palliative EBRT in patients during the last 12 wk of life^[57,58]. In a secondary analysis of 274 patients treated within the Dutch study, the proportion showing a pain response did not differ between the SF and MF arms^[57]. A retrospective review evaluated 232 patients dying within 3 mo of beginning treatment, 34% with lung cancer, 64% men, median KPS 60, median age 69, and 58% received SF. Overall response rates were 70% at one month and 63% at two months, controlling for analgesic usage. The authors concluded that despite limited lifespan, patients with painful BM with an estimated survival of three months should still be considered for RT^[58].

In terms of risk of pathologic fracture, 35% of the lesions classified as impending fracture in Harada *et al*^[36] study responded to multifraction RT, and 81% did not require surgical intervention. Both the degree to which recalcification is dependent on dose, and helps to prevent future fracture, remain unclear, however^[46].

Finally, no significant differences have been found in responses rates of elderly (≥ 65 years) compared to younger patients at one, two and three months after RT, when controlling for analgesic usage, supporting referral of patients regardless of age^[59].

Surveys are valuable in assessing practice when it diverges from published data, but have well-known limitations, reviewed in Fairchild *et al*^[9]. Exploration of differences in attitude may provide a more realistic basis for the construction of international consensus, leading to increased ownership. The results might not be entirely representative because it is not possible to conclude

whether answers accurately reflect practice. When the questionnaires were completed in comparison to when practitioners became aware of results of new published data cannot be determined. When facts are being solicited about existing systems, such as reimbursement method, accuracy of the answers cannot be checked. Some studies included trainee respondents, some did not, and some did not specify. Multiple calculations for associations are often performed, but rarely taken into account in the statistical analysis (*i.e.*, lack of Bonferroni correction). Possible explanations for differences in practice include a lack of histology-specific data^[19], demographics of respondents, contradictory definitions of uncomplicated BM, and varying availability of alternative treatment modalities such as vertebroplasty, radiofrequency ablation, radiopharmaceuticals and speciality surgery teams^[9]. Additionally, increasing use of systemic therapy in patients with advanced lung cancer may add local anti-tumour effects^[36], and case histories often did not describe planned or delivered systemic therapy. Overall, a survey is still a useful method of exploring attitudes, beliefs and practices, although it is not possible to extrapolate beyond the data reported.

CONCLUSION

Palliative EBRT has an essential role as a well-tolerated, minimally toxic, cost conscious and effective treatment for symptom control in this setting. However, survey studies concerning hypothetical cases of patients with lung cancer and both complicated and uncomplicated bone metastases continue to show a large discrepancy between published literature and patterns of practice. From a common sense perspective, the shortest RT regimen which maximizes outcomes in an evidence-based manner seems preferable. Schedules prescribed as multifraction courses, when SF would be appropriate, disadvantage all patients and overextend many centres' already strained resources.

Abstract

Erlotinib and gefitinib are among the most widely researched, used and available molecularly targeted therapies for treatment of advanced non-small cell lung cancer (NSCLC). They are both tyrosine kinase inhibitors (TKIs) of the epidermal growth factor receptor (EGFR). In the past decade, there have been reports on clinical benefit from use of erlotinib after gefitinib failure in NSCLC patients. A review of published literature on this focussed topic is provided herein. Pooled analysis of published literature shows that majority of patients were female (60.6%), non-smokers (64.5%), had adenocarcinoma histology (88.3%) and were of East Asian ethnicity (92.3%). Presence of sensitizing EGFR mutation was detected in 48.4% of subjects. Disease control rates with prior gefitinib therapy and with subsequent erlotinib treatment were 79.4% and 45.4% respectively. Based upon our review, the most important predictive factor for clinical benefit from erlotinib identified was previous response to gefitinib. The exact explanations for the potential benefit from erlotinib use in this patient population is still not known and further studies are required to determine the role of molecular mechanisms

especially those related to resistance to initial EGFR TKI therapy.

Key words: Gefitinib; Erlotinib; Non-small cell lung cancer; Epidermal growth factor receptor; Tyrosine kinase inhibitor

Core tip: This manuscript is focused on the controversial yet interesting topic of whether erlotinib provides clinical benefit amongst patients who have experienced disease progression after prior therapy with gefitinib—both drugs being tyrosine kinase inhibitors of the epidermal growth factor receptor. We have reviewed available literature on this topic, carried out a pooled analysis on available data and hope readers find it useful in clearing the confusion related to this topic.

INTRODUCTION

Lung cancer remains among the most commonly occurring cancers in the world with majority of the cases being of non-small cell lung cancer (NSCLC)^[1,2]. As in other malignancies, molecularly targeted therapies are being increasingly researched and approved for clinical use in case of NSCLC especially adenocarcinoma. Among the molecularly targeted therapies available for advanced

NSCLC, the epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (TKIs) occupy a central place and form part of the standard treatment algorithms^[3]. Gefitinib, erlotinib and recently afatinib are the available, orally active agents in this group. Gefitinib was approved for use after two randomised trials-the Iressa Dose Evaluation in Advanced Lung Cancer 1 and 2 (IDEAL 1 and 2) studies-showed survival benefit as compared to placebo amongst patients with advanced NSCLC who had progressed after initial platinum based chemotherapy^[4,5]. However, based on a subsequent trial, *i.e.*, the Iressa Survival Evaluation in Lung Cancer study, which did not show an improvement in overall survival (OS), the use of gefitinib was disallowed in the United States by the Federal Drugs Authority (FDA)^[6]. Erlotinib was demonstrated to have efficacy in advanced NSCLC in the BR.21 trial. This was a randomised, double blind, placebo controlled trial in which the administration of erlotinib to patients with advanced NSCLC who had received prior chemotherapy led to an improvement in response rates (RR), progression free survival (PFS) and OS with an acceptable toxicity profile^[7]. Subsequently, erlotinib was approved by the FDA for use in advanced NSCLC. In all of the above studies, the clinical benefit and treatment response was more evident in certain subgroups namely female gender, non-smoker status, Asian ethnicity and adenocarcinoma. Subsequently, these subgroups were proven to have a higher incidence of sensitizing EGFR mutations which till date remains the most important predictive factor for clinical benefit with EGFR TKIs^[8].

Almost a decade ago, there was an initial report on the use of erlotinib after gefitinib failure in patients of non-small cell lung cancer^[9]. Following this, several case reports, case series, retrospective reviews and even a few prospective trials have been published related to use of erlotinib in patients who had received prior therapy with gefitinib. This is surprising, considering that the mechanism of action of both drugs is similar. No satisfactory explanation has been found till date, though many have been postulated. In the current article, we have reviewed published literature on this focused area and carried out a pooled analysis with the data available.

MECHANISM OF ACTION OF TKIS

EGFR is a transmembrane protein which functions as the receptor for the epidermal growth factor (EGF) pathway^[8]. The EGFR protein consists of three domains: an extra-cellular binding site for the EGF molecule, a transmembrane unit which spans the cell membrane and an intracellular unit which has tyrosine kinase activity. The binding of EGF causes conformational changes in the receptor which further leads to phosphorylation/dephosphorylation of the intracellular tyrosine kinase domain and subsequent downstream signalling. Mutations in the EGFR lead to a constitutive activation of the EGF pathway and subsequent activation of cell survival pathways^[10].

The mutations underlying the activation of this pathway were elucidated in the earlier part of the last decade^[11-13]. Based on the experience with imatinib in chronic myeloid leukaemia, inhibitors of the EGFR tyrosine kinase pathway were developed. The first of these was gefitinib, which acts by interfering with the tyrosine kinase activity of the intracellular domain of the EGFR. It was followed by erlotinib, which has a somewhat similar mechanism of action. These function as adenosine triphosphate (ATP) mimetic molecules and bind to the intracellular domain of the EGFR and block receptor phosphorylation and subsequent downstream signalling and activation of dependent pathways^[14].

LITERATURE REVIEW

We carried out a PubMed search for all published literature in the English language on this topic till 2013. Multiple case reports, retrospective reviews and prospective studies were identified that have been listed in Table 1. The studies included in this review used standard treatment protocols for gefitinib and erlotinib, *i.e.*, 250 mg/d and 150 mg/d respectively. Tumour response was assessed according to the Response Evaluation Criteria in Solid Tumours^[15]. The outcome measures reported in the studies included: RR, defined as combination of complete response (CR) and partial response (PR); Disease control rate (DCR), defined as the combination of CR, PR and stable disease (SD); PFS, defined as the period from the start of treatment to the date when disease progression or death was observed and OS, defined as the period from the start of treatment to the date of death (Tables 2 and 3).

Use of erlotinib after gefitinib failure was first reported in 2005^[9]. Subsequently, sporadic case reports were published which demonstrated similar findings^[16-18]. A prospective phase II study evaluated the use of erlotinib in patients of NSCLC who had been treated with chemotherapy followed by gefitinib and then had failure on gefitinib. A total of 21 patients were included in this study. Out of these 21 patients, who had progressed on gefitinib, 2 patients achieved PR and 4 patients SD while the remaining 15 patients had progressive disease (PD). The DCR was 28.6% (95%CI: 9.3% to 47.9%) while the median PFS and OS were 60 d (95%CI: 43 to 77 d) and 158 d (95%CI: 141 to 175 d), respectively. An interesting point noted was that the only predictor of a response to erlotinib was the presence of a prior response to gefitinib. Surprisingly, the presence of EGFR mutations was not associated with a response to erlotinib. In fact, 4 out of 6 responders to erlotinib did not have the EGFR mutation^[19].

A retrospective study analysed 14 patients who had received erlotinib after failure of gefitinib over a two year period. The initial DCR for gefitinib was 64.3% (9 of 14), while it was 35.7% (5 of 14) for erlotinib. Predictors for good clinical response to erlotinib included never smoker status, adenocarcinoma subtype, good response to initial

¹Of the 104 patients, only 54 had prior treatment with gefitinib. A: Adenocarcinoma; S: Squamous cell carcinoma; M: Male; F: Female; NA: Not available; smokers: Includes current and ex smokers; NS: Non-smokers.

gefitinib and presence of EGFR mutations^[20].

23 patients of metastatic or advanced NSCLC who had documented progression on gefitinib were studied in an open label, single institution, phase II study. All patients were never smokers and 22 out of the 23 patients were of the adenocarcinoma subtype. The initial DCR on gefitinib was 65.3% (15 out of 23). 2 patients responded to erlotinib, giving a DCR of 8.7% and a RR of 4.3%, while the rest 21 patients developed PD within 3 mo^[21].

Another study included 4 males and 4 females in their study, with a mean age of 70 years. All of these patients had received chemotherapy at least twice, followed by gefitinib. 4 patients had achieved PR with gefitinib and 4 patients SD, and the median PFS was 17 mo. Two (25%) patients achieved PR and 3 (37.5%) patients SD, while 3 developed PD. The median PFS and OS were 5.9 and 14.6 mo, respectively with erlotinib. The authors observed that patients who had a longer PFS on initial gefitinib therapy had better disease control with erlotinib^[22].

Another retrospective study published in 2008 included 18 patients. These patients had received primary chemotherapy and had subsequently been given gefitinib. The initial response to gefitinib included 14 patients with either CR or PR, 2 patients with SD and 2 with PD. After treatment with erlotinib, 14 out of the 18 patients developed PD, while 3 patients had SD and only 1 PR. The median PFS was 2 mo and no patient had a PFS over 6 mo^[23].

The utility of established predictive factors for re-

sponse to EGFR TKIs namely female sex, adenocarcinoma subtype, Asian ethnicity and never smoking status, were also assessed for their predictive value in the context of erlotinib use following progression on initial gefitinib therapy. They included 14 patients and noted a DCR of 68.8% (95%CI: 0.44-0.86) on initial gefitinib treatment and a rate of 25.0% (95%CI: 0.10-0.50) after treatment with erlotinib. The median PFS was 6.3 mo for gefitinib and 1.7 mo for erlotinib. The above mentioned factors were found to be unreliable for predicting response to erlotinib after treatment failure with gefitinib^[24].

A more heterogeneous population of 10 (47.6%) smokers, 9 (42.9%) patients with squamous cell carcinoma, 8 (38.1%) with adenocarcinoma and 4 (19%) with other NSCLC subtypes, totalling 21 were included in another trial. All of them had progressed on gefitinib therapy after chemotherapy. 6 of the 21 patients responded, with 2 (9.5%) showing PR and 4 (19.0%) showing SD, giving an overall RR of 9.5% and a DCR of 28.5%. The median PFS was 55 d and the median OS was 135 d. All of these 6 patients had also had disease control with prior gefitinib therapy, either PR or SD^[25].

All of the previously mentioned trials included patients who had received chemotherapy prior to initial gefitinib therapy. A retrospective review of 21 patients who had received gefitinib as first line therapy instead of chemotherapy was conducted. The patient population was selected based on clinical characteristics *i.e.*, never smokers, females, Asian ethnicity and adenocarcinoma

RR: Response rate; DCR: Disease control rate; PFS: Progression free survival; OS: Overall survival.

subtype. Only 3 of these 21 patients had EGFR mutation status known. Disease control was achieved in 18 patients (85.7%) with first line gefitinib therapy and in 12 out of these 18 patients (66.7%) who received erlotinib as salvage therapy. The overall DCR for erlotinib was 57.1% (12 out of 21). All 3 patients who progressed on gefitinib did not respond to erlotinib^[26].

In a retrospective review of 42 patients with lung adenocarcinoma receiving erlotinib with history of prior gefitinib treatment, PFS (4.7 mo *vs* 1.8 mo) and OS (9.2 mo *vs* 4.7 mo) were better in patients who had experienced prior response with gefitinib as compared to those who had not^[27]. On multivariate analyses for prognostic factors for OS, only prior response to gefitinib was found to be significant but not presence of EGFR mutations. Interestingly in this cohort, 69% of patients had a sensitizing EGFR mutation (exon 19 deletion or L858R mutation exon 21).

A systematic review included 3 prospective studies, 3 retrospective studies and 7 case reports leading to a total of 106 patients. Out of these 9.9% patients had PR, 18.9% SD and 70.8% PD. The DCR was 37.5% in patients who had EGFR mutations and 21.7% in patients without EGFR mutations, which was not statistically different. The mean PFS varied from 1.7 to 5.9 mo. Analysis showed that the only factors which predicted response to erlotinib were the presence of SD on initial treatment with gefitinib and the presence of PFS to initial gefitinib for more than 6 mo^[28].

In a large retrospective analysis of 125 patients all of whom had experienced disease progression following initial gefitinib therapy, the RR was 9%, DCR 44% and median PFS 2 mo with erlotinib treatment. Multivariate analysis showed that disease control was predicted by

Table 4 Pooled analysis of demographic profile, prevalence of epidermal growth factor receptor mutations and disease control rates with erlotinib following prior gefitinib therapy

Female gender : 60.6% (292 of 482)
Adenocarcinoma histology: 88.3% (421 of 477)
Non smokers: 64.5% (304 of 471)
East Asian ethnicity: 92.3% (445 of 482)
EGFR mutation positive status ¹ : 48.4% (224 of 463)
Disease control rate with prior gefitinib treatment: 79.4% (336 of 423)
Disease control rate with subsequent erlotinib treatment: 45.4% (194 of 427)

¹Indicates presence of sensitizing EGFR mutations (exon 19 deletion or exon 21 L858R mutation). EGFR: Epidermal growth factor receptor.

three factors: good performance status [Eastern Cooperative Oncology Group (ECOG) PS 0/1], EGFR mutation-positive status (or unknown) and benefit from prior gefitinib therapy. Longer PFS was predicted by insertion of cytotoxic chemotherapies between gefitinib and erlotinib therapies in addition to ECOG PS 0/1 and benefit from prior gefitinib therapy^[29].

In another retrospective review published recently, 44 of the 54 patients had a sensitizing *EGFR* gene mutation (exon 19 deletion or L858R mutation exon 21) and all 54 patients had received gefitinib initially. DCR of 63% was observed with subsequent erlotinib treatment. The authors observed no significant differences in erlotinib efficacy between EGFR-mutated NSCLC who had developed gefitinib resistance as compared to another 50 patients of NSCLC with wild-type EGFR in whom gefitinib had not been given earlier. This study also showed that presence of skin rash was associated with better outcomes—an observation that has been reported by others also^[30].

POOLED ANALYSIS

We also carried out pooled analysis of published literature involving patients who had received erlotinib treatment following prior gefitinib therapy. This has been summarized in Table 4. It was not possible to analyse objective RRs and SD separately since some of the publications included in this review had only provided DCRs which is the sum of objective responses (CR/PR) and SD. There are three important observations that are apparent from the pooled analysis. First, majority of the patients were of East Asian ethnicity, females, non-smokers and had adenocarcinoma histology all of which are clinical surrogates for presence of sensitizing EGFR mutations. Second, approximately one of every two subjects in the pooled population had a sensitizing EGFR mutation (exon 19 deletion or exon 21 L858R mutation). However, the true prevalence in this population database is likely to be higher than the figure of 48.4% that arose on pooled analysis because in several of the publications, results of EGFR mutation testing were either not mentioned or were performed in subgroup of patients included in the article. An indirect indicator that this was a highly enriched pooled population is the fact that approximately

Table 5 Potential factors predicting response to erlotinib following prior gefitinib therapy

four of five patients had initial disease control with gefitinib. Third, despite progressing on gefitinib treatment, approximately 45% of patients achieved disease control with erlotinib. However, it was not possible to carry out analysis regarding the molecular mechanisms that led to gefitinib failure or resistance since these have not been provided in majority of the publications.

RATIONALE

A satisfactory explanation as to cause of responsiveness to erlotinib after failure of gefitinib is yet to be given. However, several hypotheses have been put forward. One possibility is that gefitinib is usually given at a clinical dose of 250 mg, which is around one third of the maximum tolerated dose, about 750 mg. In contrast, the clinical dose of erlotinib is 150 mg, which is very close to the maximum tolerated dose. Therefore, the biological dose of these two drugs may not be equal. However, in the IDEAL 1 and 2 trials, higher doses of gefitinib were not associated with a better RR^[4,5,19].

Another possibility invokes the presence of both EGFR TKI sensitive and resistant clones at the start of treatment with gefitinib. The administration of gefitinib leads to the selective dying out of the sensitive clones and subsequent development of resistance. When the TKI is stopped, the sensitive clones again propagate and are the reason for the response to the subsequent TKI^[21]. This is borne out by case reports demonstrating that readministration of gefitinib to some patients after progression may sometimes lead to disease control similar to that achieved with erlotinib^[31].

Patients who develop resistance to EGFR TKIs, acquire common mutations such as T790M secondary mutation or amplification of the MET oncogene. Other secondary mutations have also been reported. Some mutations, such as the L748S or E884K mutation, may result in differing sensitivities to the oral EGFR TKIs, resulting in different tumour responses^[12,19,21].

An overview of the potential factors predicting clinical benefit with erlotinib is provided in Table 5. The most consistent predictive factor has been prior response to gefitinib. However the predictive role of presence of

EGFR mutations in this setting has not been as strong as it is for first line therapy. The clinical surrogates for presence of EGFR mutations namely, female gender, Asian ethnicity, adenocarcinoma histology and non-smoking status, are the other factors that remain associated with clinical benefit from erlotinib in this setting.

CONCLUSION

Oral EGFR TKIs are widely available drugs that are an important component of the therapeutic armamentarium against advanced NSCLC. The use of sequential EGFR TKIs, especially of erlotinib after prior treatment with gefitinib has remained a controversial area so far. Given the disease control rate of approximately 45% in the current pooled analysis, such an approach can be considered in carefully selected patients especially those in whom alternate treatment options are not being considered. The exact explanation of this response is still not known. Possible predictive factor for clinical benefit with erlotinib includes previous response to gefitinib. The predictive value of sensitizing EGFR mutations requires further evaluation and further studies are required to determine the underlying molecular mechanisms for observed clinical benefit with erlotinib in this setting.

Abstract

Lung cancer is the leading cause of cancer-related mortality throughout the world. Non-small cell lung cancer (NSCLC) accounts for 85% of all diagnosed lung cancers. Despite considerable progress in the diagnosis and treatment of the disease, the overall 5-year survival rate of NSCLC patients remains lower than 15%. The most common causes of death in lung cancer patients are treatment failure and metastasis. Therefore, developing novel strategies that target both tumour growth and metastasis is an important and urgent mission for the next generation of anticancer therapy research. Heat shock proteins (HSPs), which are involved in the fundamental defence mechanism for maintaining cellular viability, are markedly activated during environmen-

tal or pathogenic stress. HSPs facilitate rapid cell division, metastasis, and the evasion of apoptosis in cancer development. These proteins are essential players in the development of cancer and are prime therapeutic targets. In this review, we focus on the current understanding of the molecular mechanisms responsible for HLJ1's role in lung cancer carcinogenesis and progression. HLJ1, a member of the human HSP 40 family, has been characterised as a tumour suppressor. Research studies have also reported that HLJ1 shows promising dual anticancer effects, inhibiting both tumour growth and metastasis in NSCLC. The accumulated evidence suggests that HLJ1 is a potential biomarker and treatment target for NSCLC.

Key words: Non-small cell lung cancer; Metastasis; HLJ1; Anticancer; Biomarker

Core tip: HLJ1, a member of the human heat shock proteins 40 family, has been characterised as a tumour suppressor. Research studies have reported that HLJ1 shows promising dual anticancer effects, inhibiting both tumour growth and metastasis in non-small cell lung cancer (NSCLC). The accumulated evidence suggests that HLJ1 is a potential biomarker and treatment target for NSCLC. We propose a hypothetical model for the roles of HLJ1 stimulator in suppressing lung cancer tumorigenesis. Investigating the integrated and coordinated molecular mechanisms of HLJ1 may shed new light on the treatment of lung cancer. The development of drug targeting HLJ1 may be an effective approach for lung cancer therapy.

Tumour suppressor HLJ1: A potential diagnostic, preventive and therapeutic target in non-small cell lung cancer. *World J Clin Oncol* 2014; 5(5): 865-873 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/865.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.865>

INTRODUCTION

Lung cancer is the most common cause of cancer death in the world, accounting for 17% of all cancer deaths^[1,2]. Non-small cell lung cancer (NSCLC) is the predominant type of lung cancer^[3]. The three major types of NSCLC are squamous cell carcinoma, large cell carcinoma, and adenocarcinoma, but several other types occur less frequently^[4]. Traditional therapeutic strategies (chemotherapy and radiotherapy) are often associated with unsatisfactory outcomes in lung cancer patients, and the problem is exacerbated by early detection difficulties^[5]. A minority of patients (approximately 30%) with NSCLC present with an early stage of the disease and receive curative surgery. However, even in those patients, up to 40% will subsequently relapse within 5 years^[6,7]. Targeted molecular therapy has become an important part of therapeutic strategies for treating lung cancer. However, the major challenges confronting targeted cancer therapies are variable responsiveness and the development of drug resistance^[8]. There have been significant advances in cancer treatments owing to our knowledge of the mechanisms underlying cell signalling pathways; however, the prognosis for patients with locally advanced or metastatic disease is still ominous.

If lung cancer is diagnosed and treated before it metastasizes, the 5-year survival rate is approximately 50%-70%. Once metastasis has occurred, the 5-year survival rate drops to < 5%^[9]. Therefore, metastasis is the most critical parameter determining survival in lung cancer patients^[10]. Improving survival in lung cancer is a major challenge for modern oncology, particularly considering the 5-year survival rate remains under 15% across all stages of disease^[11]. Metastasis, the spread of tumour cells from their primary sites to secondary sites within the body, is a multiple-step process that requires the accumulation of altered expression of many different genes. This complex process involves cell adhesion, degradation of the surrounding extracellular matrix, migration, proliferation at a secondary site, and stimulation of angiogenesis^[12,13]. Many studies on cancer metastasis have been conducted, and several molecules that participate in tumour cell invasion and metastasis, such as SLUG, NM23, CD44, MTA1, MMPs, TIMPs, KAI1, E-cadherin, KISS1 and CRMP1, have been identified in various cancer types^[14-18]. There is still no effective strategy for preventing or combating these metastatic processes. Therefore, it is important to develop novel strategies that target both tumour growth and metastasis in NSCLC.

In this review, we focus on the current understanding of the molecular mechanisms responsible for the effects of HLJ1 in lung cancer. The role of HLJ1, a member of the human heat shock protein 40 (HSP40) family, in lung cancer development and progression has been extensively investigated^[19-21]. HLJ1 has been characterised as a tumour suppressor, and research studies have identified the protein's promising dual anticancer effects in NSCLC, inhibiting both tumour growth and metastasis^[19,22,23]. The accumulated evidence suggests that HLJ1 is a potential

biomarker for NSCLC and a potential target of drug development.

HEAT SHOCK PROTEINS

The heat shock response was first described in 1962^[24], and a number of investigations have revealed that the process is an essential defence mechanism for cellular viability. HSPs are named for their increased synthesis after heat shock. In addition to elevated temperature, HSPs are markedly induced by nutrient deprivation, oxidative stress, heavy metals, radiation, pathogen infection and other stress factors^[25]. Under normal conditions, HSPs perform essential biological functions such as modulating protein activity by changing protein conformation, serving as molecular chaperones in protein transport between cell organelles, promoting multiprotein complex assembly/disassembly, and ensuring proper folding of nascent and altered proteins^[25,26]. Many other more specific functions have been identified for particular HSP types and include roles in immunological processes, cell cycle regulation, transcriptional activation and signal transduction^[27-29].

Mammalian HSPs have been classified into the following six families according to molecular size: HSP100, HSP90, HSP70, HSP60, HSP40 and small HSPs^[30]. HSPs play fundamental roles in the processes of signal transduction, cell proliferation and survival, cell cycle progression and apoptosis, and in other features of malignant cells, including invasion, tumour angiogenesis and metastasis^[28,29]. In recent years, research studies have identified several different HSPs, in a variety of tumour types, that may be putative clinical biomarkers or molecular targets for cancer therapy. The dependence of cancer cells on HSP90 has been successfully exploited in therapeutics^[30,31]. While HSP40 therapies are in the nascent stages, HSP27 and HSP70 therapies have been successfully used with HSP90 inhibitors as part of dual inhibition treatments and with antineoplastic drugs in combinational therapy^[32].

HUMAN HSP40 AND CANCER

The HSP40 family, also known as DNAJ proteins, constitutes the largest and most diverse sub-group of HSPs^[33]. All DNAJ proteins contain the 70 amino acid J domain, which is essential for interaction with HSP70. The DNAJ proteins that have been identified in humans are divided into three subclasses. Based on the presence or absence of conserved domains, DNAJ proteins are classified as type I (DNAJA, 4 members), type II (DNAJB, 13 members) or type III (DNAJC, 32 members)^[34]. DNAJ proteins are widely recognised as regulators of HSP70 function, but they also have roles as co-chaperones in the HSP90 multi-chaperone complex^[35]. The function and role of DNAJ proteins is still poorly understood. Current research is focused on understanding the role of HSP40 isoforms in regulating HSP70 and their subsequent involvement in disease progression.

The DNAJ proteins are differentially expressed in hu-

man tissues and can act as both tumour suppressors and onco-proteins^[19,36,37]. There are approximately 49 genes that encode DNAJ proteins, and several of these genes encode for multiple splice variants that may have different biological functions and cellular locations^[34]. Tid1 (DNAJA3) has 2 isoforms, Tid1-L and Tid1-S, which may function differently. Tid1-L acts as a tumour suppressor by negatively regulating cell proliferation, cell invasion, and tumorigenicity in breast cancer, lung cancer, and head and neck squamous cell carcinoma^[36,38,39]. Tid1-L overexpression in lung cancer cell attenuates epidermal growth factor receptor (EGFR) signalling and inhibits cell proliferation, colony formation, and *in vivo* tumour growth. Low Tid1-L/high EGFR expression predicts poor overall survival in patients with lung adenocarcinoma. Tid1-L has been shown to act as a tumour suppressor (though Tid1-S has not) by inhibiting EGFR signalling through interaction with EGFR/HSP70/HSP90 and by enhancing EGFR ubiquitinylation and degradation^[36]. Research studies have also suggested that Tid1-L is a novel regulator of p53-mediated apoptosis and that the use of the enhanced Tid1-L function to promote mitochondrial localisation of p53 could be an effective therapy in many cancers^[40]. In contrast, overexpression of Tid1-S in renal clear cell carcinomas enhances MetR kinase activity, leading to an increase in hepatocyte growth factor-mediated cell migration. The binding of Tid1-S to MetR may stabilise the receptor in a ligand-competent state, and this stabilising function may influence conformational changes that take place during the catalytic cycle to promote kinase activation. Targeted inhibition of Tid1-S may be a useful therapeutic tool in the management of MetR-dependent malignancies^[37].

MRJ (DNAJB6) was found to reduce tumorigenicity and metastasis of melanoma and breast cancer cells^[41]. MRJ induces β -catenin degradation and may play a role in maintaining an epithelial phenotype^[42]. Furthermore, researchers have shown that loss of MCJ (DNAJC15) expression confers resistance to specific chemotherapeutics in ovarian cancer cells^[43,44]. In clinical ovarian cancer patients, low MCJ expression was correlated with poor prognosis and resistance to chemotherapy. ABCB1 (drug transporter) gene expression is mediated by increased levels of the c-Jun transcription factor in the absence of MCJ^[43,45]. In contrast to the data on HSP70 and HSP90, there is limited information available on the expression and function of most DNAJ proteins in cancer. However, it is evident from the specific DNAJ proteins that have been identified that these proteins may play an important role in affecting cancer properties.

HLJ1 EXPRESSION IN LUNG CANCER

HLJ1, consisting 337 amino acids, was first identified from the human liver cDNA library and was classified as a member of the HSP40 family^[46]. HLJ1, also known as DNAJB4, belongs to the type II homologues of the Hsp40 family and comprises the following four conserved functional domains: a highly conserved J do-

main, a glycine/phenylalanine-rich region, a cysteine-rich region, and a COOH terminal domain^[47]. Homology analysis showed that the amino acid sequence of HLJ1 has 84% similarity with HDJ1 (DNAJB1) isolated from human placenta^[48]. HLJ1 mRNA is highly expressed in skeletal muscle and in the heart, pancreas, brain, lung, and other organs but is weakly expressed in the liver and kidney. Although the *HLJ1* gene was cloned from the liver cDNA library, the expression of HLJ1 in liver tissue is relatively low^[46].

Gene expression profiles have been used to identify possible associations with lung cancer behaviour or clinical outcome to better predict patient prognosis. We have previously established a panel of lung adenocarcinoma cell lines with increased invasiveness (CL1-0, CL1-1, CL1-5 and CL1-5-F4) that were derived from a parent lung adenocarcinoma cell line by repeatedly selecting for more invasive cells^[49]. These selected sublines have shown greater invasive and metastatic potential than the parental cells. By using a complementary DNA microarray, we identified metastasis-associated genes on a genome-wide scale in model lung cancer cell lines^[50]. Cluster analysis of the complementary DNA microarray data revealed that 589 (6.1%) genes were positively or negatively associated with cancer cell invasiveness. Moreover, most of these genes were involved in angiogenesis, cell motility, adhesion and proliferation. *HLJ1*, one of the metastasis-associated genes identified by that study, has been characterised as a novel tumour suppressor, and high HLJ1 expression is associated with reduced cancer recurrence and prolonged survival in NSCLC patients^[19].

NSCLC is a heterogeneous disease, and patients with similar clinical-pathologic features may have a broad range of outcomes^[51,52]. It is important to identify a prognostic marker that can predict clinical outcomes in NSCLC patients. We have demonstrated that HLJ1 is a novel tumour suppressor in NSCLC. Primary cancer specimens from 71 patients with histologically confirmed NSCLC were analysed using reverse transcription-polymerase chain reaction, and the HLJ1 expression in tumour tissue was lower than in adjacent normal tissue in 55/71 (77%) of the patients. Moreover, in 49% of the samples, the tumour tissue showed at least a 2-fold decrease in HLJ1 compared to adjacent normal tissue. NSCLC patients with high HLJ1 expression had significantly longer overall survival and disease-free survival times compared to those with low HLJ1 expression. Clinically, HLJ1 is a significant, independent prognostic predictor of recurrence and overall survival in NSCLC patients^[19]. Tumour suppressor genes are frequently deactivated by genetic alterations, such as chromosomal deletions and loss-of-function mutations. The *HLJ1* gene is located on human chromosome 1P31.1. Loss of heterozygosity (LOH) on the short arm of chromosome 1 has been reported in many types of cancer^[53]. High frequencies of LOH and microsatellite instability in the HLJ1 region have been detected in NSCLC patients^[19].

Microarray analysis suggests that HLJ1 expression is negatively correlated with cancer invasiveness. HLJ1 is reportedly up-regulated in less-invasive cell lines than

in highly invasive cell lines^[20,50]. Restoration of HLJ1 expression in NSCLC cells inhibited cell proliferation, anchorage-independent growth, cell motility, invasion and tumorigenesis. HLJ1 slows cell cycle progression by increasing STAT1 and p21^{WAF1} expression and decreasing cyclin D1 expression. The same study also suggested that HLJ1 can affect the expression of many genes downstream in the STAT1 pathway, including p21^{WAF1}, ISGF3G, IFIT1, IFITM1, OAS3, and GIP2 and that HLJ1 can increase p21^{WAF1} expression by affecting a p53-independent pathway^[19,20].

E-cadherin is a well-known invasion suppressor in several types of carcinoma^[54]. In a previous microarray analysis, we found that expression of the Slug gene positively correlated with invasive ability. Overexpression of Slug suppressed E-cadherin expression and increased invasive ability. The study showed that Slug promoted metastasis in lung cancer by down-regulating E-cadherin, up-regulating matrix metalloproteinase 2 (MMP2) and enhancing angiogenesis^[17]. We also found that HLJ1 indirectly up-regulated E-cadherin expression by inhibiting the repressive effect of the Slug gene on the E-cadherin proximal promoter^[20]. Recently, research studies have also indicated that HLJ1 acts as a molecular chaperone of E-cadherin that is able to sense E-cadherin folding, providing stabilisation of native folded E-cadherin in the plasma membrane or degradation of an unfolded counterpart. Post-translational regulation of E-cadherin by the HLJ1 molecular chaperone is sufficient to influence gastric cell invasion. HLJ1 is a sensor of E-cadherin structure features that might contribute to gastric cancer progression. Additionally, the expression of HLJ1 and E-cadherin is concomitantly decreased in patients with human gastric carcinoma^[55].

Nucleophosmin (NPM1) is a nucleolar phosphoprotein that localises in granular regions of the nucleolus and is highly expressed in malignant and actively dividing cells^[56]. NPM1 shuttles continuously between the nucleus and cytoplasm and acts as a multifunctional protein that plays an important role in the increased nucleolar activity needed for cell proliferation^[56,57]. Studies have proposed that the NPM1 protein has both oncogenic and tumour-suppressing effects, depending on its level of expression and cellular localisation^[58]. HLJ1 modulates NPM1 oligomerisation and NPM1-AP-2 α multi-protein complex formation, which alter AP-2 α transcriptional activity. These changes then suppress the expression of downstream genes such as MMP2 and, as a result, decrease lung cancer cell invasiveness^[22].

Evasion of apoptosis is a hallmark of most cancers^[59]. Therefore, it is important to identify genes that promote apoptosis in cancer cells, either under normal or stressful conditions, such as radiotherapy and chemotherapy. Several recent studies indicate that HSPs play important cytoprotective roles and are involved in regulating the apoptosis pathway^[60]. HLJ1 can promote cancer cell sensitivity to ultraviolet (UV) stress-induced apoptosis by enhancing c-Jun N-terminal kinase (JNK) activation and caspase activity^[61]. Moreover, the HLJ1 protein is a novel

substrate of caspase-3, which is followed by protein degradation during the apoptotic process. HLJ1 appears to play an important role in apoptosis. However, further studies are necessary to determine the underlying mechanism of HLJ1 in UV-induced apoptosis and the effects of reduced HLJ1 in late apoptosis^[61].

TRANSCRIPTIONAL REGULATION OF HLJ1

Elucidation of the roles and the regulatory mechanism of tumour suppressors may facilitate the development of rational therapeutic targets that inhibit cancer cell proliferation, angiogenesis and metastasis. YY1 is a 65-kDa multifunctional zinc-finger transcription factor belonging to the human GLI-Kruppel family of nuclear proteins^[62]. It can bind to a specific DNA consensus sequence, 5'-CGCCATNTT-3', which is present in many promoters. YY1 can either activate or repress the target genes, depending on the cofactors that it recruits^[62,63]. YY1 is a complex protein that plays pivotal roles in cell development, differentiation, proliferation, and apoptosis^[64,65]. Because the expression and function of YY1 are intimately associated with cell cycle progression, its physiologic significance has recently been applied to models of cancer biology^[64]. YY1 overexpression has been demonstrated in several human cancers such as breast cancer, prostate cancer, cervical cancer, brain cancer and colon cancer^[65,66]. However, functional and clinical analysis of the YY1 in NSCLC remains unclear. As a transcription factor, YY1 regulates the expression of numerous genes that are mostly involved in tumorigenesis. The HLJ1 promoter contains four YY1-binding sites that positively regulate HLJ1 expression. When compared with the WT construct, the mutants of these four potential YY1-binding sites resulted in different levels of reduction in HLJ1 promoter activity, from 17% to 34%, respectively^[20]. However, deletion of all four YY1-binding sites reduced the HLJ1 promoter activity by 93%, indicating that YY1 regulation plays an important role in HLJ1 expression. Overexpression of YY1 in NSCLC cells indicated that up-regulates the HLJ1 expression by directly binding to the promoter region, thus inhibiting cancer cell invasion^[20]. In addition, an enhancer segment was identified in the *HLJ1* gene at -2125 to -1039 bp upstream of the transcription start site, which includes the activator protein 1 (AP-1) site. The activation and synergistic up-regulation of the tumour suppressor HLJ1 is the result of the binding of the transcription factors AP-1 and YY1 to the gene's enhancer and promoter regions, respectively^[21].

Hepatitis B virus (HBV) is a major cause of human hepatocellular carcinoma (HCC). HBV proteins promote migration-related factors such as MT1-MMP, MMP9, and hypoxia-inducible factor 1- α and contribute to the HCC metastatic process^[67-69]. However, HBV could also promote HLJ1 expression in HCC cells by up-regulating the transcription factor YY1. The role of the HLJ1 in HCC cells still unclear^[70].

HLJ1 AS A MOLECULAR TARGET IN ANTICANCER THERAPIES

Curcumin (diferuloylmethane), a natural compound derived from the spice turmeric (*Curcuma longa*), has been used in the treatment of various inflammatory diseases in traditional Indian and Chinese medicine^[71]. The anticancer or chemopreventive effects of curcumin are the result of a variety of molecular mechanisms, including its direct or indirect interaction with various transcription factors, regulatory proteins and enzymes that all play a central role in key cancer-related processes such as inflammation, proliferation, survival, migration, angiogenesis, invasion and metastasis^[72,73]. Curcumin may have potential as a multi-target drug in anticancer therapy^[74-76]. Previous evidence has shown that AP-1 complexes enriched with c-Jun and JunB may result in morphologic alterations and anchorage-independent cell growth, whereas complexes enriched with JunD showed anti-proliferative effects. It has been suggested that curcumin inhibits tumour growth by inhibiting AP-1 activation^[77,78]. Curcumin increases JunD expression, stimulates HLJ1 enhancer activity, and triggers HLJ1 expression, which may subsequently reduce filopodia formation and up-regulate E-cadherin expression. Curcumin may inhibit cancer cell migration and invasion not only by inhibiting MMP2, MMP9 and MMP14 but also through HLJ1/E-cadherin induction^[23,74]. Curcumin may be a template for new antitumor drug developments that target the tumour suppressor HLJ1^[23].

Dimethyl sulfoxide (DMSO) is an amphipathic molecule that has a highly polar domain and two apolar methyl groups, making it soluble in both aqueous and organic media^[79]. DMSO is commonly used as a very efficient solvent for water-insoluble compounds in biological studies and as a cryoprotectant for cultured cells^[80]. In particular, DMSO has been approved by the United States Food and Drug Administration for the treatment of interstitial cystitis^[81]. DMSO was also used to treat leukaemia for several years, based on its ability to induce cellular differentiation, which caused leukaemia cells to lose their proliferative properties^[82,83]. DMSO has been found to arrest the cell cycle at the G1 phase in lymphoid cell lines^[84]. Additionally, DMSO treatment can modulate AP-1 activity, and DMSO is involved in the suppression of intercellular adhesion molecule 1 expression in a rat model of peritonitis sepsis^[85]. Our results suggest that DMSO is an important stimulator of the tumour suppressor protein HLJ1, and DMSO works by activating JunB and JunD in highly invasive lung adenocarcinoma^[86]. These efforts will help us to develop not only novel anticancer drugs that affect lung cancer progression but also new therapeutic strategies for the disease. For instance, a therapeutic strategy combining both induced expression of HLJ1 by DMSO-derived analogues and irradiation would synergistically increase the efficacy of radiotherapy and prolong lung cancer patient survival.

Recently, several types of herbal compounds were proven to be potential anti-cancer drugs. These com-

pounds, including curcumin from a spice turmeric^[74], epigallocatechin-3-gallate from green tea^[87] and lycopene from tomato^[88], could target important mechanisms in tumour growth and metastasis^[89]. Screening drugs from traditional Chinese medicine has been suggested as a shortcut in searching for new leading compounds. Using the HLJ1 promoter and luciferase reporter assays, the HLJ1-targeting drug-screening platform was established to screen and identify traditional Chinese herbs that can target the novel tumour suppressor gene HLJ1. Among the herbal drugs identified, the andrographolide is a promising new anticancer agent that could significantly induced HLJ1 expression and suppress tumour growth and invasion in NSCLC^[90]. Andrographolide, a diterpenoid lactone isolated from the Chinese herbal medicine *Andrographis paniculata*, is known for its wide pharmacological activities, such as its anti-inflammatory, anti-angiogenesis, pro-apoptosis and anticancer activities^[91]. Moreover, *Andrographis paniculata* has long been perceived as safe in traditional Chinese medicine as well as in the traditional medicine in Thailand and India. *Andrographis paniculata* is genotoxically safe and has been applied to clinical investigations on the treatment and prevention of upper respiratory tract infections^[92,93].

Previously, andrographolide was reported to inhibit colorectal cancer cell invasion and migration by suppressing the activity of c-Fos and c-Jun and thus reducing MMP7 expression^[94]. Andrographolide was also reported to suppress invasion and migration in lung cancer cells through attenuation of the PI3K/Akt signalling pathway^[95]. The HLJ1-targeting drug-screening platform is useful for screening novel anticancer compounds. Using this platform, we identified andrographolide as a promising new anticancer agent that could suppress tumour growth and invasion in NSCLC. The onco-suppressive effects of andrographolide may be partially mediated by JunB-regulated HLJ1 expression, which modulates the transcription factor AP-2 α binding at the MMP2 promoter and represses the expression of MMP2^[90]. In addition, silencing HLJ1 partially reverses the inhibition of cancer cell invasion by andrographolide. The results also establish the potential for using andrographolide as a multi-target lead compound in developing anti-cancer therapies.

CONCLUSION

In the past decade, improved understanding of the molecular mechanism of HLJ1 in NSCLC progression has been greatly appreciated. Accumulated data support HLJ1 as a novel tumour suppressor and a potential druggable target for NSCLC. Restoration of HLJ1 expression in NSCLC cells inhibits cell proliferation, anchorage-independent growth, cell motility, invasion, and tumourigenesis. HLJ1 can inhibit cell cycle progression by increasing the STAT1 and p21^{WAF1} pathways and by decreasing cyclin D1 expression. The activation of the STAT1 pathway by HLJ1 was independent of p53. We

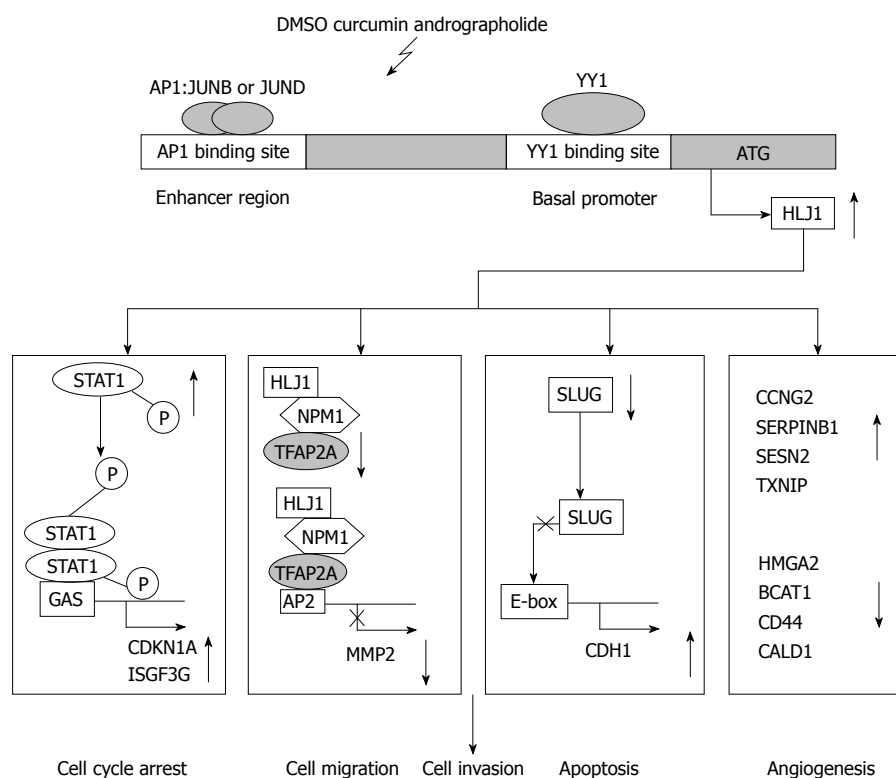

Figure 1 Schematic summary of the molecular mechanisms of HLJ1 in suppressing lung cancer tumorigenesis. The endogenous transcriptional expression of HLJ1 is the result of the binding of the transcription factors AP1 and YY1 to the gene's enhancer and promoter regions, respectively. HLJ1 inhibited lung cancer cell proliferation, anchorage-independent growth, cell motility, invasion and tumorigenesis through STAT1/p21WAF1 pathway, HLJ1/NPM1/AP2- α complex, SLUG/E-cadherin pathway and modulated cancer-related genes. DMSO: Dimethyl sulfoxide; AP1: Activating protein 1; GAS: Interferon-gamma activated sequence; CDKN1A: Cyclin-dependent kinase inhibitor 1A; YY1: Yin yang 1; STAT1: Signal transducer and activator of transcription 1; ISGF3G: Interferon-stimulated gene factor 3 gamma; NPM1: Nucleophosmin 1; TFAP2A: Transcription factor AP2 alpha; AP2: Activator protein 2; MMP2: Matrix metalloproteinase 2; SLUG: Snail homologue 2; CDH1: Cadherin 1; CCNG2: Cyclin G2; SERPINB1: Serine proteinase inhibitor B1; SESN2: Sestrin 2; TXNIP: Thioredoxin interacting protein; HMG2: High-mobility group AT-hook 2; BCAT1: Branched-chain aminotransferase 1; CALD1: Caldesmon 1; E-box: E-box transcription factor binding site.

also found that HLJ1 indirectly up-regulates E-cadherin expression through inhibiting the repression effect of the Slug gene on the E-cadherin proximal promoter. Increased HLJ1 expression is associated with prolonged disease-free and overall survival of patients with NSCLC. The endogenous transcriptional expression of HLJ1 is up-regulated through the binding of the enhancer AP-1 to its promoter YY1 with the co-activator p300 and the formation of bending DNA structure. Importantly, HLJ1 was reported to promote UV-induced apoptosis through JNK and caspase-3 activation in NSCLC. HLJ1 is a novel substrate of caspase-3 and is degraded at a late stage of apoptosis^[51]. In this review, we summarize the molecular mechanisms of the HLJ1 involved in lung cancer progression and propose a hypothetical model for the roles of HLJ1 stimulator in suppressing lung cancer tumorigenesis (Figure 1). Due to its tumour suppressor properties, HLJ1 is a potential target for anticancer therapy. Targeted induction of HLJ1 is a promising approach for cancer therapy, which also means that curcumin, DMSO, and andrographolide may serve as potential lead compounds or coordinated ligands for the development of novel anti-cancer drugs. Investigating the integrated and coordinated molecular mechanisms of HLJ1 may shed new light on the treatment of lung cancer. The develop-

ment of drug targeting HLJ1 may be an effective approach for lung cancer therapy.

Abstract

Breast cancer (BC) is the most common cancer among women worldwide. The aetiology and carcinogenesis of BC are not clearly defined, although genetic, hormonal, lifestyle and environmental risk factors have been established. The most common treatment for BC includes breast-conserving surgery followed by a standard radiotherapy (RT) regimen. However, radiation hypersensitivity and the occurrence of RT-induced toxicity in normal tissue may affect patients' treatment. The role of DNA repair in cancer has been extensively investigated, and an impaired DNA damage response may increase the risk of BC and individual radiosensitivity. Single nucleotide polymorphisms (SNPs) in DNA repair genes may alter protein function and modulate DNA repair efficiency, influencing the development of various cancers, including BC. SNPs in DNA repair genes have also been studied as potential predictive factors for the risk of RT-induced side effects. Here, we review the literature on the association between SNPs in base excision repair (BER) genes and BC risk. We focused

on X-ray repair cross complementing group 1 (*XRCC1*), which plays a key role in BER, and on 8-oxoguanine DNA glycosylase 1, apurinic/apyrimidinic endonuclease 1 and poly (ADP-ribose) polymerase-1, which encode three important BER enzymes that interact with *XRCC1*. Although no association between SNPs and radiation toxicity has been validated thus far, we also report published studies on *XRCC1* SNPs and variants in other *BER* genes and RT-induced side effects in BC patients, emphasising that large well-designed studies are needed to determine the genetic components of individual radiosensitivity.

INTRODUCTION

Female breast cancer (BC) is the most prevalent malignancy worldwide, with 5.2 million cases diagnosed between 2004 and 2008^[1], and it is the primary cause of cancer-related death among women (<http://globocan.iarc.fr>).

Breast cancer is considered a multifactorial disease, and its occurrence is related to genetic, reproductive, environmental and lifestyle factors.

Breast cancer susceptibility has a complex genetic basis, which has been widely investigated over the past 20 years. Linkage analysis and a candidate gene approach have been used to identify susceptibility loci for BC with high and moderate penetrance. Rare mutations, principally in genes involved in DNA repair such as *BRCA1*, *BRCA2*, *TP53*, *ATM*, *CHEK2*, *PALB2* and *BRIP1*, are associated with a greatly increased risk of BC^[2].

Case-control and, in recent years, genome-wide association studies (GWAS) have identified more than 70 low-penetrance common variants [single nucleotide polymorphisms (SNPs)] associated with BC risk. Although many of the associations identified in GWAS are localised in non-coding regions of the genome, which are most likely involved in gene expression regulation, some common patterns have been identified among the BC susceptibility loci. Low-penetrance BC loci are related to mammary gland development, the DNA repair pathway, growth factors, the cell cycle, differentiation and apoptosis^[3].

Common SNPs in DNA repair genes have been extensively investigated in candidate-gene and case-control association studies in the context of breast carcinoma and other types of cancer. SNPs in such genes can affect the efficiency of the DNA repair machinery and contribute to genomic instability and cancer development^[4].

Among the different DNA repair pathways, base excision repair (BER) is responsible for the repair of bases damaged by the effects of X-rays, reactive oxygen radicals and alkylating agents. Many epidemiological studies have investigated the association between common variants in BER genes and human cancer, including breast cancer^[5]. Furthermore, DNA repair genes, including BER genes, have been extensively examined in several epidemiological studies to determine their association with radiation-induced toxicity in cancer patients undergoing radiotherapy (RT)^[6]. In fact, inter-individual differences in response to therapeutic radiation exposure have been observed, and this variability may be influenced by genetic factors affecting DNA repair efficiency^[7]. The side effects induced by RT in normal tissue largely depend on the capacity of cells to repair DNA damage caused by irradiation.

Here, we survey association studies on the most common variants in BER genes, evaluating their role in BC susceptibility and in the risk of developing adverse reactions after RT.

BER PATHWAY

The BER pathway is the primary mechanism that pro-

Figure 1 Base-excision repair. Simplified schematic representation of the short-patch base-excision repair pathway showing the key steps and main proteins involved in the repair of a damaged DNA base. ducts cells from oxidative DNA damage; it acts on small DNA lesions or modified bases, where it removes and replaces the damaged base^[4]. This process starts with the release of the damaged base by base-specific DNA glycosylases (*e.g.*, the oxidised base 8-oxoguanine is excised by 8-oxoguanine DNA glycosylase), followed by the cleavage of the sugar-phosphate chain, excision of the apurinic/aprimidinic (AP) site by endonuclease action, DNA synthesis and ligation (Figure 1). This pathway is referred to as short-patch BER and results in the replacement of the AP site *via* the incorporation of a single nucleotide. In contrast, the long-patch BER pathway produces a repair tract of at least two nucleotides^[8,9].

Enzymes involved in BER include 8-oxoguanine DNA glycosylase 1 (OGG1); AP endonuclease 1 (APE1 or APEX1), which excises the abasic residue; poly (ADP-ribose) polymerase-1 (PARP-1), which binds DNA-containing strand breaks; polynucleotide kinase; DNA polymerase-β (Polβ); and DNA ligase III (LIG III), which completes the restoration phase.

Another protein that plays a central role in BER is X-ray repair cross-complementing group 1 (XRCC1), which is a scaffold protein that coordinates both the initial and late steps of abasic site restoration *via* multiple protein-protein interactions^[10]. XRCC1 stabilises OGG1 on an AP site present in double-stranded DNA until APE1 is able to bind to the DNA, allowing the transfer

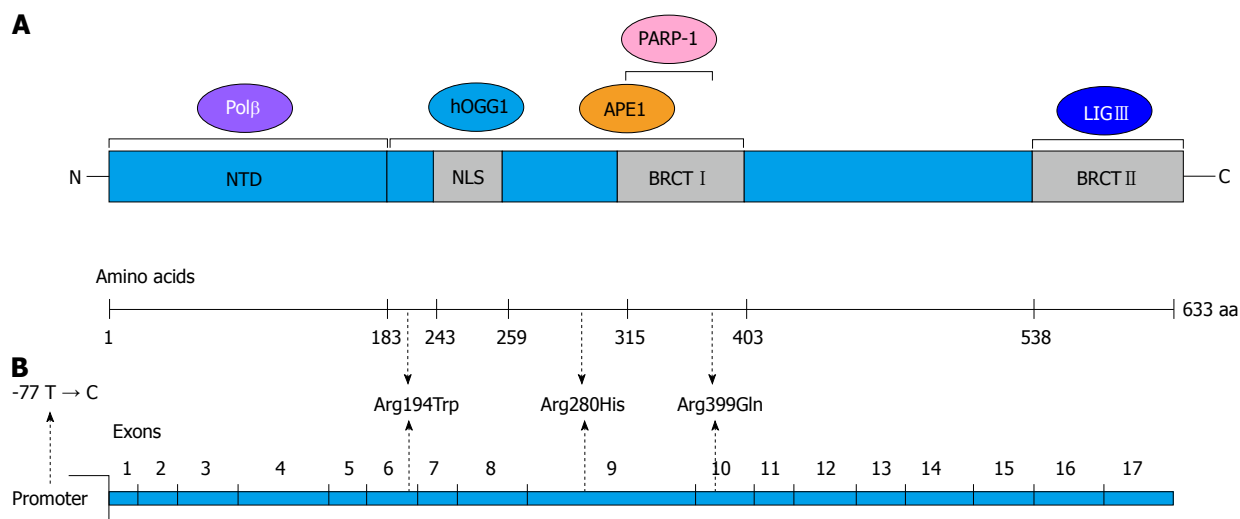

Figure 2 Domains of the X-ray repair cross-complementing group 1 protein and X-ray repair cross-complementing group 1 gene structure. of the DNA substrate from the DNA glycosylase product to the AP endonuclease. Polβ is then recruited by its interactions with APE1 and XRCC1. The binding of XRCC1 with PARP-1 also plays a role in BER. Moreover, XRCC1 is essential for the stabilisation of LIGIII.

Interactions between XRCC1 and its BER partners are mediated by different domains of the protein, which introduces the possibility that all four proteins, namely XRCC1, Polβ, PARP-1 and LIGIII, could form a single complex^[11]. Some of the interactions between BER proteins are illustrated in Figure 1.

Many polymorphisms have been identified in genes encoding proteins involved in BER and in other DNA repair pathways^[12]. In particular, many epidemiological studies have been performed to evaluate the association between XRCC1 SNPs and different types of cancer^[13].

SNPs IN BER GENES AND BREAST CANCER RISK

XRCC1 gene

The human XRCC1 gene maps to chromosome 19q13.2 and encodes a scaffold protein of 633 amino acids that plays a major role in the BER pathway and is also involved in other DNA repair mechanisms, such as single-strand break repair and non-homologous end joining. XRCC1 interacts with several BER proteins such as DNA polymerase β, APE1, OGG1, PARP-1 and LIGIII^[14]. A schematic representation of XRCC1 and its interactions is shown in Figure 2A.

Among the many SNPs found in the XRCC1 gene, three polymorphisms resulting in non-conservative amino acid substitutions have been identified: Arg194Trp (rs1799782), Arg280His (rs25489) and Arg399Gln (rs25487)^[15]. Another XRCC1 variant located in the 5'-un-

translated region (5'UTR), -77 T > C (rs3213245), was identified in 2004^[16]. The structure of the XRCC1 gene and the localisation of the most common SNPs are illustrated in Figure 2B. XRCC1 variants could affect the function of the protein and impair DNA repair efficiency. In particular, the XRCC1 Arg399Gln variant has been the subject of many case-control studies to investigate its possible association with breast cancer risk. The published data on this association, which are often contradictory, have been collected in several meta-analyses^[17-20] (Table 1). Huang *et al*^[17] showed that the Arg399Gln SNP is associated with a trend of increased breast cancer risk using both dominant and recessive models. In ethnic subgroups, and considering the recessive model, this polymorphism is associated with BC risk in Asians and Africans, although it is weakly related with breast cancer in Caucasians. The association between the Arg399Gln variant and BC risk was confirmed in Asian and African populations^[19], whereas other studies confirmed these data only among Asians^[18,20]. These findings suggest that the role of the XRCC1 Arg399Gln SNP as a risk factor for breast cancer may differ between Caucasian and Asian populations.

A very recent meta-analysis of 297 case-control studies evaluated the association between the XRCC1 Arg399Gln polymorphism and overall cancer risk^[13]; a significantly increased cancer risk was found in all genetic models. In stratified analyses by cancer type, significantly enhanced breast cancer risk was observed in Asians and particularly in Indians.

XRCC1 haplotypes

Some case-control studies assessing the association between XRCC1 haplotype and susceptibility to breast cancer were collected in a meta-analysis^[21]. Haplotypes for the most common non-synonymous XRCC1 SNPs

(Arg194Trp and Arg399Gln) were considered, and the analysis showed a slight increased risk of BC associated with the Arg194-Gln399 haplotype in comparison with the Arg194-Arg399 haplotype. In the stratified analysis according to geographic location, the Arg194-Gln399 haplotype was significantly associated with breast cancer risk among individuals from Asian countries, while no association has been found between the *XRCC1* haplotype and BC susceptibility in Caucasian populations.

Thus far, a few *XRCC1* haplotype analyses have included the -77 T > C SNP in the 5'UTR^[22-24]. Two studies^[22,24], one performed on French and the other performed on Chinese BC patients and controls, considered *XRCC1* SNPs at position -77 and at codons 194, 280 and 399. Brem *et al.*^[22] found that the haplotype carrying the variant allele at codon 280 and the wild-type (wt) alleles at the other positions was associated with an increased risk of BC, although the association was not significant. In contrast, Liu *et al.*^[24] observed a significantly higher BC risk for the haplotype containing the variant allele at position -77 and the wt alleles at other positions.

In a case-control study on Caucasian BC patients, Sterpone *et al.*^[23] performed a haplotype analysis based on *XRCC1* genotypes at position -77 and at codons 194 and 399. The haplotype containing the wt allele at position 194 and the variant alleles at other positions was significantly associated with a higher BC risk in this study.

OGG1 gene

The human *OGG1* gene is located on chromosome 3p26.2 and encodes the key enzyme in the repair of 8-oxoguanine, which is one of the most common products generated by exposure to reactive oxygen species^[25]. Among the SNPs in *OGG1*, the most studied variant is the functional substitution Ser326Cys (rs1052133), which is located in exon 7 of the *OGG1* gene and causes an amino acid change (from serine to cysteine). Comparative functional analysis *via* a complementation assay of a defective *Escherichia coli* mutant revealed that the repair activity of the 326Ser protein was higher than that of the

326Cys protein^[26]. Therefore, this *OGG1* polymorphism may result in changes in DNA repair activity in human cells.

Many studies that have highlighted the association between the *OGG1* Ser326Cys SNP and breast cancer risk have produced conflicting results. To clarify the findings, several meta-analyses have been performed (Table 2)^[27-29]. Yuan *et al.*^[27] collected data published from 2003 to 2008 and evaluated the association between the *OGG1* Ser326Cys SNP and BC onset according to menopausal status and ethnicity by performing a stratified analysis. This meta-analysis suggested that the 326Cys allele had a significant protective effect against BC in European women, both in the additive (326Cys allele *vs* 326Ser allele) and dominant (Cys/Cys + Cys/Ser *vs* Ser/Ser) genetic models. No significant association was found between this SNP and menopausal status or other ethnicities. These results were discussed by Ding *et al.*^[28], who combined all of the studies on European populations and performed a new meta-analysis, which indicated a lack of association between the *OGG1* 326Cys allele and BC risk for this ethnicity. This result was confirmed by the meta-analysis performed by Gu *et al.*^[29], who identified 11 case-control studies published from 2003 to 2009; however, they did not observe any significant association between Ser326Cys SNP and BC risk, even in the analyses stratified by ethnicity, source of controls and menopausal status. An additional case-control study not included in the aforementioned meta-analysis also showed a lack of association between the *OGG1* Ser326Cys variant and BC susceptibility^[30].

Nevertheless, a recent study in a Korean population^[31] revealed that different SNPs in BER genes (including the *OGG1* Ser326Cys and rs2072668 SNPs) function in combination to increase the risk of breast cancer. Another recent study showed that *OGG1* 326Cys was significantly associated with an increased BC risk in specific subgroups of Chinese Han women (younger than 55 years, premenopausal, triple-negative or p53-positive)^[32].

The Ser326Cys SNP was also significantly associated

Ref.	BER gene	SNPs	Number of studies analysed	Result
Yuan <i>et al</i> ^[27]	<i>OGG1</i>	Ser326Cys	10	This SNP is significantly associated with a protective effect against BC in European subjects (additive and dominant model)
Ding <i>et al</i> ^[28]	<i>OGG1</i>	Ser326Cys	4	There was a lack of association between this SNP and BC risk in a European population
Gu <i>et al</i> ^[29]	<i>OGG1</i>	Ser326Cys	11	There was a lack of association between this SNP and BC risk
Wei <i>et al</i> ^[33]	<i>OGG1</i>	Ser326Cys	12	This SNP did not have a significant effect on BC
Wu <i>et al</i> ^[35]	<i>PARP-1 (ADPRT)</i>	Val762Ala	6	There was no association between this SNP and BC (all genetic models)
Wu <i>et al</i> ^[35]	<i>APE1</i>	Asp148Glu	5	There was no association between this SNP and BC (all genetic models)

OGG1: 8-oxoguanine DNA glycosylase 1; APE1: Apurinic/apyrimidinic endonuclease 1; PARP-1: Poly (ADP-ribose) polymerase-1; SNP: Single nucleotide polymorphism; BC: Breast cancer; BER: Base excision repair; Ser: Serine; Cys: Cysteine; Val: Valine; Ala: Alanine; Asp: Aspartic acid; Glu: Glutamic acid; ADPRT: ADP ribosyl transferase.

with overall cancer risk in a more recent meta-analysis^[33], and it showed a stronger association with lung cancer risk.

Therefore, there is evidence that the *OGG1* Ser326Cys polymorphism is associated with cancer risk, and in particular that it may be a low-penetrance susceptibility factor for lung cancer. Moreover, the Ser326Cys variation could interact with other factors such as age, triple-negative status and p53-positive status, thereby influencing breast cancer carcinogenesis.

PARP-1 and APE1 genes

PARP-1, also referred to as ADP ribosyl transferase, and APE1 are two of the most important enzymes in the BER pathway.

The human *PARP-1* gene is localised to chromosome 1q41-42 and encodes a nuclear protein that specifically recognises and binds DNA strand breaks. PARP-1 also recruits other BER proteins, including the XRCC1-LIG III complex, to facilitate the core BER reaction.

APE1 initiates the restoration step of the BER pathway by hydrolysing the 5'-phosphodiester bond of the AP site^[5]. The human *APE1* gene maps to chromosome 14q12^[34].

Several studies have assessed the association between common polymorphisms (*PARP-1* Val762Ala-rs1136410 and *APE1* Asp148Glu-rs3136820) in these two BER genes and BC risk, although inconclusive results were obtained. A meta-analysis of the literature, updated to 2011, was performed to obtain a more accurate estimate of this association^[35]. In total, 8 studies were included in the meta-analysis (Table 2). No association between *PARP-1* Val762Ala and breast cancer risk was found in any of the genetic models. Additionally, there was no association between BC risk and *APE1* Asp148Glu considering all genetic models; therefore, the analysis suggests that these two polymorphisms are not associated with BC susceptibility.

Two additional papers on *APE1* SNPs and breast cancer risk were recently published^[36,31]. A case-control study performed on a Chinese population reported no association between Asp148Glu and BC susceptibility, as

indicated by the above-cited meta-analysis. In contrast, a significant association between a SNP in the *APE1* promoter (-656 T > G) and decreased BC risk was found, suggesting that this polymorphism may influence breast cancer occurrence^[36]. In a study by Kim *et al*^[31], the association between *APE1* Asp148Glu and two *OGG1* SNPs, including *OGG1* Ser326Cys, and BC risk was evaluated. Whereas *APE1* Asp148Glu was weakly associated with BC risk, a combined analysis including the two BER genes revealed a significant effect on breast cancer occurrence, suggesting the importance of assessing a combination of SNPs in different genes and gene haplotypes for the prediction of BC risk.

SNPs IN BER GENES AND RADIOSENSITIVITY

Breast-conserving surgery followed by a standard RT regimen is the most common treatment for breast cancer. However, therapeutic exposure to IR can induce adverse reactions in normal tissue. These reactions show considerable variation among individuals, suggesting the involvement of genetic factors. Because IR hypersensitivity may lead to interruption of therapy, in the last several years, significant effort has been devoted to the identification of molecular factors that could increase radiotherapy-induced side effects.

SNPs in genes involved in processes such as DNA repair, cell-cycle control, apoptosis, cellular antioxidant defence and cytokine production may influence the individual radioresponse. Several experimental approaches, such as candidate SNP association studies and GWAS, are being used to investigate the genetic basis of normal tissue radiosensitivity^[37]. Radiogenomics studies are most numerous in breast cancer patients treated with RT and are aimed at identifying SNP profiles that can be used to select radiosensitive patients. In particular, several studies on BC patients evaluating the association between the risk of acute and late skin reactions to RT and SNPs in DNA repair genes (especially *XRCC1*) were performed; however, these studies yielded conflicting results. Eleven studies on *XRCC1* SNPs, mainly involving Caucasian patients, were collected in a recent meta-analysis^[38].

Table 3 Association between X-ray repair cross-complementing group 1 single nucleotide polymorphisms and radiotherapy-induced side effects in breast cancer patients

Ref.	XRCC1 SNPs	Number of studies analysed	Result
Xie <i>et al.</i> ^[38]	Arg399Gln	8	The 399Gln variant allele is associated with a higher risk of RT-induced toxicity (only in some subgroups of BC patients)
	Arg194Trp	6	No predictive value was found for this SNP
	-77 T > C	4	No predictive value was found for this SNP
	Arg280His	4	The 280His variant allele is protective against RT-induced toxicity (in BC patients treated with RT only)

XRCC1: X-ray repair cross-complementing group 1; SNP: Single nucleotide polymorphism; RT: Radiotherapy; BC: Breast cancer; Arg: Arginine; Gln: Glutamine; Trp: Tryptophan; His: Histidine; T: Thymine; C: Cytosine.

In these studies, the severity of acute and/or late side effects of RT was assessed according to various evaluation criteria, including the Common Terminology Criteria for Adverse Events (CTCAE) (http://ctep.cancer.gov/protocolDevelopment/electronic_applications/docs/ct-caev3.pdf), the criteria proposed by the Radiation Therapy Oncology Group (RTOG) and European Organization for Research and Treatment of Cancer (EORTC)^[39], the Late Effects of Normal Tissue-Subjective Objective Management Analytical (LENT/SOMA)^[40] and the Common Toxicity Criteria of the United States National Institutes of Health (NIH) ([http://ctep.cancer.gov/protocolDevelopment/electronic_applications/docs/ctcmanual_v4_10-4-99.pdf#search="ctc"](http://ctep.cancer.gov/protocolDevelopment/electronic_applications/docs/ctcmanual_v4_10-4-99.pdf#search=)).

To evaluate acute RT side effects in BC patients, the following clinical skin reactions within the radiation field of the breast were documented during treatment: erythema, epilation, desquamation and decreased sweating in addition to more severe morbidities such as edema, ulceration, haemorrhage and necrosis. Common late radiation effects (*i.e.*, effects that first occur at least 90 d after the initiation of RT) include fibrosis, telangiectasia and atrophy.

Both early and late normal tissue reactions are graded on a 5-point ordinal scale (0 indicating absence of a radiation effect and 5 indicating an effect leading to death). The grade of toxicity induced by radiotherapy was assessed according to different evaluation criteria, with high-grade toxicity considered as grade ≥ 2 (according to CTCAE, RTOG-EORTC and LENT/SOMA) or grade $\geq 2c$ (according to the NIH).

The results of the meta-analysis by Xie *et al.*^[38] are summarised in Table 3. No significant association between the XRCC1 Arg399Gln SNP and IR-induced toxicity was observed in the overall analysis. Nevertheless, stratified analyses showed that the Arg399Gln SNP was predictive of side effects in some subgroups of BC patients. For example, carriers of the XRCC1 399Gln allele were at higher risk of RT-induced side effects in studies using high-quality genotyping methods, in studies with mixed treatment regimens or when studies on only late toxicity were excluded. On the contrary, the XRCC1 Arg280His variant allele had a protective effect against RT-induced toxicity only in BC patients treated with radiotherapy alone. XRCC1 Arg194Trp and -77 T > C did not have any

predictive value.

This analysis indicated that large well-designed studies are needed to more clearly establish the predictive value of XRCC1 variants and SNPs in other DNA repair genes for radiation-induced side effects. The choice of genotyping method and the selection of well-characterised patient cohorts should be carefully considered.

Few studies investigating the association between SNPs in other BER genes and the risk of adverse reactions to RT in BC patients are available in the literature. Concerning the APE1 Asp148Glu SNP, the 148Glu allele was found to have a protective effect against the development of acute toxicity to radiation in Caucasian BC patients; however, this effect was only observed in the normal-weight subgroup of patients^[41]. Moreover, the authors observed that the APE1 148Glu and XRCC1 399Gln alleles exerted a combined protective effect. No association between APE1 SNPs and late complications in normal tissue after radiotherapy has been identified thus far for BC^[42,43].

The association of DNA repair SNPs with late RT effects in normal tissue has also been investigated in prostate cancer patients, although the radiogenomics studies reported thus far present interpretive difficulties because of numerous confounding factors^[37]. A GWAS was recently performed to identify SNPs associated with the development of erectile dysfunction following RT for prostate cancer^[44]. Twelve candidate SNPs identified in this study were associated with cellular functions such as adhesion, signalling and hormone metabolism rather than DNA damage repair. Therefore, the involvement of DNA repair SNPs in the radioresponse after RT for prostate cancer remains an open question.

Few studies have examined patient populations with tumours other than carcinomas of the breast or prostate, although significant acute and late toxicities are frequent in patients with squamous carcinomas of the head and neck who are treated with RT. The association of DNA repair SNPs with effects on normal tissue in the head and neck and in other types of cancers should be more extensively explored^[37].

The attempts made thus far to validate the published data on genotype and radiation toxicity did not confirm a clinically relevant predictive value for any published SNP^[45]. Currently, it remains controversial whether SNPs could significantly influence the risk of complications in normal tissue^[46].

CONCLUSION

In the last decade, there has been increasing interest in identifying associations between SNPs in DNA repair genes and susceptibility to various cancers, including BC^[4,5]. In this context, BER gene polymorphisms have been extensively investigated; however, their association with BC has not been clearly defined. The Arg399Gln SNP, which is the most common variant in the *XRCC1* gene, showed an overall weak association with BC risk that became stronger only for some ethnicities. In general, SNPs may contribute to the genetic risk for BC, although their effect is usually only slightly statistically significant. In some studies, SNP-SNP interactions have been examined to evaluate epistatic effects contributing to BC^[47]. SNPs in different DNA repair pathways, or in other pathways related to DNA metabolism, were selected, and specific SNP pairs showed a statistical association with BC risk. Significant trends in BC risk were also observed in association with an increasing number of risk alleles in different DNA repair genes^[48,23]. Concerning BER genes, *XRCC1* SNPs and haplotypes play an important role because they result in amino acid substitutions, which may affect the interaction of the protein with the other BER enzymes and alter DNA repair efficiency. Studies on the interaction between SNPs in BER genes should be encouraged because although a single SNP may have a negligible effect, interactions between different SNPs in genes of the BER pathway could significantly affect cancer risk.

Studies on the interactions between SNPs in genes of different DNA damage signalling and repair pathways should also be performed. Newly available techniques, principally GWAS, will help to explain the role of moderate-risk alleles and common lower-penetrance alleles in sporadic and familial BC risk.

Furthermore, gene-environment interactions should be investigated to elucidate the complex mechanism underlying BC carcinogenesis.

Similarly, it has been demonstrated that SNPs in BER genes (particularly *APE1* and *XRCC1*) may contribute to IR hypersensitivity. Until now, no association between SNPs and late toxicity has been confirmed, either for BC or for prostate cancer^[38]. Therefore, large, well-designed studies are needed to obtain more robust results.

Although the analysis of gene polymorphisms for the individualisation of cancer therapy is not yet widespread in routine clinical practice, understanding the genetic components of individual radiosensitivity remains an important goal. To properly assess the value of pre-treatment genotyping approaches, prospective collection of genomic DNA from patients enrolled in clinical trials should be planned to develop personalised radiotherapy protocols for both sensitive and resistant patients.

The establishment of gene polymorphism databases will significantly contribute to these tasks, and meta-analyses that collect a large amount of data will permit faster access to scientific results.

Abstract

The purpose of this study was the overview of current knowledge regarding the use of survivin and its isoforms in prognosis and treatment of breast cancer. An advanced search of Medline was performed using the following search strategy: "(survivin isoforms) OR (survivin transcript variants) AND (breast cancer) AND (neoplasm OR tumor OR cancer OR carcinoma)". Relevant studies were retrieved and processed thoroughly in order to analyze the related data. Besides wild-type survivin full-length transcript, another six splice variants have been identified. Overexpression of survivin and its isoforms leads to shorter overall and disease-free survival; the transcript variants are correlated with apoptosis and could assist prognosis prediction. It has been proved through numerous studies that inhibiting survivin isoforms might become a promising target of drug therapy of carcinomas. Use of small molecule YM155 could offer new therapy for triple negative breast cancer patients, while, chemotherapy with 5-fluorouracil + epirubicin + cyclophosphamide and Tax-Epi could be guided by survivin splice variants measurements. Survivin transcript variants could become prognostic biomarkers and could provide information about clinical management

of patients suffering from breast cancer.

INTRODUCTION

Globally, breast cancer is the most common type of non-skin human malignancy and the second cause of cancer-related deaths amongst women in the Western developed World. Breast cancer is responsible for 22.9% of all new cancer cases among women worldwide and 13.7% of

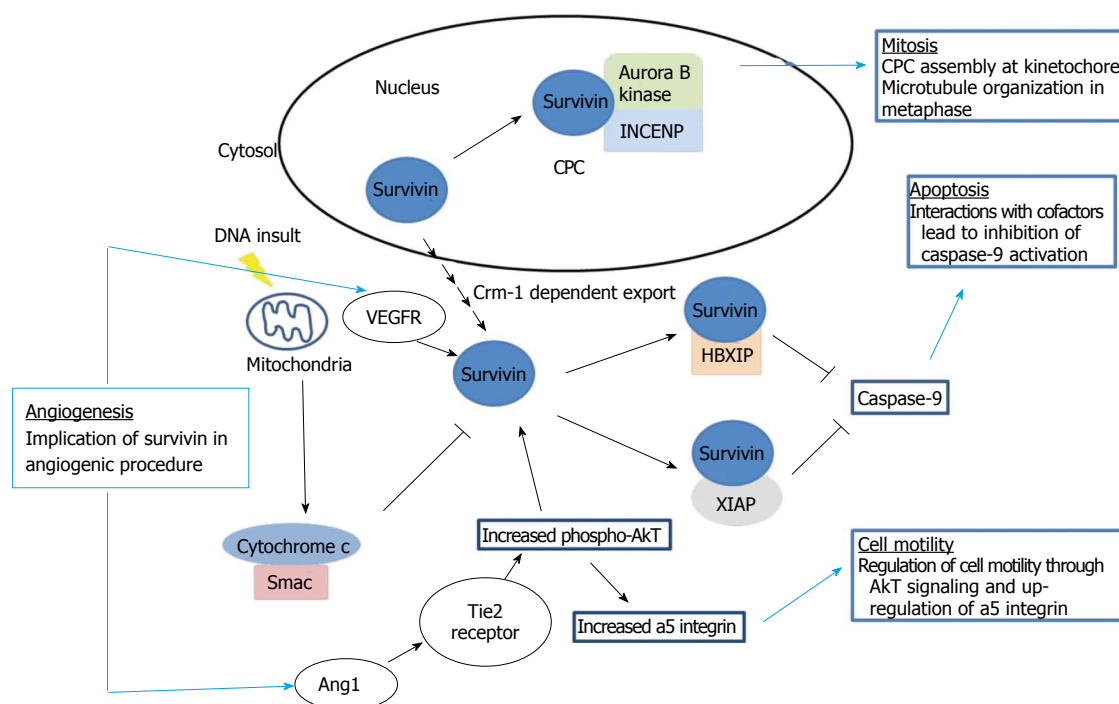

Figure 1 Survivin functions that contribute to tumor development and metastasis; chromosomal passenger complex, inner centromere protein, hepatitis B X-linked interacting protein and X-linked inhibitor of apoptosis protein, angiopoietin-1, vascular endothelial growth factor receptor, receptor tyrosine kinase 2 (modified from ref.[59]). cancer deaths^[1]. There are numerous factors associated with the occurrence of breast cancer, such as: genetic susceptibility arising from mutations in high/moderate penetrance genes (such as *BRCA1/2*, *PALB2*, *CHEK2*, *BRIP1*, *RAD50*, *NSB1* etc.)^[2-3], hormone-associated reproductive factors such as increased menstrual cycles arising from either earlier age at menarche or later age at menopause or decreased parity, older age at first birth and use of hormone therapy; consumption of alcohol and type of diet; obesity; exposure to radiation; atypical hyperplasia of the mammary gland^[4].

Inhibition of apoptosis causes tumorigenesis through cell survival resulting in accumulation of genetic mutations that lead normal tissues to transformation. Apoptosis is a tightly controlled procedure of cellular death, which is crucial for tissue homeostasis. Proteins of the bcl-2 family and the inhibitors of apoptosis (IAP) family belong to key regulators of apoptosis^[5].

The main characteristics of the IAP family are the baculovirus IAP repeat (BIR) domains and the blocking of apoptosis by inhibiting directly caspases and procaspases. Till today eight proteins of IAP family were identified, survivin corresponds to the baculoviral IAP repeat-containing 5 domain (BIRC5). Among them, survivin and XIAP have attracted the research interest as therapeutic targets for various malignancies^[6].

Survivin is the smallest member of IAP family and is a multifunctional protein, which participates in the control of apoptosis, angiogenesis and proliferation (Figure 1). Additionally, since survivin is a member of the family

of the chromosomal passenger complex (CPC) proteins, it interacts with Borealin, the Aurora B kinase and the inner centromere protein (INCENP) in order to carry out substantial roles in cell division^[7]. Recently, a critical role for survivin in the control of autophagy was also reported^[8]. Survivin, normally expressed during embryonic and fetal development, is downregulated in adult tissues and overexpressed in a variety of human cancers^[9-12]. Inhibition of apoptosis by survivin is a predictor of poor prognosis and shorter survival in patients suffering from various carcinomas^[13].

In this review, we analysed the literature data regarding the correlation of survivin isoforms with clinicopathological characteristics of breast cancer and their prognostic significance in order to explore the inclusion of survivin isoforms -besides wild-type survivin- as prognostic biomarkers in emerging multiparameter technologies examining tissue RNA expression (analogous to Oncotype, Mammaprint, PAM50^[14,15] or their clinical use in target-oriented therapies.

SURVIVIN TRANSCRIPT VARIANTS AND FUNCTIONS

The survivin gene is located on chromosome 17q25 and up to seven alternatively spliced surviving transcripts have been detected so far^[7]. Alternative splicing of precursor messenger RNA (mRNA) is a process by which the exons are connected, so they could generate different mRNAs and proteins. Alternative splicing is a

significant procedure which maintains the diversity of the genome. Over 95% of the human genes produce different splice variants which in many occasions present opposite tasks^[16]. Recently there has been evidence that differences in the splicing process can provoke myeloid cancer^[17], while comprehending this process is important in designing new therapies for cancer. One more research uncovered the fact that a common regulatory network is responsible for the simultaneous expression of a number of functionally associated splice isoforms^[18], which supports the idea that we should consider better as therapeutic targets the whole group of different transcript variants or their common regulatory network, rather than targeting on a single gene product^[19].

Except for wild type survivin full-length transcript, six other aberrant splice variants have been identified (Figure 2): (1) survivin-ΔEx3 that is created from the removal of exon 3 and also contains part of the 3' untranslated region; (2) survivin-2b that arises from the inclusion of part of intron 2 termed in this variant as “exon 2b”; (3) survivin-3b that originates from the inclusion of part of intron 3 termed in this variant as “exon 3b”; (4) survivin-2a stems from the insertions of exon 1 and 2 at the 5' end of intron 2, 197nt of intron 2 are added, of which 195nt are noncoding^[20]; (5) the recently described survivin-2b + 32 which combines intronic sequence 2b and an insertion of 32 additional nucleotides from intron 2 and therefore includes “exon 2b + 32”^[5] and finally the latest addition is (6) survivin-image (SI), which consists from a part

of the survivin gene (345 bp), a part of the image gene (155 bp) of eye cancer and another insertion of 7 bp. SI alternatively spliced isoform could be involved in other functional pathways related to tumorigenesis^[21].

The survivin variants present differential intracellular localization that possibly regulates their antiapoptotic potential. Co-expression experiments have showed that wild-type survivin can heterodimerize with its splice variants. Heterodimer formation can lead to specific subcellular localization patterns, implying that high expression in tumor cells can lead to formation of functionally distinct survivin complexes. Co-expression of wild-type survivin with survivin-ΔEx3 results in the recruitment of these complexes to the mitochondria, where they inhibit mitochondrial dependent apoptosis^[22]. The intracellular localization of survivin isoforms according to one study, depends on a Crm1-dependent nuclear export signal (NES) present in survivin, survivin-2b and survivin-3b, but absent in survivin-ΔEx3 and survivin-2a. These survivin isoforms enter the nucleus by passive diffusion since they lack an active nuclear import signal. The NES acting in consortium with an appropriate CPC formation are responsible for the cytoprotective activities of some of the survivin isoforms, as well as for their correct localization and function during cell division. Among all isoforms, only survivin-3b is cytoprotective and interacts efficiently with CPC proteins^[7].

The functions of the variants are not fully understood. Survivin-ΔEx3 has been described as an anti-apoptotic protein. Survivin-2b probably has pro-apoptotic action since it possesses a truncated BIR domain and still it dimerizes readily with wild type survivin causing the reduction of the anti-apoptotic effects of wild type survivin. Survivin-3b contains a complete BIR domain and therefore has a potential anti-apoptotic activity. Survivin-2a does not have the domain involved in inhibition of apoptosis and seems to have opposed activity to wild-type survivin.

Survivin-ΔEx3, is probably associated with cell immortality, or else remains inactive or assists angiogenesis. In the same way, survivin-2a and survivin-2b are cytoprotective, proapoptotic or sometimes they seem to be inoperative by conflicting manuscripts. Current research suggested that cancer development and survival of people suffering from tumors could be associated with the differential expression of survivin transcript variants. An explanation of this hypothesis could be that survivin variants display a trans-dominant negative (TD) phenotype enacted by the creation of silent heterodimers with survivin-wild type or by the titration of CPC proteins and/or Crm1. In conclusion, survivin-3b fulfils the molecular requirements, *i.e.*, interaction with Crm1 together with the capability to cooperate with all CPC components, demanded to perform “wt survivin-like” biological functions^[7].

It should be certainly noted that is difficult to unify all data concerning survivin variants, since results are controversial, but the accumulated information could be

Table 1 Summarized data from research articles that examined the expression of survivin transcript variants (used method is provided) accordingly to clinicopathological characteristics of patients and their survival

Ref.	Examined variants	Methods	Association with patient characteristics	Conclusion
Végran <i>et al</i> ^[22]	wt, sur2b, surΔEx3, sur3b, sur2a	Real time qPCR	Tumor grade, estrogen receptors, lymph nodes	High expression sur3b tumors had shorter OS and DFS
Span <i>et al</i> ^[23]	wt, sur2b, surΔEx3, sur3b, sur2a	Reverse transcription qPCR	Age, tumor grade, lymph nodes, steroid hormone receptors	High expression of sur2a, sur3b and wt indicate poorer prognosis

Pavlidou <i>et al</i> ^[4]	wt, sur2b, surΔEx3	Real time qPCR	Tumor grade, estrogen receptors	Sur2b/wt had significant association with estrogen receptors
Athanassiadou <i>et al</i> ^[24]	wt	Immunocytochemistry, immunohistochemistry	Grade, lymph nodes, tumor size	increased wt may indicate a worse prognosis

wt: Wild-type surviving; sur2b: Survivin-2b; surΔEx3: Survivin-ΔEx3; sur3b: Survivin-3b; sur2a: Survivin-2a; qPCR: Quantitative polymerase chain reaction; OS: Overall survival; DFS: Disease free survival.

important for designing future strategies of therapy by using specific survivin transcripts as targets.

PROGNOSTIC VALUE OF SURVIVIN TRANSCRIPT VARIANTS IN BREAST CANCER

It is possible that survivin may be of great value in the prognosis of breast cancer patients. In this part of the review, we compiled the experimental data of four studies, examining the expression of survivin transcript variants accordingly to clinicopathological characteristics of patients with breast cancer and their survival (Table 1).

In the study of Végran *et al*^[22], survivin-3b variant expression provided the major findings in patient samples, presenting with inverse correlations with ten proapoptotic genes and five anti-apoptotic genes. These results may suggest a feedback loop at the gene levels with survivin-3b and could be a way that cancer cells use in order to counteract survivin-3b overexpression. The data are in agreement with the putative anti-apoptotic role of survivin-3b suggested initially by its amino acid sequence. The results also confirm previous observations concerning the higher expression of the antiapoptotic survivin-ΔEx3 and survivin-3b in p53-mutated breast tumors. However, some studies found out that survivin-ΔEx3 expression increases with histological grade and is more expressed in ER-negative tumors. Survivin-2b isoform is overexpressed in high-grade ER-negative and node-invasive tumors. This result is not in accordance with its putative proapoptotic role but it indicates that survivin-2b could be a marker of aggressiveness. Survivin-2a -probably due to its potential pro-apoptotic role- is more present in low-grade and non-invasive tumors. Végran *et al*^[22] results revealed that survivin, survivin-ΔEx3, and survivin-2b have no prognostic role in breast carcinoma. A pro-apoptotic role for survivin-2a has been ascribed; however, in this study it was found to be associated with the worst prognosis of breast cancer patients.

Span *et al*^[23] 2006 discovered that survivin-wild type, survivin-2a, and survivin-3b were associated in patient samples with poor relapse free survival. Survivin, survivin-ΔEx3 and survivin-2a variants were associated with younger age, advanced histological grade and steroid hormone-receptor-negative tumors, all factors that indicate poor prognosis for a breast cancer patient. Tumors from patients with many involved lymph nodes had lower amounts of the proapoptotic survivin-2b variant in the primary tumor than those with a limited number of involved lymph nodes. This negative correlation with lymph node status could suggest a role for survivin-2b in counteracting the antiapoptotic and/or cell cycle stimulating role of wild-type survivin. The data in this study confirm that some of the splice variants interact with each other and modify the prognosis of the patients. Specifically, high expression of the survivin-2a and survivin-3b, in addition to survivin indicate a poorer prognosis and the prognostic value of survivin is strongest in the presence of higher concentrations of these variants^[23].

In the report of Ryan *et al*^[10], both wild-type survivin and survivin-ΔEx3 mRNA correlated moderately with apoptosis in patient samples. Levels of the survivin-2b and survivin-ΔEx3 but not wild-type survivin were significantly higher in positive lymph nodes compared to the primary tumor. A weak but significant inverse relation was found between survivin-ΔEx3 and both tumor size and number of positive lymph nodes. This form of survivin was also detected more frequently in the ductal histological type compared to the lobular one. Previously, they have reported that caspase 3 levels were also significantly higher in ductal than lobular breast cancers. These findings suggest that the regulation of apoptosis is different in these two histological types^[10].

In a previous study of ours (Pavlidou *et al*^[4]) we have reported that survivin-2b, survivin-ΔEx3 and the ratio of survivin-2b/wild-type survivin showed *in vivo* a positive correlation with the grade of the tumor in breast cancer samples ($P < 0.05$). The two isoforms presented an increased expression in advanced histopathologic grade, a

finding that was expected for survivin-ΔEx3 but not for survivin-2b due to its pro-apoptotic activity. The fact that the two isoforms are elevated in high grade tumors makes them possible markers of tumor aggressiveness. Perhaps, these two isoforms have important but opposite roles in cancer development. The ratio of survivin-2b/wild-type survivin is increased in the early stages I and II, a result which may be due to different and antagonistic functions of the two proteins. Also it was found a significant association between the ratio of survivin-2b/wild-type survivin and estrogen receptors, which further reinforces the fact that this particular variation of survivin mRNA could predict survival of breast cancer patients.

Nectins are cell adhesion molecules involved in epithelial cell physiology. Nectin-4 is a new tumor-associated antigen and a reliable biomarker for breast carcinoma. The *in vivo* association of survivin and Nectin-4 with unfavourable prognostic indicators, and with one another, suggests that these proteins may also interact in breast carcinoma in order to exert their adverse effect. In conclusion, the combined survivin and Nectin-4 expression demonstrates a strong independent association with poor prognosis^[24].

GENOMIC EXPRESSION ASSAYS AND SURVIVIN

The search for novel prognostic and predictive biomarkers could deter cancer patients from unnecessary, inadequate and toxic therapy. This effort has culminated in the availability of few -but useful-commercial standardized assays for breast cancer patients. Besides the routine immunohistochemical measurements of hormone receptors and the HER2 oncogene protein product, only one other effort looked at the protein level: the Mammostrat test (by Clariant Diagnostic Services, GE Healthcare) that assesses 5 molecules: SLC7A5, HTF9C, P53, NDRG1, and CEACAM5 by IHC^[25]. It is not known whether the addition of survivin would strengthen the value of this approach (monoclonal antibodies to survivin now exist).

The majority of the other available assays have looked at the RNA level either with microarray expression arrays or with real-time PCR (RT-PCR) assays. The technology of microarray gene expression emerged as the best method to categorize patients based on their molecular signature and distinguish those who could use other therapy strategies. Nevertheless it is not yet inducted into the clinical practice due to some restrictions^[6,26]. An FDA approved kit, Mammaprint (by Agendia Inc.) assessing the mRNA expression of 70 genes from frozen breast cancer tissues is being extensively used in order to stratify patients into two distinct groups: low risk or high risk of distant recurrence (with no intermediate results). The tumor cell percentage and an RNA integrity score are also provided. Survivin (BIRC5) was included in the genes tested in the original validation study; however it was not selected for the final 70-gene panel^[27,28].

Other commercial kits employ RT-PCR assays for

selected genes from RNA extracted from formalin-fixed paraffin-embedded tissues: (1) an 8-gene panel from Avira (now Biotheranostics Inc) combining the Breast Cancer Index HOXB13:IL17BR ratio with the Molecular Grade Index consisting of the average expression of five cell cycle-associated genes (*BUB1B*, *CENPA*, *NEK2*, *RACGAP1* and *RRM2*)^[29]; (2) the PAM 50 assay (by ARUP Laboratories) that includes wild-type survivin among the 50 selected genes^[30]; and (3) the FDA-approved Oncotype DX Breast Cancer Assay (by Genomic Health). Oncotype DX testing may aid a patient by preventing redundant chemotherapy and its connected toxicity, while reduction of chemotherapy also leads to economical changes in health systems^[31,32].

It provides breast cancer patients with a Recurrence Score (RS) (a number between 0 and 100) that corresponds to a specific likelihood of breast cancer recurrence within 10 years of the initial diagnosis. This score is based on the relative expression of 16 different cancer genes measured in triplicate) normalized relative to a set of 5 reference genes within a range 0-15. A one unit increase reflects the doubling of expression. The Recurrence Score arises from the following equation^[31]:

$$RS = + 0.47 \times \text{HER2 Group Score} - 0.34 \times \text{ER Group Score} + 1.04 \times \text{Proliferation Group Score} + 0.10 \times \text{Invasion Group Score} + 0.05 \times \text{CD68-0.08} \times \text{GSTM1} - 0.07 \times \text{BAG1}$$

As seen in Table 2, survivin is one of the cancer genes belonging to the proliferation group and it corresponds to the highest positive factor in the RS equation (1.04). A low risk of recurrence is defined of less than 18, an intermediate risk as less than 31 and a high risk as 31 and higher.

In Stemmer's *et al*^[32] 2013 article, Oncotype DX testing seems to have significant impact on minimising chemotherapy in node positive/estrogen positive (N1+/ER+) patients with breast tumor. It has been proven that Recurrence Score is correlated with tumor grade; higher Recurrence Score results are associated with higher histologic grade. Only patients belonging to the high Recurrence Score group were prescribed for chemotherapy. The differences in the proportions of patients treated with chemotherapy between the low, intermediate, and high Recurrence Score groups were statistically significant^[32]. The clinical application of Oncotype DX testing was correlated with a decrease in chemotherapy and change of treatment recommendations^[32].

In another recent study, Solin *et al*^[33] 2013 used the so-called 12-gene Oncotype DX DCIS Score, which quantifies local recurrence risk and provides risk information independent of traditional clinical and pathologic characteristics. The treatment of ductal carcinoma *in situ* (DCIS; intraductal carcinoma) of the breast is variable, with concerns about both overtreatment and undertreatment. Among those 12 genes is survivin, in the group of cancer proliferation-related genes as shown in Table 2. The DCIS Score for proliferation group, where survivin belongs, arises from the following equation:

$$\text{DCIS Score} = + 0.31 \times \text{Proliferation Group Score} -$$

Table 2 Panel of 21 genes used in oncotype DX breast cancer assay

Proliferation group	Invasion group	Estrogen group	HER2 group	Reference genes
Ki-67 ¹	ST3	ER	GRB7 (growth factor receptor-bound protein 7)	GSTM1 ¹ <i>ACTB</i> ¹
STK15 ¹	CTSL2	PR ¹	HER2 [human EGF (epidermal growth factor) receptor 2]	CD68 <i>GAPDH</i> ¹
BIRC5 (Survivin) ¹ CCNB1 ¹		Bcl2 SCUBE2 [Signal peptide CUB (complement proteins C1r/C1s, Uegf, and Bmp 1)-EGF domain-containing protein 2]		BAG1 <i>RPLPO</i> ¹ <i>GUS</i> ¹
MYBL2 ¹				<i>TFRC</i> ¹

¹Genes used in 12-gene oncotype DX for ductal carcinoma *in situ*. ER: Estrogen receptor; PR: Progesterone receptor; Bcl2: B-cell CLL/lymphoma 2; ST3: Stromelysin 3; CTSL2: Cathepsin L2; Ki-67: Kinase inhibitor; STK15: Serine/threonine kinase 15; CCNB1: Cyclin B1; MYBL2: Myeloblastosis family transcription factor-like 2; ACTB: Beta-actin; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; RPLPO: Ribosomal phosphoprotein; GUS: β -glucuronidase; TFRC: Transferrin receptor; GSTM1: Glutathione S-transferase M1 gene; CD68: CD68 molecule; BAG1: Bcl2-associated athanogene 1.

$0.08 \times \text{PR} - 0.09 \times \text{GSTM1}$.

The DCIS Score predicts the risks of invasive local recurrence and provides information that complements traditional clinicopathologic prognostic factors for women with DCIS. The differences in the risks of developing local recurrence and invasive local recurrence between patients with a lower DCIS Score and a higher DCIS Score were statistically significant and clinically meaningful^[33].

In the future, it would be very intriguing to explore the inclusion of the other survivin isoforms as prognostic biomarkers in such emerging multiparameter technologies examining tissue expression (analogous to Oncotype, Mammaprint, PAM50 *etc.*^[14-15] since it has been proved that they possess potential importance in apoptosis and proliferation of breast cancer cells, especially when compared to wild-type full-length survivin.

APPROACHES FOR TARGETING SURVIVIN ISOFORMS

A lot of studies were designed in order to find out pathways and compounds, which can interact with survivin and its isoforms, since they seem to provide promising therapeutic targets in cancer. Initially these efforts had as an obstacle the structural properties of survivin, which assigned the molecule of survivin under the label “non-druggable”. Despite the difficulties, numerous ways concerning survivin inhibition have been utilized and depend mostly on indirect mechanisms, *e.g.*, by interference with the expression of the survivin gene, its mRNA processing, the intracellular localization and the binding partners, or by affecting stability of survivin protein or by provoking survivin-specific immune responses^[34]. Research is continuing in order to deploy drugs which cooperate with survivin and restrain its operation^[34,35].

TARGETING SURVIVIN mRNA

Numerous proteins and protein complexes were recognized and are necessary for the growth and survival of cancer cells. RNA interference experiments-for example-

can reduce the production of these proteins and confirm the fact that they are crucial for tumor cells in order to survive^[34,36].

RNA-based therapeutics comprise small interfering RNA (siRNA), antisense oligonucleotides, and microRNAs (miRNAs)^[19].

Chemically-modified antisense oligonucleotides consist approximately of 20 nucleotides and their annealing to mRNA permits its cleavage by ribonuclease H. A variety of alterations in their chemical structure was achieved, like using a phosphorothioate linkage instead of natural phosphates as a backbone of nucleotides and 2'-O-methyl residues. 2'-O-methoxyethyl residues or locked nucleic acids^[19,37] were also developed in order to improve pharmacological quality and structural stability. However, the chemistry-dependent toxicities due to their structures are a significant problem expected to be solved^[19].

siRNA is another structure of a double-stranded RNA which is composed by 21-22 nucleotides. The antisense strand of the siRNA after interacting with multi-protein RNA-induced silencing complex, anneals to the complementary mRNA and an endonuclease cleaves the annealed mRNA^[19]. There is data showing that survivin is a transcriptional target of HA-CD44 signalling, therefore the specific inhibition of CD44 expression by siRNA, resulted in a specific decrease in survivin expression. This correlated with a significant loss of breast cancer cell invasiveness. Simultaneous increased expression of both CD44 and survivin was detected in late-stage metastatic breast cancer cells, expression that was absent in normal breast tissue samples^[38].

Recently, a group of small non-coding RNAs, known as microRNAs, attracted cancer researchers^[39,40]. MiRNAs are small, non-coding RNAs of 19-25 nucleotides in length that are endogenously expressed in mammalian cells. miRNAs regulate gene expression post-transcriptionally, by pairing with complementary nucleotide sequences in the 3'-UTRs of specific target mRNAs. miRNAs act either as oncogenes or as tumor suppressors. More than 50% of miRNA genes are located in cancer-associated regions of the genome. Deletion or epigenetic

silencing of a miRNA that *e.g.*, normally suppresses one or more oncogenes could cause tumorigenesis, progression and invasion, as it was showed for miR-200, miR-122 and miR-203. Survivin was recognized as direct target of miR-203 in TNBC cells. Furthermore, the fact that overexpression of miR-203 can repress proliferation and migration of TNBC cells and is escorted by a reduction in BIRC5 expression, proves that miR-203 acts as a tumor suppressor in TNBC^[41].

SECONDARY ALTERATIONS OF SURVIVIN CONTROLLING ITS SUBCELLULAR LOCALIZATION AND FUNCTION

The multiple operations of survivin in individual subcellular compartments are probably fulfilled through the domain structure of the molecule and finely regulated by secondary alterations. The modifying enzymes could also become probable targets in order to investigate how the interference with survivin functions and its specific subcellular localization may be utilized in cancer therapy^[34,42].

INTERFERENCE WITH SURVIVIN FOLDING, STABILITY, AND INTERACTION PARTNERS

Heat shock proteins (HSPs) are molecular chaperones participating in the folding and stable protein conformation. One of their tasks is to block the creation of protein complexes and usually they are over-expressed in cancer cells. Survivin is a HSP90 client protein and the association among these proteins was used to generate preventive compounds. The formation of survivin-HSP90 complex is inhibited when shepherdin is bound to HSP90. Thus, incubation of glioblastoma cells with shepherdin triggered the irreversible destruction of mitochondria and HSP90 client proteins in the cytosol and finally tumor cell death. Targeting the action of HSP90 in different subcellular compartments might contribute a lot in cancer therapy, particularly when affecting its interaction with survivin^[34].

The transcription factor GATA 1 that was found to upregulate survivin expression in breast carcinoma could be a novel target of therapy. A research group revealed that the extraction of the grape seed regulates the function of a transcription factor, which is associated with the core promoter of survivin and can finally reduce its activity^[43].

IMMUNE RESPONSE AGAINST SURVIVIN

Isolating antibodies specific for survivin peptides seems significant, as the structure and sequence of the epitope binding groove of the antibody could be examined and possibly additional epitopes are discovered. Also this study could define with accuracy the peptide portion of

the survivin protein that is bound most efficiently and most commonly by humoral antibodies generated against survivin^[19]. This will lead to more specific survivin vaccines that would elicit better immune response, generate immune memory and offer protection from tumor progression^[44]. The development of antibodies is still costing a large amount of money and there are several considerations for their use^[19,45].

Comprehending the molecular principles of cancer and the function of immune defense mechanisms guided to development of novel therapeutic strategies. The most significant immune cells against the development of the tumor are the differentiated cytolytic CD8+ lymphocytes (CTLs)^[34]. Survivin is a tumor-associated antigen so it could be a potential target for immunotherapy^[34]. During the search for immunogenic tumor antigens, spontaneous CTL responses against survivin were identified^[45]. Survivin is an attractive target for vaccination since immune escape by down regulation or loss of expression of this protein would impair sustained tumor growth. The therapeutic effectiveness is improved by the availability of multiple survivin epitopes presented by different HLA restriction elements^[45,46]. Survivin-derived epitopes have been exploited in vaccination so that CD4+ responses were initiated in prostate cancer and melanoma patients. Tumor response and patient survival were correlated with the activities of survivin specific T cells^[34].

RADIOTHERAPY AND SURVIVIN

Radiotherapy enhances apoptosis and destroys cells once and for all. Survivin mRNA expression was inversely correlated with the sensitivity to ionizing radiation^[43,47,48]. Additionally, survivin could be a radio resistance factor since its production was increased by sublethal doses of radiation^[49]. Transfer of tumor-specific adenovirus-mediated PUMA gene using the survivin promoter enhances the radiosensitivity of breast cancer cells *in vitro* and *in vivo*^[43]. Also, signal transducer and activator of transcription 3 (Stat 3) could be used as target therapy in sensitization by radiation for patients with breast carcinomas, because these two molecules influence survivin. Radiotherapeutic sensitization approach has not been widely used in all clinical trials, despite the fact that survivin inhibitors might be a new group of antagonists, which might enhance the effects of radiotherapy when survivin is over-expressed^[43,50].

CHEMOTHERAPY AND SURVIVIN

In preclinical and clinical models, a variety of experiments were performed in order to block IAPs and therefore to lead breast malignant cells to apoptosis and to decreased size even in chemoresistant tumors, reinforcing their possible future utilization as cancer therapy targets^[6].

Overexpression of survivin has been shown to restrain apoptosis and to develop multi-drug resistance (MDR)^[51]. MDR in cancer therapy is represented by

resistance to a large variety of structurally unrelated cytotoxic compounds, resulting in insufficient death of tumor cells and chemotherapeutic failure in patients with solid tumors. Both breast cancer resistance protein (BCRP, ABCG2) and apoptosis-related molecules are associated with the evolution of MDR in tumor cells^[51].

It has been shown that survivin expression is significantly higher in cell lines after treatment with anticancer drugs. High levels of HER2 or survivin are related to chemo/endocrine therapy resistance and are predicting poor clinical outcome for breast carcinomas. Moreover, it was shown that low survivin expression levels increased the sensitivity of breast cancer cells to etoposide and 5FU^[43]. Prodigiosin (a bacterial metabolite), which down-regulates survivin transcriptionally, could be used in the treatment of paclitaxel-resistant breast tumors^[43].

It seems that p53 possesses an important role in the survivin-regulated BCRP expression: through downregulation of p53 expression, survivin reduces the inhibitory action of p53 on NF- κ B (p50) and then increases the expression of BCRP. In the majority of carcinomas, overexpression of survivin and loss of wild-type p53 expression/function take place simultaneously, hence BCRP overexpression and MDR to multiple compounds such as mitoxantrone, anthracyclines, methotrexate, topoisomerase I inhibitors, gefitinib, doxorubicin (dox), and 5-fluorouracil. Consequently, suppression of survivin expression can be a novel strategy to overpower BCRP-mediated MDR in tumors^[51].

1,25(OH)₂D3 (active vitamin D3) regulates genes involved in calcium homeostasis and bone formation through its interaction with the vitamin D receptor (VDR). Vitamin D3 inhibits survivin and TP73 isoforms in colon and breast carcinomas. *In vitro* and *in vivo* approaches speculate that the downregulation of TP73 isoforms by 1,25(OH)₂D3 could be survivin-dependent^[52].

Research is still in progress in order to design new agents aiming survivin either at the genomic level or at the protein level. A prominent member of these agents is YM155 (sepantronium bromide), a tiny molecule which inhibits survivin and decreases production of survivin by binding to the C-terminal region of interleukin enhancer-binding factor 3^[19]. LY2181308 is a second-generation antisense oligonucleotide with a phosphorothioate backbone and other structural alterations targeting the translation initiation site of survivin isoforms. YM155 and LY2181308 can inhibit expression of all survivin isoforms. Recently, it was found that amiloride can regulate the mechanism of different survivin splicing^[19].

It has been shown that survivin can block apoptosis when agents such as tamoxifen, paclitaxel and trastuzumab are used. It was also shown that a reduction of apoptosis caused by tamoxifen occurs after increasing the expression of survivin. Recent research in mammary tumors proved that survivin acts downstream the human epidermal growth factor receptor-2 (Her2) and (Her3)/PI3K/Akt pathway, so it seems to be essential in moderating paclitaxel impedance when Her2 is over-expressed^[6]. An additional study showed that cells overexpressing survivin

showed no decreased viability when treated with trastuzumab, providing evidence that survivin can overcome trastuzumab-induced cell growth inhibition^[6].

Despite the fact that doxorubicin, an anthracyclic agent of chemotherapy, is extensively used in the treatment of breast cancer, the research community has little information on the role of survivin in resistance to doxorubicin^[6]. Survivin-induced overexpression does not block dox-mediated lethal effects in invasive and non-invasive breast tumor cells. In the same way, silencing survivin by siRNA, with or without blocking XIAP too, cannot provoke cytotoxic stimuli and sensitize cells. In conclusion, these data imply that survivin and XIAP expression do not affect dox resistance in breast carcinomas^[6].

It has been well documented that the downregulation of survivin by chemotherapeutic agents sensitizes cancer cells to TRAIL-induced apoptosis. Consistently, it was also found that nemadipine-A potentiates TRAIL-induced apoptosis by reducing survivin expression in lung cancer cells. Although, the precise mechanisms are not clear, it was recently reported that survivin expression could be up-regulated by cellular calcium level^[53].

Moreover, derivatives of the natural alkaloid camptothecin have the ability to provoke proteasomal degradation of survivin in cells with defective p53 function and elevated XAF1 (another tumor suppressor) expression^[54].

Also, it was reported that overexpression of survivin-3b in breast tumor cell lines strongly inhibits 5-fluorouracil + epirubicin + cyclophosphamide (FEC) toxicity, a combination used widely in breast carcinoma treatment. Recently, the cytoprotective effect of survivin-3b after cisplatin treatment was reported. These results also showed for the first time the cytoprotective effect of survivin-3b after FEC treatment in less and in more aggressive cell lines by a p53-independent manner. In addition, increased expression of survivin-3b after one course of docetaxel/epirubicin treatment was associated with reduced disease free survival (DFS) of breast cancer patients. Indeed, high survivin-3b expression tumors had a shorter overall and DFS^[23]. All these findings suggest that the role of survivin is probably therapy specific in resistance. Recently, the complete pathologic response to GAT therapy (dox on first day, paclitaxel and gemcitabine on second day, every 14 d for 6 cycles) underlined its relation with tumor markers and unveiled a reduction in survivin expression in tumors after treatment^[6]. These results suggested that the decrease of survivin expression could be associated with the response to GAT^[6].

TRIPLE NEGATIVE BREAST CANCER AND CHEMOTHERAPY ENHANCED BY SURVIVIN ISOFORMS INHIBITION

Patients with local breast cancer could be cured by surgical resection combined with adjuvant therapy, including radiation, anti-estrogen therapy and Her2-targeting agents. Unfortunately, the management of metastatic breast cancer is far less successful than treatment of lo-

Table 3 Summarized data for research articles, which correlated survivin isoforms with breast cancer treatment

Ref.	Examined variants	Methods	Approaches for inhibition of survivin variants	Conclusion
Yamanaka <i>et al.</i> ^[55]	wt, sur2b, surΔEx3, sur3b	Real time qPCR	YM155	Survivin suppressing activity of YM155 may offer novel therapeutic option in TNBC
Boidot <i>et al.</i> ^[57]	wt, sur2b, surΔEx3, sur3b, sur2a	Real time qPCR	FEC/Tax-Epi	Alternative survivin transcript expression levels may be predictive markers in FEC and Tax-Epi treatment
Zheng <i>et al.</i> ^[58]	wt, sur2b, surΔEx3	MMT, flow cytometry	Recombinant plasmids pGEM-T	Feasibility of targeting wt and surΔEx3 in treating breast cancer

wt: Wild-type surviving; sur2b: Survivin-2b; surΔEx3: Survivin-ΔEx3; sur3b: Survivin-3b; sur2a: Survivin-2a; MMT: 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; YM155: Sepantronium bromide; FEC: 5-fluorouracil + epirubicin + cyclophosphamide; Tax-Epi: Docetaxel + epirubicin; TNBC: Triple negative breast cancer.

cal disease. Metastatic cancer -despite the progress in molecular-targeted therapies- is the first cause of breast cancer death and presents a true challenge for selecting optimal treatment. Triple negative breast cancer (TNBC) is a high-risk category with negative expression of both estrogen and progesterone hormone receptors and no Her2 protein overexpression (or c-erbB2 gene amplification) that has limited therapeutic options^[2]. TNBC patients represent approximately 15% of total breast cancers. This cancer type may be very aggressive, with rapid tumor growth, a high incidence of metastasis, an increased possibility of distant recurrence and a higher mortality rate than other breast cancers. The need to develop novel therapeutic options that are suitable for this subgroup of patients is obvious^[55].

Microtubule-targeting agents, like taxanes and vinca alkaloids are one of the most common classes of chemotherapeutic drugs for the treatment of TNBC. Survivin siRNA and a dominant-negative mutant of survivin enhanced the antitumor activity of taxanes in several types of cancer. Survivin suppression by YM155 increases susceptibility to apoptosis and enhances the disruption of mitosis, resulting in an enhanced response to microtubule-targeting agents. In previous studies, it was demonstrated that tumor regression induced by YM155 in combination with docetaxel was accompanied by a decrease in intratumoral survivin and an increase in apoptosis rate. These results support the conclusion that survivin inhibition might be an effective way to enhance the efficacies of microtubule-targeting agents against TNBC^[56].

EXPERIMENTAL DATA AND TREATMENT OF BREAST CANCER

In this section of the review, we present the experimental data of three studies correlating survivin isoforms with breast cancer treatment. The group of studies examined includes the articles of Yamanaka *et al.*^[55], Boidot *et al.*^[57] and Zheng *et al.*^[58] (Table 3).

Yamanaka *et al.*^[55], by using cell lines and mouse models, underscored the need for extensive investigation of the role of YM155 in breast cancer treatment and to develop this compound as a novel therapeutic option

for metastatic breast cancer patients. YM155 downregulated both levels of survivin mRNA and protein. RT-PCR revealed that YM155 suppressed the expression of survivin-2b, survivin-ΔEx3, and survivin-3b isoforms in human TNBC cells. The decrease of survivin, which was induced by YM155, was accompanied by spontaneous apoptosis. YM155 caused tumor regression with negligible systemic toxicity as evidenced by an absence of body weight loss. Furthermore, in this study there is the first evidence that YM155 may have therapeutic value in reducing the spontaneous metastasis of human TNBC cells *in vivo*. Considering the fact that survivin is overexpressed in high grade invasive and metastatic human tumors, it is suggested that dysregulation of survivin expression may confer an ability to evade immune responses and physical barriers to invasion of normal tissues. On the contrary, breast cancer cells may remain sensitive to apoptosis induction when survivin is downregulated by YM155, even after distant metastasis has been established. Taken together, therapeutic targeting of the survivin pathway may be beneficial for the treatment of TNBC patients^[55].

In their study, Boidot *et al.*^[57] examined with a real-time quantitative PCR technique, five survivin isoforms in breast cancer patients that were using as treatment either the combination of docetaxel + epirubicin (Tax-Epi) or the combination of FEC. Before therapy, survivin-2a was considerably higher in resistant than in sensitive tumors in the FEC treatment arm, suggesting for the first time that survivin-2a may be involved in resistance to FEC treatment. This result may be consistent with the finding that survivin can heterodimerize with its splice variants causing specific subcellular localisation patterns leading to formation of the functionally distinct survivin complexes. The ratio of survivin-ΔEx3 to wild type was also higher in sensitive than in resistant tumors in the Tax-Epi treatment arm. Increased measurements of survivin-3b after only one course of chemotherapy were significantly correlated with resistance in the FEC regimen cluster, and the ratios of survivin-ΔEx3 and survivin-2b to wild type were significantly higher in sensitive than in resistant tumors in the Tax-Epi treatment arm. Especially, elevated expression and ratio of survivin-3b, after one course of Tax-Epi, showed correlation with decreased

DFS and with reduced overall survival of the patients. These results indicate that an imbalance in the alternative transcript ratios may render the cells resistant or sensitive to apoptosis. They also show for the first time that measurements of alternative survivin transcript levels may become useful predictive biomarkers in FEC and Tax-Epi treatment in breast carcinomas^[57].

During their research Zheng *et al.*^[58] 2011 created four vectors by merging (1) the antisense gene of survivin; (2) the survivin gene (T34A); (3) the antisense gene of survivin-ΔEx3; and (4) the survivin-2b gene with enhanced green fluorescent protein gene (eGFP) in cell lines. Their data suggested that using survivin as a target had great effects on blocking cell development and promoting apoptosis. Utilizing survivin-ΔEx3 as a target resulted in reducing the anti-tumor action. This study uncovered the fact that the use of survivin as a target, by antisense RNA or survivin gene (T34A), was almost in the same manner efficient in prohibiting cell development and urging cell apoptosis in breast cancer cells (B-Cap-37). The advantage of survivin (T34A) could be that the dominant negative mutant competed with survivin, thus leading to phosphorylation-defective survivin. Antisense survivin-ΔEx3 notably prohibited the proliferation and promoted the apoptosis of breast cancer cells *in vitro*. These data suggest that restraining or preventing survivin may be a major step in designing drugs for breast cancer therapy and survivin-ΔEx3 may as well become a useful target for drugs against breast carcinomas^[59].

Abstract

In the last decades, surgical treatment of breast cancer has evolved from more extensive procedures like radical mastectomy to less invasive breast conserving surgery. Similarly, surgical management of axilla has enormously changed from routine axillary dissection to sentinel lymph node biopsy. Traditional surgical approach to the axilla in case of sentinel lymph node negativity is to avoid completion axillary dissection. However, surgeons even avoid performing axillary dissection in selected patients with positive sentinel lymph node in clinical practice depending on the recent randomized controlled studies supporting this concept. All of the recent changes in the management of positive axilla necessitate surgeons to refresh their knowledge on this challenging topic.

INTRODUCTION

In the last decades, surgical treatment of breast cancer has evolved from more extensive procedures like radical mastectomy to less invasive breast conserving surgery. Similarly, surgical management of axilla has enormously changed from routine axillary dissection to sentinel lymph node biopsy (SLNB). Introduction of modern imaging modalities and the increase in public awareness about breast cancer resulted in higher number of early breast cancer cases. This achievement helped more conservative surgical methods to overwhelm classic radical procedures in clinical practice. In addition, patients' preferences towards less invasive surgery and better cosmetic outcome forced surgeons to develop new surgical techniques to satisfy the patients' desires.

Currently, axillary dissection is not performed in patients with negative SLNB. On the other hand, traditional surgical approach to the axilla in case of SLNB positivity is to perform completion axillary dissection. However, surgeons avoid performing axillary dissection in selected patients in clinical practice. In addition, recent studies suggest that application of radiotherapy including the axillary field may be an alternative to axillary dissection

in the near future. Recent changes in the management of positive axilla necessitate surgeons to refresh their knowledge on this challenging topic.

SENTINEL LYMPH NODE BIOPSY

Sentinel lymph node biopsy concept has evolved to avoid unnecessary regional lymph node dissections in most probably tumor-free lymph node regions. This technique is based on the excision and pathological examination of sentinel lymph node(s) which is assumed to be the first lymph node(s) draining the primary tumor. Sentinel lymph node biopsy was first introduced into the treatment of penile cancer and malignant melanoma and feasibility of SLNB was later proven in breast cancer^[1]. In recent years, SLNB has largely replaced axillary dissection in the surgical treatment of breast cancer patients. Morbidity observed after axillary dissection such as seroma and hematoma formation, paresthesia, pain, lymph edema, restricted arm and shoulder function decreased in 6%-30% of patients treated with SLNB. Sentinel lymph node biopsy is primarily indicated in patients with clinically and radiologically normal axilla. Sentinel lymph node biopsy is a safe and accurate procedure to detect malignant cells in regional lymph nodes. However, 5%-10% false negativity rate in breast cancer has been disputed over the years, but this rate has definitely decreased to less than 5% in experienced centers. Sentinel lymph node biopsy can be performed using a blue dye and/or radiocolloid^[2,3]. Combined method increases the accuracy of sentinel lymph node detection and decreases the false negativity rate, especially during the learning stage of the procedure. Patent blue, isosulfan blue, and methylene blue are the agents used as blue dyes. On the other hand, technetium labelled sulfur colloid and albumin are utilized as radioactive agents.

Sentinel lymph node biopsy can be performed in almost all patients with few exceptions. Presence of a clinically and radiologically suspicious lymph node in the axilla is an absolute contraindication. Ultrasound guided fine needle aspiration biopsy should be performed in such patients in order to exclude axillary lymph node metastases. After a negative biopsy result, caution must be taken during SLNB. Any macroscopic lymph nodes should be excised even though they do not take up blue dye or radiocolloid.

Although they cannot be predicted before the procedure, allergic reactions to either blue dye or radiocolloid could be another contraindication to SLNB. Any cross-reactivity between the dyes and/or radiocolloid or drugs with similar chemical structure was not reported. Preoperative use of anti-allergic drugs does not prevent anaphylactic reactions, however, may decrease the severity of allergic reaction. In addition, administration of any blue dye during pregnancy and lactation is not accepted as a safe procedure. In contrast, radiocolloids can be safely utilized during pregnancy as the calculated fetal dose is low.

Previous surgery to the breast and axilla is a relative contraindication for SLNB. Surgical diagnostic method is extremely important for breast cancer patients. Core needle biopsy, especially under radiologic guidance, is the preferred method for diagnosis. Surgical open biopsies such as incisional or excisional biopsy affect further breast conserving and axillary surgery. False negativity rates of SLNB after excisional biopsy may increase and periareolar subdermal injections of blue dye and radiocolloid instead of peritumoral injections increase the success rate of this procedure. However, previous axillary surgery definitely increases the false negativity in SLNB^[4]. When SLNB is performed in patients with previous excisional biopsy or axillary surgery, the results should be carefully assessed.

NEW DEFINITIONS IN NODAL STAGING

After the introduction of SLNB in the axillary management of breast cancer, new concepts have been introduced into the nodal staging of breast cancer^[5]. Isolated tumor cells and micrometastases were the new definitions for nodal staging in addition to macrometastases. Isolated tumor cells were defined as cell clusters less than 0.2 mm in diameter or tumor cells fewer than 200 in number. On the other hand, micrometastases refer to malignant cell clusters between 0.2-2 mm in size or cells more than 200 in number. When the size of metastases is more than 2 mm, it is called as macrometastases. Presence of isolated tumor cells in an axillary lymph node is staged as N0 whereas micrometastases and macrometastases were accepted as N1. In addition, detection method of axillary metastases affects nodal staging and determines the significance of axillary metastases. Nodal metastases detected by either immunohistochemistry or molecular methods such as polymerase chain reaction are staged as N0 (+ or mol+). Clinical significance and impact on survival of metastases detected by immunohistochemistry or polymerase chain reaction is less important compared to metastases seen on hematoxylin-eosin sections.

AXILLARY MANAGEMENT IN CASE OF SENTINEL LYMPH NODE NEGATIVITY

The histopathologic examination result of SLNB determines the surgical approach to axillary lymph node basin. Main objective of SLNB is to prove that clinically and radiologically negative axilla is actually tumor-free after histopathologic examination. Previous prospective randomized studies reported false negativity rates of < 10% with SLNB^[6]. These results encouraged the surgeons not to perform axillary dissection in cases with negative SLNB. Without axillary dissection, detected loco-regional recurrences were much less than the predicted ones in patients with long term follow-up possibly due to beneficial effects of adjuvant radiotherapy and systemic treatment. Five-year axillary recurrence rate changes be-

tween 0.5%-1.5% in patients with negative SLNB^[7-9]. Axillary recurrence rates continued to be low even after ten years^[10]. In a meta-analysis of 48 studies including 14959 patients, axillary recurrence rate was reported as 0.3% after a median follow-up time of 34 mo^[11]. According to the results of previously mentioned studies, currently, axillary dissection is not performed in patients with a negative SLNB result to avoid possible morbidity due to dissection.

AXILLARY MANAGEMENT IN CASE OF SENTINEL LYMPH NODE POSITIVITY

On the other hand, axillary lymph node dissection has been the standard of care for patients with a positive sentinel lymph node. However, a meta-analysis including 8059 patients with a positive axilla from 69 trials reported that a sentinel lymph node is the only involved node in 40%-60% of cases^[12]. Frequency of non-sentinel lymph node positivity was dependent on tumor burden in sentinel lymph node and the detection method of metastases^[12,13]. Tumor size (> 2 cm), macrometastases (> 2 mm) and extracapsular extension in sentinel lymph node, number (> 1) and ratio (> 50%) of positive sentinel lymph nodes and lymphovascular invasion determine the probability of metastases in non-sentinel lymph nodes^[14]. Thus, axillary lymph node dissection in case of a positive sentinel lymph node has been questioned in recent studies. As a result, detection of isolated tumor cells or micrometastasis in sentinel lymph nodes is not accepted as a definite indication for axillary dissection. Even in case of macrometastasis in the sentinel lymph node, axillary lymph node dissection can be avoided in selected patients according to the results of recent studies.

Studies based on breast cancer patients' information from large data bases support this trend in daily practice^[15,16]. Axillary dissection is omitted in 16.4%-20.8% of the patients with sentinel lymph node positivity^[15,16]. In retrospective studies, older age, severe comorbidities, smaller tumor size, low grade, and hormone receptor positivity were reported as the most frequent reasons for avoiding axillary dissection^[15,17]. Besides, higher number of removed sentinel lymph nodes, lower percentage of positive sentinel lymph nodes and pathologic N stage support the decision on only SLNB^[18]. In addition, surgeons feel reluctant to perform axillary dissection when metastases in the sentinel lymph nodes were identified postoperatively. Low axillary recurrence rates reported in retrospective studies encouraged the surgeons not to perform completion axillary dissection^[18-21].

Presence of metastases in the remaining axilla in only 40%-60% of patients led to the development of nomograms to predict the patients with further metastases in the axilla^[12]. However, low sensitivity, specificity, and predictive values of these nomograms raised concerns about their use in clinical practice. Since each of these nomograms was developed according to the properties of the related patient population, applicability of the results to

every patient may be misleading. Besides, all of the tumor and sentinel lymph node characteristics utilized in nomograms may be unavailable during SLNB. This might challenge the surgeon's decision to proceed with or avoid axillary dissection during surgery.

In addition, results of the recent studies questioned the necessity of completion axillary dissection after positive SLNB. Several meta-analysis reported acceptably low axillary recurrence rates without any dissection in the axilla. Sentinel lymph node positivity should be categorized according to metastatic tumor load to definitely determine the risk of axillary recurrence. Recurrence rate is expected to be different for isolated tumor cells, micrometastases, and macrometastases.

ISOLATED TUMOR CELLS/ MICROMETASTASES AND AXILLARY DISSECTION

Surgeons first started to avoid axillary dissection in patients with isolated tumor cells or micrometastasis in sentinel lymph nodes. Primarily, patients with favorable tumor characteristics such as smaller tumor size and lower grade were selected. In a meta-analysis, 30 studies including patients with positive SLNB and without completion axillary dissection were reviewed^[22]. In these studies, 3468 patients with micrometastatic disease in SLNB were included. After a median follow-up time of 42 mo, only 0.3% of the patients developed an axillary recurrence. Another study including patients from Surveillance, Epidemiology, and End Results database reported even less regional recurrence rate of 0.1% among 1767 patients with micrometastatic disease and no further axillary dissection^[16]. Bilimoria *et al*^[15] evaluating the patients in the United States National Cancer Data Base reported an axillary recurrence rate of 0.6% in 530 patients with micrometastatic disease. On the other hand, axillary recurrence rate was reported as less than 1% after completion axillary dissection which is similar to the rates without completion axillary dissection^[7,15].

These results from the evaluation of various data bases led to the planning of randomized controlled studies to test the role of axillary dissection in patients with micrometastases in sentinel lymph nodes. IBCSG 23-01 study randomized 931 patients with micrometastases to either axillary dissection or no further surgical treatment. Disease-free and overall survival results were similar in both groups after a median five year follow-up^[23]. Patients treated with breast conserving surgery received radiotherapy whereas almost all patients were treated with systemic therapy, mostly hormonal treatment, in this study^[23]. In contrast, another study evaluating patients with isolated tumor cells and micrometastases in Netherlands Cancer Registry reported a significantly higher rate of regional recurrence for patients with micrometastases and without axillary dissection^[24,25]. More regional recurrences were detected especially in patients with shorter doubling time,

grade 3 tumors, and hormone receptor negativity^[24,25]. As a result of these studies, surgeons avoid completion axillary dissection in patients with isolated tumor cells and micrometastases in sentinel lymph nodes.

MACROMETASTASES AND AXILLARY DISSECTION

A meta-analysis reviewed 16 studies including 3268 patients with macrometastases in the axillary lymph nodes without completion axillary dissection^[22]. These patients were followed-up for a median duration of 43 mo. Overall, axillary recurrence was detected in only 0.7% of the patients. Type of surgery and application of adjuvant radiotherapy were not clearly reported in the relevant studies. These retrospective data encouraged surgeons to design randomized controlled studies on this issue.

There was a need for a randomized controlled trial to demonstrate the requirement for completion axillary dissection in case of sentinel lymph node positivity. ACOSOG Z0011 trial is the only randomized controlled trial comparing completion axillary dissection following SLNB and SLNB alone in axilla positive breast cancer patients. Although the study was closed earlier than expected with less patient accrual than initially planned, the results of this study certainly changed daily surgical practice. Patients with T1/T2 tumors, treated with breast conserving surgery, and with 1 or 2 positive sentinel lymph nodes were included in the study. Six hundred patients were randomized into two groups and disease-free and overall survivals of the patients were compared. Almost all of the patients (96%-97%) received adjuvant chemo- and radiotherapy. After a median follow-up of 6.3 years, no significant difference was reported between the two groups concerning disease-free and overall survival rates^[26].

Presence of axillary metastases determines the adjuvant treatment protocols in breast cancer patients. Detection of metastases in axillary lymph nodes generally is an indication for chemotherapy. Adjuvant systemic treatment affects the axillary metastases as observed in the neoadjuvant setting. Completion axillary dissection following sentinel lymph node positivity helps better staging of the patient and may be therapeutic. In addition, presence of further metastases in the remaining axilla will change decision on systemic chemotherapy. On the other hand, information obtained after completion axillary dissection such as the number of involved lymph nodes may affect the decision on adjuvant radiotherapy. Involvement of four or more lymph nodes requires adjuvant radiotherapy to supraclavicular and infraclavicular lymph nodes. Besides, patients treated with breast conserving surgery will receive adjuvant radiotherapy to the remaining breast tissue and axilla will be involved in the tangential field. Adjuvant chemotherapy and radiotherapy definitely have a role in the low recurrence rates detected in the axilla even after sentinel lymph node positivity without further dissection.

ALTERNATIVE APPROACHES TO AXILLARY DISSECTION IN POSITIVE AXILLA

Axillary dissection is the primary method used to obtain loco-regional control in breast cancer patients. Radiotherapy could be an alternative to dissection for controlling loco-regional disease in case of sentinel lymph node positivity. Previous randomized controlled studies reported non-significant differences between axillary dissection and radiotherapy to the axilla^[27-29]. Recently, axillary dissection and radiotherapy were compared in a randomized controlled study regarding efficacy in loco-regional control and decreasing morbidity in patients with positive sentinel lymph node^[30]. Patients with tumors 0.5 to 3 cm in size and clinically negative axilla were initially treated with SLNB. Patients with positive axilla after SLNB were randomized to either axillary dissection or axillary radiotherapy. Although the final results of the study in detail were not published, two treatment modalities seemed comparable.

CONCLUSION

The pathologic status of the axilla has a diminishing effect on the choice of adjuvant treatments. Sentinel lymph node biopsy supplies the necessary information to decide on the adjuvant treatments. Recently, presence of axillary lymph node metastases is not accepted as an absolute indication for adjuvant chemotherapy in breast cancer. Patients with smaller tumor size and favorable prognostic factors such as hormone receptor positivity, low grade and Ki-67 expression, absence of lymphovascular invasion may be spared adjuvant chemotherapy. On the other hand, prognostic factors determining the indications for adjuvant radiotherapy may require information about the remaining axilla in case of sentinel lymph node positivity. Although adjuvant radiotherapy was applied to patients with 1 to 3 metastatic lymph nodes in certain cancer centers, four or more positive nodes are accepted as a widely used indication in treatment. Completion axillary dissection can provide further information about the axilla in case of positive sentinel lymph nodes to assist on the decision of adjuvant radiotherapy. However, radiotherapy to axilla may replace axillary dissection if further randomized controlled studies report equal efficacy between the two treatment modalities.

Abstract

Photodynamic therapy is a minimally invasive and clinically approved procedure for eliminating selected malignant cells with specific light activation of a photosensitizer agent. Whereas interstitial and intra-operative approaches have been investigated for the ablation of a broad range of superficial or bulky solid tumors such as breast cancer, the majority of approved photodynamic therapy protocols are for the treatment of superficial lesions of skin and luminal organs. This review article will discuss recent progress in research focused mainly on assessing the efficacies of various photosensitizers used in photodynamic therapy, as well as the combinatory strategies of various therapeutic modalities for improving treatments of parenchymal and/or stromal tissues of breast cancer solid tumors. Cytotoxic agents are used in cancer treatments for their effect on rapidly proliferating cancer cells. However, such therapeutics often lack specificity, which can lead to toxicity and undesirable side effects. Many approaches are designed to target

tumors. Selective therapies can be established by focusing on distinctive intracellular (receptors, apoptotic pathways, multidrug resistance system, nitric oxide-mediated stress) and environmental (glucose, pH) differences between tumor and healthy tissue. A rational design of effective combination regimens for breast cancer treatment involves a better understanding of the mechanisms and molecular interactions of cytotoxic agents that underlie drug resistance and sensitivity.

Key words: Photodynamic therapy; Breast cancer; Tumor microenvironment; Treatment combination; Synergism

Core tip: Breast cancer is the most common cancer in women worldwide. However, effective therapies that reduce the high mortality rate and improve patient quality of life are still unavailable. In recent years, the use of photodynamic therapy has been examined for use in breast cancer treatment. Photodynamic therapy provides a new and promising antitumor strategy that could be implemented, alone or in combination with other approved or experimental therapeutic approaches, to a wide range of applications.

Breast cancer as photodynamic therapy target: Enhanced therapeutic efficiency by overview of tumor complexity. *World J Clin Oncol* 2014; 5(5): 901-907 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/901.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.901>

PHOTODYNAMIC THERAPY ON SOLID TUMORS: FOCUS ON BREAST CANCER

Photodynamic therapy (PDT) is one of the clinically approved and minimally invasive alternate methods for

treatment of various cancers, such as bladder, esophagus, respiratory tract and gynecologic cancers. PDT eliminates tumor cells by the combined use of nontoxic photosensitizers (PS) and light^[1]. Light activation of a PS results in energy transfer cascades that ultimately yield cytotoxic reactive oxygen species, which can then render cell death^[2]. Antitumor effects of PDT derive from three interrelated mechanisms: direct cytotoxic effects on tumor cells, indirect damage to the tumor vasculature, and induction of an inflammatory response that can activate systemic immunity^[3].

The photosensitizer is considered to be a critical element. In general, for solid tumor PDT, an ideal PS should meet at least some of the following criteria: a commercially available pure chemical, low dark toxicity but strong photocytotoxicity, good selectivity towards tumor cells, longer wavelength allowing deeper light penetration, rapid removal from the body, and multiple administration routes (oral, intravenous, intratumoral or inhalational). Although some PSs satisfy all or some of these criteria, there are currently only a few PDT photosensitizers that have received official approval around the world. Photofrin (630 nm; Axcan Pharma, Inc.), Levulan (prodrug of protoporphyrin IX, 630 nm; DUSA Pharmaceuticals, Inc.), Metvix (prodrug of protoporphyrin IX, 630 nm; PhotoCure ASA), Foscan (652 nm; Biolitec AG), Laserphyrin (664 nm; Meiji Seika Kaisha, Ltd.), and Visudyne (693 nm; Novartis Pharmaceuticals). Several second generation PSs (*e.g.*, HPPH, 665 nm; SnEt2, 665 nm; LuTex, 732 nm) have been investigated in many preclinical and clinical trials for various solid tumors, and in particular SnEt2^[4,5] and LuTex^[5] are clinically applied in the United States for breast cancer^[3]. These photosensitizers show the selectivity towards tumor cells and are ideal for cellular- and vascular-targeted PDT, and interference with cytoprotective molecular responses is of growing interest. Any interactions between PDT and PDT-sensitizing agents is confined to the illuminated area, thus, eliminating any potential systemic toxicity.

The majority of approved PDT protocols are for the treatment of superficial lesions of skin and luminal organs, such as actinic keratosis and Barrett's esophagus, whereas interstitial and intra-operative approaches have been investigated for the ablation of a broad range of superficial or bulky solid tumors located in the head and neck, brain, breast, lung, gastrointestinal, and genitourinary regions^[2]. Although breast cancer is the most common cancer in women's cancer in the worldwide. The effective therapies that would not only effective in both reduce reducing the high mortality rate and associated with the disease, but also improve improving patient the quality of life patients with breast cancer are still searching for have not yet been achieved.

In recent years possibilities of PDT has recently been examined for using in breast cancer treatment, though are analyzed, and the full-potential range of potential applications alone or in combination with other approved or experimental therapeutic approaches needed to be has

yet to be explored defined.

This article reviews article will discuss recent progress in researches focused mainly on concerning the efficacy's assessing of different various photosensitizers used in photodynamic therapy PDT, as well as the combinatorial strategies of various therapeutic modalities with non-overlapping toxicities, in order to improve the therapeutic index of treatments of parenchymal and/or stromal tissues of in breast cancer solid tumors. Any interactions between PDT and PDT-sensitizing agents will be confined to the illuminated area. Therefore, the potentiated toxicity of the combinations is not systemic

PDT COMBINED WITH CONVENTIONAL BREAST CANCER THERAPIES

Most women with breast cancer undergo some type of surgery as the main strategy for tumor removal, including breast-conserving surgery or mastectomy (removal of breast). The breast can be reconstructed at the same time as the surgery or later on. Radiotherapy or systemic therapy is commonly given as adjuvant treatment after surgery^[6]. Radiotherapy involves the external (sometimes internal) application of high-energy rays (ionizing rays) to destroy cancer cells, which is typically accompanied by short-term side effects such as swelling and heaviness in the breast, sunburn-like skin changes in the treated area, and fatigue^[6]. In addition, synergistic treatments offer favorable outcomes, such as increasing the efficacy, decreasing the dosage, avoiding toxicity, and minimizing the development of drug resistance^[7].

In recent years, researchers have become increasingly interested in combining antitumor therapies in order to improve the patient outcome and to avoid, at least in part, unwanted side effects. In this context, there are reports indicating that some PSs can act as radiosensitizers^[8,9]. With regard to breast cancer, several *in vitro* studies have shown a synergism between PDT and ionizing radiation in killing cells. The combined application of nontoxic doses of indocyanine green^[10], rhodamine 123 and its platinum complex^[11], zinc phthalocyanine and meso-tetrahydroxyphenylchlorine^[12] with light proved to be very effective and resulted in a nearly complete reduction of survival. These reports suggest that treatment of tumors with a combination of PS-mediated PDT and ionizing radiation could be superior to their individual use. The interaction of PDT and ionizing radiation could enhance the therapeutic effect, thus reducing the dose of radiation dose and potential side effects.

Systemic therapy, better known as chemotherapy, is a treatment with cancer-killing drugs that are given intravenously or by mouth. The drugs travel through the bloodstream to reach cancer cells in most parts of the body. There are several situations in which chemotherapy may be recommended in breast cancer patients: after surgery (adjuvant chemotherapy), before surgery (neoadjuvant chemotherapy) or for advanced breast cancer. In most

cases (especially adjuvant and neoadjuvant treatment), chemotherapy is most effective when combinations of more than one drug are used. Although many combinations are currently being used, there is no clear indication that any particular combination is more effective. The most common chemotherapeutics used for early breast cancer include the taxanes (such as docetaxel and paclitaxel) and the anthracyclines (epirubicin and doxorubicin). These may be used in combination with other drugs, such as cyclophosphamide and fluorouracil. Platinum agents (cisplatin, carboplatin) have also been useful for treating women with breast cancer. The type and amount of drug(s), as well as the length of chemotherapy treatment, determine the extent of side effects, which include nausea and vomiting, mouth sores, easy bruising, hair loss, change in appetite, increased chance of infections, low blood cell counts, bleeding and fatigue^[6].

Recently, the effect of PDT combined with traditional chemotherapy for the treatment of breast cancer has been studied. Low doses of cisplatin *in vitro*, which are unlikely to cause severe side effects, are more effective when appropriately combined with indocyanine green-based PDT^[13]. Additionally, another *in vitro* study showed that the combination of meso-tetrahydroxyphenylchlorine-mediated PDT and the chemotherapeutic 5-fluoro-2-deoxyuridine resulted in a lower cell survival than single-mode treatment^[14]. Benzoporphyrin derivative monoacid ring A-based PDT enhanced the antitumor effects of doxorubicin on breast cancer *in vivo*, which was associated with the cooperative regulation of extrinsic apoptotic pathways and the inhibition of tumor angiogenesis^[15]. However, the mechanisms involving the interactions between chemotherapeutic drugs and PSs, as well how they can be combined to increase cell killing while reducing side effects, needs to be examined in more detail.

We recently reported that the pre-clinical chemotherapeutic drug β -lapachone interacts with methyl aminolevulinic acid-PDT in breast cancer *in vitro*. However, we also demonstrated that the application scheme of both therapies have relevance on the outcome. Synergism was observed when chemotherapy was applied 24 h after PDT, due to the photodynamic induction of NQO1, the principal determinant of β -lapachone cytotoxicity. The combination of PDT followed by β -lapachone treatment is a potentially promising modality for the treatment of cancer^[16].

When treating cancer, cytotoxic agents are intended to exert their effect on rapidly proliferating cancer cells. However, cancer therapeutics often lack specificity, which can lead to toxicity and undesirable side effects. Many approaches have been designed to target tumors. Selective therapies can be established by focusing on distinctive intracellular and environmental differences between the tumor and healthy tissue. Additionally, a strategy to treat breast cancer involves the combination of drugs. The molecular interactions with cytotoxic agents, combined with increasing knowledge of the mechanisms underlying drug resistance and sensitivity, allow for the rational de-

sign of effective combination regimens for the treatment of patients^[17]. In this sense, combinations of PDT and tumor-targeted strategies will be reviewed.

PDT AND BREAST CANCER RECEPTOR-TARGETED AGENTS

The overexpression of many receptors in breast cancer cells, such as estradiol receptors, the human epidermal growth factor receptor 2, gonadotropin-releasing hormone receptors, and tistular factor VII receptors, is strongly associated with increased disease recurrence and a poor prognosis^[18]. Thus, therapies have been developed to target removal of ligands or inhibit their activation^[6]. As these receptors represent a potential site for directing receptor-mediated cellular uptake, photodynamic researchers utilized them as vehicles to selectively deliver photosensitizing agents. Thus, the overexpression of receptors in breast cancer was harnessed synergistically with the tumor-migrating effect of several PSs to selectively deliver target molecule-PS conjugates into breast tumor cells, and preferentially kill the tumor cells upon exposure to red light^[19-32] (Table 1). Developments in these specific types of receptor-targeting approaches highlight their potential advantages in the discovery of more effective cancer photochemotherapy agents.

PDT COMBINED WITH ANTI-APOPTOTIC STRATEGIES

PDT leads to the generation of cytotoxic oxygen species that appear to stimulate several different signaling pathways, some of which lead to cell death, and some that mediate cell survival. In this context, we observed that methyl-5-aminolevulinic acid-mediated PDT resulted in overexpression of survivin^[33], a member of the inhibitor of apoptosis family that inversely correlates with patient prognosis and whose role in resistance to anti-cancer therapies is a subject of intensive investigation. We demonstrated a specific role for survivin in modulating the PDT-mediated apoptotic response. Silencing survivin expression increased apoptotic indices and cytotoxicity exhibited by PDT on metastatic breast human cancer cells. In contrast, the overexpression of survivin increased cell viability and reduced cell death. Expression of another antiapoptotic protein, Bcl-2, was suppressed by genistein, and PDT with hypericin may represent a mutual therapeutic combination favoring apoptosis^[34]. The combination of genistein and PDT may therefore achieve a higher therapeutic outcome in human breast adenocarcinoma cell lines previously identified as PDT-resistant.

PDT AND MULTIDRUG-RESISTANCE INHIBITORS

One of the principal requirements of successful PDT is sufficient intracellular accumulation of the photosensi-

Table 1 Receptor-targeted photodynamic therapy on breast cancer cells

Targeted receptor	Photosensitizer	Result	Ref.
Estradiol receptor	Tetraphenylporphyrin	High-affinity conjugate protein binding	James <i>et al</i> ^[19]
Estradiol receptor	Tetraphenylporphyrin	High-affinity conjugate cell binding	Swamy <i>et al</i> ^[20]
Estradiol receptor	Pyropheophorbide a	Conjugate-selective cell death	Fernandez Gacio <i>et al</i> ^[21]
Estradiol receptor	Pyropheophorbide a	Conjugate-selective cell death	El-Akra <i>et al</i> ^[22]
Estradiol receptor	Pyropheophorbide a	High conjugate internalization	Sadler <i>et al</i> ^[23]
Estradiol receptor	Chlorin e6-dimethyl ester	Conjugate-selective cell death	Swamy <i>et al</i> ^[24]
Human epidermal growth factor receptor	Verteporfin and pyropheophorbide a	Conjugate-selective but less phototoxic	Savellano <i>et al</i> ^[25]
Human epidermal growth factor receptor	Verteporfin and pyropheophorbide a	Conjugate-selective cell death	Bhatti <i>et al</i> ^[26]
Human epidermal growth factor receptor	Zinc phthalocyanine (plus nanoparticles)	Conjugate-selective cell death	Stuchinskaya <i>et al</i> ^[27]
Human epidermal growth factor receptor	Sn-(IV) chlorin e6 monoethylenediamine	Conjugate-selective cell death	Gijssens <i>et al</i> ^[32]
Tisular factor (factor VII receptor)	Verteporfin	Conjugate-selective cell death	Hu <i>et al</i> ^[28]
Tisular factor (factor VII receptor)	Chlorin e6	Conjugate-selective cell death	Duanmu <i>et al</i> ^[29]
Gonadotropin-releasing hormone receptor	Zinc phthalocyanine	Conjugate-selective cell death	Xu <i>et al</i> ^[30]
Gonadotropin-releasing hormone receptor	Protoporphyrin IX	Conjugate-selective cell death	Rahimipour <i>et al</i> ^[31]

tizer drug. Mechanisms of anticancer drug elimination [or multidrug-resistance (MDR)] by tumor cells are mostly linked to the elevated expression and activity of drug efflux transporters that constitute a dominant impediment to curative cancer chemotherapy. Hence, novel strategies that overcome MDR modalities are considered a major goal of cancer research. The ATP-binding cassette protein ABCG2 (breast cancer resistance protein) effluxes some of the PSs used in PDT, and thus, has been associated with photodynamic resistance. It was reported from *in vitro* and *in vivo* experiments, that the tyrosine kinase inhibitor imatinib mesylate blocked ABCG2 function and enhanced the efficacy of PDT by increasing intracellular PS levels, and may therefore enhance the efficacy and selectivity of clinical PDT on breast cancer^[35].

ABCG2 is a putative cancer stem cell marker. Cancer stem cells, also known as tumor-initiating cells, are a small group of cancer cells involved in drug resistance, metastasis, and relapse of cancers and tumor-drug resistance^[36]. Hence, it is of importance to develop PSs that are not substrates of ABCG2, or design strategies to avoid ABCG2-mediated antitumor therapy resistance^[37]. Recently, ABCG2 was implicated in a mechanism that targets and kills cancer cells with an MDR phenotype. The MDR mediates extracellular vesicles (EVs) rich in ABCG2 in attached breast cancer cells that highly concentrate chemotherapeutics, thereby sequestering them away from their intracellular targets. The authors showed that the accumulation of photosensitive cytotoxic drugs, such as imidazoacridinones (IAs) and topotecan, damaged EV membranes and resulted in tumor cell lysis. Furthermore, the accumulation of IAs in lysosomes killed MDR cells by organelle rupture upon photosensitization. Therefore, a synergistic and cytotoxic effect resulting in MDR reversal is elicited by combining targeted lysis of IA-loaded EVs and lysosomes. In contrast, a selective photocytotoxic effect exerted by topotecan is achieved by accumulation in EVs of MDR cells. Thus, MDR modalities can be converted into a pharmacological, lethal Trojan horse to selectively eradicate MDR cancer cells by ABCG2-dependent drug sequestration within EVs^[38].

PDT AND NITRIC OXIDE (NO) SCAVENGERS

Photodynamic intervention generates reactive oxygen species that can destroy tumor cells. NO produced by photosensitized cells could be pro-carcinogenic by inhibiting apoptosis. It was shown that NO from chemical donor or activated macrophages made breast tumor cells sensitized by 5-aminolevulinic acid-generated protoporphyrin IX more resistant to photo killing by providing substantial protection against apoptosis^[39,40]. Additionally, it was demonstrated that PDT-treated breast cancer cells acquired the ability to upregulate inducible-nitric oxide synthase (iNOS) expression^[41]. In this sense, apoptotic cell killing was strongly enhanced by iNOS inhibition or knockdown and a NO scavenger^[42]. These findings strongly indicate that stress-elicited NO in PDT-treated breast tumors could compromise therapeutic efficacy and suggest that NOS-based pharmacologic interventions could prevent this.

PDT AND (BREAST) TUMOR MICROENVIRONMENT (TME) INTERVENTION

The TME is a well-defined ecosystem comprised of parenchymal (tumor) and stromal (non-tumor) populations that coexist and establish interspecific interactions, which contribute to malignancy^[43]. The TME of solid neoplasias is very different from those of normal tissues. The implementation of interstitial and estimation of PDT dosimetry relies on the complexity of the solid tumor. Moreover, the TME should be studied if stromal cells affected by photodynamic regimes extinguish the tumor ecosystem by destroying their network within tumor cells. In this sense, we have recently reviewed the term “Ecological Photodynamic Therapy” to emphasize the need to modulate PDT application regimens to exploit their effect on interspecific relationships and thus achieve complete tumor eradication^[43].

Figure 1 Photodynamic therapy (PDT) combined with tumor microenvironment intervention on breast cancer. PDT is one of the alternative methods for breast cancer treatment and involves: (1) administration of a photosensitizer (PS), which is internalized into either tumor cells or surrounding vasculature; (2) local irradiation at a wavelength corresponding to the absorbance peak of the PS; and (3) light activation of the PS, which promotes cell death mainly by apoptosis. Because of the benefits of improving PDT outcome, researchers have developed strategies to target the vasculature surrounding breast tumor cells by conjugating the PS with endothelial cell (EC)-specific ligands. Immunoactivation of dendritic cells using CpG increases phagocytosis of PDT-killed tumor cells and leads to their maturation and activation, thereby promoting an antitumor immune response. Regarding abiotic environmental factors, it was shown that photodynamic therapy sensitivity is reduced in glucose-deprived cells, and that a lower extracellular pH leads to increased PS uptake, reinforcing the photodynamic response.

Endothelial cells (ECs) are the stromal population whose principal function is to supply the TME with oxygen, hormones, nutrients, circulating cells and other fluids. A mutualistic interaction has been observed between ECs and tumor cells within TME: ECs provide nutrients and tumors cells develop a paracrine stimulation to finally sustain the angiogenic endothelial process^[43]; angiogenesis refers to the growth of blood vessels from pre-existing ones^[44]. Therefore, researchers have developed strategies to target the vasculature surrounding breast tumor cells. A novel and effective ligand-targeted PDT for breast cancer was synthesized by conjugating factor VII (fVII), a natural ligand with high affinity and specificity for tisular factor, with the PSs veterporfin^[28] or chlorin e6^[29] (Figure 1). The rationale for targeting tisular factor is based on its overexpression in breast cancer and its selective expression in pathologic neovascular ECs in cancer. fVII-targeted PDT improves the selectivity and efficacy of PDT for the treatment of breast cancer and induces apoptosis and necrosis as the underlining mechanisms of action. Moreover, fVII-targeted PDT was effective and safe for treatment of chemoresistant breast tumors *in vivo*, presumably by simultaneously targeting both the tumour neovasculature and chemoresistant cancer cells^[28,29]. Strategies to favor the vascular effect of PDT by targeting tumor vasculature are constantly evaluated. Recently, PSs conjugated to a peptidase-resistant peptide that targets neuropilins overexpressed in tumor angiogenic vessels were developed. Intravenously injected peptidase-conjugated PSs selectively accumulate in vascular cells with no degradation in plasma^[45] (Figure 1). This finding provides useful information for the future design of stable, targeted molecules to improve the outcome of PDT-treatment.

Treatment with PDT alone is often non-curative due

to tumor-induced immune cell dysfunction and immune suppression. This phenomenon has motivated a new approach of combining immunostimulants with PDT to enhance anti-tumor immunity. Thus, verteporfin-mediated PDT was combined with an immunomodulation approach using CpG oligodeoxynucleotide for the treatment of metastatic breast cancer *in vivo*. CpG primes immature dendritic cells *via* toll-like receptor 9 to phagocytose PDT-killed tumor cells, leading to dendritic cell maturation and activation. Peritumoral injection of CpG after PDT in mice gave improved local tumor control and a survival advantage compared to either treatment alone (Figure 1). In conclusion, CpG may be a valuable dendritic cell-targeted immunoadjuvant to combine with PDT^[46].

With regard to the TME, in addition to the cellular or biotic factors that modulate the photodynamic response, abiotic components also have a strong influence on PDT outcome. In this sense, the effect of chronic hypoglycemia on sensitivity to aminolaevulinic acid-induced PDT *in vitro* was studied in human breast cancer cells. It was shown that photodynamic therapy sensitivity was reduced in glucose-deprived cells^[47] (Figure 1). Additionally, tumors, due to their abnormal vasculature, are characterized by a more acidic environment compared to their surrounding normal tissues. The low pH can enhance the lipophilicity of several PSs, such as hematoporphyrin IX^[48]. It has been shown that increasing the lipophilicity of a drug leads to increased tumor uptake^[48] (Figure 1). As a result, it is possible to find a concentration gradient of the drug within the breast TME between the tumor tissue and the normal surrounding tissue. By injecting glucose, it is possible to further selectively reduce the extracellular pH value of tumors^[49], and to make tumor cells more sensitive to PDT treatment^[47]. This will, in

turn, increase the pH gradient between tumor and normal tissue and finally result in an increased concentration gradient for drugs that becomes more lipophilic at low pH values. If the low tumor pH explains the selective localization of such drugs, the clinical outcome of PDT can be improved by combining it with glucose injections. It is therefore necessary to characterize the interactions and biotic and abiotic components of the TME in order to achieve the disruption of ecological networks which finally can lead to the destruction of the ecosystem.

CONCLUSION

Despite major advances in the knowledge and treatment, breast cancer remains an enormous problem in terms of morbidity and mortality. It is expected the pharmaceutical industry and research institutes will continue to launch numerous clinical trials to evaluate applications of PDT in conjunction with, or as a replacement for, traditional methods for treating solid tumors.

Abstract

Breast cancer is a leading cause of cancer death in women, worldwide. Fortunately, breast cancer is relatively chemosensitive, with recent advances leading to the development of effective therapeutic strategies, significantly increasing disease cure rate. However, disease recurrence and treatment of cases lacking therapeutic molecular targets, such as epidermal growth factor receptor 2 and hormone receptors, referred to as triple-negative breast cancers, still pose major hurdles in the treatment of breast cancer. Thus, novel therapeutic approaches to treat aggressive breast cancers are essential. Blood coagulation factor VII (fVII) is produced in the liver and secreted into the blood stream. Tissue factor (TF), the cellular receptor for fVII, is an integral membrane protein that plays key roles in the extrinsic coagulation cascade. TF is overexpressed in breast cancer tissues. The TF-fVII complex may be formed in the absence of injury, because fVII potentially exists in the tissue fluid within cancer tissues. The active form of this complex (TF-fVIIa) may stimulate the expression of numerous malignant phenotypes in breast cancer cells. Thus, the TF-fVII pathway is a potentially attractive target for breast cancer treatment. To date, a number of studies investigating the mecha-

nisms by which TF-fVII signaling contributes to breast cancer progression, have been conducted. In this review, we summarize the mechanisms controlling TF and fVII synthesis and regulation in breast cancer cells. Our current understanding of the TF-fVII pathway as a mediator of breast cancer progression will be also described. Finally, we will discuss how this knowledge can be applied to the design of future therapeutic strategies.

Key words: Breast cancer; Blood coagulation; Tissue factor; Coagulation factor VII; Gene regulation; Therapeutic strategy

Core tip: Breast cancer is a worldwide problem. Difficulties with treating the disease and its recurrence persist due, in part, to a lack of therapeutic molecular targets. Blood coagulation factor VII (fVII) is generally produced in the liver. Tissue factor (TF), the cellular receptor for fVII, is an integral membrane protein that plays key roles in the extrinsic coagulation cascade. Formation of the TF-fVII complex causes contributes to the malignant phenotype of breast cancer cells. In this review, we summarize the breast cancer biology associated with the TF-fVII pathway. Further, we will discuss how these mechanisms can be targeted as therapeutics for this aggressive disease.

Koizume S, Miyagi Y. Breast cancer phenotypes regulated by tissue factor-factor VII pathway: Possible therapeutic targets. *World J Clin Oncol* 2014; 5(5): 908-920 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/908.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.908>

INTRODUCTION

Breast cancer is a global health problem and remains a

Figure 1 Extrinsic coagulation cascade initiated by the tissue factor-coagulation factor VII pathway. TF-fVIIa complex formation on the plasma membrane triggers an extrinsic coagulation cascade in response to injury. The TF-fVIIa complex located on the cell surface initiates the coagulation cascade by activating factor X via two different (coagulation factor IX-dependent or -independent) routes. This leads to fibrin deposition via the formation of thrombin. Blood coagulation completes by clot formation with other factors, such as platelets and red blood cells. FVII: Coagulation factor VII (fVII); TF: Tissue factor.

common cause of cancer death in women, worldwide^[1]. Currently, breast cancer may be treated using multiple chemotherapeutic programs depending on the histologic and molecular classification, such as the presence of hormone (estrogen and progesterone) receptors and/or epidermal growth factor receptor 2 (referred to as ERBB2 or HER2). However, difficulties associated with treating recurrent disease and triple-negative breast cancers that lack expression of apparent therapeutic molecular targets, remain^[2,3]. Therefore, a greater understanding of breast cancer biology is essential to translate these findings into novel, therapeutic strategies to combat aggressive breast cancers.

Coagulation factor VII (fVII) is a serine protease component of the extrinsic coagulation cascade, that is primarily synthesized and secreted by hepatocytes^[4]. Tissue factor (TF) is a 47-kD cell surface glycoprotein and a cellular receptor of fVII. fVII from blood plasma, associated with TF, gives rise to the activated complex, TF-fVIIa. This triggers a downstream coagulation cascade, eventually resulting in fibrin deposition (Figure 1). Previous studies have identified a correlation between cancer and blood coagulation, known as Trousseau's syndrome^[5]. It is likely that TF-fVII signaling is a major factor underlying this syndrome, although several other molecular mechanisms are possible^[5]. Indeed, hypercoagulation is a complication commonly associated with cancer patients and potentially contributes to patient mortality^[6]. Venous thromboembolism (VTE) is frequent in ovarian, pancreatic, and liver cancers^[7], and breast cancer during chemotherapy^[8].

Previous studies have revealed that plasma TF levels are elevated in cancer patients, including those with advanced breast cancer^[9]. Furthermore, breast cancer cells can release cell membrane-derived particles (generally referred to as microvesicles) with TF under various pathological conditions, leading to the hypercoagulation^[10]. A truncated form of TF, derived from alternative mRNA splicing, may be secreted into the blood stream^[11]. Therefore, TF-fVIIa complex formation may represent a major

cause of thromboembolic events. Numerous studies have also suggested that TF-fVIIa complex formation on the cell surface also contributes to the malignant phenotypes of cancer, including an increase in cell motility, invasiveness, cell survival, and angiogenesis^[12,13]. Recently, there is growing experimental evidence to suggest that TF also contributes to tumor initiation^[13]. Therefore, therapeutic strategies targeting TF may be advantageous to breast cancer, although the possible impairment of the physiological hemostatic process should be considered.

fVII is thought to penetrate hyperpermeabilized blood vessels around the tumor tissue^[14]. fVII may also exist in the lymph^[15]. This extravascular fVII may bind to TF, which is present on the surface of cancer cells. Notably, multiple breast cancer cells have been shown to ectopically synthesize fVII^[16]. This fVII is functional^[16], suggesting that aberrantly synthesized fVII may also contribute to the malignant phenotypes of breast cancer. In this review, we summarize the recent progress in breast cancer biology associated with aberrant coagulation mechanisms. In particular, we focus on the TF-fVII pathway, among the multiple coagulation mechanisms, because breast cancer phenotypes associated with platelets and fibrinolysis have been extensively reviewed^[17]. We also describe the mechanisms underlying TF and fVII overexpression and how their functions may be regulated in breast cancer cells. Finally, we discuss potential therapeutic strategies for breast cancer based on our current knowledge of the molecular mechanisms of TF-fVII signaling.

GENERAL BIOLOGY OF TF IN BREAST CANCER CELLS

TF-fVIIa signaling regulates breast cancer phenotypes

TF exists as either full-length or truncated forms, depending on the cell type. Full-length tissue factor (referred to hereafter as TF) is a 47-kDa membrane bound protein, essential for initiation of the extrinsic coagulation cas-

Figure 2 Activation of protease-activated receptors is a major mechanism of tissue factor-coagulation factor VIIa signaling in breast cancer cells. The proteolytic activities of the TF-fVIIa binary complex [potentially (designated as dotted line) ternary complex with fXa] cleave the N-terminal end of PARs. PARs are then activated via intra-molecular binding between the newly created N-terminus and an extracellular loop region of the receptors. Activation of these G-protein-coupled receptors subsequently activates downstream signaling cascades. A number of studies have indicated that PAR2 is crucial for activation of a TF-fVII-driven signaling cascade in breast cancer cells. The role of TF-fVII on PAR1 signaling in breast cancer cells is less evident. FVII: Coagulation factor VII; TF: Tissue factor; PARs: Protease-activated receptors.

cade (Figure 1). TF is widely, but selectively expressed in normal human tissues^[18] including normal breast tissue^[19]. In contrast, TF expression is minimally expressed in the liver^[18]. Thus, upon injury, the liver may use a coagulation pathway independent of TF-fVII formation^[20]. The role of liver TF remains elusive, however, because a recent study revealed that TF expression in mouse hepatocytes significantly contributes to thrombosis during liver injury caused by drug toxicity and hepatocyte transplantation^[21].

TF tends to be overexpressed in breast cancer tissues associated with malignant phenotypes^[22]. TF was initially classified as a member of the cytokine/growth factor receptor family owing to its amino acid sequence similarity^[23,24], suggesting that it may transmit intracellular signals. Indeed, TF-fVIIa is capable of transmitting intracellular signals *via* multiple pathways, predominantly those involving the activation of protease-activated receptors (PARs) (Figure 2). To date, a number of studies have made significant advances towards our understanding of how TF-fVIIa complex formation contributes to cancer progression^[12,13,25]. Until now, many studies concerning the biology of TF-fVIIa-dependent signaling were performed using breast cancer cell lines, possibly owing to their functional dependency on TF signaling^[26-29]. Among the breast cancer cell lines, MDA-MB-231 cells are well

characterized for their high TF expression, and are frequently used as a TF-dependent breast cancer model. Indeed, previous studies have shown that *in vitro* and *in vivo* phenotypes such as motility, invasiveness, and growth of MDA-MB-231 cells are highly TF-dependent^[26-30]. Moreover, in these cells, TF has been shown to act as an angiogenic switch, leading to breast tumor development in a spontaneous breast cancer model recapitulating the human disease^[31,32].

Regulation of TF expression in breast cancer cells

In human cells, the Sp1 transcription factor is a major regulator of the *F3* gene encoding TF, under normal conditions. Transcription may be affected by the presence of multiple single nucleotide polymorphisms (SNPs) within the *F3* regulatory region and these SNPs have been previously associated with disease characteristics^[33-36]. Immunohistochemical analyses demonstrate that TF is highly expressed in breast cancer tissues, in addition to ovarian and pancreatic cancer tissues^[9,22]. Although the detailed mechanisms are not clear, transcriptional activation appears to be a major mechanism of TF overexpression.

The mechanisms regulating *F3* gene expression are well characterized^[37]. Constitutively high *F3* gene expression is controlled by multiple transcription factors (Figure 3). It is likely that the aberrant activation of these factors causes higher TF levels in breast cancer cells, given that AP-1 and NFκB are proinflammatory transcription factors which are frequently activated in breast cancer cells^[38]. Indeed, previous studies have shown that these transcription factors strongly bind to the *F3* gene promoter in MDA-MB-231 cells. However, the promoter is poorly occupied in TF low-expressing MCF-7 cells^[39].

Breast cancer progression is dependent on sex steroid hormones. It was previously shown that TF expression increases in response to progesterone exposure^[40], resulting in breast cancer phenotypes *via* a TF-dependent pathway^[41]. Furthermore, a steady state level of TF mRNA in breast cancer cells may be determined by valance of its positive and negative regulatory mechanisms as it was found that PI3K/Akt and MAPK/ERK signaling pathways inversely regulate TF transcript levels in MDA-MB-231 cells^[42].

Inducible gene expression may also account for high TF expression in cancer tissues, although such mechanisms may not necessarily apply to breast cancer cells. For example, *F3* gene expression may be regulated by exposure to various environmental stimuli including cytokines^[13], growth factors^[13], and hypoxia^[13], resulting in the activation of AP-1 and NFκB.

It is likely that the tumor microenvironment and the associated blood supply affect the expression level of TF. In addition to serum factors, *F3* expression is also influenced by oncogenic events^[43-45] (Figure 3). Recent studies have shown that these factors play an important role in the regulation of *F3* expression in glioblastoma cells^[44,45], and similar mechanisms may also exist in breast cancer cells.

Figure 3 Possible mechanisms of expression and functional regulation of tissue factor and coagulation factor VII in breast cancer cells. Schematic overview summarizing the multiple mechanisms of gene expression, functional tuning, and intracellular signaling in breast cancer cells, as described in this review. It has been suggested that breast cancer cell phenotypes associated with the TF-fVII pathway may be specifically controlled via multiple autocrine and/or paracrine mechanisms, depending on tumor microenvironmental conditions. EGFR: Epidermal growth factor receptor; EPCR: Endothelial protein C receptor; FVII: Coagulation factor VII; TF: Tissue factor.

The Egr-1 transcription factor also plays a major role in controlling TF expression^[37]. As previously discussed, Sp1 largely controls the basal activation of *F3* gene. However, Egr-1 expression may be induced in cancer cells upon various stimuli within the cellular microenvironment. Because Egr-1 and Sp1 share a common DNA binding motif, Egr-1 may subsequently displace Sp1's occupancy of the *F3* gene promoter, thereby enhancing gene expression. A similar mechanism of *F3* activation may also apply under conditions of hypoxia (Figure 3). Hypoxia inducible factors (HIFs) are the major transcription factors responsible for adaptation to hypoxic environments within cancer tissues. Interestingly, however, it appears that Egr-1 rather than HIFs, is the major cause of *F3* activation under hypoxia, at least in glioblastoma multiforme cells^[45].

Recent studies also point to a role for microRNAs in the regulation of TF expression. In one study, miR-19 was shown to bind the 3'-UTR of the TF mRNA, repressing translation in breast cancer cells^[46] (Figure 3). This study also demonstrated that miR-19 is highly expressed in a TF low-expressing breast cancer cell line, MCF-7. Thus, regulation by this microRNA can determine TF levels.

Detailed mechanisms of TF-fVIIa signaling

Mechanisms of TF-fVIIa signaling potentially giving rise to malignant phenotypes can be classified as follows. In all cases, however, the TF-fVIIa-PAR axis plays a major role in the regulation of these cancer phenotypes (Figure 2). The first mechanism involves TF-fVIIa binary complex formation. Various studies indicate that the TF-fVIIa complex activates PAR2. This active PAR2 participates in determining the breast cancer phenotype, *via* activation of the mitogen-activated protein kinase (MAPK) cascade (Figure 3)^[27,28,30].

In the second mechanism, TF-fVIIa-dependent signaling may involve coagulation factor X (fX) for signal transmission (Figure 2). The TF-fVIIa complex can produce a TF-fVIIa-fXa complex^[26,47,48]. This tertiary complex can cause breast cancer phenotypes *via* not only activating PAR2-dependent signals, but also by activating PAR1 to trigger thrombin signals^[29]. In addition to MAPK, protein kinase B (PKB/Akt) is also involved in a signaling cascade mediated by the TF-fVIIa-fXa ternary complex^[48] (Figure 3). This ternary complex may also phosphorylate mTOR to activate components downstream of this signaling cascade in breast cancer cells^[29], thereby promoting cell migration. In addition, recent studies using non-breast cancer cells demonstrated that the endothelial protein C receptor (EPCR) supports this ternary complex to transmit signals^[49] (Figure 3).

The G protein-independent signaling pathway associated with PAR2 is one candidate mechanism for TF-fVIIa signaling in breast cancer cells^[50]. Indeed, enhanced breast cancer cell motility involves the recruitment of a scaffold protein, β -arrestin, to support cellular signaling^[51,52] (Figure 3). Which TF-fVIIa signaling mechanism is eventually used by breast cancer cells likely depends on the environmental conditions within the tumor, which may induce the expression of the downstream effectors of angiogenesis^[27,53]. Previous studies have shown that connective tissue growth factors such as Cyr61^[54], CTGF^[54] and the homeodomain DNA binding protein, CUX1^[55], are up-regulated in response to TF-fVIIa stimuli, however these experiments were performed using non-breast cancer cell lines.

cDNA microarray analyses in MDA-MB-231 cells also identified various factors downstream of the TF-fVIIa-PARs axis that may contribute to different breast cancer phenotypes. These studies identified novel target genes regulated by TF-fVIIa signaling, that result in a wound-

healing type response, including the chemokine ligand (angiogenic), CXCL1^[31,56], anti-apoptotic protein, Birc3^[56] and a component of basement membrane, CSF^[56].

MODULATORS OF TF FUNCTION IN BREAST CANCER CELLS

Conformational changes modulating TF function

Functional modification is an additional post-transcriptional mechanism regulating TF activity. Multiple mechanisms can control the procoagulant activity of TF by a conformational change referred to as encryption/decryption^[57] (Figure 3). Previous studies have shown that disulfide bond isomerization by protein disulfide isomerase (PDI), controls the function of TF as a mediator of coagulation or signaling, in endothelial and keratinocyte cell lines^[58]. However, this model appears to be controversial, because recent studies using the same endothelial cell line and MDA-MB-231 cells, indicate that decryption of TF is mediated *via* its interaction with anionic phospholipids^[59]. PDI has also been shown to activate the procoagulant activity of TF *via* its molecular chaperone activity^[60]. In conclusion, it is likely that the procoagulant activity of TF is specific for the decrypted form, while encrypted TF still transmits signals.

Tissue factor pathway inhibitors: negative regulators of TF-fVIIa activity

Tissue factor pathway inhibitors (TFPIs) are known to directly inhibit the enzymatic activity of TF-fVIIa complex^[61] (Figure 3).

Tissue factor pathway inhibitors (TFPI-1 and TFPI-2) are endogenous Kunitz-type inhibitors of TF-fVIIa-Xa complex formation, and thereby negatively regulate coagulation^[61]. TFPI-1 may exist as two alternatively spliced isoforms, TFPI α and TFPI β ^[62]. TFPI α is secreted or attached to the cell membrane *via* a glycosylphosphatidylinositol anchor, whereas TFPI β may be expressed as a membrane-bound form^[62]. Both forms are primarily synthesized in endothelial cells^[63]. Various cell types including macrophages, monocytes, platelets, and fibroblasts also produce TFPI-1^[64], thereby contributing to the physiological regulation of bleeding^[65]. TFPI-2 is highly expressed in the placenta, but is also synthesized in various normal tissues, including the endothelial cells of various blood vessels^[66].

Previous studies have shown that breast cancer tissues may also synthesize TFPI-1^[67] and TFPI-2^[66], and TFPI-1 expression levels were correlated with disease malignancy. In keeping with this observation, multiple breast cancer cell lines also express TFPI α and TFPI β ^[68]. Overexpression of both TFPI-1 isoforms induces apoptosis of breast cancer cells^[69]. Downregulation of TFPI-1 increases cell motility and breast cancer cell invasiveness^[70], suggesting that TFPI-1 acts as a suppressor of breast cancer phenotypes. In contrast, TFPI-1 may augment certain malignant phenotypes, such as adhesion of bladder cancer cells^[71]

and invasiveness of breast cancer cells^[66], *via* interaction with the TF-fVIIa complex. Thus, the therapeutic value of TFPIs is unclear, even though these anti-coagulants are aberrantly expressed in breast cancer tissues. Further *in vivo* studies are therefore required to completely understand the role of TFPIs in breast cancer progression.

POTENTIAL FUNCTIONS OF TF IN BREAST CANCER PROGRESSION

Tumor cell-derived TF

To date, numerous studies have been performed aiming to uncover the role of TF-fVIIa signaling in the malignant phenotypes of breast cancer using multiple cell lines. These cell lines represent useful models, because a number of tumor-associated processes such as motility^[28,29], invasiveness^[28,29], and survival^[48] are TF dependent. MDA-MB-231 is a good model cell line for TF-dependent breast cancer as this cell line synthesizes high levels of TF. Characteristics of this cell line, such as motility and invasiveness, are highly TF dependent *in vitro*^[26-28]. Furthermore, the growth of xenograft tumors derived from MDA-MB-231 cells is dependent on TF activity and subsequent PAR2 activation *in vivo*^[30]. This finding was supported by a PyMT mouse model characterized by spontaneous breast cancer development^[31]. These findings are also consistent with earlier studies using colorectal cancer cells, which revealed that TF does not contribute to cell proliferation *in vitro*^[43]. This suggests that host-tumor interactions are essential for the expression of a malignant phenotype in TF-driven breast cancer.

Another potential contributor of TF-driven breast tumor progression is EPCR (Figure 3). As previously discussed, EPCR can regulate TF-fVIIa signaling, and the importance of EPCR in breast cancer progression was recently demonstrated using both human xenograft^[72] and spontaneous murine breast tumor development^[73,74] models. Accumulating evidence indicates that TF largely contributes to the metastatic potential of breast cancer cells, and a recent study demonstrated that PAR1 signaling in both tumor and host cells is essential for TF-dependent lung metastasis of breast cancer cells^[74].

Breast cancer phenotypes regulated by TF-fVIIa complex formation are predominantly dependent on PAR2-dependent signals. However, PAR1 signaling may function to augment breast cancer cell invasiveness and tumorigenesis^[29,75-77], irrespective of TF dependency. PAR1 is a receptor of thrombin highly synthesized in metastatic breast cancer cells. Indeed, treatment of breast cancer cells with thrombin increases their PAR1-dependent invasiveness. PAR1 may also act as a receptor for matrix metalloproteinase-1, which is released from stromal cells within cancer tissues, and is capable of enhancing MDA-MB-231 cell invasiveness and tumorigenesis^[77]. Thus, the function of PAR1 and PAR2 signaling associated with breast cancer progression may vary, according to the cellular microenvironment and relative expression levels.

Exogenous TF

Expression of TF is not limited to tumor parenchyma cells, but is also expressed in the tumor stroma, where it promotes breast cancer metastasis^[78]. It was shown that transforming growth factor β released from cancer cells, may stimulate stromal cells to secrete TF, leading to the promotion of breast cancer progression in a paracrine manner^[78].

Exogenously synthesized TF in patients may affect a number of breast cancer cell characteristics. It was revealed that a paracrine effect of TF can influence the growth and metastasis of breast cancer cells^[79]. Treatment of cells with recombinant TF, mimicking stromal-derived TF (Figure 3), enhances the invasive and proliferative properties of these cells. This occurs *via* activation of β 1-integrins and/or PAR2-dependent signals, followed by inactivation of transcription of the estrogen receptor (ER) gene^[79] (Figure 3). The involvement of integrins in TF-driven phenotype expressions of breast cancer cells is similar to the findings that association of TF integrated into plasma membrane of keratinocytes and breast cancer cells bind integrins and may support growth of breast tumor^[30]. Furthermore, because ER positivity determines clinically distinct groups of breast cancer patients, ER gene regulation *via* TF signaling may affect the selection of therapeutic strategies used to treat breast cancer patients.

Previous studies reveal that TF expression within the stromal area of breast cancer tissues is due to production from immune cells^[80]. TF levels were closely associated with extravascular fibrin deposition and VEGF expression levels, suggesting that stromal-derived TF contributes to the angiogenic phenotype of breast cancer.

Truncated forms of TF

In addition to full-length TF, alternatively spliced, truncated forms of TF (asTF) also exist in humans^[81]. Recently, it was reported that asTF is highly expressed in breast cancer cells and contributes to the malignant phenotype^[82]. Similar to TF, asTF binds to integrins and therefore exists on the cell surface (Figure 3). However, the asTF-integrin complex augments cell proliferation, migration and anchorage-independent cell growth in a PAR2-independent manner^[82]. These results are in contrast to an earlier report that demonstrated that the growth of breast tumors derived from MDA-MB-231 cells is dependent on PAR2 signaling, downstream of membrane-integrated TF^[30]. It is possible that the distinct binding characteristics of these two TF isoforms underlie such differences.

TF EXPRESSION IN BREAST CANCER PATIENTS

TF as a serum component of breast cancer patients

In addition to asTF, breast cancer cells may also shed TF into the bloodstream as a component of microparticles (MPs), derived from plasma membrane in response to multiple stimuli^[83,84] (Figure 3). Thus, it is likely that these

TF-positive MPs contribute to plasma TF levels associated with clinical parameters^[9]. Indeed, TF-positive MPs may be secreted from human breast tumors in a mouse xenograft model, resulting in a coagulation-prone status^[10]. However, previous studies indicate that the risk of thrombosis during chemotherapy is independent of TF plasma levels in breast cancer patients, who display high levels of TF^[8,85]. Therefore, to date, it is not clear how, and to what extent, plasma TF derived from breast cancer cells, contributes to breast cancer malignancy. Conversely, a recent study demonstrated that circulating tumor cells (CTCs) of breast cancer patients may be detected by labeling cell surface TF^[86], suggesting that TF may be used as a diagnostic tool for breast cancer patients.

TF expression and its association with breast cancer patient clinical outcome

Activation of platelets^[8] and elevated plasma TF levels^[10] may be determinants of the thrombotic events observed in cancer patients. Indeed, VTE post-chemotherapy is a major event in breast cancer patients, prompting an investigation into the relationship between hemostatic markers and thrombosis^[8]. These studies revealed that plasma TF levels in patients were significantly elevated compared with those of non-cancerous individuals. However, TF levels did not increase during chemotherapy, indicating that chemotherapy-associated VTE does not correlate with TF, and more likely associated with neutrophil extracellular traps composed of cell free nucleic acids and neutrophils^[87].

TF is highly synthesized in breast cancer tissues as revealed by the analysis of clinical samples. In addition, TF is synthesized in the vascular endothelial cells of invasive breast cancer tissues. Thus, TF may be a marker for angiogenic phenotypes in patients^[22]. In addition to its expression in breast cancer tissues, TF levels are also increased in the plasma of breast cancer patients^[9]. Plasma TF levels were not significantly different between normal and benign tumors. However, TF levels were significantly higher in primary and recurrent cancer patients^[9]. Notably, this pattern of TF expression correlated with that observed in cancer tissues. The urine TF levels were also associated with poor prognosis of breast cancer^[88]. Taken together, these results suggest that the analysis of plasma and urine TF levels may be used to stratify patients into personalized treatment regimes.

Although the molecular mechanisms of the TF-driven breast cancer phenotypes may be explained by the various cellular events associated with the TF-fVIIa signaling cascade, recent studies indicate that post-translational modifications affecting TF expression also play an important role. Immunohistochemical analyses of breast cancer xenografts and clinical samples reveal that phosphorylation of TF (Figure 3) is correlated with the recurrence and aggressive phenotypes of breast cancer^[89]. It was found that the phosphorylation of TF in association with PAR2 expression correlates with breast cancer recurrence^[89]. In addition, *in vivo* studies using TF

cytoplasmic domain-deleted mice revealed interplay between the TF cytoplasmic domain and PAR2 signaling, to promote breast cancer by modulating the host angiogenic response^[32]. These studies provide a mechanism for the observed clinical association between TF phosphorylation and PAR2 signaling.

ECTOPIC EXPRESSION OF FVII IN BREAST CANCER CELLS

Constitutive expression

Similar to TF, the transcriptional regulation of human *FVII* has been extensively studied^[90-92]. In contrast to TF, biosynthesis of fVII in the mammalian body is limited. The primary site of fVII production is liver. Previous studies demonstrate that the human *FVII* gene promoter is typically bound by HNF-4 and Sp1 transcription factors, and is therefore highly activated in liver cells. The efficiency of *FVII* gene expression may be affected by genetic alterations, including SNPs and decanucleotide insertion^[93], as in the case of the *F3* gene. However, unlike *F3*, it appears that binding sites for inflammatory transcription factors such as NFκB and AP-1, do not exist within the *FVII* promoter region. Instead, the activity of *FVII* may be regulated in response to hormones such as estrogen^[94] and insulin^[95]. Plasma fVII levels are also known to associate with plasma lipid concentration^[96,97]. In addition to the liver, fVII may also be synthesized in monocytes and macrophages^[98,99], although the mechanisms of *FVII* regulation in these non-hepatocytic cells remains unknown.

fVII is primarily synthesized in the liver. However, various cancer cells may ectopically express fVII^[16]. Notably, multiple breast cancer cell lines constitutively synthesize high levels of the fVII transcript^[16]. Cancer cells with fVII expression exhibit pro-coagulant activity as TF-fVIIa complex is formed on the cell surface, suggesting that aberrantly synthesized fVII may be functionally active and contribute to breast cancer progression. Indeed, fVII expression is frequently observed in breast cancer specimens^[100].

Given the high expression of fVII in breast cancer cells and tissues, the molecular mechanisms of *FVII* activation were subsequently investigated using breast cancer cells. Binding of HNF-4 to the *FVII* promoter was shown to be essential for eutopic transcriptional activation. However, HNF-4 is not expressed in breast cancer cells^[100], suggesting that other factors are responsible for ectopic activation of *FVII*. Reporter gene assays revealed that reporter activity is fully activated by the authentic *FVII* promoter region in breast cancer cells^[100]. As expected, the HNF-4 binding site is dispensable for ectopic *FVII* gene expression in breast cancer cells. Further reporter assays revealed that an Sp1 binding site within the *FVII* promoter region is crucial for ectopic *FVII* gene expression. This study further demonstrated that the transcriptional regulators, USF-1 and Egr-1, also regulate ectopic expression of *FVII* in breast cancer cells^[100] (Fig-

ure 3).

Histone acetylation of gene promoters also plays a crucial role in the regulation of gene transcription, prompting analysis of such epigenetic modifications at the *FVII* gene promoter. These studies revealed that the histone acetyltransferases (HATs), p300 and CBP, predominantly occupy the *FVII* promoter region in breast cancer cells^[100]. In contrast, PCAF and SRC-1 HATs were also involved in the regulation of hepatocytic *FVII* expression^[100]. Thus, p300 and CBP may predominantly acetylate histones within the *FVII* promoter region, followed by accession of transcription factors responsible for transcriptional regulation in breast cancer cells. Conversely, various HATs may be responsible for eutopic *FVII* regulation.

Inducible expression under hypoxia

FVII transcription is inducible in ovarian cancer cells under hypoxic and hypoxia mimetic (CoCl₂ treatment) conditions^[16]. To date, the expression of fVII transcripts in response to hypoxia have been tested in several breast cancer cell lines^[100,101]. These studies revealed that fVII transcript levels are not enhanced in response to hypoxic stimuli in breast cancer cell lines with high fVII expression^[100]. Conversely, fVII mRNA levels were inducible in the breast cancer cell line, MDA-MB-468 under CoCl₂ stimuli^[101], suggesting a cell-type dependent induction of fVII.

The detailed mechanisms controlling *FVII* induction under hypoxic conditions were recently defined using ovarian cancer cell lines^[102], although it is not clear to what extent these mechanisms are applicable to breast cancer cells. These studies revealed that physical interaction between Sp1 and hypoxia inducible factor-2α (HIF2) may contribute to *FVII* activation in ovarian cancer cells, although HIF1 also indirectly affects *FVII* expression (Figure 3). This indicates that the promoter region occupied by HIF2 is devoid of a hypoxia response element (HRE)^[16,102], suggesting that HRE-independent mechanisms are responsible for *FVII* activation under hypoxic conditions. Indeed, chromatin immunoprecipitation analysis with MDA-MB-468 cells revealed that HIF2 predominantly associates with the *FVII* promoter region^[101], as in the case of ovarian cancer cells^[16]. Furthermore, this mechanism was synergistically induced following simultaneous exposure of ovarian cancer cells to hypoxic conditions and serum deprivation, *via* a HDAC4 (a class II histone deacetylase)-dependent pathway^[102]. These results suggest that the TF-fVII pathway is controlled by a stress-responsive, transcriptional mechanism, mediated by an HIF2/Sp1/HDAC4 network.

Exogenously supplied fVII vs autonomously produced fVII: Are there any functional differences?

Cell surface-bound TF binds fVII, irrespective of its source (eutopic or ectopic synthesis), raising the question of whether the TF-fVIIa complex functions differently depending on the source of fVII. Previous studies have

shown that the plasma concentration of fVII is quite low^[4]. Therefore, we can envision that self-production of fVII may facilitate TF-fVII complex formation compared with exogenously expressed fVII. This may be particularly important in hypoxic cancer microenvironments, where the supply of fVII from the bloodstream is likely limited because of poor and aberrant vasculature. In addition, it was recently described that ectopically synthesized fVII can augment the growth of breast cancer cells^[101]. This is an unexpected result as it had previously been observed that TF does not contribute to cell proliferation under *in vitro* cell culture conditions^[43]. Indeed, this study demonstrated that proliferation of breast cancer cells with high TF expression was not enhanced by exogenous supply of fVII^[101]. To date, however, the mechanisms regulating differential cell growth between cells exposed to exogenously supplied fVII and ectopically synthesized fVII remain unclear. Our knowledge concerning other functional differences in cancer cells associated with differential routes of fVII supply is currently poor; however, this represents an interesting field for future study.

TF-FVIIa SIGNALING AS A THERAPEUTIC TARGET

Potential therapeutic strategies targeting TF-fVIIa signaling

To date, several attempts have been made to inhibit TF-fVIIa activity associated with breast cancer *in vitro* and *in vivo*. One simple method used to block TF-fVIIa activity involves treatment with anti-TF antibodies. The use of monoclonal antibodies has been successfully used in breast cancer therapy to target cell surface HER2, and therefore represents a promising strategy^[103]. However, the major concern of this strategy is that blocking TF-fVIIa may also impair normal hemostasis, causing bleeding^[30]. Previous studies have shown that growth and lung metastasis of orthotopically transplanted MDA-MB-231 cells is profoundly suppressed by successive administration of the humanized anti-TF antibody, CNTO859^[104]. In this murine model, the CNTO859 antibody binds to human TF but not rodent TF, and therefore does not preclude normal hemostatic processes. However, the effect of this antibody in humans remains unclear. Similarly, a recent study demonstrated that the tick protein, Ixolaris, binds predominantly to the TF-fVIIa-fX ternary complex, thereby inhibiting downstream signaling involving PAR2 activation and suppressing tumor growth derived from MDA-MB-231mfp cells^[105]. However, this protein is unable to suppress the growth of murine breast cancer tumors, because Ixolaris does not bind the murine TF-fVIIa complex^[105].

One strategy to overcome the negative effects of TF-targeting antibodies on normal hemostasis is to use an antibody specifically inhibiting TF-fVIIa signaling. To date, we have identified a mouse monoclonal antibody, TF10H10, that fulfils this purpose^[30]. Similar to the CNTO859 antibody, growth of xenograft tumors

derived from MDA-MB-231 cells was shown to be effectively inhibited following treatment of cancer cells with a TF10H10 antibody prior to inoculation of mice^[30].

Inhibition of TF at the transcriptional level represents another strategy to target TF-fVIIa activity. As previously discussed, TF levels are transcriptionally controlled by various transcription factors regulating constitutive and inducible expression. Overexpression and/or functional activation of transcription factors such as Egr-1, NFκB, and AP-1 may be involved in this process. Previous studies have shown that curcumin, a major component of turmeric spice can inhibit binding of these transcription factors to gene promoter regions required for cell survival and invasion activities^[106]. Indeed, several studies showed that expression of the *F3* gene may be inhibited by this natural pigment in endothelial cells^[107,108] and monocytes^[109]. Thus, pharmaceutical inhibition by curcumin may suppress aberrant expression of TF in breast cancer cells.

Finally, there have been various attempts to combat breast cancer by targeting TF on the cell surface by increasing target selectivity. In these studies, fVII was conjugated with photosensitizers^[110,111], and the effect of this fusion fVII on tumor growth was monitored following injection into mice. Strikingly, tumor volume derived from breast cancer cells was markedly decreased in response to irradiation, compared with negative controls using non-fused fVII. This is likely because of the accumulation of photosensitizing drugs in tumor tissues with high TF expression. A similar approach was tested using fVIIa conjugated to a synthetic curcumin analog instead of photosensitizers^[112]. fVIIa successfully delivered curcumin to target breast tumor cells, thereby reducing toxicity and enhancing therapeutic efficacy.

Another interesting approach that may be harnessed to enhance tumor selectivity is the use of prodrugs that can be activated within the tumor microenvironment in a TF-dependent manner^[113]. In this study, doxorubicin-based prodrugs conjugated with albumin were used to treat tumors in a murine breast cancer model. These prodrugs penetrated tumor tissues and were predominantly activated by TF-fVIIa activity, because TF is highly expressed on the surface of cancer cells, leading to efficient suppression of breast cancer. Taken together, these studies demonstrate that increasing tumor selectivity of pharmaceutical compounds by targeting TF represents a promising strategy for cancer therapy, although careful control of dosage is necessary to prevent side effects, such as bleeding.

Possible strategies to inhibit ectopic fVII expression

Ectopic expression of fVII contributes to several breast cancer phenotypes *in vitro*. Thus, in addition to targeting TF expression, inhibition of fVII expression may also represent a potentially valuable therapeutic strategy. Importantly, the success of this strategy would rely on the selective inhibition of ectopic fVII, without inhibiting function of ectopically produced fVII in the liver.

Ectopic activation of the *FVII* promoter in breast cancer cells is associated with binding by p300 and CBP, while the *FVII* promoter in hepatocytes is occupied by various HATs, suggesting that targeting p300/CBP activities may selectively inhibit *FVII* expression in breast cancer cells^[100]. Curcumin is also capable of blocking the HAT activity of p300/CBP compared with other HATs. Indeed, curcumin markedly reduced fVII transcript levels in breast cancer cells in a dose-dependent manner, while normal expression of *FVII* in hepatic cells was only weakly impaired^[100]. Levels of constitutively expressed TF mRNA were not significantly diminished by curcumin treatment in these cells, consistent with the notion that curcumin specifically inhibits inducible TF expression. Furthermore, anacardic acid, another natural, small compound inhibitor of p300 and PCAF, did not selectively inhibit ectopic *FVII* expression, highlighting the specificity of curcumin for p300/CBP activity^[100]. The effect of curcumin on *FVII* expression was subsequently confirmed at the protein level. In contrast, HAT activity associated with the *FVII* promoter in hepatocytes, including p300 and CBP, is heterogeneous. It should be noted however, that selective inhibition of ectopic fVII synthesis was demonstrated using a limited number of cell lines. Therefore hepatocytic fVII synthesis may be considerably impaired by curcumin if p300/CBP is a component of the transcriptional machinery regulating the *FVII* gene in hepatocytes.

SUMMARY AND PERSPECTIVES

In this review, we describe various therapeutic strategies based on our current understanding of breast cancer biology associated with the TF-fVII pathway. The TF-fVIIa pathway in breast cancer cells may be regulated *via* multiple molecular mechanisms (summarized in Figure 3), enabling us to envisage a number of possible therapeutic strategies. Indeed, accumulating evidence suggests that TF is a promising target in breast cancer. Many breast cancer cell lines constitutively and perhaps inducibly express fVII. Given that TF-fVIIa signaling is a major mechanism underlying breast cancer-associated malignant phenotypes, strategies targeting ectopic fVII expression may also be considered in future therapeutic designs. How ectopic fVII expression affects breast cancer progression *in vivo*, however, remains an important question. Previous studies have shown that curcumin selectively inhibits ectopic fVII synthesis by removing p300/CBP from the *FVII* promoter region. Furthermore, animal studies have shown that curcumin can cure cardiovascular diseases^[114,115] and cancer^[116] by targeting p300 activity. Therefore, anti-p300 strategies using curcumin may be clinically applicable, without posing significant toxicity. Based on this, it may be of interest to investigate anti-p300/CBP strategies in fVII-expressing breast cancer models. It should be noted however, that anti-p300/CBP strategies may be compromised because HATs can also be targeted to the hepatocytic *FVII* promoter. The iden-

tification of novel molecular targets, specifically associated with ectopic fVII synthesis in breast cancer cells is therefore critical.

From a clinical point of view, the identification of relationships between fVII expression and various clinical parameters, such as chemoresistance, relapse, and overall survival, is essential to predict which patients may benefit from anti-TF-fVIIa treatment. Finally, many issues concerning the biology of ectopic fVII synthesis in breast cancer cells remain unresolved. Why do breast cancer cells tend to synthesize more fVII compared with other cancer cells? How does ectopically expressed fVII associate with TF to express the TF-fVIIa complex on the cell surface? It will be intriguing to investigate whether ectopically expressed fVII is equivalent to ectopically expressed fVII. A more detailed understanding of how ectopic fVII expression is regulated, and how it can contribute to breast cancer biology, is essential for translating our current knowledge to anti-breast cancer strategies.

Abstract

Cervical cancer is the third most common cancer in women worldwide; definitive radiation therapy and concurrent chemotherapy is the accepted standard of care for patients with node positive or locally advanced tumors > 4 cm. Brachytherapy is an important part of definitive radiotherapy shown to improve overall survival. While results for two-dimensional X-ray based brachytherapy have been good in terms of local control especially for early stage disease, unexplained toxicities and treatment failures remain. Improvements in brachytherapy planning have more recently paved the way for three-dimensional image-based brachytherapy with volumetric optimization which increases tumor control, reduces toxicity, and helps predict outcomes. Advantages of image-based brachytherapy include: improved tumor coverage (especially for large volume disease), decreased dose to critical organs (especially for small cervix), confirmation of applicator placement, and accounting for sigmoid colon dose. A number of modalities for image-based brachytherapy have emerged including: magnetic resonance imaging (MRI), computed tomography (CT), CT-MRI hybrid, and ultrasound with respective benefits and outcomes data. For

practical application of image-based brachytherapy the Groupe Europeen de Curietherapie-European Society for Therapeutic Radiology and Oncology Working Group and American Brachytherapy Society working group guideline serve as invaluable tools, additionally here-in we outline our institutional clinical integration of these guidelines. While the body of literature supporting image-based brachytherapy continues to evolve a number of uncertainties and challenges remain including: applicator reconstruction, increasing resource/cost demands, mobile four-dimensional targets and organs-at-risk, and accurate contouring of "grey zones" to avoid marginal miss. Ongoing studies, including the prospective EM-BRACE (an international study of MRI-guided brachytherapy in locally advanced cervical cancer) trial, along with continued improvements in imaging, contouring, quality assurance, physics, and brachytherapy delivery promise to perpetuate the advancement of image-based brachytherapy to optimize outcomes for cervical cancer patients.

Key words: Cervical cancer; Brachytherapy; Image-based brachytherapy; 3D-planning; Magnetic resonance imaging-based brachytherapy; Groupe Europeen de Curietherapie-European Society for Therapeutic Radiology and Oncology Working Group guidelines

Core tip: Brachytherapy is an integral part of radical pelvic radiation therapy for cervical cancer. While image-based planning has gained wide acceptance in external beam radiotherapy, the integration of image-based planning for brachytherapy has lagged significantly. More recently advances in planning software/hardware have lead to increased use of image-based brachytherapy. Herein, we highlight the clinical advantages of 3D brachytherapy planning for cervical cancer. We present multiple modalities for image-based brachytherapy including outcome data and dose constraints. Finally we outline practical guidelines for contouring target volumes and critical organs; and present future

directions in image-based brachytherapy aimed towards improving cervical cancer outcomes.

INTRODUCTION

Cervical cancer is the third most common cancer in women worldwide with an estimated annual death rate > 275000^[1,2]. For early stage disease, prospective randomized data has established the equivalence of radical hysterectomy (\pm adjuvant radiation therapy based on risk factors) *vs* radical pelvic radiation therapy in terms of survival and disease control with increased toxicity with surgery \pm adjuvant therapy; however surgery is often the treatment of choice for early stage disease because of decreased treatment time, the potential opportunity for ovarian and/or fertility preservation, and a decreased risk of second malignancy^[3]. Definitive radiation therapy is the accepted standard of care for early stage patients not suitable for surgical resection and is integrated with concurrent cisplatin chemotherapy for patients with node positive or locally advanced tumors > 4 cm (all node positive and FIGO stage I B2, II A2, and higher). Definitive radiation therapy consists of a combination of external beam radiotherapy and brachytherapy; the addition of brachytherapy represents an integral part of definitive radiation therapy for cervical cancer shown to improve overall survival^[4,5]. Traditionally, as outlined in the International Commission on Radiation Units and Measurements (ICRU) 38 and the 2000 American Brachytherapy Society (ABS) guidelines for cervical cancer, brachytherapy dose was based on two-dimensional (2D) planning prescribed to a modification of the classical Manchester system point A for target coverage and conventional points for critical organs^[6,7]. The results for 2D X-ray based brachytherapy have been good in term of local control especially for early stage disease with acceptable toxicities, but there are unexplained toxicities and treatment failures^[8-10]. Additionally, the correlations between toxicities and critical organ point doses have not been consistent, limiting toxicity improvements through planning optimization in 2D brachytherapy^[10]. Computed tomography (CT) based three-dimensional (3D) planning and more recently more sophisticated image-based planning (Intensity Modulated Radiotherapy) has been widely accepted and implemented for external beam radiotherapy, however the acceptance and implementation of 3D image-based brachytherapy has lagged substantially. The relatively slow integration of 3D image-based brachytherapy can be attributed to a decreased availability of planning software/hardware, increased cost, and a lack of optimal training/expertise.

ADVANTAGES OF IMAGE-BASED BRACHYTHERAPY

Improvement in hardware and software for brachytherapy planning have more recently paved the way for 3D image-based brachytherapy which allows volumetric optimization improving tumor coverage and critical organ sparing which potentially increases local control, reduces toxicities, and helps predict outcomes. Early data for 3D planning has substantiated the potential improvements of 3D over 2D planning overcoming challenges in optimizing technique, reproducibility, uncertainties in target delineation, and the dosimetric planning processes. Several studies have compared the cervical tumor coverage and critical organ sparing by 3D image-based brachytherapy to doses delivered by 2D radiography-based brachytherapy^[11-18]. Investigators from University of Alabama Birmingham were some of the first to show that the 2D radiography-based approach using point A overestimates the tumor dose, especially in more advanced tumors where on average the gross tumor volume prescribed dose coverage was 98.5%, 89.5%, 79.5%, and 59.5% for stages I BI, I B2, II B, and IIIB, respectively^[11]. Others have shown that for smaller cervical tumors, the point A dose may achieve adequate tumor coverage, but over treats surrounding critical organ which can be improved with magnetic resonance imaging (MRI) image-based planning^[12]. These results were further validated by University of Pittsburgh data showing that the mean dose to 90% and its standard deviation was 83.2 ± 4.3 Gy that was significantly higher ($P < 0.0001$) than the mean dose 78.6 ± 4.4 Gy to Point A^[13]. Numerous early reports showed the orthogonal X-ray ICRU point doses underestimate doses to rectum and bladder as compared to CT based volumetric calculation by 1-5 folds (Table 1) especially for the bladder point doses^[19-22]. These results were later validated in a prospective study from MD Anderson, showing that the ICRU bladder point significantly underestimated the CT based highest dose to 2cc by a mean difference of 6.8 Gy, but did not differ significantly for the rectum with a mean difference of 0.21 Gy^[23]. Prospective studies from Korea and Vienna using all image-based brachytherapy correlated late changes in rectal mucosa on serial rectosigmoidoscopy with volumetric doses of 2cc, 1cc, and 0.1cc (D2cc, D1cc, and D0.1cc), showing significant dose cutoffs (Table 2) for both asymptomatic and symptomatic rectal changes^[24,25]. With longer follow-up the Vienna group has established well-defined dose-response curves for D2cc doses to the rectum and bladder (Table 3), which provide an invaluable risk-assessments for rectal and bladder constraints^[26]. While with 2D planning consistent validated constraints had been elusive impeding reductions in brachytherapy toxicity, these outcome data provide practical dose constraints for 3D brachytherapy optimization to limit the risks of late toxicity.

In addition to the well-established dosimetric advantages of 3D as compared to 2D brachytherapy planning

for cervical cancer, 3D planning additionally offers clinical advantages including: confirmation of applicator placement, decreased critical organs-at risk (OAR) dose for patients with a small cervix, accounting for sigmoid colon dose, and improved coverage for large volume disease while maintaining critical organ dosimetry. At the time of brachytherapy application, tandem placement can result in unsuspected uterine perforation despite the clinical impression of adequate tandem placement (Figure 1); 3D planning increases the diagnosis of perforation and avoids overtreatment of fundus/lower uterine segment^[27]. Patients with a small cervix represent a challenge to adequate brachytherapy delivery, where suboptimal weighting and positioning can lead to over-dosage of critical organs when using the conventional 2D planning one-size-fits-all optimization process (Figure 2). Investigators from Princess Margaret Hospital compared 2D *vs* 3D (MRI based) planning for patients with small cervix showing that tumor coverage (volume receiving 100% of the prescription dose > 95% of target) was adequately in 70% of the patients with the conventional 2D plans, respectively, and in 75% of the patients with the optimized plans and the minimal dose to the contiguous D2 cc of the rectal, sigmoid, and bladder wall volume was 16 ± 6.2 Gy, 25 ± 8.7 Gy, and 31 ± 9.2 Gy, respectively^[12]. While with MRI-guided brachytherapy optimization, it was possible to maintain tumor coverage and reduce the dose to the normal tissues, especially in patients with small cervix where the target volume treated to $\geq 100\%$ of the intended dose approached 100% in all cases, and the

minimal D2cc of the rectum, sigmoid, and bladder was 12%-32% less than with conventional 2D brachytherapy planning^[12]. Dose to the sigmoid colon and small bowel was not accounted for in conventional 2D planning, which can receive > 70% of the point A dose^[28]. Image-based brachytherapy offers the added advantage of sparing dose to the sigmoid colon and small bowel, which potentially reduces the risk of stricture and ulceration (Figure 3). Large volume disease creates a challenge in achieving adequate coverage as portions of the disease extend larger distances from the central applicator with increasing tumor size; image-based planning in combination with a combined interstitial/intracavitary approach (Vienna applicator) help to create an asymmetric dose distribution improving tumor control and affording dose-escalation (Figure 4); which is especially important for larger tumors > 5 cm as highlighted in the Vienna group experience where comparing outcomes for cervical cancer patients prior to the introduction of image-based brachytherapy and the Vienna applicator, 3-year actuarial overall survival was 28% for tumors > 5 cm as compared to 58% ($P = 0.003$) with image-based brachytherapy^[29,30].

MODALITIES FOR IMAGE-BASED BRACHYTHERAPY-MRI

A number of imaging modalities have emerged for image-based brachytherapy planning. The Groupe Européen de Curietherapie-European Society for Therapeutic Radiology and Oncology Working Group (GEC-ESTRO) and ABS have developed guidelines to standardize contouring definitions and dosimetry for tumor targets and OARs^[31-33]. Both the ABS and GEC-ESTRO guidelines are based on MRI-based brachytherapy planning, with MRI offering superior soft tissue contrast^[34]. The largest experience with MRI-based planning comes from the Vienna group which incorporated MRI-based planning which each fraction, the mean dose to 90% of the target volume (D90) was 86 ± 16 Gy for the high-risk clinical target volume (HR-CTV) with a mean D2cc for the bladder, rectum, and sigmoid of 95 ± 22 Gy, 62 ± 12 Gy, and 62 ± 12 Gy^[35,36]. Similar dosimetric results have been published in the Aarhus and Leuven experience for definitive chemo-radiotherapy in advanced disease^[37,38]. The long-term outcome data from the Vienna experience

showed an excellent 3-year 95% local control^[39].

MODALITIES FOR IMAGE-BASED BRACHYTHERAPY-CT

MRI is not universally available in radiation oncology departments; and the need for serial repeat imaging to account for changes in position of critical organs and tumor regression create logistical and financial impediments that have limited the universal applicability of MRI-based brachytherapy planning. Contrastingly, CT simulators are widely available in radiation oncology departments, thus interest grew in using CT based brachytherapy planning. To address these concerns, a prospective international cooperative group trial compared CT to MRI based planning showing that tumor height, thickness, and total volume measurements as determined by CT were not significantly different compared with the MRI volumes; similarly the MRI and CT dose-volume-histogram values of the D2cc, D1cc, and D0.1cc for the OARs were similar^[40]. However, the width measurements differed in HR-CTV for CT *vs* MRI based planning, resulting in statistically significant differences in the volume treated to the prescription dose or greater (MRI 96% *vs* CT 86%, $P = 0.01$) and dose to 90% of the treatment volume (MRI 8.7% *vs* CT 6.7%, $P < 0.01$)^[40]. Outcomes from Addenbrook, where a lack of access to MRI for brachytherapy

Figure 4 Use of the Vienna applicator to improve posterior disease coverage for locally-advanced cervical cancer. A and B: 3D reconstruction of Vienna applicator showing posterior needles; C and D axial magnetic resonance imaging (MRI) showing advanced disease with posterior extension, and improved coverage with combined interstitial and intracavitary MRI image-based planning.

planning forced CT image-based planning with each fraction, for 86% of the included patients the D90 was ≥ 74 Gy, with the only patient with local recurrence having a D90 of 63.8 Gy^[41]. When comparing their experience at Addenbrook with CT image-based planning to a previous institutional cohort of patients treated with chemoradiotherapy and 2D planning showed a significant 20% improvement ($P = 0.04$) in local control^[41].

MODALITIES FOR IMAGE-BASED BRACHYTHERAPY-CT AND MRI HYBRID

More recently, The University of Pittsburgh has shown a hybrid approach using MRI for first fraction and CT for subsequent fractions which allows for initial dose optimization based on the gold-standard MRI based imaging, with serial CT imaging to account for variations in applicator geometry and changes in OARs and target volumes throughout subsequent fractions^[42]. In the first report on a hybrid CT/MRI image-based approach in 42 patients we reported a mean D90 of 83.3 Gy with a mean D2cc for bladder, rectum, and sigmoid of 79.7, 57.5 and 66.8 Gy respectively. The complete response rate by PET/CT was 92.5%, with a 2-year local control rate of 88%^[43]. Dosimetric study from the Vienna group incorporating automated applicator based image registration compared the gold standard of MRI-based planning with each fraction to the hybrid MRI/CT approach, there was small systemic underestimation with the hybrid approach with

the mean difference in HR-CTV volume of $-1.7 \pm 6.6\text{cc}$ in HR-CTV, mean difference in D90 of -1.5 ± 4.3 Gy, and mean difference in D2cc for rectum, sigmoid, and bladder of 0 ± 4.9 Gy, 1.3 ± 1.2 Gy, and 1.1 ± 4.2 Gy, respectively^[44]. However all the outliers where the difference in D90 was greater than 1 Gy were large tumors requiring more complex applications (including Vienna applicator), thus the authors conclude that the hybrid approach is quite similar for small tumor and intracavitary applicators; however maybe suboptimal for larger tumors and more complex applicators^[44].

MODALITIES FOR IMAGE-BASED BRACHYTHERAPY-ULTRASOUND

Alternatively, investigators from Australia and Indian have incorporated trans-abdominal ultrasound for image-based planning, which also represents a more widely available and cost effective imaging modality that does not interfere with conventional stainless steel applicators^[45,46]. In a prospective planning study, investigators from Mumbai showed a reasonable correlation in trans-abdominal ultrasound and MRI-based planning^[45]. For outcome data, in the Australian experience planning was based on trans-abdominal ultrasound with each fraction, MRI was only available for one insertion and was used to assess response and later to validate the ultrasound volume. For ultrasound based planning, the mean D90 was 80.8 Gy with D2cc for bladder and rectum of 57.7 Gy

Table 4 Summary of clinical outcomes in published results for image-based brachytherapy for cervical cancer

	Local control	Disease free survival	Overall survival	Late toxicity (G3+)
STIC ^[47] (2-yr)	78.5%-100%	60.3%-89.7%	74%-96%	2.6%-8.9%

NR: Not-reported; G3+: Grade ≥ 3 toxicity.

and 58.8 Gy, respectively^[46]. There was no significant difference in dosimetry between ultrasound and MRI planning, with a 90% local control rate^[46].

CLINICAL OUTCOMES FOR IMAGE-BASED BRACHYTHERAPY

While the integration of cisplatin chemotherapy to radical radiation therapy has improved outcomes, outcomes remain suboptimal especially for more advanced disease and novel chemotherapeutic agent development has been slow; as such improvements in radiation therapy, such as image-based brachytherapy which through improved target delineation and coverage, promises to be the next major step in improving cervical cancer outcomes. Recently international data for outcomes using image-based brachytherapy have been published (Table 4) substantiating the potential for improved outcomes suggested in prior planning studies^[39,41,47-51]. The international series outlined in Table 4 use a variety of treatment schedules, but highlight the potential advantages of image-based brachytherapy, high rates of local control 79%-100% with low rates of late complications 0%-14%. Building on these single institutional experiences, a prospective non-randomized multi-institutional series from the French Soutien aux Techniques Innovantes et Coûteuses with > 800 cervical cancer patients compared 2D PDR brachytherapy *vs* 3D (CT or MRI) PDR brachytherapy^[47]. Patients were divided into three groups based on the integration of radio-chemotherapy with surgery (pre-operative, post-operative, or no surgery). At a median 2-year follow-up, 3D planning significantly improved local (78.5%-100% *vs* 73.9%-91.9%, $P = 0.003$) and loco-regional (69.6%-96.1% *vs* 61.2%-87.9%, $P = 0.001$) relapse free survival which transcended treatment groups; there were trends towards improved disease-free (60.3%-89.7% *vs* 55.2%-86.5%, $P = 0.086$) and overall survival (74%-96% *vs* 65%-95%, $P = 0.27$) especially for the more advanced patients treated with radical radio-chemotherapy alone^[47]. Additionally 3D brachytherapy translated into statistically significant decreases in grade 3+ urinary (1.2%-5.5% *vs* 5.8%-9.2%, $P = 0.02$), gynecologic (1.4%-7.5% *vs* 5.7%-15.4%, $P = 0.01$), and global toxicity (2.6%-8.9% *vs* 12.5%-22.7%, $P = 0.002$)^[47]. The largest series using MRI based planning based on the GEC

ESTRO guidelines from Vienna group similarly showed excellent 3-year local control of 95% which represents a 65% relative improvement in local control from prior Vienna cervical cancer series using 2D planning, this local control advantage translated into 20%-30% improvement in disease-specific and overall survival primarily for more advanced tumors > 5 cm, respectively^[39]. One explanation for these improvements is dose-escalation with an increased mean dose to 90% of the volume (D90) from 90 Gy with conventional planning to 94 Gy with MRI-based planning, this is supported in a strong dose-response relationship which advocates that a D90 equivalent-dose-2 Gy (EQD₂) of at least 87 Gy is required for local control > 90% for advanced disease^[30,39,52].

RECOMMENDATION FOR PRACTICAL APPLICATION OF IMAGE-BASED BRACHYTHERAPY

For the practical application of image-based brachytherapy the guidelines published by the GEC-ESTRO and ABS working groups serve as invaluable tools for image acquisition, target/OAR delineation, and dosimetry/optimization^[31-33,53-55]. Briefly to summarize our institutional integration of these guidelines, for MRI-based planning it is recommended to use T2-weighted images, with either high signal intensity (if brachytherapy alone) or intermediate signal intensity (if brachytherapy following external-beam radiotherapy). Tumor target volumes consist of two clinical target volumes (CTV): the high-risk CTV (HR-CTV) which is optimized to receive a dose enough to sterilize macroscopic tumor representing the entire cervix plus presumed tumor extension (based on clinical assessment and/or residual grey zones on MRI) without safety margin and the intermediate-risk CTV which is optimized to received a dose enough to sterilize microscopic tumor (representing the HR-CTV plus a safety margin of 5-15 mm according to potential tumor spread-up to 5 mm anterior-posterior limited by bladder or rectum, 10 mm cranially in uterine corpus but only 5 mm if endocervical tumor, and 5-10 mm laterally into parametria). The rectum, bladder, sigmoid colon, and relevant parts of the small bowel loops adjacent to the target volumes are considered as the main OARs that are contoured with

each fraction. We typically initiate cervical brachytherapy during the 4th or 5th week of external beam radiotherapy with MRI-compatible Smit Sleeve placement. We primarily employ a ring and tandem intracavitary HDR technique (though also incorporate a Vienna applicator or template-based interstitial application where appropriate) with 5-6 Gy per fraction times 5 fractions (25-30 Gy) based on response to external beam radiotherapy using weekly fractionation during external beam radiotherapy and twice weekly after completion of external beam radiation therapy.

As outlined in the GEC-ESTRO and ABS guidelines we advocate MRI for each application; however if logistics preclude MRI-based planning with each fraction, alternative methods would be for MRI with the first fraction and serial CT-based planning for subsequent fractions^[43]. Alternatively if MRI-based planning is not available, outcome data for CT-based or US-based planning shows improved outcomes over 2D planning^[41,46,51]. An additional consideration would be to incorporate a diagnostic pre-brachytherapy MRI with CT-based or US-based brachytherapy planning to aid in soft-tissue delineation in brachytherapy planning^[56].

For optimization, we aim for a HRCTV D90 \geq 100% with a planned EQD₂ 80-85 Gy, except for patients with a poor response to external beam radiotherapy with large residual tumors where based on the Vienna dose-response data we push the dose to EQD₂ 85-90 Gy to attempt to improve local control^[52]. While based on the outcome data outlined in Table 2 and 3, we limit the rectum D2cc EQD₂ \leq 70 Gy, sigmoid D2cc EQD₂ \leq 70 Gy, and bladder D2cc EQD₂ \leq 90 Gy.

UNCERTAINTIES AND CHALLENGES IN IMAGE-BASED BRACHYTHERAPY

Despite the observed dosimetric and clinical benefits of image-based brachytherapy many uncertainties and challenges remain. Applicator reconstruction is a challenge to quality assurance in image-based brachytherapy, where a lack of a MRI compatible dummy catheter forces a reconstruction of source channels. A number of reconstruction methods have been purposed, but uncertainties in the reconstruction of source channels can generate both random and systematic errors in dose-volume-histogram (DVH) parameters^[57-59]. In an era of increasing emphasis on curtailing health-care costs, it is unclear how much the increase in demands on resources and total cost will limit applicability of image-based brachytherapy. Dosimetric uncertainties are challenged by reproducibility of mobile four-dimensional targets, OARs which can have dramatic inter-fraction differences based on distention/filling, and mobile applicators subject to intra- and inter-fraction motion^[57]. Finally the steep dose gradients of brachytherapy dose distributions place increased hopes on accurate contouring which is challenged by “grey zone” interpretation on MR imaging and evaluation of tumor response changes^[34].

FUTURE DIRECTIONS OF IMAGE-BASED BRACHYTHERAPY

To prospectively validate the adoption of image-based brachytherapy, a multi-institutional international trial, EMBRACE (an international study of MRI-guided brachytherapy in locally advanced cervical cancer) is currently accruing (<http://www.embracestudy.uk>). EMBRACE includes patients with FIGO stage IB-IVA cervical cancers, all patients receive concurrent cisplatin (40 mg/m² weekly) chemotherapy and conventionally fractionated external beam radiation therapy followed by MRI image-based brachytherapy according to the GEC-ESTRO guidelines with brachytherapy dose and DVH constraints at the discretion of the enrolling department standards. The study aims to enroll 600 patients over 3-year and promises to establish a benchmark for cervical cancer management in terms of tumor control, complications, dose specification, and a prospective assessment of quality-of-life. This trial along with continued improvements in imaging, contouring, dosimetry, quality assurance, physics, and brachytherapy delivery promise to perpetuate the advancement of image-based brachytherapy to optimize outcomes for locally-advanced cervical cancer patients.

Abstract

Screening for cervical cancer with DNA ploidy assessment by automated quantitative image cytometry has spread throughout China over the past decade and now an estimated 1 million tests per year are done there. Compared to conventional liquid based cytology, DNA ploidy has competitive accuracy with much higher throughput per technician. DNA ploidy has the enormous advantage that it is an objective technology that can be taught in typically 2 or 3 wk, unlike qualitative cytology, and so it can enable screening in places that lack sufficient qualified cytotechnologists and cytopathologists for conventional cytology. Most papers on experience with application of the technology to cervical cancer screening over the past decade were published in the Chinese language. This review aims to provide a consistent framework for analysis of screening data and to summarize some of the work published from 2005 to the end of 2013. Of particular interest are a few studies comparing DNA ploidy with testing for high risk human papilloma virus (hrHPV) which suggest that DNA ploidy is at least equivalent, easier and less expensive than hrHPV testing. There may also be patient management benefits to combining hrHPV testing with DNA ploidy. Some knowledge gaps are identified and some suggestions are made for future research directions.

Key words: Cervical cancer screening; DNA ploidy; Automated quantitative image cytometry; High risk HPV testing

Core tip: Although application of automated quantitative image cytometry to screen for cervical cancer was first developed in Canada, the United States and Europe, it is most widely used clinically in China where it is applied to about one million tests annually. Over sixty papers reporting the clinical results have been published in Chinese since 2005. As the first review of this topic in any language, in addition to the usual goals of a review, it has the opportunity to increase the awareness of the Chinese clinical experience for those outside of China and to increase awareness of the technology background for English readers in China.

Garner D. Clinical application of DNA ploidy to cervical cancer screening: A review. *World J Clin Oncol* 2014; 5(5): 931-965 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/931.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.931>

INTRODUCTION

In a 2005 paper based on a study conducted in China^[1], this reviewer and coworkers stated the study objective as: "To establish if measurements of DNA ploidy could be used to assist cytopathologists and cytotechnologists in population based cervical cancer screening programs in countries where manually reading the slides is impossible due to the lack of sufficient skilled cytotechnologists." Based on the study results, we concluded that it could work. Since that time, DNA ploidy technology has been approved for cervical cancer screening, endorsed by several medical societies and fairly widely disseminated throughout China. The goal of this paper is to review the current status of automated quantitative image cytometry

(AQIC) to measure DNA ploidy as applied to cervical cancer screening.

The structure of this review is: (1) A very general introduction to the technology, with some historical perspective and with discussion of some practical issues; (2) A detailed development of a framework for evaluation of screening tests, mostly as a suggestion for how published data analysis might be made more clinically relevant. This section also attempts to alert readers to various well known and less well known pitfalls these evaluations are prone to and to estimate them to discriminate those that are important from those that are not; (3) A summary of existing published results, mostly from China, including reworking some of the published data in terms of the proposed framework; and (4) A discussion of some research still to be done especially in light of the huge advances in cervical cancer control made in the past decade due to the developments of human papilloma virus (HPV) vaccines and HPV testing. Does the objective from the 2005 paper still apply? Does DNA ploidy still have a potential cervical cancer screening role to substitute for nonexistent cytologists in this world of HPV vaccines and HPV testing?

TECHNOLOGY BACKGROUND

DNA ploidy

“Ploidy” is the genetics term for the number of basic sets of chromosomes in the nucleus of a cell. Cells that have an integer multiple of the basic set of chromosomes are “euploid”. Most human cells are euploid and have 46 chromosomes or two times the basic set of 23 chromosomes (one set from the mother and one from the father), referred to as “diploid”. Some human heart, liver and other cells are euploid with 92 chromosomes or 4 times the basic set and are known as “tetraploid”^[2]. Human gametes have one set of the 23 chromosomes, unpaired, and so are also “euploid”. Curiously, mature red blood cells in mammals have no chromosomes.

Cells which do not have an integer multiple of the basic set of chromosomes are “aneuploid”, simply meaning “not euploid”. Most human embryos that have an extra or missing single chromosome do not survive gestation, but some do^[3]; for example, Down’s syndrome occurs when there are three instances of chromosome 21 in all cells.

Some degree of aneuploidy is observed in virtually all solid tissue cancers^[4] in a “mosaic”; that is, the normal cells remain “euploid” but the cancer tumor cells are “aneuploid”. (This contrasts with “non-mosaic” aneuploidy like Down’s syndrome in which almost all cells are aneuploid.) Elucidation of the role of aneuploidy in cancer has a fascinating history, briefly sketched next, and remains an active area of study today. The key point is that aneuploidy is the hallmark of cancer cells in general and, in the case of cervical cancer, is present both in the early “pre-cancer” or “pre-invasive cancer” phases as well as in the later “invasive” phases. Generally, to detect aneuploid cells is to detect cancer cells.

Aneuploidy and cancer: A brief history

By the year 1890, chromosomes had been discovered and, although their function was not yet proven, it was known that the material responsible for heredity was contained in the cell nucleus where chromosomes are found. The German pathologist, Hanseemann^[5], published a paper in 1890 entitled “About asymmetric cell division in epithelial cancers and its biological significance” and another in 1891^[6] entitled “About pathological mitoses”; both papers are available online and contain wonderful hand drawn illustrations of asymmetric mitoses, as well as other phenomena, such as what is now known as apoptosis. Cells in the process of division are more commonly seen in tumors than in normal tissue and the division in normal tissue is almost always symmetric, producing identical daughter cells, whereas in cancer, one daughter cell often has more chromosomes than the other. These observations had been noted earlier by others, but Hanseemann suggested that the defining characteristic of cancer cells is that they lose their ability to divide symmetrically and, in the process, cease to have tissue specialization and increase their ability to live more autonomously, as cancer cells do in metastasis^[7].

Although both cameras and light bulbs were invented before 1890, they were not commonly available for microscopy and the illustrations in the journals were usually hand drawn by the author, sometimes assisted by “Abbe’s drawing apparatus”, rather than printed photomicrographs. Electric light commercialization slowly started in the 1880s, but incandescent light bulbs were not very practical until the invention of the tungsten filament in 1904. Also, it was not until 1893 that Köhler^[8] published the method that bears his name and is still used on most modern transmission microscopes to evenly illuminate a microscope slide without also seeing an image of the light source superimposed on the specimen image. Yet, with minimal technology and very limited knowledge of chromosomes, genetics and cancer, Hanseemann was able to make accurate observations and to formulate valuable hypotheses on the cellular mechanism of cancer.

A German zoologist named Boveri^[9] studied multicentric cell division in double fertilized sea urchin eggs and, when he learned of the work of Hanseemann on asymmetric cell division in cancer, he proposed a chromosomal theory of cancer in 1902 (an English translation is available online^[10]). In essence, the theory is that cancer cells come from normal cells that divide asymmetrically for various reasons and, although this is usually fatal for the daughter cells, sometimes a daughter cell will survive and become the progenitor for all the subsequent cancer cells. The Boveri theory of cancer is that aneuploidy, resulting from an error in the division of a normal cell, is the cause of cancer.

Boveri was jointly credited with the American, Walter Sutton (working independently), in 1903 with the discovery that chromosomes are the vectors for heredity.

Boveri^[11] published a more complete theory of cancer in 1914 (an English translation is available online^[12]) and

Figure 1 A simplified flow diagram of the relationship between screening and diagnosis showing that screening generally has not 2 but 3 outcomes: positive, negative and equivocal, which is managed by time and re-testing.

he died a few months later. Partly due to World War 1, this work was largely ignored. A translation into English was published by his wife in 1929^[13] but received only limited attention outside of Germany until the 1970s. This paper included 20 important insightful hypotheses about cancer, anticipating such concepts as the existence of oncogenes, tumor suppressor genes and cancer induced by infectious agents. Arguably, all 20 hypotheses were subsequently shown to be substantially correct, starting some 50 years after his death^[14]! The zoologist Boveri never studied or experimented with tumors or tumor cells and it has been speculated that it was because he was an “outsider” that he was able to form intuitive, imaginative and correct insights, uninhibited by the medical orthodoxy of the day^[14].

Boveri’s hypothesis that aneuploidy is the cause of cancer remains unresolved today, but is a topic of active study^[3,15-17]. Recent work shows that aneuploidy can be both a promoter and an inhibitor of cancer, depending upon the degree of chromosomal instability^[18].

Again, the key point for this review is that generally to detect aneuploid cells is to detect cancer cells.

It should be noted that “definitive diagnosis”, including tumor type, is usually determined by a diagnostic test, not by the screening test (Figure 1). In the case of cervical cancers, colposcopy directed biopsy is the usual diagnostic test. Screening by detecting DNA aneuploidy alone cannot determine what type of tumor is present, although advanced cytometry techniques, beyond the scope of those discussed here, could make such determination.

DNA Cytometry

“Cytometry” means “cell measurement” which comes in two basic technology flavors: “flow” and “image” (sometimes called “static”) cytometry. There are a broad range of techniques to measure chromosomes, both in flow and image cytometry, ranging from the simple measurement of the total DNA content of a cell nucleus to the complex and sophisticated enumeration of small segments of individual chromosomes.

This paper is limited to consideration of AQIC that measures the total DNA content of cell nuclei, along with features that describe the distribution of the DNA within the nucleus and the morphology of each nucleus. These cytometer systems compare the DNA content of each cell nucleus measured to the average DNA content of the measured normal cell population^[19]. Cervical “Pap” samples are predominantly comprised of normal cells, even when taken from a woman with invasive cervical cancer. This comparison identifies aneuploid cells even though the technique does not actually identify or count individual chromosomes. A cell with a DNA content 2.5 times that of a normal cell is reliably determined to be aneuploid, even though it is not possible to say that cell has, *e.g.*, 115 chromosomes. This technique is also known as “quantitative DNA Cytometry” or just “DNA Cytometry”.

When AQIC was first developed, it was common to apply the genetic language of “ploidy”. Unfortunately, this can be misleading, especially in today’s world of genomics, because one will be inclined to infer that individual chromosomes are identified and counted. The

Figure 2 Liquid based cervical samples stained with A: Feulgen thionin and B: Pap stain.

Figure 3 Liquid based cytology cervical sample example of a cell cluster obscured by cytoplasm.

term “DNA ploidy” was coined to be distinct from simply “ploidy” or “chromosomal ploidy” in an attempt to correct this sloppy language, with only middling success because today’s young life science students will certainly have encountered the terms of genetics and genomics, but are much less likely to have encountered DNA Cytometry. So it is important to understand that the AQIC technology discussed here does detect aneuploidy by cell measurement, but without explicitly enumerating chromosomes as a geneticist might expect^[20].

How DNA is measured

Automated quantitative image cytometers are comprised of a microscope fitted with a digital camera, motorized X-Y stage, robotic slide loader and automatic focus mechanism, all under computer control. The cytometers of this review operate on absorbance microscopy.

Most cytometry relies on staining particular molecules in the specimen and then quantifying the stain. For the automated quantitative image cytometry considered here, the Feulgen^[21] reaction stains the nuclear DNA specifically and proportionately to the amount of DNA present, everything else remains clear and unstained^[22]. For cervical samples, this greatly simplifies the scene on the slide because the cell cytoplasm is left unstained, as is any red blood (no DNA). Only the DNA contained in the nuclei of epithelial cells, white blood cells and, if pres-

ent, sperm cell nuclei are stained; the possibility of “false aneuploidy” arising from epithelial cells being overlaid by other epithelial cells, white blood cells or sperm cells is discussed later. Several microorganisms are commonly found in cervix samples, especially Döderlein’s bacillus which can completely cover the cervix epithelial cells; the staining protocol does not stain any of these microorganisms either.

Figures 2 are liquid based cytology (LBC) cervical samples with the blue DNA stain thionin (Figure 2A) and with the Pap stain used by conventional cytology (Figure 2B). The images were taken with the same optics (magnification, *etc.*) on the same cytometer. Notice that there are many more cells in the 2A image than in the 2B image and, even so, the scene is much simpler. Notice also that not all cells are in focus at the same time in either image due to the 3-dimensional stacking of the cells. Figure 3 shows a cluster of cells that is very difficult to examine due to the overlapping stained cytoplasm; this would not be a problem with only the DNA stain. Figure 4 shows “low grade abnormality” in the 3 Pap stained photos (arrows), which is especially difficult to see in Figure 4D. The large blue nucleus (Figure 4A) is aneuploid with a DNA content about 2.7 times normal. The key message is that the DNA stained slides are much simpler to measure and interpret than the conventional Pap stained slides.

Measurement of the amount of DNA with a cytometer is identical to the measurement of a chemical with a spectrometer. The basic idea of a spectrometer is shown in Figure 5—light is selected by a slit into a beam which directs it onto a monochromator. A particular color is selected by another slit, the beam is passed through the chemical sample which absorbs some of the light and any remaining light is detected with a photosensor. The concentration of the chemical in the sample can be precisely measured by applying a rule of physics known as Beer’s Law.

A quantitative cytometer is a very simplified spectrometer (Figure 6). The optimum light color is selected with color filter and passes through the glass microscope slide. Some of any light that passes through stained DNA is absorbed and the remaining light is detected by the pix-

Figure 6 Basic principle of an image cytometer.

els of a digital camera. Beer’s law applies separately to every pixel of the camera-in effect, a cytometer is a “Mega-Micro-Spectrometer”-that is, millions of tiny, pixel-sized spectrometers. The total DNA present in a nucleus is obtained by adding up the DNA measured by each pixel of the image of that nucleus. A recent extensive review discusses all of the technical considerations for quantitative cytometry^[23].

AUTOMATED QUANTITATIVE IMAGE CYTOMETRY: OVERVIEW

Scanner operation

This review is focused on AQICs that feature “walk away automation” where barcoded stained slides are placed in a slide loader and the operator initiates scanning on a supervisor computer and the cytometer operates without

Figure 7 Gallery of potentially aneuploid cell nuclei.

further intervention. Although such machines can scan smears, they are generally employed with LBC samples; indeed, LBC was invented by Cytec Corp. (now Hologic) with the intended goal to simplify the task of automated imaging^[24]. All of the operations of focusing, image capture, segmentation of the scene into foreground and background, feature measurement *etc.* are performed without operator intervention.

Modern AQICs scan a LBC cervical slide in typically 5-10 min and are constantly getting faster, especially due to improvements in computer and digital camera speeds. While the scan rate is typically between 5 and 10 samples per hour, the throughput is generally defined by the slide loader capacity for overnight scanning and so, depending on the particular vendor's design, can range from 75 to 250 per cytometer per day or 15000 to more than 50000 slides per cytometer per year, based on 225 working days per year. If a large volume of samples is available, as is the case for tests in an organized screening program, automated quantitative image cytometry can be very efficient.

Scan review and report generation

Reporting with an automated quantitative image cytometer is done at the conclusion of an interactive review of the scan data for each slide which is comprised of stored images of the cell nuclei, counts of various cell types, and histograms and scatter plots of cell DNA content and other features of the cell nuclei. The reviewer follows a very simple checklist procedure to systematically examine the data, looking: (1) first to check that the DNA scale (normalization) is valid, then; (2) checking any images that could be of aneuploid cell nuclei, then; (3) looking for aneuploid "stemlines", then; (4) assessing cell proliferation; and (5) if none of these are present, then the case is negative and an assessment of scanning adequacy is made.

The idea that a scan has examined enough cells to be deemed to be a "satisfactory" or "adequate" assessment only applies to slides that are free of abnormality because slides deemed to be positive for abnormality are considered to be satisfactory regardless of how many cells were measured.

More than 90% of slides are clearly negative or clearly positive and so working through this checklist for those slides typically takes 1 min or less, including generating the report, once the technician has several days of train-

ing and experience. The remaining < 10% of cases are more problematic because their result hinges on the detailed assessment of typically 5 or fewer images of what could be aneuploid cells. The central issue is not "exactly what kind of cell is this an image of?", but the much simpler question of "is this the image of a single cell nucleus or an artifact caused by the overlap of two or more cell nuclei or white blood cells or sperm?"

Figure 7 shows a mini image gallery. The leftmost image is clearly a single nucleus and the next image is clearly of overlapping nuclei as evidenced by the distinct overlapping boundaries and dark overlap area. In fact, the scan computer has no difficulty identifying the second image as being of overlapping cells and automatically places it into a separate group, so in "real life" the reviewer would be unlikely to ever look at this second image.

The last image in the red box (previously shown in Figure 4A) is possibly more difficult because the shape suggests two overlapping ovals but the distinct boundaries and dark overlapping areas are absent. This is actually a single nucleus and the reviewer has the option of clicking on the image and the slide is automatically moved to place that cell into the center of the field of view of the review microscope and it is easily determined to be a single nucleus by panning slightly through focus.

Even when some images must be revisited with the review microscope, the overall task is simple and fast. Most revisit cases take less than 5 min each, so a typical reviewer can work through 40 cases per hour on a sustained basis (4 slides requiring revisiting plus 36 slides without revisiting). Some vendors provide review/revisit microscopes that are separate from the cytometer, while for other vendors the cytometer serves both scan and review/revisit functions.

The report that is generated summarizes the data showing a gallery of images of the most significant cell nuclei, a histogram of the DNA content, a scatter plot of area *vs* DNA content and a summary of cell counts in different DNA ranges.

In conventional cytology of the Pap test, most of the world reports according to TBS 2001 (The Bethesda System, revision of 2001^[25]) which is very rich, very nuanced, very complicated and with rather poor inter- and intra-observer agreement^[26]. From the viewpoint of patient management, there are really only 4 basic recommendations: (1) Return for another test at the routine screening interval (typically 3-5 years), the test is negative (no abnormality found); (2) Go to colposcopy within a few weeks for a detailed gynecological examination and possible biopsy, the test is positive (abnormality clearly found); (3) Return for another test at an interval shorter than the routine screening interval (typically 6 mo), the test was equivocal (too atypical to call "negative" but not enough to call "positive")-such cases are usually resolved by time; and (4) Return for another test at an interval shorter than the equivocal repeat interval (typically 1 mo), there was no valid test result due to some process failure.

The basic scheme for screening is shown in Figure 1

(recommendation #4 above is not shown). The key focus and goal of the DNA ploidy test is to provide the correct management recommendation from this set of 4 for each woman. A set of objective rules is applied to the data in each report to make the correct follow up patient management recommendation.

These rules can be adjusted to adapt to the reality of each local situation. For example, in a setting where a woman is unlikely to be tested more than once or twice in her lifetime, it may be decided to adjust the rules to make the “negative predictive value” (the chance that a woman who has a negative test result is actually free of cervical cancer or significant pre-cancer) higher than it would be where more testing is done per lifetime. Or, if there are very limited gynecology and colposcopy resources, it may be required that the “positive predictive value” (the chance that a woman who has a positive test result actually has cervical cancer or significant pre-cancer) be adjusted so as to not overwhelm the diagnostic and therapeutic resources available.

The key advantage of DNA Cytometry is that it takes typically only 2-4 wk to train a technician (good high school graduate with some work experience) to competently perform all tasks: cell deposition onto glass slides, staining, operation of the DNA scanner, scan data review and reporting. This contrasts with the 1-2 years of special training for cytotechnologist^[27,28] and 3-6 years of specialization training following receipt of an MD degree for a cytopathologist^[29-32]. This is not to suggest equivalence between a minimally trained technician and skill of well trained cytotechnologists and cytopathologists, but it is to suggest comparable cervical cancer screening test performance, as summarized later in this review. It is this key advantage that makes automated quantitative image cytometry a candidate for screening in low resource settings where the conventional cytology Pap test cannot be performed due to the lack of trained cytotechnologists or cytopathologists. In such settings, AQIC could mean the difference between screening and not screening.

AQIC DNA PLOIDY: CLINICAL CONSIDERATIONS

Scanner operation: What constitutes a scan?

Two different endpoints are used to define what constitutes an adequate scan for AQIC of liquid based cervix slides: (1) scan all cells deposited on the slide; and (2) scan a preset number of epithelial cells on the slide. Option (1) is the approach primarily motivated by litigation—if an abnormal cell is present on the slide there could be liability. Option (2) is based on science and is completely consistent with current international cervical cancer screening guidelines^[33].

What minimum number of epithelial cells must be measured for a scan to be satisfactory? A starting point to answer this question is to consider the guidelines for conventional cytology. TBS 2001^[25] stated “Minimal squamous cellularity requirements for a specimen to qualify as

“satisfactory” ... (is) 5000 squamous cells for liquid-based preparations.” It has been reported^[34] that this guideline was based on “...personal communications from the authors of two (subsequently published) papers^[35,36].” In fact, reference^[36] showed a threshold behavior of a jump in sensitivity for ASCUS+, LSIL+ and HSIL+ on Surepath (Becton Dickinson) LBC samples with < 5000 epithelial cells compared to those with > 5000 epithelial cells, supporting this guideline. However, reference^[35] concluded that “Cellularity does not provide assurance of adequacy. Any cellularity criterion should be based on measurement of the prevalence of abnormal cells on abnormal slides.” McQueen^[34] seems to be the only publication so far to take this approach with ThinPrep slides (Hologic) and yet they also conclude: “We have demonstrated that the range of ratios of dyskaryotic to total squamous cells in ThinPrep® preparations is such that it is not feasible to set a minimum acceptable total squamous cellularity so that there is an acceptable probability that all specimen vials containing dyskaryotic cells will be identified. In the light of this, a pragmatic approach should be adopted by deciding on an arbitrary minimum acceptable total squamous cellularity which ensures a rate of detection of abnormality that is at least as good as that for (smears) and which does not impose undue burdens on the users and providers of the screening program.” The 2008 American Society for Colposcopy and Cervical Pathology (ASCCP) committee review^[33] fell just short of endorsing this recommendation but noted that the TBS 2001 guidelines have been in wide use for many years and stated: “The Bethesda 2001 squamous cellularity criteria provide an acceptable threshold of unsatisfactory results for most patient populations and laboratory settings, although additional studies and data would be useful.”

McQueen^[34] estimated that for ThinPrep slides there must be at least 16 “targets” (scenes of abnormality) and comprised of at least 87 dyskaryotic cells in total in order to reduce the probability of a false negative result to 2%. This is for Pap stained samples screened visually by experienced cytotechnologists. What is the situation for DNA Cytometry?

Automated quantitative image cytometry is measurement-based and so the detection of even a single aneuploid cell is done with a high degree of confidence, as discussed more in the next section. If we assume that LBC mixes the sample so that the subsample of both physiological cell clusters and isolated cells deposited on the slide is statistically randomized and representative of what is in the vial, then it is possible to calculate from the Poisson distribution, the probability of a real false negative case, defined as having no aneuploid epithelial cell present among the epithelial cells measured. Figure 8 shows the probability of a real false negative occurring given that 5000 epithelial cells are measured. Note that the figure is a log-log plot. Figure 8 shows that when the ratio of normal to abnormal cells is less than about 1000:1, the probability of a real false negative is less than

Figure 8 The probability of a real false negative occurring given that 5000 epithelial cells are measured.

Figure 10 Given an aneuploid cell fraction, how many cells must be measured to get 1% chance of a real false negative or a 95% chance of a positive test result.

about 1% when 5000 epithelial cells are measured. McQueen *et al*^[34] counted the number of dyskaryotic cells and total squamous cells on 23 HSIL slides and found only 1 (4.3%) to have a normal:abnormal ratio of $> 1000:1$ -that case was 4600:1.

A more general way of looking at this is shown by the black line in Figure 9 (note the log-linear scale). The X-axis is the aneuploid:normal cell ratio times the number of epithelial cells measured, so it does not just apply to the case of 5000 cells as in Figure 8. The simple “rules of thumb” are: (1) if the aneuploid:normal cell ratio times the number of cells measured is about 5, then the probability of a real false negative is just under 1%; and (2) if this product is about 7, then the probability of a real false negative is approximately 0.1%, which is well into the realm of diminishing returns. That is, to get a $\leq 1\%$ chance of a real false negative case when the ratio of normal to abnormal cells is 1000:1 requires measuring 5000 epithelial cells; if the normal to abnormal ratio is 5000:1, then 25000 epithelial cells must be measured and

Figure 9 General relationship between number of cells measured and the probability of a real false negative. The red line is considered “equivocal”.

so on. Setting a goal of a real false negative rate of $\leq 1\%$ is probably very aggressive for screening.

A final way to look at this is Figure 10 which shows how many cells must be measured for a 1% chance of a real false negative case (black line) or for a 95% chance of the being 3 or more aneuploid cells measured (blue line). Most publications on AQIC applied to cervical cancer screening report measuring 6000 or 8000 epithelial cells and so theoretically have a $< 1\%$ probability of having a real false negative when the normal:aneuploid cell ratio is less than 1300:1 and 1700:1, respectively.

SCAN REVIEW AND REPORT GENERATION

Normalization and DNA scale

Previously, it was mentioned that Beer’s law is applied to measure DNA for each pixel of the image and that the DNA content of each cell is determined by simply adding up the DNA content of each pixel of the image of that cell nucleus. This procedure quantifies the DNA on an arbitrary scale, but it is more useful to convert this to a relative DNA scale by normalizing to the normal diploid cell population. Again, cervical “Pap” samples are predominantly comprised of normal diploid cells, even when taken from a woman with invasive cervical cancer, and so for Pap samples such an internal reference cell population always exists. The normalized scale described here is called “DNA Index” or “DI” in which diploid cells have a DI = 1, tetraploid have DI = 2, *etc*. Figure 11 is an example of such a histogram measured for a pig liver “touch” preparation. The green peak represents purely single diploid hepatocytes, but the other peaks include mixtures of single tetraploid cells and clusters of diploid and/or tetraploid cells used to check the linearity of the DNA measurement. Arguably, the DNA Index is the natural scale to use for cancer screening which is primarily concerned with deviations from diploid for somatic cells.

Figure 11 DNA index for pig hepatocytes for DNA linearity calibration.

However, the original DNA scale is the “C-index” scale in which $DI = 1$ is designated as “2C”, $DI = 2$ is “4C” *etc.* This scale was first used in 1950 by the American, Swift^[37], in a study employing DNA measurement by microphotometry of Feulgen stained cells of various plant species (basically the same technique as AQIC). Swift found that within the non-dividing cells of a species, the DNA content of cells tended to be in quanta that he labeled “C” for “classes”: “Non-Dividing Tissues: Photometric measurements made on tissues where mitoses were uncommon tended to fall in certain well marked classes. Means of these classes fit in the series 1:2:4:8:16:32.” On this scale, 1C is the quantum of DNA in a (plant or animal) sperm cell. The DNA amount corresponding to 1C varies from species to species. An earlier similar study of various animal species^[38] noted the ratio 1:2:4 for DNA in cells from rat liver, but did not describe this in terms of the C-index, which would have been 2C:4C:8C. Arguably, the C-index is the natural scale for biology, in general, as opposed to the narrow field of cancer.

The first step in the data review checklist is to determine that the DNA normalization is valid, meaning that the normal diploid cell population was correctly identified and that the normalization was correctly applied. Figure 12 is a typical, correctly normalized DI histogram of the cervix sample taken from a healthy woman. The scatter plot 12 shows almost all diploid epithelial cells to be in a tight distribution except for a very few hypo-diploid epithelial cells highlighted by the blue oval. This hypo-diploid skewing is a general feature of cervix samples and is comprised of dead epithelial cells in which the DNA has degenerated. The amount of skewing increases with the presence of infection, particularly, but not limited to, *trichomonas vaginalis*. The skewing is much more obvious in Figure 13 where it does not affect the normalization. The last example (Figure 14) is of a case of *trichomonas vaginalis* and shows a peak of cells with degenerated DNA that is bigger than the normal diploid peak that should be used to normalize and define the DNA scale. It is beyond the scope of this review to dis-

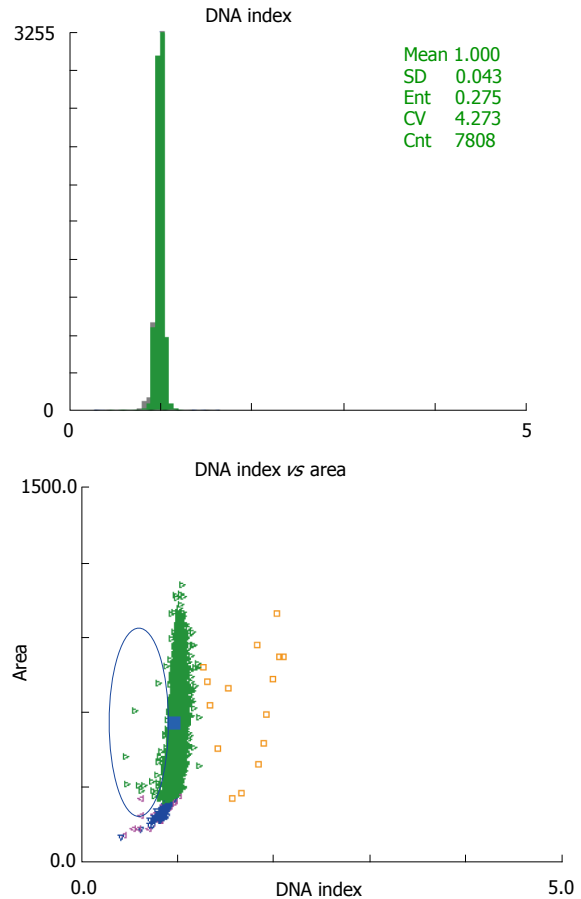

Figure 12 Typical DNA ploidy data for sample taken from a healthy cervix.

cuss automatic normalization algorithms and technician training strategies to deal with this. However, this problem is minimized if the sample taker cleans the cervix of excess discharge and secretions prior to taking the sample, as is called for by most sampling protocols^[33,39]. Some gynecologists believe this to compromise the sample, but an Randomized controlled trial (RCT) that involved taking two consecutive samples has shown the results to be independent of sampling sequence^[40].

High DI aneuploid cells and $DI > 2.5$ (or $> 5C$)

The second step in the data review checklist is to examine any images that could be of aneuploid cell nuclei, most usually defined as having $DI > 2.5$ or “5C exceeding”. Why is this the practical definition of aneuploidy?

Since AQIC does not identify and count individual chromosomes, it is usually not possible to discriminate normal cells in cell cycle (mitosis), for which the DNA content ranges from $1 \leq DI \leq 2$, from aneuploid cells with similar DI. Given that no measurements are exact, it is usual to apply a 10% uncertainty^[20] meaning that normal cell cycle ranges from $0.9 \leq DI \leq 2.2$ and hence the likelihood is that cells with $DI > 2.2$ are aneuploid. The convention of $DI > 2.5$ ($> 5C$) was probably a “padding” to the 10% DNA measurement uncertainty, for broad, conservative generalizability. However, Guillaud *et al*^[41] looked directly at the DNA ploidy sensitivity and speci-

Figure 13 Typical DNA ploidy data for sample taken from a cervix without removing excess secretions or discharge.

Figure 14 DNA ploidy data for sample taken from a cervix infected with *trichomonas vaginalis* without removing excess secretions or discharge.

ficiency for cervical cancer screening by AQIC as a function of DNA content of putative aneuploid cells. When 3 or more aneuploid cells were present, the threshold converged to $DI \geq 2.2$ (4.4C), but when only 2 or 1 aneuploid cells were present, the threshold rose to $DI \geq 2.3$ (4.6C) and $DI \geq 2.4$ (4.8C), respectively. These results may be specific to their cytometer and their particular laboratory operations standards; other labs may want to calibrate their performance if they choose to adjust the definition of high DI aneuploidy.

Another potential ambiguity is due to polyploidy which refers to euploid cells with $DI = 2, 4, 8, 16, \text{etc.}$ (4C, 8C, 16C, 32C...). As mentioned previously, this condition does occur normally in some tissues^[2] and, even when abnormal, does not necessarily indicate cancer. Concern for polyploidy induced by koilocytosis led Chatelain *et al.*^[42] to propose setting the threshold for aneuploidy in cervical cancer to $DI \geq 4.5$ ($\geq 9C$). However, for cervical cancer screening, such restrictively defined aneuploid cells are too rare to give the test reasonable sensitivity, even in high risk HPV (hrHPV) positive cases^[41,43-45] and no evidence of threshold behavior at $DI = 4.5$ was observed by Guillaud *et al.*^[41]. For the purposes of cervical cancer screening, the effective definition of an aneuploid cell is one with $DI \geq 2.5$ (5C). Although the 9C aneuploidy threshold is not useful for cervical cancer screening, it

may have utility in diagnosis.

Figure 15 shows the histogram, scatter plot and gallery of the 8 aneuploid cells found in this typical positive case.

Aneuploid stemlines

The third step in the data review checklist is to check aneuploid stemlines which appear as a peak in the DNA histogram, but not at $DI = 1$ or 2 (2C or 4C) where normal cycling cell peaks appear^[20]. The fact that stemline cells are in a DI peak means that they have more or less the same DNA content and so they must divide coherently and with a relatively minor amount of chromosomal instability. By definition, such stemlines are aneuploid. Stemline cells are usually in mitotic cell cycle and so a smaller G_2/M peak is usually present at twice the DI of the stemline G_1/G_0 , which is usually but not always found between $1 \leq DI \leq 2$. Figure 16 is an example of a stemline histogram with G_1/G_0 at $DI = 1.6$ and with cells consistent with G_2/M at $DI = 3.2$, highlighted in blue in the right histogram with the broken vertical scale. Figure 17 is the quite rare case where the stemline G_1/G_0 is at $DI = 2.3$ (≥ 2 is rare) and with cells consistent with G_2/M at $DI = 4.6$ also highlighted in blue in the right histogram with the broken vertical scale.

Although looking for aneuploid stemlines is a step in the review checklist, it is rare for a sample to have a stem-

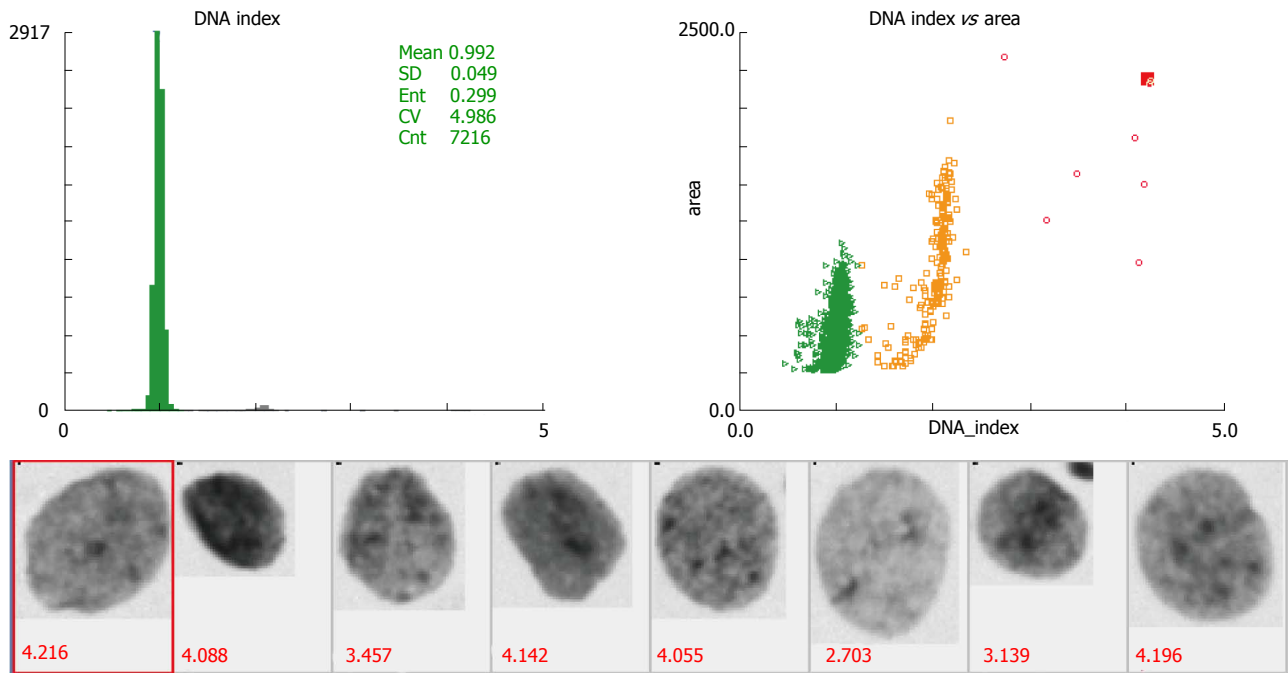

Figure 15 DNA ploidy data from a typical positive case with several aneuploid nuclei with DI > 2.5, the aneuploid nucleus gallery is shown with measured DI indicated in red.

Figure 16 DNA ploidy histograms of aneuploid stemline at DI = 1.6. A: Full histogram; B: Histogram with broken vertical scale.

line without there also being aneuploid cells with $DI \geq 2.5$, so identifying stemlines is usually redundant.

The relative lack of chromosomal instability on an aneuploid stemline may mean that the cell morphology looks rather normal and a biopsy may be interpreted as displaying hyperplasia rather than neoplasia, causing the stemline to be seen as an apparent false positive. However, hyperplasia is genetically normal but stemlines identified by DNA Cytometry are genetically abnormal and so are neoplastic. Presumably, the presence of identifiable stemlines occurs early in the process of neoplastic transformation. This author is not aware of any publications on the malignant potential or aggressiveness of lesions of the uterine cervix that are primarily characterized by aneuploid stemlines.

Cell proliferation

The fourth step in the data review checklist is to determine if there is unusual cell proliferation. Epithelial cells in a properly taken sample from a healthy cervix should almost all be completely differentiated and so do not divide. As mentioned previously, in the range $0.9 \leq DI \leq 2.2$ it is not possible by simple DNA Cytometry to discriminate aneuploid cells from normal cells in mitotic cell cycle. Li *et al*^[40] added anti-Ki67 immunostain (marker of cells in mitosis) to Feulgen stained cervical samples, but found no improvement in sensitivity and specificity compared to DNA Cytometry alone.

Excessive cell proliferation could indicate, among other things: (1) repair of wounds or repair processes due to fungal, bacterial and other infections; (2) response

Figure 17 DNA ploidy histograms of a rare aneuploid stemline at DI = 2.3. A: Full histogram; B: Histogram with broken vertical scale.

Figure 18 DNA ploidy data of a high proliferation case which also shows high DI aneuploid cells.

to hormones, drugs or radiation, especially in cancer treatment; (3) response to viral infections like HPV; (4) hyperplasia as an epigenetic response to some chemical, mechanical or other stress; and (5) neoplasia.

One expects that applying this criterion alone for cancer screening will have a relatively high false positive rate with so many non-neoplastic causes for cell proliferation. This criterion is usually applied by comparing the number of epithelial cells with $1.25 \leq DI \leq 2.5$ to the total epithelial cell count. Figure 18 is a typical example showing over 15% proliferation and, as is usually the case, there are 4 aneuploid cells also present, making the proliferation rate determination redundant. Figure 19 is a rare case without any measured aneuploid cells and has a proliferation fraction of 8.7%.

The original proliferation rule was derived from unpublished data of the author at the British Columbia Cancer Agency (BCCA) about 20 years ago (Figure 20), which set a threshold of 10% proliferation for calling a case positive, which is approximately the boundary between LSIL and HSIL. Most of the papers published in China in the past 10 years report using this value. A

second “equivocal” threshold is set at 5% proliferation which is approximately the value for ASCUS and is used as an “equivocal” diagnosis, discussed later.

No evidence of abnormality-sample adequacy

The fifth and last step in the data review checklist only applies when none of the preceding criteria for positivity are present. When no abnormality is found, the assessment of sample adequacy must be applied—were enough cells examined for a high probability that the case is actually negative? There is always some reluctance to declare a sample to be “unsatisfactory” with a recommendation of a return visit of the woman for another sample, which must balance the increased but unknown risk to the woman with an unsatisfactory test^[33] against “... undue burdens on the users and providers of the screening program”^[34], including costs. Although the background of this has already been discussed at length, none of the publications reviewed here have included a definition of what their laboratory uses for an adequacy standard. Guillaud *et al*^[41] determined 2000 or more epithelial cells on ThinPrep slides to optimize the sensitivity and speci-

ficity in a research setting.

FRAMEWORK FOR EVALUATING SCREENING TESTS

Arbyn *et al*^[47] and Adriaensen *et al*^[48] reviewed how to evaluate cervical cancer screening technologies through their various phases, in 2009 and updated in 2013, with extensive references.

However, most of the papers available for examination for this review are cross-sectional, observational studies that compare automated quantitative image cytometry to liquid based conventional cytology and the analysis centers on 2×2 contingency tables and the extraction of comparative sensitivity, specificity, positive and negative predictive values, usually also reported in the paper abstract. The literature has similar analyses for screening for other cancers with other technologies^[49]. In the opinion of this reviewer, these analyses are confusing at best and highly misleading at worst and most are singular in their absence of insight into genuine clinical utility of the tests. This section attempts to provide some suggestions to improve the data analysis with particular focus on the clinical meaning.

A typical study reviewed here is observational, ap-

plied to 10000 subjects screened with both Tests 1 and 2; the 600 who are positive by either test receive a recommendation to attend colposcopy; and the 250 available biopsy results become the exclusive focus of the analysis—the other 9750 cases of the study are ignored! In this analysis example there are "excluded" data (the $10000 - 600 = 9400$ cases that test negative by both Tests 1 and 2) and "missing" data (the $600 - 250 = 350$ cases who tested positive by at least one of Test 1 and 2 but with no follow-up result). Typically, there are 5 biopsy outcomes: negative (or cervicitis or inflammatory), CIN1, CIN2, CIN3 and invasive cancer. Tests 1 and 2 also typically have several diagnostic grades, such as NILM, ASCUS, LSIL, *etc*. The study applies some thresholds to collapse Test 1 *vs* histology and Test 2 *vs* histology to 2×2 contingency tables and the well-known formulae are applied to calculate sensitivity, specificity and predictive values. Typically, the reported specificities are very low as are the negative predictive values (NPVs), which is entirely an artifact of the failure to include the other 9400 negative cases in the analysis. Some statistics software even extracts the area under the receiver operator characteristics (ROC) curve from this single measured point, which is also often reported in the paper abstract. Finally, many papers also report the result of combining Tests 1 and

2 based on these same 2×2 tables, almost always as the logical “or” of positive results (the combined test is positive if either 1 or 2 is positive).

What is the interpretation of the results based solely on the 2×2 tables for the small subset of cases that have biopsy results available? For the moment, let us ignore the problems of verification bias, missing data and imperfect “gold standard” reference diagnosis—they are discussed later. Because the table is comprised only of cases testing positive by one or both screen tests, both the sensitivity and positive predictive value (PPV) are legitimate estimates of the screen test values and the PPV can be interpreted as the probability that a woman sent for biopsy will have a positive result. The specificity and negative predictive values are meaningless, however, because the “excluded” data is the vast majority of negative cases. In fact, the negative cases that are included in this 2×2 table are very strongly biased because the cases negative by Test 1 were positive by Test 2 and *vice versa*—otherwise colposcopy would not have been recommended (a few cases may be negative by both Test 1 and 2, but a biopsy resulted from other clinical evidence, which is not usually consistent with the notion of “screening”^[50]). In this fictional example, the vast majority of the 9400 subjects who tested negative by both tests are indeed negative and with less doubt than the highly biased negative cases included in the 2×2 table of biopsy results. The only value this “specificity” and “NPV” have is to show them to be higher in one test than the other, but the real magnitude of this difference cannot be estimated from these results. This reviewer believes that authors who perform such analysis should not report these as “specificity” and “NPV” but should find new terms, such as “reduced” or “biopsy biased” specificity and NPV, or better yet, not report them at all as they have no clinical meaning. It is ironic that for this kind of observational study the specificity and NPV are so grossly miscalculated and reported when, in fact, they can usually be quite reliably determined, as discussed later.

Given a 2×2 contingency table, the mathematical definitions of sensitivity, specificity, positive and negative predictive values are crystal clear, but the same is not true for their meaning. It is very common to have different definitions of “sensitivity”, “specificity” or “predictive” values”, even though the formulae by which they are extracted for the 2×2 tables are invariant; that is, the meaning depends on the table content. For example, in the world of HPV testing, there is the “analytic sensitivity” which refers to the ability of the test to detect the presence of HPV as distinct from “clinical sensitivity” which refers to the ability of the test to predict the presence of CIN^[51-53]; in general, too high analytic HPV sensitivity causes very low clinical specificity. As another example, in the screening mammography program of British Columbia^[54], the positive predictive value of a single screening mammogram ranges from about 2% to 20%, depending on the age of the woman, averaging to about 6.5% across all ages. This is the “test PPV”.

However, the screening program does not send women with a positive screen mammogram to biopsy but instead performs other tests, primarily diagnostic mammograms and/or ultrasound. Of the women actually sent for biopsy, about 33% are found to have cancer or DCIS—this is the “program PPV” and its clinical interpretation is “the probability that a woman sent for biopsy actually has breast cancer.”

Excluded data

While a screening test ideally should have both high sensitivity and specificity, high specificity is more critical. A screen test with a sensitivity of 50% and specificity of 95% would be inefficient but could be useful; the conventional Pap test has approximately this performance and it has reduced cervical cancer mortality by 70% in countries where it has been effectively applied. A screen test with a sensitivity of 95% and specificity of 50% would not be useful by itself because half of the screened population would have false positive test results. Depending on the follow-up consequences of a positive screen test result, most screen tests must have a specificity of at least 90% and probably many require specificity > 98%. In many of the papers reviewed here, the specificities are reported as “test” specificities in the abstract and are very low, often 40%-80% and even as low as 2%-3%^[55], entirely an artifact of failing to include most of the negative test data. On seeing these low values, those who understand screening might dismiss both Tests 1 and 2 as being completely useless.

These considerations show that the excluded cases that tested negative by both Test 1 and 2 should be included in the contingency tables (the effect of verification bias is discussed later) in order to obtain reasonable estimates of the specificity and NPV.

Screening does not have binary results

A key problem with 2×2 tables is the clinical reality that there are not two but three screening test results^[56]: positive, negative and equivocal, as shown in Figure 1, and defined as “too atypical to call ‘negative’ but not enough to call ‘positive’.” It is common to use time and re-testing to resolve equivocal cases, which is especially important for cervical cancer screening given that most “pre-cancers” resolve without medical intervention, especially in younger women^[57-64]. A recent study estimates that < 2% of CIN2/3 lesions progress to cancer within 10 years^[65]. At BCCA, ASCUS and LSIL are considered to be equivocal and the management recommendation is for repeat Pap testing at 6 mo intervals up to 4 times; if there is no resolution of the case by then, colposcopy is recommended^[50]. The most recent ASCCP management guidelines^[66] treat cytology ASCUS and histology CIN1 in all women and LSIL and CIN2 in young women as equivocal, with follow-up intermediate between how negative and positive cases are managed. While there is concern for loss of the patient to follow-up and undue burden on the patient, this must be balanced against the burdens

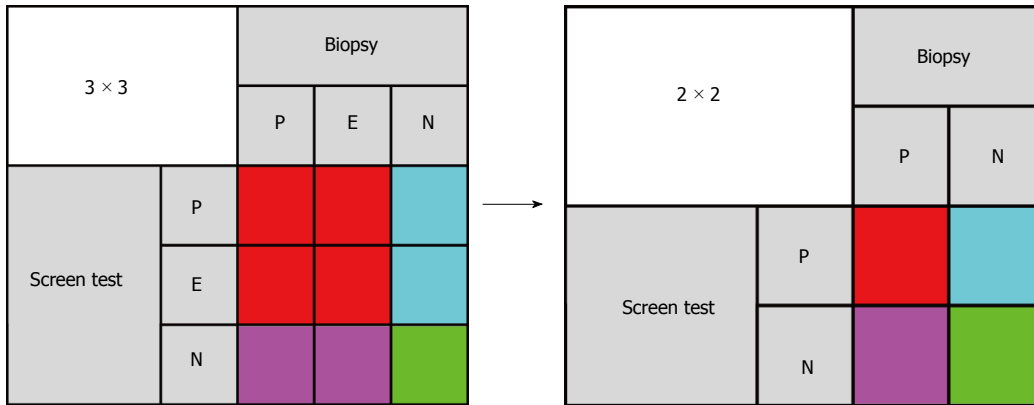

Figure 21 Mapping of 3×3 to 2×2 tables for sensitivity, specificity and negative predictive value.

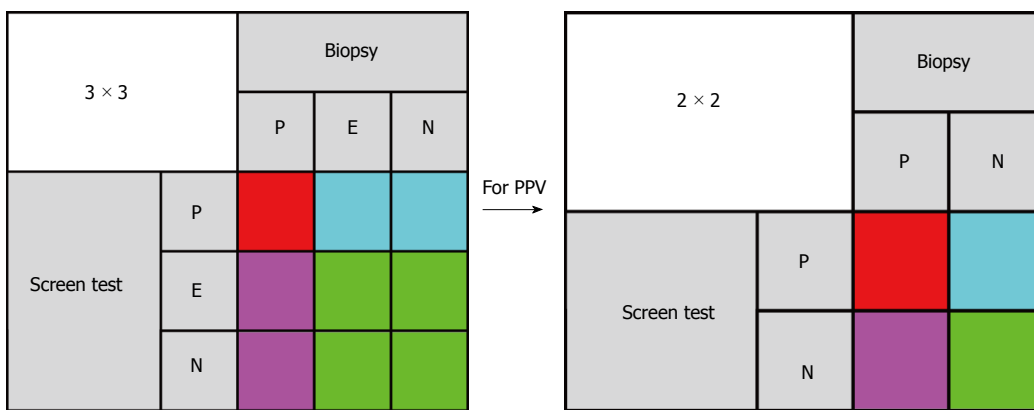

Figure 22 Mapping of 3×3 to 2×2 tables for positive predictive value.

and possible negative consequences of overtreatment, especially in younger women^[67-75]. Various strategies are possible to mitigate the burden of repeat testing.

For DNA Cytometry, most authors follow the recommendation that cases with the detection of 1 or 2 high DI aneuploid cells should be considered “equivocal” while ≥ 3 are considered positive (Figures 9, 10). Some laboratories also call cases equivocal that have between 5 and 10% proliferation fraction, as shown in Figure 20.

Unfortunately, there are no standard formulae for managing 3×3 tables, so some consideration should be given to the clinical meaning of what is calculated and reported. In collapsing the screen Test 1 or 2 and histology “gold standard” 3×3 tables to 2×2 contingency tables, one possible clinically relevant approach is to set the thresholds between “negative” and “equivocal” for sensitivity, specificity and NPV as shown in Figure 21.

Here the clinical interpretation of the screen test performance is: Sensitivity-the probability that positive gold standard cases had screen test results of positive or at least of equivocal. The notion is that equivocal screen cases cannot be called negative since they do carry a recommendation for follow-up; equivocal screen tests may represent delayed diagnosis cases but not missed diagnosis cases; Specificity-the probability that screen Test 1 negative cases are also screen Test 2 negative and biopsy

negative (when biopsy is available) cases; and Negative Predictive Value-its complement, (1-NPV), is the probability that a woman who is told she is disease free is actually not.

For PPV, the collapse of the 3×3 to 2×2 table follows a different scheme (Figure 22) because its usual clinical interpretation is: Positive Predictive Value-the probability that a patient sent for biopsy will have a positive biopsy result. Women with equivocal screen test results will not generally be recommended for colposcopy and possible biopsy.

A worked example

To illustrate the magnitude of the differences between these different approaches to analysis we work through an example based on data by Bao^[76] from 2009, selected because it is one of the larger studies published and because it has reasonably complete reporting of the data. Table 1 shows the overall results for cytology and DNA Cytometry for almost 20000 cases.

The screen test vs biopsy results are Table 2 for Cytology and Table 3 for DNA Cytometry.

The 2×2 tables used in the publication are shown in Table 4 using CIN2+, LSIL+ and DNA Positive as the thresholds for histology, cytology and DNA Cytometry, respectively.

Table 1 Cytology and DNA Cytometry results from Ref^[76]

Cytology ¹		DNA Cytometry	
NILM	18503	Negative	17855
ASCUS	720 (0.40)	Equivocal	1395
LSIL	296 (0.89)	Positive	371
HSIL	59 (1.00)		
Total	19621	Total	19621

¹Number in parenthesis is the fraction with at least 1 aneuploid cell by DNA Cytometry. NILM: Negative for intraepithelial lesion or malignancy; ASCUS: Atypical squamous cells of undetermined significance; LSIL: Low grade squamous intraepithelial lesion; HSIL: High grade squamous intraepithelial lesion.

Table 2 Biopsy results vs Cytology from Ref^[76]

Histology	Total	Cytology			
		NILM/inflam	ASCUS	LSIL	HSIL
Ca	15		6	5	4
CIN3	43	5	10	14	14
CIN2	66	12	15	23	16
CIN1	98	42	22	21	13
CC/Neg	401	285	86	18	12
Total	623	344	139	81	59

NILM: Negative for intraepithelial lesion or malignancy; ASCUS: Atypical squamous cells of undetermined significance; LSIL: Low grade squamous intraepithelial lesion; HSIL: High grade squamous intraepithelial lesion; Ca: Invasive cancer; CIN: Cervical intraepithelial neoplasia; CC: Cervicitis.

Table 3 Biopsy results vs DNA Cytometry from Ref^[76]

Histology	Total	DNA Cytometry		
		Neg	Equiv	Pos
Ca	15		2	13
CIN3	43	1	12	30
CIN2	66	3	19	44
CIN1	98	15	55	28
CC/Neg	401	87	280	34
Total	623	106	368	149

Ca: Invasive cancer; CIN: Cervical intraepithelial neoplasia; CC: Cervicitis.

The test performance results are given in Table 5. The authors did not report the NPV and PPV in their publication. Based on these numbers, the performance of the two tests is quite comparable, although cytology missed 6 of 15 invasive cancers using the LSIL+ threshold while DNA Cytometry missed 2.

Next are 3 × 3 tables that include the previously excluded negative cases, but also with the missing data still deleted (as with the author's analysis above); biopsy results are compared with Cytology in Table 6 and with DNA Cytometry in Table 7. The definitions of Positive, Negative and Equivocal are arbitrary and arguable but used for illustration.

Following the approach outlined above to collapse the 3 × 3 tables to 2 × 2 tables according to the clinical interpretation described above yields new test performance

Table 4 2 × 2 Contingency Tables for Biopsy results vs Cytology and vs DNA Cytometry from Ref^[76]

Histology	Total	Cytology		DNA Cytometry	
		LSIL +	NILM/ASCUS	Pos	Neg/Equiv
CIN2+	124	76	48	87	37
Neg/CIN1	499	64	435	62	437
Total	623	140	483	149	474

NILM: Negative for intraepithelial lesion or malignancy; ASCUS: Atypical squamous cells of undetermined significance; LSIL+: Low grade squamous intraepithelial lesion or higher; CIN: Cervical intraepithelial neoplasia.

Table 5 Cytology and Cytometry test performance based on data and analysis from Ref^[76]

	Cytology	DNA Cytometry
Sensitivity	61.3%	70.2%
Specificity	87.2%	87.6%
PPV	54.3%	58.4%
NPV	90.1%	92.2%

PPV: Positive predictive value; NPV: Negative predictive value.

Table 6 3 × 3 Contingency Table for Biopsy results vs Cytology from Ref^[76]

Histology	Total	Cytology		
		Positive (LSIL +)	Equivocal (ASCUS)	Negative
Positive (CIN2+)	124	76	31	17
Equivocal (CIN1)	98	34	22	42
Negative	18560	30	86	18444
Total	18782	140	139	18503

ASCUS: Atypical squamous cells of undetermined significance; LSIL+: Low grade squamous intraepithelial lesion or higher; CIN2+: Cervical intraepithelial neoplasia, grade 2 or higher; CIN1: Cervical intraepithelial neoplasia, grade 1.

Table 7 3 × 3 Contingency Table for Biopsy results vs DNA Cytometry from Ref^[76]

Histology	Total	DNA Cytometry		
		Positive	Equivocal	Negative
Positive (CIN2+)	124	87	33	4
Equivocal (CIN1)	98	28	55	15
Negative	18150	34	280	17836
Total	18372	149	368	17855

CIN2+: Cervical intraepithelial neoplasia, grade 2 or higher; CIN1: Cervical intraepithelial neoplasia, grade 1.

results shown in Table 8.

The increase in sensitivities is due to considering equivocal cases as positive since they include a recommendation for follow-up. The PPVs are unchanged. The specificities and NPVs are much higher when the negative cases are included and are consistent with the

Table 8 Cytology and Cytometry test performance based on data from Ref^[76] and revised analysis

	Cytology	DNA Cytometry
Sensitivity	73.4%	91.4%
Specificity	99.4%	98.3%
PPV	54.3%	58.4%
NPV	99.68%	99.89%

PPV: Positive predictive value; NPV: Negative predictive value.

requirements for screening test performance.

Many authors interpret the high NPVs as being almost equal and so to be uninteresting. In fact, the clinical significance of the NPV is seen from its complement (1-NPV), which relates to “false negative” cases. In this example of 10000 women who are advised that they are disease free, in fact, 32 or 11 are not, based on cytology or DNA Cytometry, respectively. In this regard, the performance is quite different between the two tests. This is especially important when routine screening is infrequent, say once or twice during a woman’s lifetime.

An alternative approach to compare the tests is to simply tabulate the results descriptively as in Table 9.

This study was primarily of rural women who had not previously been screened.

The impact of uncorrected verification bias

Most observational screening studies suffer from verification bias because the “gold standard” of colposcopy guided biopsy is only applied to the cases that test positive by the screen test, so the true disease state of those who test negative is not verified. There are statistical methods to correct for this kind of bias (e.g.^[77]). RCTs sometimes manage this by performing colposcopy and biopsy on a random sample of the negative cases, under proper informed consent and ethics board approval (e.g.^[78]), although this also has its pitfalls^[47].

It may be instructive to look at the impact when this kind of verification bias is left uncorrected. Figure 23 plots the “DNA Cytometry” data of the previous example (Table 8) as a function of the fraction of positive and equivocal cases detected in the study; the left axis is where all positive and equivocal cases were detected and it declines to where only 50% were detected at the right axis. PPV is completely unaffected because it relates only to ratio of positives that the screen correctly identified to the total that it tested positive; hence, any false negatives do not affect this ratio. NPV and specificity decline only slightly over the range plotted. It is the sensitivity, of course, that is potentially most impacted by this kind of verification bias, with an inverse proportional linear dependence; that is, if only half of the positive cases were detected in the study, then the measured sensitivity is double the correct value.

In summary, when this kind of verification bias is left uncorrected it has no impact or almost no impact on predictive values or specificity but it can significantly inflate the measured sensitivities. However, in studies such

Figure 23 Effect of uncorrected verification bias on test performance indicators.

as those described above, it is likely that well over 90% of the true positive cases were detected by one or both of the screening tests^[47,79], so the impact of uncorrected verification bias in this type of study is unlikely to be very large.

Unbiased comparisons of test performance

It has been shown that the ratio of (Test 2) : (Test 1) for true positive rate and for false positive rate determined just from the complete biopsy results (with no missing data) does not suffer verification bias of the type discussed above (not subjecting negative cases to the “gold standard” test)^[80,81]. This may be enough to rank Test 1 *vs* Test 2.

Table 10^[80] summarizes the biopsy data required and the relative true positive rate, *relTPR*, and relative false positive rate, *relFPR*, are simply^[81]:

$$relFPR (\text{Test 2/Test 1}) = \{(a + b)/[n]\} / \{(a + c)/[N]\} = (a + b)/(a + c)$$

$$relTPR (\text{Test 2/Test 1}) = \{(A + B)/[N]\} / \{(A + C)/[N]\} = (A + B)/(A + C)$$

The key point is that the unknown [n] and [N] are eliminated, leaving only known values from the biopsy result table. If *relTPR* increases and *relFPR* decreases, then Test 2 is easily judged to be the better test, although as Arbyn *et al*^[47] points out, such cross-sectional results do not necessarily translate into longitudinal improvement in the screening program. It is more generally the situation that both *relTPR* and *relFPR* increase at the same time, in which case it is necessary to consider the disease prevalence in the target screen population to determine if the cost of increased false positives justifies the benefit of the increased true positive detection. In the special case where the target population and the study population have the same prevalence (this is generally true for observational studies of routine clinical data), then the *FP/TP* ratio is given by: $FP/TP = (B - C)/(b - c)$. This ratio is one “figure of merit” in deciding if Test 2 is better than Test

Table 9 Descriptive summary of the data of Ref [76] as re-analyzed *n* (%)

Clinical result		Cytology number of cases	DNA Cytometry number of cases	Cytometry-Cytology number (%)
1	Number of women immediately returned to routine screening	18503	17855	-648 (-3.5)
2	Number of CIN1+ cases (false negative cases) per 10000 women returned to routine screening	32	11	-21 (-66)
3	Number of women referred to immediate colposcopy	140	149	9 (6)
4	Number of cases of invasive cancer immediately diagnosed	9	13	4 (44)
5	Number of CIN3+ cases immediately diagnosed	37	43	6 (16)
6	Number of clinically positive cases (CIN2+) immediately diagnosed by colposcopy	76	87	11 (15)
7	Number of women requiring 6 mo follow-up due to equivocal result	139	368	229 (165)
8	Number of women with potentially delayed clinically positive (CIN2+) diagnosis	31	33	2 (6)
9	Number of CIN3+ cases missed	5	1	4 (80)
10	Number of CIN2+ cases missed	17	4	13 (76)

Table 10 Definitions of the biopsy data required for comparison of two screening tests independent of simple verification bias, Ref^[80]

	Gold standard positive			Gold standard negative		
	Test 1+	Test 1-	Total	Test 1+	Test 1-	Total
Test 2+	a	b	a + b	A	B	A + B
Test 2-	c	[d]	[c + d]	C	[D]	[C + D]
Total	a + c	[b + d]	[n]	A + C	[B + D]	[N]

Variables in square brackets have unknown values.

Table 11 Biopsy data from Ref^[82] for simple verification bias free comparison of Cytology vs DNA cytometry

	Biopsy +			Biopsy -		
	Cytology +	Cytology -	Total	Cytology +	Cytology -	Total
AQIC+	130	37	167	30	23	53
AQIC-	1	0	1	0	0	0
Total	131	37	168	30	23	53

AQIC+: Positive by automated quantitative image cytometry; AQIC-: Negative by automated quantitative image cytometry.

1 and comes down to the judgment of “how many extra false positive cases are acceptable for each additional true positive case detected?” The value of this ratio will depend upon the undiagnosed disease prevalence.

Exactly the same results are obtained by inspection of the appropriate 2×2 tables for each test *vs* the biopsy results; both calculation methods are illustrated next.

Tian *et al*^[82], provided the case by case data for that paper to allow illustration of the method here. The first look at this is based on “positive” defined as ASCUS+, Equivocal+ and CIN1+ for cytology, DNA Cytometry (AQIC) and pathology, respectively, summarized in Table 11. The *re*TPR = 1.3 and *re*FPR = 1.8, both increasing as expected. However, the *FP*/*TP* ratio is just 0.64, meaning that for every extra true positive detected by AQIC, 2/3 additional false positive cases occur, which is probably an acceptable trade-off.

The same result is obtained from the published^[82] 2×2 tables, using the same thresholds for positive, as shown in Table 12. By inspection *re*TPR = $167/131 = 1.3$ and *re*FPR = $53/30 = 1.8$ and *FP*/*TP* = $(53-30)/(167-131) = 23/36 = 0.64$.

These ratios may provide a useful, unbiased “figure of merit” with which to compare one test to another. The key message is that these ratios-the relative true positive rate, *re*TPR, relative false positive rate, *re*FPR and *FP*/*TP*-are not subject to verification bias of the type due to failing to perform the “gold standard” reference test on the large number for cases that test negative by both Test 1 and Test 2. However, they may be subject to bias due to missing data, discussed next.

Missing data

But what about the missing data-the cases recommended for colposcopy for whom there is no follow-up information? This is a particular kind of verification bias and there are formal methods to correct for it (for example^[77,83-87]) that involve using statistical methods to impute the missing data with minimal bias, but they are beyond the scope of this paper. The simplest method is to delete these cases from the analysis, as was done in the example above and in all of the DNA Cytometry papers reviewed here. This is approximately equivalent to assuming that the missing data is the same as the known data. Because the missing data is all from cases that tested positive by either or both Tests 1 and 2, this has no effect on the NPV, for reasons analogous to why the PPV was unaffected in Figure 23. There is no simple, general statement one can make about the impact of the missing data on the sensitivity, specificity or PPV except that the range of possible deviation between the uncorrected measurements and the true values is proportional to the amount of missing data. Each of the three performance measures could rise, fall or stay the same if the missing data were not missing. The key message is that it is extremely important to organize studies so as to minimize the amount of missing data. In the Bao paper, they did not report the total number of colposcopy follow up recommendations but, depending on the correlations between cytology and cytometry, at least 65% of the biopsy follow up data is missing, which is very typical for this series of papers from China.

Table 12 Alternative presentation of Biopsy data from Ref^[82] for simple verification bias free comparison of Cytology vs DNA Cytometry

Histology	Cytology			Histology	DNA Cytometry		
	Total	ASCUS+	NILM		Total	Pos/equiv	Neg
CIN1+	168	131	37	CIN1+	127	167	1
Neg	53	30	23	Neg	121	53	0
Total	221	161	60	Total	221	220	1

NILM: Negative for intraepithelial lesion or malignancy; ASCUS: Atypical squamous cells of undetermined significance; CIN1+: Cervical intraepithelial neoplasia, grade 1 or higher.

Effects of an imperfect “gold standard” reference

The “gold standard” reference diagnosis for cervical cancer studies is usually colposcopy directed biopsy, which a number of studies over the past decade have shown to be imperfect^[88-92]. More worrying were studies that showed that the measured sensitivity of Visual Inspection with Acetic Acid (VIA) were substantially inflated (by 1/6 to 1/3) due to use of colposcopy directed biopsy as the “gold standard” reference^[93-95]. Theoretical studies^[96] of such use of imperfect references have shown that if the screen and reference test errors are statistically correlated, then the test accuracy (sensitivity and specificity) measurements are over-estimated; conversely, if the screen and reference test errors are statistically independent, then the test accuracy measurements are underestimated. VIA is essentially a variation of colposcopy and so is highly correlated.

It has also become clear over the past decade that colposcopy sensitivity improves the more biopsies that are taken^[88,93,95,97,98], independent of the skill^[99] or medical training^[90] of the person performing the colposcopy, ranging from nurse-practitioner to gynecological oncologists. Many propose supplementing any lesion biopsies with a random biopsy from any quadrant without visible lesions^[97,99]. However, while this increases the rate of detection of CIN2+, it does not appear to affect the measured sensitivity of cytology, although it may improve the specificity slightly^[94]. It is unknown if taking more biopsies has any effect on the DNA Cytometry accuracy measurements but one might expect any effect to be small based on the cytology situation.

Combining binary test results

A great many papers, including several reviewed here, look at combining the results of two binary (or dichotomous) tests with the hope that the combined test result is an improvement over either of the component Tests 1 and 2. This is also applied to tests like Hybrid Capture 2 (HC2) HPV test that measures continuously valued viral load but which is made binary by applying a threshold, ≥ 1 RLU/Cutoff is positive, otherwise it is negative^[100].

It can be proven that there are only two non-trivial ways to combine 2 binary tests: as the logical “and” of positive cases, in which the result is positive only if both Tests 1 and 2 are positive, and as the logical “or” of posi-

Table 13 The test performance limits for the combination of two binary valued tests

	Sensitivity		Specificity	
	Minimum	Maximum	Minimum	Maximum
Logical “AND”	$(Se_1 + Se_2) - 1^1$	$\text{Min}(Se_1, Se_2)$	$\text{Max}(Sp_1, Sp_2)$	$(Sp_1 + Sp_2)^3$
Logical “OR”	$\text{Max}(Se_1, Se_2)$	$(Se_1 + Se_2)^4$	$(Sp_1 + Sp_2) - 1^2$	$\text{Min}(Sp_1, Sp_2)$

¹0% if $(Se_1 + Se_2) \leq 100\%$; ²0% if $(Sp_1 + Sp_2) \leq 100\%$; ³100% if $(Sp_1 + Sp_2) \geq 100\%$; ⁴100% if $(Se_1 + Se_2) \geq 100\%$. Se: Sensitivity; Sp: Specificity.

tive cases, in which the result is positive if either or both Tests 1 and 2 are positive. It is also possible to prove that the combined test results will conform to the limits in Table 13, where “Min” and “Max” are the minimum or maximum of the two entries in parenthesis and where Sp = specificity and Se = sensitivity.

For the logical “and” of positive results, the specificity of the combined test will be at least as high as the specificity of the most specific component test and could be 100%; however, the sensitivity will be no better than the sensitivity of the least sensitive component test and could be zero.

Conversely, for the logical “or” of positive results, the sensitivity of the combined test will be at least as high as the sensitivity of the most sensitive component test and could be 100%; however, the specificity will be no better than the specificity of the least specific component test and could be zero.

Examples of “and” and “or” combinations of binary tests and their compliance to these limits can be found in refs^[101-103].

Furthermore, it can also be proven that the result of combining these tests does not depend on the test order (they are commutative).

In either combination, it is not necessary to perform both tests on all subjects^[104]. For the logical “and” of positive test results, if the first test result is negative then the combined test result will also be negative, regardless of the second test result; similarly, for the logical “or” of positive test results, if the first test result is positive, it does not matter what the second test result is, the combined test result will be positive. This, plus the fact that the test order does not affect the results, means that a test strategy can be adapted to minimize costs in clinical practice (both must be done for comparative performance studies, of course).

There is one caveat with these rules: they apply for analytical tests that are independent in the sense that one test does not impact the other. For example, if one test compromised the sample for the other test, these rules might not apply. It is not so clear that cytology is a test that is independent of DNA Cytometry or HPV status, if the cytologist is aware of the DNA Cytometry or HPV results. Since most of the papers reviewed here are observational studies looking at both tests in routine use, it would be expected that the cytologist would, in general,

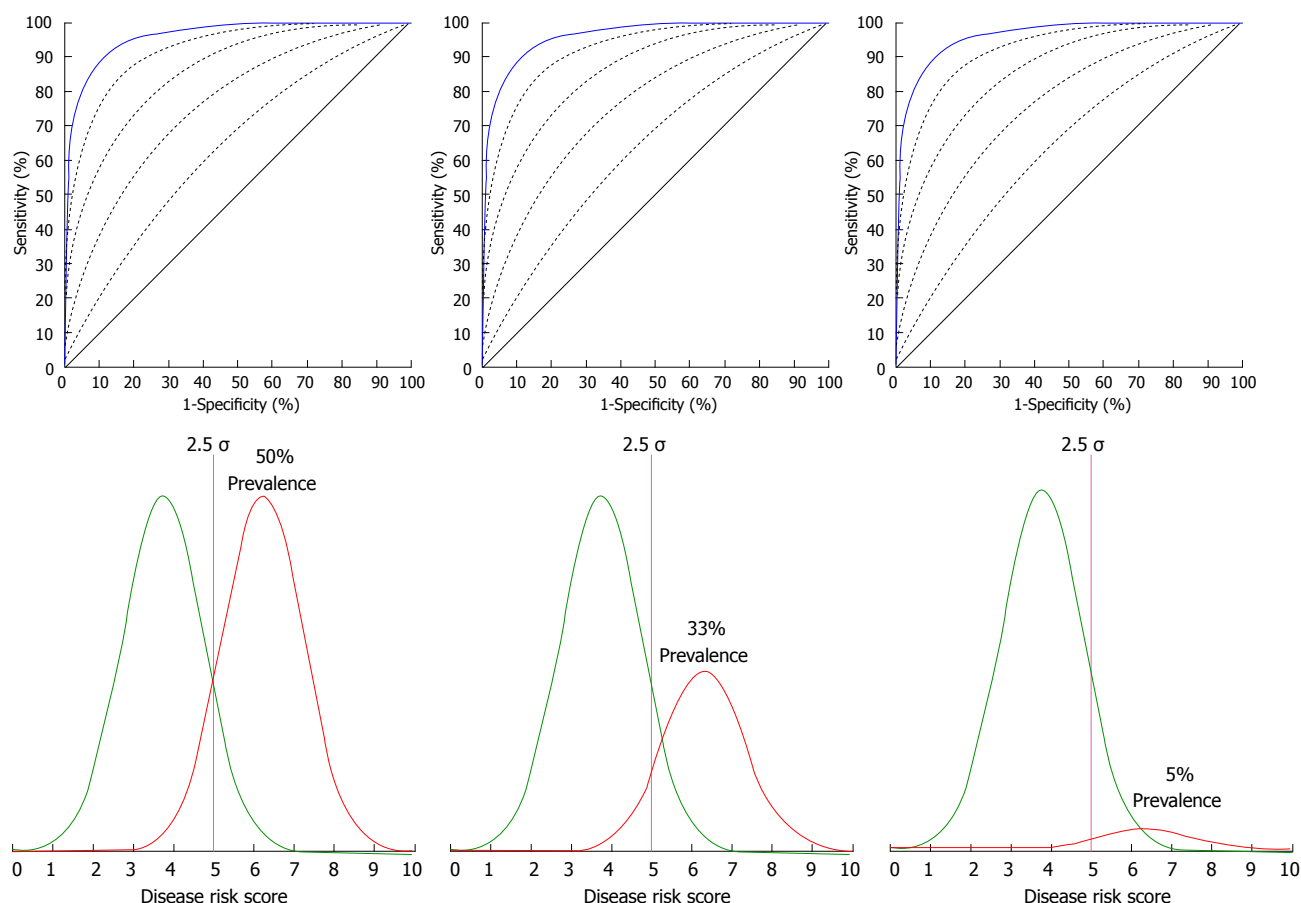

Figure 24 Sensitivity and specificity are independent of disease prevalence when the change in prevalence is only a scalar multiplier that does not change position, width or shape of the population distribution.

be aware of the results of the other tests since the goal is to get the correct answer for the patient, not to do a strict clinical study.

It does not seem to be appreciated by many authors that the limits in Table 13 seriously constrain any potential benefits from combining binary tests. Since one of sensitivity and specificity will rise as the other falls when the tests are combined, it usually only makes sense to combine tests that have very similar and high values for the one that will fall, so that it does not fall much and stays in range of what is useful. For example, cytology has poor sensitivity, but excellent specificity; hrHPV testing has excellent sensitivity, but only good specificity. Combining these tests will result in either excellent sensitivity and less than good specificity, or excellent specificity and poor sensitivity. There is no simple combination of HPV testing and cytology that works well. The work around for this until a better test or test combination is found is in the patient management algorithms, which are becoming increasingly complex^[6]. These algorithms manage “equivocal” cases with a combination of time and re-testing, in recognition that screen tests, even in combination, have 3 outcomes, not 2, as already discussed.

Impact of disease prevalence on estimates of test performance

A key issue in appreciating published study results is

to determine their degree of generalizability. A basic concept of epidemiology is that while predictive values explicitly depend strongly on disease prevalence, sensitivity and specificity are completely independent of it^[105]. Although this prevalence independence of sensitivity and specificity is certainly true, it is a fragile truth that may not survive test generalization. That is, if a published study demonstrates that Test A has sensitivity X and specificity Y with a particular disease prevalence Z, it does not mean that when applied to a different population with a disease prevalence of $1.5 \times Z$, Test A will have the same sensitivity and specificity found in the study, except if the mean, width and shape of the underlying distributions of positive and negative populations is also the same as in the study. Figure 24 illustrates ROC curves, which should be independent of disease prevalence since they essentially plot sensitivity *vs* specificity, for the case where the mean, width and shape of both positive and negative populations remains the same and only the positive distribution is multiplied by a scalar to reduce the distribution area without distortion or shifting of the peak position. As expected, the change in prevalence has no effect on the ROC curve or sensitivity and specificity, indicated by the blue line.

However, as a practical matter, “real life” changes in disease prevalence rarely occur this way. If the prevalence increases, and especially if it is a large increase, it also

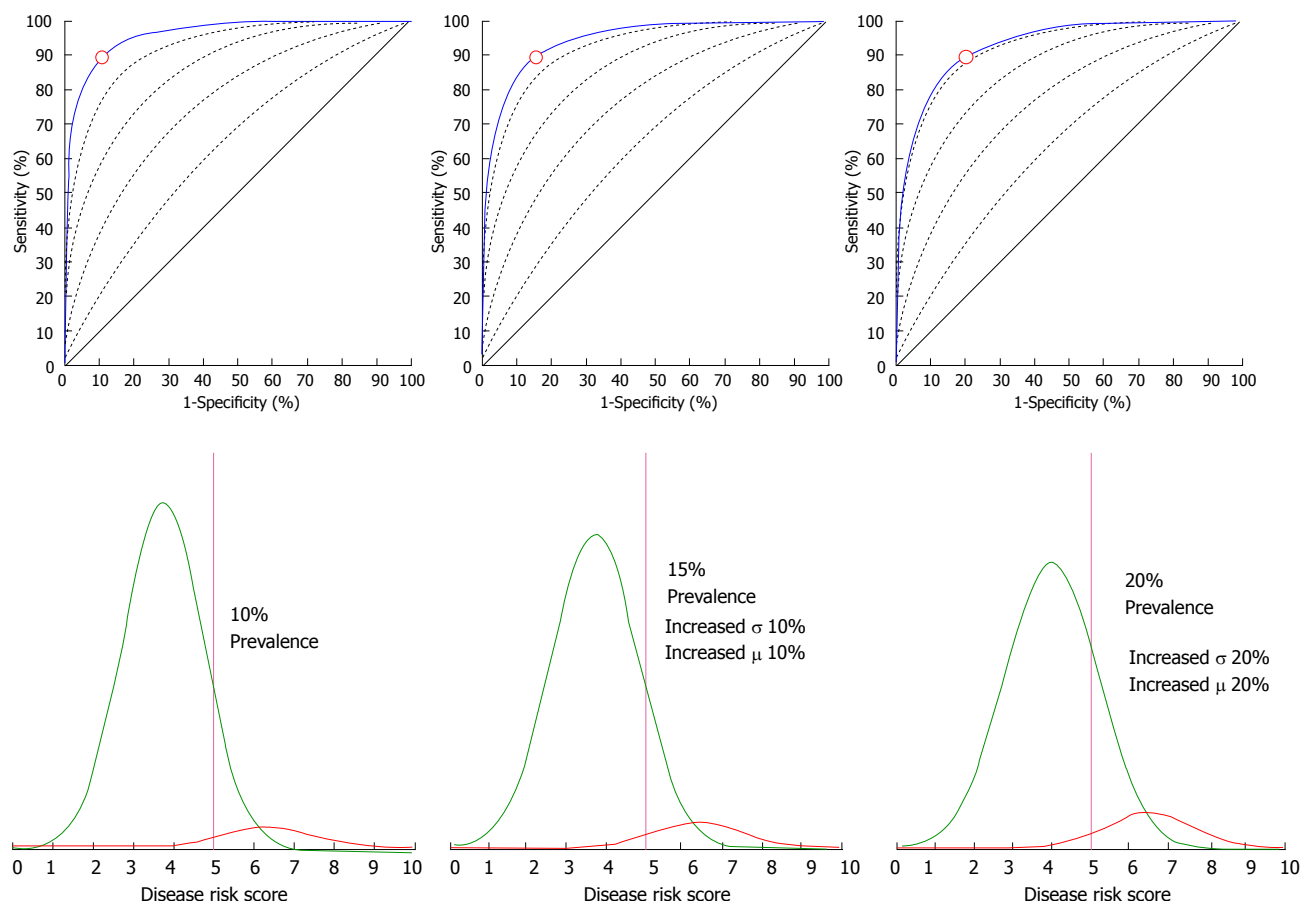

Figure 25 “Real life” changes in disease prevalence are usually accompanied by changes in both positive and negative population distribution positions, widths and shapes which do change the sensitivity and specificity.

probably causes changes in the mean, width and overall shape of both positive and negative distributions as the whole population is somewhat sicker, as illustrated in Figure 25. In scanning the figure from left to right, the prevalence increases, but the positions (μ) and widths (σ) of both distributions also increases. In this example, both distribution means (μ) shifted to the right the same amount-this would not cause any change in the ROC curve itself-the change in the ROC curve is caused by the change in widths (σ) of the distributions. The magenta line represents the Test threshold and the red point on the ROC curve corresponds to test performance at that threshold. Unless the test threshold is adjusted by re-calibrating the test to the new populations, then the test performance moves from optimal, as indicated by the shift of this operating point. This figure is based on symmetric analytic distributions for ease of calculation and drawing-there is no requirement that the underlying distributions for ROC curves are symmetric, analytic or even single peaked; hence, “real life” shifts in disease prevalence may cause different shifts in test performance than the simple ones illustrated here.

This result is technology independent and will apply not just to AQIC but also to hrHPV testing, for example. One situation where there is a large difference in undiagnosed disease prevalence is when a test is applied for

screening (testing people without symptoms) *vs* diagnosis (testing people with positive screen test results or with symptoms). Several recent publications have experimentally verified this for colposcopy^[106], hrHPV testing^[107], the conventional Pap test^[108], as well as a recent review of several meta-analyses of various diseases^[109]. The previous discussion of BCCA screening mammography *vs* diagnostic mammography is another example. Many physicians erroneously think that test sensitivity and specificity are invariant properties of the test and therefore independent of whom the test is applied to; this is not necessarily the case.

Although it is well understood that predictive values explicitly depend upon undiagnosed disease prevalence, it is less widely appreciated that this imposes significant limits on the positive predictive value. Why is the PPV not 100%? For a low prevalence disease, such as cancer in a screening setting, PPV is determined mostly by the false positives (or 1- specificity); PPV is only weakly dependent on sensitivity. Figure 26 shows the maximum possible PPV (under the condition that sensitivity is 100%) as a function of undiagnosed disease prevalence for various very high values of specificity. Even at a disease prevalence of 1% (1000/100000 persons) and with a test specificity of 99%, the PPV will only be 50%; if the test specificity falls to 98%, the PPV drops to about 33%.

Figure 26 Positive predictive value at 100% test sensitivity as a function of undiagnosed disease prevalence for various high values of test specificity.

This is another demonstration of the crucial importance of high specificity for screening tests. It also illustrates that cancer screening is more than a test—it is a process by which negative cases are progressively removed from the population under surveillance until the disease prevalence of the remainder is increased to levels that allow acceptably high PPVs.

In summary, undiagnosed disease prevalence has a big impact on screening test performance, firstly by affecting the real world generalizability of sensitivity and specificity and secondly by limiting the maximum possible test PPV.

The large Table 14 summarizes the observed crude disease prevalence in several automated quantitative image cytometry studies from China from 2005–2013. The studies were selected as having the word “screening” in the title, abstract or introduction; studies with only the word “diagnosis” were excluded. As previously discussed, there is often substantial “missing” biopsy result data in studies from China. The column “follow-up ratio” is an estimate made by this reviewer of the extent to which high grade cytology had corresponding biopsy data—the blank entries indicate that it was not possible to estimate this. With few exceptions, the listed disease prevalences are underestimated, in many cases by a factor of 2 or more. The heterogeneity of the results is quite alarming and certainly justifies the warnings just made concerning generalizing the study test results for sensitivity and specificity. The very high disease prevalence in some studies that are claimed to be “screening” is quite vexing.

PUBLICATIONS ON THE APPLICATION OF DNA PLOIDY TO CERVICAL CANCER SCREENING

Since 2005, the use of AQIC testing for cervical and other cancers has continuously expanded to about 1 million tests per year in 2013. At least 60 publications on various comparisons for AQIC performance to other means of

screening or diagnosing cervical cancer have appeared since 2005, mostly in Chinese language journals. This section reviews some of these papers.

Disease prevalence

Perhaps a good starting point is Table 14 on measured crude prevalence rates of invasive cervical cancer and CIN. As shown previously, disease prevalence is a very important epidemiological quantity that impacts the performance and deployment of tests, especially screening tests. However, prevalence is very difficult to measure and there are two very different flavors of prevalence that can cause confusion. Some cancer monitoring agencies report cancer prevalence meaning as “How many people diagnosed with cancer are alive today?” These are estimated either as “limited-duration” prevalence (limited to cases diagnosed over, say, the past 10 years)^[143] or “complete” prevalence which is independent of when the cancer was diagnosed, as is done by SEER^[144]. Neither of these is relevant to cancer screening which is focused on and influenced by “undiagnosed” cancer prevalence. From here on, the term “prevalence” will be understood to mean “undiagnosed prevalence,” unless explicitly modified.

If the cancer is undiagnosed, how do we know how much there is? In a well screened population, the disease prevalence is less important than it is in poorly screened populations. An effective screening program will detect the “prevalent” cases of cancer within several years of its introduction (depending on the screening program effectiveness and deployment details) and will remove them from the pool of undiagnosed cancers, leaving mostly what are known as new “incident” cases, approximately equal to the incident rate for that cancer among that population times the screening interval: P (cases/100,000 people) is approximately equal to I (cases/100,000 people/year) \times Screen Interval (years). In an unscreened population, the introduction of screening is usually the time when the disease prevalence can best be estimated by measurement; otherwise, it can only be estimated from cancer natural history and population models. In the absence of screening, cancer is diagnosed either by investigation of symptoms or incidentally during some other medical investigation. There is usually a delay between the onset of symptoms and diagnosis because the patient, physician or both ignore the symptoms for some time, as they are rarely specific. A crude “back of the envelope” estimate of undiagnosed invasive cancer in an unscreened population would be the incidence rate times the delay between invasion and onset of threshold symptoms—that is, symptoms strong enough to lead to diagnostic investigation: P (cases/100,000 people) is approximately equal to I (cases/100,000 people/year) \times Symptom Threshold Interval (years). What is the incidence rate of cervical cancer in China? The official rate from the 2004–2005 “Third National Survey” is 3.2/100,000/year and the mortality is 2.4/100,000/year, age standardized to the world population^[145]. If it takes on average 10 years between the onset on invasive cervical cancer and the onset of symptoms significant enough to seek

CIN2+: Cervical intraepithelial neoplasia, grade 2 or higher.

medical attention, then this would predict invasive cervical cancer prevalence of 30-60/100000, allowing for differences in age standardized rates. This is a factor 10-40 less than what is reported in several entries in Table 14.

Although the Chinese registries consistently report such cervical cancer incidence rates^[146-150] and the international reports (based on the same registries) only slightly inflate them presumably due to different age standardization^[151,152], there are good reasons for skepticism, including the fact that the registries span only 2%-6% of the population of China^[145]. Pooled and population based studies have shown prevalence rates of CIN2+ and hrHPV infection to be similar to or higher than in other Asian and south Asian countries with much higher cervical cancer incidence rates^[145,153-156]. Although the official mortality rate is slightly higher than in countries like the United States, United Kingdom or Canada with long established, effective cervical cancer screening programs, the official incidence rate in China is only 1/3-1/2 of that in these countries, even though a great many women in China have never been screened^[145,157]. In Hong Kong,

opportunistic cervical screening was introduced in 1970 at which time the age standardized incidence rate was measured to be 25-35/100000/year^[158] and even today, with a comprehensive cervical cancer screening program, has a crude rate of 9.7 and age standardized rate 6.9/100000/year^[159]. One of the requirements of screening is that the disease must be common enough to justify the expenditure of resources and it has been suggested that a crude rate of about 3/100000/year is a reasonable threshold^[160]; below this incidence rate, screening is not justified. This is likely not the situation with cervical cancer in China, but only if cervical cancer is being seriously under-reported by the registries, putting the official incidence rate in serious error. There is a clear need to resolve if the surprisingly low official incidence rate for cervical cancer in China is correct or not.

Two pooled population based analyses^[154,161] found crude prevalence for invasive cervical cancer of 170/100000 and for CIN2+ of 2.6% for combined rural and urban populations not screened within the past 5 years, including a significant proportion of women who had never been

screened. These data are consistent with many of those in Table 14.

In Table 14, in which most of the prevalences are lower limits due to missing biopsy follow-up data, 8 of 36 studies found invasive cancer prevalence $> 250/100000$; these tended to be small hospital-based studies that were possibly contaminated by diagnosis cases. In the author's experience in China, the Pap test is widely used for diagnosis rather than for screening, even though there is evidence that samples from symptomatic women are often unsatisfactory due to blood and other reasons and have a higher false negative rate than from asymptomatic women^[39]. As previously discussed, test performance can vary considerably due to differences in disease prevalence in the population tested. Laboratories that routinely use the automated quantitative image cytometry method for differential diagnosis may require re-calibration of the operating point for their instrument.

Comparisons of AQIC with LBC

The diffusion of the automated quantitative image cytometry technology in China has primarily been through existing pathology laboratories which are generally hospital based. Although the cytometers of the various vendors have regulatory approvals^[162,163] and endorsement by various medical societies and expert groups, it is natural that each lab would compare performance with existing conventional liquid-based cytology. Consequently, most of the publications from China are cross-sectional, observational studies from routine clinical practice in which both liquid based conventional cytology and AQIC are done on the same sample and the test performances compared, as detailed previously. Most of these studies found substantially increased sensitivity (up to a factor of 2)^[76,82,111,112,117,119,120,125,126,129-131,133,134,136,137,140-142], although some found essentially equal^[55,115,116,118,120,121,124,132,135,138,139] for AQIC at a slight loss of specificity compared to conventional LBC. These reports are not summarized in a table due to the great variability in analyses and reporting as outlined previously. There would be great benefit if future publications followed a more clinically meaningful standard analysis and reporting.

One RCT conducted in China spanning some 23000 women was published and claimed substantial superiority in sensitivity and PPV comparing AQIC to conventional LBC^[133]. Unfortunately, this reviewer cannot understand the analysis done in this paper^[164] and cannot even say with confidence how many cases of cancer were detected in the study, even following clarification^[165]. The study also had some disturbing longitudinal results that were not explained. On face value, the claims made in the publication of this trial are consistent with those of the observational studies listed above.

These papers, to varying degrees, speak to three intertwined issues: (1) that AQIC is simple and effective and could be applied in low resource settings where skilled cytologists are in short supply; (2) that AQIC is a good "second opinion" or "adjunct" to add on to the conven-

tional LBC Pap test; or (3) that the combined test (AQIC positive or LBC cytology positive = case positive) is best because of the increased sensitivity. To this reviewer's knowledge, issue (1) has really not been deployed in practice in China, although there seems to be a consensus belief that it would work well; most AQIC in China is deployed in hospitals with trained cytologists. Issue (3) is connected to issue (2) but generally ignores the performance cost in combined test specificity and, as previously discussed in detail, most of these papers incorrectly calculate the test specificity. Also as discussed previously, combination tests have the potential to work best when both have very high and very similar values for, say, specificity, so that the combination will greatly improve the sensitivity but only negligibly reduce specificity, or *vice versa*. This is generally not the case for conventional cytology and AQIC, so it is more likely that it is optimal to only use the best test.

Is it necessary to do both conventional cytology and automated quantitative image cytometry? First, here is some evidence that it is not necessary to do both. The biopsy data of Tian *et al*^[82] was previously used to illustrate the unbiased method to compare two tests^[80,81] and demonstrated that AQIC compared to conventional LBC increased the true positive (TP) count at the cost of less than 1 false positive (FP) case each, which is excellent for screening. When both tests are combined as the "or" of positive results, depending on what thresholds are used, the number of TPs increased by at most 1 case (a CIN1) while the number of increased FPs range from 0-19, indicating that even the combination test provides no added value. Similarly, an earlier paper by Yu *et al*^[126] spanning almost 8000 cases, found that conventional LBC found one case (CIN2) missed by AQIC, but AQIC found 29 cases of CIN2+ missed by cytology using the ASCUS+ threshold. As expected, combining the two tests also added nothing.

The results of other papers show that doing both tests is beneficial. For example, the paper by Bao^[76], already discussed, spanned almost 20000 women and conventional LBC found 4 cases (1 CIN3 and 3 CIN2) missed by AQIC, a marginal improvement. This comes down to a question of resource availability. As mentioned in the introduction, the conclusion of our 2005 paper^[1] was that AQIC made it possible to do large scale screening inexpensively and accurately, even when skilled cytologists are not available. In that situation, doing conventional LBC is not an option.

However, when conventional LBC is an option and both tests can be performed, then the choice comes down to a mixture of the medical consequences of marginally improved sensitivity at the cost of worse specificity, combined with the business consequences, such as customer perception of value, marketing, cost, price, profit, acceptability to the payer, and so on. One Chinese vendor^[166] has developed a cytometer designed to scan counterstained slides, so that the blue thionin/counterstain amounts to a fake Papanicolaou stain. This cytometer conceptually scans the slides twice-once with

Table 15 Biopsy data for DNA Cytometry and hrHPV test results for 294 cases of Cytology ASCUS, from Ref^[169]

hrHPV: High risk HPV; CIN2+: Cervical intraepithelial neoplasia, grade 2 or higher; CIN1: Cervical intraepithelial neoplasia, grade 1.

the optics set to minimize the visibility and interference of the counterstain to allow reasonably good DNA measurement, and once in full color for qualitative visual assessment by the reviewer. This system, in principle, has significant advantages over, for example, Hologic's Thin-Prep Imager which uses a similar approach^[167] to staining and imaging slides but fails to present any DNA quantitative information to the cytologist, operating instead only as qualitative assessment aid.

In summary, in most settings in China, automated quantitative image cytometry provides substantial increase in sensitivity and relatively slightly decreased specificity compared to conventional LBC. However, most labs that offer AQIC also perform conventional cytology on the same liquid based sample with the consequence of an incremental increase in sensitivity accompanied by an incremental decrease in specificity.

AQIC, cytology and hrHPV testing

Management of women with ASCUS, an equivocal cytology result and the most common non-negative result, has always been problematic. The ASCCP guidelines of 2006^[168] for the management of women with ASCUS cervical cancer screening tests called for: (1) immediate colposcopy; or (2) repeat cytology testing at 6 mo intervals until two consecutive negative follow-up Pap tests; or (3) "reflex" hrHPV testing, in which case women with hrHPV positive result are managed as if they have LSIL, or with hrHPV negative result have repeat cytology testing in 1 year.

However, these guidelines were revised in 2012^[66]. The new guidelines for management of women aged ≥ 25 with ASCUS cytology are: (1) immediate colposcopy is not recommended for women of any age; (2) hrHPV testing is preferred, in which case women: (a) with hrHPV positive result are managed as if they have LSIL, or (b) with hrHPV negative result are repeat co-tested (cytology and hrHPV) in 3 years; or (3) repeat cytology testing (not preferred) in one year, and (a) if the cytology is NILM, return to routine screening interval (3 years), or (b) if the repeat cytology is ASCUS+, attend colposcopy.

For women aged 21-24 with ASCUS, the management

is much more conservative: (1) immediate colposcopy is not recommended for women of any age; (2) repeat cytology testing in one year is preferred, and (a) if the first repeat cytology is ASC-H+, attend colposcopy, but (b) if the first repeat cytology is LSIL, ASCUS or NILM, repeat cytology in 1 year, and (i) if the 2nd repeat cytology is ASCUS+, attend colposcopy, or (ii) return to routine screening interval (3 years) when 2 consecutive annual repeat cytology test results are NILM; (3) hrHPV testing is not preferred, but women: (a) with hrHPV positive, repeat cytology in 1 year-immediate colposcopy or repeat hrHPV testing are not recommended, and (b) with hrHPV negative result are returned to the routine screening (cytology only) interval of 3 years.

A recent cross-sectional study by Zhang *et al*^[169] looked at DNA ploidy in 875 cases of ASCUS who had biopsies (of which 157 were CIN2+) and a subset of 294 of these cases (53 of which were CIN2+) were also tested for hrHPV. The raw results of the 294 cases are given in Table 15.

The performance indicators (prefaced with "b" to indicate "biopsy") for DNA ploidy for the whole data set and for hrHPV, DNA ploidy and hrHPV combined with DNA ploidy as an "and" of positive test results are given in Table 16 (the combined test result was not included in the Zhang paper). In general, DNA ploidy had better specificity and hence better PPV than hrHPV testing and both had similar NPV complement. As the authors concluded, AQIC is as effective as hrHPV testing for managing ASCUS patients, while being cheaper and easier to use.

As discussed previously, for the logical "and" of positive test results the specificity of the combined test will be at least as high as the specificity of the most specific component test and could be 100%; however, the sensitivity will be no better than the sensitivity of the least sensitive component test and could be zero. In fact, the combined test sensitivity did not fall below the least sensitive test which indicates that for detecting positive cases, DNA ploidy and HPV testing are very highly correlated. This is also an example of why it is generally the case that combining binary tests only works well if both have similarly high values for one performance indicator (either sensitivity or specificity); the idea is that this high valued performance indicator will drop only minimally when the tests are combined, while the lower valued other performance indicator will rise substantially. That is exactly what happened in this example. For reference, the PPV of cytology for all 875 ASCUS cases is only 18%.

If it is accepted that management of ASCUS will inevitably involve some equivocal cases who must be monitored over time, similar to the ASCCP guidelines above, then the 3×3 table analysis previously discussed could be applied. In this situation, only the "biopsy Positive Predictive Values" (bPPV) are revised upwards for each test, as shown in Table 17.

In the case of the combined test: (1) 60 cases would be identified as positive of which 43 will have CIN2+,

Table 16 Test performance indicators for DNA Cytometry, hrHPV tests and combined DNA Cytometry and hrHPV tests, for Cytology ASCUS cases, Ref^[169]

Performance indicator for CIN2+ (%)	875 Cases (157 CIN2+)	294 Cases (53 CIN2+)		
	DNA Ploidy	hrHPV	DNA Ploidy	DNA Ploidy and hrHPV
bSensitivity	98.8	98.1	96.2	96.2
bSpecificity	47.5	32.0	56.0	73.4
bPPV	29.1	24.1	32.5	44.3
bNPV	99.4	98.7	98.5	98.9

hrHPV: High risk HPV; CIN2+: Cervical intraepithelial neoplasia, grade 2 or higher; PPV: Positive predictive value; NPV: Negative predictive value. Prefix "b": From among biopsy cases only.

Table 17 Test performance indicators following re-analysis of the data of Table 16 from Ref^[169]

Performance indicator for CIN2+ (%)	875 Cases (157 CIN2+)	294 Cases (53 CIN2+)		
	DNA Ploidy	hrHPV	DNA Ploidy	DNA Ploidy and hrHPV
bSensitivity	98.8	98.1	96.2	96.2
bSpecificity	47.5	32.0	56.0	73.4
bPPV	40.8	24.1	47.8	71.7
bNPV	99.4	98.7	98.5	98.9

hrHPV: High risk HPV; CIN2+: Cervical intraepithelial neoplasia, grade 2 or higher; PPV: Positive predictive value; NPV: Negative predictive value. Prefix "b": From among biopsy cases only.

including 100% of the cancer cases, 88% of the CIN3 cases and 70% of the CIN2 cases, (2) 179 cases would be identified as negative, of which 2 would have CIN2+, and (3) 55 cases would be identified as being equivocal of which 8 would have CIN2+.

For comparison, if the hrHPV test was not done, the 3 state analysis outcomes would be: (1) 90 cases would be identified as positive of which 43 will have CIN2+, exactly as in the combined case above, (2) 137 cases would be identified as negative, of which 2 would have CIN2+, and (3) 67 cases would be identified as being equivocal of which 8 would have CIN2+.

The addition of the hrHPV test correctly removed 30 negative cases from the positive group and 12 from the equivocal group into the negative group.

The same research group more recently published a smaller prospective study^[170] of 327 cases of ASCUS, 193 of whom had the AQIC test and the remaining 134 had the hrHPV test. The performance indicators were essentially the same as the previous study and no statistically significant difference was detected between AQIC and hrHPV. Again, if the patient management followed the 3 × 3 table guidelines discussed previously, the PPV of DNA ploidy would have been boosted from 32% to 41%.

A tiny study from France using interactive (as opposed to automated) image analysis found similar concordance between DNA ploidy and hrHPV for ASCUS cases^[171].

A few additional studies comparing hrHPV with AQIC, but not focused on ASCUS, have been published in China^[172-174] and generally they show reasonable concordance between the two techniques but are not large

enough to draw more conclusions.

The previously mentioned study of Guillaud and co-workers^[41] compared conventional LBC (ThinPrep) with DNA ploidy and with hrHPV testing by QiaGen HC2 on more than 1500 high grade samples and concluded: "DNA ploidy shows comparable sensitivity, specificity, PPV and NPV values to conventional cytology and HC 2."

In summary, there is evidence that AQIC is at least as useful as hrHPV testing for managing ASCUS cases and probably for other abnormal cytology grades and is simpler and cheaper to perform.

CONCLUSION

Like all countries, China has low-, mid- and high-resource settings. Referring to the 2005 study objective recounted in introduction, the key resource under discussion here is the availability of experienced and highly trained cyto-technologists and cytopathologists-if they do not exist, then the conventional Pap test cannot be performed. The other key resource, of course, is money which constrains public health initiatives in all countries. This is not a discussion about the availability of electricity, water or similar resources. The objective cited in the introduction was related to this definition of low resource settings and not just in China. This review will look separately at the low resource and mid-/high-resource settings.

Training

A key element of AQIC technology is that it can be taught much more quickly than cytology and in the hands of the trainees, can perform comparably to conventional

LBC, performed by experienced and highly trained cytologists. The record in China has demonstrated that it is routinely possible to teach the technology from slide preparation and staining, to operation of the cytometer, review of the DNA ploidy data and report generation in 10 working days, especially when dedicated training facilities are available, as is the case with vendors in China. It is somewhat more difficult and inefficient to teach the technology in the end-user facility because the trainees usually have other routine work to do and so their attention is divided. Even so, this reviewer did have the opportunity to teach this technology to technicians in Morocco about 1 year ago at their facility; competition with their routine work was a big challenge, as were language and other issues, but the training was successful in a relatively short period of time (3 wk total). In this case, the trainees were experienced pathology lab technicians, so they were quick studies for sample preparation and staining. However, they had absolutely no experience in microscopy which is only done by the pathologists there and so all aspects of data and image review had to be mastered by them.

Various AQIC products from different vendors are in wide use in China in the hands of many hundreds of different operators and yet the review of publications in the previous section indicates that reasonably consistent results are being obtained under widely disparate conditions. This speaks to the inherent robustness of the DNA ploidy technology.

Low resource setting deployment

In every country, public health programs are first and foremost political initiatives, a fact that strongly shapes what is done and how. China started a “Two Cancer” screening program (cervical and breast) targeted at rural women in central and western China in 2009 that will continue until at least 2015^[175]. This is apparently a follow-on to a 2002-2010 cervical cancer screening program^[150], possibly to enjoy the anticipated high popularity and expected efficiencies of combined *vs* single disease screening^[176]. One curiosity with this initiative is that the target population is aged 30-59 for cervical cancer screening, which is appropriate, but 35-69 for breast screening by clinical breast exam^[177]; I have direct knowledge of the target age being 25-59 for breast cancer screening in Ordos under this program. Few outside of China advocate screening for breast cancer before age 50^[178] (although some, such as BCCA, initiate breast cancer screening starting at age 40^[54]) which, combined with the fact that Chinese women both inside and outside China have 1/3-1/2 the breast cancer incidence rates as other women^[179,180], has led a Hong Kong expert group, who have twice reviewed the evidence recently^[181,182], to conclude that there is insufficient evidence to recommend for or against breast cancer screening.

This reviewer has personal experience that AQIC was implemented for this program in the city of Ordos (metropolitan population 600000) in Inner Mongolia but it was required that a cytometer and support staff be

provided to each of the 8 or 10 participating hospitals rather than setting up a central lab with two technicians and only two cytometers, which would not only make QA easier to establish and maintain, but would enjoy the economy of scale that comes from a high volume, high throughput operation. The point is that the concepts of efficiency can be mixed and contradictory when public health programs are implemented because of many competing interests.

This is a point of great disappointment for this reviewer because the opportunity has so far been lost to learn in real practice how affordable cervical cancer screening could be in China. The 2012 study by Li *et al*^[176] determined the affordability limit for rural women for the “two cancer” screening to be 50 RMB, which is probably achievable with an efficient program implementation. Money remains a major constraint to this Two Cancer public health initiative^[177].

So far, China is the center of DNA ploidy application to cervical cancer screening. However, a pilot project is underway in Morocco. The first phase was to demonstrate that the technology could be taught and learned, the second phase was to compare the results with split samples and conventional LBC to determine if the technology had enough merit to move forward into phase three: the actual screening project, which is now underway. A similar project is being conducted in the Philippines^[183] but no reports on it are yet available.

Mid-and high-resource setting deployment

Most of the preceding papers reviewed are from laboratories that also perform cytology and so do not lack the key resource of trained and experienced cytologists. However, there does not seem to be the profession of “cytotechnologist” in China, except in Hong Kong^[184]. In many countries, screening by cytology is divided into 2 tasks: (1) the locator function, performed by a cytotechnologist who can sign out negative cases; and (2) the interpreter function performed by a cytopathologist who is the only one who can sign out positive cases. The locator skills of cytotechnologists are generally superior to those of cytopathologists^[185]. In China, normally these two tasks are performed by a cytopathologist. Although it is very rapidly improving, as recently as 2005 only 1/3 of licensed doctors in China held the equivalent of a bachelor's degree (only 1/8 in rural China)^[186], so there is a case to be made for AQIC technology even where cytologists are available. This is confirmed by the wide acceptance of the technology there to date.

One frustration facing the authors of most published studies in China is the previously discussed “missing data”-the inability to “close the loop” and gain access to biopsy and treatment data necessary to gauge relative success of the screening. All medical databases suffer from some “persons lost to follow-up” but there is a big difference between 60% and 6% missing data. There is no effective coordination and cooperation between the various medical providers and the various professional medical

societies and regulators seem to lack the clout to make such cooperation happen, even at the city district level, let alone the city, county, province or national level in China. There are undoubtedly many factors contributing to this situation. It is impossible to know how well any technology or program is doing if it cannot be measured. Missing data makes even cross-sectional studies, such as those reviewed here, very difficult. This situation will make longitudinal studies virtually impossible and longitudinal studies are a crucial element in the pathway to evaluating a screening strategy^[48]. Other countries, even the United States, have found ways to measure and share outcome data while still respecting patient autonomy and confidentiality. A great opportunity is being lost in China due to this lack of coordination and cooperation.

The revised ASCCP patient management guidelines^[66] were substantially informed by the remarkable database of 1.4 million women managed by Kaiser Permanente Northern California (KPNC) with both LBC and hrHPV testing from 2003 to 2010^[187-194]. This substantial longitudinal database allowed the formulation of “risk adapted” patient management guidelines. KPNC is a not-for-profit, private Health Maintenance Organization—essentially an activist insurance company that is also involved in the medical service delivery. Screening for cancer is a very easy way to spend lots of money because it involves testing people, of whom 90+% are healthy. So KPNC is highly motivated to evaluate what it does and to consider what it could do by adapting to maximize the health of its clients and minimize the cost. Perhaps, this is generalizable—that the insurer is the most motivated to effect the kind of change required to measure screening on the required scale.

FUTURE WORK

Much remains to be done, according to the framework for evaluating screening strategies outlined by Arbyn and co-workers^[48].

To this reviewer, the most exciting results to emerge from this review are the comparisons with hrHPV testing with DNA ploidy that seem to show that

DNA ploidy = LBC + hrHPV testing

The work on ASCUS needs to be repeated and expanded to all of the other categories of cytological abnormality. It would be especially interesting to conduct a study involving CareHPV^[195], the low priced hrHPV test from QiaGen for low resource settings. Combinations of DNA ploidy with HC 2 or other widely used hrHPV tests in “non-low resource” settings would also be valuable.

Much of the world has started vaccinating girls and in some cases, boys, against HPV and this is expected to expand throughout the world, including low resource countries^[196]. As the vaccinated cohorts reach screening age, existing well established cytology based screening

programs will become stressed because the frequency of abnormality will drop significantly (nominally 70% with current vaccines) which will make it increasingly more difficult for cytologists to maintain both competence and vigilance. DNA Ploidy by automated quantitative image cytometry would greatly relieve this stress.

hrHPV testing requires an accompanying “triage” test to manage the 10%-15% of women who will test positive^[197]. The ASCUS hrHPV/DNA ploidy data of Zhang *et al*^[169], reviewed above, seemed to be the ideal case for combining tests because both have comparably high sensitivity. However, in this example, both tests were made into binary tests which are constrained to increasing either sensitivity or specificity, while decreasing the other, even though both are inherently continuously valued tests. It would also be interesting to look at what happens when hrHPV and DNA ploidy are combined, not as binary tests but as continuously valued tests, for example, using Bayes’ theorem. It may then be possible to find conditions where both sensitivity and specificity increase at the same time. Nothing is free in this world, so it is unrealistic to expect that the joint improvement would exceed that of the binary test, but it might be enough to optimize the test combination for some screening applications.

The value of cervical cancer screening has been essentially limited to squamous cell carcinoma and has done little to reduce the mortality and morbidity from adenocarcinoma, which is increasing in incidence^[198-200]. It is unclear how much sampling contributes to the low sensitivity of cytology to adenocarcinoma, but studies using hrHPV testing suggest that many cases of adenocarcinoma are hrHPV positive and cytology negative, indicating that the samples are adequate^[191,201,202]. It would be interesting to compare the sensitivity for detection of adenocarcinoma for DNA Cytometry with that of conventional LBC and hrHPV testing.

A number of other issues and opportunities for further research have been brushed against in this review. The important issue of official cervical cancer incidence rates needs to be reconciled with those of the rest of the world and with the very high prevalence rates seen in many studies in China. To this end, it would be beneficial if papers more clearly defined their test populations, especially if they are an admixture of screening and diagnosis cases.

The question of whether conventional LBC done in addition to AQIC provides a net benefit remains unresolved, although it may be both vendor product and laboratory staff skill dependent.

The problem of the imperfect “gold standard” test and the possible impact, if any, that has on DNA ploidy results would be useful to know. Is there a difference in measured DNA ploidy sensitivity when the gold standard is colposcopy directed biopsy *vs* random biopsy?

Much was written here about a definition of sample adequacy but the question is not resolved. What is the best number of cells to measure to get a reliable nega-

tive test result, where “best” is a trade-off between scan time and false negative rate? How much is this influenced by sample taking? If the adequacy number is increased to, say, 50000 epithelial cells, what does this do to the diagnostic rules—that is, will 1 or 2 aneuploid cells still be “equivocal” and 3 positive? In fact, at any epithelial cell count threshold, it would be good to review all of the diagnostic rules including the proliferation rules for positive, negative and equivocal. While they seem to be working reasonably well now over a huge range of undiagnosed disease prevalence, are they optimal?

In a related matter, the concern expressed by Chatelain *et al*^[42] on HPV infection induced polyploidy may be worth looking at. That is, should cells with DI of 2, 4 or 8 be grouped separately from other DI > 2.5 cells to determine if they have different value in screening? This could be coupled to any HPV testing project.

Another similar issue is the malignant potential of aneuploid stemlines. This requires good longitudinal data and also poses possible problems with ethical approval. However, if such stemlines routinely result in negative colposcopy and/or biopsy (seen as hyperplasia), it would be interesting to follow such patients over 5 years to see how much it progresses.

Finally, one of the weaknesses in DNA ploidy by the methods described here comes from Feulgen staining which is very slow (3 to 4 h procedure) and can also be somewhat finicky. Guillaud *et al*^[203] developed a modified Feulgen process for the dye Azure A (a thiazine like thionin, methylene blue, Azure B *etc.*) that takes 30 min but produces a slightly wider diploid peak. Another rapid Feulgen reaction was reported from China^[204] but it seemed to be partly a re-discovery of acid hydrolysis at a temperature of 60°C, which was used by Feulgen^[22] originally and has been not recommended for routine work due to the need for precise control of all staining conditions. Claims are made from time to time that variations of the hematoxylin staining are quantitative, but this has been rejected experimentally by Biesterfeld^[205]. The need for an improved (faster) staining protocol remains.

Core tip: For select patient subsets the addition of chemotherapy to radiation in head and neck squamous cell cancer improves outcome. Most data is for concurrent cisplatin although other agents are also being explored. There has recently been interest in induction chemotherapy, the induction studies although heterogeneous have failed to show an improvement in overall survival. In this article we discuss the data regarding concurrent chemotherapy and also the data regarding induction therapy and which patient subsets we feel are best suited for induction chemotherapy (patients with N3 disease and those expected to have a delay in starting concurrent concurrent chemoradiotherapy).

Chemotherapy advances in locally advanced head and neck cancer. *World J Clin Oncol* 2014; 5(5): 966-972 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/966.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.966>

Abstract

The management of locally advanced unresectable head and neck squamous cell cancer (HNSCC) continues to improve. One of the major advances in the treatment of HNSCC was the addition of chemotherapy to radiation in the treatment of non-surgical patients. The majority of the data regarding chemotherapy in HNSCC involve cisplatin chemotherapy with concurrent radiation. However, several new approaches have included targeted therapy against epidermal growth factor receptor and several recent studies have explored the role of induction chemotherapy in the treatment of HNSCC. The purpose of this article is to provide an overview of the role of chemotherapy in the treatment of locally advanced HNSCC.

Key words: Head and neck cancer; Chemotherapy; Induction

SOURCES AND SELECTION CRITERIA

We performed a Pubmed search for manuscripts published between 1995 and November 2013 using the following search keywords: “head and neck cancer and chemotherapy”, “head and neck cancer and radiation”, “head and neck cancer and chemoradiation”, “head and neck cancer and induction chemotherapy”, and “head and neck cancer and epidermal growth factor receptor (EGFR) targeted therapy”. The search was limited to the English language to and humans. In addition, we reviewed the references from the National Comprehensive Cancer Network (NCCN) guidelines and those from the selected publications to include landmark articles. Manuscripts were selected for inclusion based on the author’s assessment of the paper’s relevance to the topics included

in this review.

CONCURRENT CHEMORADIOTHERAPY

Head and neck squamous cell carcinoma (HNSCC) is a challenging cancer to treat and cure. Surgical management continues to be the standard of care for many HNSCC including most cancers in the oral cavity. For patients with locally advanced disease not amenable to surgical resection, concurrent chemoradiotherapy (CRT) is now recognized worldwide as a standard treatment option^[1]. Evidence has largely supported the use of radiation treatment concurrent with three cycles of bolus cisplatin^[2], although several other agents have also been studied^[3-5]. Despite improved outcomes with CRT, disease recurrence and treatment toxicity continue to be challenges with this treatment paradigm^[6]. To obtain improved outcomes and mitigate disease recurrence and treatment toxicity, new agents such as cetuximab^[7] and induction chemotherapy^[8] have been explored.

Prior to 2000, radiation alone was the predominant non-surgical treatment modality offered to patients with HNSCC. The introduction of CRT was based on several phase III trials showing a survival benefit of adding chemotherapy to radiation *vs* radiation alone in locally advanced HNSCC^[1,3-5].

A meta-analysis of 87 trials conducted by Pignon *et al*^[9] from 1965 to 2000, which included 16485 patients, found an absolute survival benefit for chemotherapy of 4.5% at 5 years and an absolute benefit for concurrent CRT of 6.5%. The hazard ratio (HR) of death was 0.81 (0.78-0.86, $P < 0.0001$). In this meta-analysis, there was a statistically insignificant benefit for induction chemotherapy with an absolute benefit of 2.4% at 5 years with a HR of death of 0.96 (0.9-1.02, $P = 0.18$)^[9]. Another important finding of this meta-analysis is that adding chemotherapy to radiation was not beneficial in certain patient subsets, an observation that would have been impossible to establish in smaller studies due to limited sample size in individual trials. These subsets included patients with Eastern Cooperative Oncology Group (ECOG) performance status 2 and 3, stage I - II tumors, and "orphan cancers", which included HNSCC outside the oral cavity, oropharynx, larynx, hypopharynx, and nasopharynx. Additionally, no survival advantage was seen in patients over age 70 when concurrent platinum based chemotherapy was administered concurrently with radiation. Analysis of various chemotherapeutic regimens showed that single agent platin was the most efficacious.

Although chemotherapy in combination with radiation improves survival in patients with locally advanced HNSCC, it does increase toxicity. Adelstein *et al*^[1] showed increased treatment related toxicities such as nausea/vomiting, leukopenia, anemia and kidney injury. In the CRT arm 77% of patients exhibited grade 3 or higher toxicity when given CRT using 70 Gray (Gy) five days per week and cisplatin *vs* 52% of patients who received radiation alone^[1].

ROLE OF EPIDERMAL GROWTH FACTOR RECEPTOR TARGETED THERAPY

EGFR is overexpressed in almost all HNSCC tumors, and overexpression of EGFR correlates with higher disease stage, lymph node metastasis, and poorer survival^[10,11]. An important breakthrough has been molecular targeted therapies to target EGFR^[12,13]. Cetuximab, a chimeric humanized monoclonal antibody against EGFR, has lead the way in targeted therapy after first receiving Food and Drug Administration (FDA) approval in 2011 in HNSCC for recurrent and metastatic HNSCC and subsequently in 2006 for locally advanced HNSCC, which we discuss below in the Bonner *et al*^[14] study. It has also received FDA approval in the first line setting for metastatic colorectal cancer in 2012. Other monoclonal antibodies and oral tyrosine kinase inhibitors, specifically erlotinib and gefitinib, have shown modest activity without a survival advantage^[13].

Prior to CRT being established as standard of care, Bonner *et al*^[14] completed a phase III study looking at the addition of cetuximab to radiation therapy in patients with locally advanced HNSCC. In this trial, 213 patients were randomized to receive either radiation therapy alone and 211 were randomized to radiation therapy given concurrently with cetuximab. Cetuximab was administered as a onetime dose of 400 mg/m² prior to starting radiation therapy, followed by 250 mg/m² weekly for the duration of radiotherapy therapy for six or seven weeks. As compared to the radiation therapy alone arm, patients who received concurrent cetuximab and radiation had a statistically significant increase in median locoregional control (LRC) of 9.5 mo (14.9 mo *vs* 24.4 mo, $P = 0.005$), progression free survival (PFS) of 17.1 mo *vs* 12.4 mo ($P = 0.006$) and overall survival (OS) of 49 mo *vs* 29.3 mo ($P = 0.03$). Toxicity was minimally increased in the cetuximab arm, with adverse events related to infusion reactions, fevers, chills, pruritus, acneiform rash, nausea, weight loss, and anemia^[14]. This trial was designed prior to adoption of CRT as standard of care for locally advanced HNSCC, and thus, the standard arm of the study was the standard treatment at that time (radiation alone).

Panitumumab, a fully monoclonal antibody, targeting EGFR was also evaluated in the treatment of HNSCC in an attempt to decrease toxicity. Concert-1, a phase II trial, randomized patients with previously untreated HNSCC in a 2:3 fashion to receive concurrent therapy using cisplatin for three doses with or without panitumumab. The primary endpoint of the study was LRC rate at 2 years. There was no statistically significant difference in LRC between the cisplatin plus radiotherapy arm (CisRT 68%) and the panitumumab plus CisRT (PCisRT 61%). Progression free survival was 35% in the CisRT arm *vs* 40% in the PCisRT group ($P = 0.61$). There was increased grade 3+ toxicity noted in the group treated with panitumumab, and this included mucositis, skin injury in the radiation field, and dysphagia^[15].

Both cisplatin and cetuximab have demonstrated survival advantages when used as single agents in combination with radiation therapy in the management of locally advanced HNSCC. RTOG 1055 was designed to evaluate whether multi-agent therapy in combination with radiation would provide added benefit. This is a phase III clinical trial in which 940 patients were randomized to receive either chemoradiation therapy with cisplatin on day 1 and 22 or the same regimen with the addition of weekly cetuximab. After a median follow-up of 2.4 years, there was no difference in progression free survival between the two arms. However, there was an increase in acute toxicity, including mucositis and skin reactions within the radiation field. Long term toxicity was similar in the two groups^[16]. While the addition of single agent cisplatin or cetuximab to radiation therapy can improve outcomes in locally advanced HNSCC, combination therapy with cisplatin and cetuximab does not improve outcomes.

While the abundance of data in HNSCC support chemotherapy using cisplatin administered at a bolus of 100 mg/m² every 3 wk during radiation, data supporting the use of cetuximab is confined to one phase III study. Additional studies are needed to directly compare concurrent chemoradiation with cetuximab *vs* cisplatin. RTOG 1016 is such a trial in progress which is comparing radiation with cetuximab to radiation with cisplatin in patients with human papillomavirus (HPV) positive HNSCC of the oropharynx. It will be several years before survival data becomes available^[17].

CHEMOTHERAPY AND RADIATION SCHEDULES

In addition to advancements in chemotherapy, there have been significant improvements in radiation treatment and delivery. RTOG 9003 showed that accelerated radiation, given over six weeks rather than seven weeks, was associated with better locoregional disease control at five years than standard radiation, although more toxic^[18]. Despite improvements in disease control, several studies have shown that accelerated radiation schedules are not a substitute for chemotherapy^[3,4]. When patients receiving concurrent chemotherapy were randomized to standard *vs* accelerated radiation, there was no benefit in the accelerated radiation arm^[5]. Therefore, conventional radiation is preferable to accelerated radiation when administered concurrently with chemotherapy.

SEQUENTIAL THERAPY: THE ROLE OF INDUCTION THERAPY

In an attempt to improve distant disease control and overall survival in unresectable locally advanced HNSCC, induction chemotherapy has emerged over the last decade as an alternative treatment modality. In the meta-analysis by Pignon *et al*^[9], 31 induction chemotherapy trials that included 5311 patients showed that induction chemotherapy

did not have a statistically significant improvement in survival with a [HR of 0.96 (0.9-1.02), *P* = 0.18]. On the other hand, induction chemotherapy did show a greater benefit in regard to distant disease control at 3.5% [HR = 0.73 (0.61-0.88), *P* = 0.001] *vs* 2.9% for concurrent platinum and 5FU studies [HR = 0.88 (0.77-1.00), *P* = 0.04]. The comparison of the two hazard ratios was insignificant (*P* = 0.12 for all trials, *P* = 0.56 for 5-FU-platin trials)^[9].

Two large subsequent clinical trials evaluated the addition of Taxotere[®] (docetaxel) to an induction regimen using cisplatin and fluorouracil in locoregionally advanced HNSCC. The TAX 324 study compared induction therapy with docetaxel, cisplatin, and fluorouracil (TPF) to cisplatin and fluorouracil (PF), followed by chemoradiotherapy. In this trial, 501 patients were randomly assigned to receive induction chemotherapy with either TPF or PF administered every 3 wk for 3 cycles. Both groups were subsequently treated with concurrent chemoradiotherapy using weekly carboplatin at an area under the curve (AUC) of 1.5. Radiation was administered to a total of 70 to 74 Gy. After a minimum follow up of 2 years, the survival benefit was significant in the TPF group with a hazard ratio for death of 0.7 (*P* = 0.006). The median overall survival was 71 mo for the TPF group *vs* 30 mo in the PF group (*P* = 0.006). There was also better LRC for the TPF group (*P* = 0.04)^[19].

Additionally, the TAX 323 study compared induction therapy with TPF to PF followed by radiotherapy alone. In this European trial, 358 patients were randomized to receive induction chemotherapy with TPF *vs* PF every 3 wk for four cycles followed by radiotherapy alone administered on different schedules (conventional, accelerated, hyperfractionated) to 66-74 Gy. After a median follow-up of 32.5 mo, there was a 2.8 mo progression free survival benefit in the TPF group. The HR for disease progression or death in the TPF group was 0.72 with a *p* value of 0.007. The main toxicity associated with the TPF regimen in both the TAX 323 and the Tax 324 was leukopenia and neutropenia^[20].

In 2010, Paccagnella *et al*^[8] reported a phase II study comparing concurrent therapy to sequential therapy using TPF as induction. One hundred and one patients were randomized to receive concurrent chemoradiotherapy *vs* induction chemotherapy (TPF) followed by concurrent treatment. The primary end point of the trial was radiologic complete response (CR) rate, evaluated 6-8 wk after the completion of concurrent therapy. This study showed superiority of sequential chemotherapy with CR of 50% compared to 21.2% (*P* = 0.004). Although the study was not powered for assessing PFS and OS, there was a 13.6 mo and 9.2 mo PFS and OS advantage respectively when induction chemotherapy was used, without an increase in toxicity^[8].

Additional data regarding the use of induction therapy is provided by two recently completed phase III studies. The PARADIGM trial randomized patients to concurrent chemoradiotherapy *vs* sequential therapy. The study was halted early due to slow accrual with only

Table 1 DeCIDE and PARADIGM Protocols

	DeCIDE	PARADIGM
Stages	IV	III, IV
Arm 1 (standard)	CRT CRT: five 14 d cycles of docetaxel (day 1), fluorouracil (day 0-4) and hydroxyurea (day 0-4) with twice daily radiation (day 1-5)	CRT cisplatin (100 mg/m ²) Q 3 wk, 12 cycles Radiation: accelerated concomitant boost over 6 wk (72 Gy)
Arm 2 (experimental, induction)	TPF (2) → CRT TPF two cycles: docetaxel 75 mg/m ² day 1, cisplatin 100 mg/m ² day 1, fluorouracil 1000 mg/m ² per day continuous for 5 d CRT: five 14 d cycles of docetaxel (day 1), fluorouracil (day 0-4) and hydroxyurea (day 0-4) with twice daily radiation (day 1-5)	TPF (3) → CRT TPF three cycles: docetaxel 75 mg/m ² , cisplatin 100 mg/m ² day ¹ , fluorouracil 1000 mg/m ² continuous for 4 d Responders to induction: CRT (carboplatin AUC 1.5, weekly) Poor responders to induction CRT (docetaxel 20 mg/m ² weekly) Radiation: accelerated concomitant boost over 6 wk (72 Gy) for poor responders. Induction chemotherapy responders 70 Gy over 7 wk

¹Statistically significant. CRT: Chemoradiation.**Table 2 DeCIDE and PARADIGM results**

Study	Patients	Randomization (induction regimens)	PFS (3 yr)	OS (3 yr)	DM
PARADIGM	145	CRT	69%	78%	11%
		TPF (3) → CRT	67%	73%	7%
DeCIDE	280	CRT	59%	73%	19% ¹
		TPF (2) → CRT	67%	75%	10% ¹

¹Statistically significant. CRT: Chemoradiation; DM: Distant metastasis.

145 out of the originally planned 330 patients accrued. Patients were randomized in a 1:1 fashion to induction therapy using TPF × 3 followed by concurrent therapy using either weekly carboplatin and conventional radiation or weekly docetaxel and accelerated boost radiotherapy (Arm A) or accelerated boost concurrent therapy using bolus cisplatin × 2 (Arm B). This study allowed for post-induction chemotherapy to be based on response to induction chemotherapy. Patients with poor response including progression of disease, not completing all cycles of TPF, gross disease left at primary site after induction, lymph nodes > 2 cm after induction, or partial response with biopsy proven residual at primary were subsequently treated with weekly docetaxel (20 mg/m²) and accelerated radiation whereas induction chemotherapy responders had weekly carboplatin (AUC 1.5) and conventional radiation as illustrated in Table 1. The primary endpoint was overall survival. After a median follow-up of 49 mo, three-year survival was excellent in both arms, 78% in the concurrent therapy arm *vs* 73% in the sequential therapy arm ($P = 0.77$) as shown in Table 2. The secondary end point of the study, progression free survival was not statistically significant at 69% in the concurrent therapy arm *vs* 67% in the induction therapy arm, $P = 0.82^{[21]}$. There was no significant difference in acute toxicity and evaluation for late toxicity is ongoing.

The DeCIDE protocol by Cohen *et al*^[22] randomized patients to concurrent CRT using 5 d of docetaxel, 5-FU, and hydroxyurea and radiation given twice daily at 1.5 Gy per fraction followed by a 9 d break *vs* two cycles of TPF followed by the same CRT regimen as demonstrated in

Table 1. Of note, radiation in this study was delivered *via* a split course, considered the standard at University of Chicago Medical Center, though this is not often used outside that institution. The study was able to recruit 280 out of 400 patients originally planned. The primary end point of the study was overall survival. After a three years of follow-up, the overall survival was 73% for the CRT arm *vs* 75% for the induction chemotherapy arm ($P = 0.70$). In terms of secondary end points, progression free survival was 59% for the CRT arm *vs* 67% for the induction therapy arm, not statistically significant with a P value of 0.18. Cumulative incidence of distant failure was 19% in the CRT *vs* 10% in the induction therapy arm, and this was statistically significant in favor of induction chemotherapy with a P value of 0.025 as noted in Table 2^[22].

DISCUSSION

Concurrent CRT is superior to radiation alone for a selected group of patients with unresectable HNSCC, including patients with stage III and IV disease, younger than 70 years of age, and who have an ECOG performance status of 0-1. The chemotherapy regimen with the most evidence is three cycles of single agent cisplatin, although other agents have also been studied and have demonstrated efficacy, such as cetuximab. In order to further improve on these results several studies have examined induction chemotherapy.

The TAX 324 and TAX 323 trials clearly demonstrated superiority of the TPF induction regimen over PF

Table 3 Tax 323 and 324 results

Study	Patients	Randomization (induction regimens)	PFS (mo)	OS (mo)	DM (%)
Tax 323	358	PF	8.2 ¹	14.5 ¹	10.3
		TPF	11 ¹	18.8 ¹	12.9
Tax 324	501	PF	13 ¹	30 ¹	9
		TPF	36 ¹	71 ¹	5

¹Statistically significant. PFS: Progression free survival; OS: Overall survival; DM: Distant metastasis.

in the management of locoregionally advanced HNSCC. However, neither study addressed or included a control arm of concurrent chemoradiation therapy, which is the current standard of care^[20] (Table 3). Though these studies resulted in FDA approval of docetaxel as part of induction chemotherapy, they were criticized for comparing two experimental regimens, rather than comparing them to the accepted standard of care^[23,24]. It remains unknown if induction chemotherapy is more effective than concurrent CRT in the treatment of local advanced, unresectable HNSCC.

The notion that induction chemotherapy reduces distant metastasis and thus improves overall survival seems compelling; however, the induction studies to date do not support this. There was no difference between the groups in rates of distant metastasis in the PARADIGM study. In the DeCIDE study, there was a decrease in distant metastasis from 19% to 10%; however, the study failed to show an improvement in OS or distant failure free survival (DFFS) for the induction arm. Both PARADIGM and DeCIDE trials were limited by several factors. Both studies had accrual difficulties, which caused each to close prior to planned accrual. The difficulty with accrual was due to competing trials in the United States at that time, patient preference, and strong physician preferences within the community. A strong pre-existing preference in regards to induction chemotherapy for more advanced disease might have created a selection bias against the risk of randomization to chemoradiotherapy alone^[21]. Additionally, the importance of HPV was not known when these studies were initiated. An increasing number of new HNSCC cases are HPV positive which has an improved prognosis. As a result of growing number of HPV related oropharyngeal cancers, the overall outcome was better than expected for both studies. This limited the study's power to detect differences in the treatment arms, and would have meant that even larger numbers would have been required in what was already a poorly accrued study. All current HNSCC studies stratify by HPV status because of the significantly improved outcome for HPV positive patients^[25].

Even with the limitations of these studies, it is clear that there is no improvement in PFS or OS to using induction chemotherapy, as opposed to CRT for all patients. It remains unclear from the current data if there is a subset of patients who may benefit from induction chemotherapy. One of the advantages of induction therapy is the theoretical ability to eliminate systemic micro-

metastatic disease and thus prevent distant failure^[26]. The TAX 324 study noted a trend towards improved distant metastasis rates with TPF *vs* PF induction therapy (5% DM with TPF *vs* 9% with PF, $P = 0.14$). TAX 323 did not confirm this trend. The PARADIGM study showed DM rates of 7% and 11% using induction and concurrent therapies, respectively, and this did not reach statistical significance. The DeCIDE study did show a reduction in DM using induction (10%) as compared to concurrent treatment (19%). There were subtle differences in study design that could have accounted for the discrepancy in reduction in rates of distant metastasis between the two studies. The PARADIGM study allowed stage III patients to enroll whereas DeCIDE was limited to stage IV. The inclusion of lower stage patients may have accounted for patients with less distant metastases in the PARADIGM study. Additionally, the CRT regimens were different in the two studies. It is possible that induction chemotherapy is more useful in split course radiation and is not beneficial in conventional RT.

Induction chemotherapy has theoretical advantages in terms of reducing distant metastasis and may be useful in patient subsets at increase risk for distant metastasis such as those with bulky, or lower cervical lymph node involvement. Induction chemotherapy may also be useful for patients who would have a delay in starting concurrent CRT. For example, it is common practice to have dental extractions of diseased teeth prior to starting radiation in order to help prevent osteoradionecrosis. After the dental extraction, it takes 2 wk for the extraction site to heal enough to begin radiation. Thus, if patients are expected to have long delays in starting CRT secondary to getting dental consult, extractions, and post-extraction healing, it may be beneficial to start induction chemotherapy while the dental issues and radiation planning is under way. At the current time, further clinical trials will be helpful in refining the role of induction chemotherapy in those subsets of patient with HNSCC most likely benefit from this treatment. Several studies have found that pre-treatment PET scans may also help guide therapy. Independent studies have shown that HNSCC lymph node SUV greater than 10 is predictive for higher rates of distant metastasis^[27]. This or other predictive tests may help determine risk for distant metastasis and potentially select patients to benefit from induction chemotherapy.

The optimal induction regimen is unclear from the limited studies performed. As seen in Tables 1 and 4, there are many differences in both induction and post-

Table 4 Tax 323 and 324 Protocols

	Tax 323 study	Tax 324 Study
Stages	III, IV	III, IV
Induction therapy regimens	TPF: docetaxel 75 mg/m ² day 1, cisplatin 75 mg/m ² day 1, fluorouracil infusion 750 mg/m ² per day continuous infusion day 1 to 5 PF: cisplatin 100 mg/m ² day 1, fluorouracil 1000 mg/m ² continuous infusion days 1 to 5	TPF: docetaxel 75 mg/m ² day 1, cisplatin 100 mg/m ² day 1, fluorouracil 1000 mg/m ² per day, continuous 24 h IV infusion for 4 d PF: cisplatin 100 mg/m ² day 1, fluorouracil 1000 mg/m ² per 24 h continuous infusion for 5 d
Concurrent therapy regimens	Start 4-7 wk after completing induction therapy: Radiation administered over 7 wk, either conventional (66 to 70 Gy), accelerated (70 Gy) or hyperfractionated (74 Gy)	Start 3-8 wk after completing induction therapy: Radiation 2 Gy per day, 5 d a week for a total of 70-74 Gy plus weekly carboplatin AUC 1.5

Gy: Gray; TPF: Docetaxel, cisplatin, and fluorouracil; PF: Cisplatin and fluorouracil.

Table 5 Concurrent regimens after induction

Study	Concurrent chemotherapy	Radiation	Notes
Tax 323	None	Conventional (66 to 70 Gy), accelerated (70 Gy) or hyperfractionated (74 Gy)	Only study not to use concurrent chemotherapy
Tax 324	Carboplatin AUC 1.5, weekly	Radiation 2 Gy per day, 5 d a week for a total of 70-74 Gy	
PARADIGM: responders	Carboplatin AUC 1.5, weekly	70 Gy over 7 wk	Regimen varied by response to induction
PARADIGM: non-responders	Docetaxel 20 mg/m ² weekly	Accelerated concomitant boost over 6 wk (72 Gy)	Regimen varied by response to induction
DeCIDE	CRT: five 14 d cycles of docetaxel (day 1), fluorouracil (day 0-4) and hydroxyurea (day 0-4)	Twice daily radiation (day 1-5)	Split course radiation

induction treatment regimens. As summarized in Table 5 there is evidence to support a wide range of post-induction chemoradiation regimens including docetaxel, carboplatin, radiation alone and the more complex split-course poly-chemotherapy University of Chicago regimen.

CONCLUSION

Chemotherapy is an important component in the treatment of local advanced HNSCC in selected patients. Most published chemotherapy data supports the use of bolus cisplatin given concurrently with radiation. Newer data supports targeted therapy with cetuximab as well. The role of alternative chemotherapy regimens is less clear. Studies looking at induction chemotherapy did not reveal a survival benefit to induction chemotherapy although it is possible that patients at increased risk for distant metastatic disease may benefit from induction chemotherapy, future studies will need to be performed to further clarify which patients are best suited to an induction chemotherapy approach.

While waiting for further data to help pick ideal patients for induction chemotherapy, at our institution we currently recommend induction chemotherapy for patients with N3 disease and patients who are expected to have a delay in starting concurrent CRT. We feel that this patient subset is most likely to benefit from induction therapy.

Abstract

With improved outcomes associated with radiotherapy, radiation-induced sarcomas (RIS) are increasingly seen in long-term survivors of head and neck cancers, with an estimated risk of up to 0.3%. They exhibit no subsite predilection within the head and neck and can arise in any irradiated tissue of mesenchymal origin. Common histologic subtypes of RIS parallel their de novo counterparts and include osteosarcoma, chondrosarcoma, malignant fibrous histiocytoma/sarcoma nitric oxide synthase, and fibrosarcoma. While imaging features of RIS are not pathognomonic, large size, extensive local invasion with bony destruction, marked enhancement within a prior radiotherapy field, and an appropriate latency period are suggestive of a diagnosis of RIS. RIS development may be influenced by factors such as radiation dose, age at initial exposure, exposure to chemotherapeutic agents and genetic tendency. Precise pathogenetic mechanisms of RIS are poorly understood and both directly mutagenizing effects of radiotherapy as well as changes in microenvironments are thought to play a role. Management of RIS is challenging, entailing surgery in irradiated tissue and a limited scope for further radiotherapy and chemotherapy. RIS is associated with significantly poorer outcomes than stage-matched sarcomas that arise independent of irradiation

and surgical resection with clear margins seems to offer the best chance for cure.

Key words: Post-irradiation; Nasopharyngeal carcinoma; In-field; Radiotherapy; Head and neck cancer

Core tip: Radiotherapy is an important modality in the curative management of head and neck carcinoma. However, it is also associated with significant morbidity. Radiation-induced second malignancies, particularly radiation-induced sarcomas (RIS), are arguably the most devastating sequelae associated with radiotherapy. This review examines the common trends, pathophysiology, clinical presentation, diagnosis and management of RIS in head and neck cancers.

Thiagarajan A, Iyer NG. Radiation-induced sarcomas of the head and neck. *World J Clin Oncol* 2014; 5(5): 973-981 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/973.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.973>

INTRODUCTION

Radiotherapy is a commonly used in a curative setting to treat head and neck cancers, being utilized in both definitive as well as adjuvant settings. With prolongation of survival amongst head and neck cancer patients stemming from advances in therapeutic regimens and improvements in general oncologic care, attention to treatment-related morbidity becomes increasingly important. Radiation-induced second malignancies, in particular radiation-induced sarcomas, are arguably the most devastating of the late complications of radiotherapy (Table 1). With improved oncologic outcomes, post-irradiation sarcomas are increasingly seen in long-term survivors of head and neck cancers with an estimated risk of up to 0.3%^[1,2].

Table 1 Summary of key findings

With improved oncologic outcomes, RIS are increasingly seen in long-term survivors of head and neck cancers
There is no subsite predilection; They can arise in any irradiated tissue of mesenchymal origin
Common histologic subtypes parallel their de novo counterparts
Imaging features of RIS are not pathognomonic but large size, extensive local invasion with bony destruction, and marked enhancement within a prior radiotherapy field are suggestive of a diagnosis of RIS
RIS development may be influenced by factors such as radiation dose, age at initial exposure, exposure to chemotherapeutic agents, and genetic tendency
Precise pathogenetic mechanisms of RIS are poorly understood
Management is challenging, entailing surgery in irradiated tissue and limited scope for further radiotherapy and chemotherapy
RIS is associated with significantly poorer outcomes than stage-matched de novo sarcomas
Surgical resection with clear margins appears to offer the best chance for cure

RIS: Radiation-induced sarcomas.

In order to established causality between radiation and sarcomagenesis requires the the following conditions: (1) the sarcoma should arise within the irradiated field (in the area encompassed by the 5% isodose line); (2) the sarcoma must be histologically distinct from the index lesion; and (3) there must be a latency of several years between radiation exposure and subsequent diagnosis of the sarcoma^[3,4]. This time interval is necessary to differentiate post-irradiation sarcomas from sporadic sarcomas that may have predated radiation therapy. However, the best interval to establish this distinction continues to be a subject of debate: The original stipulation for this latent period was 5 years or longer. Subsequent modifications have seen a reduction in this time interval ranging from 6 mo to 4 years^[5-7]. For post-irradiation head and neck sarcomas, arbitrary time frames of 3-4 years have been used as cutoffs based on a loose consensus that this was a sufficient gap for radiation carcinogenesis to occur^[8,9]. Finally, patients with inherited syndromes that predispose to sarcomas even in the absence of radiation such as Li-Fraumeni or Rothmund-Thomson are generally excluded from the Radiation-induced sarcomas (RIS) subgroup of patients as defined above.

Squamous cell cancers comprise the commonest histologic sub-type of radiation-induced malignancy occurring in the head and neck region. RIS is the second most common, accounting for approximately 12% of radiation-induced malignancies; lifetime risk has been estimated to be 0.03%-0.3% in patients who have been previously radiated. Radiation-induced sarcomas exhibit no predilection for any single subsite within the head and neck. They can arise within any irradiated tissue of mesenchymal origin and as connective tissue is ubiquitous, any site within the head and neck can be a primary site for RIS. In one of the larger series of post-irradiation sarcomas of the head and neck recently published by our institution, the most common subsite was found to be the nose and paranasal sinus region, consistent with the fact that the vast majority of our cases (greater than 80%) were seen in nasopharyngeal carcinoma survivors^[10]. This finding has been replicated in a few other studies from China^[11]. That said, these data represent the spectrum of RIS observed in regions where nasopharyngeal carcino-

ma is endemic and should not be generalized to all post-irradiation sarcomas of the head and neck.

RIS include osseous and soft tissue sarcomas, and the vast majority are high-grade^[12,13]. The most common histologic subtypes of RIS parallel their de novo counterparts and include osteosarcoma, chondrosarcoma, malignant fibrous histiocytoma/sarcoma nitricoxide synthase, and fibrosarcoma. Other histologies encountered include rhabdomyosarcoma (particularly in children), angiosarcoma, synovial sarcoma, and malignant peripheral nerve sheath tumors^[1,2,9]. In our series, the commonest RIS subtype was sarcoma NOS and this is in keeping with much of the published literature on post-irradiation sarcomas of the head and neck.

In general, the imaging features of RIS are not pathognomonic and are often indistinguishable from those of sporadic sarcomas or recurrent primary tumors. However, the large size, extensive local invasion with bony destruction, marked enhancement within a prior radiation therapy field, and an appropriate latency period, suggests a diagnosis of RIS^[14,15].

The development of radiation-induced sarcomas may be influenced by factors such as dose, age at initial exposure, exposure to chemotherapeutic agents, and genetic tendency. As radiation carcinogenesis is a stochastic late effect, there is no "safe" or threshold dose below which RIS are not seen; In fact, RIS have occurred at doses less than 15Gy^[16,17]. However, the risk of RIS does appear to increase with increasing radiation dose^[2,18,19]. That said, there is some uncertainty about the shape of the dose-response curve at high radiation doses. RIS is generally thought to occur at doses that induce sublethal damage in normal tissues resulting in mutagenic responses and disorganized reparative proliferation and ultimately, tumor induction. Hence, some have postulated a downturn in RIS risk at ultra-high radiation doses where lethal damage predominates but a recent systematic review of the epidemiologic studies evaluating patterns of secondary malignancy risks after high-dose fractionated radiation therapy showed no clear evidence of nonlinearity in the dose-response in the direction of a reduction in risk even at very high doses, *i.e.*, 60Gy or higher^[20].

Greater risks for secondary sarcomas have been asso-

ciated with younger age at initial diagnosis. In the Childhood Cancer Survivor Study, the risk of RIS was more than nine-fold higher amongst childhood cancer survivors when compared with the general population, with highest risk observed in patients younger than four years of age at the time of primary cancer diagnosis^[21]. The reasons for these observed variations in susceptibility to RIS with age are not well understood and may be related to biology and not just longer follow-up times after treatment. Plausible explanations for this phenomenon include higher numbers of stem cells in irradiated tissues at a young age or their high proliferative rates, rendering them more sensitive to the tumorigenic effects of radiation. In addition, the microenvironmental constraints which inhibit proliferation of initiated cells may be less effective in some organs during youth and promotion by growth hormones is likely to be greater during youth. Finally, many cases of childhood cancer involve a germline mutation, and the distinct possibility exists that this mutation may include an increased sensitivity to radiation-induced cancer.

Radiotherapy with adjuvant chemotherapy is associated with higher relative risk of RIS in children. Alkylating agents and anthracyclines have been particularly implicated in this regard. They appear to increase RIS risk by a factor of 4 or more in some studies, after adjusting for radiation therapy, with risk increasing with cumulative drug exposure^[22,23]. Whether chemotherapy also potentiates the tumorigenic effects of RT in adults is less clear.

In addition, it has been postulated that the use of newer radiation techniques such as intensity-modulated radiation therapy (IMRT) may result in an increase in radiation-induced second malignancies. The reasons for this are twofold: First, IMRT involves the use of more fields compared to three-dimensional conformal radiation therapy, and as a consequence, the integral dose to the patient is higher, *i.e.*, a larger volume of normal tissue is exposed to lower doses of radiation. Second, delivery of a specified dose to the isocenter from a modulated field, delivered by IMRT, will require the linear accelerator to be energized for longer (*i.e.*, more monitor units are needed) compared with delivering the same dose from an unmodulated field. It therefore follows that the total body dose due to leakage radiation will be increased^[24,25]. That said, radiation-induced sarcomas are thought to be primarily a complication of high-dose radiation, rarely occurring at doses below 40Gy.

Previous reports suggest that RIS develop after a median latency period of approximately 17 years, although shorter latency has been reported among pediatric patients^[26-28]. Some of these reports suggest an indirect relationship between latency and dose of radiation dose especially for doses higher than 40Gy. However this remains unproven.

PATHOPHYSIOLOGY

The precise pathogenetic mechanisms underlying suscep-

tibility to and development of radiation-induced tumors are poorly understood. The prevailing paradigm focuses on radiation-induced DNA damage leading to mutations in susceptible cells. In this regard, *p53* point mutations and genetic aberrations in the *Rb* gene have been implicated^[29-34]. However, more recent literature suggests that radiation carcinogenesis is in fact much more complex. In addition to the directly mutagenizing effects of radiotherapy, changes in microenvironments are thought to play a critical role in tumorigenesis. Several studies have demonstrated that irradiated microenvironments can independently promote genomic injury in stem cells and enhance the expression of a neoplastic phenotype^[35].

In addition, there is mounting evidence that radiotherapy can influence cell function in non-targeted tissues in diverse ways. The bystander effect, which has been observed after radiation and chemical exposures, refers to a setting in which untreated cells demonstrate abnormalities mimicking exposure, such as chromosomal instability after irradiation. Radiation-induced signals transmitted between irradiated (in-field) cells and neighboring unirradiated cells can promote the development of persistent reactive oxygen species in unirradiated cells and hence, tumorigenesis. The mechanisms underlying the bystander effect are not well-defined, but have been postulated to involve secretable factors such as cytokines and intercellular gap junctions^[36,37]. The radiation-induced sarcomas referred to in this review are, by definition, tumors arising within the irradiated region and as such, a discussion of the bystander effect is outside the scope of this review.

CLINICAL PRESENTATION

In general, radiation-induced sarcomas present in a similar manner to *de novo* primary sarcomas of the head and neck. However, radiation-associated tissue changes such as induration may render them more difficult to identify by physical examination.

In the vast majority of cases, these tumors manifest as a painless palpable mass. They may also present with skin changes on the scalp or face, or subsite-specific symptoms (*e.g.*, cranial nerve palsies with skull base tumors, dysphagia with oropharyngeal tumors, or hoarseness with laryngeal tumors).

As with sarcomas occurring elsewhere in the body, lymph node involvement is uncommon in RIS of the head and neck, occurring in only about 10% of patients. The most common histologic subtypes associated with nodal metastases are RMS and angiosarcoma.

Rarely, patients may present with symptoms attributable to metastatic disease, most often involving the lungs (*e.g.*, SOB, cough/haemoptysis, chest pain *etc.*).

DIAGNOSTIC AND STAGING EVALUATION

Computed tomography of the primary tumor site offers

Table 2 Advantages and disadvantages of computed tomography and magnetic resonance imaging in head and neck oncologic imaging

CT	MRI
Advantages	
Fast	Superior soft tissue resolution including better assessment of perineural invasion, intracranial extension of disease, marrow infiltration
Well tolerated	Multi-planar imaging capability, better definition of craniocaudal extent
Relatively inexpensive	Less image degradation caused by artifacts arising from dental amalgam
Provides assessment of tissue composition (vascularity, lipid content <i>etc.</i>)	Does not involve ionizing radiation
Ideal at demonstrating cortical bone erosion	Contrast material is less likely to produce allergic reaction
Disadvantages	
Involves exposure to small amounts of radiation	May take more time to perform
Inferior soft tissue resolution compared with MRI	More expensive
Higher risk of allergic reactions and nephrotoxicity associated with the use of iodinated contrast agents	Lower patient tolerance; Claustrophobic patients may need sedation
	Contraindicated in patients with pacemakers and other implanted metallic devices which may malfunction following exposure to strong magnetic fields
	More susceptible to motion artefact

CT: Computed tomography; MRI: Magnetic resonance imaging.

three-dimensional information about locoregional tumor extent, provides assessment of tissue composition (vascularity, lipid content *etc.*), and assists in directing biopsies for histopathologic confirmation, planning surgical extirpation, and guiding target delineation during adjuvant radiotherapy planning^[14,15]. However, in the head and neck region, magnetic resonance imaging (MRI)s offer several well-recognized advantages over computed tomography (CT)s (Table 2). Firstly, they provide superior soft tissue resolution compared with CTs. Secondly, their multiplanar imaging capability permits better definition of the craniocaudal tumor extent. Thirdly, while CTs are ideal at demonstrating cortical bone erosion, marrow infiltration is better appreciated on MRIs. Finally, MRIs are far less susceptible to image degradation caused by artifacts arising from dental amalgam^[38]. For these reasons, MRIs should be an integral part of the workup of RIS of the head and neck and combined CT and MRI use is ideal.

In addition to radiologic evaluation of the primary tumor site, CT of the chest should be routinely undertaken as a component of staging in light of the fact that the lungs are the predominant site of metastases for both soft tissue and bone sarcomas. Guidelines from the National Comprehensive Cancer Network also suggest either an FDG-PET scan and/or bone scan in the staging workup of bone sarcomas to evaluate the entire skeleton for the presence of skip lesions.

Head and neck sarcomas including RIS are staged using the same staging schema applied to sarcomas arising at other body sites. The staging system used for soft tissue sarcomas, rhabdomyosarcomas, and for primary bone sarcomas (both osteosarcomas and chondrosarcomas) are presented in Tables 3-5 respectively.

PATHOLOGIC FINDINGS

As previously mentioned, imaging features of RIS are

not pathognomonic and it is difficult to exclude primary tumor recurrence and occasionally even post-operative or post-radiotherapy changes when relying on imaging alone. Hence, examination of tissue is mandatory in establishing the diagnosis of a soft tissue or bone sarcoma. The diagnostic biopsy must be carefully planned to ensure that adequate tissue is obtained in a manner that does not compromise definitive therapy. Core needle biopsy is considered the preferred method to achieve an initial biopsy in most cases.

The vast majority of RIS are high-grade and display a significant degree of tumor necrosis^[12,13]. The histopathologic spectrum of RIS is broad and is considerably dependent on the nature of the reporting institutions and/or the clinical practice of the reporting physicians. For instance, many studies in this field exclude bone sarcomas, paediatric sarcomas as well as benign tumors and tumors of low malignant potential, *e.g.*, desmoids and dermatofibromasarcoma protuberans. In most reported series, the commonest histologic subtype of RIS encountered is sarcoma NOS (formerly referred to as malignant fibrous histiocytoma). Other encountered histologies include but are not limited to osteosarcoma, chondrosarcoma, fibrosarcoma, rhabdomyosarcoma (particularly in children), and Angiosarcoma^[1,2,9,10].

There are as yet no specific histopathologic criteria to guide distinction between radiation-induced sarcomas and sporadic sarcomas arising within the radiation field, although the morphology of tissues in the immediate vicinity may be suggestive if it shows radiation-related changes (*e.g.*, dense cellular fibrosis, atypical fibroblasts, alteration of the vascular architecture, and abundant fibrous stroma in the dermis adjacent to the sarcoma)^[39].

Likewise, there has been considerable interest in identifying molecular markers or genetic signatures that can differentiate between RIS and spontaneously occurring sarcomas. Radiation-induced angiosarcomas consistently

Table 3 TNM staging for soft tissue sarcoma

Primary tumor (T)				
TX	Primary tumor cannot be assessed			
T0	No evidence of primary tumor

	Any T	N1	M0	Any G
Stage IV	Any T	Any N	M1	Any G

show MYC amplification, a finding not seen in primary angiosarcomas^[40]. Studies using microarray analysis have implicated mitochondrial genes and genes involved in antioxidant pathways in radiation-induced tumors, suggesting that mitochondrial dysfunction or chronic oxidative stress could play key roles in their pathogenesis^[39,41].

While promising, none of these markers are in clinical use. Most studies have used some modification of the Cahan criteria for classifying sarcomas as radiation-induced^[3]. While satisfying these criteria is likely to result in a high probability that the sarcoma is radiation related, there remains no gold standard for defining a radiation-associated sarcoma.

MANAGEMENT

Head and neck sarcomas are relatively rare clinical entities and radiation-induced head and neck sarcomas even more so. Their rarity coupled with their diversity of histologic subtypes makes rigorous clinical study difficult. As such, treatment algorithms for RIS of the head and neck are derived from retrospective case series and principles of management are drawn from those utilized to treat sarcomas at other body sites, rather than from large randomized clinical trials.

Management of these patients is complex. Surgical resection with clear margins seems to offer the best out-

comes for this group of patients. However, the confining and complex functional anatomy of the head and neck region and proximity to critical neurovascular structures makes adherence to traditional margin-driven therapy challenging even in de novo sarcomas^[5]. Treatment of RIS presents added challenges-entailing surgery in irradiated tissue and a limited scope for further radiotherapy and chemotherapy in selected sarcoma subtypes.

Not unexpectedly, RIS results in worse outcome compared to stage-matched de novo soft tissue and osteogenic sarcomas. Five-year disease-free survival rates for the former are 10%-30% compared to 54% for de novo tumors^[42]. The poorer outcomes could be due to: (1) difficulties and hence delayed diagnosis in previously radiated tissue; (2) compromised resection margins, due to proximity of the tumor to critical structures; (3) limited of treatment options in a maximally radiated field *i.e.*, technical difficulties of operating within an irradiated area, difficulties with reirradiation when surrounding normal tissues have been treated to near tolerance; (4) poor tumor sensitivity to chemotherapy; (5) the high-grade nature of the vast majority of RIS; and (6) host immunosuppression resulting from a combination of tumor related factors and previous treatment^[5,13,42-44].

That said, a noteworthy study of radiation-induced head and neck sarcomas conducted at our institution found that patients treated with curative intent had similar

Table 4 TNM staging for bone tumors other than lymphoma and myeloma

Primary tumor (T)				
TX	Primary tumor cannot be assessed			
T0	No evidence of primary tumor			
T1	Tumor 8 cm or less in greatest dimension			
T2	Tumor more than 8 cm in greatest dimension			
T3	Discontinuous tumors in the primary bone site			
Regional lymph nodes (N)				
NX	Regional lymph nodes cannot be assessed			
N0	No regional lymph node metastasis			
N1	Regional lymph node metastasis			
Distant metastasis (M)				
M0	No distant metastasis			
M1	Distant metastasis			
M1a	Lung			
M1b	Other distant sites			
Histologic grade (G)				
Grade is reported in registry systems by the grade value. A two-grade, three-grade, or four-grade system may be used. If a grading system is not specified, generally the following system is used:				
GX	Grade cannot be assessed			
G1	Well differentiated-low grade			
G2	Moderately differentiated-low grade			
G3	Poorly differentiated-high grade			
G4	Undifferentiated-high grade			
Anatomic stage/prognostic groups				
Stage I A	T1	N0	M0	G1, 2 Low grade, GX
Stage I B	T2	N0	M0	G1, 2 Low grade, GX
	T3	N0	M0	G1, 2 Low grade, GX
Stage II A	T1	N0	M0	G3, 4 High grade
Stage II B	T2	N0	M0	G3, 4 High grade
Stage III	T3	N0	M0	G3, 4 High grade
Stage IV A	Any T	N0	M1a	Any G
Stage IV B	Any T	N1	Any M	Any G
	Any T	Any N	M1b	Any G

outcomes regardless of whether they were radiation-induced or de novo sarcomas^[10]. This finding has a number of important implications. Firstly, heightened awareness of this entity and early recognition through careful surveillance of previously irradiated patients to detect tumors at an earlier stage would theoretically increase the likelihood of curative treatment. Secondly, optimal management not only demands multidisciplinary involvement of head and neck, neuro-, and reconstructive surgeons to maximize resectability, but also radiation oncologists and medical oncologists to consider the role of re-irradiation and/or adjuvant systemic therapy respectively, preferably in the context of a clinical trial.

Adjuvant radiotherapy may have a role in treatment of RIS of the head and neck, but its major limitation is the amount of prior radiation delivered in the same field. Factors that need to be considered include the previously treated volume and dose fractionation schedule, critical tissues and organs at risk, and time elapsed since the first treatment course. Reirradiation should only be considered if there are no other practical alternatives to treatment, since there is an increased risk of serious complications. General principles in patients undergoing reirradiation include the use of hyperfractionated radiotherapy regimens, use of highly conformal radiotherapy techniques such as brachytherapy, IMRT or increasingly, intensity-modulated proton therapy, use of previously unirradiated

normal tissue flaps for surgical resections, and the use of chemotherapy in association with lower-dose RT^[45]. In this regard, tertiary centers with high-volumes of head and neck sarcoma patients and extensive experience in re-irradiation are best suited to plan therapy in patients with RIS^[46].

The benefit of chemotherapy for head and neck soft tissue sarcomas after optimal local therapy is uncertain^[47]. Even for large, high-grade extremity sarcomas, the role of adjuvant chemotherapy is controversial, and existing data suggests that a survival benefit, if one exists, is small. However, there is some evidence suggesting improved local control with adjuvant chemotherapy^[48], which may be of particular relevance to head and neck sarcomas where treatment failure is usually consequent to local.

Likewise, there is little data addressing the benefit of chemotherapy specifically in RIS. Some investigators believe that chemotherapy will prove to be less effective in RIS compared with de novo sarcomas due to fibrotic changes in the previously irradiated field, thus preventing chemotherapeutic agents from reaching adequate concentrations in target organs. The contribution of chemotherapy to outcomes was addressed in a retrospective study of 80 cases of RIS treated between 1975 and 1995; the majority of analyzed cases were soft tissue sarcomas. Treatment included surgery alone, surgery plus chemotherapy, surgery plus radiotherapy with or without

Table 5 TNM staging system for rhabdomyosarcoma

Stage	Sites	Tumor stage invasiveness	T stage size	N	M
1	Orbit Head and neck Genitourinary Biliary tract	T1 or T2	a or b	Any N	M0
2	Bladder/prostate Extremity Cranial paraneural Other Δ	T1 or T2	a	N0 or NX	M0
3	Bladder/prostate Extremity Cranial paraneural Other Δ	T1 or T2	a b	N1 Any N	M0
4	All	T1 or T2	a or b	N0 or N1	M1

T: Tumor stage; T1: Confined to anatomic site of origin; T2: Extension; a: ≤ 5 cm in diameter; b: > 5 cm in diameter; N: Regional nodes; N0: Not clinically involved; N1: Clinically involved; NX: Clinical status unknown; M: Metastases; M0: No distant metastases; M1: Distant metastases present.

chemotherapy, chemotherapy alone, radiotherapy alone, and best supportive care. Overall survival was shortest in patients undergoing chemotherapy alone (median: 6 mo), and longest in those who underwent surgery alone (median: 42 mo). It was intermediate in patients who underwent surgery plus chemotherapy (median 28 mo). Interpretation of this data is limited by the retrospective nature of this study with small sample sizes and inherent selection biases, the heterogeneity of systemic agents used, as well as suboptimal chemotherapy administration often limited by performance status^[49].

While the majority of trials have evaluated the role of adjuvant chemotherapy in the management of soft tissue sarcomas, neoadjuvant chemotherapy has also been used in this setting and has several theoretical advantages: (1) tumor cytoreduction in bulky disease both to facilitate curative surgical resection and to permit smaller, less morbid surgery; (2) early treatment of micrometastases; and (3) avoidance of delay in commencement of systemic therapy due to postoperative complications. Potential disadvantages include impaired wound healing and delayed time to definitive local treatment particularly in the event that chemotherapy is ineffective. The discussion and decisions regarding neoadjuvant and adjuvant chemotherapy should be individualized and take into account factors such as patient age, comorbidities, performance status, histopathologic subtype of the sarcoma, as well as wishes of the patient. Needless to say, any systemic therapy should preferably be undertaken in the context of a clinical trial where tumor outcomes and toxicities are closely monitored.

On the other hand, there are certain clinical scenarios where the use of chemotherapy is less controversial. For instance, radiation-associated bone sarcomas are generally treated with chemotherapy in addition to surgery^[50]. Systemic therapy is also a routine component of treatment for several soft tissue sarcomas that occur predominantly

in children (*i.e.*, rhabdomyosarcoma, Ewing sarcoma)^[27]. Although these soft tissue sarcoma subtypes are particularly rare as radiation-associated sarcomas, most modern treatment plans utilize initial induction chemotherapy followed by local treatment, then additional adjuvant chemotherapy.

CONCLUSION

Since a significant proportion of head and neck cancer patients treated curatively receive high-dose radiotherapy as a component of their oncologic care, it is critical that clinicians are aware of radiation-induced sarcomas as a potential toxicity. RIS typically occurs after prolonged latent periods, occasionally spanning decades following initial radiotherapy and a high index of clinical suspicion assumes great importance in the outcome of these patients. Any suspicious masses should be biopsied, and if RIS is detected, the treatment of choice, where possible, is surgical resection with negative margins as this appears to offer the best chance for long-term survival. Adjuvant chemotherapy and re-irradiation may have a role in carefully selected cases and should preferably be undertaken in the context of a clinical trial. Future studies analyzing the genetics of RIS are also warranted to identify mechanisms responsible for sarcomagenesis and to attempt to target them in efforts to improve outcome.

Abstract

Fluorodeoxyglucose positron emission tomography/computed tomography (FDG PET/CT) is not indicated or recommended in the initial staging of early breast cancer. Although it is valuable for detecting distant metastasis, providing prognostic information, identifying recurrence and evaluating response to chemotherapy, the role of FDG PET/CT in evaluating locoregional nodal status for initial staging of breast cancer has not yet been well-defined in clinical practice. FDG PET/CT has high specificity but compromised sensitivity for identifying axillary nodal disease in breast cancer. Positive axillary FDG PET/CT is a good predictor of axillary disease and correlates well with sentinel lymph node biopsy (SLNB). FDG PET/CT may help to identify patients with high axillary lymph node burden who could then move directly to axillary lymph node dissection (ALND) and would not require the additional step of SLNB. However, FDG PET/CT cannot replace SLNB or ALND due to unsatisfactory sensitivity. The spatial resolution of PET instruments precludes the detection of small nodal metastases. Although there is still disagreement regarding the management of internal mammary node (IMN) disease in breast cancer, it is known that IMN involvement is of prognostic significance, and IMN metastasis has been associated with higher rates of distant metastasis and lower overall survival rates. Limited clinical observations

suggested that FDG PET/CT has advantages over conventional modalities in detecting and uncovering occult extra-axillary especially IMN lesions with upstaging the disease and an impact on the adjuvant management.

Key words: Breast cancer; Fluorodeoxyglucose positron emission tomography/computed tomography; Locoregional nodal disease; Axillary lymph node; Internal mammary lymph node; Axillary lymph node dissection; Sentinel lymph node biopsy

Core tip: The presence and extent of locoregional nodal metastasis at diagnosis is the single most important prognostic factor in breast cancer. The predominant lymphatic drainage pathway from the breast cancer is toward the axilla. Fluorodeoxyglucose positron emission tomography/computed tomography (FDG PET/CT) is a good predictor of axillary disease and correlates well with sentinel lymph node biopsy (SLNB). FDG PET/CT may help to identify patients with high axillary lymph node burden who could then move directly to axillary lymph node dissection (ALND) and would not require the additional step of SLNB. However, FDG PET/CT cannot replace SLNB or ALND due to unsatisfactory sensitivity secondary to the limitation of its spatial resolution. The internal mammary node (IMN) involvement is of prognostic significance in breast cancer, and IMN metastasis has been associated with higher rate of distant metastasis and lower overall survival rates. Limited preliminary data indicated that FDG PET/CT plays a role in identification of positive IMN, and it is superior to conventional imaging modalities.

Liu Y. Role of FDG PET-CT in evaluation of locoregional nodal disease for initial staging of breast cancer. *World J Clin Oncol* 2014; 5(5): 982-989 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/982.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.982>

INTRODUCTION

Breast cancer is the most common solid malignancy in women in the Western world, and a woman's lifetime risk of developing breast cancer exceeds 10%^[1]. The treatment and prognosis of breast cancer depend on the size of the lesion, pathologic grade, estrogen receptor status, locoregional nodal involvement and metastatic disease. Of these, the presence and extent of locoregional nodal metastasis at diagnosis is the single most important prognostic factor in breast cancer, which is reflected by 5-year survival rates of 99% in the absence of nodal metastasis, and 84% and 23% respectively for locoregional and distant metastatic disease^[2,3]. An increase in the number of tumor-positive axillary nodes is related to a worsened prognosis irrespective of primary tumor size. Approximately 30% breast cancer with local or locoregional-confined disease eventually relapse^[4,5]. Therefore, accurate evaluation of locoregional nodal status in breast cancer remains essential because of its implications for treatment and prognosis.

Imaging plays a critical role in the initial evaluation of breast cancer and serves as an important adjunct to surgical, pathologic and clinical staging. Several imaging modalities are used in the diagnosis and staging of breast cancer, including mammography, ultrasonography, computed tomography (CT), magnetic resonance imaging and positron emission tomography/computed tomography (PET/CT). For initial assessment of primary breast cancer, mammography is still the most used modality usually complemented with ultrasonography for the evaluation of axillary nodal involvement. Today metabolic imaging PET/CT with F18-fluoro-2-deoxy-D-glucose (FDG) has gained widespread clinical applications in oncology, and is accepted as a standard care in many malignancies. FDG is an analog of glucose and is used as a tracer of glycolysis. Malignant tissue and cells often demonstrate increased rate of glycolysis for rapid proliferation, due to increased numbers of glucose transporter protein and increased intracellular hexokinase and phosphofructokinase levels^[6]. The intensity of FDG is proportional to the rate of glycolysis, therefore is potentially semi-quantitative with standardized uptake value (SUV). It is well known that FDG PET/CT is valuable for detecting distant metastasis, providing prognostic information, identifying recurrence, and evaluating response to chemotherapy^[7]. However, knowledge of the value of FDG PET-CT for locoregional nodal staging is limited and somehow controversial. This review aims to present the role of FDG PET/CT in evaluating locoregional nodal status of breast cancer.

FDG PET/CT FOR AXILLARY LYMPH NODES

The most important prognostic factor in breast cancer is the axillary lymph node status. However, management of the axilla in patients with operable breast cancer is

still one of most controversial areas in clinical oncology. The best procedure to examine the axillary lymph nodes is still axillary lymph node dissection (ALND) or sentinel lymph node biopsy (SLNB). SLNB remains the gold standard for axillary nodal evaluation. Lymphoscintigraphy is a radionuclide imaging method to localize sentinel node in the axilla for biopsy. However, SLNB and ALNB carry significant surgical complications^[8].

The accuracy of FDG PET-CT for detecting axillary nodal lesion has been studied primarily in early-stage disease. Veronesi *et al*^[9] compared SLNB and FDG PET/CT in detecting occult axillary metastases in 236 consecutive patients. All patients with pathological confirmed cancer and negative axillae on clinical examinations underwent FDG PET/CT and SLNB. PET/CT identified positive axillary nodes in 43 patients (18.2%), 38 of these were confirmed true-positive on ALND (34) and SLNB (4). The results indicated a high positive predictive value of FDG PET/CT, and those with FDG PET positive axillae preoperatively should proceed directly to ALND without the need for SLNB. But SLNB identified 65 axillary positive cases, which was greater than the number of positive cases identified by FDG PET/CT. FDG PET/CT was unable to detect occult axillary metastases in one third of cases.

In a prospective multicenter trial, FDG PET-CT was performed in 360 women with newly diagnosed invasive breast cancer, and the PET results were compared to pathologic findings^[10]. Overall, FDG PET was 61% sensitivity and 80% specificity for axillary metastases, with a positive predictive value of 62% and a negative predictive value of 79%. Patients with false negative PET had significantly smaller and fewer tumor-positive lymph nodes than true-positive cases. The results indicated the limitation of FDG PET in detection of micrometastases and small, tumor-infiltrated axillary lymph nodes.

Another prospective study was obtained by Ueda *et al*^[11], which evaluated the utility of FDG PET/CT in combination with ultrasound for axillary staging in breast cancer. 183 patients underwent both FDG PET/CT and ultrasound within 5 wk of surgery. All patients had SLNB and/or ALND. FDG PET/CT was positive in the axillary lymph nodes in 40 (22%) patients, 34 (85%) of those were true-positive on correlation with surgical pathology. Of 143 negative PET/CTs, 25 (17%) were false-negative. The sensitivity and specificity of FDG PET/CT were 58% and 95%, respectively. The authors concluded that FDG PET/CT added incremental diagnostic confidence to axillary ultrasonography.

Kim *et al*^[12] tried to determine whether pre-surgical FDG PET/CT could be used as a guide for ALND or SLNB. 137 patients with biopsy-proven breast cancer underwent preoperative FDG PET/CTs, those who were positive in the axillae went to ALND directly, and those who were negative in the axillae proceeded to SLNB. There were 8 false negative and no false positive scans. The overall sensitivity and specificity of FDG PET/CT in predicting axillary metastases were 77% and 100%. 27

patients were spared unnecessary SLNB by using FDG PET/CT.

A study by Choi *et al*^[13] suggested that FDG PET/CT has similar sensitivity and specificity to breast ultrasonography in detecting axillary nodal lesions. One hundred and fifty-four consecutive biopsy-proven invasive breast cancer patients were enrolled in this study. All patients had preoperative FDG PET/CT and conventional image studies. Postoperative histopathologic results were used as the final standard. The sensitivity and specificity of FDG PET/CT to detect metastatic axilla were 37.3% and 95.8%, respectively; whereas the corresponding estimates of breast ultrasonography were 41.2% and 93.7%, respectively.

A meta-analysis by Cooper *et al*^[14] examined 7 studies with a combined 862 patients who underwent PET-CT for breast cancer staging. The mean sensitivity for detecting nodal metastasis was 56%. However, although the overall sensitivity of nodal evaluation in early-stage breast cancer is low, PET-CT still outperformed traditional imaging modalities.

The sensitivity of FDG PET-CT for axillary nodal metastasis depends on both axillary tumor burden and FDG avidity of primary tumor^[15,16]. A significantly higher proportion of metastases are detected in patients with aggressive histologic features.

In a study of 61 consecutive breast cancer patients by Heusner *et al*^[17], FDG PET/CT was obtained and compared to either SLNB or ALND, or both. Of 24 histologically positive axillae, FDG PET/CT predicted lymph node involvement in 17. In 14 true positive PET/CT cases, the mean diameter of the nodal lesions was 9 mm (range 4–22 mm). In 10 false negative PET/CT cases, the mean diameter of the axillary nodes was 3 mm (range 0.8–6 mm). The overall sensitivity was 58%, and specificity was 92%.

In a more recently published Ontario Clinical Oncology Group Study with 325 patient enrollments and ALND or SLNB as the gold standard following FDG PET/CT, the sensitivity, specificity, positive predictive value and negative predictive value were 23.7%, 99.6%, 95.8% and 75.4%^[18]. Using logistic regression, primary tumor size was predictive for prevalence of the nodal lesion and for PET sensitivity.

Table 1 outlines the major studies about the role of FDG PET/CT in evaluation of axillary nodal disease in breast cancer.

In conclusion, the data above indicate that positive axillary FDG PET/CT is a good predictor of axillary disease and correlates well with SLNB. FDG PET/CT may help to identify patients with high axillary lymph node burden who could then move directly to ALND and would not require the additional step of SLNB^[1]. However, FDG PET/CT cannot replace SLNB or ALND due to unsatisfactory sensitivity. False-negative FDG PET/CT in the evaluation of the axillary disease is mainly secondary to small size of the lymph nodes. A negative scan cannot exclude micrometastasis in the axilla. The spatial resolution (approximately 5–6 mm) of PET instruments

precludes the detection of small nodal metastases.

FDG PET/CT FOR INTERNAL MAMMARY LYMPH NODES

Although the predominant lymphatic drainage pathway from the breast cancer is toward the axilla, nodal metastases outside the axilla may be present in up to 56% of breast cancer^[1]. The sites of extra-axillary nodes include the internal mammary chain, interpectoral space, supraclavicular/infraclavicular region^[19,20]. In which, breast cancer drainage to internal mammary node (IMN) happens in as many as 30% of patients^[21,22]. Most of IMN metastases have concomitant axillary metastases, but 8%–10% patients with breast cancer may have IMN metastases only^[23].

The presence of IMN metastasis is classified as stage N3. IMN involvement is of prognostic significance in breast cancer, and IMN metastasis has been associated with higher rate of distant metastasis and lower overall survival rates^[24–28]. Yao *et al*^[24] examined the relationship between lymphoscintigraphic evidence of IMN drainage and survival in early stage breast cancer patients. The results show a near 3-fold increase mortality in IMN positive patients. Prognosis of patients with both axillary and IMN metastases is poor when compared with axillary nodal metastasis only^[29]. IMN involvement might predict treatment failure, early recurrence or distant metastasis in breast cancer^[30]. Multiple studies have consistently found that medial breast cancers carry a worse prognosis compared with lateral cancer, even after adjusting for other known prognostic factors. Because there is no plausible evidence that medial tumors are more biologically aggressive, it is likely that the worse outcome is a result of the un-treatment of IMN metastases, which is more common in medial cancer^[31,32].

The assessment of IMN remains a challenge. IMN metastasis is often clinically occult. Visualization of IMN drainage by lymphoscintigraphy depends on the use of peritumoral injection^[24], and drainage to IMN varies by locations of tumors^[24]. The peritumoral, or intratumoral injection of radiotracer was a useful method for identifying a significant portion of tumors that have primary IMN drainage because anatomic studies have shown that IMN is supplied primarily by retro-mammary lymphatic^[33,34]. With peritumoral or intratumoral injection technique, up to 25% IMN drainage could be identified by lymphoscintigraphy^[21,34]. However, subareolar injection, which improves axillary lymph node detection, rarely shows IMN uptake due to the superficial lymphatic channels. Although the gold standard for establishing the status of IMN metastasis is surgical, most surgeons do not routinely perform IMN sampling or dissection due to the relative inaccessibility and lack of convincing data for established survival benefit^[26,33]. In studies where biopsy was performed for hot internal mammary sentinel node on lymphoscintigraphy, tumor was detected patho-

Table 1 The studies evaluating the role of fluorodeoxyglucose positron emission tomography/computed tomography in axillary lymph nodes in breast cancer

Author	Year	Patient No.	Ref.	PET/CT Sensitivity (%)	PET/CT Specificity (%)	PET/CT PPV (%)	PET/CT NPV (%)	Conclusions
Wahl <i>et al</i> ^[10]	2004	360	ALND	61	80	62	79	FDG PET was limited in detection of micrometastasis
Veronesi <i>et al</i> ^[9]	2007	236	SLNB	37	96	88	66	High specificity of FDG PET/CT indicated that patients with positive PET should have ALND directly
Ueda <i>et al</i> ^[11]	2008	183	SLNB and/or ALND	58	95	85	83	Diagnostic accuracy of PET/CT was nearly equal to ultrasound
Kim <i>et al</i> ^[12]	2009	137	ALND or SLNB	77	100	100	94	FDG PET/CT could help to select patients for either ALND or SLNB
Heusner <i>et al</i> ^[17]	2009	61	SLNB	58	92	82	77	FDG PET/CT could not replace invasive approaches for axillary staging
Choi <i>et al</i> ^[13]	2012	154	Biopsy or additional imaging and follow-ups	37	96	83	74	FDG PET/CT could not be recommended as a primary diagnostic procedure
Groheux <i>et al</i> ^[16]	2011	70	SLNB or US-FNA	63	91	63	91	FDG PET/CT might impact cancer management in small portions of patients
Koolen <i>et al</i> ^[3]	2012	290	SLNB or US-FNA	82	92	98	53	FDG PET/CT could be recommended as a standard staging procedure
Pritchard <i>et al</i> ^[18]	2012	325	SLNB or ALND	24	100	96	75	FDG PET/CT was not sufficiently sensitive to detect positive axillary nodes

FDG PET/CT: Fluorodeoxyglucose positron emission tomography/computed tomography; PPV: Positive predictive value; NPV: Negative predictive value; ALND: Axillary lymph node dissection; SLNB: Sentinel lymph node biopsy.

logically in 8% to 27% of patients^[33]. Usually, if there is drainage to IMN, there is concomitant drainage to axillary node. In such case, general practice is surgical excision of only axillary sentinel node^[22]. Systemic treatment strategy is rarely influenced by IMN metastasis, due to concurrent axillary nodal metastasis and unfavorable primary tumor characteristics. Most of these patients would need adjuvant therapy such as chemotherapy and/or radiation and/or hormonal therapy. However, two recent European studies showed that IMN dissection improved accuracy of breast cancer staging and survival^[35,36]. The patients with IMN metastases had a better 5-year survival after IMN radiotherapy and chemotherapy^[34]. Heuts *et al*^[36] also suggested that tailored adjuvant systemic therapy and additional parasternal radiotherapy have a beneficial effect on the prognosis of these patients. However, the value of IMN radiation is uncertain and subject of debate partially due to a concern about the risk of cardiac toxicity associated with IMN radiotherapy^[36].

Although data are limited regarding the role of FDG PET/CT for IMN metastasis in breast cancer, some studies had demonstrated that FDG PET is superior to conventional diagnostic techniques in the detection of extra-axillary nodal metastases, particular to the IMN. Eubank *et al*^[37] compared the detection rates of CT and FDG PET/CT in 73 patients with recurrent or metastatic breast cancer. All patients had CT and PET/CT within 30 d of each other. The prevalence of abnormal FDG uptake in the IMN or mediastinum doubles that of abnormal CT findings in the extra-axillary nodal regions. FDG PET/CT could uncover disease in these nodal regions not detected by conventional staging methods. In

another prospective study with 154 preoperative patients with breast cancer by Choi *et al*^[13], 7 extra-axillary nodal lesions were detected by FDG PET/CT only although all patients had additional conventional imaging studies. Aukema *et al*^[38] found that in 60 breast cancer patients with tumor size greater than 3 cm and/or proven axillary nodal metastasis, pre-chemotherapy FDG PET/CT detected abnormal IMN in 8 patients. In 4 of the 8 patients, treatment planning was changed and radiotherapy was added. Koolen *et al*^[3] reported that in 310 patients with breast cancer and scheduled for neoadjuvant chemotherapy, FDG PET-CT detected 26 (8%) abnormal IMN. PET/CT findings helped selecting patients for postoperative internal mammary chain radiotherapy. Bernsdorf *et al*^[39] analyzed FDG PET/CT data of 103 consecutive patients with newly diagnosed operable breast cancer and tumors greater than 2 cm. Extra-axillary lymph node involvement was detected in the internal mammary chain by PET/CT in 10 patients, 5 of them had adjuvant treatment modifications. Recently, Wang *et al*^[40] reported the role of FDG PET/CT in the detection of IMN metastases with pathologic correlation in a large series of patients. One hundred and ten of 1259 patient had FDG avid IMNs on PET/CT. Twenty-five patients underwent ultrasound-guided fine needle aspiration of suspicious IMN based on PET/CT, and 20 IMNs (80%) were cytologically proven metastases from the primary breast malignancies. The results indicated a very high likelihood of malignant involvement of FDG avid IMNs. In another recently reported study by Koolen *et al*^[41], pre-chemotherapy FDG PET/CT scans identified IMN nodal lesions in 17 of 278 patients with breast cancer. The results show

Figure 1 Fluorodeoxyglucose positron emission tomography/computed tomography. A: In a 61-year-old woman with newly diagnosed breast cancer. There was

a single palpable axillary lymph node on physical examination. The images demonstrated a 1.5 cm axillary node with intense uptake (SUV 10, arrows), consistent with metastasis. There were also additional smaller axillary nodes with abnormal uptake. The patient underwent axillary lymph node dissection (ALND), and surgical pathology revealed that two axillary nodes were positive; B: In a 51-year-old woman with newly diagnosed right breast cancer. There were palpable right axillary lymph nodes on physical examination. The images demonstrated a few enlarged right axillary nodes with intense uptake (SUV 6.5, arrows). The patient had ALND, which showed three metastatic lymph nodes; C: In a 54-year-old woman with newly diagnosed right breast cancer. The images showed a 3.0 cm fluorodeoxyglucose (FDG) avid tumor in the right breast (arrows), but were negative in the right axilla. The patient had lymphoscintigraphy for sentinel lymph node biopsy, which was negative for axillary metastasis; D: In a 40-year-old woman with history of left breast cancer and post lumpectomy. On physical examination, there was a palpable lymph node in the left axilla. Positron emission tomography/computed tomography (PET/CT) showed a 1.5 cm left axillary lymph node with very mild uptake (SUV 1.4, arrows), consistent with a benign etiology. Subsequent SLNB confirmed lymphadenitis; E: FDG PET/CT in a 41-year-old woman with newly diagnosed inflammatory carcinoma of the right breast. In addition to large right breast necrotic mass and axillary nodal lesions, there are a 1.2 cm right internal mammary node (IMN) and a 1.0 cm left IMN, and both are mildly FDG avid (SUV 3.2) and suspicious for IMN metastases (arrows). The patient was excluded as a surgical candidate based on FDG PET/CT findings. She received chemotherapy and radiation. SUV: Standardized uptake value.

that FDG PET/CT contributes to pretreatment staging and therapy planning, upstaging substantial proportion of patients to the high risk group, thereby potentially changing prognosis and possibly implicating postoperative irradiation.

In conclusion, there is a significant disagreement in the oncologic community regarding the management of IMNs in breast cancer, most likely due to the difficulties in assessment of IMN and conflicting evidence of significance of IMN treatment. Lymphoscintigraphy may help to identify the IMN drainage, but the IMN sampling or dissection is much more difficult than for axillary nodes, and only a small portion of hot sentinel IMNs are positive for metastases on pathological studies. As a non-invasive imaging modality, FDG PET/CT plays a role in identification of positive IMN, which may renew the oncologists' interest in IMN management. But to date, the data regarding FDG PET/CT for IMN in breast cancer are very limited, and more clinical studies are warranted.

CASE EXAMPLES

Figure 1 illustrate the role of FDG PET/CT in locoregional nodal staging of breast cancer. In the case 1 and 2 (Figure 1A and B), FDG PET/CT was positive in the axillae. The patients avoided SLNB and directly had ALND. Pathology confirmed true-positive PET/CT findings.

FDG PET/CT was negative in the axilla in the case 3 (Figure 1C), and suggested a benign axillary lymph node in the case 4 (Figure 1D). In spite of negative PET/CT results, both patients had SLNB due to large primary tumor (the case 3) or palpable axillary lymph node (the case 4). SLNB demonstrated negative axillary disease consistent with PET/CT findings.

In the Case 5 (Figure 1E), FDG PET/CT identified positive IMNs, which updated staging, and subsequently changed the patients' managements.

CONCLUSION

Although FDG PET/CT is valuable for detecting distant metastasis, identifying recurrence and evaluating response to chemotherapy, the role of FDG PET/CT in evaluating locoregional nodal status for initial staging of breast cancer has not yet been well-defined in clinical practice. FDG PET/CT is not recommended as a routine imaging modality for initial staging of early breast cancer^[42],

although the direct scientific evidence to support this recommendation is limited. FDG PET/CT has high specificity but compromised sensitivity for identifying axillary nodal disease in breast cancer. Positive axillary FDG PET/CT is a good predictor of axillary disease and correlates well with SLNB. FDG PET/CT may help to identify patients with high axillary lymph node burden who could then move directly to ALND and would not require the additional step of SLNB. However, FDG PET/CT cannot replace SLNB or ALND due to unsatisfactory sensitivity. The spatial resolution of PET instruments precludes the detection of small nodal metastases.

There are substantial disparities in regard to the significance of IMN in breast cancer, and evaluation of IMN status is difficult in practice. Limited Data suggested that FDG PET/CT has advantages over conventional modalities in detecting and uncovering occult extra-axillary especially IMN lesions with upstaging the disease and an impact on the adjuvant management.

Positive FDG PET/CT is highly predictive for locoregional nodal disease in locally advanced breast cancer. Although the indications and role in initial staging of breast cancer remain to be validated, FDG PET/CT can be used in concert with other imaging modalities especially for patients with high risk.

Abstract

About 75% of all breast cancers are estrogen receptor (ER)-positive. They generally have a more favorable clinical behavior, prognosis, and pattern of recurrence, and endocrine therapy forms the backbone of treatment. Anti-estrogens (such as tamoxifen and fulvestrant) and aromatase inhibitors (such as anastrozole, letrozole, and exemestane) can effectively control the disease and induce tumor responses in a large proportion of patients. However, the majority of patients progress during endocrine therapy (acquired resistance) and a proportion of patients may fail to respond to initial therapy (de novo resistance). Endocrine resistance is therefore of clinical concern and there is great interest in strategies that delay or circumvent it. A deeper knowledge of the molecular mechanisms that drive endocrine resistance has recently led to development of new strategies that have the promise to effectively

overcome it. Many resistance mechanisms have been described, and the crosstalk between ER and growth factor receptor signaling pathways seems to represent one of the most relevant. Compounds that are able to inhibit key elements of these pathways and restore endocrine sensitivity have been studied and more are currently under development. The aim of this review is to summarize the molecular pathophysiology of endocrine resistance in breast cancer and its impact on current clinical management.

Key words: Everolimus; Mammalian target of rapamycin; PI3K inhibitors; Estrogen receptor; Endocrine resistance

Core tip: Endocrine therapy forms the backbone of treatment for hormone receptor (HR)-positive metastatic breast cancer (MBC) patients. Unfortunately, resistance to endocrine agents develops in the majority of patients. A deeper knowledge of the molecular mechanisms that drive endocrine resistance has boosted the development of strategies designed to overcome resistance to endocrine therapies. In particular, co-targeting of receptor tyrosine kinase and intracellular signaling pathways (such as the PI3K-Akt-mTOR pathway) has emerged as a particularly promising strategy. We predict that the development of new drugs with a strong underlying biological rationale will quickly result in more personalized treatment of patients with HR-positive MBC and further improve outcomes.

INTRODUCTION

Breast cancer is a leading cause of female death worldwide^[1]. There has been a continuous decline in mortality over recent years as a direct result of improvements in early diagnosis and increased availability of more effective treatments^[2,3]. However, despite these improvements, metastatic breast cancer (MBC) remains a largely incurable disease and new treatments need to prolong survival, relieve symptoms, and delay progression.

Approximately 75% of breast cancers express either or both the estrogen receptor (ER) and progesterone receptor (PgR)^[4]. Hormone receptor (HR)-positive and negative disease differ in terms of clinical behavior, prognosis, patterns of recurrence, and aggressiveness. Patients with HR-positive disease are likely to have more indolent disease, bone metastases, and late recurrences^[5]. For most HR-positive MBC patients, endocrine therapy is the preferential initial treatment and has a positive impact on survival.

Recently, a number of compounds with different mechanisms of action, low toxicity, and superior efficacy have become available for patients with HR-positive disease. Three classes of endocrine therapies are commonly used to treat HR-positive MBC: selective estrogen receptor modifiers (SERMs), such as tamoxifen, which directly bind to the ER and block its transcriptional activity; selective estrogen receptor downregulators (SERDs), such as fulvestrant, which bind to ER and induce its degradation; and aromatase inhibitors (AIs), such as letrozole, anastrozole, and exemestane, which reduce the production of estrogen *via* inhibition of the aromatase enzyme in peripheral tissues and within the tumor itself^[6].

Unfortunately, although long-term remission is possible^[7], the majority of patients develop resistance to endocrine therapy^[8]. Moreover, a proportion of patients may have primary resistance to endocrine therapy^[9]. There is therefore a lot of interest in developing strategies that delay the onset of endocrine resistance or circumvent acquired resistance to specific drugs.

It has recently been suggested that dysregulation of growth factor signaling networks and crosstalk between overexpressed growth factor receptors and ER play an important role in the endocrine-resistant phenotype^[10]. Manipulating these networks is an attractive and potentially effective strategy that aims to delay the onset, or eventually overcome, resistance to endocrine therapies.

The aims of this review are to provide an overview of the known mechanisms of resistance to endocrine therapies and to focus on emerging strategies aimed at circumventing its development.

THE BIOLOGY OF THE ER

The ER is mainly a nuclear protein that modulates gene expression *via* several different pathways. A schematic of the biology of ER signaling is presented in Figure 1.

The “classical” pathway

Estrogen is a steroidal hormone that passively diffuses

through cell membranes to enter the cell. The “classical” ER pathway is initiated by estrogen-induced dimerization of ER and subsequent binding to specific DNA promoter regions, known as estrogen response elements (EREs), which activates transcription of genes involved in promoting cellular proliferation and survival^[11]. ER can also inhibit gene expression, particularly those involved in downregulation of the cell cycle or pro-apoptotic actions. The transcriptional activity of ER is regulated by a number of co-activators (for example, members of the p160 family of nuclear receptor co-activators such as SRC1 and SRC2) that bind to ER to form large complexes^[12,13]. In breast cancer cells, SERMs such as tamoxifen lead to the formation of ER-co-repressor complexes that inhibit ER-dependent transcriptional activity to induce anti-proliferative and pro-apoptotic effects.

The “non-classical” pathway

In addition to the “classical” regulation of gene expression, ER also regulates genes that do not harbor EREs in their promoter regions in a “non-classical” manner. ER can, in fact, interact with other proteins that are known to be involved in promoting gene expression, such as Fos and Jun^[14].

Non-nuclear activities of the ER

Although the majority of cellular ER localizes in the nucleus, the ER can also localize in the cytoplasm and cell membrane, where it can interact with receptor tyrosine kinase (RTK) growth factor receptors, such as the epidermal growth factor receptor (EGFR), human epidermal growth factor receptor-2 (HER2), or insulin-like growth factor-1 receptor (IGF-1R)^[15]. In fact, the ER plays a key role in this complex intracellular signaling network and is strictly linked to other signaling networks^[16]. A complex network of bi-directional crosstalk exists at multiple levels in breast cancer cells, whereby the ER pathway and growth factor receptor signaling pathways interact and potentiate one another, resulting in dysregulated proliferation and growth^[12].

Therefore, through direct DNA binding, co-activation, or molecular crosstalk, ER can influence tumor cell proliferation, survival, and malignant progression by amplifying the intracellular proliferative signals from RTKs and their downstream effectors.

Putative mechanisms of endocrine resistance

There is strong evidence that crosstalk between growth factor receptor and ER pathways can mediate resistance to endocrine therapy. The ER exists as part of a highly complex and adaptive signaling network that enables cancer cells to escape simple perturbations, such as those presented by the currently available endocrine therapies.

For example, overexpression of members of the EGFR family of RTKs, particularly HER2, has been described as a molecular alteration that is able to confer *de novo* resistance to anti-estrogens^[12]. HER2 directly phosphorylates ER and its co-regulators, leading to enhanced

Figure 1 The biology of the estrogen receptor and a schematic representation of the key mechanisms of endocrine resistance. A: Estrogen induces gene regulation via the “classical” pathway. Estrogen passively diffuses through cell membranes and binds to the estrogen receptor (ER), inducing receptor dimerization. This complex recruits co-activators (CoA) and binds regions of DNA known as estrogen response elements (EREs), promoting transcription. Aromatase inhibitors (AIs) negatively regulate ER activity by reducing circulating estrogen levels; B: The ER can also cooperate with other transcription factors (TFs) and regulate the transcription of genes not harbouring EREs via the “non-classical” pathway; C: ER strictly interacts with receptor tyrosine kinases (RTKs) via their downstream effectors. ER can, in fact, be directly phosphorylated and activated, the final result being gene expression and a cascade of second intracellular effectors (the non-nuclear activity of ER); D: This strict and bi-directional crosstalk between ER and RTKs and downstream effectors is responsible for endocrine resistance; E: In breast cancer cells, SERMs [such as tamoxifen (Tam)] bind ER and induce the recruitment of co-repressors (CoR) that negatively regulate the activity of ER. Mutated forms of ER are able to enhance gene expression in spite of the presence of Tam.

ligand-independent gene expression, even in the presence of negative regulators such as SERMs.

There are data to suggest that patients with early breast cancers that overexpress HER2 obtain less benefit from adjuvant tamoxifen than those with HER2-negative tumors; furthermore, HER2 overexpression seems to be predictive of a poor clinical response to tamoxifen^[17,18]. EGFR overexpression is also predictive of decreased benefit from tamoxifen^[19,20] and increased risk of disease progression during anti-estrogen treatment^[21].

There is emerging evidence to suggest that long-term estrogen deprivation can directly induce the transcription of growth factor receptors such as EGFR, HER2, and IGF-1R, resulting in increased activity of their downstream mediators and increased cellular proliferation, the final result being escape from estrogen deprivation and ligand-autonomous growth^[22-24].

Another interaction that seems to be crucial in mediating resistance to endocrine therapies involves the phosphatidylinositol 3-kinase (PI3K)-Akt-mammalian target of rapamycin (mTOR) pathway, an ubiquitous signal transduction pathway that is also interconnected with other RTKs, including, but not limited to, the EGFR family (Figure 1)^[25-27]. This pathway regulates many cellular functions, not least growth and proliferation, differentiation, metabolism, migration, and survival^[28], and it is abnormally activated in many different cancer types,

including breast cancer, in which it has an important role in the development of anti-cancer drug resistance.

Dysregulation of this pathway is crucial in the development of acquired endocrine resistance. The pathway can become activated *via* increased upstream signaling due to activation of RTKs, PI3K-activating mutations, or decreased expression of negative regulators of the pathway, such as through loss of the tumor suppressor PTEN (phosphatase and tensin homolog). For example, several studies have established a link between upregulated Akt protein expression and/or phosphorylation and resistance to endocrine therapy^[29,30], and it is known that an mTOR subunit phosphorylates and activates the functional domain 1 of the ER^[31,32].

In a preclinical study, deGraffenried *et al.*^[33] reported that breast cancer cells with high Akt activity are resistant to hormonal therapy but that sensitivity could be restored with the use of mTOR inhibitors. Furthermore, in another study of ER-positive breast cancer cells, a combination of mTOR inhibitor and letrozole acted synergistically to inhibit proliferation and trigger apoptosis^[34].

However, several other mechanisms have been described that contribute to endocrine resistance. For example, loss of ER expression in the evolution from primary to metastatic disease may contribute to the emergence of estrogen resistance; data from clinical studies suggest that 17% of ER-positive patients treated with adjuvant

tamoxifen may convert to an ER-negative phenotype at the time of relapse^[35].

Mutations in *ESR1*, the gene encoding ER, also seem to negatively affect responses to hormonal therapy^[36,37]. Recently Toy *et al.*^[36] reported frequent mutations in *ESR1* that affect the ligand-binding domain (LBD) of ER in metastatic hormone-resistant breast cancers after prolonged exposure to hormonal therapy. These highly recurrent mutations mainly affected p.Tyr537Ser, p.Tyr537Asn, and p.Asp538Gly, and as a consequence caused an agonist conformation of the receptor. In addition, they noted that LBD-mutant receptors have a hormone-independent active state that is likely to promote resistance to estrogen-depriving therapies. Interestingly, mutant ER retains some sensitivity to drugs that directly target the receptor, suggesting that more potent ER antagonists may be of substantial therapeutic benefit in this subgroup of individuals.

There may also be individual biological variability in drug metabolism that might influence responses to therapy. For example, about 8% of Caucasian women fail to convert tamoxifen to its active metabolite, endoxifen, which has been suggested to be a mechanism of *de novo* resistance^[38].

In summary, multiple complex and adaptive mechanisms contribute to the development of endocrine resistance (Figure 1). As our understanding of the mechanisms that underpin resistance improves, the goal of future studies is to prolong responses to endocrine manipulation and potentially restore endocrine sensitivity in those tumors that have become resistant, with or without drugs that target interconnected pathways. Based on this theory, we describe three different approaches to overcome endocrine resistance that have recently been explored clinically in randomized trials.

OVERCOMING ENDOCRINE RESISTANCE

Combined inhibition of the ER and RTKs

Combined inhibition with ER- and HER2-targeting agents: HER2 is amplified and/or overexpressed (positive) in around 15% to 20% of human breast cancers. Although overexpression of HER2 is a marker of aggressiveness and poor prognosis, HER2-positive cells are sensitive to anti-HER2 targeted therapy, such as trastuzumab^[39,40]. About half of HER2-positive breast cancers co-express hormone receptors and this is associated with resistance to both tamoxifen and AIs, as shown in a number of pre-clinical and clinical studies^[25]. As a result of this pre-clinical evidence, several trials have explored using a combination of endocrine and HER2-targeting agents to overcome endocrine resistance.

Specifically, three trials have been published to date. The “Trastuzumab and Anastrozole Directed Against ER-Positive HER2-Positive Mammary Carcinoma” (Tandem) phase 3 study compared anastrozole alone with the combination of anastrozole and trastuzumab as first-line treatment for patients with HER2/HR-positive ad-

vanced breast cancer^[41]. The results showed that the combination of trastuzumab and anastrozole doubled median progression free survival (PFS) (2.4 mo *vs* 4.8 mo) and significantly increased the overall response rate (ORR) (6.8% *vs* 20.3%), compared to anastrozole alone. Side effects were modest and manageable (maximum grade 2) and consisted mainly of fatigue, vomiting, diarrhea, pyrexia, and arthralgia. There was no statistically significant treatment difference in overall survival; however, this may have been due to 70% of patients in the anastrozole arm crossing over to receive trastuzumab after progression on anastrozole alone.

The “Efficacy and Safety of Letrozole Combined With Trastuzumab in Patients With Metastatic Breast” (eLEcTRA) study prematurely closed due to slow recruitment. The design was the same as Tandem but a different AI (letrozole) was prescribed^[42]. Similar to Tandem, eLEcTRA showed that the addition of trastuzumab to letrozole was associated with improved PFS and clinical benefit rate (CBR) at the cost of a modest increase in overall toxicity.

The third study was “EGF30008”, a large, phase 3, double-blind, randomized-controlled trial conducted in 1286 women with HR-positive breast cancer; they were not selected on the basis of HER2 status (of the 1286 patients enrolled, 219 had HER2-positive tumors)^[43,44]. These patients were randomized to daily oral treatment with letrozole (2.5 mg) plus the dual HER1-HER2 tyrosine kinase inhibitor lapatinib (1500 mg) *vs* letrozole (2.5 mg) plus placebo. In the ER-positive/HER2-positive population (*n* = 219), the addition of lapatinib to letrozole resulted in a significantly lower risk of disease progression than with letrozole alone. The PFS was 8.2 mo in the combined arm *vs* 3.0 mo in the placebo arm. The ORR (28% *vs* 15%) and CBR (48% *vs* 29%) were also significantly greater in lapatinib treated women. In contrast to the other two studies, the addition of lapatinib was accompanied by a significant increase in the grade 1 and 2 side effects commonly associated with dual tyrosine kinase inhibition, namely diarrhea (68%) and cutaneous rash (46%). The impact of lapatinib plus letrozole on OS has not been reported. However, based upon a clinically meaningful increase in PFS, the United States Food and Drug Administration (FDA) and the European Medicines Agency (EMA) have approved lapatinib in combination with an aromatase inhibitor in this setting.

As expected, the HER2-negative patients enrolled in EGF30008 derived no benefit in PFS from the addition of lapatinib to letrozole. Interestingly, however, in the sub-group of “tamoxifen-resistant” patients (*i.e.*, those relapsing during or within six months from the completion of adjuvant tamoxifen treatment), the improvement in PFS was similar to HER2-positive patients, suggesting that the disruption of crosstalk between the ER and RTK signaling pathways might restore sensitivity to anti-estrogens.

Recently, Finn *et al.*^[45] showed that weak ER expression is associated with worse outcomes for postmeno-

pausal women with advanced HR-positive disease when treated with letrozole alone compared to a combination with lapatinib. Their data suggest that the population of patients with low quantitative expression of ER within the HER2-negative population may be most likely to benefit from the addition of lapatinib to letrozole, at least in terms of PFS improvement. They hypothesize that this benefit could be related to the anti-EGFR effect of lapatinib.

In conclusion, these three trials suggest that the combination of an anti-HER2 agent and an AI has significant clinical benefit and improves PFS compared to endocrine therapy alone. No significant differences in overall survival (OS) were observed in any of the trials, possibly due to the influence of crossover and/or the number of lines of treatment received after progression. Interestingly, these three trials also confirm that HER2-positive patients have relative endocrine resistance; in fact, women receiving endocrine therapy alone had response rates ranging only from 7% to 15% and median time-to-progression (TTP) ranging from 2.4 to 3.3 mo.

These three trials provide proof-of-concept that HER2-associated endocrine resistance may be reverted by targeting HER2 and that combination therapy represents a therapeutic opportunity for patients with these particular clinicopathological features.

Combined inhibition with ER- and EGFR-targeting agents

As previously discussed, the crosstalk between the ER and EGFR has been reported to mediate endocrine resistance. Therefore, combination strategies have been evaluated in the clinic^[12,46].

Although the clinical and prognostic role of EGFR in breast cancer has yet to be fully characterized and is mainly restricted to “basal-like” tumors, a few randomized trials have explored the effect of combined ER and EGFR targeting in women with MBCs not selected on the basis of EGFR status^[47].

NCT00229697 was a randomized phase II trial that evaluated the addition of the pure EGFR inhibitor gefitinib to tamoxifen in patients with HR-positive advanced breast cancer^[48]. Patients with newly metastatic disease, or who had recurred after adjuvant tamoxifen, during/after adjuvant AI, or after first-line AI, were randomized to receive tamoxifen plus placebo or tamoxifen plus gefitinib. A trend towards benefit from the combination therapy was seen in patients with tamoxifen-sensitive disease, with an increase in median PFS from 8.8 to 10.9 mo. In the AI-resistant population, no improvement in outcome was observed.

Another randomized phase II trial (NCT00077025), presented by Cristofanilli *et al.*^[49], evaluated the efficacy and tolerability of anastrozole combined with gefitinib or anastrozole with placebo in tamoxifen-resistant women with HR-positive MBC^[49]. Unfortunately, this study was closed prematurely due to slow accrual, but the data that were gathered showed that PFS was longer in patients

receiving the combination therapy than for those patients receiving anastrozole plus placebo (14.7 mo *vs* 8.4 mo).

Both of these studies suggest that the observed benefit of EGFR inhibition can be explained by EGFR activation as a mechanism of adaptation to tamoxifen inhibition. It would be therefore interesting to explore this association in an EGFR overexpressing population, like in the neoadjuvant study published by Polychronis *et al.*^[50]. In this study, both the combination of anastrozole and gefitinib and, interestingly, gefitinib alone showed clinical activity. Although the ORR was similar in both arms, patients assigned to gefitinib and anastrozole had a greater decrease in tumor proliferation (as measured by Ki67 labeling), than those assigned gefitinib and placebo.

Combined inhibition of the ER and PI3K-Akt-mTOR signaling

Crosstalk between the ER signaling pathway and the PI3K-Akt-mTOR signaling pathway is thought to play a crucial role in the development of resistance to endocrine therapy (Figure 2). Specifically, PI3K-Akt-mTOR pathway upregulation is associated with ligand-independent activation of ER and an associated increase in expression of genes regulated by ER, albeit in the presence of anti-estrogens^[30]. Moreover, several studies have shown that this effect can be reverted using mTOR inhibitors, such as everolimus or temsirolimus^[33,34].

These data provide a strong rationale for combining agents that target this pathway and anti-estrogens in an attempt to restore endocrine sensitivity. Based on this, we present a series of clinical studies below that explore the efficacy of this approach.

Everolimus

Everolimus, the 40-O-(2-hydroxyethyl) derivative of sirolimus (a rapamycin analogue), is an oral mTOR inhibitor that binds with high affinity to its intracellular receptor FKBP12, a protein belonging to the immunophilin family. The everolimus-FKBP12 complex interacts with mTOR to inhibit downstream signaling^[51,52].

In the phase II trial “TAMRAD”, Bachelot *et al.*^[53] evaluated the efficacy and safety of everolimus in combination with tamoxifen in 111 patients with MBC who had relapsed after first line treatment with AIs. Fifty-four patients were randomized to receive everolimus 10 mg/d and tamoxifen 20 mg/d, and the remainder received tamoxifen alone. Patients were stratified in two sub-groups: those who progressed during or within six months after the end of treatment with adjuvant AIs or progressed during the first six months of AIs with metastatic disease were defined having *ex novo* or primary resistance, whereas those who relapsed six or more months after completion of adjuvant AIs or after the first six months of therapy with AIs with metastatic disease were defined having acquired resistance.

The CBR was higher in patients treated with everolimus (61% *vs* 42%; $P = 0.045$) and TTP was longer in the combination arm (8.6 mo *vs* 4.5 mo; HR 0.54; 95%CI:

Figure 2 A representation of the molecular crosstalk between estrogen receptor and the receptor tyrosine kinases and PI3K-Akt-mTOR axes. In breast cancer, the PI3K-Akt-mTOR pathway modulates responses to signals communicated through growth factor receptors and the estrogen receptor (ER), and this crosstalk is important for sensitivity to anti-endocrine therapy. In particular, Akt and ERK1/2 phosphorylate ER on key residues involved in the induction of ligand-independent activation of DNA transcription. Furthermore, the converse occurs: estradiol, bound to membrane ER, interacts with and activates a regulatory subunit of PI3K. The mammalian target of rapamycin (mTOR) signaling cascade is another key regulatory pathway that controls proliferation and survival in cancer cells and plays an important role in the molecular crosstalk with the ER pathway. Two mTOR-interacting proteins, raptor and rictor, define distinct branches of the mTOR pathway: mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2). Both active mTORC1 (via the phosphorylation of downstream targets, such as 4E-BP1 and p70S6 Kinase) and active mTORC2 contribute to promoting cellular survival and proliferation. EGF: Epidermal growth factor; IGF: Insulin-like growth factor; PDGF: Platelet derived growth factor; PI3K: Phosphatidylinositol-3-phosphate kinase; E2: Estradiol; IRS-1: Insulin receptor substrate-1; RAS-RAF-MEK-ERK: Mitogen activated protein kinase pathway; HSP90: Heat shock protein 90; PDK-1: Pyruvate dehydrogenase lipoamide kinase isozyme 1; p70S6K: Protein 70S6 kinase; 4EBP1: Eukaryotic translation initiation factor 4E-binding protein 1; ERE: Estrogen response element.

0.36-0.81). The subgroup analysis showed that the benefit of the combination therapy was greater in patients with acquired resistance (74% in the secondary resistance subgroup *vs* 46% in the primary resistance subgroup).

Baselga *et al.*^[54] explored the activity of this combination in the neoadjuvant setting. In a phase II trial, 270 postmenopausal patients with ER-positive breast cancer were randomized to receive letrozole 2.5 mg/d plus everolimus 10 mg/d or letrozole 2.5 mg/d plus placebo for 16 wk prior to surgery. The primary endpoint was clinical response. The clinical response rates were 68.1% *vs* 59.1% in the combination and placebo arms, respectively ($P = 0.062$). Moreover, everolimus showed greater anti-proliferative activity (57% *vs* 30% in the everolimus and placebo arm, respectively; $P < 0.01$), defined as the reduction in cell proliferation assessed in pre- and post-surgical biopsy specimens.

Following these phase II results, a larger randomized, double-blind, phase III study was conducted by the same group^[55]. The 'BOLERO-2' study enrolled 724 patients with HR-positive advanced breast cancer who had recurred or progressed after previous therapy with a non-steroidal AI (letrozole or anastrozole). Patients were randomized to receive exemestane 25 mg/d plus everolimus 10 mg/d or exemestane 25 mg/d plus placebo. The

primary endpoint was PFS and the secondary endpoints were OS, ORR, CBR, safety, and quality of life.

The trial was stopped early because the pre-planned interim analysis showed a better PFS in the combination therapy arm (6.9 mo *vs* 2.8 mo in the combination and exemestane alone arms, respectively; $P < 0.001$) and a 57% reduction of risk of progression (HR = 0.43; 95%CI: 0.35-0.54; $P < 0.001$). These data were confirmed in the final PFS analysis conducted at a median follow-up of 18 mo^[56]. PFS was 7.8 mo *vs* 3.2 mo (HR = 0.45; 95%CI: 0.38-0.54; $P < 0.001$) in the combination and placebo arms, respectively, and the magnitude of benefit was irrespective of clinicopathological characteristics, including previous treatment. The ORRs were 12.6% *vs* 1.7% ($P < 0.001$) in the combination and placebo arms, respectively; the CBR was better in the combination arm (51.3% *vs* 26.4% in the everolimus and placebo arms, respectively; $P < 0.001$). The final OS results are still not available and are awaited with interest.

Although generally well tolerated, all the clinical studies have reported toxicity related to everolimus. Data from BOLERO-2 showed that a greater proportion of patients discontinued treatment in the everolimus arm than in the placebo arm (19% *vs* 4%, respectively) due to adverse events. However, no significant difference

in overall quality of life was reported between the two arms^[57]. The most commonly reported toxicities related to everolimus were stomatitis, fatigue, rash, anorexia, and diarrhea; a less common but life-threatening adverse event was non-infectious pneumonia (presenting as an acute deterioration in respiratory function with ground glass or patchy opacities on computed tomography scans), which was reported in about 3% of patients. This non-infectious pneumonia seemed to be immunologically mediated and the clinical management often required immediate drug interruption and high doses of corticosteroids. Other concerning toxicities reported were hyperglycemia, hypercholesterolemia, and hypertriglyceridemia^[58,59].

Temsirolimus

Temsirolimus is a compound that, similar to everolimus, inhibits the kinase activity of mTOR by complexing with FKBP12. However, it differs from everolimus in its pharmacokinetics and toxicity profile^[60].

In a randomized phase II study, Carpenter *et al.*^[61] explored the activity and safety of oral temsirolimus with letrozole in heavily pre-treated ER-positive MBC patients. This trial had a three-arm design: one arm received letrozole alone, whereas the other two arms received letrozole plus temsirolimus daily (10 mg) or intermittently (30 mg), respectively. One-year PFS was higher in both combination arms with letrozole alone (69%, 62%, and 48%, respectively).

However, these results were not confirmed in a subsequent larger randomized phase III trial conducted by Chow *et al.*^[62] in heavily pre-treated MBC patients; no improvement in PFS was seen in the investigational arm and the study was stopped early.

Temsirolimus has also been evaluated in AI-naïve patients. In a randomized phase III study, 1112 postmenopausal women with ER-positive locally advanced or metastatic BC with no prior exposure to AIs were randomly assigned to receive letrozole plus oral temsirolimus 30 mg/d for five days every two weeks or placebo with the same schedule^[63]. The independent data monitoring committee also stopped this trial early at the second pre-defined interim analysis because the study was deemed unlikely to reach its primary endpoint. The published data showed no difference in PFS (8.9 and 9.0 mo, respectively; $P = 0.25$) between the groups at a median follow-up of 9.5 mo.

PI3K inhibitors

Alterations in the *PIK3CA* gene are the most common somatic mutations in breast cancer, and both crosstalk between the ER and PI3K pathways and PI3K activation are thought to play a role in endocrine resistance^[64,65].

Specifically, PI3K pathway alterations occur in about 70% of breast cancers and include mutations and/or amplifications of the genes encoding the PI3K catalytic subunits, p110 α (*PIK3CA*) and p110 β (*PIK3CB*), the PI3K regulatory subunit p85 α (*PIK3R1*), and the PI3K effectors *AKT1*, *AKT2*, and *PDK1*. The loss of lipid

phosphatases, such as PTEN and INPP4B (inositol polyphosphate-4-phosphatase type II), can also activate the pathway^[66-69].

In 2012, the Cancer Genome Atlas Network described that luminal ER+ tumors commonly harbor PI3K mutations, 49% in luminal A and 32% in luminal B^[70]. Fu *et al.*^[71] have recently shown that activation of RTK signaling induces transcription of growth-related genes and causes decreases in ER levels and activity, leading to an inferior response to endocrine therapy. Co-targeting this pathway with ER and PI3K inhibitors therefore appears to be a promising therapeutic opportunity for patients with ER+ breast cancer. In support of this, Fu *et al.*^[71] found that the combination of tamoxifen with a dual PI3K/mTOR inhibitor (BEZ-235) additively reduces cell growth in different ER-positive HER2-negative breast cancer cell line models^[71,72]. Furthermore, Sanchez *et al.*^[73] suggested in pre-clinical testing that fulvestrant may sensitize long-term estrogen deprived ER+ breast cancer cells to the therapeutic effects of PI3K inhibitors, with an associated synergistic increase in apoptosis.

At the most recent San Antonio Breast Cancer Conference, Juric *et al.*^[74] presented results from a phase 1b study of the PI3K α inhibitor GDC-0032 in combination with fulvestrant in patients with ER+ advanced breast cancer. GDC-0032 was administered to 17 patients at a range of doses (six to nine mg/d) in combination with fulvestrant 500 mg every four weeks (with loading dose of 500 mg at day one, 14, and 28). The combination appeared to be well tolerated and had promising preliminary efficacy, with a final recommended dose of six mg per day. No dose limiting toxicities (DLTs) were observed and the main adverse events were gastrointestinal toxicities (anorexia, nausea, and diarrhea), metabolic toxicity (hyperglycemia), and rash. Metabolic partial responses were observed in eight out of 11 patients (73%), including those previously treated with fulvestrant^[75].

At the same conference, another phase 1 trial reported on BKM120, a novel oral pan-PI3K inhibitor, in combination with fulvestrant in postmenopausal women with ER-positive MBC. Fulvestrant 500 mg IM was administered monthly on day one of each 28-d cycle (following the loading dose) and BKM120 was administered daily on day one to 28 of each cycle. 18 patients have been treated at three doses of BKM (80 and 100 mg/d continuously and 100 mg/d, five days on and two days off). Both BKM120 100 mg schedules (continuous or intermittent) with fulvestrant were tolerable without DLTs. Liver toxicity (assessed by ALT) has been reported with BKM120, especially with continuous dosing, and often requires dose reduction but not interruption. The results of this trial were promising, with over 50% clinical benefit, one partial response, and five prolonged disease stabilizations.

Phase III studies of this combination have also been started in the same setting and preliminary information was reported at the 2012 American Society of Clinical Oncology (ASCO) annual meeting. For example, the BELLE (buparlisib breast cancer clinical evaluation) tri-

Table 1 Ongoing clinical trials of PI3K inhibitors in combination with endocrine therapy in hormone receptor-positive metastatic breast cancer

Treatment	Disease conditions	Trial status	Trial number
Phase I			
BYL719 + letrozole	Postmenopausal women hormone receptor-positive stage IV breast cancer	Ongoing	NCT01791478
BKM120 + fulvestrant	Postmenopausal women estrogen receptor-positive stage IV breast cancer	Ongoing	NCT01339442
BKM120 or BEZ235 + letrozole	Postmenopausal women hormone receptor-positive stage IV breast cancer	Ongoing, not recruiting	NCT01248494
XL147 or XL765 + letrozole	Postmenopausal women hormone receptor-positive stage IV breast cancer	Completed	NCT01082068
Phase II			
PF-04691502 + exemestane <i>vs</i> exemestane alone	Estrogen receptor-positive stage IV breast cancer	Withdrawn prior to enrolment	NCT01658176
PF-04691502 + letrozole <i>vs</i> letrozole alone	Postmenopausal women estrogen receptor-positive early (phase II) and advanced (phase I b) breast cancer	Terminated	NCT01430585
GDC-0941 or GDC-0980/placebo + fulvestrant	Postmenopausal women estrogen receptor-positive, AI treated, stage III B-IV breast cancer	Ongoing	NCT01437566
Phase III			
BKM120/placebo + fulvestrant	Postmenopausal women hormone receptor-positive, AI treated, stage III B-IV breast cancer progressed on or after mTOR inhibitor-based treatment	Ongoing	NCT01633060
BKM120/placebo + fulvestrant	Postmenopausal women hormone receptor-positive, stage III B-IV breast cancer refractory to AIs	Ongoing	NCT01610284

als are investigating the safety and efficacy of buparlisib (BKM120) with fulvestrant.

BELLE2 is a phase III of BKM120 plus fulvestrant in HR-positive HER2-negative advanced breast cancer that has progressed on or after AI therapy, while BELLE3 is a similar phase III trial in patients with advanced breast cancer previously treated with AIs and refractory to endocrine and mTOR inhibitor combination therapy. The results from these trials will not be available for a few years (NCT01610284 and NCT01633060). BELLE4 is a phase II, randomized, double-blind and placebo-controlled study of BKM120 in combination with paclitaxel in patients with HER2-negative, locally advanced or metastatic breast cancer, with or without PI3K pathway activation. Other combination trials using different PI3K inhibitors are currently recruiting, for example BYL719 with letrozole or fulvestrant, and ongoing trials of PI3K inhibitors combined with endocrine agents are summarized in Table 1.

Multiple targeting of ER

Although the functional crosstalk between different molecular pathways and ER are thought to be the largest contributor to the development of endocrine resistance, many other mechanisms have also been described. For example, cells that express mutated ER circumvent inhibition by tamoxifen or long-term estrogen deprivation, as described above, and due to its peculiar mechanism of action, fulvestrant appears to be more active in these situations. Fulvestrant mediates the down-modulation and accelerated degradation of ER, thereby reducing its activity and its availability to other interacting molecules. Moreover, preclinical data suggest that fulvestrant retains and enhances its antitumor activity in the low estrogen

environment, such as in the presence of AIs^[76]. These data support a strong rationale to explore the activity of combining fulvestrant with AIs.

To this end, three large randomized trials have assessed this approach in postmenopausal women with ER-positive MBC^[77-79]. Mehta *et al*^[79] explored the activity of fulvestrant (500 mg loading dose, followed by 250 mg on days 14 and 28 and monthly thereafter) in combination with anastrozole compared to anastrozole alone (1 mg/d in both arms) in the first-line setting in women with MBC previously exposed to AIs and tamoxifen in the adjuvant setting. Overall, the study was positive in terms of its primary endpoint, with a small but statistically significant 1.5-mo increase in median PFS. However, the combination was only beneficial in the tamoxifen-naïve population. No differences in ORR and CBR were observed in the two arms of the trial.

In the second study, conducted by Bergh *et al*^[77], women with HR-positive MBC were randomized to receive the same two treatments as above in the first-line setting. Sensitivity to AIs was defined as either no prior exposure or administration of these drugs in the adjuvant setting and relapse occurring after one year from completion of adjuvant endocrine therapy. This trial failed to show differences between the study arms in the primary endpoint of TTP, or in ORR, CBR, and OS.

In the third study, recently published by Johnston *et al*^[78], patients with MBC resistant to AIs were randomized to fulvestrant (dose and schedule as above) plus anastrozole (1 mg/d), fulvestrant plus placebo or anastrozole, or to exemestane 25 mg/d. Patients were eligible if they progressed while on AIs after a period of at least 12 mo for adjuvant therapy or six months for metastatic disease.

This study also reported no differences in terms of PFS, OS, ORR, and CBR between the treatment arms.

CONCLUSIONS AND FUTURE PERSPECTIVES

Endocrine therapy was traditionally thought to be less effective than chemotherapy for the treatment of women with MBC and was consequently demoted to a secondary role. Recently, our understanding of ER biology has improved and, in parallel, our therapeutic armamentarium has expanded with the development of several classes of compounds with different mechanisms of action. As a result, endocrine therapy is the confirmed leader in the treatment of HR-positive MBC due to greater efficacy and negligible toxicity.

However, most women treated with endocrine therapies develop resistance, and several mechanisms of resistance have been described. In particular, ER appears to be a key player in a complex network of signaling pathways that leads to proliferation and survival of cancer cells. Due to the adaptability of this network, cells can easily escape simple perturbations, such as those presented by the currently available endocrine therapies.

Moreover, these observations have provided the rationale for developing drugs that target other interconnected pathways. Combinations of endocrine agents with or without these drugs have recently been tested in randomized trials, with exciting results.

In this paper, we have described three possible strategies to overcome endocrine resistance, some of which are already becoming part of clinical practice.

Of these, co-targeting the RTK signaling pathways and intracellular signaling networks is the most effective. Lapatinib has recently been approved in patients with HER2- and ER-positive breast cancer, and everolimus has been approved in combination with exemestane for women refractory to AIs. Many other drugs that target intracellular signaling networks, especially the PI3K-mTOR-Akt axis, are currently under development and some of these have shown promising results.

However, recent advances in the understanding of the biology of ER signaling and of the molecular markers of resistance have highlighted that ER and its pathway remain central to endocrine resistance. These findings are likely to translate into new strategies to overcome endocrine resistance in the near future. For example, targeting tumors with specific ER mutations with more potent and specific anti-estrogens seems to be a fascinating approach.

All these advances have positively impacted on survival of women with HR-positive MBC. They chart a course towards the biology-based selection of treatments and a more rational use of chemotherapy to improve efficacy and limit toxicity in women with breast cancer.

Abstract

Human papillomaviruses (HPVs) are a large family of double strand DNA viruses comprising more than 180 types. Infection with HPV is very common and it is associated with benign and malignant proliferation of skin and squamous mucosae. Many HPVs, considered low-risk such as HPV 6 and 11, produce warts; while high-risk viruses, such as HPVs 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, and 58, induce tumors. About 5% of all cancers in men and women are associated with HPV infection. Because there are not antiviral drugs for HPV infection, current therapies for low-risk HPV infections involve physical removal of the lesion by cryotherapy, trichloroacetic acid, laser, or surgical removal. Surgical procedures are effective in the treatment of pre-cancerous lesions, however after these procedures, many recurrences appear due to new re-infections, or to failure of the procedure to eliminate the HPV. In addition, HPV can inhibit recognition of malignant cells

Core tip: Infection with human papillomavirus (HPV) is very common and it is associated with benign and malignant proliferation of skin and mucosae. Low-risk HPV produce warts; while high-risk HPV induce tumors. Because there are not antiviral drugs for HPV infection, current therapies involve surgical removal of the lesion. Unfortunately, after surgery many recurrences still appear and about 50% of the HPV-cancer patients die. In the past decade, new therapeutic strategies geared to generate an efficient virus-specific cytotoxic response have been developed. This review describes the current status of the several therapeutic strategies used to treat HPV-induced lesions.

INTRODUCTION

In the mid 70s human papilloma virus (HPV) was described as a mild viral infection that caused benign warts, that in most cases would regress spontaneously^[1]. In few years however, it became evident that there are many HPV with selective tropism for various cutaneous mucosae, and that HPV infection could cause severe diseases. Especially, some HPVs infecting the ano-genital area are real oncogenic viruses that lead to cervical carcinoma^[2], the seventh most common cancer in the world^[3] and the second most common cancer among women^[4].

More than 180 types of HPV have been identified from different lesions, classified by DNA sequences, and named sequentially^[5]. HPV have selective tropism for cutaneous or mucosal epithelia and are divided into two groups: low-risk that cause benign lesions, named papillomas (small wart-like neoplasias) that usually regress on their own; and high-risk that cause malignant transformation and develop into large tumors. The two most common low-risk HPV are HPV 6 and HPV 11. They are responsible for 90% of genital warts and recurrent respiratory papillomas^[6]. There are about 15 high-risk HPV causing around 95% of all cervical carcinomas^[7]. The types HPV 16 and HPV 18 account for about 50% and 14% of all cases respectively^[4]. High-risk HPV are also involved in other types of cancer. Around 80% of tumors of the anus, 60% of the vagina, and 40% of vulva and penis are induced by HPV, mainly the type HPV 16^[8]. Also, around 60% of tongue, tongue^[9], and tonsil tumors are also caused by HPV^[10].

Natural history studies of HPV show that 60% of sexually active people will be infected with at least one high-risk HPV during their lifetime^[11]. Most of these infections are eliminated by the immune system in about 1 or 2 years from exposure^[12]. However, in the remaining cases, the virus persists for a long time causing lesions that can progress into cancer^[13]. Early detection of HPV-induced lesions becomes important in order to prevent the development of cancer. The best way to diagnose an HPV infection is to confirm the presence of HPV DNA in the lesion by hybridization or by PCR^[14,15]. This type of testing is expensive and difficult to implement in poor parts of the world^[16]. Therefore, regular screening of cytological (Pap smear) or colposcopic abnormalities, which are signs of HPV infection, continues to be an effective preventive strategy for cervical cancer^[17] particularly in developing countries. Unfortunately, this strategy is not without problems. There is great variability due to the lack of trained personnel resulting in high rate of false negative results^[18]. Clearly a combination of screening strategies is needed to detect as early as possible HPV-induced lesions.

Once HPV lesions are detected, the main therapeutic approach involves physical elimination of the lesion by cryotherapy, trichloroacetic acid, laser or surgical removal^[19]. In pre-cancerous lesions however, surgical procedures alone are not very effective, since recurrences

occur at rates of 20%-30% or more with lesions both at previously treated sites due to failure of the procedure to eliminate the HPV, and at new sites due to new infections^[20]. In addition, HPV can inhibit recognition of malignant cells by the immune system^[21], leading to the development of cancer lesions. When this occurs, radiotherapy and chemotherapy are then used with relative success, since about 50% of the HPV-cancer patients still die^[22]. Clearly, new therapeutic strategies are in urgent need to control the burden of HPV-related cancer^[23].

The fact that most HPV infections are cleared spontaneously shows that the immune system can effectively eliminate virus-infected cells. But, in the case of persistent infections, the immune system clearly has failed. HPV has evolved several mechanisms to evade the immune system. First, HPV infects keratinocytes, which are distant from immune cells, presents a minimal expression of viral proteins in the keratinocyte, and thus does not induce lysis of keratinocytes. In addition, HPV down-regulates the expression of major histocompatibility complex (MHC) class I molecules, Toll-like receptor (TLR) 9, and cytokines such as, interferon and interleukin (IL)-8^[21]. New therapeutic approaches take advantage of our knowledge on how the immune system deals with viral infections and eliminates virus-infected cells mainly through cytotoxic activity of various leukocytes, mainly T cells^[21]. These new therapies involve the use of anticancer vaccines and intralesion immunotherapy with the idea to activate specific cytotoxicity towards HPV-infected cells^[24,25]. In this review, we describe the current status of the several therapeutic strategies used to treat HPV-induced lesions, and discuss the various new therapies now being tested.

PAPILLOMAVIRUS

Papillomavirus belong to the Papovaviridae family of DNA viruses. These viruses contain a double strand DNA with 8000 pb approximately arranged in an 8 well-defined genes (Figure 1). Six early genes are involved in virus replication and two late genes are involved in virus assembly. HPV infect the epithelium of the cervix, and their replication is closely linked to the differentiation of the epithelium (Figure 2)^[26,27].

IMMUNE RESPONSE TO HPV

Protection against viral infections is provided by both arms of the immune system. First, HPV can infect cells through damaged skin tissue. When the damage reaches the basal layer of the epidermis, the virions can infect dividing keratinocytes. The initial inflammatory response induced by tissue damage leads to infiltration of immune cells mainly neutrophils, followed by macrophages and later lymphocytes. These nonspecific innate immune cells detect "danger" by recognizing viral molecules, such as the double-stranded DNA HPV genome or the L1 and L2 capsid proteins. These molecules are detected by pat-

Figure 1 Human papilloma virus genome. The genomic organization of the human papilloma virus 16 (HPV 16) is shown. The double strand DNA is close to 8000 base pairs. The early genes code for proteins involved in viral replication and transcription: E1, E2, E6, and E7 genes. The E4 and E5 genes are expressed a little later and have functions in immune evasion and virus release. The late genes code for the virus structural proteins: the major capsid protein L1, and the minor capsid protein L2. The E6 and E7 proteins of the high-risk HPV types have oncogenic properties. The long consensus repeat (LCR) sequence contains the promoter and enhancer elements of the virus.

tern recognition receptors, such as Toll-like receptors^[28], which signal to activate defense mechanisms *via* the production of inflammatory cytokines such as IL-1 β , IL-6, IL-8, IL-12, and α -, β - and λ -interferon (IFN) to activate natural killer (NK) cells^[29] and other immune cells. Later, antigen presenting cells (APCs), such as Langerhans cells or dendritic cells (DCs) in the skin and mucosa^[30], can uptake viral antigens and process them into small peptides that are presented together with MHC (HLA in humans) molecules on the cell membrane, to lymphocytes for initiation of an adaptive immune response (Figure 3). For this process, DCs migrate to lymph nodes where they undergo maturation through the expression of co-stimulatory molecules. The processed viral antigen/MHC complex on DCs binds to antigen-specific T cell receptors on naïve CD4⁺ and CD8⁺ T cells. This binding induces T cell proliferation, IL-2 production, and activation of T cells. Activated CD4⁺ helper T cells can differentiate into Th1, Th2, or Treg/Th3 phenotypes depending on the cytokines they produce. Th1 produce IL-2, IL-12, IL-15, tumor necrosis factor (TNF)- α , and λ -IFN; Th2 produce IL-4, IL-5, IL-6, IL-10, and IL-13; and Treg/Th3 produce IL-10, transforming growth factor (TGF)- β , and λ -IFN. On the other hand, activated CD8⁺ T cells differentiate into cytotoxic T lymphocytes (CTL) which secrete the

Figure 2 Papilloma virus replication is tissue specific. The human papilloma virus (HPV) infects a keratinocyte in the basal layer of the epithelium after a micro trauma (a small cut of the epithelium that uncovers the basal membrane). The virus DNA is maintained in the proliferating cells at a low-copy number (E1 and E2 viral proteins are expressed). When the infected cells begin to differentiate into mature keratinocytes, the virus activates other genes (E4, E6, E7 viral proteins are expressed) and replicates its DNA to a high-copy number. In the top layers of the epithelium all viral proteins (including E4 and the capsid proteins L1 and L2) are expressed. Thousands of new virions are formed and released from the cells without causing cell death.

proteolytic enzymes, granzyme and perforin^[31]. CTLs migrate back to the infected sites and destroy HPV-infected cells (Figure 3).

The majority of HPV infections are cleared spontaneously within two years from infection and without any clinical manifestation by immune-competent individuals^[12,26]. In spontaneously regressing HPV-related lesions, infiltration of CD4⁺ and CD8⁺ T cells has been detected, while in persistent lesions these immune cells are not seen^[32]. In addition, in immunosuppressed individuals such as organ transplant recipients^[33] or human immunodeficiency virus (HIV)-infected people a higher incidence of HPV-related lesions are observed^[34]. These observations indicate that the adaptive immune response against the virus is important and for the most cases effective. This adaptive response comprises elements of humoral and cellular immunity^[21]. However, HPV has also evolved mechanisms both to avoid initial detection and to interfere with adaptive response that allow the virus to persist and lesions to progress into cancer.

Humoral response

The majority of patients with HPV infections present a humoral immune response that is detected by the presence of antibodies against different papillomavirus proteins such as L1, E2, and E4 proteins in the first stage of infection. At later times when viral DNA gets integrated into cellular genome, antibodies against E6 and E7 proteins can be detected in low- and high-grade lesions as well. However, this antibody response is usually weak and variable and it does not seem to protect from future re-

Figure 3 Cellular immune response against human papilloma virus. Dendritic cells (DC) can take human papilloma virus (HPV) antigens from the infected epithelium, and then migrate (black arrows) to lymph nodes. There, DC present the processed antigen together with MHC class I and class II molecules, to CD8+ T cells and CD4+ T cells, respectively. CD4+ T cells proliferate and differentiate (blue arrows) into T helper cells, either Th1 or Th2, depending on the type of cytokines they produce. CD8+ T cells differentiate (blue arrow), with help (green arrow) from Th1 cells, into cytotoxic T cells (CTL). Then, CTL migrate (black arrow) back to the infected epithelium to destroy virus-infected cells. CD4+ T cells can also differentiate (blue arrow) into regulatory T cells (Treg), which inhibit (red line) the cytotoxic activity of CTL.

infections^[35]. For high-risk HPVs, the seroconversion rate is about 50% within 18 mo of detecting the corresponding HPV DNA^[36], and important differences have been found in the proportion of seropositivity among HPV 16 DNA-positive individuals, depending on the site of the cancer around the ano-genital area, indicating that cancer development may lead to changes in antibody responses in a site-specific fashion^[37]. Thus, humoral responses are not efficient at eliminating established HPV lesions. In addition, antibody titers can persist for many years even after the virus is cleared, so seropositivity is a useful marker for past infection rather than current infection.

Cellular response

Cell-mediated immune responses are more important in clearing HPV-related lesions. HPV-specific CD4⁺ (helper) and CD8⁺ (cytotoxic) T cells are generated to fight and eliminate infected cells (Figure 3). Patients who successfully eliminated previous HPV 16 infections present memory T cell responses to viral proteins^[38], and in patients with spontaneous regression of grade 3 vulvar intraepithelial neoplasia strong CD4⁺ and CD8⁺ T cell responses are found^[32]. A high ratio of CD4⁺ to CD8⁺ T cells^[39,40] with a predominance of Th1 cytokines^[41,42] is also observed during regressing lesions. Thus both CD4⁺ and CD8⁺ T cells are important for elimination of HPV infection. In contrast, patients with cervical intraepithelial neoplasia or cervical cancer present deficient T cell responses^[39]. A low ratio of CD4⁺ to CD8⁺ T cells^[42,43] and a strong shift to Th2 cytokine profile^[44-46] are observed in persistent lesions. Also, responses that include HPV-specific Treg that inhibit cytotoxic activity^[38]. Thus, an efficient cytotoxic cell-mediated immune response is critical for elimination of HPV-related lesions. Unfortunately,

the virus has also evolved mechanisms to interfere with the immune response.

HPV mechanisms to evade the immune system

The best mechanism against the immune system is to avoid detection. HPV replication takes place in areas where immune surveillance is poor. In the stratified squamous epithelium of the uterine cervix, surveillance by DCs greatly declines towards the keratinized layers (Figures 2 and 3). In addition, the virus links its own replication with the differentiation state of the keratinocyte. At the beginning of the infection, in the keratinocytes of the basal layer, expression of viral genes is minimal. Expression of viral gene products up-regulates progressively with differentiation and upward migration of keratinocytes (Figure 2). In this way, HPV late proteins, which are the most immunogenic, are expressed at areas of poor immune surveillance (Figure 3). In addition, new virions are released through the normal rupture of surface epithelium, reducing any possible inflammatory response and avoiding uptake by DCs. Therefore, HPV replication is a local phenomenon with minimal activation of the immune system.

In addition of keeping a low profile during replication, HPV has other mechanisms that help the virus interfere with the immune response^[21]. The E6 and E7 proteins block IFN production by the infected cell. E6 inhibits the transcription factor IRF-3 that binds to the -IFN promoter, downregulating expression of interferon-responsive genes^[47]. E7 also inhibits the expression of -IFN responsive genes^[48,49]. In addition both E6 and E7 reduce the expression of TLR 9^[50], and cytokines, such as IL-8^[51], and IL-18^[52], which are pro-inflammatory molecules. The proteins E5, E6, and E7 downregulate the expression of MHC class I molecules, reducing recognition of the HPV-infected cell by NK cells and by specific CTLs^[53].

Moreover, a reduced inflammation state is found in persistent lesions and in tumors. This condition correlates with a change in the cytokine profile produced at the site of infection. A shift to Th2 cytokines is also common in persistent lesions^[45,54]. This leads to an inhibitory state for helper CD4⁺ T cells. In addition, Tregs have been found infiltrating tumors, especially in the early stage of tumor progression^[55]. Tregs are able to strongly inhibit activation of CD4⁺ T cells, cytokine production, and activation of CTLs^[56]. In patients with cervical cancer, larger numbers of Tregs and increased suppressive activity have been observed, both in the tumor and in draining lymph nodes^[57,58]. Presence of these Tregs associates with an increased risk for progression of premalignant lesions to cancer^[59]. Thus, when trying to activate the immune system special attention should be paid to the possible development of HPV-specific Tregs that may block the cytotoxic response needed to eliminate virus-infected cells^[60]. Indeed, it has been proposed that immunogenic tumors (those with abundant tumor-infiltrating lymphocytes) may display potent immunosuppressive potential^[61]

and should be treated with Tregs-depleting agents or with inhibitors of co-stimulatory molecules such as cytotoxic T-lymphocyte antigen-4 (CTLA-4) with the therapeutic monoclonal antibody ipilimumab^[62].

There is much information in the literature regarding cellular immune responses in patients with HPV infection, with cervical lesions, and with cervical cancer. These reports are beyond the limits of this review, but a general description of the cell responses from HPV infection to development of cancer is as follows. During the initial infection an inflammatory state favors activation of innate immune cells^[63,64] and secretion of cytokines that induce CD4⁺ T cell activation^[39]. As mentioned before in regressing lesions, both CD4⁺ and CD8⁺ T cells are found with a high ratio of CD4⁺ to CD8⁺ T cells, and also cytokines of the Th1 type are produced^[42,43]. However, when the CD4⁺ to CD8⁺ T cell ratio is low and a shift to Th2 type cytokines is observed a persistent infection is found in lesions^[45,46] and a progression to cervical cancer is more likely^[44,54,65]. Finally the presence of Tregs in lesions seems to increase the risk for progression of premalignant lesions to cancer^[59,66]. Thus, any therapeutic approach must be able to induce a strong HPV-specific immune cell response that involves CD4⁺, CD8⁺ cells, and Th1 type cytokines.

PREVENTION

In principle, if HPV infection could be prevented, HPV-associated cancers would disappear. Following this idea, HPV vaccines that could prevent infection were developed in the last decade. Taking advantage of the fact that capsid L1 proteins spontaneously assemble in virus-like particles (VLP) without viral DNA, it was possible to have the immunogenic L1 proteins in a non-infective form. Two pharmaceutical companies, Merck in the United States and Glaxo Smith Kline (GSK) in Europe, used VLP produced by overexpressing HPV L1 protein in yeast or insect cells, to create prophylactic vaccines. Gardasil® (Merck) is a quadrivalent vaccine against HPV types 6, 11, 16, and 18^[67], and Cervarix® (GSK) is a bivalent vaccine against types 16 and 18^[68]. Both vaccines have been approved and are commercially available. They induce an antibody response that prevents new infections with high efficacy against HPV 16 and 18 (Cervarix®)^[69,70] and HPV-6, 11, 16, and 18 (Gardasil®)^[71]. They promise, in the long-term (30-50 years) to reduce the incidence of disease associated with the vaccine HPV types^[72]. However, this type of protection could only be achieved with a large vaccination coverage (larger than 50%) of uninfected people, which are boys and girls 10 years old, to predate the debut of sexual activity. Unfortunately, full vaccination coverage of large populations will not be easy in many parts of the world^[73], and a large unvaccinated population will remain at a high risk of HPV-related disease, and in need of treatment.

In addition, other factors indicate that current vaccines will not be useful to prevent all types of HPV-

related cancers. These vaccines target only HPV 16 and 18 and in the case of Gardasil® HPV 6 and 11. Despite some cross-reactivity^[69], these vaccines show a small prophylactic effect on many HPV subtypes not included in the vaccine^[74,75]. Also, the HPV subtype distribution in cervical cancer varies throughout the world^[76,77]. For example, in Japan less than 60% of cervical cancer cases are due to HPV 16 and 18^[24]. Thus, current vaccines cannot cover all oncogenic types even in a single population, and their general use in other parts of the world is questionable^[75]. To be completely effective, future vaccines would need to be multivalent for all described oncogenic HPV types. But these formulations will certainly be much more expensive than current vaccines. Despite government subsidies trying to achieve full vaccination coverage, weaknesses in current prophylactic vaccines dictate that even vaccinated females must continue cervical cancer screening^[78]. Clearly, large numbers of people remain at risk of developing HPV-related disease, and thus virus-specific therapies remain a priority.

CURRENT THERAPIES

HPV infections that are not cleared by the immune system usually persist in latent form as cells of the basal layer maintain low viral copy numbers indefinitely. Tissue damage or immunosuppression can then induce an active infection that depending on the HPV type, may progress to neoplasias. HPV infection of the ano-genital area produces two types of lesions: warts (condyloma acuminata) and squamous intraepithelial lesions. Condylomata are mostly related to low-risk HPV infections, and represent a low risk of malignant transformation. In contrast, squamous intraepithelial lesions are related to high-risk HPV infections. These malignant lesions display various degrees of histological abnormalities. For the cervix these lesions are classified as cervical intraepithelial neoplasia (CIN) 1, mild, CIN 2, moderate, and CIN 3, severe. A similar classification is used for vaginal intraepithelial neoplasia, vulvar (VIN), penis (PIN) and anus (AIN) intraepithelial neoplasias. All of these lesions can progress to invasive cancer. Treatment for CIN and similar lesions has predominantly involved ablative therapies which purpose is to eliminate the damaged HPV-infected tissue, leaving the healthy tissue of the cervix intact^[79]. Hysterectomy is not acceptable as primary therapy for high-grade CIN because most patients are women of reproductive age^[80]. Ablative therapies include cryotherapy, excision procedures (conization), laser therapy, and electrosurgery^[81].

Ablative therapies

Cryotherapy: Also known as cryosurgery, it is a surgical treatment to freeze and destroy abnormal tissue in the cervix. It is performed with a cryoprobe, which is a metal rod cold enough to freeze and eliminate the tissue. The procedure is more effective when the tissue is frozen for 3 min, allowed to thaw for about 5 min, and frozen again

Figure 4 Conization of human papilloma virus cervical intraepithelial neoplasia 3 lesions. Colposcopy of papillomavirus cervical intraepithelial neoplasia 3 lesions from a patient treated with conization. Photographs of cervix before (A) and immediately after conization (B).

for another 3 min. Cryotherapy is widely used because it is easy of use and can be performed at the doctor's office. In fact, in many countries it is the only option available outside surgical settings. So, it is important that diagnosis and visualization of lesions be accurate before the cryotherapy is performed, in order to avoid missing small or deep lesions. During colposcopy, vinegar (acetic acid) or iodine (Lugol's solution) are applied to vagina and cervix with a swab or cotton balls to see areas of abnormal tissue more clearly, prior to cryotherapy. In summary cryotherapy is used mainly when ectropion (cervical eversion), cervicitis, or an HPV infection is present. If low- and high-grade lesions are detected after histology, then conization is recommended.

Excision procedures: For larger lesions excision procedures are used. The most commonly procedures are the loop electrosurgical excision procedure (LEEP) and the cold knife cone biopsy (conization). These methods are relatively inexpensive (between United States \$ 500 and United States \$ 1000^[82]) and can be performed at the doctor's office (Dysplasia clinic) in an outpatient setting. LEEP uses a thin, low-voltage electrified wire loop to cut out abnormal tissue, which is either visible during colposcopy, or hidden in the cervical canal and not visible during colposcopy. Conization is an extensive form of cervical biopsy used to remove abnormal tissue. It is called a cone biopsy because a cone-shaped piece of

tissue is removed. Conization removes abnormal tissue, usually high in the cervical canal, and also some normal tissue around the damaged tissue, so that a perimeter of normal cells is left in the cervix. Usually conization is the standard treatment if invasive disease (CIN 1, CIN 2, and CIN 3 lesions) is suspected, because it can remove tissue deep in the endocervical canal and can avoid diathermy artifacts (Figure 4).

Laser therapy: In this type of surgery a highly focused beam of light is used to obliterate the damaged tissue. Commonly a carbon dioxide laser is used to create the light beam. The laser light destroys the tissue and cauterizes the wound at the same time, reducing bleeding and pain, and shortening the healing time.

Electrosurgery: Electrofulguration is a type of electro-surgery used to burn the cancerous tissue^[83]. It consists of applying a moderately damped alternating electrical current through an electrode that is held close to the tissue so that sparks hit and destroy the lesion.

Hysterectomy: In this surgery, complete removal of the uterus, and other reproductive organs, such as ovaries, fallopian tubes and surrounding structures, is performed. This radical procedure is done when initiation of invasive cancer in female patients is diagnosed.

The choice to use one treatment over another depends mainly on infrastructure and is usually made by the provider. All these ablative therapies are very effective in initial treatments where elimination of lesions can be as high as 80%. However, removal of damaged tissue, does not always guarantee elimination of viral DNA, and high rates of recurrence (up to 40%) are found^[20] even after several treatments^[84].

Non-surgical therapies

Non-surgical therapies that kill cells on contact are also used to eliminate HPV-infected lesions^[85]. Some of these alternative treatments can be self applied by the patient, and generally are the first line of treatment for genital warts^[86].

Trichloroacetic acid: Trichloroacetic acid is applied topically by the physician directly on warts. The acid action produces a chemical burn of the wart. This treatment is effective in clearing up to the 50% of lesions; it does not present systemic toxicity and can be used during pregnancy. However, it is associated with adverse effects such as ulceration, dermal scarring and secondary infections.

Podophyllotoxin: Podophyllotoxin is a non-alkaloid lignan extracted from the roots of *Podophyllum* species (e.g., *P. peltatum*-Mayapple)^[87]. This toxin is used as an initial treatment for genital warts. It is found as a gel (Condylox) or as a solution or cream (Wartec), that can be self-applied by the patient. The mechanism of action is not clear, but it may be related to the binding of lignans to micro-

tubule proteins, inducing cell cycle arrest at metaphase. Podophyllotoxin treatment can achieve 50% clearance, but recurrence rates are 25%-30%^[84]. Podophyllotoxin is contraindicated in pregnancy.

Imiquimod: Imiquimod is a low-molecular-weight imidazoquinoline compound that modulates the innate immune system. In the form of a patient-applied cream (Al-dara) it is used to treat genital warts. Reduction in genital warts was observed in 50% of patients that used the 5% cream for 12 wk, with only 19% recurrence^[88]. Imiquimod was also reported to have certain therapeutic effects on basal cell carcinoma^[89], vaginal^[90], vulvar^[91], and anal intraepithelial neoplasia^[92], but the drug is not licensed for these treatments. Imiquimod has important inflammatory side effects, including itching, erythema, burning, irritation, tenderness, ulceration, and pain, thus its use on mucosal tissue is limited^[93].

The mechanism of action of Imiquimod is not completely clear, but it is known that Imiquimod is an agonist for TLR 7, commonly involved in pathogen recognition^[94]. Imiquimod binding to TLR 7 activates immune cells such as dendritic cells, macrophages, and keratinocytes to produce γ -IFN^[95] and other pro-inflammatory cytokines, such as IL-6 and TNF- α ^[96,97]. There is also evidence that Imiquimod, when applied to skin, can activate antigen presenting cells, which then migrate to local lymph nodes to induce an adaptive immune response^[95]. Because Imiquimod induces IFN production, it should be used with caution on intra-epithelial lesions infected with high-risk HPV types. Both α -IFN and β -IFN inhibit cell growth of keratinocytes with episomal HPV DNA, leading to virus elimination. However, IFNs do not affect cell growth of cells containing integrated HPV DNA. The result is that it selects for keratinocytes with integrated HPV DNA^[98,99]. The continued use of Imiquimod may then select for transformed cells with integrated HPV, and induce progression to high-grade intra-epithelial neoplasia.

Polyphenon: Polyphenon is a high-grade extract of green tea leaves from *Camellia sinensis*, manufactured by the Mitsui Norin Co., Ltd. of Japan. In the form of a topical ointment it can be self applied by the patient for treatment of genital warts. It has shown efficacy (54%) to reduce warts in treated patients with fewer recurrences^[100]. The main component in polyphenol is the catechin (a plant natural phenol belonging to the flavonoids family) (-) Epigallocatechin gallate (EGCG). EGCG is a potent antioxidant that reduces nitric oxide production by inhibiting inducible nitric oxide synthase *via* inactivation of the transcription factor nuclear factor-B (NF-B)^[101,102]. EGCG has also been shown to induce inhibition of growth and apoptosis^[103].

Cidofovir: Cidofovir is an acyclic nucleoside phosphonate analog to cytidine. It is used for the treatment of cytomegalovirus infections^[104], and it is also used off-license

as a topical treatment against benign low-risk HPV infections^[105]. Cidofovir is phosphorylated in the cell and then blocks incorporation of cytidine into viral DNA thus arresting virus replication. Small trials with CIN patients have shown promising efficacy^[106], but safety issues are a concern^[107].

NOVEL IMMUNOTHERAPIES

Prophylactic vaccination as discussed above, concentrates on preventing virus infection of epithelial cells, by generating a humoral immune response with antibodies that recognize viral capsid proteins and neutralize the virus. However, this approach is not effective for treating existing infections or established HPV-related diseases. Thus, a high prevalence and mortality of cervical cancer continues around the world, especially in developing countries. An effective therapy for established disease should stimulate a cellular immune response, with activation of both CD4⁺ (helper) and CD8⁺ (cytotoxic) T cells, which can recognize and eliminate virus infected cells^[108]. Cytotoxic cells need to recognize a viral antigen expressed in the infected cells. Several of the HPV proteins are potential targets to induce a good immune cytotoxic response. Capsid proteins L1 and L2 are poor antigens for a therapeutic vaccine, since these proteins are expressed mainly in terminally differentiated keratinocytes and in advanced-stage infections of cervical tissue low levels of these protein are detected (Figure 2). In contrast, HPV early proteins, such as E1, E2, E6, and E7, are expressed in multiple stages of the virus infection, and in HPV-associated cancers the E6 and E7 proteins are constitutively expressed (Figure 2). Thus, these proteins are all good antigenic targets for a therapeutic vaccine.

E2 is a DNA-binding protein involved in activation or repression of different HPV promoters^[109], and it also has a relevant role in controlling migration of viral DNA to daughter cells during mitosis of infected cells^[110]. Due to its importance in the whole virus replication cycle, E2 protein expression is maintained throughout most stages of infection (Figure 2) and thus, it becomes an excellent target for stimulating the immune system to eliminate infected cells independently of the stage of pathogenesis. Based on this, earlier studies using dogs immunized against papilloma E1 and E2 proteins, found that dogs were protected from papilloma growth after viral challenge, or had complete regression of papilloma after post challenge immunization^[111,112]. These results in animal models led to the design of new vaccines intended to induce a cellular immune response to the E2 protein. In clinical trials very encouraging results have been obtained with this approach (see next section)^[113,114].

The oncogenic HPV E6 and E7 proteins are essential for progression to, and maintenance of, the malignant phenotype. Therefore, these two proteins are also possible antigenic targets for therapeutic vaccines. The high-risk HPV 16 and 18 E6 and E7 proteins have been selected predominantly for induction of a cellular response.

Table 1 Immune therapies for human papilloma virus-related lesions in clinical trials

Name	Target protein	Platform	Immune response/clinical efficacy	Ref.
Peptide-based				
HPV16-SLP	E7 E6, E7	Synthetic peptides restricted to HLA-A2 Synthetic overlapping long peptides	T helper cell response, but no CTL response HPV-specific T cell response. Neither tumor regression nor prevention of progressive disease	[118,152] [120-122]
Protein-based L1VLPE7	E7	Chimeric L1-E7 VLP	Histological reduction to CIN 1 in 39% of treated patients compared to 35% of placebo recipients. This trend was not significant	[123]
SGN-00101 HPV16 E6/E7	E7 E6, E7	Fusion protein of M. bovis Hsp and HPV 16 E7 Fusion protein of HPV 16 E6 and E7 proteins administered with the adjuvant ISCOMATRIX	Complete regression in 35% of patients with CIN 3 Demonstrated important CD8+ T cell responses	[125,126] [128]
TA-CIN	E6, E7, L2	Recombinant fusion protein consisting of E6, E7, and L2 from HPV	Imiquimod, for 8 wk, followed by 3 doses of TA-CIN induced complete regression in 32% of patients with VIN	[131]
DNA vaccine pConE6E7	E6, E7	DNA vaccine that encodes a HPV 16 or 18 consensus E6/E7 fusion gene	Cellular immune response against HPV E6 and E7 antigens and protection against HPV E6 and E7-expressing tumors	[133,134]
ZYC101a	E7	Microencapsulated DNA vaccine encoding E7-specific CTL epitopes	In younger patients a 70% reduction of lesions was detected	[135]
Amolimogene	E6, E7	A poly (lactide co-glycolide) encapsulated plasmid DNA encoding T cell epitopes from HPV 16 and 18	Increase in HPV-specific T cells to epitopes from HPV 16, 18, 6 and 11. No correlation between cellular immunity and clinical response	[136]
Sig-E7(detox)-HSP70	E7	Fusion protein between HPV 16 E7 and heat shock protein 70	Low frequency and weak HPV E7-specific T-cell responses with no correlation to clinical results	[137]
Recombinant virus TA-HPV	E6, E7	Vaccinia virus encoding modified HPV 16/18 E6 and E7 proteins	60% patients with high-grade VIN had partial reduction in lesion diameter, and an increase in lesion-infiltrating CD4+ and CD8+ T cells	[142,143]
TG4001	E6, E7	Vaccinia virus encoding modified HPV 16 E6 and E7 proteins, and the human IL-2	Ten patients (48%) with CIN 3 showed promising clinical responses at 6 mo, but no data on related immune response	[144]
MVA E2	E2	Vaccinia virus (MVA) encoding bovine papilloma virus (BPV) E2	19 out of 34 patients with high-grade CIN 3 lesions had complete regression. Specific cytotoxic activity against cancer cells correlated with clinical outcome	[113,114]
MVA-E1	E1	Vaccinia virus encoding the E1 sequence of HPV 16	MVA-E1 into C57BL/6 mice resulted in sustained HPV 16 E1-specific T cells with cytotoxic activity	[147]

HPV: Human papillomavirus; CTL: Cytotoxic T lymphocytes; VLP: Virus-like particles; VIN: Vulvar; CIN: Cervical intraepithelial neoplasia.

Immunization has been tried with different delivery systems in transplantable rodent tumor models^[115] and in some clinical trials. The types of therapeutic vaccines tested so far in clinical trials can be grouped into five categories: peptide-based, protein-based, DNA vaccination, viral vectors, and DC-based immunization (Table 1). These therapeutic approaches are described next.

Peptide-based vaccines

Peptides are easy to use, inexpensive, and safe, but they are in general weakly immunogenic and they need to be mixed with adjuvants to improve their recognition by the immune system. The design of peptides involves identification of what parts of the HPV antigen are immunogenic. Short peptides may miss the relevant epitope needed for stimulation of an efficient immune response. Thus, current preparations contain mixtures of peptides. In addition, the polymorphic nature of the MHC may result in some peptides not being presented because the

corresponding HLA molecule is missing in particular patients. Therefore, the peptide vaccine approach has also used restricted HLA-binding peptides. A potential problem with this strategy is that exogenously added peptides may load onto MHC class I molecules on cells other than antigen presenting cells, leading to tolerance instead of stimulation because non-APC lack co-stimulatory molecules^[116]. The best approach seems to be the use of long overlapping peptides, which appear to be processed and presented better than whole proteins by DC^[117].

A vaccine consisting of two synthetic HPV 16 E7 peptides (representing HLA-A*0201-restricted cytotoxic T lymphocyte epitopes) and one helper peptide (a pan-HLA-DR-binding T-helper epitope) emulsified in adjuvant was tried in a phase I - II clinical trial with cervical carcinoma patients. The peptide preparation was safe, and induced proliferative immune responses in 4 out of 15 patients. Unfortunately, no cytotoxic T lymphocyte responses against the HPV 16 E7 peptides were detect-

ed^[118]. In a different study, 20 patients with HPV 16-positive, high-grade vulvar intraepithelial neoplasia were immunized with a mix of long peptides from the HPV 16 viral oncoproteins E6 and E7 in incomplete Freund's adjuvant. Five patients had complete regression, and HPV 16 was not longer detected in four of them. These patients also presented an increased T cell response^[119].

Another peptide vaccine (HPV 16-SLP) consists of a mix of 9 HPV16 E6 and 4 HPV 16 E7 overlapping long peptides. This vaccine was used to immunize patients with resected HPV 16-positive cervical cancer. HPV 16-specific T-cell immune responses were found with a preference of CD4⁺ -IFN- γ -producing T cells. Interestingly, there was also proliferation of T cells with a CD4⁺, CD25⁺, Foxp3⁺ phenotype that is associated with Treg, suggesting that the response against HPV was not completely effective^[120]. In another study, this vaccine was given to women with high-grade cervical squamous intraepithelial lesions. Immunization induced increased HPV 16-specific T-cell immunity, but not infiltration of HPV 16-specific T cells into the lesions, nor HPV clearance at the time of LEEP excision^[121]. More recently, in a small trial including 20 patients with HPV 16-positive advanced or recurrent gynecological carcinoma, HPV 16-SLP was subcutaneously administered with Montanide ISA-51 adjuvant. A good HPV-specific T cell response was detected. However, no tumor regression nor prevention of progressive disease were found^[122].

Recombinant proteins

Another approach for HPV immunization is the use of complete or recombinant proteins. Recombinant proteins have the advantage of providing all potential epitopes of an antigen, after processing by APC; but they are also more difficult to produce than peptides. Despite their longer size, proteins present low immunogenicity and they need to be mixed with adjuvants. For this reason, the E6 and E7 protein vaccines are made of viral proteins fused to proteins with more immunogenicity such as capsid proteins or bacterial heat shock proteins (Hsp).

L1VLPE7: L1VLPE7 is made of chimeric VLPs consisting of a carboxyl-terminally truncated HPV 16 L1 protein fused to the amino-terminal part of the HPV 16 E7 protein. The recombinant fusion proteins self-assembles into VLPs. In a small placebo-controlled clinical trial with 39 HPV 16-infected CIN 2/3 patients, these chimeric VLPs were able to induce antibodies with high titers against HPV 16 L1 and low titers against HPV 16 E7. Also cellular immune responses against both proteins were detected. Unfortunately, only a small no significant trend for histological improvement to CIN 1 or normal was observed in 39% of the patients^[123].

Another similar vaccine made with a recombinant HPV 16 L1(Δ N26)-E7(Δ C38) protein, expressed in *E. coli* has been tested in a murine of cervical cancer. This chimeric protein also assembles into chimeric VLPs. Immunization with these chimeric VLPs induced neutralizing antibodies and triggered cell-mediated immune

responses^[124].

SGN-00101: SGN-00101 is a fusion protein consisting of a Hsp from *Mycobacterium bovis* and HPV 16 E7 protein. This protein was given to patients with CIN 3, *via* three monthly subcutaneous immunizations. In 22% of patients regression to CIN 1 was observed. However, it was unclear whether this response was due to natural regression rather than the treatment^[125]. In another study, SGN-00101 was given in four injections 3 wk apart to patients with high-grade CIN. With this protocol seven of 20 patients (35%) had a complete regression that correlated with immune response^[126]. This vaccine also showed a partial response in 60% HIV-infected men with anal intraepithelial neoplasia^[127].

HPV16 E6/E7: A fusion protein formed by HPV 16 E6 and E7 proteins was mixed with the adjuvant ISCOMATRIX and given to patients with CIN. A specific HPV 16 E6 and E7 immune response was detected with an important contribution of CD8⁺ CTL response in immunized individuals than in placebo recipients. Elimination of HPV 16 DNA from lesions was detected in some treated patients and placebo recipients, but it did not correlate to immune status of patients^[128].

TA-CIN: Tissue antigen-cervical intraepithelial neoplasia (TA-CIN) is a recombinant fusion protein consisting of E6, E7, and L2 from HPV 16 and HPV 18. This fusion protein was tested in 29 patients with ano-genital intraepithelial neoplasia. They received three intramuscular doses of TA-CIN at four weekly intervals. Several immune parameters indicated an HPV-specific response. However, there was not a correlation between induction of systemic immunity and clinical outcome^[129]. Another study examined immunization of patients with vulval intraepithelial neoplasia with TA-CIN followed by one dose of a recombinant vaccinia virus encoding HPV 16 and 18 E6/E7 (TA-HPV). Only six out of 29 patients presented partial regression, and CTL activity was found in only four patients. Due to the poor outcome, this protocol has been abandoned^[130]. More recently a different protocol with TA-CIN was examined in patients with vulval intraepithelial neoplasia. In a phase II clinical trial 19 patients were given a topical application of the immunomodulator, Imiquimod, for 8 wk, followed by 3 doses of TA-CIN at four-week intervals. Complete regression was observed in 32% (6 out of 19) patients at week 10, increasing to 58% (11 out of 19) at week 20. At this time, there was also a significant local infiltration of CD8⁺ and CD4⁺ T cells in lesions of responding patients. Interestingly, non-responders had an increase of Treg cells. It seems that the inflammatory state induced by Imiquimod enhances the immune response, but the therapeutic effect still depends on the individual immune response of patients^[131].

DNA-based vaccines

Another interesting approach for immunization against HPV early proteins has been the use of plasmid DNA that

codes for the corresponding viral proteins. It is known that plasmid DNA, when injected into the skin or muscle can induce immune responses to encoded antigens. The process is relatively inefficient, but new technological advancements such as improved physical methods of delivery can induce more-potent cellular and humoral responses^[132].

pConE6E7: A DNA vaccine that encodes a HPV 16 or 18 consensus E6/E7 fusion gene (pConE6E7) has been tested in mice and rhesus monkeys. Immunization induced a potent cellular immune response against HPV 18 E6 and E7 antigens^[133]. Moreover, prophylactic immunization with this vaccine also induced complete protection against HPV E6 and E7-expressing tumors. In the case of established HPV-tumors, the vaccine was able to delay the growth of tumors^[134].

ZYC101a: ZYC101a is a microencapsulated DNA vaccine. It consists of plasmid DNA encoding E7-specific CTL epitopes from HPV 16 and 18 embedded in biodegradable micro particles. In a placebo-controlled trial, patients with histologically confirmed CIN 2/3 neoplasia were treated with three intramuscular doses of ZYC101a. Forty three percent of patients presented regression, compared to 27% of patients receiving placebo, but the difference was not statistically significant. However, in a subset of younger patients (less than 25 years of age) a significant reduction of lesions was detected in treated patients (70%) *vs* patients receiving placebo (23%). Unfortunately, no correlation between cytotoxic activity and clinical outcome was detected^[135].

Amolimogene: Amolimogene is another encapsulated plasmid DNA proteins of HPV types 16 and 18. In a phase II trial of patients with HPV-associated high-grade CIN, 11 out of 21 patients had elevated CD8⁺ T cell responses to HPV 16 and/or 18 peptides, and seven of these patients also had increases to corresponding HPV 6 and/or 11 peptides. No correlation between cellular immunity and clinical response was reported^[136].

Sig-E7 (detox)-HSP70: Sig-E7(detox)-HSP70 is a DNA vaccine encoding a fusion protein between HPV 16 E7 protein and heat shock protein 70. This vaccine was evaluated in patients with HPV 16 positive CIN 2/3. Patients received three intramuscular immunizations with increasing doses of plasmid DNA. Low frequency and weak HPV E7-specific T-cell responses were detected after treatment. Regression of lesions was seen in only 3 out of 9 patients, but the difference was not significant. Thus, no correlation was found between immune response and clinical outcome^[137].

Recombinant virus

The therapeutic approaches described above have given interesting results at the level of *in vitro* or animal models. Clinical results are at best slightly better than those expected for spontaneous regression, and in many cases

no clear correlation between the immune response and the clinical outcome were found. Another approach that has shown better results for treatment of HPV-induced lesions is the use of recombinant viruses. With this method, the HPV early gene products can be delivered directly into the cells. All the immune system responses against viruses get activated and a much better presentation of antigens takes place leading to a stronger cellular immune response. The highly attenuated poxvirus strain modified vaccinia virus Ankara (MVA) has become the vector of choice for novel HPV therapeutic vaccines^[115]. MVA is a non-replicating derivative of the uniquely successful smallpox vaccine, thus its use in humans is completely safe. In addition MVA is genetically stable, easy to manufacture, and very immunogenic^[138,139], in part due to cross-presentation of dying vaccinia virus-infected cells by DC to CD8⁺ T cells^[140]. Several MVA vectors against various diseases are now being evaluated in phase I/II clinical trials^[141].

TA-HPV: TA-HPV is a vaccinia virus encoding modified versions of the E6 and E7 genes from HPV 16 and HPV 18. In a phase II trial of HPV 16-positive high-grade vulval intraepithelial neoplasia, patients were immunized intramuscularly with TA-HPV. Forty two percent of patients showed partial reduction in total lesion diameter at 24 wk. Although, there was no increase in cytotoxic activity against selected individual HLA class I-restricted HPV 16 E6/7 peptides^[142]. In another study, eight out of 13 patients with high-grade VIN presented a partial reduction in lesion diameter, and an increase in lesion-infiltrating CD4⁺ and CD8⁺ T cells, however no increase in cytotoxic activity was detected^[143].

TG4001: TG4001 is a recombinant vaccinia virus (MVA) encoding a modified sequence of HPV 16 E6 and E7 proteins, and the human IL-2 gene. In a clinical study, 21 patients with HPV 16-related CIN 2/3 received three weekly subcutaneous injections of TG4001. Ten patients (48%) showed promising clinical responses at six months after treatment, but the related immune response was not reported^[144].

MVA E2: MVA E2 is also a recombinant vaccinia virus (MVA) encoding bovine papilloma virus E2 protein^[145]. In a series of studies, MVA E2 was evaluated in patients who had established HPV-induced CIN lesions. In a phase I / II clinical trial, for CIN 1 to CIN 3 lesions, 36 women received the recombinant virus vaccine at a total of 10⁷ MVA E2 virus particles injected directly into the uterus once every week over a 6-wk period. Ninety four percent (34) of patients showed complete elimination of precancerous lesions after treatment. In the other two patients, precancerous lesions were reduced from grade CIN 3 to CIN 1. In addition, 50% of patients eliminated completely the HPV, and in the remaining 50% of patients, HPV DNA was only 10% of the original viral load^[113]. Later, in a phase II clinical trial for high-grade

Figure 5 Effects of vaccinia virus Ankara E2 on cervix and vulva. Colposcopy of papillomavirus-induced intraepithelial lesions from patients treated with the therapeutic recombinant vaccinia virus Ankara E2. Photographs of (A) cervix with a cervical intraepithelial neoplasia 3 lesion, and (B) vulva with a condyloma lesion, before and after treatment. MVA: Modified vaccinia virus Ankara.

lesions (CIN 2 and CIN 3), 19 out of 34 (56%) patients had a complete regression, while in 11 (32%) more patients the lesions were reduced by 90%-60%. Specific cytotoxic activity against cancer cells correlated with clinical outcome^[114]. More recently, in a phase III clinical trial, 1176 female patients with ano-genital intraepithelial lesions were injected directly into the uterus, vulva, or anus lesions with 10^7 MEL-1 (MVA E2) virus particles. One thousand and forty-five out of 1176 (89%) treated patients showed complete elimination of lesions, and generated a specific cytotoxic response against papilloma-transformed cells (Figure 5) (Rosales, R. Manuscript in preparation). Thus, local application of MEL-1 vaccine is an excellent therapy for stimulating the immune system and creating regression of HPV-induced intraepithelial lesions. In support to this conclusion, a recent report, using the murine model of cervical cancer with HPV 16 E6- and E7-expressing TC-1 tumor cells, indicated that another recombinant HPV vaccine (TA-HPV) increased its efficacy when it was administered directly into the tumor. An augment in E7-specific CD8⁺ T cells was found in the blood, together with a significant decrease in tumor size^[146].

MVA-E1: As described above, both HPV E1 and E2 proteins are expressed early in the HPV life cycle, and are necessary to maintain coordinated viral replication and gene expression during differentiation of keratinocytes

along the epithelium. Thus, E1 is also a good candidate target for immunotherapy. Recently a new recombinant vaccinia virus has been reported, MVA-E1. This new vaccine consists of the MVA vector encoding the E1 sequence of HPV 16. Multiple injections of MVA-E1 into C57BL/6 mice resulted in sustained HPV 16 E1-specific cellular immune response involving T cells with cytotoxic activity^[147].

DC-based vaccines

Another approach to develop a cellular therapeutic vaccine is the use of dendritic cells pulsed with HPV antigens. Autologous monocytes are differentiated into DCs *in vitro* and then loaded with recombinant HPV proteins. The cells are then administered back to the patient in order to stimulate a better cellular immune response. Previous studies used autologous DCs loaded with HPV 16 or HPV 18 E7 protein to induce *in vitro* a specific T cell response. In 18/20 T cell lines from healthy blood donors E7-specific T cells were detected^[148]. This approach was also evaluated in patients with cervical cancer. Autologous monocyte-derived DCs were pulsed with recombinant HPV 16 E7 or HPV 18 E7 oncoprotein and administered to 15 stage IV cervical cancer patients^[149]. Four out of 11 patients had T cell proliferative responses, and three out of 11 patients showed γ -IFN production by ELISpot assay. Treatment was well-tolerated with no side effects. Unfortunately, an objective clinical response

was not observed^[149]. In a different study, a pilot trial gave autologous DCs pulsed with HPV E7 to four cervical cancer patients. E7-specific γ -IFN secreting CD8⁺ T cells were detected in all patients after vaccination^[150]. Later, in a phase I trial, autologous DCs pulsed with HPV 16/18 E7 protein and keyhole limpet hemocyanin were injected five times subcutaneously at 21-d intervals into 10 cervical cancer patients. Eight out of 10 patients had elevated counts of E7-specific γ -IFN secreting CD8⁺ T cells. Contribution of this immune response to therapy could not be evaluated since all patients were treated by surgery^[151]. These results show that this approach may be useful in the future for some difficult advanced cervical cancer patients. Another autologous DC vaccine for prostate cancer treatment, Provenge® (first FDA-approved therapeutic cancer vaccine) has given good results with metastatic patients. Thus, a great interest for new DC vaccines exists. However, this kind of treatment is labor-intensive and expensive, and has to be performed individually for each patient.

CONCLUSION

HPV infections remain an important public health issue because they are associated to cervical carcinoma, the second most common cancer among women^[4]. Two approved prophylactic vaccines, promise in the long run a reduction in HPV-related cancer incidence. However, the fact that full vaccination coverage of large populations will no be easy in many parts of the world^[73], and that these vaccines target only HPV 16 and 18 (HPV types responsible for about 60% of all cervical cancers), a large population will remain at a high risk of HPV-related disease, and in need of treatment.

Treatment for CIN and similar lesions has predominantly involved ablative therapies which purpose is to eliminate the damaged HPV-infected tissue, leaving the healthy tissue of the cervix intact^[79]. Ablative therapies include cryotherapy, excision procedures, laser therapy, and electrosurgery^[81]. Unfortunately, these surgical procedures are only effective in the treatment of pre-cancerous lesions, since after surgery many recurrences appear due to new re-infections.

Novel HPV protein-expressing vaccines are being evaluated for their potential to stimulate the immune system and generate a cellular cytotoxic response against the HPV-infected tissue or tumor. These new therapeutic vaccines can be grouped into five categories: peptide-based, protein-based, DNA vaccination, viral vectors, and DC-based immunization. They have shown variable results, but the ones using recombinant virus have demonstrated significant clinical efficacy and systemic HPV-specific cytotoxic T cell responses, particularly when the recombinant vaccinia virus is administered directly to lesions. Thus, recombinant vaccinia therapies are today the best candidates for a successful treatment of HPV-induced cancers.

Abstract

Although a wide range of studies have addressed the relationship between estrogen receptor (ER) expression and prognosis in non-small cell lung cancer (NSCLC), that relationship remains controversial. This is in large part because there is no consensus on the rate of ER expression in NSCLC or on the intracellular distribution of ER expression. This suggests that establishing the relationship between ER expression and prognosis will require standardization of the antibodies used as well as the definition of a positive response. For example, it is supposed from previous studies that ERs in the cytoplasm and nucleus have different relationships to prognosis than ERs in the cytoplasm. Moreover, ER signaling in NSCLC is known to be affected by aromatase, progesterone receptor and epidermal growth factor receptor mutation. However, there has been little functional analysis these mutants and subtypes. This review will focus on what is known about the role of ERs in NSCLC and whether ER can be a useful prognostic marker or therapeutic target in NSCLC.

INTRODUCTION

The estrogen receptor (ER) is one of the main targets of breast cancer therapy, and hormone therapy is generally administered to ER-positive breast cancer patients. There are two known ER subtypes, α and β . ER- α is the conventional receptor and is a useful prognostic marker in breast cancer. On the other hand, ER- β is a recently identified ER subtype, widely expressed in various organs including mammary gland and uterus. ER has also been detected in lung cancer cells. The first report of ER expression in lung cancer appeared in 1982^[1]. At that time, ERs were detected using radioimmunoassays, and the detection rate was relatively low. The first use of immunohistochemical staining to detect the ER in lung cancer tissue was reported by Canver *et al*^[2] in 1994. Since then, several different anti-ER antibodies have been employed to detect the receptor, and it has become apparent that there are differences in the detection rates and localization of the antigen, depending upon which antibody is used or the definition of a positive result^[3-30]. Further-

more, Stabile *et al*^[31] demonstrated that both NSCLC and normal lung express ERs and show biological responses to estrogen. Consequently, the role of ER in lung cancer remains controversial.

It is now known that ER affects other signals, such as that mediated *via* epidermal growth factor receptor (EGFR)^[32]. Based on this finding, a clinical trial of the target plus hormone therapy is now ongoing^[33]. However, many questions remain unanswered. This is in part because the reasons for differences in the ER detection rate and the apparently different functions of ERs at different sites remain unclear. This review will focus on previous findings to assess the potential utility of ER as a prognostic factor and as the basis for novel therapeutic strategies for NSCLC, as well as the challenges that will need to be overcome in the future.

IMMUNOHISTOCHEMICAL DETECTION OF ER IN NSCLC

In breast cancer cells, the intracellular localization of ER- α is generally performed using clone 1D5 antibody, the epitope for which is in the N-terminus of ER- α . Using this antibody, ER- α is detected in the nucleus. Nuclear ER- α has also been detected using clone 6F11 antibody, which was raised against the full-length form of the receptor molecule^[7,8,15,17-20,25]. On the other hand, the rate of ER- α detection in NSCLC using clone 1D5 is very low, from 0%-7%^[5-8,10,17,19,23,25]. Moreover, ER- α is report-

edly located not only in the nucleus, but also in the cytoplasm and in the plasma membrane^[9,11-14,16,17,20-22,24]. Cytoplasmic and plasma membrane ER- α is mainly detected using clone HC-20 antibody, the epitope for which is in the C-terminus. The detection rate with this antibody is 70%-80%, much higher than with clone 1D5^[5-14,16,17,19-25]; indeed, we confirmed that ER- α detected using clone HC-20 is nearly always missed by clone 1D5. This suggests that ER- α detected by clone HC-20 may have an N-terminal deletion mutation that prevents its translocation to the nucleus^[9,31].

The reports published to date on the immunohistochemical detection of ER- α expression in NSCLC are listed in Table 1. It is noteworthy that the positivity rates vary depending on the definition of "positive" used and on the antibody. To establish ER- α as a prognostic marker in NSCLC, it will necessary to standardize the definition of "positive" based on the use of a particular antibody.

ER- β was first identified in 1996^[34], and the first report of ER- β expression in NSCLC was from Omoto *et al*^[6] in 2001. They observed that ER- β is expressed in lung carcinomas as well as in normal lung tissue. They also showed that adenocarcinomas expressed significantly more ER- β than squamous cell carcinomas. Unlike ER- α , strong expression of ER- β is observed in the cytoplasm as well as the nucleus of NSCLC cells. The reports published to date on immunohistochemical detection of ER- β expression in NSCLC are listed in Table 2. Three

antibody clones were mainly used in those studies. The epitopes for clones H-150 and 14C8 are in the N-terminus of ER-β, and their detection rates in the nucleus are 51%-74% and 42%-71%, respectively^[9,16-18,27,28]. The epitope for the third clone, PPG5/10, is in the C-terminus, and the detection rate in the nucleus is 61%-84%^[10,14,26,29]. In recent years, expression of ER-β in NSCLC has been the focus of study more frequently than ER-α, including immunohistochemical analysis of ER-β variants^[29]. However, further study will be needed to determine which ER-β variant has the most impact in NSCLC. In immunohistochemical study, it should be made clear which ER expression (*i.e.*, type or location) is more responsible for the NSCLC progression. In addition, it should be also evaluated which antibody is reliable for detecting ER as the biomarker for NSCLC therapy.

On the other hand, there were some new studies on RNA expression of ERs in NSCLC^[35,36]. Brueckl *et al*^[35] reported that ER-α high expression was of significant positive prognostic value and patients with ER-α high tumors did not have any benefit from adjuvant chemotherapy. Atmaca *et al*^[36] demonstrated that ER-α mRNA expression was an independent prognostic factor in metastatic NSCLC. These studies were interesting because of different approach from immunohistochemistry, however, there were small size and needed to be more studied in the future.

ER AS A PROGNOSTIC MARKER IN NSCLC

It is well known that ER-α expression is a useful prog-

nostic marker in breast cancer^[37,38]. In 2005, we first proposed that ERs could potentially serve as prognostic factors in NSCLC^[9]. In that study, we observed that cytoplasmic ER-α was predictive of a survival rate in NSCLC. The reports published to date on the relationship between ER expression and prognosis in NSCLC are listed in Table 3. Unlike in breast cancer, expression of ER-α in NSCLC cells is mainly observed in the cytoplasm, and its detection is associated with a poorer prognosis. Among those studies, only one reported that ER-α is predictive of a better prognosis in NSCLC^[25]. In that paper, unlike the others, ER-α was detected in the nucleus. Recently, Mauro *et al*^[20] reported that nuclear immunostaining for ER-α expression declines with age. However, it is unclear whether the age-related reduction in nuclear ER-α is associated with prognosis in NSCLC. The cytoplasmic ER-α in NSCLC is a variant type and may be associated with non-genomic signaling. However, it is still unclear whether or not cytoplasmic ER-α affects wild type nuclear ER-α. Thus, many questions remain unanswered about the role of ER-α in NSCLC.

In the time since we first reported that ER-β expression was an independent factor associated with a better prognosis of NSCLC^[9], there have been several other studies on the relation between ER-β and prognosis in NSCLC (Table 3). Most found that nuclear ER-β was predictive of a better prognosis in NSCLC. When nuclear ER-β is high in NSCLC, nuclear ER-α is low; *i.e.*, wild type ER-α is low. It is therefore thought that ER-β dominates estrogen signaling in NSCLC. On the contrary, a study by Stabile *et al*^[21] found that cytoplasmic ER-β is associated with a poorer prognosis. Interestingly, both ER-α and ER-β are associated with a poor prognosis in NSCLC when they are detected in the cytoplasm. This might be indicative of the non-genomic actions of ER variants.

Figure 1 Intracellular estrogen receptor and epidermal growth factor receptor signaling pathway in non-small cell lung cancer. **A:** Mechanisms of ER and EGFR signaling in NSCLC. E2 (17 β -estradiol)-bound ER acts in part as a transcription factor in the nucleus. Once the ER binds to the DNA in the estrogen response element of a gene, it generally recruits co-activator complexes to modulate gene transcription (genomic signal). In addition, E2-bound ER also acts in the cytoplasm (non-genomic signal) by interacting with downstream mediators of EGFR signaling, such as MAPK and PI3K/AKT. EGFR is a cell membrane receptor tyrosine kinase that transmits a signal when it binds EGF; **B:** Mechanisms of combination therapy for NSCLC. The estrogen antagonist fulv binds to ERs and blocks estrogen signaling. EGFR-TKIs, such as gefitinib or erlotinib, bind to mtEGFR and inhibit EGFR signaling. Both treatments block the interaction between ER and EGFR signaling. EGFR: Epidermal growth factor receptor; ER: Estrogen receptor; TKI: Tyrosine kinase inhibitor.

THE ROLE OF ER VARIANTS IN CANCER CELLS

The role of ER variants in cancer cells has attracted much interest^[39-43]. It now appears that the oncogenic potential of ER variants derives from their ability to suppress the action of the normal hormone receptor, thereby acting as a dominant negative oncogene, or from their ability to activate hormone-responsive genes in a hormone-independent manner^[44]. ER has two functional domains: AF-1, which associates with a hormone-independent signaling pathway, and AF-2, which associates with a hormone-dependent pathway. Consequently, the oncogenic activity of an ER variant likely depends on specific site of its mutation.

In breast cancer, ER variants are often co-expressed with the wild type receptor, which can affect disease sensitivity to hormone therapy^[40,42]. For example, expression of the variant ER- α 36 affects estrogen signaling and is associated with tamoxifen resistance in breast cancer^[45]. In addition, the localization of ER variants in breast cancer cells reportedly differs from that of wild type ER^[42,46].

There has been very little study of ER- α variants in NSCLC, although they appear to be present, given the observed antibody-dependent variation in the ER positivity rate and intracellular localization. There have also been reports that the ER- β 1, 2 and 5 variants have distinct distributions within NSCLC cells and distinct effects on prognosis^[29]. However, there has been no analysis of the relationship between wild type ER- β and its variants, or their influence on estrogen signaling.

INTERACTION OF ASSOCIATED FACTORS WITH ER IN NSCLC

EGFR is a receptor tyrosine kinase involved in path-

ways leading to DNA synthesis and cell proliferation^[47]. Evidence suggests that ER interacts with one or more of the downstream mediators of EGFR signaling in NSCLC^[32,48-51], and that mutation of EGFR makes it susceptible to EGFR-tyrosine kinase inhibitor (EGFR-TKI), and thus a therapeutic target^[52,53]. The scheme of the interaction of between ER and EGFR signaling in NSCLC is shown in Figure 1A. It is well known that cancers usually become resistant to EGFR-TKI^[54], which raises the possibility that this drug resistance is related to the interaction between the EGFR and ER signals. For example, Stabile *et al*^[32] showed that ER signaling is activated by EGFR-TKI in lung cancer cells, while EGFR signaling is activated by anti-estrogen drugs.

Other ER-related mediators include progesterone receptor (PR), androgen receptor (AR) and aromatase. The functional importance of PR and AR in NSCLC remains unknown because expression levels are very low. Aromatase catalyzes the synthesis of estrogen in adipose tissue, and is associated with endogenous estrogen expression in NSCLC^[15]. In addition, BRCA1 is a regulator of ER signaling in breast cancer^[55-57], and was also recently detected in NSCLC^[58-60]. Rosell *et al*^[61] suggested that expression of BRCA1 and an EGFR variant carrying a T790M mutation (known as the EGFR-TKI resistant gene) is predictive of outcome and could provide the basis for alternative individualized treatment to patients with NSCLC. Although it is not yet clear whether BRCA1 is associated with ER in NSCLC, such an association could be a critical determinant of ER signaling in NSCLC.

NOVEL THERAPEUTIC STRATEGIES TARGETING ER AND EGFR IN NSCLC

Clinical trials of lung cancer treatments targeting ER and EGFR are currently ongoing^[62]. In these trials, fulvestrant,

an ER antagonist, is used in nearly all tests. Fulvestrant acts on ER, blocking its signal, irrespective of whether the receptor is localized in the nucleus, cytoplasm or cell membrane (Figure 1B)^[63]. It is therefore thought that fulvestrant would be effective, even in tamoxifen-resistant breast cancers^[64]. However, fulvestrant is a selective ER- α antagonist, and in one report fulvestrant acted to stabilize, and thus enhance, ER- β signaling^[63]. In NSCLC, extranuclear ER- α is a variant type thought to be involved in non-genomic signaling^[31], whereas ER- β is localized in the nucleus, where it exerts genomic effects and associates with a better prognosis^[9-11,14,18,20]. It is possible that the genomic signal mediated by ER- β is enhanced by fulvestrant's blocking of the non-genomic signal of the ER- α variant. Further studies will be needed to resolve the mechanism underlying the therapeutic effects by fulvestrant in NSCLC.

Erlotinib and gefitinib are two tyrosine kinase inhibitors used in the treatment of lung cancer. Erlotinib is used far more to target EGFR and, notably, the effects of both these medications may vary depending upon the race and/or gender of the patient. The intratumoral concentration of gefitinib reaches levels 40 times higher than that in blood^[65]. In other words, gefitinib is well distributed to the target tissue. By contrast, intratumoral concentrations of erlotinib are generally lower than its blood concentration^[65,66]. Nonetheless, erlotinib's IC50 for EGFR is more than 10 times lower than that of gefitinib^[67]. That is, the effective anti-EGFR dose of erlotinib is substantially lower than that of gefitinib. Clinical findings show that both drugs produce an effective response against mutant EGFR, but are less effective against wild type EGFR. To establish a combination therapy targeting both ER and EGFR signaling, development of an antagonist effective against wild type EGFR will be necessary. For example, if the intratumoral concentration of erlotinib could be increased without raising its blood concentration, it may be possible to enhance its antitumor effects without worsening its side effects. With that aim, the use of erlotinib with the angiogenesis inhibitor bevacizumab is being considered^[68]. In addition, because EGFR forms a heterodimer with HER-2, the use of the HER-2 inhibitor trastuzumab may be an effective approach to treatment. It may also be useful to consider the interaction of EGFR and/or ER with the ALK fusion protein, which is expressed exclusively with the variant receptors.

CONCLUSION

The role of ER in NSCLC is gradually becoming clearer. However, ER is involved in a complicated network through its interaction with a variety of mediators. In conventional immunohistochemical studies, wild type ER and its variants are handled similarly, but this may not be the best approach to future development of new strategies for treating NSCLC. Instead, it will be important to establish novel treatments based on the specific ER types

dominant in the particular lung cancer being treated, and to select the most effective drugs in that context.

common side effects were diarrhea, stomatitis, fatigue, hypertension, weight loss, loss of appetite, abdominal pain, and headache. As the use of Ziv has become more widespread in oncology practices, familiarity with the toxicity profile of the drug and the use of practice guidelines for their treatment has become increasingly important. This review will address the toxicities noted in trials using Ziv for the treatment of mCRC, and will provide recommendations for toxicity management.

Key words: Ziv-aflibercept; Colon cancer; Metastatic; Bleeding; Hypertension

Core tip: Ziv is an anti-angiogenic agent which has shown survival benefit in colorectal cancer. Side effects of this drug include hypertension, bleeding, perforation and delayed wound healing among others. In this paper, we review the side effects of Ziv and discuss how to manage those toxicities.

Abstract

Ziv-aflibercept (Zaltrap, Ziv) is a humanized fusion protein constructed by joining the vascular endothelial growth factor (VEGF) binding portions of human VEGF receptors 1 and 2 to the Fc portion of human immunoglobulin IgG1. Recently, a randomized, open-label, phase III study compared 5-fluorouracil, leucovorin, irinotecan (FOLFIRI)/Ziv with FOLFIRI/placebo in patients who had been previously treated with oxaliplatin based chemotherapy for metastatic colon cancer (mCRC). Patients who had received prior bevacizumab therapy were also eligible. This study showed that the addition of Ziv improved overall survival with median survival time of 13.5 mo *vs* 12.06 mo in ziv *vs* placebo arm. Ziv also improved progression free survival from 4.67 mo to 6.9 mo with a response rate of 19.8% in the Ziv/FOLFIRI group *vs* 11.1% in FOLFIRI alone group. This led to the approval of Ziv in combination with FOLFIRI in metastatic colon cancer patients treated with prior oxaliplatin regimens. The most

INTRODUCTION

Angiogenesis is critical for tumor proliferation and metastasis for several malignant tumors^[1]. Vascular endothelial growth factor (VEGF) is a homodimeric protein that binds to and activates receptors VEGFR1 and VEGFR2, located on the vascular endothelium^[2]. This leads in stimulation of downstream signaling leading to inhibition of apoptosis, stimulation of mitosis and cytoskeletal changes associated with motility^[3]. The family of VEGF

proteins binds to several different VEGFRs with distinct binding and signaling properties. VEGFR-1, VEGFR-2, and VEGFR-3 have similar structural features and form homodimers upon ligand binding. VEGFR-1 interacts with placental growth factor (PlGF), VEGF-B, and VEGF-A. VEGF has a higher affinity for VEGFR1, but VEGFR1 has relatively weaker tyrosine kinase activity. VEGFR-2 can interact with the processed forms of VEGF-C and D in addition to VEGF. This receptor is the major mediator of the mitogenic and angiogenic effects of VEGF. VEGFR-3 only interacts with VEGF-C and D and is involved in lymphangiogenesis^[2,4,5].

VEGF is an important regulator of angiogenesis and is principally stimulated by hypoxia. VEGF is over-expressed in several malignancies including gastro-intestinal tumors. Over expression has been associated with increased tumor vascularity, proliferation, progression, invasion, and metastasis^[6,7]. VEGF inhibition represents a promising venue for an anticancer approach. Furthermore, VEGF levels are elevated in patients with metastatic colorectal cancer, suggesting that VEGF induced vascular permeability could contribute to the formation of malignant ascites^[8]. VEGF antagonists have also been shown to increase the intratumoral delivery of cytotoxic chemotherapeutic agents thereby improving their anti-tumor efficacy without increasing toxicity^[9]. Previously, bevacizumab had shown promising results in patients with untreated metastatic colorectal cancer (mCRC). Hurwitz *et al.* showed the benefit of adding bevacizumab to standard chemotherapy in this first phase III trial of mCRC^[10].

Ziv-Aflibercept (Ziv) is a novel antiangiogenic agent which is a fusion protein consisting of human VEGF receptor extracellular domains fused to the Fc portion of human immunoglobulin G1 (IgG₁). It contains sequences encoding IGg domain 2 from VEGFR1 fused to Ig domain 3 from VEGFR2, which in turn is fused to the hinge region of the human IgG₁ Fc domain. Ziv complexes with VEGF in the blood and extravascular space and prevents VEGF from interacting with its receptors on endothelial cells. The VEGF trap binds with high affinity to soluble VEGF but also binds to the proangiogenic factors VEGF-B and PlGF 1 and 2. The combination of these actions may lead to the increased activity of Ziv as an antiangiogenic agent.

CLINICAL EFFICACY OF ZIV-AFLIBERCEPT

A phase I, dose escalation study of Ziv in combination with infusional fluorouracil, leucovorin and oxaliplatin, (FOLFOX4) was studied in 32 patients with advanced solid tumors^[11]. The types of cancer of these 32 patients were as follows: 8 pancreatic, 3 cholangiocarcinoma, 3 gastric, 5 breast, 4 ovarian and 7 other malignancies. In this study, 5 partial responses were noted in the pancreatic, cholangiocarcinoma and colorectal cancers while 10 patients had stable disease. Given the study results, Ziv 4

mg/kg combined with FOLFOX4 was selected for further investigations.

Another Japanese phase I study assessed the use of Ziv with infusional fluorouracil, leucovorin, and irinotecan (FOLFIRI) in metastatic colorectal cancer^[12]. Ziv, at two dose levels, was administered in combination with FOLFIRI in 16 patients who had received prior chemotherapy and the combination was found to be well tolerated. A phase III, randomized study published recently evaluated Ziv in combination with FOLFIRI in metastatic colorectal cancer patients^[13]. Six hundred and twelve patients were randomized to Ziv or placebo in combination with FOLFIRI with the primary endpoint of overall survival (OS). This study showed that the addition of Ziv to FOLFIRI significantly improved OS and progression free survival as compared to placebo. Response rates were also better in the Ziv group with the main side effects being anti-VEGF related effects.

ZIV-AFLIBERCEPT RELATED TOXICITIES

In the phase III trial of Ziv in colorectal cancer, grade 3 and 4 toxicities were increased in the Ziv arm as compared to the control arm. These included bleeding (2.9% *vs* 1.7%), arterial thromboembolic events (1.8% *vs* 0.5%) and venous thrombotic events (7.9% *vs* 6.3%) (Table 1). Grade 3 hypertension was seen in 19.1% of patients receiving Ziv *vs* 1.5% of patients in the control arm. Grade 4 hypertension was seen in only 1 patient (0.2%) in the Ziv arm. There was no difference in the development of gastrointestinal (GI) fistulae, other fistulae, or GI perforation between the groups. Acute infusion related reactions, grade 3 or 4, were no different and were reported to be 0.5% in both arms. The development of grade 3 or 4 proteinuria was found in the 7.9% of patients in the Ziv arm as compared to 1.2% in control arm. Two of the patients with grade 3 or 4 proteinuria in the Ziv arm developed nephrotic syndrome.

The incidence of chemotherapy related toxicities was also found to be increased with the addition of Ziv. The toxicities included diarrhea (19.3% *vs* 7.8%), asthenia (16.9% *vs* 10.6%), stomatitis and ulceration (13.7% *vs* 5%), infections (12.3% *vs* 6.9%) and palmar plantar erythrodysesthesias (2.8% *vs* 0.5%). Hematologic toxicity was seen more commonly with this agent. Grade 3 or 4 neutropenia occurring in 36.7% of the patients in Ziv arm *vs* 29.5% in the control arm; complicated neutropenia also occurred more frequently in the Ziv arm (0.7% *vs* 2.8%). Thrombocytopenia was also seen more commonly in Ziv arm (3.3% *vs* 1.7%). Permanent discontinuation of chemotherapy due to adverse events was also seen more commonly in the Ziv arm (26.8% *vs* 12.1%). The toxicities most frequently leading to discontinuation of chemotherapy in the study *vs* control arm were asthenic conditions (3.8% *vs* 1.3%), infections (3.4% *vs* 1.7%), diarrhea (2.3% *vs* 0.7%) and hypertension (2.3% *vs* 0%) (Table 2).

Hypertension

Grade 3 hypertension (HTN), defined as hypertension re-

Table 1 Selected grade 3/4 adverse events (%) with FOLFIRI/ziv-aflibercept in VELOUR study

Adverse event	Grade 3 %	Grade 4 %
Fatigue	11.9	0.7
Asthenia	4.9	0.2
Proteinuria	7.5	0.3
Urinary tract infections	0.8	0.0
Neutropenia	23.1	13.6

quiring the addition or modification of antihypertensive agents, is one of the more common toxicities associated with Ziv treatment. HTN can occur at any time during the course of treatment. There have been no deaths due to HTN reported. In the phase I Japanese study, any grade level of HTN was noted in 8 of 13 patients (61.5%) in 4 mg/kg arm and grade 3/4 in 4 patients (30.8%)^[14]. In the phase II study of Ziv administered at 4 mg/kg, the most common treatment related adverse events were HTN, proteinuria, fatigue and headache^[15]. In another phase I study of Ziv in advanced solid tumors, HTN was observed in 38.3% of patients^[16]. HTN of any grade occurred in 0%, 14.3%, 16.7%, 14.3%, 57.1%, 75.0%, and 61.5% of patients at the increasing dose levels of 0.7, 1, 2, 3, 4, 5 and 7 mg/kg respectively, and hypertension of grades 3 to 4 occurred in 0%, 0%, 16.7%, 0%, 42.9%, 75.0%, and 46.2% of patients respectively. The median time to onset of HTN in this study was 3.5 d.

In the phase III trial by Van Cutsem *et al*^[13], HTN in Ziv/FOLFIRI treatment group for all grades, grade 3 and 4 was 41.4%, 19.1% and 0.2%, respectively. In the FOLFIRI/Placebo group, HTN of all grades and grade 3 was 10.7 and 1.5% respectively. There was no grade 4 HTN in the chemotherapy alone arm^[13].

The variation in rates of higher grade of HTN among all of these trials may be due to several factors, including the differing sample sizes across the studies, differing thresholds among practitioners to initiate anti-hypertensive therapy, or variations in patient population across studies. In general, though, most studies do indicate that Ziv increases the risk of developing HTN.

Proteinuria

The risk of developing proteinuria has been shown in the VEGF inhibition pathway as demonstrated with previous bevacizumab related therapies. In the phase I study of Ziv at 2 dose levels, proteinuria of grade 2 or lower was observed in 3 patients (23.1 %) receiving the 4 mg/kg dose^[14]. In the phase I dose escalation study of Ziv in advanced cancers, proteinuria was observed in 10.6% of patients at different dose levels, but none of them were grade 4^[16]. The median time of onset of proteinuria was 15 d in this study.

In the phase III study, the incidence of proteinuria seen in Ziv/FOLFIRI treatment group in all grades, grade 3 and 4 was 62.2%, 7.5% and 0.3%, respectively. Two patients developed nephrotic syndrome. In the FOLFIRI/Placebo group, proteinuria of all grades and grade 3 was 40.7% and 1.2% respectively. There was no

grade 4 proteinuria reported in the placebo arm. There was no correlation between proteinuria and HTN.

Gastrointestinal perforation

There was no GI perforation noted at different dose levels of Ziv in the phase I study by Lockhart *et al*^[16]. In the phase III trial by Van Cutsem, the incidence of all grades, grade 3 and 4 toxicities were 0.5, 0.2 and 0.3%, respectively in Ziv + FOLFIRI treatment group compared to 0.5, 0.2 and 0.2%, respectively, in placebo + FOLFIRI group. The incidence of grade 3 or 4 GI fistula, other fistulae or GI perforation was less than 2% in both treatment groups^[13]. In the phase II study of recurrent ovarian cancer with malignant ascites, Ziv *vs* placebo showed a higher rate of intestinal perforation (three patients) than placebo (one intestinal fistula)^[17].

Thromboembolism

In the phase I study by Lockhart, there were no reported thromboembolic events^[16]. In a phase I dose escalation study of 18 patients treated with Ziv, pemetrexed, and cisplatin, pulmonary embolism was observed in 11% and deep vein thrombosis was seen in 6% of the patients^[18]. In the recent Phase III study, arterial thromboembolic events were seen in 1.8% in the Ziv + FOLFIRI arm compared to 0.5% in the placebo + FOLFIRI arm. Venous thromboembolic events were seen in 7.9% of patients receiving Ziv + FOLFIRI compared to 6.3% receiving placebo + FOLFIRI^[13].

Hemorrhage

In the previous phase III trials of bevacizumab, there was no significant increase in the risk of bleeding with bevacizumab^[10]. In the phase III VELOUR trial of Ziv with FOLFIRI, 37.8% patients had any grade of hemorrhage, 2.8% patients had grade 3 and 0.2% of patients had grade 4 hemorrhage in Ziv arm^[13]. In the chemotherapy only arm, 19% patients had any grade of hemorrhage and 1.7% patients had grade 3 hemorrhage. There was no reported grade 4 hemorrhage. A higher incidence of grade 3 and 4 hemorrhages was observed in the Ziv group (2.9%) as compared to the placebo group (1.7%).

PATHOGENESIS OF TOXICITIES ASSOCIATED WITH ZIV

The exact of mechanism underlying the toxicities related to Ziv is not fully known at this time.

Hypertension

The effect of Ziv on the development of hypertension is not completely understood. The control of blood pressure is complicated and is related to the factors affecting cardiac output and/or total peripheral vascular resistance^[19]. One explanation for Ziv-associated hypertension may be due to its effects on VEGF inhibition. Under normal circumstances VEGF stimulates nitrous oxide release which in turn causes vasodilation. Inhibition

Table 2 General guidelines for Ziv-aflibercept dosing and schedule modification due to adverse events per CTCAE 4.0

Event	Action to be taken
Hypertension	
Grade 3	If not controlled with medication, discontinue Ziv
Grade 4	Discontinue Ziv
Proteinuria	
> 2 g protein/24 h	Hold Ziv until proteinuria improves to < 2 g of protein/ 24 h
	Discontinue Ziv in a patient with > 2 g proteinuria/24 h that does not resolve in 3 mo time after holding Ziv. Work-up for proteinuria such as renal biopsy should be considered
grade 4 proteinuria (nephrotic syndrome)	Discontinue Ziv treatment
Gastrointestinal perforation	
Gastrointestinal perforation or dehiscence	Discontinue Ziv
Thromboembolic events	
Grade 3 venous thromboembolic event	Hold Ziv treatment
or incidentally discovered pulmonary embolus first occurrence	If the planned duration of therapeutic-dose anticoagulant therapy is ≤ 2 wk, Ziv should be held until the period of therapeutic-dose anticoagulant therapy is over
	If the planned duration of therapeutic-dose anticoagulant therapy is > 2 wk, Ziv should be held for 2 wk and then may be resumed during the period of therapeutic-dose anticoagulant therapy as soon as all of the following criteria are met:
	The patient must be on a stable dose of anticoagulant and, if on warfarin, have an INR within the target range (usually between 2 and 3) prior to restarting study drug treatment
	The patient has no history of Grade 3 or 4 hemorrhagic events before starting Ziv
	The patient has no evidence of tumor invading or abutting major blood vessels on any prior CT scan
Any grade arterial thromboembolic event or symptomatic	Discontinue Ziv
Grade 4 venous thromboembolic event first occurrence	
Hemorrhage	
Grade 1 and 2	No dose modification
Grade 3 or 4 (first occurrence)	Discontinue study treatment

of VEGF may reduce the amount of nitrous oxide available in turn causing vasoconstriction^[20]. This vasoconstriction leads to increased peripheral vascular resistance resulting in hypertension^[21]. VEGF may also have effects on the renin-angiotensin system, which plays a part in the regulation of homeostasis and blood pressure^[20]. The exact mechanism of the VEGF and the angiotensin system interaction is not well known at this time.

Proteinuria

The pathogenesis of proteinuria may be related to the effects of VEGF on the renal glomerulus. VEGF inhibition induces downregulation of nephrin, sometimes leading to nephritic syndrome or glomerular thrombotic microangiopathy^[22]. In this MEDLINE review, authors found that mild proteinuria ranged from 21%-63% and severe proteinuria in up to 6.5% of renal cell carcinoma patients. In some cases, discontinuation of the anti-VEGF agent induced improvement of proteinuria, but in many cases proteinuria persisted. Thus urinary protein should be checked periodically in these patients and if patients develop proteinuria they should be referred to nephrologists.

Neutropenia

Grade 3-4 neutropenia occurred in 30% of patients in the FOLFIRI arm and 37% of patients in the FOLFIRI + Ziv arm. Complications of grade 3 neutropenia occurred in 1.7% of patients in chemotherapy alone group and 4.4% in Ziv group. Complications of grade 4 neutropenia were seen similarly in both groups.

Wound healing

VEGF is associated with wound healing and VEGF inhibitors can affect dermal-wound angiogenesis causing delayed wound healing.

Gastrointestinal perforation

The mechanism underlying GI perforation is not known. However, it seems to be multi-factorial. The role of GI pathology related to the tumor, such as carcinomatosis, cannot be excluded in addition to the inhibition of VEGF. To date, however, no baseline risk factors for GI perforation have been identified.

Thromboembolism

Malignancies cause a hypercoagulable state from the procoagulant activity of cancer cells associated with tissue factor and fibrin generation^[23]. Thrombosis associated with VEGF inhibition was initially thought to be mainly arterial, but recent data have also reported venous thrombosis^[24]. The pathogenesis of thrombosis could be related to VEGF's role in vascular integrity. VEGF inhibition is speculated to cause apoptosis of endothelial cells thus resulting in the exposure of subendothelial cells which initiate the coagulation cascade causing the thrombosis^[25].

Hemorrhage

The exact mechanism of abnormal hemorrhage from VEGF inhibition is complex and yet not fully understood. The bleeding risk could be from VEGF's effect on the vascular endothelium promoting endothelial cell survival and vasculature integrity. VEGF inhibition may

decrease the renewal capacity of damaged endothelial cells causing bleeding^[26].

MANAGEMENT OF TOXICITIES

Hypertension

Patients receiving Ziv should have baseline documentation of blood pressure and frequent monitoring. Blood pressure should be monitored done at least once every 2 wk while on treatment. It is optimal for the measurement to be done after the patient has been in a resting/seated position for more than 5 min. If the initial reading is ≥ 140 mmHg systolic and/or ≥ 90 mmHg diastolic then a repeat measurement should be taken for verification.

For Grade I hypertension, defined as an asymptomatic, transient (< 24 h) increase by > 20 mmHg (diastolic) or to $> 150/100$ mmHg in a patient previously within normal range, no intervention is indicated. For Grade 2 hypertension, defined as recurrent or persistent (> 24 h) or a symptomatic increase by > 20 mmHg (diastolic) or an increase to $> 150/100$ mmHg if previously within normal range, anti-hypertensive medications such as calcium channel blockers, beta blockers, and/or ACE inhibitors should be considered. One can consider temporary discontinuation of Ziv if the blood pressure is not controlled with anti-hypertensive medications and once hypertension is controlled to $< 150/100$ mmHg, patients may continue on Ziv. For persistent or symptomatic hypertension or Grade 3 hypertension the Ziv should be held. Once the blood pressure is controlled subsequent cycles of Ziv should resume at a dose of 2 mg/kg. This dose should not be re-escalated. If blood pressure cannot be controlled with anti-hypertensive medications then the Ziv should be permanently discontinued.

Although ACE inhibitors seem more logical as they can control HTN and may also decrease the amount of proteinuria, no data to determine the best anti-hypertensive agent is available. Moreover, caution should be taken when using diuretics as these patients on cytotoxic agents are at risk for diarrhea, dehydration and volume depletion. In the event of grade 4 hypertension or hypertensive crisis or encephalopathy, Ziv should be permanently discontinued.

Proteinuria

Patients should be evaluated for proteinuria prior to starting the treatment and monitored regularly throughout treatment. We recommend a baseline urinalysis (dipstick or microscopic) to assess for protein before initiating Ziv. If the degree of proteinuria is \leq grade 1, Ziv can be given. If proteinuria is \geq grade 2, urinary protein creatinine ratio should be obtained. If protein creatinine ratio is more than 1, a 24-h urine collection to quantify protein should be sent for further evaluation. In a patient with urine protein > 2 g/24 h, as recommended in the package insert, we recommend holding Ziv until proteinuria improves to < 2 g/24 h of protein. If the 24-h urine does not improve within 3 mo, we recommend discontinuing Ziv permanently.

If proteinuria recurs, Ziv should be held till it improves to < 2 g/24 h and consider reducing Ziv dose to 2 mg/kg (rule of 2). Some clinicians elect to continue Ziv therapy until protein levels exceed 3.0 to 3.5 g/24 h. As there is no definitive data at this point, the decision of when to stop Ziv therapy requires clinical judgment. In patients with Grade 4 proteinuria (nephrotic syndrome) or thrombotic microangiopathy, Ziv should be permanently discontinued.

Neutropenia

Complete blood count should be monitored at baseline and prior to each cycle of therapy. If the neutrophil count is less than $1.5 \times 10^9/L$, chemotherapy + Ziv should be delayed until the neutrophil counts recover above $1.5 \times 10^9/L$.

Wound healing complications

Patients who undergo any invasive procedure while receiving Ziv may encounter problems with wound healing as seen previously with other VEGF inhibitors. Thus, we recommend holding Ziv at least 4 wk prior to and after the elective surgery. Ziv should be held until the surgical wound is fully healed. For minor surgeries like tooth extraction, biopsy or port placement, Ziv should be held till the wound is healed. If the wound is not healing well, Ziv should be discontinued permanently. For emergent surgery, the patient, surgeon, and nursing staff should be aware of the possible risks due to Ziv. In general, clear communication of the risks of Ziv should be done with the surgeon.

Gastrointestinal perforations

In the phase III trial of Ziv in colorectal cancer, grade 3 GI perforation was same in the chemotherapy and chemotherapy with Ziv arms^[13]. Grade 4 GI perforation was seen in 0.2% of patients in the FOLIRI arm and 0.3% of patients in the Ziv arm. Since previous VEGF inhibitors, such as bevacizumab, have shown a possible increase in the risk of GI perforation, Ziv should be held for 1-2 mo after surgery and till the surgical wound is completely healed. Patients should be closely monitored for signs and symptoms of GI perforation.

The exact interval for holding Ziv is unknown; however its long elimination half-life of 6 d should be taken into account. For elective operations, Ziv should be discontinued at least 30-60 d prior to a scheduled surgery. Even though Ziv's half-life is shorter than bevacizumab, we recommend holding Ziv for at least 4 wk prior to or after the surgery until more data is available. In cases of emergent procedures, Ziv should be held and patients followed closely for complications. Once patients develop GI perforation, Ziv should be discontinued.

Thrombosis

In patients who develop grade 3 thromboses, Ziv should be held. If a patient has grade 4 thrombosis, Ziv should be discontinued. We recommend that patients with a se-

vere arterial thromboembolic event during Ziv treatment should discontinue treatment permanently. Many patients with a prior arterial thromboembolic event are routinely treated with low dose aspirin. These patients can continue with Ziv. The use of high dose aspirin cannot be recommended due to the lack of safety data. Warfarin treatment during Ziv therapy should be followed very closely with serial INRs. If the INR is therapeutic, Ziv can be resumed as long as there is no history of severe bleeding associated with Ziv.

Hemorrhage

In patients who experience grade 3 hemorrhage, in the absence of any coagulation disorder that could increase their risk of bleeding, Ziv should be held till the bleeding resolves. Patients with grade 3 hemorrhage on full-dose anticoagulation, Ziv should be discontinued. If the patient experiences a repeat grade 3 or a new grade 4 hemorrhagic event, Ziv should be permanently discontinued. Brain metastases were excluded from the clinical trials and the use of Ziv in these patients could not be recommended.

CONCLUSION

Ziv in combination with FOLFIRI has shown a survival benefit in colorectal cancer^[13]. Ziv has been shown to be associated with the following higher ($\geq 5\%$) grade 3-4 adverse events including neutropenia, diarrhea, hypertension, leucopenia, stomatitis, fatigue, proteinuria and asthenia. Hypertension and proteinuria can occur at any time during treatment, while the risk of GI perforation is increased within 60 d of starting Ziv treatment. While hypertension is the most common adverse event, it is usually managed with oral agents. Wound healing difficulties, while infrequent, are most common when major surgery occurs while the patients are being treated with Ziv. There is potential for GI perforation, and while it is a rare complication, care must be given to patients who require surgery before, during or after Ziv treatment.

This review is mainly focused on Ziv in the treatment (Table 3) of colorectal cancers. Ziv has been studied in other malignancies including lung cancer and with other combinations of chemotherapy. The nature and rate of toxicities was similar in trials with other malignancies. Overall, the risk of grade 3 or 4 hypertension, hemorrhage and thromboembolism with Ziv appears to be low across all studies. In the colorectal cancer studies, GI perforations, while a serious event, have been relatively infrequent. In other malignancies this toxicity may be more of a concern. While the mechanism underlying this increased incidence of GI perforation is unknown, it may be related to the fact that these patients had very advanced disease and many patients had undergone multiple debulking surgeries.

To date, the efficacy and toxicity of Ziv has primarily been evaluated in patients with advanced disease, and the side effects of long-term therapy with Ziv in patients

with less advanced tumors is still unclear. This paper summarizes the guidelines by taking the information from the published data and extrapolating from related drugs like bevacizumab which has similar mechanism of action. As the trial data matures, we will have more clarity on the safety of Ziv. As more data becomes available, specific guidelines for the management of Ziv-related toxicities will become more detailed as well. This will be vital as anti-angiogenic agents become a more integral part of the standard care of patients with colorectal and other malignancies. Overall, though, the clear benefits of anti-angiogenic therapy vastly outweigh the small risks in the majority of patients. The key to administering treatment safely will be through education of patients, nurses and other healthcare providers.

EXPERT OPINION

Ziv is a recombinant fusion protein consisting of VEGF-binding portions from extracellular domains of human VEGF receptors 1 and 2 fused to the Fc portion of the human IgG1 that is designed to inhibit VEGF, thus inhibiting angiogenesis. Ziv has shown to extend survival in previously treated colorectal cancer. Ziv has provided an increase in median overall survival (13.5 mo *vs* 12.06 mo, $P = 0.0032$) when combined with FOLFIRI *vs* FOLFIRI alone. Clinical benefit, as measured by overall survival, was observed across all patients. Significant improvements in response rate and duration of response in combination with FOLFIRI were also achieved. The overall response rate was also improved in Ziv arm compared to FOLFIRI. Based on these data, Ziv was approved in combination with FOLFIRI by the FDA for the treatment of metastatic CRC, and is currently undergoing vigorous exploration in clinical trials for the treatment of many solid tumors, including non-small cell lung cancer.

In trials, Ziv was combined with conventional chemotherapy making it difficult to identify which toxicities are unique to it. However, since the adverse effects of chemotherapy are well characterized it is reasonable to assume that any new or unexpected adverse effects can be attributed to Ziv. It does not appear that any overlapping hematologic or gastrointestinal adverse effects exist between Ziv and conventional chemotherapy. Common adverse events associated with Ziv include HTN, proteinuria, and epistaxis (mainly mild). More patients in the Ziv arm of these studies experienced at least one grade 3 or 4 toxicity compared with chemotherapy alone, primarily attributable to HTN. Other frequent adverse events associated with Ziv are bleeding episodes and thrombotic events. The manufacturer has issued a black box warning regarding the risk of gastrointestinal perforation, wound dehiscence, and fatal hemoptysis.

The overall rate of grade 3-4 hypertension related to Ziv was approximately 19%. HTN can occur at any time during the course of treatment. No deaths from HTN have been reported and $< 1\%$ of patients has discontinued therapy due to HTN. Blood pressure is typically

Table 3 Recommendations for Dose Modification and Treatment Delay for Zaltrap

Discontinue ZALTRAP for:	Severe hemorrhage Gastrointestinal perforation Compromised wound healing Fistula formation Hypertensive crisis or hypertensive encephalopathy Arterial thromboembolic events Nephrotic syndrome or thrombotic microangiopathy (TMA) Reversible posterior leukoencephalopathy syndrome (RPLS)
Temporarily suspend ZALTRAP:	At least 4 wk prior to elective surgery For recurrent or severe hypertension, until controlled. Upon resumption, permanently reduce the ZALTRAP dose to 2 mg per kg For proteinuria of 2 grams per 24 h. Resume when proteinuria is less than 2 grams per 24 h. For recurrent proteinuria, suspend ZALTRAP until proteinuria is less than 2 grams per 24 h and then permanently reduce the ZALTRAP dose to 2 mg per kg (RULE OF 2)

Table 4 Special Situations about Toxicities of Zaltrap

Geriatric Use	The effect of ZALTRAP on overall survival was similar in patients < 65 yr old and ≥ 65 yr old who received ZALTRAP/FOLFIRI. No dose adjustment of ZALTRAP is recommended for patients ≥ 65 yr of age.
Paediatric Use	The safety in paediatric patients has not been established.
Hepatic Impairment	No dedicated clinical studies have been conducted to evaluate the effect of hepatic impairment on the pharmacokinetics of ziv-aflibercept.
Renal Impairment	No dedicated clinical studies have been conducted to evaluate the effect of renal impairment on the pharmacokinetics of ziv-aflibercept.
Contraception and Nursing Mothers	Females and males of reproductive potential should use highly effective contraception during and up to a minimum of 3 mo after the last dose of treatment.
Overdose	No information on the safety of aflibercept given at doses exceeding 7 mg/kg every 2 wk or 9 mg/kg every 3 wk is present. No specific antidote to ZALTRAP overdose exists. Patients of Zaltrap overdose should be managed with supportive measures.
Infections	The Velour study showed an increased incidence of infections in patients receiving ZALTRAP/FOLFIRI (46%, all grades; 12%, Grade 3-4) than in patients receiving placebo/FOLFIRI (33%, all grades; 7%, Grade 3-4), including urinary tract infection, nasopharyngitis, upper respiratory tract infection, pneumonia, catheter site infection, and tooth infection. Be vigilant about recognizing them. Treat them according to general guidelines.

controlled with an antihypertensive agent(s). The most common bleeding events in clinical trials were grade 1 and 2 epistaxis, which were transient. More serious bleeding events include central nervous system hemorrhage, hemoptysis, and gastrointestinal hemorrhage.

Ziv was associated with 2.6% of arterial thromboembolic events (ATE) including transient ischemic attack, cerebrovascular accident and angina pectoris compared to 1.7% of patients treated with placebo/FOLFIRI. In Ziv patients, grade 3-4 ATE occurred in 1.8% compared to 0.7% in placebo arm. Risk factors for arterial thromboembolic events included a history of prior arterial thromboembolic events such as stroke or heart attack, and age of 65 years or older.

There is paucity of data on drug interaction with other medications. However, based on the available data it is recommended that Ziv be used cautiously with medications that can increase the risk of bleeding, such as non-steroidal anti-inflammatory drugs, aspirin, and warfarin. Caution should be observed with the use of Ziv when administered to patients with a history of HTN, thromboembolism, bleeding, or preexisting proteinuria, as these conditions may be exacerbated by Ziv.

In elderly patients (above or 65 years), there was slightly increased (5%) incidence of diarrhea, dizziness,

asthenia, weight decrease and dehydration as compared to younger patients. Overall survival was same in all these patients. There is no dose adjustment recommended for elderly. Its safety profile in children is unknown. Animal studies in rabbits have shown that Ziv causes fetal abnormalities. Although there is no data on the effects of Ziv on human fetal development (Table 4), its use during pregnancy is not recommended based on experimental data in animals.

Currently there are no specific dose recommendations for patients receiving Ziv who have preexisting renal or hepatic dysfunction. Consideration of withholding Ziv should also be done in patients with low platelet counts or who are at an increased risk of bleeding. The manufacturer recommends permanent discontinuation of Ziv in patients with serious bleeding, gastrointestinal perforation or wound dehiscence requiring medical intervention. Patients who develop moderate to severe proteinuria while on treatment with Ziv should have treatment held until resolution or proteinuria.

Ziv was shown to be of benefit in metastatic colorectal cancer, while increasing patient response rates and prolonging survival. Additional information is needed to identify other diseases and stages most likely to benefit from anti-angiogenic agents and the optimal sequences

and therapeutic combinations also should be studied.

Abstract

The morbidity and mortality attributable to heritable and sporadic carcinomas of the colon are substantial and affect children and adults alike. Despite current colonoscopy screening recommendations colorectal adenocarcinoma (CRC) still accounts for almost 140000 cancer cases yearly. Familial adenomatous polyposis (FAP) is a colon cancer predisposition due to alterations in the adenomatous polyposis coli gene, which is mutated in most CRC. Since the beginning of the genomic era next-generation sequencing analyses of CRC continue to improve our understanding of the genetics of tumorigenesis and promise to expand our ability to identify and treat this disease. Advances in genome sequence analysis have facilitated the molecular diagnosis of individuals with FAP, which enables initiation of appropriate monitoring and timely intervention. Genome sequencing also has potential clinical impact for individuals with sporadic forms of CRC, providing means for molecular diagnosis of CRC tumor type, data guiding selection of tumor targeted therapies, and pharmacogenomic profiles specifying patient specific drug tolerances. There is even a potential role for genomic sequencing in surveillance for recurrence, and early de-

tection, of CRC. We review strategies for diagnostic assessment and management of FAP and sporadic CRC in the current genomic era, with emphasis on the current, and potential for future, impact of genome sequencing on the clinical care of these conditions.

Core tip: The era of genomic sequencing is beginning to make significant impact on the diagnosis and management of sporadic and inherited colorectal adenocarcinoma (CRC) such as familial adenomatous polyposis. This review will discuss the current guidelines for diagnosis and management of CRC and how genomic sequencing is enabling earlier definitive diagnosis with associated intensive surveillance and preventative interventions, molecular tumor characterization directing tumor specific therapy, germline patient genome analysis which informs individual drug tolerance and efficacy, and is evolving to develop post-treatment surveillance, with the potential to ultimately decrease the current prevalence and mortality of CRC, sporadic and hereditary.

INTRODUCTION

The annual incidence in the United States of colorectal adenocarcinoma (CRC) is almost 140000^[1]. The morbidi-

ty and mortality attributable to heritable and sporadic carcinomas of the colon are substantial and affect children and adults alike, with CRC being the third highest cause of cancer mortality among men and women alike. The average individual lifetime risk in the United States of developing sporadic CRC is estimated at 5%, with average onset being over 50 years of age. CRC mortality can be mitigated by early detection and intervention, such as by polypectomy^[2-4]. Accordingly, recommendations have been established for surveillance colonoscopy screening, the goal being to detect and remove adenomatous polyps at an early and curable stage.

However, according to the Centers for Disease Control and Prevention, only about 59% of adults aged 50-75 years undergo recommended colonoscopy^[5]. Though early detected CRC can be successfully removed, CRC which remains undetected until an advanced stage with metastases remains incurable^[6]. The molecular etiology of CRC has been studied extensively, revealing that it develops from an accumulation of genomic mutations. CRC has been associated with mutations in various genes that are altered in other forms of cancer, such as *ATM* in leukemia and lymphoma, *PPP2R1B* in lung and breast carcinoma, and *MYC* in hepatocellular carcinoma^[7-11], among others. However, the genes more commonly found mutated in CRC include the *APC* (approximately 80%), *KRAS*, *SMAD4*, and *p53*, and the cell signaling pathways most commonly impacted by mutations in CRC include the WNT, RAS, TGF-beta, PI3K and P53 pathways^[7,12].

While CRC often occurs sporadically, germline mutations in a number of genes can cause syndromes which predispose to the development of CRC. The heritable CRC syndromes are broadly categorized as polyposis associated [including familial adenomatous polyposis (FAP), *MUTYH*-associated polyposis or MAP, Gardner and Turcot syndromes] and non-polyposis associated (including Lynch, Peutz-Jeghers and PTEN hamartoma tumor syndromes)^[13,14]. This review will focus on polyposis associated heritable CRC, and FAP in particular. Inherited mutations in *APC* cause FAP, which is a colon cancer predisposition syndrome of autosomal dominant inheritance affecting children as early as 9 years of age, with reports of carcinoma in the first decade of life.

Characteristic features of FAP include development of hundreds to thousands of adenomatous polyps beginning in early adolescence, with development of CRC in the absence of treatment. About 7% of patients develop CRC by age 21, about 95% by age 50. In all FAP patients colon cancer is inexorable in the absence of colectomy. Though the classic course of FAP results in CRC, it can also become complicated by non-colonic expressions, in particular gastric and duodenal polyps, and is associated with elevated risk for duodenal, stomach, pancreatic, thyroid, liver, and CNS cancer^[15]. While FAP is known to be initiated by a germline mutation of *APC*, studies have yet to establish whether CRC in FAP requires a similar accumulation of genetic alterations as has been observed in

sporadic CRC. Since the beginning of the genomic era^[16] at the completion of the Human Genome Project^[17], the growth in capacity and availability of genomic sequencing has made it possible to more clearly elucidate the molecular etiology of conditions such as FAP related CRC. Genomic sequencing facilitates the identification of individuals with FAP, enabling and guiding appropriate intervention and is augmenting the ability to characterize CRC tumors on a molecular scale, for selection of targeted therapies that can be personalized per patient tolerance.

FAP DIAGNOSIS

Initial presentation and evaluation

FAP is second most common inherited CRC, with prevalence estimated at 1:10000, and is caused by mutations in *APC*^[13]. Patients will often present with occult blood in the stool, as polyps develop on average by 16 years of age^[18]. The average age at identification of CRC in untreated individuals is 39^[13]. Clinical diagnosis of classic FAP is established when 100 or more colonic polyps are observed on colonoscopy, or less than 100 colonic polyps are observed in a patient with a family history of FAP^[15]. A related syndrome, attenuated FAP, associates with a lower polyp burden (average of 30) and later age at diagnosis of CRC, though it is also caused by *APC* gene mutations^[19]. Identification of a mutation in *APC* provides molecular confirmation of FAP. The American College of Medical Genetics and Genomics guidelines recommend complete *APC* gene analysis be considered in any individual with 100 or more colonic polyps, autosomal dominant inheritance and/or extra-colonic manifestations of FAP (*e.g.*, congenital hypertrophy of retinal pigment epithelium, desmoids, gastric fundic gland polyps, among others), when no prior family member has undergone testing^[20]. If a familial mutation is identified, targeted *APC* analysis can be performed^[21]. This testing provides clinical confirmation necessary to guide predictive counseling and enable assessment of family members at increased risk, as *APC* alterations are found in as high as 90% of families with classic FAP. Testing is also important when the patient's presentation is not completely typical for classic FAP, such as demonstrating a lower than expected polyp burden or later age at onset. In some cases, *APC* gene analysis will confirm a mutation consistent with attenuated FAP, though *APC* alterations in the attenuated form are only discovered in 10%-56% of cases^[22].

Of particular importance in patients presenting with polyps not clearly identifiable as classic FAP, attenuated FAP, Gardener syndrome, Turcot syndrome, *MUTYH* associated polyposis (MAP) or one of the nonpolyposis syndromes, are the gene panels made possible by genomic sequencing. Three of these multi-gene sequencing panels are currently offered by Clinical Laboratory Improvement Amendments (CLIA) certified labs in the United States. They are performed with patient blood derived genomic DNA *via* next-generation sequenc-

ing of the coding regions of up to 19 different genes for point mutations associated with various hereditary colon cancer syndromes, are complemented by duplication/deletion analysis of the genes using microarray comparative genomic hybridization or multiplex ligation-dependent probe amplification, and point mutations are confirmed *via* Sanger sequencing. The OncoGene Dx gene panel offered by GeneDx analyses a total of 18 genes (including *APC*, *ATM*, *AXIN2*, *BLM*, *BMPR1A*, *CDH1*, *CHEK2*, *EPCAM*, *MLH1*, *MSH2*, *MSH6*, *MUTYH*, *PMS2*, *PTEN*, *SMAD4*, *STK11*, *p53*, *XRCC2*) and requires about 4 wk to complete the assay for a new patient (<http://www.genedx.com/test-catalog/disorders/colorectal-cancer>)^[23]. Ambry Genetics' ColoNext gene panel assays 15 genes (including *APC*, *BMPR1A*, *CDH1*, *CHEK2*, *EPCAM*, *MLH1*, *MSH2*, *MSH6*, *MUTYH*, *PMS2*, *PTEN*, *SMAD4*, *STK11*, *p53*) with analysis turnaround time approximately 12-16 wk for new patients (<http://www.ambrygen.com/tests/colonext>)^[24]. The University of Washington Genetics Laboratory offers ColoSeq which sequences the coding regions of 19 genes (*APC*, *AKT1*, *BMPR1A*, *CDH1*, *EPCAM*, *GALNT12*, *GREM1*, *MLH1*, *MSH2*, *MSH6*, *MUTYH*, *PIK3CA*, *POLD1*, *POLE*, *PMS2*, *PTEN*, *SMAD4*, *STK11*, *p53*), the estimated time to complete assessment is 12 wk for a new patient (<http://tests.labmed.washington.edu/COLOSEQ>)^[25]. Other assays are certain to be introduced. Through these genomic testing panels, patients with an ambiguous presentation can be tested simultaneously for multiple hereditary colon cancer syndromes, decreasing the time to molecular diagnosis and appropriately tailored familial testing and clinical surveillance.

Familial genetic testing

For unaffected individuals in families with FAP, testing is not generally offered until about 10-12 years of age, which would be the recommended age to initiate surveillance colonoscopy in an affected individual^[21]. Furthermore, efforts are made to identify an affected family member for whom testing has already confirmed an *APC* mutation, to allow targeted testing in the unaffected individual. If testing is performed in an affected family member and no mutation is found, unaffected individuals must undergo clinical surveillance empirically "as if" they were mutation carriers, because their carrier status cannot be ruled out.

Nondiagnostic and variants of unknown significance challenges

Approximately 90% of *APC* alterations in FAP introduce a stop codon causing truncation of the resulting protein at the C-terminus, with over 900 different germline *APC* alterations having been discovered in FAP individuals to date^[26-29]. Though clinical genetic testing of the *APC* gene has a 90% mutation detection rate^[30], approximately 10% of classic FAP cases do not have an identifiable mutation in *APC*, requiring greater reliance on clinical presentation and empiric surveillance screening in all at risk indi-

viduals in these families^[21,31]. The growing awareness of genetic and genomic testing and its utility in diagnosing FAP has also lead to the observation of non-truncating *APC* mutations, including missense and silent mutations in the coding sequence and splice-site mutations in less conserved intronic sequence, some of which have been correlated with FAP^[29,32,33]. The relevance of these variants of unknown significance (VUS) in some cases can be suggested by *in silico* prediction algorithms, however *in vivo* or *in vitro* functional analyses of these VUS provide more reliable data to predict the functional impact of *APC* variants. For example, a silent alteration in exon 14 (c.1869G > T) was reported to cause exon skipping due to its impact on splice enhancer sites^[34]. Also the p.I1307K missense mutation in *APC*, though not causing classic FAP, carries a 10%-20% increased lifelong risk of CRC, but the p.E1317Q missense mutation in *APC* has an, as yet, uncertain role in colon cancer^[20]. Though a minority of patients suspected to have FAP are found to carry VUS, with the increasing availability of *APC* gene testing and broader testing such as whole exome sequencing, its expected the number of patients with *APC* VUS will grow. Multiple groups have worked to better characterize the biological and clinical significance of these VUS^[29,35]. For example, *in vitro* and *in vivo* methods of evaluating VUS in MAP are being developed, providing additional information to facilitate characterization of VUS in an effort to clarify the diagnosis of patients suspected to have MAP^[36,37]. Further functional evaluation of VUS for FAP, and other hereditary CRC, is a critical step, with the increasing application of genomic sequencing technologies, for improving diagnostic accuracy of *APC* sequencing for patients with features concerning for FAP.

FAP MANAGEMENT

Surveillance strategies

Individuals with a family history of FAP meet criteria for additional assessment for high-risk syndromes if they present with > 10 adenomas in the same individual, per the most recent NCCN guidelines^[38]. Management of FAP includes surveillance colonoscopy every 1-2 years, starting at about 10 years of age. After polyp development is observed, annual colonoscopy is recommended. Colectomy is considered when more than 20 adenomatous polyps develop, when adenomas greater than 1 cm are noted or when concerning histology appears, and is recommended when polyp burden precludes safe colonoscopic surveillance^[15]. After colectomy surveillance continues. Annual colonoscopy is recommended if any rectal tissue remains. Upper GI endoscopy is recommended about every 1-3 years, starting at about age 25, as about 20% of patients will eventually require treatment of duodenal adenomas^[15,39].

Some correlation between genotype and clinical presentation of classic FAP has been suggested, for example patients with alterations in codon 1309 tend to have an increased number of colon adenomas at an early age,

with symptom onset at about 20 years of age. Those with alterations between codons 168 and 1580 had symptom onset about 30 years of age, and those with alterations affecting the 5' of codon 168 and the 3' of codon 1580 had symptom onset about 52 years of age^[40,41]. Profuse polyposis has been observed (average of 5000 polyps) in patients with mutations in codons 1250-1464^[42]. In contrast, attenuated FAP has been associated with the 5' portion of *APC*^[43], exon 9^[43-45] and the distal 3' portion of the gene^[43,46-48], interstitial deletions of chromosome 5q22 including *APC*^[49], partial and whole gene deletions^[50] and somatic mosaicism for *APC* mutations usually associated with classic FAP^[51-53]. While these correlations might help predict the course of polyposis in an individual, and suggest more or less aggressive surveillance and intervention strategies, these genotypes are not routinely applied to this purpose at present, though such applications could be clinically significant for management decisions in the future^[13].

Treatment options

Certain pharmacological treatments have attempted to abrogate the accumulation of polyps in FAP patients, however surgical resection remains the mainstay of intervention. Chemoprevention strategies, including non-steroidal anti-inflammatory drugs such as celecoxib and sulindac, have been shown to temporarily decrease size or quantity of polyps in FAP patients, however polyps may return while patients are still taking chemopreventive therapy^[54]. Currently, no chemopreventative strategy can replace regular surveillance, though this treatment may, in some cases, temporarily delay colectomy^[54-56].

Lifelong risk for CRC in FAP individuals approaches 100% by 50 years of age. Because of the significant increase in cancer incidence about the third decade, prophylactic colectomy is often recommended in the second decade^[57]. Generally three surgical strategies are available to FAP patients, including total proctocolectomy with ileal pouch anal anastomosis, total abdominal colectomy with ileorectal anastomosis and proctocolectomy with ileostomy^[58]. Selection of a surgical strategy takes into consideration rectal polyp burden, personal and familial phenotype, with classic FAP patients receiving proctocolectomy, if possible, due to the increased risk for rectal cancer^[58]. After surgical resection, surveillance continues, including endoscopic evaluation of any remaining rectal tissue and endoscopy of the upper gastrointestinal tract, as patients remain at increased risk for tumor formation despite colectomy^[57].

Molecular etiology

FAP is caused by germline alterations in *APC*, a tumor suppressor acting in the WNT signaling cascade^[59]. De novo *APC* mutations cause about 25% of FAP cases^[15]. Studies in sporadic CRC show mutations in *APC* appear to instigate the development of CRC^[12]. These studies show that *APC* acts in the colon to down regulate Wnt signaling by targeting beta catenin for degradation^[59].

Wild-type APC protein is an important component of the composite that includes Axin, GSK-3beta and casein kinase 1^[59]. This molecular composite regulates the phosphorylation of beta catenin necessary to target it for degradation^[59]. When *APC* is altered, beta catenin increases, translocates to the nucleus, and is thought to coactivate TCF-LEF, which is involved in the transcriptional activation of cell regulatory genes such as c-myc and cyclin D1^[59]. The multi-hit hypothesis of CRC tumor development suggests mutation or dysregulation of a number of genes occurs in the evolution of colon cancer, with *APC* mutations being present earlier in the process and *KRAS*, *SMAD4* and *p53* alterations being observed in later stages of cancer development^[12,15,60]. As FAP patients carry one germline *APC* mutation from birth, it is possible that the accumulation of molecular changes leading to malignancy in FAP recapitulates, to some degree, the molecular cascade observed in sporadic CRC (Figure 1), however no comprehensive analysis of the molecular etiology of tumorigenesis in FAP has been reported. Future genomic analyses of FAP may contribute to the understanding of FAP tumorigenesis as well as improving interventional and preventative strategies.

CRC DIAGNOSIS

Screening techniques-stool based

The morbidity and mortality of CRC can be minimized *via* prompt detection and appropriate intervention, such as polypectomy. Screening guidelines have been established to monitor individuals based on their estimated risk of developing CRC. An individual is stratified into a risk category based on their age, personal history (adenoma, CRC or inflammatory bowel disease) and family history^[38]. For patients of average risk (lifetime risk of approximately 5%), both structural and fecal based screening tests are available. Fecal occult blood tests (FOBT), both guaiac-based and immunochemical, are designed to detect blood in fecal matter as evidence suggestive of possible CRC. These are recommended annually alone, or in combination with flexible sigmoidoscopy every 5 years.

Positive FOBT results should prompt assessment by colonoscopy^[38]. Stool DNA tests are an evolving screening option which detect the presence of known CRC related DNA alterations in tumors cells excreted in stool. Single target stool DNA tests appear to have low sensitivity^[61], with multi-target stool DNA tests (assessing 21 alterations in genes such as *APC*, *KRAS* and *p53*) detecting up to 52% of CRC with sensitivity ranging from 20%-94% in different trials^[62,63]. ColoSure is the only stool DNA test available in the United States^[64], nevertheless the FDA has yet to approve stool DNA analysis. While it is not presently acknowledged as a first line assessment tool, additional stool DNA assays are under development^[65]. Stool screening tests have the advantage of being non-invasive and not requiring bowel clearance, which can enhance patient adherence to screening rec-

ommendations.

Screening techniques-colonoscopy

Structural based screening tests include colonoscopy, flexible sigmoidoscopy and computed tomography (CT) colonography. CT colonography, also referred to as virtual colonoscopy has the advantage of being non-invasive and not requiring sedation^[38]. Flexible sigmoidoscopy also proceeds without sedation and requires decreased bowel preparation, however is limited to evaluating the distal portion of the colon. In both cases positive findings (lesions greater than 1 cm in the case of flexible sigmoidoscopy) require follow up evaluation by colonoscopy and polypectomy as indicated^[38,66]. Colonoscopy remains the most complete screening procedure, permitting visualization of the complete colonic tract and simultaneous polypectomy, and is the gold standard against which other screening methods are measured. Studies have shown colonoscopy to reduce by an estimated 50% the incidence of CRC, and an inverse correlation between colonoscopy use and death from CRC^[67-72]. A recent study also found colonoscopy and sigmoidoscopy to be associated with a lower mortality from CRC of the distal colon, and colonoscopy associated with decreased mortality from proximal CRC^[69]. Their observations support the ten year assessment interval endorsed by current recommendations for individuals of average risk with a negative colonoscopy, documenting 1164 cases of CRC in individuals without endoscopy compared with 209 cases of CRC in individuals from 3 to 15 years post negative colonoscopy^[73].

Screening guidelines

Patients 50 years of age and older, without personal history of polyps, CRC or inflammatory bowel disease and without family history of CRC or advanced adenomatous polyps, are considered at average risk^[38]. A positive family history should prompt consideration of a CRC predisposition syndrome. The preferred screening strat-

egy in these individuals is colonoscopy. If no polyps are found, repeat colonoscopy is recommended in 10 years. If polyps are identified, polypectomy is performed and repeat colonoscopy recommendations depend on polyp characteristics. Patients with hyperplastic, non-sessile serrated and less than 1 cm polyps should have follow up colonoscopy in 10 years if polyps are left-sided or 5 years if right-sided^[38]. Adenomas or sessile serrated polyps are considered low risk if there are no more than 2 tubular polyps less than 1 cm and require repeat colonoscopy in 5 years. Follow up colonoscopy in 3 years is recommended if 3 or more villous polyps are observed, diameter is 1 cm or larger, or they demonstrate high-grade dysplasia^[38]. If more than 10 polyps are observed, one of the polyposis syndromes should be considered^[38].

CRC MANAGEMENT

Tumor characterization and resection

Current intervention for CRC includes diagnosis, staging, resection, adjuvant chemotherapy, treatment of recurrent disease and ongoing surveillance. Diagnostic determination depends in part on histological assessment of the resected polyp. All adenomatous polyps have some degree of dysplasia, falling on a spectrum from low to high. No specific definition of "high grade" dysplasia has been established, but a number of histological features are assessed in an effort to grade the level of dysplasia, which can include loss of glandular differentiation, cellular and nuclear pleomorphism, nuclear hyperchromatism, loss of nuclear polarity, multi-layered irregular nuclei and loss of mucin, nuclear atypia with prominent nuclei and focal cribriform patterns^[74,75]. Polyps with favorable histologic features are graded 1 or 2; those with less favorable histology are assigned grades 3 or 4. Histological grade, features such as angiolymphatic invasion and positive or negative resection margin help guide clinical decisions regarding the need for additional surgical resection. A polyp is considered malignant if cancer is observed infiltrating through the muscularis mucosa into the submucosa, and is designated T1^[76]. As nearly one third of CRC in the United States is associated with family clustering, once histological diagnosis of CRC has been confirmed, an individual should be counseled regarding the increased risk of CRC in their first degree relatives^[77].

Complete staging of malignant tumors is facilitated by pre-operative colonoscopy and CT scans of chest, abdomen and pelvis, is ultimately accomplished during surgical resection, and is categorized according to the TNM (tumor/node/metastasis) system^[76,77]. Staging takes into consideration local invasion of the primary tumor, evidence of lymph node metastasis and evidence of metastasis to other organ sites or the peritoneum, and is considered one of the most important indicators of post treatment outcome^[6]. Generally, stage I and II are assigned to lower and higher grade tumors, respectively, without nodal metastasis, stage III tumors have lymph node metastasis and stage IV tumors have metastasis to

other organ sites or the peritoneum, with stages II, III and IV having additional subclassifications^[76,78]. Though 20% of CRC is metastatic at presentation, 80% is localized to the colon wall or lymph nodes and surgical resection can be curative for localized CRC, accordingly treatment for CRC is primarily surgical. For resectable colon cancer, colectomy with regional lymph removal is the preferred surgical strategy, with the extent of colectomy based in part on tumor location as well as family history of polyposis^[77].

Adjuvant therapy and surveillance

For stage I CRC, post resection adjuvant chemotherapy is not recommended, however various studies have shown a role for adjuvant therapy in more advanced CRC. Current recommendations are for patients with high-risk stage II and stage III CRC to receive 6 mo of adjuvant chemotherapy after primary surgical resection, and for patients with low-risk stage II CRC to be considered for adjuvant chemotherapy, enrolled in a clinical trial or observed without adjuvant therapy^[77,79]. The specific chemotherapeutic regimens have been reviewed recently in detail^[77,80]. These recommendations are derived from various studies which have shown survival benefit in patients with resected early stage CRC who received adjuvant chemotherapy, with most of the benefit being seen with stage III CRC, but not with node negative stage II disease, suggesting the benefit is increased in patients at higher risk related to nodal status^[81-83]. Chemotherapy also has a role in patients presenting with more advanced CRC, including stage IV metastatic CRC. In individuals diagnosed with unresectable or medically inoperable CRC, chemotherapy is recommended in an effort to convert the lesion to a resectable state, and can be used to convert unresectable metastases, such as those in the liver, to resectable lesions, with the particular chemotherapeutic agents having been recently reviewed^[77,84,85].

Posttreatment surveillance includes application of a variety of tools in an effort to discover any recurrence that is potentially curatively resectable. These tools include serial history and physical examination by a physician, CEA testing, colonoscopy and in some cases CT scans of the chest, abdomen and pelvis^[77]. The advantages of more intensive surveillance regimens for patients with stage II and III CRC have been shown^[86-88] and current recommendations for patients with successfully treated stage I-III CRC include history and physical examination every 3-6 mo for 2 years, CEA testing every 3-6 mo for 2 years and colonoscopy 3-6 mo post-resection (if not performed preoperatively)^[77]. Surveillance colonoscopy is repeated based on findings (3 years if normal and 1 year if concerning adenomatous polyp removed), with CEA, history and physical exam spaced to every 6 mo to complete the first 5 years of posttreatment surveillance^[77].

Patients with a history of CRC have a particularly high risk of another cancer within 2 years after resection, and recommended surveillance frequencies for the first 5

years post treatment vary with stage of CRC and patient characteristics such as age of onset and history of hereditary CRC^[80]. Chest, abdominal and pelvic CT scans are recommended yearly for 3-5 years for stage II-III CRC patients at high risk for recurrence and every 3-6 mo for 2 years spaced to every 6-12 mo for a total of 5 years for individuals with stage IV CRC^[77]. If disease recurrence is observed, the steps of diagnosis, staging, treatment *via* resection and/or adjuvant chemotherapy are revisited as with a primary presentation, with the potential complications of a more advanced presentation and chemotherapy resistant lesions.

CRC genomics

In the more than ten years since the completion of the Human Genome Project^[17], advances in the capacity, speed and accuracy of genomic DNA sequencing have rapidly increased our knowledge of the molecular basis of multiple diseases, and ushered in the genomic era^[16]. These powerful tools of genomic analysis have been recently trained on CRC, the results of which are just beginning to exert what is expected to be a substantial effect on the diagnosis and treatment of this disease.

Genome scale sequencing (including whole exome and whole genome sequencing) of over 200 CRC samples was recently completed by The Cancer Genome Atlas Network (TCGA), with a primary goal of characterizing somatic mutations in these lesions. The 24 genes which they found to be significantly mutated included somatic alterations in genes known to act in CRC, namely *APC*, *TP53*, *SMAD4*, *PIK3CA* and *KRAS* (Figure 1), as well as *ARID1A*, *SOX9* and *FAM123B*^[7]. They observed significantly different somatic mutations rates among the tumors assessed, classifying them into two categories: hypermutated and non-hypermutated. As a potential etiology for the elevated mutation rate, they tested and found 77% of hypermutated tumors to have elevated levels of micro-satellite instability (MSI), which is caused by DNA mismatch repair (MMR) deficiency^[77], and can occur due to deleterious mutations to the genes *MLH1*, *MLH3*, *MSH2*, *MSH3*, *MSH5* and *PMS2*^[7]. In fact, in the majority of these same hypermutated lesions with high MSI were found evidence of epigenetic silencing of *MLH1* and frameshift/nonsense/missense mutations in *MLH1*, *MLH3*, *MSH2*, *MSH3*, *MSH5* and *PMS2*^[7]. They proposed that the higher survival rate of patients with high MSI-related cancers, with these tumors being hypermutated, the mutation rate may be a prognostic indicator^[7].

Increasing understanding of the role of MMR in tumorigenesis has already impacted the clinical approach to CRC. Current recommendations include assessment of new CRC for evidence of MMR deficiency for patients younger than 50 years old, though many centers assess for MMR deficiency, and sometime MSI, on all patients with CRC. This is done for two reasons: (1) it can be used as a screening tool to identify individuals at risk to have Lynch syndrome, causing hereditary colon and endometrial cancer^[14], for whom genomic sequence analysis

Table 1 Evolving genomic tools for management of colon cancer

	Detection	Diagnosis	Management

for mutations in *MLH1*, *MSH2*, *MSH6* or *PMS2* would be diagnostic; (2) deficiency in tumor MMR (as measured by protein immunohistochemistry) or high MSI tumor status is suggested to indicate decreased likelihood to metastasize^[80] and be a prognostic indicator of more favorable outcome^[89,90].

The application of genome sequencing technology has also led to an evolving array of clinical tools to augment the diagnosis and treatment of CRC (Table 1). For example, multigene assays have been developed to provide prognostic and predictive information about individual CRC tumors, as well having the potential to guide tumor specific therapeutic choices. Several such multigene panels are currently available (Oncotype DX Colon, ColoPrint, ColoDX), simultaneously assessing 18 genes or more, using the data to predict an individual tumor's risk of recurrence^[80]. While early trials have found such multigene panels can help predict recurrence risk for stage I - III CRC, they do not appear to predict the benefit of adjuvant therapy^[80], and further studies are necessary before such genomic assessment tools will have clinical relevance for choice of adjuvant therapy.

With detailed genomic information now more easily obtainable for individual tumors, the potential for delivering treatments more specifically targeted to a tumor's molecular signature is becoming a reality. For example, MSI observed in CRC tumors by the TCGA study, has been found to be a potential predictor of benefit from adjuvant therapy, with fluoropyrimidine specifically^[89]. MSI in CRC has been shown to be a predictor of more favorable outcome, and studies suggest high MSI, or deficient MMR, to be a marker predicting decreased benefit, and potential deleterious effect, of adjuvant treatment with fluoropyrimidine alone in individuals with stage II CRC^[89,90]. It is currently recommended that MMR tumor analysis be considered for individuals with stage II disease and planned fluoropyrimidine adjuvant treatment alone^[77].

In another example, TCGA genomic analysis of CRC further confirmed the presence of a significant number of *KRAS* mutations (in 43% of non-hypermutable CRC), consistent with its role in the molecular etiology of CRC (Figure 1)^[7]. Additional studies have shown up to 40% of CRC tumors have alterations in codons 12 and 13 of exon 2 in the coding region of *KRAS*^[91,92]. These particular *KRAS* alterations have been shown to be predictive of a lack of response to specific chemotherapies, anti-EG-

FR drugs cetuximab and panitumumab in particular^[93-97], and the FDA has stated that these drugs should not be used for management of CRC with these specific *KRAS* alterations [Cetuximab (package insert). Branchburg, NJ: ImClone Systems Incorporated; 2009; Vectibix (package insert). Thousand Oaks, CA: Amgen Inc.; 2009].

Furthermore, downstream of activated *KRAS*, the *BRAF* gene protein product is activated. *BRAF* mutations were observed in the TCGA CRC genomic analysis (46% of hypermutated tumors)^[7] and up to 9% of CRC contain the *BRAF* gene V600E mutation^[98]. Retrospective studies have suggested that mutated *BRAF*, in the presence of wild-type *KRAS*, also confers a lower response rate to cetuximab^[99]. For this reason, patients with stage IV CRC whose tumor has tested wild-type for *KRAS*, should have the option of *BRAF* tumor genotyping, in an effort to avoid potentially ineffective therapy choices^[77]. With these potential opportunities to positively impact the selection of chemotherapeutics on a tumor specific basis, genotyping of CRC tumor tissue in all individuals with metastatic CRC diagnosed as stage IV is now strongly recommended (Table 1)^[77].

Pharmacogenomic data represents another advance in CRC therapy with the ability to personalize the selection of agents for CRC treatment to each patient's tolerance. Germline genomic sequencing of individual CRC patients is enabling the identification of individuals who have increased susceptibility to the side effects of particular drugs as well as increased or decreased metabolism of specific pharmacological agents. Each of these characteristics can positively, or negatively, impact the efficacy of a selected therapeutic agent in treating the patient's CRC. Data is growing to provide clinical guidance in the selection of chemotherapeutics for CRC based in part on a patient's germline genomic sequence, to avoid excessively toxic drugs and promote optimal dosing. For example, patients with a particular variant of the uridine diphosphate-glucuronosyl transferase 1A1 (*UGT1A1*) gene are at higher risk of developing neutropenia and diarrhea when treated with irinotecan for CRC^[100-102]. Accordingly, the FDA currently recommends genotyping of patients under consideration of irinotecan treatment for CRC prior to initiation (Table 1)^[103].

Genomic analysis of CRC by TCGA continued the expansion of our understanding of the molecular etiology of CRC by identifying somatic mutations in novel genes not previously associated with CRC, such as *SOX9*^[7].

Their analysis also found a majority of recurrent CRC mutations could be grouped into several major cellular networks, specifically the WNT, MAPK, PI3K, TGF-beta and p53 pathways. For example, though alterations in *APC*, a component of the WNT pathway commonly altered in CRC, was mutated in 81% of non-hypermuted and 53% of hypermutated CRC, the overall WNT signaling pathway was altered in 93% of non-hypermuted and 97% of hypermutated CRC^[7]. This observation suggests that almost all CRC are driven in part by a very similar molecular mechanism to that which initiates CRC in patients with FAP (Figure 1). This also suggests that pathway or network-level convergence would be an important methodology whereby the functional impact of non-synonymous point mutations in CRC might be predicted^[104]. The TCGA data also suggest various potential targets for therapeutic intervention including proteins in the WNT, RTK-RAS and PI3K pathways which could be targets for inhibition^[7]. Some of these targets are already under investigation and have shown initial potential (Table 1), such as inhibitors of WNT signaling and beta-catenin inhibitors^[105-107].

The diagnosis of CRC, both at initial presentation and during surveillance for recurrence, has yet to be significantly impacted by genomic sequencing applications. However, the developing ability to more accurately sequence cell free genomic DNA isolated from the serum, as has been done for prenatal diagnostics^[108], and the detection of significant levels of tumor DNA in the blood of cancer patients^[109], suggest there is significant potential for genomic advances in the diagnosis of CRC (Table 1). Many exciting discoveries remain on the horizon for the diagnosis and management of CRC as the genomic era continues to unfold.

CONCLUSION

We have discussed the current diagnosis and management of sporadic and FAP related CRC, and the initial impacts genomic sequencing is having on these diseases. The diagnosis of FAP continues to rely on the performance of a thorough patient history and physical examination, which includes a detailed familial medical history. Clinical diagnosis *via* colonoscopy provides the gold standard for identifying the physical manifestations of FAP related CRC. Genomic sequencing has begun to manifest its impact on the diagnosis of FAP in the availability of *APC* gene sequencing and next generation sequencing based multi-gene panels, through which patients without a significant family history or with an ambiguous presentation, can be tested simultaneously for several hereditary cancer syndromes, minimizing the time to confirmed diagnosis and initiation of recommended surveillance protocols, testing of at risk family members. Molecular testing of at risk but asymptomatic family members has the added benefit of confirming individuals as being unaffected by an *APC* gene mutation, and allowing them to safely avoid unnecessary colonoscopic surveillance beyond that recommended

for individuals of average risk^[38]. With the increasing availability of these genomic sequencing assays to assess the molecular status of *APC*, a small but growing number of VUS are accumulating, which complicates the diagnostic capacity of these tests and leaves patients having to undergo empiric intensive FAP CRC screening protocols in the absence of a definitive “positive” or “negative” result. Further functional characterization of VUS remains an important area of research to improve the accuracy and applicability of diagnostic genomic sequencing.

Sporadic CRC has also begun to benefit from the tools of genome sequencing analysis. Recent whole exome and whole genome sequencing of hundreds of CRCs have confirmed the presence of the canonical genetic mutations contributing to its pathogenesis, while also identifying novel genes with potential roles in CRC tumor development^[7]. The genomic era has begun to contribute new tools to facilitate both diagnosis and guide management of sporadic CRC. Fecal derived DNA sequencing assays are being tested as a precursor to colonoscopic assessment, providing a vast amount more information than its antecedent the fecal occult blood test, though these remain unready at this time for clinical application. Direct genomic analysis of patient CRC tumors is being actively pursued in the research setting, with growing evidence that such information may provide prognostic and predictive information about clinical course and response to intervention, with the current standard of care already requiring certain CRC genes be assessed prior to treatment with specific chemotherapeutic agents^[7]. Germline genomic sequencing of CRC patients has the potential to allow personalization of treatment to patient tolerances, and some pharmacogenomic studies have already lead to screening of patients prior to initiation of specific regimens in order to avoid deleterious side effects. These advances, brought about in the short time since the advent of the genomic era^[16], have already significantly impacted the clinical management of sporadic and FAP related CRC, with the promise of further discoveries on the horizon with the potential to ultimately decrease the current prevalence and mortality of CRC, both sporadic and hereditary.

Abstract

Postoperative recurrence occurs in approximately half of patients with non-small cell lung cancer (NSCLC), even after complete resection. Disease recurrence after surgical resection reduces the patient's life expectancy sharply. The prognosis after postoperative recurrence is considered to largely depend on both the mode of first recurrence (distant, locoregional or combined) and the treatment modality: (1) The majority of cases of postoperative recurrence involve distant metastasis with or without locoregional recurrence. Platinum-based systemic chemotherapy is practically accepted as the treatment for these diseases on the basis of evidence for original stage IV disease. The advent of both pemetrexed and molecular-targeted drugs has improved the survival of nonsquamous NSCLC and changed the chemotherapeutic algorithm for NSCLC; (2) Among patients with distant metastatic recurrence without locoregional recurrence at the primary tumor site, the metastasis is often limited in both organ and number. Such metastases are referred to as oligometastases. Local therapy, such as surgical resection and radiotherapy, has been suggested to be the first-line treatment of choice for

oligometastatic recurrence; and (3) While locoregional recurrence is likely to cause troublesome symptoms, it is a potentially limited disease. Therefore, providing local control is important, and radiation is usually beneficial for treating local recurrence. In order to obtain better control of the disease and provide treatment with curative intent in patients with limited disease, the administration of concurrent platinum-based chemoradiotherapy is recommended according to the results of originally nonresectable stage IIIA and IIIB disease.

Key words: Non-small cell lung cancer; Postoperative recurrence; Distant metastasis; Oligometastases; Local treatment; Locoregional recurrence

Core tip: The postrecurrence survival in non-small cell lung cancer (NSCLC) is considered to largely depend on both the mode of first recurrence (distant, locoregional or combined) and the treatment modality. Therefore, the therapeutic strategy for treating postoperative recurrence in patients with NSCLC should be considered according to the mode of first recurrence. In this way, proper treatment specific to the mode of recurrence will be developed and improvements of the postrecurrence survival can be obtained.

Therapeutic strategy for postoperative recurrence in patients with non-small cell lung cancer. *World J Clin Oncol* 2014; 5(5): 1048-1054 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/1048.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.1048>

INTRODUCTION

Primary lung cancer is currently the leading cause of cancer-related mortality worldwide. Despite progress in

Figure 1 Postrecurrence survival according to the mode of postoperative recurrence. From 1994 through 2004, 418 consecutive patients with NSCLC underwent complete resection at Kyushu University Hospital. Of these patients, 138 experienced postoperative recurrence by December 2005, and were followed until the end of 2009.

both chemotherapy regimens and radiotherapy, surgical resection still remains the first choice of treatment for locally limited non-small cell lung cancer (NSCLC). Although the results of surgery for NSCLC have improved, this is mostly attributed to improvements in diagnostic techniques and early detection of the disease. In fact, the outcomes of surgical resection for locally advanced stages (II or IIIA) of disease are not acceptable, when a complete resection can be performed. According to the international database of the IASLC Lung Cancer Staging Project in 2007, the five-year-survival rate after complete resection is 73% for pathologic stage I A disease, 58% for I B disease, 46% for II A disease, 36% for II B disease, and 24% for IIIA disease^[1].

Postoperative recurrence occurs in approximately 45% of patients, even after complete resection of NSCLC^[2]. Disease recurrence after curative surgery reduces the patient's life expectancy sharply. The median postrecurrent survival time ranges from 8.1 to 17.7 mo in the literature^[3-5]. The postrecurrence survival is considered to largely depend on both the mode of recurrence (Figure 1) and treatment modality^[6,7]. To date, however, there have been few studies regarding the treatment of postoperative recurrence according to the mode of recurrence.

In this review article, the authors would like to propose a perspective treatment strategy according to the mode of postoperative recurrence, which is expected to prolong postrecurrence survival in patients with a good performance status.

FIRST SITE OF POSTOPERATIVE RECURRENCE

Information regarding the first recurrence site after surgery is useful for patient management. The mode of postoperative recurrence is usually classified into distant recurrence, locoregional recurrence and combined recur-

Figure 2 Mode of postoperative recurrence in reference to the initial stages of disease.

rence. From the point of view of the selection of treatment modality, local recurrence is defined as recurrent disease within the ipsilateral hemithorax and mediastinum, excluding pulmonary lesions. Postoperative recurrence in the ipsilateral lung or even the contralateral lung was previously classified as intrathoracic local failure. However, in view of the pathophysiological analysis and selection of treatment modalities, pulmonary lesions appearing after surgery should be differentiated into hematogenous distant metastases, locoregional recurrent tissues at the surgical margin or second primary cancer tumors. Therefore, ipsilateral pulmonary lesions including the surgical margin should be diagnosed as lesions of local recurrence.

It was first reported in 1994 that the mode of recurrence does not differ with respect to the pathological stage at the time of surgery (Figure 2) and that the first site of recurrence is distant organs in 73.4% of cases, locoregional sites in 19.0% of cases, and combined sites in 7.6% of cases^[2]. Common sites of distant metastasis include the brain, bone and lungs^[8]. Recently, both whole-body ¹⁸fluorine deoxy-²fluoro-*D*-glucose positron emission tomography (FDG-PET) and brain magnetic resonance imaging have become commonly included for meticulous preoperative screening. Consequently, the incidence of distant metastasis after surgery has decreased due to better preoperative staging and improved selection of surgical patients. Hence, the incidence of distant metastases as the first site of recurrence site has decreased substantially^[6,9].

TREATMENT OF POSTOPERATIVE DISTANT METASTASIS WITH OR WITHOUT LOCOREGIONAL RECURRENCE

The majority of recurrent NSCLC patients after surgery involve distant metastasis with or without locoregional recurrence^[2,6,8,10]. Although there are no definitive therapeutic guidelines for the treatment of recurrent disease

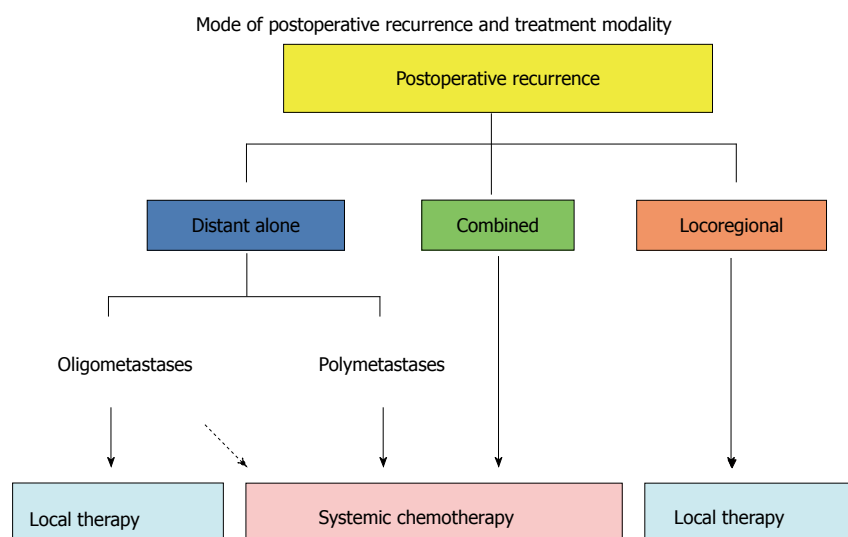

Figure 3 Mode of postoperative recurrence and treatment modality.

after complete resection, the administration of systemic chemotherapy is practically accepted as the treatment for these diseases on the basis of evidence for original stage IV disease (Figure 3).

As to the first-line treatment for distantly metastatic stage IV disease, platinum-based chemotherapy is known to prolong survival, compared with the administration of best supportive care alone^[11]. The median overall survival (OS) of NSCLC patients with clinical stage IV disease has been reported to be about one year with a median progression-free survival (PFS) of about five months in those treated with platinum-doublets chemotherapy consisting of platinum and third-generation cytotoxic drugs including paclitaxel, docetaxel, gemcitabine, vinorelbine and CPT-11^[12,13]. The advent of both pemetrexed and molecular-targeted drugs has improved the survival of patients with nonsquamous NSCLC and drastically changed the chemotherapeutic treatment algorithm for NSCLC (Figure 4). Since pemetrexed has been identified to be more effective for nonsquamous NSCLC than squamous cell carcinoma^[14], regimens of platinum plus pemetrexed are now standard first-line treatments for nonsquamous NSCLC. Furthermore, it is evident that both the PFS and OS are prolonged by treatment with platinum plus pemetrexed followed by continuous maintenance chemotherapy with pemetrexed alone^[15]. In addition, the combined use of bevacizumab, anti-VEGF (vascular endothelial growth factor) antibodies prolongs the PFS in both the induction phase of platinum-doublet regimens and the continuous maintenance phase in the setting of nonsquamous NSCLC^[16-19].

Recently, on the other hand, various types of molecular-targeted drugs have been developed in addition to conventional cytotoxic agents. It is now well-known that the response to epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKIs), such as erlotinib and gefitinib, is largely limited to specific mutations of the EGFR gene (*EGFR*) at exons 18 through 21^[20-22] and that EGFR-TKIs thereby achieve a longer PFS (9.2-13.7 mo) than can be obtained with standard platinum-

based chemotherapy (4.6-5.4 mo) for *EGFR* mutational NSCLC^[23-26]. In patients with *EGFR* mutations, EGFR-TKIs are now preferentially administered as first-line treatment (Figure 4). In the subgroup analysis of a phase II study of first-line erlotinib, the MST of the patients with postoperative recurrence who exhibited *EGFR* mutations was 18.2 mo^[27].

Following the identification of the *EGFR* mutation, the echinoderm microtubule-associated protein-like 4 (EML4)-anaplastic lymphoma kinase (ALK) fusion gene was discovered to be a driver oncogene for nonsquamous NSCLC in 2007^[28]. Crizotinib, an ALK inhibitor, has been identified to be effective for EML4-ALK-positive NSCLC, with both a response rate of 60.8% and a PFS of 9.7 mo^[29,30].

Since novel driver oncogenes have been extensively explored, it is essential to properly preserve surgical specimens for the future evaluation of biomarkers of molecular-targeted therapy.

TREATMENT OF OLIGOMETASTATIC RECURRENCE

Among patients with distant metastatic recurrence without locoregional recurrence at the primary tumor site, the metastasis is often limited in both organ and number. Such limited metastases are referred to as oligometastases. Local therapy, such as surgery and radiotherapy, has been applied successfully in appropriately selected patients, especially for patients with either brain metastasis alone or those with adrenal metastasis alone^[31-34]. Recently, Yano et al. reported a retrospective study reviewing their therapeutic experience with postoperatively recurrent NSCLC patients and demonstrated that a histology of adenocarcinoma, a longer disease-free interval (≥ 1 year) and the use of local therapy are significantly preferable prognostic factors for the postrecurrence OS of patients with distant metastasis alone^[6]. It has been suggested that local control of the metastatic tumor prolongs both the

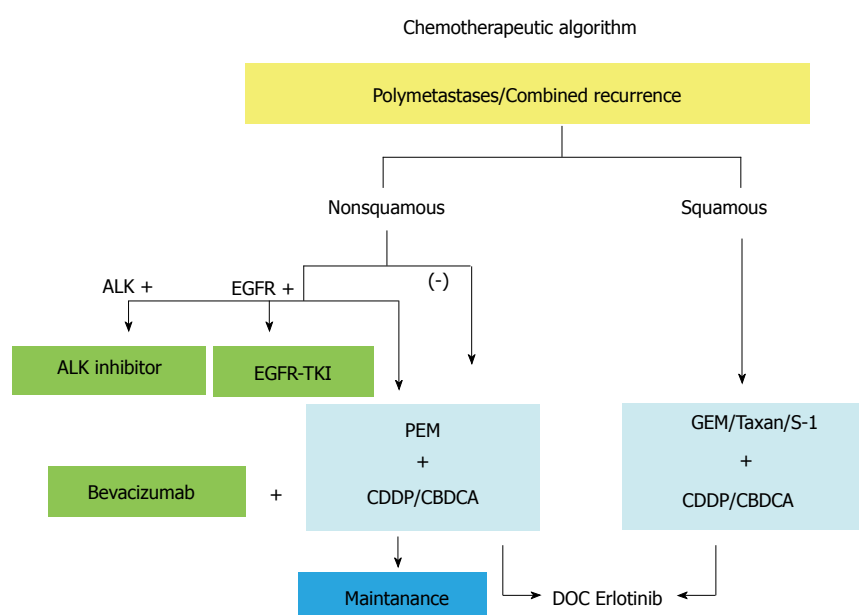

Figure 4 Chemotherapeutic algorithm. PEM: Pemetrexed; GEM: Gemcitabine; CDDP: Cisplatin; CBDCA: Carboplatin; DOC: Docetaxel; EGFR-TKI: Epidermal growth factor receptor tyrosine kinase inhibitor; ALK: Anaplastic lymphoma kinase fusion gene.

PFS and OS when distant metastases are limited in organ and number without local relapse at the primary site. These investigators subsequently reported findings of a prospective observational study that showed that 54.8% of postoperatively recurrent patients with distant metastasis alone exhibit oligometastatic metastasis without primary site recurrence and that the administration of local therapy, such as surgical resection or radiotherapy, results in a relatively long PFS of the patients with oligometastasis^[35]. In that study, patients with only brain metastasis were excluded from the survival analysis since stereotactic radiotherapy is already practically accepted as the standard treatment for these limited brain metastases. In the oligometastatic patients who received local treatment, the median PFS was 20 mo. In that series, patients with metastasis to the lungs or bone were present among the long-term progression-free survivors.

Prior to application of local treatment for postoperative oligometastatic recurrence, it is essential to rule out both locoregional recurrence at primary site (in the locoregional lymph nodes) and other systemic metastasis. Therefore, for an accurate clinical diagnosis of oligometastases, FDG-PET examinations should be performed at the time of postoperative recurrence, as this modality has a high ability to detect asymptomatic recurrence^[36].

TREATMENT OF LOCOREGIONAL RECURRENCE

While locoregional recurrence is likely to cause troublesome symptoms, it is a potentially limited disease. Therefore, providing local control is important, and the administration of local treatment, such as radiotherapy, is usually beneficial for local recurrence after complete resection in patients without pleural dissemination or effusion (Figure 3). In a study by Yano *et al.*^[2], half of the locoregionally recurrent patients who received radiation

treatment exhibited a good local response, resulting in a prolonged survival, with a median survival time (MST) of 27 mo. On the other hand, the MST of the patients with uncontrolled disease was only six months. The administration of modern three-dimensional conformal radiotherapy with a curative dose of 60–66 Gy has been reported to achieve approximately 90% response rate (65% complete response and 24% partial response) for postoperative thoracic lymph node recurrence^[37]. As a result, the five-year PFS and OS rates are 22.2% and 36.1%, respectively.

Postoperative locoregional recurrence is considered to be pathophysiologically the same as originally nonresectable stage IIIA and IIIB diseases, although the MST after treatment of a curative dose of radiation is longer for patients with postoperative locoregional recurrence (ranging from 14 mo to 19 mo^[38–40]) than for nonresectable stage IIIA and IIIB diseases (ranging from 8.5 to 14.1 mo^[41]). The therapeutic outcomes of the nonresectable stage IIIA and IIIB disease have been improved with recent developments in chemoradiotherapy, particularly platinum-based regimens, compared with that achieved with radiation alone^[41]. In patients with a good performance status, the administration of concurrent chemoradiotherapy improves survival compared with the use of sequential chemoradiotherapy. Therefore, postoperative locoregional recurrence should be treated with concurrent chemoradiotherapy in order to obtain better control of the disease and provide curative treatment in patients with limited disease.

The potential of radiotherapy to control localized lesions is clearly best with small-volume disease^[37]. Furthermore, in patients with small-volume disease which potentially remains localized without any hematogenous distant metastasis, curative radiotherapy is considered to be the treatment of choice. When deemed feasible, surgical resection is also another potential treatment of choice. However, early small-volume locoregional recur-

rence, especially in the hilar and mediastinal lymph nodes, is rarely detected on chest X-rays. Therefore, in addition to periodically obtaining chest X-rays, chest computed tomography should be performed annually for the first two years during the postoperative period^[42].

CONCLUSION

In conclusion, the therapeutic strategy for treating postoperative recurrence in patients with NSCLC should be considered according to the mode of first recurrence. In this way, proper treatment specific to the mode of recurrence will be developed and improvements of the postrecurrence survival can be obtained. Based on the treatment algorithm shown in Figures 3 and 4, a multi-institutional prospective cohort study on treatment modalities for postoperative recurrence is currently proceeded by the Kyushu University Lung Surgery Study Group.

transformation of boundaries points has been applied successfully to map the two breasts interior points. Some of advantages for using shape context method in this work are as follows: (1) no special land marks or key points are needed; (2) it is tolerant to all common shape deformation; and (3) although it is uncomplicated and straightforward to use, it gives remarkably powerful descriptor for point sets significantly upgrading point set registration. Results are very promising. The proposed algorithm was implemented for 32 cases. Boundary registration is done perfectly for 28 cases.

CONCLUSION: We used shape contexts method that is simple and easy to implement to achieve symmetric boundaries for left and right breasts boundaries in thermal images.

Abstract

AIM: To achieve symmetric boundaries for left and right breasts boundaries in thermal images by registration.

METHODS: The proposed method for registration consists of two steps. In the first step, shape context, an approach as presented by Belongie and Malik was applied for registration of two breast boundaries. The shape context is an approach to measure shape similarity. Two sets of finite sample points from shape contours of two breasts are then presented. Consequently, the correspondences between the two shapes are found. By finding correspondences, the sample point which has the most similar shape context is obtained.

RESULTS: In this study, a line up transformation which maps one shape onto the other has been estimated in order to complete shape. The used of a thin plate spline permitted good estimation of a plane transformation which has capability to map unselective points from one shape onto the other. The obtained aligning

Key words: Breast thermal images; Shape contexts; Registration; Cancer detection; Infrared

Core tip: Breast thermography has shown to be as a non-invasive safe method to detect breast abnormalities. Comparison between two breast temperature distributions is helpful to identify irregularities. Since in many cases real thermal breast images do not have symmetric boundaries, a registration is needed. A registration shape context approach is applied in this work.

INTRODUCTION

Breast abnormalities are major concerns in health issues

Figure 1 An example of known and unknown objects as well as their points sets. A: Known object; B: Unknown object.

Figure 2 The correspondences between the two shapes.

for women today. Identification of potentially malignant cells has a great significance for physician. Breast thermal imaging for early detection has an arguable history. With developing high sensitive infrared cameras besides great knowledge of advanced image processing and advanced computer algorithms have renewed attention to breast infrared imaging. The level of blood perfusion can affect the surface temperature that results infrared radiation emitted from skin breasts^[1]. By utilizing a sensitive infrared camera, the skin temperature changes can be captured. Since cancerous cells are hotter than normal cells, they are appeared as hot spots in thermal images^[2]. Usually healthy subjects are symmetric^[3]. Consequently, asymmetrical temperature patterns between two contra lateral breasts could be a sign of abnormality^[4-12]. In practice, most of the real IR breast images do not have symmetric boundaries. Hence, in order to compare the thermal distribution of two contra lateral breasts, a registration for two breasts is needed. In this work, first the shape context method is applied for registration of two contra lateral breasts boundaries. Then the obtained transformation function of boundaries points is utilized to transfer breasts interior points. The paper is organized as follows: The shape context method and the thin plate spline (TPS) are introduced in section 1. Section 2 explains dataset and describes the proposed algorithm steps. The experimental results are presented in section 3. Section 4 concludes the findings.

MATERIALS AND METHODS

Shape context

The shape context is an algorithm was proposed by Var-

Figure 3 Alignment of the two shapes after applying alignment transformation.

dasca *et al* in 2002^[13]. It is an approach to describe shapes in measuring shape alikeness and improving of point similarities. In this way, there are two objects, known and unknown. Assuming the shape of the known object is captured by points set $p = \{p_1, | p_n\}$ and the unknown object by $q = \{q_1, | q_n\}$. The expansion of relative places is vigorous, dense, and thoroughly differential descriptor. Hence, the coarse histogram of relative coordinates of $n - 1$ points are being left, for point p_i , is described as the shape context of p_i which is expressed in Eq. (1)

$$h_i(k) = \#\{q \neq p_i : (q - p_i) \in \text{bin}(k)\} \quad (1)$$

First, the correspondences between two shapes are found. A set of finite representative points from shape boundaries illustrates shapes. They are not required to be special points such as curvature extrema or landmarks, *etc.* The more samples are used, the better approximations to the underlying shape are obtained. Using the shape context, we outline the coarse expanding of the remaining of the shape regarding to a specified point on the shape by utilizing the shape context. By discovering similarities between two shapes, for each representative point on one shape, the representative point on the other shape that has the most sameness shape context will be ascertained. The calculation of a mapping function that transfers one shape onto the other is extended by given correspondences at representative points. Euclidean, affine, and regularized thin plate splines can be used for transformation. Aligning shapes can be considered as a measure of shape similarity. We are able to obtain the differences between two shapes by calculating a sum of fitting errors

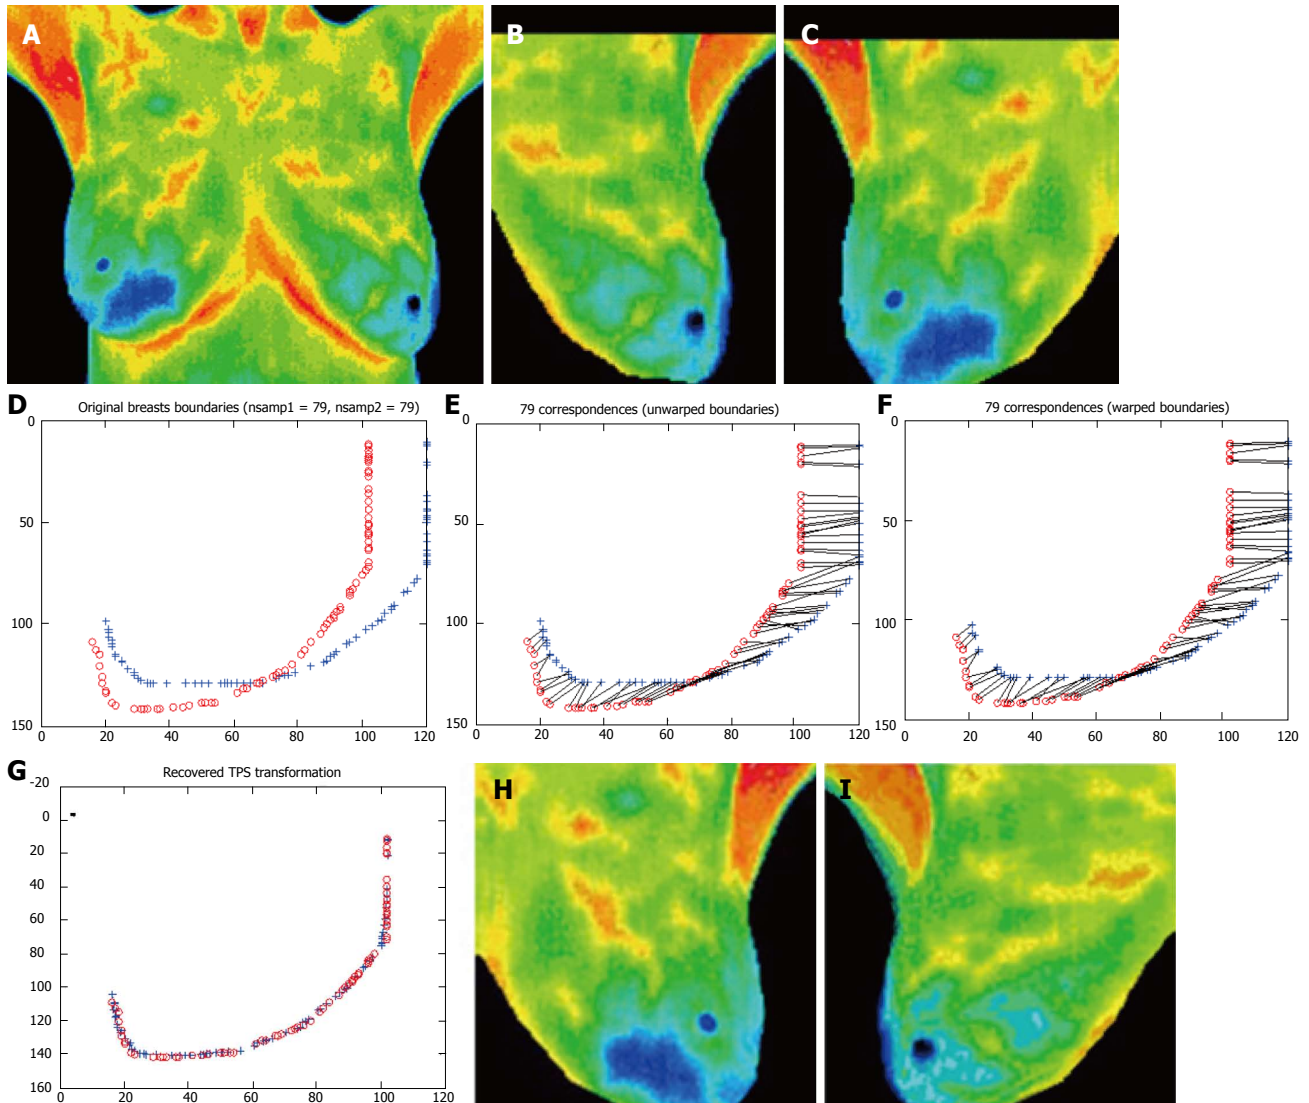

Figure 4 First sample. A: Original image; B: Left breast; C: Right breast; D: Points set of boundaries of right breast (+ in blue), points set of boundaries of left breast (o in red); E: Unwarped boundaries; F: Warped boundaries; G: Boundaries of two breasts after using the mapping function; H: Interpolated left breast; I: Interpolated left breast.

between similar points, in conjunction with an expression obtaining the magnitude of the mapping function.

Considering p_i a point on the known shape and q_j a point on the unknown shape. Supposing $C(p_i, q_j)$ is the cost of matching p_i with q_j . We represent shape contexts as histogram which is X^2 test statistics

$$C(p_i, q_j) = 1/2 \sum_{k=1}^K \{ [h_i(k) - h_j(k)]^2 / [h_i(k) + h_j(k)] \} \quad (2)$$

where $h_i(k)$ and $h_j(k)$ show the k bin normalized histogram at p_i and q_j respectively. It denotes the set of costs c_{ij} between all pairs of points p_i on the known shape and q_j on the unknown shape. It is desired to minimize the total cost of matching expressed by Eq. (3)

$$H(n) = \sum_i c(p_i, q_{\pi(i)}) \quad (3)$$

where π is a permutation. By using Hungarian technique it can be solved in $O(N^3)$ time. Examples of known object as well as unknown object with their point sets are shown in Figure 1A, Figure 1B respectively. Besides, the correspondences between the two shapes are depicted in Figure 2.

Moreover, Figure 3 shows the alignment of two shapes after applying alignment transformation. By evaluating a finite set of similarities between points on two shapes, we obtain a plane transformation. In this work, TPS was used. In the following, a brief description of TPS is provided.

Thin plate spline

Bookstein^[14] realized the model changes in biological forms where TPS is the mostly powerful candidate. When working with shape contexts TRS is greatly preferable. It is applied to map randomly points from one shape to another. TPS is 2D generalization of the cubic spline. Supposing that position (x_i, y_i) are not collinear and are all different. The Bending energy is minimized by the TPS interpolant $f(x, y)$ and has the form I_f .

$$I_f = \iint (\partial^2 f / \partial x^2)^2 + 2(\partial^2 f / \partial x \partial y)^2 + (\partial^2 f / \partial y^2)^2 dx dy$$

$$f(x, y) = a_0 + a_1 x + a_2 y + \sum_{i=1}^n w_i U(|(x_i, y_i) - (x, y)|) \quad (4)$$

where $U(r)$ is defined as Eq. (5)

$$U(r) = r^2 \log r^2 \quad (5)$$

In this work, thermal images, available from Thermal imaging lab in the San Francisco Bay Area^[15], Ann Arbor thermography center^[16], American College of Clinical Thermology^[17], Sun State thermal imaging center in Australia^[18], and Thermography of Iowa^[19] were studied^[20].

From the Department of Diagnostic Radiology, Singapore General Hospital, some data were also collected^[21]. For imaging the room temperature was selected in the range of 20 °C–22 °C (within ± 0.1 °C) in addition with humidity at $60\% \pm 5\%$. To stabilize and reduce basal metabolic rate, patients were required to rest at least 15 min. Since the vascularization is at basal level with least engorgement of blood vessels during the period of the 5th to 12th and 21th day after the onset of menstrual cycle, the patients were recommended to have examinations within these periods. The algorithm follows the following steps: (1) Randomly choosing a set of points of left breast boundaries as well as a set of points of right breast boundaries; (2) Evaluating similarities between points on

two breasts boundaries; and (3) Utilizing the similarities to obtain mapping function. The obtained mapping function is applied to map the interior points. In digital images, pixels are limited to set on a sampling grid, to occupy an integer lattice. Usually the output grid is not correlated with the integer lattice. However, the place of grid points may be any continuous values that are obtained by utilizing the mapping function. Consequently, an interpolation is required to fit a continuous surface through the data. Hence, non-integer places of output grid are attainable by sampling the continuous surface. The output image quality is very depended on the accuracy of interpolation; and (4) Determining the R,G,B amounts of the output grid by applying cubic spline properly.

RESULTS

The algorithm was implemented in 32 cases. It works perfectly for 28 cases. Implementations of the algorithm

for two cases are shown in Figure 4 and Figure 5. Left breasts are shown in Figure 4A and Figure 5A as well as right breasts in Figure 4B and Figure 5B. Points set of boundaries of right breasts and points set of boundaries of left breasts are depicted in Figure 4D and Figure 5D. Unwarped boundaries are shown in Figure 4E and Figure 5E and warped boundaries in Figure 4F and Figure 5F respectively. The boundaries of two breasts after employing the mapping function are presented in Figure 4G and Figure 5G. Moreover interpolated left and right breasts giving the mapping of the interior points are shown in Figure 4H and Figure 5H.

In conclusion, we have proposed an approach to achieve symmetric boundaries for left and right breasts boundaries in thermal images. The algorithm is based on using shape contexts method. Then, to map the interior points of two breasts, the calculated mapping function of boundaries points is used. Some of advantages for using shape context method in this work are as follows: (1) no special land marks or key points are needed; (2) it is tolerant to all common shape deformation; and (3) although it is uncomplicated and straightforward to use, it gives remarkably powerful descriptor for point sets significantly upgrading point set registration. Results are very promising. The algorithm was implemented for 32 cases. It works perfectly for 28 cases.

In future work, we can use the two obtained symmetric breasts in thermal images to compare their thermal profiles by comparing some extracted features from contra lateral breasts in order to identify thermal dissimilarities.

COMMENTS

Background

Breast health is one of major concerns of women's health today. Moreover safe modality can play an important role to identify breast irregularities. Breast thermography has shown that is a non-invasive, safe method to detect breast abnormalities.

Research frontiers

In practice, most of the real thermal breast images do not have symmetric boundaries. Hence, in order to compare thermal distribution of two breasts by comparing extracted features, a registration is needed.

Innovations and breakthroughs

Since symmetry usually indicates healthy subjects, asymmetrical temperature distribution between left breast and right breast could be a strong sign of abnormality. In practice, most of the real thermal breast images do not have symmetric boundaries. Therefore, in order to compare thermal distribution of two breasts by comparing extracted features, a registration is needed. In this work, a registration method based on shape context algorithm is introduced.

Applications

The study results suggest a registration method based on shape context algorithm for comparison between contra lateral breast temperature distributions.

Terminology

Shape context: an approach to measure shape similarity. First, two sets of finite sample points from shape contours of two breasts are introduced. Second, the correspondences between the two shapes are found. Third, by finding correspondences, the sample point which has the most similar shape context is obtained. Forth, an aligning transformation that maps one shape onto the other in order to complete shape is estimated.

Peer review

This article shows promising outcomes and it very technical and tough for common physicians.

RESULTS: We analyzed 49 brain stem glioma (BSG) patients from July 2001 to December 2012; 31 of them were males (63.3%) with a median age of 12.6 years (range: 8-64 mo). Twenty-two patients (44.9%) had diffuse intrinsic pontine gliomas (DIPG) and 15 (30.6%) presented with focal/tectal BSG. Histopathology was available in 30 patients (61.2%). Median survival time for the whole cohort was 1.5 years. One and two year OS rates were 51.1% and 41.9% respectively. Two year OS rates for focal/tectal, dorsally exophytic, cervicomedullary and DIPG tumors were 60%, 33.3%, 33.3% and 13.6% respectively ($P < 0.0001$). Significant prognostic factors related to OS were age at diagnosis (worse for > 18 years) $P = 0.01$, KPS < 70 $P = 0.02$, duration of symptoms (< 60 d) $P = 0.002$, histology (better for favorable) $P = 0.002$, surgery (maximal resection) $P = 0.002$, and concurrent chemotherapy with radiation therapy in DIPG (better if given) $P = 0.01$.

CONCLUSION: BSG, especially the DIPG subgroup, had a dismal prognosis, needing more aggressive neurosurgical, radiation and chemotherapy techniques, while focal and tectal tumors were found to have a better prognosis.

Abstract

AIM: To analyze experiences to identify treatment outcomes and prognostic factors in a Saudi population.

METHODS: Medical records of patients with brainstem gliomas treated from July 2001 to December 2012 were reviewed to identify treatment outcomes of surgery, radiation therapy and chemotherapy and associated prognostic factors in a Saudi population.

Core tip: Brain stem gliomas (BSG) are a heterogeneous group of tumors with a poor prognosis. We analyzed 49 BSG patients from July 2001 to December 2012 with a median age of 12.6 years (range: 8-64 mo). Twenty-two patients (44.9%) had diffuse intrinsic pontine gliomas (DIPG) and 15 (30.6%) presented with focal/tectal BSG. Histopathology was available in 30 patients (61.2%). Median survival time for the whole cohort was 1.5 years. One and two year OS rates were 51.1% and 41.9% respectively. Two year OS rates for

focal/tectal, dorsally exophytic, cervicomedullary and DIPG tumors were 60%, 33.3%, 33.3% and 13.6% respectively ($P < 0.0001$). We concluded that BSG, especially the DIPG subgroup, had a dismal prognosis, needing more aggressive neurosurgical, radiation and chemotherapy techniques, while focal and tectal tumors were found to have a better prognosis.

INTRODUCTION

Brain stem gliomas (BSG) account for about 10%-20% of all central nervous system tumors in children and 1%-2% in adults^[1,2]. Traditionally, the term “brain stem glioma” was designed as a clinical diagnosis without histological confirmation because the morbidity for surgical intervention within the pons was high and the relevance of a histological diagnosis was low. With the advent of newer diagnostic modalities, BSG are now considered a heterogeneous group of tumors which are mainly divided into three categories according to treatment and prognosis^[3]: (1) the dorsally exophytic and cervicomedullary tumors appear to benefit significantly from surgical resection^[3]; (2) focal tectum glioma (solid or cystic) may be associated with a long history of symptoms and with neurofibromatosis type I^[4]; and (3) the largest subgroup of diffuse intrinsic pontine glioma (DIPG), in contrast, have a poor prognosis^[5]. The DIPG subgroup clearly differs from focal, dorsally exophytic and cervicomedullary tumors on various points as DIPG is typically seen with rapidly progressing symptoms and signs comprising multiple erratic cranial nerve palsies, long track deficits, cerebellar symptoms and/or raised intracranial pressure with a median survival of 9 mo^[6,7]. Gadolinium enhanced magnetic resonance imaging (MRI) allows easy confirmation of diagnosis for DIPG and high-grade BSG^[8].

Surgery is the mainstay of therapy for focal, dorsally exophytic and cervicomedullary BSG; however, for DIPG the radiation therapy remains the standard treatment option^[9,10]. Various chemotherapeutic agents investigated as monotherapy neoadjuvant agents (carboplatin or irinotecan) or as combination neoadjuvant chemotherapeutic agents (carboplatin, etoposide and vincristine or cisplatin, cyclophosphamide, etoposide and vincristine) have offered no significant improvements^[11,12]. Similarly, concurrent chemotherapeutic agents (etanidazole, topotecan, carboplatin and temozolomide) or high-dose chemotherapy followed by stem cell support have not shown any significant improvements in overall and progression free survival rates^[13,14].

Our aim was to evaluate the frequency of BSG and to

identify treatment outcomes of surgery, radiation therapy and chemotherapy and associated prognostic factors in a Saudi population.

MATERIALS AND METHODS

After formal approval from the institutional ethical committee, medical charts of patients with confirmed brainstem gliomas who were treated in our hospital were reviewed. Patients were selected if they met the following criteria.

Availability of a complete medical record: (1) demographic data [age at diagnosis, gender, main symptoms and duration, performance status according to Karnofsky Performance Scale (KPS) and main neurological signs]; (2) radiological characteristics of the tumors on MRI (T1 and T2-weighted images); and (3) surgical procedures including histopathological characteristics and other treatment modalities (radiation therapy and chemotherapy).

The epicenter (main bulk) of the tumor was located in the brainstem (midbrain, pons and medulla oblongata) and diagnosis was either based on clinical history and characteristic MRI features or histopathological confirmation.

Exclusion criteria were: (1) the epicenter of the tumor was located in the thalamus, cerebellar peduncles or cervical spinal cord; and (2) suspicion of infection could not be ruled out on MRI in the absence of biopsy results.

Toxicity

The National Cancer Institute Common Toxicity Criteria (NCI-CTC) version 2.0 was used to score acute radiation and chemotherapy toxicity (< 90 d from the start of radiation therapy). The Radiation Therapy Oncology Group Late Radiation Morbidity Scoring Criteria was used to score radiation toxicity persisting beyond 90 d from the completion of radiotherapy.

Follow-up

Functional recovery after surgical and other treatment modalities was assessed. Radiological response to radiotherapy and chemotherapy was reported according to Response Evaluation Criteria in Solid Tumors (RECIST): (1) a complete response (CR), *i.e.*, disappearance of all visible tumor; (2) a partial response (PR), *i.e.*, a decrease of > 50% in the axial cross-section of the greatest surface area; (3) progressive disease (PD), *i.e.*, > 25% increase in axial cross-section of the greatest surface area; or (4) stable disease (SD), *i.e.*, all other situations.

Statistical analysis

The primary endpoints were functional recovery, response rates and the overall survival. Progression-free survival (PFS) was defined as the duration between the completion of treatment and the date of documented disease progression, death resulting from the cancer and/or last follow-up visit (censored). Overall survival (OS) was defined as the duration between the completion of

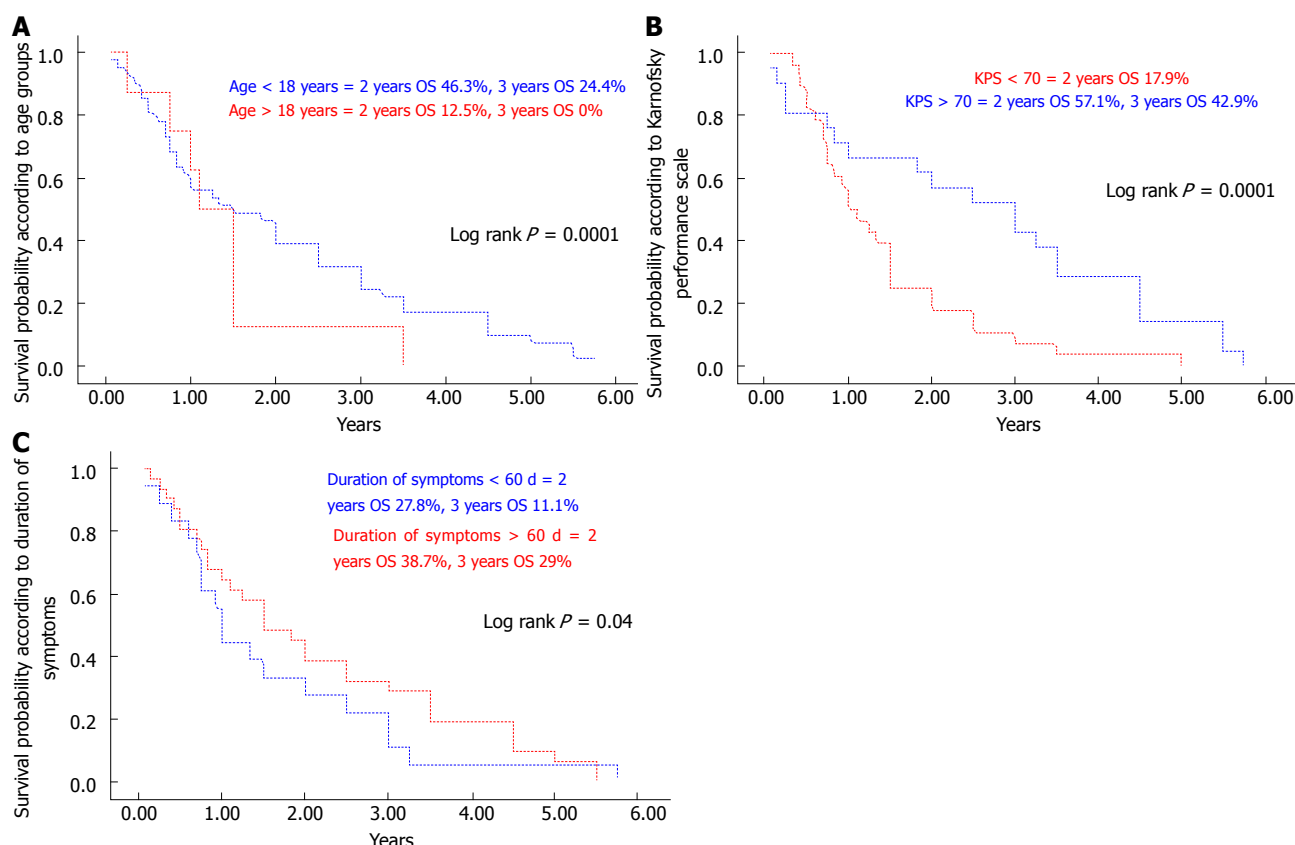

Figure 1 Kaplan-Meier curve. A: Showing overall survival probability according to age groups (< 18 years vs > 18 years); B: Showing overall survival probability according to Karnofsky performance scale (< 70 vs > 70); C: Showing overall survival probability according to duration of symptoms (< 60 d vs > 60 d). OS: Overall survival.

treatment and the date of patient death or last follow-up visit (censored). The probabilities of OS were determined with the Kaplan-Meier method and its 95%CI by the Rothman method. The comparisons for various endpoints were performed using the log-rank test. A P value of 0.05 was considered statistically significant. The multivariate analysis was used to test prognostic factors in multivariate analysis. Results are expressed with relative risk and its 95%CI. Statistical analyses were performed using the computer program SPSS (Statistical Package for the Social Sciences, version 17.0, SPSS Inc., Chicago, IL).

RESULTS

Study population

Between July 2001 and December 2012, 49 patients with BSG from the institutional database fulfilled the criteria and were analyzed.

Clinicopathological characteristics

Among forty-nine patients, the majority of the cohort consisted of children and adolescents (81.6%) with a median age of 12.62 years (range: 0.8-64). An age of > 18 years at diagnosis was associated with a significantly shorter OS compared with a younger age ($P = 0.0001$) (Figure 1A). Median Karnofsky performance status (KPS) at diagnosis was 80 (range: 40-100). KPS < 70 was related to a shorter OS ($P = 0.0001$) (Figure 1B). Main

symptoms at time of diagnosis were headaches (42.8%), diplopia or squint (38.8%), gait disturbance (34.7%), nystagmus (37.7%) and difficulty in swallowing or choking (26.5%). Mean duration of symptoms before diagnosis was 83.4 ± 47.5 d. Patients with short duration of symptoms (< 2 mo) had poor OS ($P = 0.04$) (Figure 1C). Main neurological signs were cranial nerve palsies, mainly VI, VII, IX, X (65.3%), cerebellar dysfunction (51%), bilateral papilledema (38.8%), nystagmus (37.7%) and motor weakness (28.6%). Histopathological diagnosis was available in 30 patients (61.2%), mainly of astrocytic origin (23/28) and high grade (63.3%) (Table1).

MRI characteristics at time of diagnosis

The main MRI characteristics are illustrated in Table 2.

On MRI, patterns were identified representing non-enhancing diffusely infiltrative tumors (54.5%), contrast-enhancing localized masses (33.3%) and tectal tumors (33.3%). Presumed necrosis on MRI, defined as a zone of irregularly shaped T1 hyposignal surrounded by contrast enhancement, was found in 5 (10.2%) patients.

Treatment characteristics

Thirty patients (61.2%) had surgery. Complete resection was done in dorsally exophytic (83.3%), focal tectal (66.7%) and focal (50%) tumors. Cerebrospinal fluid (CSF) shunts, including ventriculoperitoneal shunt, endoscopic third ventriculostomy and endoscopic ven-

Focal tectal (3)	-	-	-
Dorsally exophytic (6)	-	-	-
Cervicomedullary (3)	1 (33.3)	-	2 (66.6)
DIPG (22)	6 (27.3)	12 (54.5)	6 (27.3)

DIPG: Diffuse intrinsic pontine glioma.

The majority of cases (17/32) were treated with intensity modulated radiation therapy (Table 4). Among all 32 patients who received radiation therapy, the treatment protocol completion rate was 90% (95%CI, 85-100). Chemotherapy in an adjuvant or salvage setting was given mainly for the DIPG subgroup and patients with leptomeningeal dissemination which was seen in 5/49 patients (10.2%) (Table 5).

Toxicity profile

Common acute grade 2 radiation induced toxicities were nausea and vomiting (30/32) and worsening of weakness (21/32). Grade 3 toxicities were nausea and vomiting (2/32) and worsening of weakness (4/32) and were treated with antiemetics and corticosteroids. Acute grade 2 otitis media was seen in one patient. Late toxicities at time of analysis were minimal and grade 2 skin pigmentation was seen in one patient. Common acute grade 3 chemotherapy induced toxicities were myelosuppression (5/23), thrombocytopenia (2/23), rash (1/23) and febrile neutropenia (5/23), of whom three had repeated episodes. No treatment related death was seen.

Response rates

Clinical response of radiotherapy \pm chemotherapy (defined as regression of cranial nerve palsies or weakness of the limbs or cerebellar symptoms for > 3 mo) was seen in 16/32 (50%) patients, confirmed by a neurologist. Radiological response was also evaluated in all patients and response rates according to RECIST were CR (0/32), PR (16/32), SD (6/32) and PD (11/32). The mean response time was 12 ± 8 mo (range: 7-30). The mean reduction of tumor volume was 50% and clinical benefit (PR + SD) was 68.7% for all patients. Clinical response of adjuvant chemotherapy was seen in 2/11 (18.1%) at the mean time of 5 mo (range: 4-18). Three months after chemotherapy, radiological PR was seen in two patients, SD in five (45.7%) and progressive disease in four cases (36.2%).

Progression free survival and overall survival

Median survival time for the whole cohort was 1.5 years and 1, 2, 3 year OS rates for the whole cohort were 51.1%, 41.9% (29/49 died) and 23.1% (Figure 2). PFS rates at 1 and 2 years were 57.3% and 38.2% respectively.

At 2 years, the OS rate for radiologically low grade (favorable) tumors was clearly high (57.1%) compared to high grade (unfavorable) in which the OS rate was 17.9% ($P < 0.001$) (Figure 3A). Furthermore, among the subgroups, two year OS rates for focal/tectal, dorsally exophytic, cervicomedullary and DIPG tumors were 60%, 33.3%, 33.3% and 13.6% respectively ($P < 0.0001$) (Figure 3B).

Two year OS rates for patients (14/30) with complete or maximal resection and patients (16/30) with incomplete resection or biopsy only were 53.8% and 27.8% respectively ($P = 0.002$) (Figure 3C).

Figure 2 Median survival time, one, two and three years overall survival rates for whole cohort. OS: Overall survival.

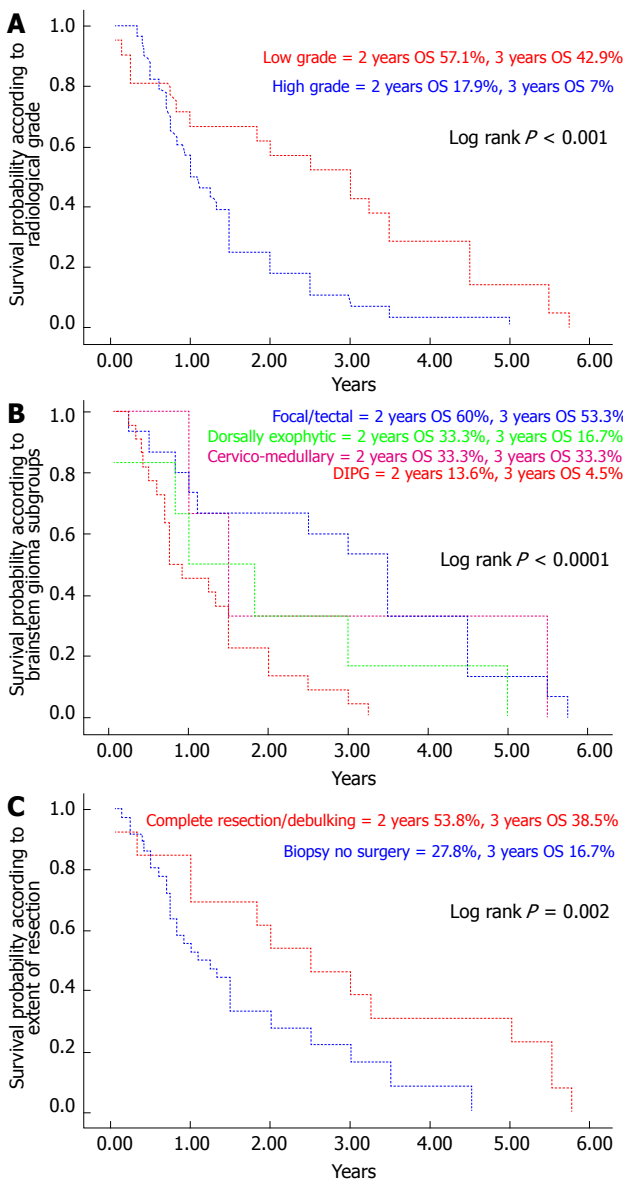

Figure 3 Kaplan-Meier curve. A: Showing overall survival probability according to grade of tumors (< low grade vs high grade); B: Showing overall survival probability according to tumor subgroups (focal/tectal vs dorsally exophytic vs cervicomedullary vs diffuse intrinsic pontine glioma); C: Showing overall survival probability according to type of resection (complete/maximal vs incomplete/biopsy). OS: Overall survival.

Figure 4 Median time of survival, one and two year overall survival rates for patients. A: Treated with radiation therapy (postoperative or radical radiation therapy); B: Treated with chemotherapy (neoadjuvant, concurrent or adjuvant/salvage). OS: Overall survival.

Median time of survival, one and two year OS rates for patients who were treated with postoperative (16/32) or radical radiation therapy (16/32) were 1.09 years, 50% and 17.9% respectively (Figure 4A). Patients treated with chemotherapy (neoadjuvant, concurrent or adjuvant/salvage) had a median survival time of 1.3 years and one and two year OS rates of 56.5% and 21.7% respectively (Figure 4B).

Multivariate analysis showed that for favorable tumors, important prognostic factors were: (1) age at diagnosis (worse for > 18 years); (2) KPS < 70; (3) histopathologically high grade; and (4) incomplete resection. Important prognostic factors for unfavorable tumors including DIPG were: (1) age at diagnosis (worse for > 18 years); (2) KPS < 70; (3) histopathologically high grade; (4) radiological high grade (necrosis on MRI); and (5) no concurrent chemotherapy, as shown in Table 6.

DISCUSSION

BSG remains a therapeutic dilemma because of the location and heterogeneous biological behavior of these tumors, as seen in our cohort, comprised mainly of children and adolescents (81.6%). A median survival time of 1.5 years, one and two year OS rates of 51.1% and 41.9%, and clinical prognostic factors in our cohort were found to be in agreement with previously reported data^[15,16]. We found no significant difference between

Table 6 Multivariate analysis of various prognostic factors in brainstem glioma

Variables	RR (95%CI)	P value
Age at diagnosis (> 18 yr)	3.0 (1.8-6.0)	0.01
KPS < 80	3.3 (1.7-5.3)	0.02
Duration of symptoms (< 60 d)	6.7 (4.3-9.4)	0.002
Histopathology (high grade)	6.1 (3.5-10.2)	0.002
MRI characteristics (presence of necrosis)	3.0 (1.9-5.9)	0.01

children, adolescent and adult BSG in clinical presentation, MRI characteristics and treatment course, but there was a significant difference in median survival times (1.8 years in children/adolescents *vs* 1.2 years in adults) which is similar to other previous pediatric studies, although clearly shorter than reported by previous studies in adult BSG. The possible explanation for shorter median survival rates in adults could be high grade histology in our cohort. Similar findings were reported by Kaplan *et al*^[15] and Reithmeier *et al*^[16].

In our cohort, the most common subgroup was DIPG, of whom 27.3% underwent biopsy and subtotal resection, which is far from routine practice. The majority of biopsy proven DIPG had high grade astrocytoma on histology, which reflects the poor prognosis and shorter median survival in DIPG cases without histopathological confirmation. In addition, DIPG were also found to be more responsive to radiotherapy with concurrent chemotherapy in our cohort, suggesting that OS rates differ with different treatment strategies. However, trials of dose escalation (> 54Gy), hyperfractionated radiation therapy and incorporation of novel chemotherapeutic agents have failed to produce any meaningful change in the outcomes^[11-14,16]. These findings are confirmatory for the heterogeneous nature of DIPG^[17].

The subgroup of focal gliomas was the second most predominant in our cohort and these tumors were clearly found to be different from DIPG; however, the clinical picture was similar to DIPG. Complete removal in the majority of cases in our cohort reflected the improvement in median survival for such cases. Focal tectal gliomas constituted a small subgroup and these cases required CSF shunts for raised intracranial pressure, as reported by other studies^[18]. However, adjuvant radiotherapy can be criticized in children as such patients have been managed with a CSF shunt or observation alone for long periods^[19].

The third most common subgroup of dorsally exophytic gliomas in our cohort were managed successfully with complete resection in the majority of patients. However, in contradiction to the literature, our patients had a shorter median survival. A possible explanation could be high grade histology and no adjuvant radiotherapy^[20,21]. A similar explanation for shorter median survival was also

justified in our cohort of cervicomedullary glioma. Non-specific BSG, including medullary astroblastoma and pontomedullary BSG, had a similar clinical behavior and treatment outcome to DIPG^[22].

In conclusion, brain stem gliomas have heterogeneous biological behavior. The DIPG subgroup had a dismal prognosis, needing more aggressive neurosurgical, radiation and chemotherapy techniques, while focal and tectal tumors were found to have a better prognosis.

COMMENTS

Background

BSG remains a therapeutic dilemma because of the location and heterogeneous biological behavior of these tumors and treatment is mainly through a multidisciplinary approach.

Research frontiers

The present study focused on a Saudi population and found that the DIPG subgroup had a dismal prognosis, requiring more aggressive neurosurgical, radiation and chemotherapy techniques.

Innovations and breakthroughs

The present study revealed that stereotactic biopsy is feasible in DIPG and radiation therapy is associated with improvement of survival in patients with DIPG.

Applications

This study provides a treatment algorithm in brainstem glioma.

Peer review

The article addressed an important disease with a poor prognosis.

Abstract

AIM: To investigate the expression of miR-210 and the role it plays in the cell cycle to regulate radioresistance in oesophageal squamous cell carcinoma (ESCC).

METHODS: MiR-210 expression was evaluated in 37 pairs of ESCC tissues and matched para-tumorous normal oesophageal tissues from surgical patients who had not received neoadjuvant therapy, and in the cells of two novel radioresistant cell lines, TE-1R and Eca-109R, using quantitative reverse transcription-polymerase chain reaction (qRT-PCR). The transient up-regulation of miR-210 expression in TE-1R and Eca-109R cells was studied using liposomes and was confirmed using qRT-PCR. The rate of cell survival after a series of radio-treatment doses was evaluated using the clone

formation assay. Flow cytometry was used to detect the changes to the cell cycle patterns due to radiation treatment. RT-PCR and Western blot were used to detect the expression of ataxia telangiectasia mutated (ATM) and DNA dependent protein kinase (DNA-PKcs) after irradiation, and the cell sphere formation assay was used to evaluate the proliferative ability of the cancer stem-like cells.

RESULTS: The level of miR-210 expression was significantly decreased, by 21.3% to 97.2%, with the average being $39.2\% \pm 16.1\%$, in the ESCC tissues of most patients (81.1%, 30 of 37 *vs* patients with high miR-210 expression, $P < 0.05$). A low level of expression of miR-210 was correlated with a poorly differentiated pathological type ($P < 0.01$) but was not correlated with the T-stage or lymph node infiltration (both $P > 0.05$). Early local recurrences (< 18 mo, $n = 19$) after radiotherapy were significantly related with low miR-210 expression ($n = 13$, $P < 0.05$). The level of miR-210 was decreased by approximately 73% (*vs* TE-1, 0.27 ± 0.10 , $P < 0.01$) in the established radioresistant TE-1R cell line and by 52% (*vs* Eca-109, 0.48 ± 0.17 , $P < 0.05$) in the corresponding Eca-109R line. Transient transfection with a miR-210 precursor increased the level of miR-210 expression, leading to a significant increase in cell survival after radiotherapy ($P < 0.05$). Twenty-four hours after radiation, the proportion of pmiR-210 cells in S phase was increased (*vs* control cells, $30.4\% \pm 0.4\%$, and *vs* untreated TE-1R cells, $23.3\% \pm 0.7\%$, $P < 0.05$ for both). The levels of DNA-PKcs (0.21 ± 0.07) and ATM (0.12 ± 0.03 , $P < 0.05$) proteins were significantly lower in the PmiR-210 cells than in control cells, but no differences were found in the levels of the corresponding mRNAs in the two cell types ($P > 0.05$ for all). Exogenous miR-210 expression decreased the diameter of pmiR-210 cell spheres (*vs* control cells, 0.60 ± 0.14 , $P < 0.05$).

CONCLUSION: MiR-210 expression is negatively correlated with the pathological type and the local survival

rate after radiotherapy, and high expression of miR-210 may reverse the radioresistance of ESCC stem-like cells.

Key words: MiR-210; Oesophageal squamous cell carcinoma; Radiation resistance; Cell cycle arrest; Stem-like cells

Core tip: A low level of miR-210 expression, which is common in oesophageal squamous cell carcinoma (ESCC) tissues, was found to be negatively correlated with the tumour pathological type and the prognosis in ESCC patients after radiotherapy, although the sample size was small. A relatively high level of *in vitro* miR-210 expression reversed the radioresistance of ESCC stem-like cells by decreasing the extent of ataxia telangiectasia mutated/DNA dependent protein kinase-dependent cell cycle arrest, failure of DNA double-strand break repair and stem cell proliferation.

Chen X, Guo J, Xi RX, Chang YW, Pan FY, Zhang XZ. MiR-210 expression reverses radioresistance of stem-like cells of oesophageal squamous cell carcinoma. *World J Clin Oncol* 2014; 5(5): 1068-1077 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/1068.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.1068>

INTRODUCTION

Oesophageal squamous cell carcinoma (ESCC) has occult symptoms and signs and is difficult to diagnose in the early stages. Radiation therapy is currently one of the main treatments for ESCC, particularly in the case of cervical and upper thoracic lesions. Even with concurrent chemoradiotherapy, the 5-year survival rate is still less than 30%, worse than those of many other squamous cell carcinomas. Local recurrences and the apparently increased radioresistance of recurrent tumours are the main reasons for treatment failure.

The mechanism of tumour resistance to radiotherapy is still unclear. There is a growing body of evidence that microRNAs (miRNAs) involved in the regulation of multiple cellular pathways are associated with radiation resistance. A number of miR-210 target genes have been identified that play roles in the cell cycle^[1], DNA repair^[2], vascular generation^[3] and tumour stem cell survival^[4]. MiR-210 was shown to be involved in the radiosensitivity of tumour cells^[5,6]. Ataxia telangiectasia mutated (ATM) is a key signalling gene in the early reaction to irradiation, which causes the double-strand break (DSB)-induced DNA damage response^[7]. ATM is a Ser/Thr kinase that phosphorylates more than a hundred proteins to orchestrate cell cycle checkpoint activity^[8-10].

However, there is no evidence that miR-210 affects the radiosensitivity in ESCC. Thus, the purpose of this study was to evaluate miR-210 expression in oesophageal cancer tissues, to explore the possibility that it participates in regulating cellular radioresistance, and to study its pos-

sible role in cell cycle regulation to explore the feasibility of miR-210 as a radiation-sensitive therapeutic target.

MATERIALS AND METHODS

Patients

This study included 37 male patients with a median age of 54 (range, 42-71) years. All of the patients had been diagnosed with ESCC by biopsy. The para-tumorous normal oesophageal tissues, which comprised the oesophageal mucosa 5 cm from the cancer tissue collection site and close to the resection margin, were normal in appearance. The tissue specimens were collected less than 15 min after resection, fixed for 30 min in liquid nitrogen and stored at -80 °C. All of the selected patients received radiotherapy or concurrent chemoradiation in 2008-2009. All of the patients received radiotherapy no more than 3 mo after surgery and were followed until a local recurrence arose or for at least 35 mo. The median follow-up time was 23.4 (range, 8.7-35.3) mo. This study was approved by the Institutional Review Board of the First Affiliated Hospital of the Medical School of Xi'an Jiaotong University.

Cell lines and cell culture

The human ESCC cell lines Eca-109 and TE-1 (a gift of the Department of Cardiothoracic Surgery, Second Military Medical University, Shanghai, China) were cultured using high-glucose Dulbecco's modification of Eagle's medium (DMEM) that was supplemented with 10% foetal bovine serum (10000 units of penicillin and 10000 µg of streptomycin per mL, all of which were purchased from Gibco Invitrogen, CA, United States). The stem-like radioresistant cell lines were created using fractionated radiation of up to 100 Gy, as previously described^[11], and were named TE-1R and Eca-109R. Cell spheres were cultured using DMEM/F12 medium (Gibco Invitrogen) that was supplemented with 2 ng/mL of epidermal growth factor and basic fibroblast growth factor (b-FGF) (all obtained from Pepro Tech Inc., NJ, United States) on 50 g/L agarose-phosphate Buffered Saline (PBS) coated plates. All of the cells were cultivated in a humidified atmosphere containing 50 g/L of CO₂ at 37 °C.

MiRNA precursor transfection

Pre-miR-210 (50 pmol; Genetimes Tech Inc., Shanghai, China) and a scrambled control (50 pmol; Genetimes Tech Inc.) were transfected into TE-1R cells growing in six-well dishes (plated at 2×10^5 cells per well 24 h before transfection), which were called PmiR-210 cells and Ctrl cells, respectively. Transfection was conducted using Lipofectamine 2000 (Invitrogen). The transfection efficiency (> 200%) at 24, 36, 48 and 72 h after transfection was determined using quantitative reverse transcription-polymerase chain reaction (qRT-PCR).

RNA extraction and real-time PCR profiling of the content of mature miRNA

The total RNA was extracted from cell lysates according

Figure 1 MiR-210 expression in selected oesophageal squamous cell carcinoma patients. The level of MiR-210 expression in an oesophageal squamous cell carcinoma tumour tissue was related to the level in that patient's para-tumorous normal oesophageal tissue.

to the manufacturer's protocol. The concentration of the RNA was determined using Ultraviolet Rays spectrophotometry (NanoDrop® ND-8000 Spectrophotometer, Thermo Fisher Scientific, CA, United States). The quality of RNA was determined by electrophoresis on a 10 g/L agarose gel. All of the RNA samples were confirmed to be non-degraded by visualisation of the distinct 28S and 18S rRNA species. The total RNA was used to synthesise first-strand cDNA. The expression of mature miRNA-210 was profiled using a real-time quantitative PCR assay (all of the kits were obtained from Fermentas, Thermo Scientific, CA, United States) as previously described^[11].

Cell irradiation and measurement of cell viability

Cells (3×10^3 cells per well in a 12-well plate) were irradiated at room temperature with 10 mV photons from a linear accelerator (Electa, WI, United States) at doses of 2, 4, 6 or 8 Gy (a uni-dose of 6 Gy for the cells that were used in the cell-sphere formation and cell-cycle analyses). The controls were handled identically as were the irradiated cells with the exception of the radiation treatment. The cells were allowed to grow for 7 d before analysis of the clones or spheres that formed.

Analysis of the cell cycle distribution

Cells were seeded in 100-mL culture flasks at a density of 5×10^5 cells per flask. After 24 h, the cells were treated with uni-dose irradiation at 6 Gy. The attached and floating cells were harvested at different time points. The cells were then suspended at 1×10^6 /mL of propidium iodide solution (3.8 mmol/L of sodium citrate; 0.05 g/L of propidium iodide and 1 g/L of Triton X-100) supplemented with RNaseB and were maintained in the dark at 4 °C. The cells were then analysed using flow cytometry.

Western blot

The cells were twice washed with phosphate-buffered solution and then directly lysed for 30 min on ice using

radio-immunoprecipitation assay lysis buffer (Beyotime Institute of Biotechnology). After centrifugation at $12000 \times g$ for 26 min, the protein concentrations were determined using a bicinchoninic acid protein assay kit (Beyotime Institute of Biotechnology, Jiangsu, China). The proteins were transferred onto nitrocellulose membranes. After blocking with 5% milk in Tris-buffered saline containing 0.5 g/L Tween-20, the membranes were incubated with anti-ATM (rabbit monoclonal antibody, 1:500, Epitomics, CA, United States), anti-DNA-PKcs (rabbit monoclonal antibody, 1:500, Cell Signaling Technology, MA, United States) and anti-glyceraldehyde-3-phosphate dehydrogenase (rabbit monoclonal antibody, 1:1000, Cell Signaling Technology). The immune complexes were detected using horseradish peroxidase-conjugated immunoglobulin G (goat anti-rabbit antibody, Cell Signaling Technology). The labelled antibodies were visualised using an enhanced chemiluminescent substrate (34079, Thermo Fisher Scientific). All of the membranes were exposed to Kodak X-OMAT X-ray film. The details of the method were previously described^[11].

Statistical analysis

The data are expressed as mean and standard deviation or standard error of the mean of the results of two or three independent experiments. Normalisation of the miRNA expression levels was obtained using the comparative DCt method (2-delta-delta computed tomography using the miR-210 expression levels in normal tissues and that of RNAU6B as references). The difference between the times of local recurrence of the groups was tested for significance using the log rank test. The clones were counted using Photoshop cs3 as previously described^[12]. After filtration through 100-µm pores and suspension in 100 µL of cold PBS, the cell spheres in three randomised images taken at $100 \times$ were compared using Photoshop cs3. Student's *t*-test was used to analyse the significance of the differences between the different treatment groups whenever applicable with the ^a*P*-value set at < 0.05 and the ^b*P*-value set at < 0.01 . The statistical analyses were performed using SPSS version 13 software.

RESULTS

A low level of miR-210 expression in ESCC tissues is related to early recurrence

In most of the ESCC patients, the level of miR-210 expression in the ESCC tissue was significantly lower than that in the para-tumorous normal oesophageal tissue from the same patient (81.1%, 30 of 37 patients *vs* patients with high miR-210 expression, $P < 0.05$). The expression levels ranged from 21.3% to 97.2%, and the average level was $39.2\% \pm 16.1\%$ in the patients with low miR-210 expression. Seven patients had a higher level of miR-210 expression in their ESCC tissues than in their normal tissues. The level of high expression ranged from 170.4%-360.8%, and the average level was $193.5\% \pm 36.2\%$ (Figure 1). A poor pathological type was significantly related to a low level of miR-210 expression in

Table 1 Clinical and pathological data and levels of miR-210 expression in the selected oesophageal squamous cell carcinoma patients

Clinical feature		n	MiR-210 expression level		Local recurrence time

^a $P < 0.05$, ^b $P < 0.01$, patients *vs* the patients with miR-210 expression. All of the patients were male, with a median age of 54 (range, 42-71) years. The level of miR-210 expression was determined using quantitative reverse transcription-polymerase chain reaction. The level of expression in the oesophageal squamous cell carcinoma tissue was compared with that in the same patient's para-tumorous normal oesophageal tissue. The endpoint of the follow-up period was when a local recurrence arose or at least 35 mo, and 18 mo was chosen to distinguish early and non-early recurrences.

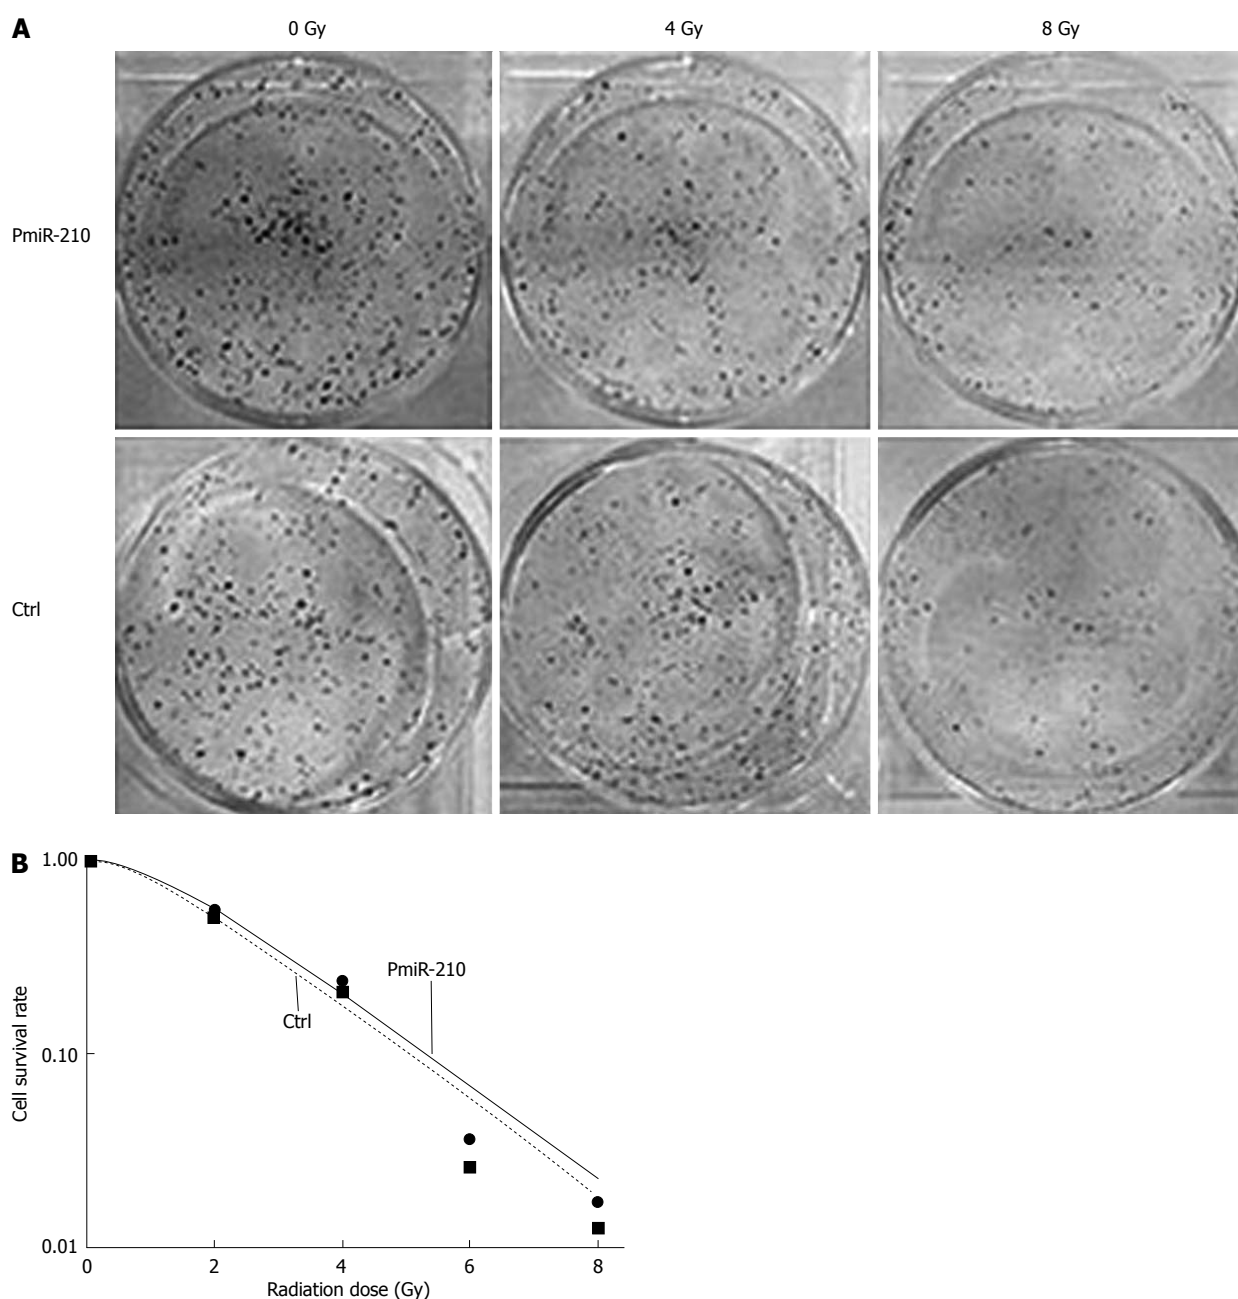

Figure 2 MiR-210 reverses the radioresistance of TE-1R cells. A: Clonal formation of TE-1R cells that were transfected with the miR-210 mimic (pmiR-210) or with a nonsense sequence (Ctrl) after irradiation at 0, 4 or 8 Gy of 10 mV X-rays. The experiments were performed in triplicate; B: Cell survival curve for TE-1R cells that were transfected with the miR-210 mimic (pmiR-210) or with a nonsense sequence (Ctrl). The cell survival rates were plotted on a logarithmic scale.

Table 2 Rates of clone formation of irradiated TE-1R cells

	D ₀	D _q	N	SF ₂
PmiR-210	1.73% ± 0.01%	1.56% ± 0.02% ^a	1.97% ± 0.03% ^a	43.62% ± 0.14% ^a
Ctrl	1.75% ± 0.02%	1.89% ± 0.13%	3.13% ± 0.07%	67.83% ± 0.16%

^a $P < 0.05$, *vs* Ctrl. PmiR-210: TE-1R cells transfected with the miR-210 mimic; Ctrl: TE-1R cells transfected with a nonsense sequence. The experiments were performed in triplicate. D₀: Mean lethal dose; D_q: Quasi-threshold dose; N: Extrapolated number; SF₂: Survival fraction after 2-Gy irradiation. The lower D₀ and N of the pmiR-210 cells compared with those of the Ctrl cells indicate a less efficient repair of radiation damage. A low SF₂ value indicates a level of high sensitivity to radiotherapy.

the ESCC tissue ($P < 0.01$, Table 1). However, there was no significant correlation between the level of miR-210 expression and the T stage ($P > 0.05$) or lymph-node infiltration ($P > 0.05$). However, early local recurrences (< 18 mo, $n = 19$) were significantly correlated with low miR-210 expression ($n = 13$, $P < 0.05$). Four patients did not experience local recurrence over the 35-mo observation period.

Up-regulated miR-210 expression reverses the radioresistance of TE-1R cells

The level of miR-210 expression was decreased by approximately 73% (*vs* TE-1, 0.27 ± 0.10 , $P < 0.01$) in radioresistant TE-1R cells and by approximately 52% (*vs* Eca-109, 0.48 ± 0.17 , $P < 0.05$) in radioresistant Eca-109R cells. Transient transfection of an miR-210 precursor into TE-1R cells led to a high level of miR-210 expression at 72 h (*vs* TE-1, > 120 times higher, $P < 0.001$), compared with that of Ctrl cells, which remained high even at 5 d (approximately 19.4 times higher, $P < 0.05$). PmiR-210 and Ctrl cells were irradiated with a series of Gy doses and a significant difference in cell clone formation at 7 d of culture was observed in the cells that had been irradiated with high dosages (Table 2, Figure 2A). A significant left-downward trend in the pmiR-210 cell-survival curve compared with that of the Ctrl cells was observed (Figure 2B). The radiobiological indices (D₀, N, SF₂) of the pmiR-210 cells that were obtained by regression of their survival curve data were lower than those of the Ctrl cells (Table 2, $P < 0.05$ for all; Table 3), indicating their higher sensitivity to irradiation.

MiR-210 transfection induces S-phase arrest caused by radiation stress

PmiR-210 and Ctrl cells were uni-irradiated with 6 Gy and then the cell cycle distribution was analysed using flow cytometry (Figure 3). There were no significant differences between the cell cycle distributions of the

Ctrl and untreated cells in terms of the proportion of cells in G₀/G₁ phase ($64.2\% \pm 0.5\%$ *vs* $61.8\% \pm 0.7\%$, $P > 0.05$), in S-phase ($23.3\% \pm 0.8\%$ *vs* $27.6\% \pm 0.5\%$, $P > 0.05$) or in G₂/M phase ($13.4\% \pm 0.4\%$ *vs* $12.1\% \pm 0.5\%$, $P > 0.05$). However, compared with that of the Ctrl cells, a significantly larger proportion of the pmiR-210-transfected cells were in S phase ($30.4\% \pm 0.4\%$ *vs* $23.3\% \pm 0.7\%$, $P < 0.05$), although no significant differences in the proportion of cells in the G₀/G₁ ($69.2\% \pm 0.7\%$ *vs* $62.5\% \pm 0.6\%$, $P > 0.05$) or G₂/M ($12.4\% \pm 0.5\%$ *vs* $20.2\% \pm 0.3\%$, $P > 0.05$) phases were observed. The levels of DNA-pkcs and ATM mRNAs and proteins were also analysed using RT-PCR and Western blot, respectively, (Figure 4) and no differences in the relevant mRNA levels in the two cell types were found ($P > 0.05$ for all), but the levels of the proteins were significantly lower in the pmiR-210 cells than in the Ctrl cells, with the DNA-pkcs level at 0.21 ± 0.07 and the ATM expression level at 0.12 ± 0.03 ($P < 0.05$ for both) in the former cells.

Up-regulated miR-210 expression reduces the size of the spheres formed by the stem-like cells

The spheres that had the various cell types had developed in serum-free medium at 7 d after irradiation were compared (Figure 5). The diameters of the cell spheres that pmiR-210 transfected TE-1R cells formed were smaller than those formed by Ctrl cells (0.60 ± 0.14 , $P < 0.05$) or by untreated TE-1R cells (0.25 ± 0.08 , $P < 0.01$).

DISCUSSION

MiR-210 is highly expressed in glioma^[13], melanoma^[14,15], renal cell carcinoma^[16], pancreatic cancer^[17,18], breast cancer^[19-21] and lung cancer^[22] that are generally associated with a poor disease-free survival rate or poor overall survival rate. The up-regulation of miR-210 expression directly suppressed Bcl-2 adenovirus E1B 19 kDa-inter-

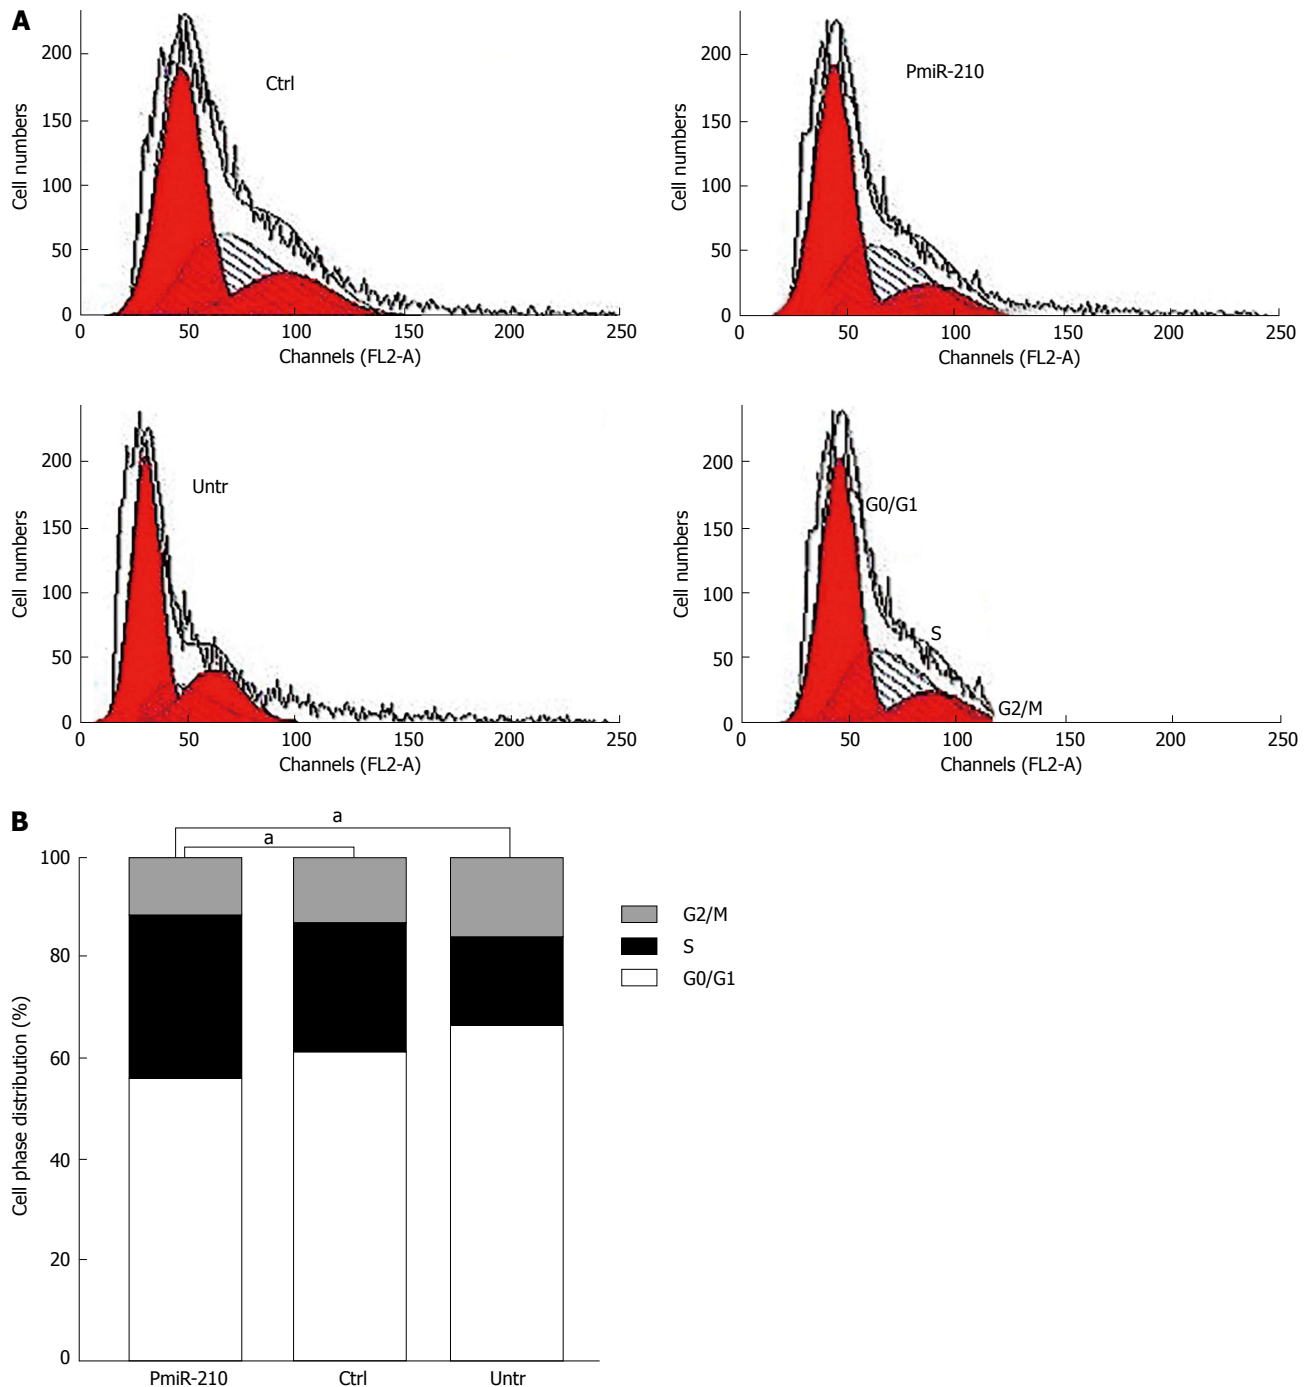

Figure 3 S-phase arrest in miR-210 up-regulated radioresistant oesophageal squamous cell carcinoma cells. acting protein 3 (BNIP3) expression to maintain the survival of neural progenitor cells^[4] and knocking down the expression of miR-210 in combination with radiotherapy was found to have enhanced its anti-tumour effect in human hepatoma xenografts^[5]; and moreover, miR-210 expression promoted more efficient DSB repair^[7]. Unexpectedly, the significantly lower expression of miR-210 in ESCC tissues was observed in paired tumour/normal tissue sets in our study. In this study, we observed a low level of miR-210 expression in 81.1% of the tumours of

male ESCC patients than in the isogenically paired tissues ($P < 0.01$), which was correlated with the early local recurrence after surgery followed by radiotherapy ($P < 0.05$). Our results were consistent with those of some of the other ESCC studies^[23,24] in which compared to that of normal oesophageal tissue, a low level of miR-210 expression in ESCC was correlated with either poorly differentiated carcinoma or a poor prognosis. Although the sample size ($n = 37$) is not large, all of our selected patients received radiotherapy after surgery, which most

Figure 4 Double-strand break-related changes in protein expression in miR-210 up-regulated radioresistant oesophageal squamous cell carcinoma cells. **A:** The expression levels of ataxia telangiectasia mutated (ATM) and DNA dependent protein kinase (DNA-PKcs) in transfected and control TE-1R cells. The mRNA levels were determined using reverse transcription-polymerase chain reaction. The protein levels were determined using Western blot. The experiments were performed in triplicate. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as the internal reference; **B:** Histogram showing the levels of ATM and DNA-PKcs protein expression in transfected and control TE-1R cells. ^a $P < 0.05$, pmiR-210 vs Ctrl.

Figure 5 Cell sphere formation of pmiR-210 cells after irradiation (bar: 100 μ m). PmiR-210: Transfected with pmiR-210; Ctrl: Transfected with a nonsense sequence; Untr: Untreated. Cell spheres were allowed to form in serum-free medium for 7 d after 4-Gy radiation. The diameter and number of pmiR-210 cell spheres were the smallest among those of the three types of cells. Bar, 100 μ m.

closely resembles the clinical reality. Obviously, the non-randomised patient selection will lead to some bias in our observations and might have caused false-positive outcomes in this study. Therefore, we used two radioresistant cell lines, TE-1R and Eca-109R, to verify the relationship between radioresistance and the level of miR-210 expression.

We found that miR-210 expression was decreased in both of the radioresistant cell lines, by 73% (0.27 ± 0.10 , $P < 0.01$) in TE-1R cells and by 52% (0.48 ± 0.17 , $P < 0.05$) in Eca-109R cells. These results confirmed our result that the down-regulation of miR-210 expression was correlated with bad local tumour control after surgery followed by radiotherapy. We then up-regulated the expression of miR-210 by transiently transfecting the miRNA-210 precursor in the more radioresistant TE-1R cells in which miRNA-210 expression was more down-regulated to analyse the relationship between miR-210

expression and radiosensitivity. The results showed that up-regulated miR-210 expression could reverse the radioresistance of TE-1R cells compared with the effect of transfection with the scrambled sequence (Ctrl cells, Figure 2, Tables 2 and 3). MiR-210 has been previously shown to repress or stimulate cell proliferation, depending on the cellular model. MiR-210 targets proteins that are crucial for cell cycle progression, such as E2F3, FGFR139, or HOXA1, to inhibit cellular growth. In contrast, miR-210 also targets the Myc-antagonist MNT41 to promote cell cycle progression in some types of cancer cells. Lung adenocarcinoma (A549 or H1975) cells that stably expressed miR-210 did not show any alteration in their proliferation rate but a high level of miR-210 expression after irradiation significantly reduced the apoptosis rate of A549 cells and improved their DSB repair rate^[6]. The lack of radiosensitisation in prostate cancer cells treated with an miR-210 inhibitor under an-

oxic conditions suggested that the extent of inhibition of miR-210 expression may depend on the type of cancer and/or the degree and duration of hypoxia^[6]. Our results regarding ESCC were consistent with those of another study, in which miR-210 was found to inhibit cancer cell survival and proliferation by inducing cell death^[24].

Consistent with the observed miR-210-mediated sensitivity to radiation, analysis of the cell cycle distribution of the cell populations revealed an increase in S-phase arrest in pmiR-210 cells compared with Ctrl TE-1R and untreated TE-1R cells after irradiation (Figure 3). In contrast, in another study, no significant changes were observed in the cell viability rate or the cell cycle profile when the expression of miR-210 was suppressed^[3]. Transfection with an miR-210 inhibitor was shown to decrease the rates of cell viability and accumulation of CAKI-2 cells in the G₂ phase of the cell cycle^[25]. However, it was previously reported that miR-210 could induce cell-type specific proliferation. In certain transformed cells, inhibiting the expression of the c-Myc antagonist and miR-210 revealed a direct target, MAX-binding protein (MNT), which was demonstrated to be functionally important in controlling the progression of the cell cycle through the reciprocal up-regulation of c-Myc activity. Increasing the level of miR-210 expression in various tumours could, through targeting E2F3 and activin receptor 1b (ACVR1b), activate G₁/S-phase cell cycle progression and increase the rate of cellular proliferation^[26]. In other types of tumours, depending on the contextual cues, miR-210 could target a different set of mRNAs, such as HOXA3 and HOXA9, and contribute to the reduction of the rate of cell proliferation^[27]. The S-phase arresting effect observed under our conditions, which contradicted the results of another study of cell cycle arrest in the G₁/G₀ and G₂/M phases^[24], might be explained by the fact that the function of miR-210 has to date been studied within 3 d following transient transfection using a relatively high concentration of an miRNA precursor. The true effect of increased miR-210 expression on the cell cycle may be observed during shorter periods, as was found in arsenic trioxide-treated tumour cells that were arrested at the G₂/M phase of the cell cycle at 30 h post-treatment and which overrode the G₂/M boundary at 48 h^[28].

To understand the potential of increased miR-210 content on the DSB repair function of TE-1R cells, changes in the ATM and DNA-PKcs levels were evaluated in pmiR-210 and Ctrl cells after irradiation. ATM and DNA-PKcs play different roles in the DNA damage response pathway (DDR), but both of them are activated by the occurrence of DSB; they have common targets in the DDR pathway and the absence of either kinase results in faulty DSB repair. The absence of ATM allows timely repair, which nevertheless, is incomplete. In contrast, the absence of DNA-PKcs leads to slower repair, which in turn gives rise to the accumulation of simple and complex chromosomal reorganisations^[7]. Consistent with the miR-210-mediated sensitivity to radiation, the levels of ATM and DNA-PKcs proteins were surprisingly significantly lower in PmiR-210 cells that were sub-

jected to 6 Gy compared with those of Ctrl cells (DNA-PKcs, 0.21 ± 0.07 and ATM, 0.12 ± 0.03 , $P < 0.05$ for all), but no differences were found in the corresponding mRNA levels of the two cell types ($P > 0.05$ for all) (Figure 4) under our conditions. In contrast, it has been shown that miR-210 expression promoted more efficient DSB repair in A549 cells^[6]. MiR-210 has been shown to repress mitochondrial metabolism by targeting a number of proteins that are crucial for normal tricarboxylic acid cycle and electron transport chain activity^[29]. To date, there is no evidence that miR-210 targets the 3'-UTR of ATM or DNA-PKcs mRNAs. MiR-101 can bind to the 3'-UTR of DNA-PKcs and ATM mRNAs^[3]. However, this miRNA targeted not only the 3'-UTR but also the 5'-UTR and coding sequences, which were still present in the expression construct in which only the 3'-UTR of ATM had been substituted, allowing ATM expression to be regulated by miR-181a, miR-326, and miR-345^[30]. Thus, there is a potential for miR-210 to target the 5'-UTR or coding sequences of their mRNAs to regulate the expression of the ATM or DNA-PKcs proteins.

A radioresistant cell is considered a type of cancer stem-like cell. Thus, we examined the effect of miR-210 expression on the sphere-formation ability of these stem cells, which is a widely accepted method to determine the proliferative ability of stem cells. The up-regulation of miR-210 content directly suppressed the expression of BNIP3 to maintain the survival of neural progenitor cells under hypoxic conditions^[4]. In contrast, it was observed that miR-210 expression inhibited the formation of cell spheres by ESCC radioresistant TE-1R cells (Figure 5), which is first reported here. This result suggested that miR-210 expression reversed the radioresistance of ESCC cancer stem cells.

Taken together, the results of this study demonstrated that a low level of miR-210 expression was common in the tumours of ESCC patients and that the level of miR-210 expression was negatively correlated with a poorly differentiated pathological type and rate of local control after radiotherapy. Increased miR-210 expression reversed the radioresistance of stem cell-like cells of ESCC by decreasing the ATM and DNA-PKcs-dependent cell cycle arrest and the rates of DSB repair and stem cell proliferation. The mechanisms underlying these processes must be determined in future investigations.

ACKNOWLEDGMENTS

We are grateful to all of the technicians for their assistance with the radiation-treatment experiments, to Prof. Chen for the use of the Translational Medicine Centre laboratory and to Prof. Wang for help with the statistical analyses.

COMMENTS

Background

The mechanism underlying tumour resistance to radiotherapy is unclear. There is a growing body of evidence showing that microRNAs are involved in the

regulation of multiple cellular pathways that are associated with radiation resistance. A number of miR-210 target genes that have been identified are involved in the cell cycle, DNA repair, vascular generation and tumour stem cell survival, most of which are important processes in the development of radioresistance.

Research frontiers

MiR-210 appears to be involved in radiosensitivity of tumour cells. However, there is no evidence that miR-210 affects the radiosensitivity of oesophageal squamous cell carcinoma (ESCC) cells. In this study, the authors demonstrated that miR-210 may affect the prognosis of radiotherapy and participate in the regulation of radioresistance in ESCC cells.

Innovations and breakthroughs

Recent reports have highlighted the importance of miR-210 expression in hepatomas and lung cancer. This is the first study to report that miR-210 is expressed at a low level in ESCC and that the level of its expression is correlated with the prognosis of ESCC patients treated with radiotherapy. Furthermore, the results of the authors *in vitro* studies suggested that this miRNA may be an important regulator of radioresistance in ESCC.

Applications

By demonstrating that miR-210 regulates the radioresistance of ESCC cells, this study presents a novel target for reversing the radioresistance in relapsed ESCC.

Terminology

The radioresistance that develops during radiotherapy leads to an increased number of cancer stem cells, which appear to be concentrated by therapeutic selection or radiation induction. Radioresistant cells are also called cancer stem-like cells. These cells have been found to have a distinctive cell cycle distribution pattern and a high efficient mechanism of DNA double-strand break repair.

Peer review

It is meaningful in that miR-210 is explored in ESCC cells with radiation resistance.

Abstract

AIM: To evaluate the M1 and M2 monocyte phenotype in patients with non-small cell lung cancer (NSCLC) compared to controls. Also, to examine the expression of Th1 and Th2 cytokines in plasma of NSCLC vs controls.

METHODS: Freshly prepared peripheral blood mononuclear cells samples were obtained from patients with NSCLC (lung adenocarcinoma and squamous cell lung carcinoma) and from non-cancer controls. Flow cytometry was performed to investigate M1 and M2 phenotypes in peripheral monocytes (classical monocytes CD14+, CD45+ and CD16-) using conventional surface markers. Th1 and Th2 cytokine production was also

analysed in the plasma using cytometric bead array technique.

RESULTS: There were no significant difference in expression of M1 (HLA-DR) and/or M2 markers (CD163 and CD36) markers on classical monocytes in patients with NSCLC compared to non-cancer controls. Expression of CD11b, CD11c, CD71 and CD44 was also shown to be similar in patients with NSCLC compared to non-cancer controls. Th1 and Th2 cytokines [interleukin (IL)-1 β , IL-2, IL-4, IL-5, IL-8, IL-10, IL-12 (p70), tumor necrosis factor (TNF)- α , TNF- β , and interferon- γ] analysis revealed no significant difference between patients with NSCLC and non-cancer controls.

CONCLUSION: This study shows no alteration in peripheral monocyte phenotype in circulating classical monocytes in patients with NSCLC compared to non-cancer controls. No difference in Th1 and Th2 cytokine levels were noted in the plasma of these patients.

Key words: Lung cancer; Monocyte; Phenotype; Polarisation; Tumour progression; Tumour regression

Core tip: Monocytes perform a critical role in immune system and have similar phenotype as seen in M1 (classically activated) and M2 (alternatively activated) tumour-associated macrophage. Nevertheless, monocyte phenotypes in human lung cancer patients are not fully understood and further investigation are really needed. Our study examines the M1 and M2 monocyte phenotypes in patients with non-small lung carcinoma [non-small cell lung cancer (NSCLC)] compared to non-cancer controls. This study indicated that freshly isolated peripheral blood monocytes from patients with NSCLC do not show an altered phenotype and/or cytokines secretion. These outcomes might enhance the knowledge regarding the connections between monocyte-macrophage phenotype and tumour progression.

INTRODUCTION

Lung cancer is now one of the most common cancers in the world and, as the leading cause of cancer mortality, is responsible for about 1.4 million deaths worldwide annually^[1]. Despite incremental advances in treatment strategies, the prognosis for lung cancer remains poor, with only 10%-15% of patients surviving five years or longer^[1,2]. Further understanding of the immunology of lung cancer may enable the development of immune-modulatory strategies beyond those in current use, such as targeted monoclonal antibodies to specific cellular receptors.

Monocytes are an important part of the innate immune response to cancer. The notion that the immune system has a protective role in tumour development is well established^[3], with recent work also suggesting a converse role in promoting tumour initiation and progression^[4]. Previous studies looking at monocytes in a range of different cancer types have demonstrated conflicting results regarding monocyte phenotype and function in different cancer microenvironments. Studies in patients with lung, breast and other cancers have described hindered monocyte function^[5,6], whereas Mariotta *et al*^[7] suggested that non-small lung carcinoma (NSCLC) does not affect monocyte adherence and phagocytosis in lung cancer patients compared to healthy controls. Other studies demonstrated that monocytes are capable of both inhibiting and stimulating tumour growth^[8].

Monocytes can be characterised into classical monocyte (pro-inflammatory) and non-classical monocyte (anti-inflammatory) phenotype, both of which have been detected in circulating peripheral blood mononuclear cells (PBMC)^[9,10]. Monocytes are known to differentiate into tissue macrophages. Classical monocytes (CD14⁺⁺/CD16) identified to differentiate into M1 macrophage, while non-classical monocytes (CD14⁺/CD16⁺⁺) differentiate into M2 macrophage^[11]. M1 works as an antigen-presenting cell and has a vital role in immune activation and function^[12]. In contrast, M2 is known to be associated with poor antigen presentation producing factors that suppress T cell proliferation and activity^[12]. Although, the main source of tissue macrophages is classical monocytes, the majority of the macrophages within the tumour area have been identified as M2 macrophage^[11]. However, a study has reported that classical monocytes can differentiate into M2 macrophage^[13].

There is a controversy regarding monocyte differentiation and effect in tumour microenvironment. Therefore in this current study, freshly isolated un-stimulated classical monocytes were used to ascertain the phenotypic changes in patients with NSCLC compared to non-

cancer controls. To the best of our knowledge this is the first study that has analysed classical monocytes from freshly isolated PBMC to give a better understanding of the NSCLC, monocyte phenotype and function and Th1/Th2 plasma expression.

MATERIALS AND METHODS

Study participants

Blood was obtained from 30 patients undergoing diagnostic bronchoscopy for investigation of NSCLC recruited through the Department of Respiratory and Sleep Medicine, Austin Health, Heidelberg, VIC, Australia. Twenty non-cancer control samples were obtained from subjects undergoing diagnostic bronchoscopy for investigation of breathlessness, or chronic cough and haemoptysis, or benign lung lesions. Ethics committee approval was received from Austin Health Ethics Committee, and informed consent of all participating subjects was obtained. Patient demographic information is presented in Table 1. Staging was applied in this study using the new TNM (tumour, node, metastases) staging system (7th edition) for lung cancer^[14].

PBMC

Venous blood was collected in heparinised tubes and PBMC isolated by Ficoll-Paque density gradient centrifugation (GE Healthcare Bio-sciences, Uppsala, Sweden). Complete blood count (CBC) was completed for all blood samples using Beckman Coulter (AcT 5 blood differentiation, RMIT Hematology Department, Melbourne) (Fullerton, CA, United States). PBMC washed twice with PBS (phosphate buffered saline) and then resuspended in RPMI completed media (2% Hepes buffer, 0.1 mmol/L 2-mercaptoethanol, 100 U/mL penicillin, 100 µg/mL streptomycin, 2 mmol/L glutamine and 10% fetal calf serum) (Sigma, St. Louis, MO). All samples were stored at -80 °C until use.

Monocytes phenotype analysis by flow cytometry

Flow cytometry was used to assess classical monocytes expression of CD14, CD45, CD71, CD11b, CD44, CD16 and CD11c (BD Pharmingen™, United States) as well as the M1 marker HLA-DR (BD Pharmingen™, United States) and the M2 markers CD163 and CD36 (BD Pharmingen™, United States). Cells were stained with antibodies directly conjugated to fluorescent probes for 30 min at 4 °C in 2% (w/v) BSA/PBS. Cells were washed and analyzed by flow cytometry (FACS Canto, BD Biosciences, San Jose, CA, United States). 10⁶ cells were stained with various combinations of antibodies for 40 min in the dark on ice. Purity of classical monocytes was assessed according to CD14, CD45 and CD16 expression by flow cytometry. At least 5000 cells were collected and analysed (BD FACS Canto BD Biosciences, San Jose, CA, United States). All analysis was completed within the RMIT Flow Cytometry Facility, Bundoora, Melbourne. All quadrants were set up according to matched isotype

control antibodies and all results are shown as surface expression (%SE) and mean fluorescence intensity (MFI).

Cytometric bead array

The Human Th1/Th2 11plex Ready-to-Use FlowCytomix Multiplex (eBiosciences, United States) was applied to detect the level (pg/mL) of Th1/ Th2 cytokines including interleukin (IL)-1 β , IL-2, IL-4, IL-5, IL-8, IL-10, IL-12 (p70), tumor necrosis factor (TNF)- α , TNF- β , and interferon (IFN)- γ in plasma samples of patients with primary lung cancer and non-cancer controls, according to the manufacturer's instructions (Human Th1/Th2 11plex RTU FlowCytomix Kit). Fluorescence was analysed using flow cytometry (FACS Canto, BD Biosciences, San Jose, CA, United States) and cytokine levels were determined using the BMS FlowCytomix Software manual within the RMIT Flow Cytometry Facility, Bundoora, Melbourne.

Statistical analysis

Experiments were performed in triplicate. Mean values \pm standard error (SEM) were compared using the one way ANOVA (GraphPad Prism 6) with *P*-values \leq 0.05 was considered to be significant.

RESULTS

Underlying CBC was investigated in patient groups to verify that the patients has significant underlying medical condition *e.g.*, infection, which could results in monocyte phenotype alteration. The total mean number of white blood cells (WBC) in NSCLC patients was significantly higher than non-cancer controls. The mean values of all WBC types (except basophile cells) and RBCs were higher in patients with NSCLC compared to non-cancer controls. However, the mean values of all WBC types and RBCs were within

the normal range in both groups (Table 2). In flow cytometry results, there were no statistically significant differences in M1 marker (HLA-DR), M2 markers (CD163 and CD36) and (CD11c and CD44) in patients with NSCLC compared to non-cancer controls. Both %SE and MFI expression of surface markers showed similar values. CD11b and CD71 expression was also shown to be similar between patient groups.

No difference in HLA-DR, CD163 and CD36 expression in patients with primary lung cancer compared to non-cancer controls

Classical monocytes were gated based on forward scatter (FSC) and side scatter (SSC) profiles within patient groups and based on the expression of CD14, CD45 and CD16 markers. Results show that there were no significant differences in %SE (*P* = 0.155) and MFI (*P* = 0.51) of HLA-DR (M1 marker) expression in patients with NSCLC compared to non-cancer controls. The expression of HLA-DR did not differ depending on tumour progression, as there were no significance differences between early and/or advanced lung cancer criteria (Figure 1). In addition, flow cytometry analysis showed there were no significant differences in the %SE (*P* = 0.505) and MFI (*P* = 0.39) of CD163 (M2 marker) in NSCLC patients compared to non-cancer controls. We also showed that there were no significant differences in the %SE (*P* = 0.160) and MFI (*P* = 0.17) of CD36 (M2 marker) staining between the two groups. Again, the expression of CD163 and CD36 showed no difference in patients with more advanced compared to early lung cancer (Figure 2).

No difference in CD11b, CD71, CD11c and CD44 expression

The %SE and MFI of CD11b, CD71, CD11c and CD44

A-F: Representative flow cytometry dot plots from PBMC stained against CD14, CD45 and CD16 and then co-stained with HLA-DR, CD163 and CD36 on patients with non-small cell lung cancer (red colour) and non-cancer controls (green colour).

Figure 2 HLA-DR, CD163 and CD36 expression on (CD14+/CD16-) blood classical monocytes in patients with primary non-small cell lung cancer compared to controls. Summary graphs show the mean values of MFI \pm SEM of (A) HLA-DR, (B) CD163 and (C) CD36 markers from patients with non-small cell lung cancer (NSCLC) vs non-cancer controls.

Figure 3 CD11b, CD11c, CD71 and CD44 expression on (CD14+/CD16-) blood classical monocytes in patients with primary non-small cell lung cancer compared to controls. Graphs show the mean values of MFI \pm SEM of (A) CD11b, (B) CD11c, (C) CD71 and (D) CD44 markers from patients with non-small cell lung cancer vs non-cancer controls.

were similar between patient groups. The %SE and MFI of the myeloid marker CD11b marker was not different between cancer and non-cancer control subjects: %SE ($P = 0.58$), MFI ($P = 0.61$). Also CD71 results indicated that there were no significant differences in the %SE ($P = 0.97$) and MFI ($P = 0.41$) of the transferrin receptor marker in patients with NSCLC compared to non-cancer controls.

CD11c results showed that there were no significant difference in the %SE ($P = 0.93$) and MFI ($P = 0.20$) of the CD11c in patients with NSCLC compared to non-cancer controls. In addition, CD44 results revealed that there were no significant differences in the %SE ($P = 0.50$) and MFI ($P = 0.53$) of the CD44 marker in NSCLC patients compared to non-cancer controls. The graphs (Figure

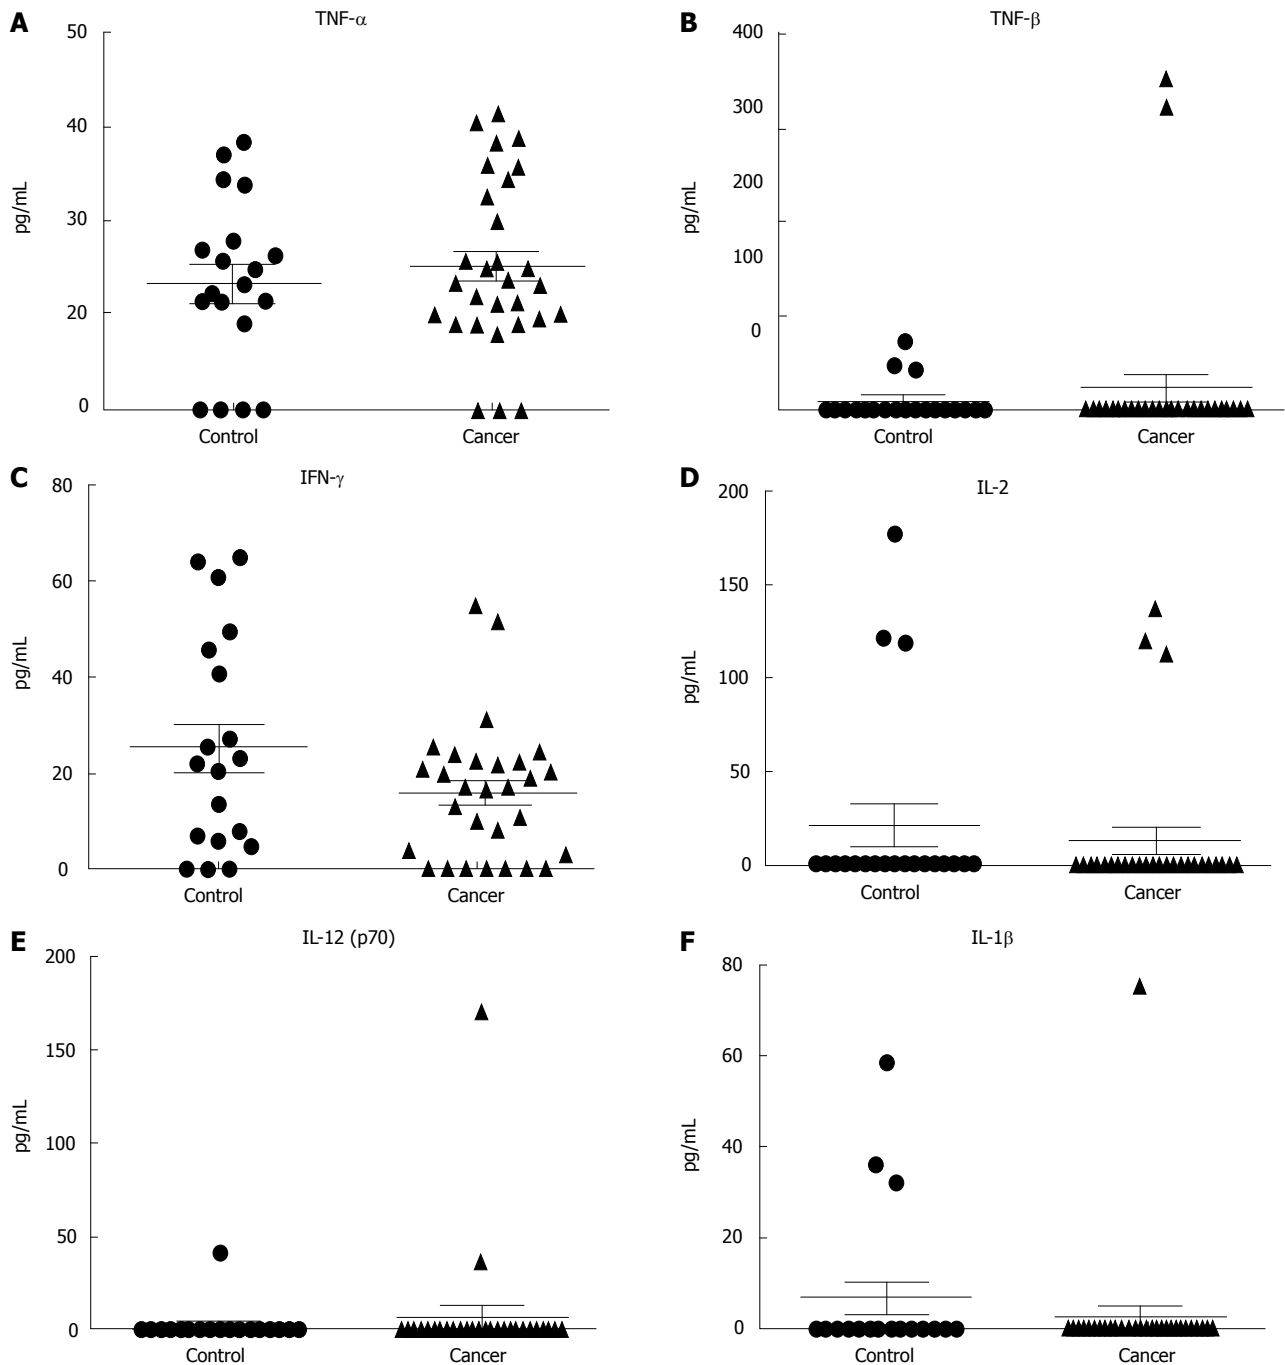

Figure 4 Th1 cytokine secretion profiles in plasma of patients with non-small cell lung cancer compared to controls. Whole plasma was analysed for (A) TNF- α , (B) TNF- β , (C) IFN- γ , (D) IL-2, (E) IL-12 (p70) and (F) IL-1 β by cytometric bead array technique using flow cytometry. Data was analysed using the FCAP Array™ v3.0.1 Software (BD Biosciences) and results are expressed as mean (pg/mL) \pm SEM. IL: Interleukin; TNF: Tumor necrosis factor; IFN: Interferon.

3) show MFI \pm SEM of all the markers (CD11b, CD71, CD11c and CD44) in classical monocytes from non-cancer controls and cancer patients (%SE results not shown).

No significant difference in plasma levels of Th1/Th2 in patients with primary lung cancer compared to non-cancer controls

Cytokine analysis revealed no significant difference in Th1/Th2 cytokines plasma levels in patients with primary lung cancer compared to non-cancer controls (Fig-

ures 4 and 5). Monocytes are known to produce several cytokines, chemokines including IL-1 β , IL-2, IL-4, IL-5, IL-8, IL-10, IL-12 (p70), TNF- α , TNF- β , and IFN- β . Cytokines were analysed in patients with NSCLC and non-cancer controls by CBA analysis. Cytokines that were detectable in patient plasma samples included Th1 cytokines TNF- α , TNF- β , IFN- β , IL-2, IL-12 (p70), IL-1 β and Th2 cytokines IL-4 and IL-5 showed no significant differences between patients with NSCLC compared to non-cancer controls.

Figure 5 Th2 cytokine secretion profiles in plasma of patients with non-small cell lung cancer compared to controls. Whole plasma was analysed for (A) IL-8, (B) IL-10, (C) IL-5 and (D) IL-4 by cytometric bead array technique using flow cytometry. Data was analysed using the FCAP Array™ v3.0.1 Software (BD Biosciences) and results are expressed as mean (pg/mL) ± SEM.

DISCUSSION

The concept that the immune system has a protective role in tumour development is well established^[3]. Recent work has demonstrated that the immune system can both prevent tumour formation but potentially function to promote tumour initiation and progression^[4]. In particular, immune cells such as blood monocytes can function differently depending on the cancer types^[8]. While some studies indicated at monocyte function in cancer patients within normal range^[7,15], other studies have shown impairment in monocyte function^[6].

In this study we demonstrated that the phenotype of freshly blood classical monocytes from patients with NSCLC is not altered and does not show skewing from a pro-tumour (M1) to an anti-tumour (M2) phenotype. There were no significant differences in expression of M1 marker (HLA-DR), M2 markers (CD163 and CD36), CD11c and CD44 marker, myeloid marker CD11b and/or transferrin receptor CD71 in patients with NSCLC compared to non-cancer controls. In addition, there were no significant differences in the secretion of Th1/Th2 cytokines between NSCLC patients and non-cancer controls.

M1 phenotype was assessed here using HLA-DR. HLA-DR molecule plays a vital role in the immune re-

sponse by regulating the interaction between antigen-presenting cells including monocytes^[16,17]. It has been described as an M1 marker in the monocyte-macrophage system^[18]. Some studies have reported reduced HLA-DR expression on blood monocytes in human cancers^[5,19]. As well as examining M1 phenotype, M2 phenotype markers (CD163 and CD36) were used to investigate skewing from M1 to M2 markers on blood classical monocytes in patients with NSCLC. CD163 is a scavenger receptor that plays a major role in the anti-inflammatory response and has been identified as a M2 marker^[20,21]. CD36 is also expressed on monocytes and is involved mainly in phagocytosis^[21,22]. Sugai *et al.*^[23] studied the alteration of monocyte characteristics by examining the intracellular expression of IL-10 and IL-12 cytokines^[23]. They found that patients with advanced gastric cancer had different monocyte phenotypic characteristics compared to those with early stage cancer and non-cancer control subjects^[23]. In our study, there were no significant differences in expression of CD163 and CD36 between non-cancer controls and NSCLC patients. Also there was no apparent influence of tumour stage upon expression of these markers. These results when viewed in the context of previous studies raises questions regarding the impact of experimental design such as culturing and the use of molecules like

lipopolysaccharide (LPS) on monocyte polarisation and function.

CD11b and CD11c are myeloid cell markers that are expressed on monocytes and macrophages^[24]. CD11b has been shown to play a major role in many functions of myeloid cells including adhesion, migration, chemotaxis and phagocytosis^[24,26]. In this study we therefore investigated the effect of NSCLC on the monocyte expression of CD11b and CD11c. There were no significant differences in expression of CD11b and CD11c in NSCLC patients compared to non-cancer controls. These results are consistent with Mariotta *et al*^[7] study outcomes, which suggested NSCLC does not affect monocyte adherence and phagocytosis in lung cancer patients compared to healthy controls^[7].

Another marker that was examined was transferrin receptor (CD71). CD71 is known to be associated with rapidly proliferation cells such as cancer cells and plays a major role in cell growth and DNA synthesis, proliferation and cell survival^[27,28]. Increased CD71 expression has been demonstrated in cancer patients including lung cancer in lung tissue and BALF (bronchoalveolar lavage fluid) but not in blood serum^[28,29]. Dowlati *et al*^[28] investigated soluble CD71 in the serum of NSCLC patients. They verified no difference in the level of secreted CD71 in blood serum between NSCLC and control groups^[28]. Similar to this outcome we demonstrated that there were no significant differences in surface expression of CD71 on classical monocytes in NSCLC patients compared to non-cancer controls.

CD44 expression was also investigated in this study as it has been suggested a potential marker of tumour initiation in lung cancer. Elevated CD44 expression has been observed in the serum of cancer patients such as gastric and renal cancer^[30,31]. However, another study showed that NSCLC does not influence CD44 expression in the serum of NSCLC patients compared to benign lung disease^[15]. Similarly, this study revealed no significant difference in surface expression of CD44 on classical monocytes in NSCLC patients compared to non-cancer controls.

The presence of cytokines is essential for immunity initiation. Th1 cells have been found to play a major role in anti-tumour immunity and stimulation of cell-mediated responses. Pro-inflammatory cytokines such as TNF- α and IFN- γ are known to stimulate Th1 cells. In contrast, Th2 cells are known to act as the helper cells that influence B-cell development and produce anti-inflammatory cytokines such as IL-4 and IL-10^[32,33]. Analysis of Th1 and Th2 cytokines in the plasma revealed no differences in NSCLC patients in compared to non-cancer controls. Similarly, Gürsel *et al*^[34] also observed no differences in TNF- α concentration between pleural effusion and serum in patients with cancer^[34]. Although many studies have not looked at specific cytokine profiles in lung cancer, it has been shown that freshly prepared monocytes do not show any differences in pro-inflammatory and anti-inflammatory cytokine responses except IL-12 (p70)

in endometrial cancer patients compared to controls^[6].

Although the findings of this study are interesting, there are some limitations including an inability to compare results from subtypes within NSCLC grouping as all patients samples were lung adenocarcinoma and squamous cell lung carcinoma and no large cell lung carcinoma. Also the majority of samples were from patients with advanced stage disease, so we could not confidently address the question of whether the NSCLC influences monocyte function and polarisation changes with tumour progression. In future studies, examining monocyte polarisation and function in non-cancer controls *vs* lung cancer should be done on all monocytes subset by using freshly un-stimulated monocytes as well as cytokine treated monocytes at the same time to observe any variation that may occur. Also other lung cancer subtypes should be considered to inspect if they have any potential role in altering monocyte functions and phenotypes.

Our results demonstrate that freshly isolated peripheral blood monocytes from patients with NSCLC (lung adenocarcinoma and squamous cell lung carcinoma) do not show an altered phenotype and/or cytokines secretion. Therefore, these results suggest that peripheral classical monocytes are not altering into M2-like phenotype in bloodstream. More studies are needed to investigate the connections between monocyte-macrophage phenotype polarisation and tumour progression associated with lung cancer.

COMMENTS

Background

Lung cancer is a common cancer that has high incidence and death rates. Monocytes play an important role in the immune response against tumour cells including lung tumour cells. Diverse monocyte phenotypes were defined previously and they act differently to tumour cells.

Research frontiers

The role of monocyte phenotype in human lung cancer patients is conflicting and still need further investigations. More studies are needed to investigate the connections between monocyte-macrophage phenotype polarisation and tumour progression associated with lung cancer.

Innovations and breakthroughs

Previous studies highlighted the importance of monocyte phenotype and function in patient with cancer including lung cancer. This is the first study that has broadly analysed classical monocytes to give a better understanding of the lung cancer, monocyte phenotype and some functions.

Applications

This study suggests that there is no monocyte-specific systemic impairment in patients with lung cancer (in particular, lung adenocarcinoma and squamous cell lung carcinoma subtypes).

Terminology

Monocytes are immune cells that are known to play an important part of the innate immune response to cancer.

Peer review

This is an interesting study. Good design and analysis. Good writing and focus.

Abstract

AIM: To show a new paradigm of simultaneously testing whether breast cancer therapies impact other causes of death.

METHODS: MA.14 allocated 667 postmenopausal women to 5 years of tamoxifen 20 mg/daily \pm 2 years of octreotide 90 mg, given by depot intramuscular injections monthly. Event-free survival was the primary endpoint of MA.14; at median 7.9 years, the tamoxifen+octreotide and tamoxifen arms had similar event-free survival ($P = 0.62$). Overall survival was a secondary endpoint, and the two trial arms also had similar overall survival ($P = 0.86$). We used the median 9.8 years follow-up to examine by intention-to-treat, the multivariate time-to-breast cancer-specific (BrCa) and other cause (OC) mortality with log-normal survival analysis adjusted by treatment and stratification factors. We tested whether baseline factors including Insulin-like growth factor 1 (IGF1), IGF binding protein-3, C-peptide, body mass index, and 25-hydroxy vitamin D were associated with (1) all cause mortality, and if so; and (2) cause-specific mortality. We also fit step-wise forward cause-specific adjusted models.

RESULTS: The analyses were performed on 329 patients allocated tamoxifen and 329 allocated tamoxifen+octreotide. The median age of MA.14 patients was 60.1 years: 447 (82%) $<$ 70 years and 120 (18%) \geq 70 years. There were 170 deaths: 106 (62.3%) BrCa; 55 (32.4%) OC, of which 24 were other malignancies, 31 other causes of death; 9 (5.3%) patients with unknown cause of death were excluded from competing risk assessments. BrCa and OC deaths were not significantly different by treatment arm ($P = 0.40$): tamoxifen patients experienced 50 BrCa and 32 OC deaths, while tamoxifen + octreotide patients experienced 56 BrCa and 23 OC deaths. Proportionately more deaths ($P = 0.004$) were from BrCa for patients

< 70 years, where 70% of deaths were due to BrCa, compared to 54% for those ≥ 70 years of age. The proportion of deaths from OC increased with increasing body mass index (BMI) ($P = 0.02$). Higher pathologic T and N were associated with more BrCa deaths ($P < 0.0001$ and 0.002 , respectively). The cumulative hazard plot for BrCa and OC mortality indicated the concurrent accrual of both types of death throughout follow-up, that is the existence of competing risks of mortality. MA.14 therapy did not impact mortality ($P = 0.77$). Three baseline patient and tumor characteristics were differentially associated with cause of death: older patients experienced more OC ($P = 0.01$) mortality; patients with T1 tumors and hormone receptor positive tumors had less BrCa mortality (respectively, $P = 0.01$, $P = 0.06$). Additionally, step-wise cause-specific models indicated that patients with node negative disease experienced less BrCa mortality ($P = 0.002$); there was weak evidence that, lower C-peptide ($P = 0.08$) was associated with less BrCa mortality, while higher BMI ($P = 0.01$) was associated with worse OC mortality.

CONCLUSION: We demonstrate here a new paradigm of simultaneous testing of therapeutics directed at multiple diseases for which postmenopausal women are concurrently at risk. Octreotide LAR did not significantly impact breast cancer or other cause mortality, although different baseline factors influenced type of death.

Key words: Breast cancer; Postmenopausal; Hormone receptor positive; Competing risks; Tamoxifen; Octreotide LAR

Core tip: With earlier detection and improved therapies, patients with early breast cancer simultaneously face multiple health risks; 54% of women ≥ 70 years at diagnosis died from other causes. Octreotide LAR, an early drug targeting the insulin pathway, might have affected both breast and other cause mortality. We demonstrated a method of jointly assessing the impact of therapy and baseline patient characteristics on multiple causes of death. Older patients with higher body mass index experienced more other cause mortality, while women with smaller hormone receptor positive tumours and less lymph node involvement were less likely to die from breast cancer.

INTRODUCTION

The focus of decades of breast cancer research has been

to reduce breast cancer mortality. In the United Kingdom in the early 1970s, 52% of women survived breast cancer for five years; five-year survival improved to 85% in 2005-2009^[1]. The US had corresponding improvements with about 75% of women diagnosed during 1975-1977 surviving 5 years, while 89% survived 5 years in 2005-2008^[2].

The early 1970s were characterized by women with larger primary breast cancer tumours with greater involvement of lymph nodes and higher risk of systemic disease at diagnosis. Systemic therapy was with less efficacious chemotherapy drugs and regimens; endocrine therapy, when administered, was tamoxifen. We lacked biologic therapy, particularly anti-human epidermal growth factor receptor 2 treatment, and there was an absence of tumour molecular assessments such as intrinsic subtyping and genetic profiling for familial cancer, which precluded our current increasing interest in targeted delivery of therapy. Radiotherapy regimens were more toxic causing more morbidity and therapeutic mortality.

Factors contributing to improvements in survival included: the routine use of screening mammography to detect invasive breast cancer earlier and increase detection of non-invasive breast cancer; use of systemic agents to prevent invasive breast cancer in high risk women; and improved management of invasive breast cancer.

Earlier detection of breast cancer has resulted in a decrease in the median age of diagnosis for invasive breast cancer: 65 years at the time Adjuvant! Online was developed^[3], to 61 years in the US in 2011^[4]. Recent studies have shown that more than fifty percent of women may now be expected to die from a cause other than breast cancer, with an increasing proportion of non-breast cancers occurring at older ages^[3,5,6].

Adjuvant! Online was established from the large prospectively and uniformly collected US Surveillance Epidemiology and Endpoints Results data and the Oxford overviews of breast cancer clinical trial meta-analyses^[3]. A patient at age 65 who was ER-positive, node negative with 1- to 2-cm tumour without adjuvant therapy would have a 10% chance of dying of breast cancer and 10% chance of dying of other causes in the next 10 years. The Adjuvant! Online website permits clinicians the opportunity to explore trade-offs in risk-benefits for different patient management options for different ages, taking into account the severity of presenting disease, and differing co-morbidity states^[4].

Concurrently, experience was reported from a smaller prospectively accrued single institution phase IV cohort at Women's College Hospital, where routine annual mammography starting at age 35 was employed in the 1960's, following early scientific reports of its effectiveness^[7,8]. This experience was from an era before both routine adjuvant radiotherapy and systemic therapy, and illustrated the effects of early detection^[7,8]. At a median 8.2 years follow-up, 20% of those older than 65% and 3% of those under 65 died of other causes ($P < 0.001$).

We previously reported the effects of competing risks in the NCIC Clinical Trials Group (CTG) MA.17 inter-

national phase III randomized placebo-controlled clinical trial of letrozole in post-menopausal hormone-receptor positive breast cancer in women who recently received 5 years of tamoxifen^[6]. MA.17 patients had a median age of 62 years. Non-breast cancer deaths accounted for 60% of the known causes of death for all patients, 72% of deaths for those 70 or older.

We face the prospect that older women may simultaneously face dual health risks, increasingly presenting with concomitant competing risks from which at least half of them are likely to die. Women have reaped survival benefits from decades of multi-modality transdisciplinary research that lead us to a new paradigm for early breast cancer management^[9]. In this context, it will be important to consider therapeutic regimens which may affect several disease outcomes.

We examine competing risks of mortality in NCIC CTG MA.14 which investigated whether octreotide LAR would affect insulin-like growth factors and subsequent clinical outcome in postmenopausal women with hormone-positive breast cancer^[10]. Octreotide was postulated to target the insulin-growth factor pathway so patients were assessed for insulin-growth factor 1 (IGF-1), insulin-growth factor binding protein 3 (IGFBP-3), and C-peptide, a byproduct created when the hormone insulin is produced. Octreotide significantly lowered IGF-1, IGFBP-3, and C-peptide ($P < 0.001$). High levels of C-peptide and body mass index (BMI) were associated with poor outcome, but octreotide did not significantly affect event-free survival ($P = 0.62$).

Nevertheless, the MA.14 trial illustrates the new paradigm we propose, that trials simultaneously target and assess more than one chronic disease. Octreotide's action could affect both breast cancer and insulin-related components of cardiovascular disease. Thus, its efficacy would be better assessed concurrently for multiple disease components of overall survival, rather than examined in totality to avoid confounding therapeutic benefits and trade-offs.

MATERIALS AND METHODS

Patient population

Between 1996 and 2000, NCIC CTG MA.14 (ClinicalTrials.gov Identifier: NCT00002864) enrolled 667 postmenopausal women with histologically proven adenocarcinoma of the breast who underwent lumpectomy or total mastectomy^[10]. Patients were to have no previous or concurrent malignancies except adequately treated carcinoma of the skin (basal cell), cervix, endometrium, colon, or thyroid, treated more than 5 years before study entry, and were presumed cured, and had no inter-current illness expected to reduce life expectancy to less than 5 years from the date of surgery. Baseline serum was assessed for IGF-1, IGFBP-3, and C-peptide for 646 patients (96.9%), and 25-hydroxy (OH) vitamin D was centrally assessed for 607 of the MA.14 patients (91%)^[10]. More detailed descriptions about patient eligibility and trial conduct are

available at ClinicalTrials.gov and in the main trial paper^[10].

Study design

Patients were randomly assigned to tamoxifen 20 mg orally once daily for 5 years or tamoxifen 20 mg orally once daily for 5 years plus octreotide long-acting release 90 mg intramuscularly monthly for 5 years by minimization (tamoxifen+octreotide). In July 2000, the duration of octreotide was reduced to 2 years because of a greater incidence of gallbladder toxicity in the octreotide arm of National Surgical Adjuvant Breast and Bowel Project (NSABP) B-29.

Stratification

Patients were stratified by adjuvant chemotherapy (none, concurrent, or sequential), nodal status (none, one to three, four or more, or unknown), and receptor status (ER and/or PgR positive, ER and PgR negative, or ER and PgR unknown).

End points

The primary end point of the trial was event-free survival (EFS); events included recurrence of disease, second malignancy, or death as a result of any cause. Overall survival (OS) was a secondary end point. The effects of insulin-like growth factor physiology on outcome were another secondary objective.

MA.14 trial experience

MA.14 investigations were by the intention-to-treat principle. Event-free survival was the primary endpoint of MA.14; at the final analysis at median 7.9 years, the tamoxifen+octreotide and tamoxifen arms had similar event-free survival ($P = 0.62$). Overall survival was a secondary endpoint, and the two trial arms also had similar overall survival ($P = 0.86$)^[10]. We used the median 9.8 years follow-up in intention-to-treat analyses here.

Primary objective of competing risks investigation

The primary objective of this investigation was to examine whether there was evidence of competing risks operative in the MA.14 trial, by way of whether there were significantly different factor effects indicated for different causes of death. The Lagakos method was used for this purpose^[11]. We assumed independent cause-specific risks for death with or from breast cancer (BrCa) and death from other causes (OC). Fuller details about the method used are reported elsewhere^[6].

We tested 3 hypotheses (H1, H2, and H3): (1) H1: A factor does not affect type or time to death, $\beta_{\text{BrCa}} = \beta_{\text{OC}} = 0$, tested with a likelihood ratio criterion ($-2\log R$) [$-\chi^2_{(2)}$], where β_{BrCa} and β_{OC} are the cause-specific effects of the factor. With rejection of H1, H2 was tested; (2) H2: A factor has the same effect for both types of death, $\beta_{\text{BrCa}} = \beta_{\text{OC}}$, tested with $-2\log R$ [$-\chi^2_{(1)}$]. With rejection of H2, a factor was differentially associated with type of death so

Table 1 Number of deaths by treatment arm and factor subgroups *n* (%)

Factor	Number of patients	Breast cancer	Other cause ¹	P-value ²
Treatment				
Tamoxifen	329 (50)	50	32	
Tamoxifen + Octreotide LAR	329 (50)	56	23	0.40
Age				
< 70	544 (83)	85	37	
≥ 70	114 (17)	21	18	0.004
BMI				
< 25	185 (28)	30	7	
25-30	221 (34)	29	20	
> 30	213 (32)	41	24	0.02
Tumour size				
T1	382 (58)	38	26	
≥ T2, unknown	276 (42)	68	29	< 0.0001
Nodal status				
N0	346 (53)	39	29	
N1, N2, Nx	312 (47)	67	26	0.002

¹Nine patients are excluded with unknown type of death; ²P-value is based on Pearson chi-square test.

was assessed separately for cause-specific mortality: β_{BrCa} (β_{OC}). When H2 is not rejected, there is a common effect, β , on all cause mortality, which was tested by H3^[11]; and (3) H3: A factor is not associated with time to all cause mortality (overall survival), $\beta = 0$, tested with $-2\log R [-\chi^2_{(1)}]$, which should produce a significant result due to rejection of H1.

Statistical analyses

Cumulative hazard plots for breast cancer and other cause mortality were used to examine the presence of substantive competing risks, that is overlapping time periods for different types of death. We then used the Lagakos method described above. Factor effects were examined in models that included all of the factors ("full-factor" models).

We examined baseline MA.14 factors: (1) treatment (tamoxifen *vs* tamoxifen + octreotide); (2) age (in years); (3) race (white, other); (4) ECOG performance status (0, other); (5) pathologic T (1, other); (6) pathologic N (0, other); (7) breast surgery (segmental mastectomy, other); (8) IGF-1 (continuous); (9) IGFBP-3 (continuous); (10) C-peptide (continuous); (11) weight (kg), (12) body mass index (BMI; continuous); (13) vitamin D (continuous), and baseline values of the stratification factors; (14) number of positive nodes (0, Nx, 1-3 +, ≥ 4 +); (15) hormone receptor status (ER-PR-, unknown, ER+ and/or PR +); and (16) adjuvant chemotherapy (no, yes).

With log-normal survival analysis, the natural logarithm of survival time, $Y = \ln(t)$, is a linear function, $Y = \alpha + \sum \beta_j z_j + \sigma W$, where σ is a scale parameter; W is $N(0,1)$; z_j , j th baseline factor; and β_j effect of j th factor.

A normal probability plot was utilized to examine the assumption of log-normal survival time. The final model fit was examined with standardized residual plots.

Treatment and baseline values of the three stratification factors had forced inclusion in the multivariable models to account for MA.14 design structure. Other factors were considered in stepwise forward regression analyses, including a factor with P value ≤ 0.05 by $-2\log R [-\chi^2_{(1)}]$. Patient experience was depicted with log-normal survivor plots, where factor effects were adjusted for the effects of treatment, and other significant factors. Breast cancer and other cause 5-year and 10-year survival were reported. Royston described the log-normal model as a pragmatic tool that provides a continuous estimate of prognosis^[12]. Of note, both Kaplan-Meier and Cox plots present discontinuous estimates of prognosis.

RESULTS

We used the MA.14 median 9.8 years follow-up for our analysis. The median age of MA.14 patients was 60.1 years: 547 (82%) < 70 years and 120 (18%) ≥ 70 years. MA.14 patients experienced 170 deaths: 106 (62.3%) BrCa; 55 (32.4%) OC, of which 24 were other malignancies, 31 other causes of death; 9 (5.3%) patients had unknown cause of death, so were excluded from competing risk assessments.

The analyses were performed on 329 patients allocated tamoxifen and 329 allocated tamoxifen+octreotide (Table 1). There were no significant differences in the number of BrCa and OC deaths by treatment arm ($P = 0.40$): tamoxifen patients experienced 50 BrCa and 32 OC deaths, while tamoxifen+octreotide patients experienced 56 BrCa and 23 OC deaths. Proportionately more deaths ($P = 0.004$) were from BrCa for patients < 70 years, where 70% of deaths were due to BrCa, compared to 54% for those ≥ 70 years of age. The proportion of deaths from OC increased with increasing BMI ($P = 0.02$). Meanwhile, higher pathologic T and N were associated with more BrCa death ($P < 0.0001$ and 0.002, respectively).

The cumulative hazard plot for BrCa and OC mortality (Figure 1) indicates the concurrent accrual of both types of death throughout follow-up, or the existence of competing risks of mortality. Meanwhile, the normal probability plot (Figure 2) supports the assumption of a log normal model up to about 10 years follow-up. We utilized log-normal survival analysis for the competing risks assessments, providing survival experience up to 10 years.

Table 2 indicates the competing risks results. MA.14 therapy was not associated with mortality ($P = 0.77$). Baseline factors associated with mortality were age ($P = 0.02$), tumour size ($P = 0.01$), nodal status ($P = 0.002$), number of positive nodes ($P < 0.0001$), and hormone receptor status ($P = 0.08$). Age ($P = 0.03$), tumour size ($P = 0.04$), and hormone receptor status ($P = 0.04$) were differently associated with BrCa and OC so cause-specific multivariate analyses were used to investigate their effects. Nodal status ($P = 0.54$) and number of positive nodes ($P = 0.89$) did not show different associations with BrCa and OC, but were associated with all cause mortality ($P <$

¹Cause-specific survival model was built using $\ln(\text{survival time})$ having linear function of $\beta \times (\text{factor values})$. The model had forced inclusion of treatment and stratification factors (adjuvant chemotherapy, nodal status, and hormone receptor status) with step-wise forward inclusion of other baseline factors; ² β is effect of factor; SE is standard error; CI is confidence interval assuming β is approximately normally distributed; ³P-value is that for a Wald statistic; ⁴Higher values of continuous C-peptide were associated with worse BrCa ($P = 0.08$).

0.0001).

The step-wise multivariate models are provided for BrCa and OC in Table 3. Treatment did not significantly affect BrCa ($P = 1.0$) or OC ($P = 0.49$). The stratification factor adjuvant chemotherapy ($P = 0.20$) was not significantly associated with BrCa mortality; however, a

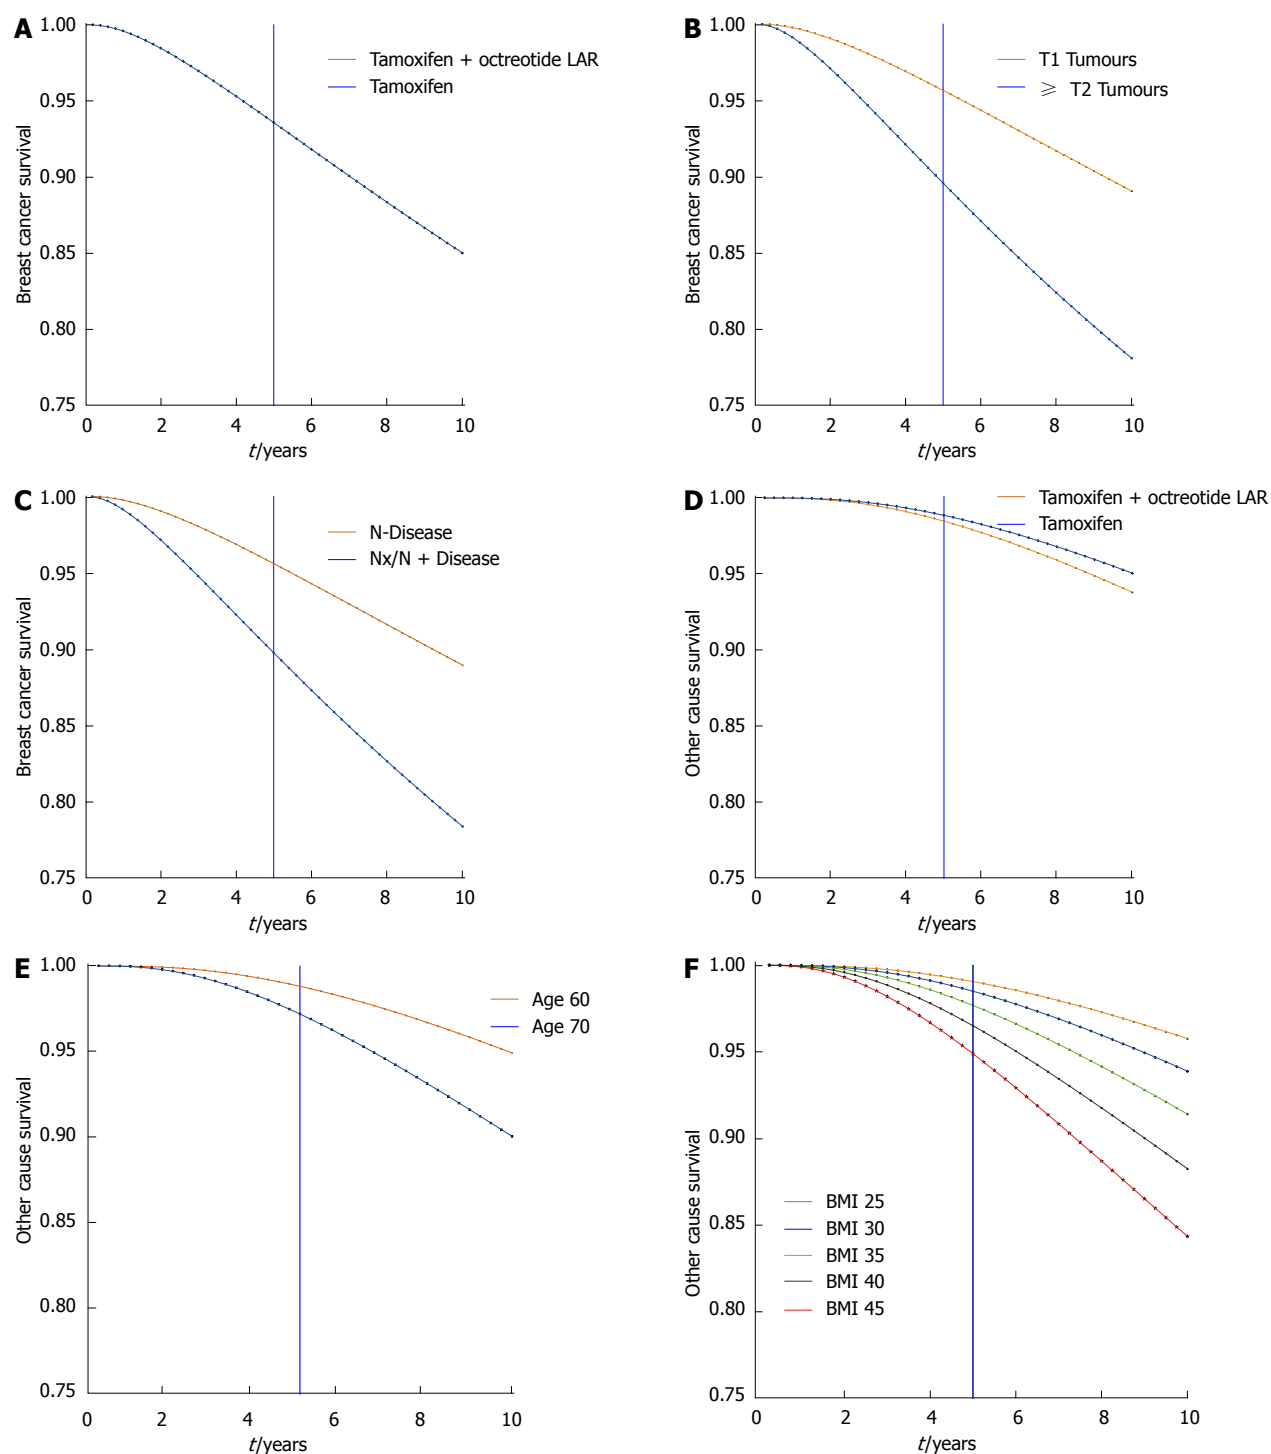

Figure 3 Breast cancer survival. A: Breast cancer survival by treatment: Experience for the two treatment arms, tamoxifen and tamoxifen + octreotide LAR overlay each other; B: Breast cancer survival by tumour size; C: Breast cancer survival by nodal status; D: Other cause mortality by treatment; E: Other cause mortality by age; F: Other cause mortality by body mass index.

lower number of positive lymph nodes ($P = 0.002$) and hormone receptor positivity ($P = 0.03$) were associated with less BrCa mortality. Larger tumours ($P = 0.0003$) led to more BrCa mortality. there was weak evidence that, lower C-peptide ($P = 0.08$) was associated with less BrCa mortality. None of the stratification factors impacted OC mortality. Older patients ($P = 0.002$) and higher BMI ($P = 0.01$) were associated with more OC mortality.

Adjusted 5 and 10 year survival is presented in Table 4 and depicted graphically for BrCa by treatment (Figure 3A), tumour size (Figure 3B), and lymph node involvement (Figure 3C) and for OC by treatment (Figure 3D), age (Figure 3E), and BMI (Figure 3F). In both the Table and plots survival is adjusted (as appropriate) for the effects of treatment, (other) stratification factors, and other significant factors.

¹Survival for is adjusted for the effects of other factors: treatment, stratification and other significant factors.

After the log-normal model was fit, each patient's observed survival time was compared to her expected survival time, based on patient and tumour characteristics. *i.e.*, for patient *i*, with survival time *t_i* [*s_i*, *y_i* = *ln(t_i)*], [*y_i* - (*α* + Σ *β_jz_{ij}*)]/*σ*] would be expected to have approximately a standard normal distribution with mean 0 and standard deviation 1. A plot of all the patient standardized residuals examines whether departures from the multivariate BrCa (Figure 4) and OC (Figure 5) models appear to be ascribable as random error. The residuals indicate that the *y_i* (*ln* of survival times) are consistently smaller than they are expected to be; there are explanatory factors for both BrCa and OC that are not included in this investigation.

DISCUSSION

The addition of octreotide therapy to tamoxifen in MA.14 was an early strategy to test the impact of targeting the insulin-like growth factor pathway for early postmenopausal breast cancer patients. In the main trial analyses, octreotide was not found to impact either the primary endpoint of EFS or OS potentially because the administration of octreotide was reduced to 2 years (from the originally planned 5 years) due to excess gallbladder toxicity^[10]. The trial was designed with the expectation that the 5 year EFS rate for patients allocated tamoxifen would be 73%. For patients treated with tamoxifen alone, the 5-year BrCa was 94%, while the 5-year OC experience was 98%. The MA.14 trial was under-powered to detect a significant octreotide effect.

However, the main trial indicated a possible role for the insulin-like growth factor pathway with significant

Figure 4 Breast cancer standardized residuals vs time: The residuals indicate that the natural logarithm of survival times are consistently smaller than they are expected to be; there are explanatory factors for breast cancer-specific that are not included in this investigation.

Figure 5 Other cause standardized residuals vs time: The residuals indicate that the natural logarithm of survival times are consistently smaller than they are expected to be; there are explanatory factors for other cause that are not included in this investigation.

treatment associated changes in the mandatory correlative biomarkers of IGF-1, IGFBP-3, and C-peptide as well as in BMI. Further, higher C-peptide levels, or higher BMI, were significantly associated (*P* < 0.001) with worse EFS. As EFS involved both breast cancer relapse and all cause mortality, the questions we addressed here were whether the patients simultaneously had substantive risks of both BrCa and OC mortality, and if so, whether there were differential effects of factors on cause-specific mortality.

We found that the early postmenopausal patients, 91% of whom had hormone-receptor positive tumours, faced the risk of both BrCa and OC mortality. The prognostic breast cancer factors of larger tumour size (*P* = 0.0003), higher number of positive lymph nodes (*P* = 0.002), and a tumour that was hormone receptor negative (*P* = 0.03) were associated with more BrCa mortality. Meanwhile, older age (*P* = 0.002) and higher BMI were associated with more OC mortality. The increase in OC mortality with older age replicates what was found with

the NCIC CTG MA.17 trial with extended adjuvant endocrine therapy where patients were randomized to 5 years of letrozole or placebo following 5 years of tamoxifen^[6].

Adjusted survival estimates were provided for BrCa by treatment, tumour size, lymph node status, and for OC by age and BMI. Graphical presentations were to 10 years, along with a table of specific 5- and 10-year survival rates.

This study represents a secondary use of a breast cancer trial database. We examined whether prognostic risk factors similarly impacted both BrCa and OC, and found that there was differential association of baseline factors and type of death. Age and higher BMI were associated with OC mortality, while T status, nodal involvement and hormone receptor status were associated with BrCa mortality. Adjuvant chemotherapy was neither mandated nor prohibited; 33% of patients received adjuvant chemotherapy (Pritchard *et al*^[10]). However, in this trial, age was not associated with BrCa death, but OC mortality.

There is a limitation in ability to delineate comorbidity with MA.14 data. Eligibility criteria were that patients have no previous or concurrent other malignancy except for carcinoma of the skin, cervix, endometrium, colon, or thyroid adequately treated 5 or more years before study entry, and had no inter-current illness expected to reduce life expectancy to less than 5 years after surgery. The number of non-breast cancer deaths was too few to refine investigations since with a median 9.8 years follow-up, 24 patients experienced other malignancies and 31 other causes of death; the two classifications were combined. Prospective collection of death type in larger trial populations, over longer follow-up would be needed to improve disease-specific interpretation.

The MA.14 trial with octreotide was an early attempt at targeting the insulin pathway for adjuvant postmenopausal breast cancer patients. octreotide therapy did not impact either BrCa ($P = 1.00$) or OC ($P = 0.49$) mortality. However, the methodology demonstrated here may be of interest in eventually assessing the effects of competing risks and the insulin pathway on both BrCa and OC mortality in the much larger metformin placebo-controlled trial, NCIC CTG MA.32.

Alternatively, other joint assessment of chronic diseases is conceptually possible in trials where therapies may be postulated to have dual modes of action. NCIC CTG MA.27 originally had a factorial design with administration of celecoxib that was postulated to also be an anti-breast cancer agent until excess cardiac toxicity led to the closing of the celecoxib arms^[13]. The dual modalities for MA.27 would have been breast cancer and possibly musculoskeletal or arthralgic sequelae^[14] which could also be targets of celecoxib therapy. The prevention trial, NCIC CTG MAP.3, likewise had to close its celecoxib arms so is not a good venue for this joint testing^[15]. We await the results of the REACT trial which was able to accrue its full sample size to celecoxib, and postulate that it will be a good candidate for this modality of joint test-

ing^[16].

In summary, the progress for earlier detection and improved management of breast cancer means that women with early breast cancer will increasingly face joint mortality risks of other chronic diseases. This situation raises the opportunity for a new paradigm of simultaneously targeting several chronic diseases, or at least assessing the joint risks of mortality, for a better understanding of predisposition of patients to mortality other than breast cancer. MA.14 was an early trial of the insulin pathway targeted therapy, octreotide, which conceptually may have affected both BrCa and OC mortality, so was used here to demonstrate analyses that might be considered for the new assessment framework. The current work is offered as a proof of principle to demonstrate the relevance of collecting detailed cause-specific mortality data and factors which may be associated with non-breast cancer death.

COMMENTS

Background

Improvements in detection and management of breast cancer lead to the prospect that many postmenopausal women will now not die from the disease as they face joint mortality risks of other chronic diseases. Investigators need to determine baseline characteristics differentially associated with breast cancer vs other causes of death for more effective overall patient care. This paper proposes a method that might provide a basis for such discernment. The method is demonstrated for a phase III clinical trial which tested an early target of the insulin pathway that could have impacted both breast cancer and other cause mortality.

Research frontiers

Successful development of therapies which would simultaneously target several chronic diseases would improve whole population survival. Additionally, the management of elderly breast cancer patients is currently an important research area given the general increase in proportion of older people worldwide.

Innovations and breakthroughs

The usual process of inferring different factors influencing different causes of death involves qualitative observations. The competing risks method demonstrated here has quantitative formal tests. Older age and higher BMI increased the prospect that a patient would die of other causes than breast cancer, as did patients having smaller, hormone-receptor positive tumours and less lymph node involvement. The authors also reported quantitative patient survival over time by type of death.

Applications

This work could be extended to existing uniformly collected databases where there was careful collection of cause of death to better delineate factors affecting a broader range of competing risks of death. The more routine collection of multiple causes of death would assist future work.

Terminology

Log-normal survival analysis examines the linear effects of factors on the natural logarithm of survival time to provide smooth continuous functions and plots of factor effects.

Peer review

Well-prepared article offered new insights in breast cancer research and in evaluation of treatment, particularly in postmenopausal women.

Abstract

AIM: To investigate the age differences in the risk factors, clinicopathological characteristics and patterns of treatment of female breast cancer patients.

METHODS: Seven thousand one hundred and fifty-two women with primary breast cancer from the Hong Kong Breast Cancer Registry were recruited after receiving patients' consent, they were asked to complete standardized questionnaires which captured their sociodemographic characteristics and risk factors associated with breast cancer development. Among them, clinicopathological data and patterns of treatment were further collected from medical records of 5523 patients with invasive breast cancers. Patients were divided into two groups according to the age at diagnosis: younger (< 40 years old) vs older patients (\geq 40 years old) for subsequent analyses.

RESULTS: Analysis on the sociodemographic characteristics and exposure to risk factors were performed on 7152 women with primary breast cancer and the results revealed that younger patients were more likely to have unhealthy lifestyles; these include a lack of exercise (85.4% vs 73.2%, $P < 0.001$), having high stress in life (46.1% vs 35.5%, $P < 0.001$), having dairy/meat-rich diets (20.2% vs 12.9%, $P < 0.001$),

having alcohol drinking habit (7.7% *vs* 5.2%, $P = 0.002$). Younger patients were also more likely to have hormone-related risk factors including nulliparity (43.3% *vs* 17.8%, $P < 0.001$) and an early age at menarche (20.7% *vs* 13.2%, $P < 0.001$). Analyses on clinicopathological characteristics and patterns of treatment were performed on 5523 women diagnosed with invasive breast cancer. The invasive tumours in younger patients showed more aggressive pathological features such as having a higher percentage of grade 3 histology (45.7% *vs* 36.5%, $P < 0.001$), having a higher proportion of tumours with lymphovascular invasion (39.6% *vs* 33.2%, $P = 0.003$), and having multifocal disease (15.7% *vs* 10.3%, $P < 0.001$); they received different patterns of treatment than their older counterparts.

CONCLUSION: Younger patients in Hong Kong are more likely to encounter risk factors associated with breast cancer development and have more aggressive tumours than their older counterparts.

Key words: Hong Kong Breast Cancer Registry; Breast cancer; Younger Chinese women; Sociodemographic characteristics; Risk factors; Clinicopathological characteristics; Breast cancer treatment

Core tip: We conducted this study to investigate the age differences in the risk factors associated with breast cancer development of female breast cancer patients in Hong Kong. Further, among patients with invasive cancers, we compared the clinicopathological characteristics and the treatments received between these two groups of patients. Younger patients in Hong Kong were found to be more likely to encounter risk factors associated with breast cancer development and have more aggressive tumours than their older counterparts. Based on the current findings, we will conduct further research to evaluate the impact of age at diagnosis on the outcomes of the disease.

Risk factors and natural history of breast cancer in younger Chinese women. *World J Clin Oncol* 2014; 5(5): 1097-1106 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/1097.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.1097>

INTRODUCTION

Breast cancer has been the most frequent cancer affecting women in Hong Kong since 1993. Female breast cancer cases diagnosed in Hong Kong has more than doubled from 1152 in 1993 to 3014 in 2010. In 2010, breast cancer comprised of 24.1% of all cancers among

women and was the third leading cause of cancer death in women^[1]. On average, about 8 women in Hong Kong were diagnosed with breast cancer every day. The median age at diagnosis among breast cancer patients was 53, compared to that of age of 61 in the United States^[2], 61 in Australia^[3] and 53 in Singapore^[4].

Breast cancer is an age-related disease and increasing age is the single most important risk factor after female gender^[5]. In Hong Kong, the age-specific incidence rates for female with invasive breast cancer increased drastically after the age of 40. However, 8.9% of the cases in Hong Kong were diagnosed before the age of 40 in 2010^[1], which was higher than that in Australia (aged below 40) (5.6%)^[6] and the United Kingdom (aged below 40) (4.2%)^[7], while the reported figure for United States patients diagnosed younger before age 45 was 11.4%^[8].

It has been reported that risk factors for early onset breast cancer differ from those for postmenopausal breast cancer. Risk factors identified for premenopausal breast cancer include positive family history, high energy (caloric) intake, sedentary lifestyle, early age at menarche, heavy alcohol consumption and a high intake of red meat, while for postmenopausal breast cancer, high body mass index is identified as a risk factor. On the other hand, intense physical activity has been associated with a decreased breast cancer risk in premenopausal women^[9].

Although breast cancer in young patients is relatively uncommon, it represents a substantial clinical problem. Extensive researches have been carried out to study the differences in the pathological features of the tumours between younger and older patients. When compared to older patients, it has been suggested that invasive breast cancer in young women has a higher proportion with more aggressive features; these include presence of lymphovascular invasion, Grade 3 histology, extensive intraductal component, presence of necrosis, over-expression of the human epidermal growth factor receptor-2 (HER-2) oncogene and absence of estrogen receptor. Irrespective of the pathological differences, younger patients were also found to have poorer prognosis, with different treatment outcome and survival pattern, when compared with their older counterparts^[10]. Younger patients were more likely to recur both locoregionally and distantly^[11]. Survival rates were also found to be relatively lower for younger women when adjusted for the histologic subtypes and stages^[9].

Although the differences in the sociodemographic characteristics, risk factors associated with breast cancer development, clinicopathological characteristics and patterns of treatment among breast cancer women in different ages have been studied extensively worldwide, only two studies were conducted to study the differences in the clinicopathological characteristics and patterns of treatment between the younger and older breast cancer patients in Hong Kong^[12,13]. These latter two studies have reported that younger patients were more likely to be diagnosed at more advanced cancer stage, had higher pathological grade, more nodal involvement and presence of lymphovascular permeation; at the same time, a

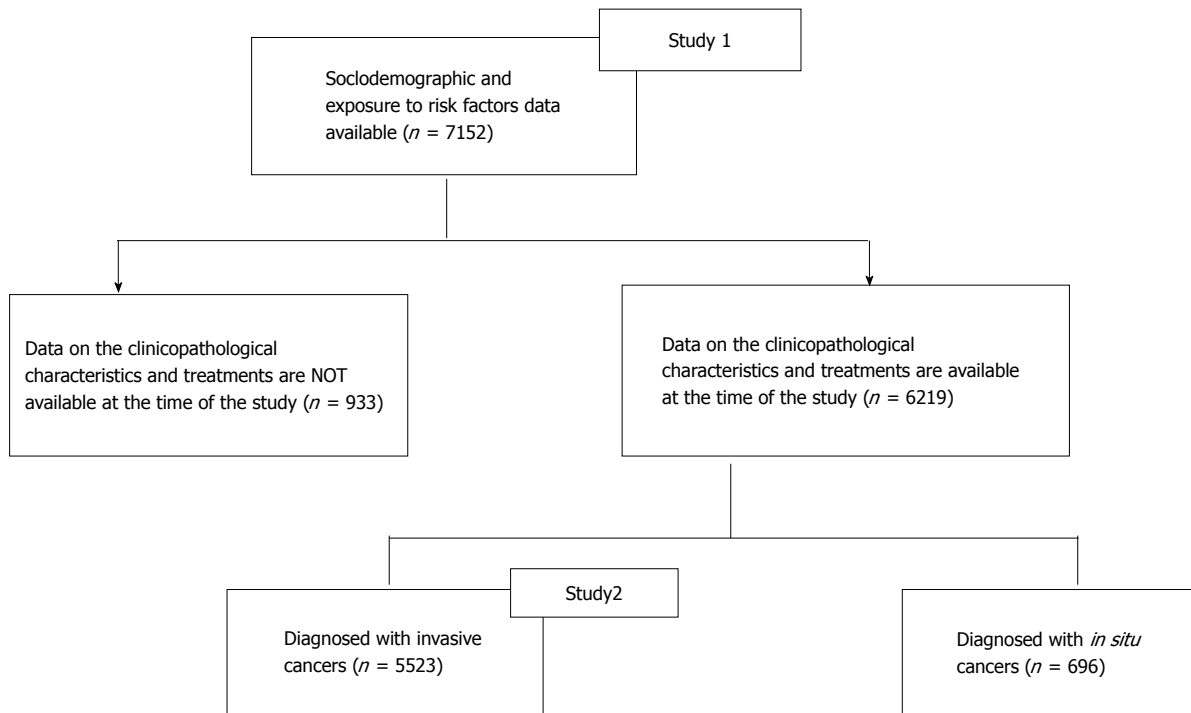

Figure 1 Patients included in the two studies. Study 1: Sociodemographic characteristic and exposure to risk factors analysis; Study 2: Clinicopathological and patterns of treatment analysis.

higher proportion of them underwent breast conservation surgery and reconstructive surgery. However, neither has focused on the differences in the sociodemographic characteristics and the risk factors associated with breast cancer development^[12,13]. Further, these studies recruited patients at a single hospital only, and as such the data might not reflect the overall clinical pattern of breast cancer in Hong Kong.

Thus, using the data from Hong Kong Breast Cancer Registry, we conducted this study to investigate the differences in the sociodemographic characteristics and risk factors associated with breast cancer development between younger female breast cancer patients and their older counterparts in Hong Kong. Further, among patients with invasive cancers, we compared the clinicopathological characteristics and the treatments received between these two groups of patients.

MATERIALS AND METHODS

Seven thousand one hundred and fifty-two consecutive Chinese women with primary breast cancer, recruited during the period of February 2008 to April 2012, from the Hong Kong Breast Cancer Registry (HKBCR) were studied. The HKBCR recruited breast cancer patients, regardless of the year of their diagnosis, from 35 centres including both private clinics/hospitals and public hospitals in Hong Kong. Among these women, 4320 (60.4%) were recruited from public hospitals. Ethics approvals for collecting patients' data for the HKBCR were obtained from the respective institutional review boards

of each participating hospital. The overall study consists of 2 parts: Study 1 and Study 2 (Figure 1). All registrants participated in Study 1 upon voluntary written consent; they were asked to complete standardized questionnaires which captured their sociodemographic characteristics data and the risk factors associated with breast cancer development. Among these 7152 patients, 5523 patients with confirmed invasive breast cancers participated in Study 2. The clinicopathological data, including method of first detection, clinical presentation for self-detected cancers, cancer stage, tumour histological type, grade, tumour size, presence of lymphovascular invasion, nodal status, breast cancer biological markers including estrogen receptor (ER), progesterone receptor (PR) and the HER-2 receptor statuses, and the treatments received were further collected for these 5523 patients from their medical records. Patients were arbitrarily divided into two groups according to age at diagnosis: younger (< 40 years old) *vs* older patients (\geq 40 years old) for subsequent analyses.

Statistical analysis

The Chi-square test was used to evaluate differences in categorical variables between the different age groups. T-test was used to evaluate the differences in the continuous variable between the two groups of patients. Median test, a non-parametric test, was used where assumptions for parametric tests were not met. A *P*-value < 0.05 was considered to be statistically significant. All statistical analyses were performed using SPSS software version 19.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Sociodemographic characteristics

Table 1 summarizes the sociodemographic characteristics of the patient cohort. Although population-based breast screening is not conducted in Hong Kong, Table 1 also provides information on patients' self-initiated breast screening habits. The age at diagnosis ranged from 18.8 to 101.4 years. Majority (71.0%) of the women was diagnosed in the age group of 40-59 years old, with a mean age \pm SD of 50.1 ± 10.4 years and a median age of 48.8 years. Around half (40.5%) of the patients were premenopausal women. 1008 (14.1%) of the patients were categorized as younger patients while 6144 (85.9%) were categorized as older patients. Younger patients were found to be more educated (education level at matriculation or above) (45.5% *vs* 19.4%, $P < 0.001$). As expected,

more younger patients were engaged in an occupation before cancer diagnosis (80.8% *vs* 56.0%, $P < 0.001$) and thus had higher monthly household income (\geq US\$3,750: 50.5% *vs* 34.6%, $P < 0.001$) than their older counterparts. In addition, younger patients were also found to have higher rates of breast self-examination (66.2% *vs* 60.3%, $P = 0.001$) and clinical breast examination (61.6% *vs* 56.0%, $P = 0.004$).

Risk factors associated with breast cancer development

The associated risk factors within the patient cohort are summarized in Table 2. The proportions having positive family history was significantly higher in younger patients (17.7% *vs* 14.5%, $P = 0.010$). A significantly higher proportion of younger patients did not have enough exercise (< 3 h/wk) (85.4% *vs* 73.2%, $P < 0.001$). Compared to their older counterparts, they also had a significantly

higher proportion of having high level of stress (> 50% of time) (46.1% *vs* 35.5%, *P* < 0.001), having diets rich in meat/dairy products (20.2% *vs* 12.9%, *P* < 0.001), and having alcohol drinking habit (7.7% *vs* 5.2%, *P* = 0.002). In addition, a significantly higher proportion of younger patients had an early age at menarche (< 12 years old) (20.7% *vs* 13.2%, *P* < 0.001) and were nulliparous (43.3% *vs* 17.8%, *P* < 0.001). On the other hand, a significantly higher proportion of younger patients who bore children had breastfed their children (46.3% *vs* 40.9%, *P* = 0.023). Overweight or obesity was more common in older patients (23.9% *vs* 38.2%, *P* < 0.001).

Clinicopathological data of patients with invasive cancers

Table 3 summarizes the differences in the clinicopathological characteristics of the invasive tumours between the two groups of patients. Most (90.5%) of the patients self-detected their cancers but a higher proportion of younger patients self-detected their cancers than the older patients (94.1% *vs* 90.3%, *P* = 0.001). Except for a higher proportion of younger patients having nipple discharge

as the presenting symptom (5.1% *vs* 3.0%, *P* = 0.012), younger and older patients did not show any differences in their presentation symptoms and the duration of symptoms prior to the first medical consultation. A significantly higher proportion of younger patients were diagnosed with early stage cancer (Stage I - II B) (88.2% *vs* 83.0%, *P* = 0.001). Although younger patients tended to have smaller tumour sizes (median tumour size: 1.90 cm *vs* 2.00 cm, *P* = 0.065) and negative axillary nodal status (59.4% *vs* 61.9%, *P* = 0.075), these tumours usually exhibited more aggressive features. Younger patients had a higher percentage of grade 3 histology (45.7% *vs* 36.5%, *P* < 0.001) and a higher proportion of tumours with lymphovascular invasion (39.6% *vs* 33.2%, *P* = 0.003). A higher proportion of younger patients had presence of multifocal disease (15.7% *vs* 10.3%, *P* < 0.001). On the other hand, the two groups of patients did not show any significant differences in hormone receptor status (ER and PR), as well as the HER2 status. The proportions of patients having triple negative biological subtype (ER-PR-HER2-) were also not significantly different between the two groups of patients.

¹Screen-detected includes monthly self-exam, clinical breast exam (routine checkups), mammography or ultrasound screening; ²Chi-square test was not available due to the small number of patients; ³Mann-Whitney U test was used; ⁴227 patients underwent neoadjuvant therapy and did not have pathology reports, thus had missing values for these parameters: tumour size, Bloom and Richardson grade, presence of lymphovascular invasion, multifocality, multicentricity, endocrine receptor status, human epidermal growth factor receptor 2 status, and nodal status.

Treatments for patients with invasive cancers

Table 4 summarizes the treatments received by the patients. Younger patients were significantly more likely to undergo breast conserving surgery (46.1% *vs* 34.3%, *P* < 0.001), reconstruction after mastectomy (35.7% *vs* 11.7%, *P* < 0.001), and sentinel node biopsy (32.2% *vs* 28.7%, *P* = 0.014). Younger patients were significantly more likely to receive radiotherapy (72.0% *vs* 66.2%, *P* = 0.002), however, such difference was not observed after adjusted for the type of surgery they received. A higher proportion of younger patients received chemotherapy; specifically, statistical significance were observed in stages I and II B patients (Stage I: 59.2% *vs* 39.7%, *P* < 0.001; Stage II B: 100.0% *vs* 91.1%, *P* < 0.001). However, younger patients were less likely to receive endocrine therapy (68.7%

vs 74.2%, *P* = 0.003).

DISCUSSION

This is the first comprehensive study to describe the differences in the sociodemographic characteristics, risk factors associated with breast cancer development, cancer characteristics and patterns of treatment among female breast cancer patients of different ages in Hong Kong. Around one-seventh (14.1%) of the patients were of younger age (aged < 40 years), which was higher than 8.7% recorded by the Hong Kong Cancer Registry^[1], reflecting a higher percentage of younger patients having participated in this voluntary study. This figure is also relatively higher than that reported from other areas of

¹ χ^2 -test was not available due to the small number of patients.

the world^[6-8].

This study revealed that among patients in Hong Kong, younger patients were more likely to be exposed to risk factors associated with breast cancer development. These included unhealthy lifestyles, such as a lack of exercise, having high stress in life, taking dairy/meat-rich diets and having alcohol drinking habit. They were also more likely to be associated with hormone-related risk factors such as nulliparity, not having breastfeeding experience and having an early age at menarche. Younger patients also had higher proportions with positive family history and these results were in line with those found in studies from other areas of the world^[9,14-23]. Combinations of these risk factors might have increased the risks of early onset breast cancer in Hong Kong. Differences in the clinicopathological characteristics and patterns of treatment were also found between younger and older patients.

This study uses the age of 40 as the cut-offs for younger patients. Although most studies categorized women age less than 35 in the “younger” age group, Zhou *et al.*^[10] found that women “35 to 40 years of age or younger” defined a group of patients in which age was an independent risk factor associated with high rates of recurrence. The age cut-off in this study is arbitrarily set at 40 years because it has been shown that in Hong Kong women, the risk of having breast cancer after the age of 40 years is significantly increased^[1].

Although no population-based breast cancer screening policy exists, younger females in Hong Kong are more aware of breast health than their older counter-

parts, which can be reflected by their regular self-initiated breast screening habits (both breast self-examination and clinical breast examination) and this might explain why younger patients were more likely to be diagnosed at earlier stages. Despite that, invasive tumours in younger patients showed more aggressive features with a higher proportion having higher grade tumours, presence of lymphovascular invasion, and tumours being multifocal; these are similar to previous report on local Chinese women which included a smaller number of patients^[13]. Between the younger and older patient population, there was no difference in the hormone receptor status, and these results were slightly different from those found in other reports from western and Asian populations^[18,24-33]. More frequently, younger women were found to have breast cancer with negative endocrine receptors than the older women^[18,19,24,25,28,30-32]. In China, a study conducted in 2012 revealed that younger patients were found to have larger tumours, higher metastatic lymph node rates and higher positivity rates for HER-2 overexpression than older patients, while older patients were less likely to be negative for estrogen and progesterone receptors^[34].

In the present study, due to the young age at diagnosis and the relatively smaller tumour size, younger patients were more likely to undergo breast conserving surgery. This is associated with a higher rate of breast radiotherapy. Previous reports have described a more aggressive therapeutic strategy with the use of chemotherapy for younger patients in an attempt to optimize the outcome^[11,29]. This study concurs with these reports and shows that younger patients with early stage breast

cancer had a significantly higher percentage receiving chemotherapy. For patients with more advanced stage disease (stages III and IV), the differences in the rate of using chemotherapy did not reach statistical significance. It has to be noted that chemotherapy can cause age-specific problems such as infertility, bone loss and changes in sexual function and physical appearance, which are of great concerns to younger patients. Thus, whilst aiming to improve the prognosis of these patients with various anticancer therapies, considerations have to be made on treatment-related long term morbidities^[35,36].

There have been conflicting reports on young age at diagnosis in breast cancer patients in relation to associated risk factors for breast cancer development, cancer characteristics and prognosis^[11,37]. Gene expression profile was suggested to be a powerful predictor of disease outcome in young patients with breast cancer, but age *per se* was not an independent prognostic factor^[38]. However, gene expression profile and outcomes of the disease were not studied in this study, and further research has to be carried out to evaluate the effects of age at diagnosis on the survival outcomes in this group of patients.

Although data from a large number of breast cancer patients are described in this study, several limitations do exist. One of the limitations is that breast cancer in Hong Kong is not a statutory notifiable disease. Although the Hong Kong Cancer Registry captures the incidence and mortality rates for all types of cancers every year, detailed information on breast cancer patients, such as the exposure of risk factors, clinicopathological data etc, were not fully captured. The HKBCR provides a more comprehensive data collection system capturing detailed information on breast cancer cases with patients' consent. Nevertheless, the respondents of HKBCR are usually a self-selected group, patients who agreed to participate in the registry are likely to be more health conscious when compared to the non-respondents. In addition, since the HKBCR collects registrants' data by asking them to fill out standardized questionnaires, it is likely that the proportions of older patients and those with difficulty in filling out questionnaires (such as those with advanced disease or recurrent disease) maybe under-represented in the HKBCR. As a result, data on patients who had worse prognosis may have been under-estimated. Another limitation is that since questionnaires were used, data on patients' stress and nutritional aspects before cancer diagnosis could not be objectively assessed and were only based on patients' subjective impression.

In conclusion, this study shows that in Hong Kong, there are differences in the sociodemographics characteristics and associated risk factors for breast cancer development in younger vs older breast cancer patients. Further, among those with invasive breast cancers, the clinicopathological characteristics and patterns of treatment between younger and older breast cancer patients vary. A higher proportion of younger women is more likely to be exposed to various breast cancer risk factors and since breast cancer has become the most common

cancer among Hong Kong women, efforts have to be made to educate women to undertake primary preventive measures against the development of breast cancer with respective to modifiable factors, for example, leading an active lifestyle and modifying diets. In addition, secondary preventive measures should be considered to enable early detection of breast cancer by increasing breast cancer awareness and conducting prompt breast assessments as clinically indicated. Younger patients were found to have more aggressive tumours than their older counterparts and further research will be conducted to evaluate the impact of age at diagnosis on the outcome of diseases.

ACKNOWLEDGMENTS

We would like to express our gratitude to patients/survivors who participate in the HKBCR, institutions and individuals working with the HKBCR to facilitate data collection at clinics and hospitals throughout the territory, and the HKBCR Steering Committee.

COMMENTS

Background

Breast cancer has been the most frequent cancer affecting women in Hong Kong since 1993. It has been reported that risk factors for early onset breast cancer differ from those for postmenopausal breast cancer. To date, only two studies were conducted to address the differences in the clinicopathological characteristics and patterns of treatment between the younger and older breast cancer patients in Hong Kong, and the findings have been limited by small sample size.

Research frontiers

Using the data from Hong Kong Breast Cancer Registry, the authors conducted this study to investigate the differences in the sociodemographic characteristics and risk factors associated with breast cancer development between younger female breast cancer patients and their older counterparts in Hong Kong. Further, among patients with invasive cancers, the authors compared the clinicopathological characteristics and the treatments received between these two groups of patients.

Innovations and breakthroughs

Analysis on the sociodemographic characteristics and exposure to risk factors were performed on 7152 women with primary breast cancer. Younger female breast cancer patients in Hong Kong were found to be more likely to encounter risk factors associated with breast cancer development and have more aggressive tumours than their older counterparts.

Applications

Based on the current findings, the authors decided to conduct further research to evaluate the impact of age at diagnosis on the outcomes of the disease.

Peer review

An excellent review of the current status of breast cancer in Hong Kong. The data are used correctly, the methodology is sound and conclusions adequate. The paper represents significant contribution to this field.

Abstract

Lymphoepithelioma-like carcinoma (LELC) is a rare type of neoplasm in which only twenty cases have been reported in the breast. This type of tumor can be difficult to distinguish from other breast tumors particularly medullary carcinoma and lymphoma in the breast. We present a case of LELC of the breast presenting as an abscess along with a review of the literature. This is the 21st reported case of LELC of the breast and the first case to present as an abscess. Her clinical picture could have been mistaken for other infectious or inflammatory diseases. Given the potential for favorable outcome, early detection and general knowledge of this neoplasm are essential to expedite treatment for this rare tumor type.

Key words: Lymphoepithelioma-like carcinoma of the

breast; Breast cancer; Breast abscess

Core tip: We present a case of lymphoepithelioma-like carcinoma (LELC) of the breast, which is a rare tumor type that can be difficult to diagnose. This particular case is the first case of LELC of the breast presenting as an abscess with radiologic and histologic studies as well as literature review of this rare tumor.

Lymphoepithelioma-like carcinoma of the breast presenting as breast abscess. *World J Clin Oncol* 2014; 5(5): 1107-1112 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/1107.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.1107>

INTRODUCTION

Lymphoepithelioma-like carcinoma (LELC) is an undifferentiated carcinoma composed of malignant epithelial cells with a lymphocytic background, which was first described in the nasopharynx by Regaud, Reverchon and Schminke. These cells have been described in other sites including the stomach, salivary gland, lung, thymus, skin and cervix^[1]. LELC in the breast was first described by Kumar *et al*^[2]. LELC of the breast is a rare disease with only 20 reported cases described in the literature^[2-15]. Distinguishing LELC from medullary carcinoma and certain types of lymphoma has been a diagnostic challenge^[3,14,15]. Making this distinction has profound impact on therapy and overall prognosis.

In this paper, we present a case of LELC of the breast in a 64-year-old female with an unusual presentation and clinical course.

CASE REPORT

A 64-year-old African American woman presented with a painful palpable lump in her left breast for four weeks.

Figure 1 Imaging findings. A: Medially exaggerated cranio-caudal mammographic view of the left breast demonstrates the anterior aspect of the palpable mass that is a partially circumscribed and partially indistinct mass at 9 o'clock, posterior left breast (arrow); B: Ultrasound of the palpable lump demonstrates a 2.1 cm indistinct irregular hypoechoic solid mass with no posterior shadowing (caliper); C: Ultrasound of the left axilla demonstrates multiple oval and rounded lymph nodes measuring up to 1.4 cm. One oval 1.1 cm lymph node is diffusely hypoechoic (arrow) and is targeted for ultrasound guided Fine Needle Aspiration. The majority of the remaining lymph nodes demonstrate a thickened cortex (arrow head); D-H: Breast MRI: axial images of the left breast shown in multiple series as below; D: On pre-contrast T1W non-fat suppressed imaging the palpable mass is a 2 cm irregular mass with a central artifact from clip (arrow); E: On pre-contrast T2W fat suppressed imaging the mass is isointense to slightly hyperintense relative to the breast parenchyma (arrow). Similar signal is noted anterior to the mass with a higher intensity area more anteriorly (arrowhead); F: On first post-contrast fat suppressed T1W imaging the 2 cm irregular mass with a clip (arrow) is enhancing. Additional non-mass enhancement is noted anterior to the mass, measuring approximately 3 cm in the anterior-posterior plane (open arrow); G: Computerized color mapping demonstrates mostly persistent kinetic pattern of the mass and non-mass enhancement (area in blue, arrows); H: First post-contrast fat suppressed T1W imaging confirms the presence of multiple abnormal level 1 (arrow) and level 2 (not shown) axillary lymph nodes and abnormal left internal mammary chain adenopathy (double arrows).

She was initially seen by her primary care physician who prescribed antibiotics without any improvement. She subsequently underwent a mammogram, which demonstrated the anterior aspect of an ill-defined density located in the most posterior medial aspect of the left breast best seen on exaggerated cranio-caudal view (Figure 1A). This mass showed no associated focal architectural distortion or cluster of microcalcification. Her prior annual mammograms were all negative 4 years in a row. Ultrasound revealed an irregular markedly hypoechoic mass with indistinct margins at the 9 o'clock position of the left breast measuring approximately 2.1 cm in maximal diameter (Figure 1B). On color Doppler, no internal vascularity was detected. There were multiple enlarged left axillary lymph nodes detected on both mammogram and ultrasound (Figure 1C). The mass was classified as highly suggestive of malignancy according to the American College of Radiology Breast Imaging Reporting and Data System (ACR BI-RADS: 5). The patient subsequently underwent ultrasound-guided core needle biopsy of the left breast mass and a fine needle aspiration of the two dominant left axillary lymph nodes. Her initial biopsy specimen was

described as an abscess-like necrotic tissue but there were atypical cells that were highly suspicious for necrotic malignancy. The fine needle aspirations of the two enlarging axillary lymph nodes were negative for malignancy. This suspicious mass demonstrated low T1 and high T2 signal intensity on the pre-contrast imaging on a subsequent breast MRI (magnetic resonance imaging) with the susceptibility artifact from a biopsy clip (Figure 1D-F). After intravenous administration of gadolinium (Omniscan, GE), the mass showed irregular margins and enhancement, initially rapid and subsequently persisted (type III curve) (Figure 1F-H). Additional linear non mass-like enhancement with similar kinetic pattern was noted anterior to the mass, near the palpable marker, which could represent both tumor extension or post biopsy change. Her right breast showed no suspicious finding. Multiple abnormal enlarged and enhancing level 1 and level 2 left axillary lymph nodes and left inter-pectoral lymph nodes were detected, measuring up to 1.4 cm. There was also a 3.0 cm enhancing soft tissue mass with irregular margins in the left parasternal region, suggestive of left internal mammary adenopathy.

Figure 2 Pathology findings. A, B: Breast, core needle biopsy: large area of necrosis with chronic inflammation and fibrosis at periphery of lesion, 4X magnification (A); 16X magnification of A showing rare, atypical cells (arrows, B); C, D: Breast, surgical excision: poorly circumscribed lesion adjacent to previous biopsy site, 10X magnification (C); high grade carcinoma with marked pleomorphism and syncytial growth somewhat obscured by marked intra- and peri-tumoral inflammatory infiltrate (D) characteristic of LELC, 10X magnification; E-H: Immunophenotype: ER negative (E), PR negative (F), Her-2/neu 1+ (G), and Ki-67 27% (H). 10X magnification. ER: Estrogen-receptor; PR: Progesterone-receptor.

Subsequently, the patient underwent left lumpectomy with axillary node dissection. Positron emission tomograph scan showed no evidence of distant metastases. Her final pathology was consistent with stage IIA (pT1c, N1a, M0) lymphoepithelioma-like carcinoma (Figure 2A-D) with three out of twenty-three lymph nodes involved along with a small focus of extracapsular extension. Additional immunohistochemistry staining (Figure 2E-H) demonstrated that the tumor was negative for both estrogen-receptor and progesterone-receptor (ER 0%, PR 0%) and there was no overexpression of human epidermal growth factor receptor 2 (1+). The staining for proliferative index or Ki67 was 27%. The patient received adjuvant chemotherapy with dose dense doxorubicin and cyclophosphamide followed by weekly paclitaxel and a course of adjuvant radiation therapy.

Her clinical course was complicated by persistent inflammation and serosanguinous drainage from the surgical site. She was given antibiotics on multiple occasions for presumed cellulitis with minimal improvement. Follow-up punch skin biopsy and imaging done of the area showed no evidence of recurrence. These skin changes at the surgical site were thought to be secondary to post-surgical changes and radiation treatments. At her 3-year follow-up, the patient was doing well with no evidence of recurrent disease.

DISCUSSION

Lymphoepithelioma-like carcinoma of the breast is a rare tumor type characterized by epithelial neoplastic cells

with a background of lymphocytic cells. Only twenty cases of this type of breast neoplasm have been described in the literature. The reported cases are summarized in Table 1. Making the diagnosis of LELC can pose a diagnostic challenge due to its morphologic similarities with medullary carcinoma and certain types of lymphoma on pathologic examination^[5,14,15]. Making the distinction between LELC-B and other histologically similar tumors has significant impact on therapy and prognosis. Medullary carcinoma of the breast as described by Rapin and Ridolfi includes the following features: syncytial growth pattern > 75%, complete circumscription, diffuse mononuclear stromal infiltrate, moderate to marked nuclear pleomorphism and absence of microglandular features^[16,17]. LELC of the breast has similar features, but specifically obscures the neoplastic cells^[13]. Though poorly differentiated carcinomas, both medullary carcinomas and LELC-B consistently express cytokeratin markers^[12,18]. In our case, the neoplastic cells expressed CK7 and CK5/6, which differentiate these entities from a large cell lymphoma, which may also be on the histologic differential. Additionally, the extensive lymphoplasmacytic infiltrate associated with the epithelial cells may raise concern for a lymphoepithelial lesion, indicating a small cell lymphoma. Special studies for kappa and lambda expression by the B lymphocytes and plasma cells associated with medullary carcinoma and LELC-B show polyclonal cell population with expression of both kappa and lambda light chains. In situ hybridization for kappa and lambda light chains was performed in our case, showing a kappa-to-lambda ratio of approximately 2:1, ruling out a

monotypic B cell population.

Although not tested in our patient, Epstein-Barr virus (EBV) and human papilloma virus (HPV) have been cited for their possible association with LELC of the breast. EBV has been linked to Burkitt's lymphoma and nasopharyngeal carcinoma. To date, EBV has not been shown to be associated with LELC of the breast; however, LELC in other anatomic sites namely salivary glands, sinonasal tract, stomach, thymus and lungs have been associated with EBV positivity^[1,19]. In addition, HPV has been associated with two cases of LELC-B^[8,11]. Another case has been seen with sclerosing lymphocytic

lobulitis^[10].

The case presented here, to the best of our knowledge, is the first case of lymphoepithelioma-like carcinoma of the breast to present as an abscess. Many of the prior case reports of LELC of the breast focus on the distinguishing histopathologic features of the disease and how to distinguish it from morphologically similar entities. Our case illustrates an unusual clinical presentation of this rare tumor type. Our patient presented with a painful breast lump and tenderness that could have easily been mistaken for an infection or other inflammatory processes which would have lead down a completely dif-

ferent diagnostic path and ultimately a significant delay in appropriate treatment. The patient's tumor also appeared to have necrotic and abscess-like features on initial pathologic examination, which has not been described in other cases of LELC. Initial clinical presentations were reported in 13 of the 20 cases. Twelve patients (60%) presented with a palpable mass while only 1 patient had abnormal findings on mammography. Her clinical course was also complicated by recurrent cellulitis and inflammation of the involved site minimally responsive to antimicrobial therapies. These changes may have been secondary to surgery and radiation therapy but did not appear to be consistent with recurrence of her primary disease.

All reported cases of LELC of the breast (Table 1) were found in women, ranging in age from 37 to 69 years. The median age was 54 years at time of presentation. The tumor sizes ranged from 1 to 4 cm and lymph node involvement seen in 25% of the patients including our patient. ER and PR status were evaluated in all but one patient (19 patients). ER was positive in nine patients (47%) and PR was positive in five patients (26%). Her-2 receptor status was reported in fifteen patients and was found to be overexpressed in three patients (20%).

Our patient regularly had annual mammography. Her last screening mammogram was performed six months prior to the detection of the palpable mass which showed no suspicious findings. However, the mass was probably not included in the field of view because of its very posterior location in the medial breast. This type of breast neoplasm appears to have overall favorable prognosis but early detection is imperative for proper treatment. After review of the literature, management of our patient went in line with most of the prior LELC-B cases. Seventeen of the reported cases mentioned some type of surgical intervention including mastectomy (complete or partial) in ten patients (59%) and axillary node dissections in nine patients (53%). Seven patients (34%) received some type of adjuvant chemotherapy and radiation therapy. Our patient underwent partial mastectomy and axillary node dissection followed by adjuvant chemotherapy along with radiation therapy. Disease-free outcome duration ranged from 2 to 72 mo in the cases reviewed while our patient was doing well without evidence of recurrent 36 mo after primary surgery.

In conclusion, this case and other cases of LELC-B demonstrate the diagnostic challenges for this particular type of tumor mainly due to its morphologic similarities with other neoplasms and rarity of the tumor. This is the first reported case of LELC of the breast presented with abscess-like clinical and pathologic features. Early recognition and appropriate diagnostic workup is the key for optimal management for this particular type of tumor.

COMMENTS

Case characteristics

A 64-year-old African American woman presented with a painful palpable lump.

Clinical diagnosis

Palpable mass of left anterior breast.

Differential diagnosis

Breast cancer, breast cellulitis/abscess.

Imaging diagnosis

Ultrasound showed an irregular markedly hypoechoic mass with indistinct margins at the 9 o'clock position of the left breast measuring approximately 2.1 cm in maximal diameter.

Pathological diagnosis

Her final pathology was consistent with stage IIA (pT1c, N1a, M0) lymphoepithelioma-like carcinoma. Additional immunohistochemistry staining demonstrated that the tumor was negative for both estrogen and progesterone receptors (ER 0%, PR 0%) and there was no overexpression of human epidermal growth factor receptor 2 (1+). The staining for proliferative index or Ki67 was 27%.

Treatment

The patient received adjuvant chemotherapy with doxorubicin and cyclophosphamide followed by weekly paclitaxel and a course of adjuvant radiation therapy.

Related reports

Lymphoepithelioma-like carcinoma (LELC) of the breast is a rare tumor type and the case presented is the first case of LELC of the breast presenting as a breast abscess.

Term explanation

LELC is an undifferentiated carcinoma composed of malignant epithelial cells with a lymphocytic background.

Experience and lessons

This case report emphasizes the importance of having knowledge of rare tumor types, particularly those in which early recognition can have profound impact on treatment outcome.

Peer review

It is an interesting and rare case of overlapping features where the diagnosis hangs between abscess and a tumour. The diagnosis is critical for appropriate management.

Abstract

Pulmonary blastoma is an uncommon lung malignancy, usually presenting itself as a large chest mass causing pain, hemoptysis, cough and dyspnea; however, it is asymptomatic in up to 40% of patients. We present the case and suggestive images of a 37-year-old non-smoking lady with a monophasic pulmonary blastoma located in the lower lobe of the left lung who underwent a left posterolateral thoracotomy with lower lobectomy, hilar and mediastinal node dissection, followed by chemo and radiation therapy. After 36 mo, there is no disease progression and the patient is in good health, clinically stable and without significant chest pain.

Key words: Pulmonary blastoma; Pleuropulmonary blas-

toma; Fetal adenocarcinoma; Lobectomy; Thoracotomy

Core tip: Pulmonary blastoma is a rare condition and diagnosis may be difficult to obtain. It is important to underline that the appropriate management of this unusual type of lesion can be achieved only by a multidisciplinary specialized team, able to plan the correct integrated strategy based on aggressive surgery and chemo-radiation therapy.

Magistrelli P, D'Ambra L, Berti S, Bonfante P, Francone E, Vigani A, Falco E. Adult pulmonary blastoma: Report of an unusual malignant lung tumor. *World J Clin Oncol* 2014; 5(5): 1113-1116 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i5/1113.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i5.1113>

INTRODUCTION

Pulmonary blastoma is an unusual lung malignancy, constituting about 0.5% of all lung tumors^[1-4]. Its histology resembles lung fetal tissue and can express both epithelial and mesenchymal features. Despite its assumed embryonal origin, the tumor predominantly affects adults^[5]. The literature reports a limited number of cases classified as adult type pulmonary blastoma or child pleuropulmonary blastoma^[5-8].

In adults, the neoplasm generally presents itself as a large and symptomatic mass causing cough, hemoptysis, fever and chest pain.

CASE REPORT

A 37-year-old non-smoking lady was admitted to the hospital with persistent chest pain, fever and hemoptysis. The chest X-ray showed a gross opacity in the left basal pulmonary field which was first suspected to be empy-

Figure 1 Computed tomography/positron emission tomography scan. A: CT-PET scan showing the large round mass in the left basal hemithorax; B: CT-PET scan showing a frontal vision of the mass inside the chest. CT-PET: Computed tomography/positron emission tomography.

ema complicating a pulmonary infection.

The computed tomography scan (CT scan) revealed the presence of a ten centimeter neoplasm located in the left basal hemithorax. Bronchoscopy showed neoplastic well vascularized vegetation occluding the left lower bronchus and histology through the biopsy permitted diagnosis of a monophasic pulmonary blastoma or the so called fetal adenocarcinoma. The immunohistochemistry obtained by fine needle aspiration biopsy of the lesion under CT scan guidance confirmed the rare lung tumor.

The stage was completed by a CT/positron emission tomography scan (CT/PET), showing an abnormal ^{18}F -FDG uptake limited to the round mass with an elevated SUV of 13, a specific feature of this type of blastoma^[1,9]. There was no evidence of other pathological localizations, confirming that the disease was enclosed in the left lung (Figure 1).

Pre-operative work-up showed no contraindications so the patient underwent surgery. We performed a left posterolateral thoracotomy with lower lobectomy and hilar and mediastinal node dissection (Figure 2).

The postoperative course was uneventful, the drains were removed three days after surgery and the patient was discharged three days later.

Definitive histology confirmed a pT3, pN2, M0 malignant monophasic pulmonary blastoma with only one metastatic mediastinal lymph node (Figure 3). The bronchial stump and the multiple specimens taken on the parietal and mediastinal pleura were negative.

A month later the patient was evaluated by our interdisciplinary team and was considered eligible for adjuvant chemo and radiation therapy.

Follow-up at 6, 12, 24 and 36 mo revealed no disease progression on PET/CT scan, with a serum decrease of oncological markers. The patient is now in good health, clinically stable and without significant chest pain.

DISCUSSION

Pulmonary blastoma is a rare neoplasm with distinctive

Figure 2 A left posterolateral thoracotomy with lower lobectomy. A: Macroscopic vision of the large tumor infiltrating the left lower lobe; B: The cutting surface of the large tumor inside the left lower lobe.

biological behavior^[4]. It was described for the first time in 1952 by Barnard as an “embryoma” and in 1961 was regularly classified by Spencer who established that the tumor arises from pulmonary blastema as tumors developed from fetal tissues^[5,10].

The neoplasm was divided by Koss *et al*^[11] into three groups: biphasic pulmonary blastoma, monophasic pulmonary blastoma with prevalent epithelial expression, and pleuropulmonary blastoma with mesenchymal expression^[2,5,10,11].

In adults, the tumor presents itself as a large chest mass causing pain, hemoptysis, cough and dyspnea; however, up to 40% of patients may be asymptomatic^[4]. Diagnosis may be difficult to obtain because of the unusual pleomorphic histology but it has to be suspected when there is cytological evidence of heterogeneity with epithelial and mesenchymal malignant cells^[12-14]. The radiological appearance consists of a well-delimited circle mass ranging in size from 1.5 to 13 cm in diameter.

Surgical excision is the treatment of choice^[4,15]. The prognosis reported in the literature is generally poor, with limited survival within 2-3 years from diagnosis. The difference in survival rate depends on mediastinal node involvement and over the last ten years a better prognosis has been shown with preoperative neoadjuvant chemotherapy^[14,16].

In a case of N2 disease, postoperative adjuvant radiation therapy and chemotherapy based on cisplatin and etoposide are considered the treatments of choice^[14,17,18].

Figure 3 Monophasic pulmonary blastoma. A: Microscopic appearance of cytology in monophasic pulmonary blastoma; B: Monophasic pulmonary blastoma: Prevalence of epithelial on mesenchymal elements.

In conclusion, adult pulmonary blastoma is an unusual lung tumor presenting itself as a large invasive mass. Diagnosis, treatment and follow-up have to be planned by a multidisciplinary team. Integrated strategy based on aggressive surgery and chemo-radiation therapy may be the best choice for a successful treatment.

COMMENTS

Case characteristics

A 37-year-old non-smoking lady with persistent chest pain, fever and hemoptysis.

Clinical diagnosis

A ten centimeter neoplasm located in the left basal hemithorax.

Differential diagnosis

Empyema complicating a pulmonary infection.

Imaging diagnosis

A well-delimited circle mass ranging in size from 1.5 to 13 cm in diameter.

Pathological diagnosis

pT3, pN2, M0 monophasic pulmonary blastoma with one metastatic mediastinal lymph node.

Treatment

Left posterolateral thoracotomy with lower lobectomy and hilar and mediastinal node dissection followed by chemo and radiation therapy.

Related reports

The rare presentation of pulmonary blastoma can make obtaining a diagnosis difficult, so a meticulous evaluation by a multidisciplinary team is mandatory in suspected cases.

Experience and lessons

Pulmonary blastoma is a rare condition that has to be managed by a multidisciplinary team to plan the correct integrated strategy based on aggressive surgery and chemo-radiation therapy.

Peer review

This is a report of a rare case of a malignant lung tumor. The presentation is simple but adequate.

Abstract

Ectopic thymic tissue can be present in the thyroid gland and a carcinoma showing thymus-like differentiation (CASTLE) may arise from such tissue. We are reported the case of a 26-year-old man with CASTLE, with cervical subcutaneous nodules relapse, who showed a good response to treatment with surgery, chemotherapy and radiotherapy. The problematic aspect of this case was the diagnosis; only on review were we able to make a final diagnosis. CASTLE is a very rare neoplasm. It is important to differentiate this cancer from others tumors such as primary or metastatic squamous cell carcinoma of the head and neck or squamous cell thyroid carcinoma, because the therapy and prognosis are different.

INTRODUCTION

It is possible for ectopic thymic tissue to be present in the thyroid gland and a carcinoma showing thymus-like differentiation (CASTLE) may arise from such tissue. CASTLE is a rare type of cancer; first described by Miy-
auchi *et al*^[1] in 1981, it was not until 2004 that the World Health Organisation recognised it as an independent clinico-pathological entity and classified it as a type of

Figure 1 Positron emission tomography scan showing carcinoma showing thymus-like differentiation local disease recurrence.

thyroid tumor^[2]. We present the case of a young man with a diagnosis of locally advanced CASTLE.

CASE REPORT

A 26-year-old Caucasian male with no family history of neoplastic diseases and no comorbidities was examined by his general practitioner after developing minimal neck oedema and throat tightness; ultrasound of the neck was requested. The first step diagnostic procedures showed normal morphology and ultrasonography of the thyroid, with the exception of a suspicious nodule (about 3 cm of diameter) which was investigated cytologically with FNA and found to be positive for neoplastic cells (even if the diagnostic material was poor). The patient consequently underwent total thyroidectomy. The histological diagnosis was a poorly differentiated carcinoma of the thyroid, pT3N1b (6/6). Immuno-histochemistry (IHC): TTF1-positive (focal), thyroglobulin-positive (focal), CD56-positive (focal), NSE- and P63-positive. No adjuvant anti-neoplastic therapy was recommended. One month later, ultrasound examination of the neck revealed pathological changes at multiple right lateral cervical lymph nodes, confirmed by head and neck magnetic resonance. Positron emission tomography (PET) scanning did not show distant disease but detected neoplastic activity in bilateral cervical lymph nodes (Figure 1). Bilateral functional type lymphadenectomy of cervical lymph nodes was done, with 5/47 lymph nodes positive for metastases of poorly differentiated thyroid carcinoma and involvement of the right anterior margin of the sterno-mastoid muscle. About one month later, the patient came to our hospital for the first time. Physical examination showed multiple subcutaneous nodules near the surgical scar. This abnormal evolution of thyroid carcinoma prompted us to review the histological examinations. We found that the thyroid was characterised by intra-thyroid tumour growth including solid nests of epithelioid elements with high mitotic activity (14×10 HPF). There were also groups of squamoid cells similar to Hassall's corpuscles. The tumour had a lobulated profile and showed marked vascular invasion.

IHC analysis revealed: (1) P63: diffuse and strong nuclear positivity; (2) CD5: multifocal cytoplasmic positivity; (3) TTF1: nuclear positivity in the remaining follicular cells (both in follicles and in the collapsed regions within the tumour); (4) Thyroglobulin: positivity in the remaining follicular cells; and (5) Synaptophysin, calcitonin, chromogranin, CD56: negative; our revised diagnosis was CASTLE.

In view of the results of the histopathological review, a second local relapse within a few months, and a Computed Tomography (CT) scan negative for distant disease, we planned a therapeutic program which included chemo-radiotherapy: 2 cycles of chemotherapy, followed by radiotherapy, followed by 3 further cycles of chemotherapy using the same regimen. The chemotherapy administered was carboplatin AUC 6 and paclitaxel 225 mg/m² q21. Radiation was delivered by daily volumetric intensity-modulated arc therapy with cone-beam CT image-guidance. A parotid-sparing simultaneous integrated boost technique allowed the delivery of three different dose levels prescribed according to tumour burden: 66.0Gy in 33 fractions on the thyroid bed (site of macroscopic residual disease), 59.4Gy in 33 fractions on the right cervical nodes, levels II-V (site of positive extracapsular nodes) and a precautionary dose of 54.45Gy in 33 fractions on left cervical nodes, levels II-V and bilateral recurrent nodes showing excellent clinical response *i.e.*, disappearance of subcutaneous nodules. The most significant side-effects during the radiation treatment were: cervical skin erythema G2, desquamation in the thyroid bed, oropharyngeal mucositis G1 and sore throat; the chemotherapy was well-tolerated. At the end of the treatment the CT scan was negative and the first follow-up 3 mo later was also negative.

DISCUSSION

CASTLE is a very rare neoplasm which arises in the thyroid gland or the soft tissue of the neck. It is necessary to differentiate CASTLE from the others tumours such as primary or metastatic squamous cell carcinoma of the head and neck or squamous cell thyroid carcinoma, because the therapy and the prognosis are different^[3]. There are two theories of the histogenesis of this cancer, the first suggests that CASTLE arises from thymic nests near the thyroid gland which occur as a result of persistence of cervical thymic tissue during embryogenesis; the alternative theory proposes that it arises from remnants of the branchial pouches that differentiate along the thymic line^[3]. The expression of the IHC marker CD5 by CASTLE cells provides support for the latter theory^[4]. The diagnosis of this disease is complicated by its cyto-histological presentation. Microscopically it appears to be arranged in broad, smooth-bordered islands abutting a desmoplastic cellular stroma^[5]. The tumour cells show squamoid characteristics, having eosinophilic cytoplasm, oval nuclei and small distinct nucleoli. Within the lymphoid stroma Hassall's corpuscles may be seen at the

**Figure 2 Hassall's corpuscle (arrow).****Figure 4 CD5 positive cells.****Figure 3 Diffuse nuclear p63-positive cells.**

periphery of the tumour; this may be an additional characteristic of this neoplasm^[6]. In this case the pathologist was alerted to the possibility of CASTLE by the presence of Hassall's corpuscles at the review of the histological findings. The IHC analysis showed a tumour that was strongly positive for pancytokeratin, CD5, P63, focal positive for CEA^[4-7], somewhat positive for chromogranin-A and synaptophysin^[8] and negative for TTF-1, thyroglobulin, chromogranin and calcitonin^[9] (Table 1). In this case CD5- and P63-positive IHC and the presence of Hassall's corpuscles were the two most important elements in the diagnosis (Figure 2, 3 and 4). In the literature this neoplasm is considered an indolent, slow-growing cancer even when regional lymph node metastasis is present^[7-10]. There is no gold standard treatment for this rare lesion although it appears that the first line treatment of choice is surgery with or without adjuvant radiotherapy^[3-11], we therefore suggested a treatment adapted to the needs of

our young patient. We used the type of chemotherapy that we normally give to patients with cancer of the thymus. In this case we administered a sandwich of chemotherapy and radiotherapy. The radiotherapy protocol was similar to that used for thymus tumours, but we reduced the dose intensity because the irradiated volumes were so big that the risk of toxicity for the patient was very high. Currently the patient is feeling well. If this patient had been given radiotherapy after the first surgery would he have relapsed? Unfortunately the literature does not provide evidence on this issue.

A further problem is determining the best radiological technique for staging and follow-up: there are currently no guidelines. In this case we did a total body CT-scan, PET-FDG and MRI of the neck for the staging, but used only a CT-scan for the first follow-up. Although our patient is younger than other cases reported in the literature, we were not able to find epidemiological, genetic or other explanations for his disease. This makes it more difficult to plan follow-up in order to prevent or achieve early diagnosis of other cancers or non-oncological diseases which may arise as ancillary pathological consequences of this rare tumour in this young patient.

COMMENTS

Case characteristics

A 26-year-old Caucasian male with a history of carcinoma showing thymus-like differentiation (CASTLE).

Clinical diagnosis

Neck edema and dysphagia.

Differential diagnosis

Metastatic squamous cell carcinoma of the head and neck or squamous cell thyroid carcinoma.

Laboratory diagnosis

Within normal limits.

Imaging diagnosis

The first step diagnostic was an ultrasonography of the thyroid that showed of a suspicious nodule, which was investigated cytologically and found to be positive for neoplastic cells.

Pathological diagnosis

The thyroid was characterised by intra-thyroid tumour growth including solid nests of epithelioid elements and also groups of squamoid cells similar to Hassall's corpuscles.

Treatment

The patient was treated with surgery followed by a sandwich of chemotherapy and radiotherapy.

Related reports

For this case there is no gold standard treatment so we were treated the patient as a patient with a thymic cancer.

Experiences and lessons

The importance of a multidisciplinary approach and the case's sharing could improve patient management.

Peer review

The manuscript is well written and reported diagnosis and treatment of a rare case of CASTLE.
