Abstract

In this article, we have reviewed available evidence for diagnosis, treatment, and follow-up in female breast cancer (BC). Into daily clinical practice some controversies are occurred. Especially, in the diagnosis field, despite the fact that the optimal age in which screening mammography should start is a subject of intense controversy, there is a shift toward the beginning at the age of 40 although it is suggested that the net benefit is small for women aged 40 to 49 years. In addition, a promising tool in BC screening seems to be breast tomosynthesis. Other tools such as 3D ultrasound and shear wave elastography (SWE) are full of optimism in BC screening although ultrasonography is not yet a first-line screening method and there is insufficient evidence to recommend the systemic use of the SWE for BC screening. As for breast magnetic resonance imaging (MRI), even if it is useful in BC detection in women who have a strong family history of BC, it is not generally recommended as a screening tool. Moreover, based on the lack of randomized clinical trials showing a benefit of presurgical breast MRI in overall survival, it's integration into breast surgical operations remains

debatable. Interestingly, in contrast to fine needle aspiration, core biopsy has gained popularity in presurgical diagnosis. Furthermore, after conservative surgery in patients with positive sentinel lymph nodes, the recent tendency is the shift from axillary dissection to axillary conserving strategies. While the accuracy of sentinel lymph node after neoadjuvant chemotherapy and second BC surgery remains controversial, more time is needed for evaluation and for determining the optimal interval between the two surgeries. Additionally, in the decision between immediate or delayed breast reconstruction, there is a tendency in the immediate use. In the prevention of BC, the controversial issue between tamoxifen and raloxifene becomes clear with raloxifene be more profitable through the toxicities of tamoxifen. However, the prevention of bone metastasis with bisphosphonates is still conflicting. Last but not least, in the follow-up of BC survivors, mammography, history and physical examination are the means of an early detection of BC recurrence.

Key words: Breast cancer; Controversies; Diagnosis; Treatment; Follow-up

Core tip: Taking into consideration the progress in diagnosis and treatment in the female breast cancer, it is inevitable that some controversies will come up in daily clinical practice. The aim of this review is to illustrate some of these conflicting issues and make them less "ambiguous". Thus, this has been achieved in the issues of mammography, magnetic resonance imaging, fine needle aspiration and core biopsy, axillary dissection, internal mammary node sampling, accelerated partial breast irradiation, the sequence of chemoradiotherapy, negative margin width, while controversial are still remain the themes of tomosynthesis, 3D ultrasound, shear wave elastography, positron emission tomography-computed tomography (PET-CT), CT-scan and bone scintigraphy, hormoneotherapy, bisphosphonates and sentinel lymph node biopsy.

INTRODUCTION

Globally, breast cancer (BC) is one of the most frequent diagnosed cancers^[1]. More than 1.6 million new cases of BC are identified among women, according to the recent worldwide available data^[2]. Especially, in North America, in western and in northern Europe the incidence rate is higher than in Asia and socioeconomical development seems to be the leading cause^[1,3,4]. In addition, the cumulative incidence of BC raised by more than a quarter between 1980 and 2010 among 187 countries^[2]. This raise has been succeeded thanks to BC awareness and early detection of breast malignancy.

Taking into consideration the progress in diagnosis and treatment, it is inevitable that some controversies will come up in daily clinical practice^[5]. The aim of this review is to illustrate some of these conflicting issues and make them less “ambiguous”. Especially, in the diagnosis field, the subjects which are discussed below are mammography, breast tomosynthesis, 3D ultrasound, shear wave elastography, magnetic resonance imaging, fine needle aspiration and core biopsy, computed tomography, positron emission tomography-computed tomography (PET-CT), axillary node dissection, sentinel lymph node biopsy, internal mammary node sampling and negative margin widths. As for the controversial issues based on treatment, these are partial breast radiotherapy, breast reconstruction, sequence of radiotherapy and chemotherapy, hormotherapy and biphosphonates. However, the follow-up of BC survivors has not been overlooked.

IS MAMMOGRAPHY NECESSARY IN WOMEN BEFORE THE AGE OF 50?

According to prevailing belief, early detection is a vital first step in defense against BC. Undoubtedly, mammography is the gold standard in BC screening and is widely used in order to reduce BC deaths. The optimal age in which mammography screening should start is a subject of intense controversy. Specifically, while there is a consensus for routine screening in women among 50-69 years, it is still under debate whether women aged 40-49 years could benefit from screening with mammography^[6]. As a result, there are different recommendations among organizations and by extension among countries concerning screening. The United States Preventive Services Task Force (USPSTF) recommended toward biennial screening at age of 50 and against screening in women aged 40-49 years^[7], “overlooking” that a mammography screening reduces BC mortality by 15% for women aged

39 to 49 years^[8] and sparking a controversy in the medical world. However, as it is shown by a recent study, the effect of those guidelines on mammography rates in women older than 40 years was negligible^[9]. Conversely, some organizations such as American Cancer Society (ACS) and American College of Radiology (ACR) have different position than that of USPSTF, recommending annual mammography screening beginning at age 40^[10,11]. It is noteworthy that a new study with 7301 patients argued in favor of screening before age 50 years, because it is proved that most deaths from BC occurred in women who were unscreened^[12]. Additionally, a meta-analysis which conducted by Greek scientists indicated a significant reduction in BC mortality, as a result of screening mammography in women younger than 50^[13]. Similar effectiveness is confirmed by a Sweden study^[14]. Taking into account all the above and the fact that BC occurs in many cases in women under age 50, there is a tendency toward offering screening mammography before 50 years. As an example, in the United Kingdom in 2010, by the age of 50 around 10000 women were diagnosed with BC and 80% of all diagnoses were in the over 50s, concluding that about 1 in 5 women were diagnosed with BC by the age of 50^[15]. It is worthwhile to note that guidelines vary between countries, depending on socioeconomic development of each one.

CAN BREAST TOMOSYNTHESIS BE PROPOSED AS A SCREENING TOOL?

Great scientific interest has been focused on breast tomosynthesis (BT), which is a relatively new three dimensional imaging technology for the fight against BC nowadays. BT uses a digital detector and an X-ray source, which moves in an arc around breast and takes multiple images^[16]. Then, BT's information is sent to a computer, where it is reconstructed in order to produce a 3D image of breast tissue thickness 1 mm. It seems that BT solves the problem of tissue overlap, which encountered in 2D mammography^[16]. Despite, BT approved by the US Food and Drug Administration^[17], it is a controversial issue whether it could be the standard care in BC screening. Although, it was found that BT has a marginally greater sensitivity and greater specificity, compared to digital mammography^[18], there were conflicting findings regarding BT's sensitivity from other data. Some investigators found that traditional mammography was slightly superior to BT in sensitivity^[19] and that BT potentially has worse performance in the detection of microcalcifications^[20]. On the other hand, it was recently demonstrated that the usage of BT in combination with digital mammography (“adjunctive BT”) has as a result an increase in BC detection rates^[21]. Similarly, a recent study concluded that adjunctive BT could improve the diagnostic performance in mammography and, summarizing older data, mentioned that BT has probably a higher sensitivity when compared with 2D mammography and reduce recall rates^[22], a similar conclusion of Haas *et al*^[23] especially

in women under the age of 50 and in women with dense breast tissue. According to all aforementioned reasons, BT is a promising revolutionary tool in BC screening. At present, BT is used only as an adjunct to conventional mammography. Consequently, clinical trials are necessary in order to justify its routine use in screening population.

SHOULD HIGH RESOLUTION 3D ULTRASOUND BE USED AS A SCREENING MODALITY IN YOUNG PATIENTS WITH DENSE BREASTS?

Although mammography is the gold standard in BC screening, it may not be effective in all patients, such as young women with dense breasts^[24]. Also, it is noteworthy that women with dense breast tissue have a 3 to 5 fold increase in BC risk, in contrast to those women with a lack of dense breast tissue^[25]. Owing to all aforementioned reasons, new tools for BC screening such as breast ultrasound, are needed. Remarkably, the United States Food and Drug Administration (FDA) approved in 2012 an automated breast ultrasound system (ABUS), as an adjunct to mammography, especially in women with dense breasts^[26]. As a screening tool, the method could be proposed for the imaging evaluation of non-palpable masses in women under 30 years of age who are not at high risk for development of BC, and in lactating and pregnant women^[27]. 3D breast ultrasound is a special advanced examination, which provides information of the coronal plane^[28]. Recent available data are full of optimism about the utility of 3D breast ultrasound in young women with mammographically dense breasts. Specifically, a study indicated that the extra usage of 3D breast ultrasound was more efficient than mammography alone^[27]. However, there is no evidence that 3D ultrasound decreases mortality rates^[29]. Thus, 3D breast ultrasound is a promising tool and may be used in screening in women with dense breasts widely. Nevertheless, there are no guidelines for its use as screening, instead of mammography until now^[30]. Summing up the discussion above, this issue remains a subject of intense controversy and randomized clinical trials are required.

IS SHEAR WAVE ELASTOGRAPHY A VALUABLE TOOL?

Elastography is a technique of breast imaging tissue stiffness which has been introduced into ultrasound in order to contribute to lesion differentiation^[31,32]. Namely, shear wave elastography (SWE) uses the acoustic radiation force provided by the ultrasound beam itself. Although, the predictive significance of this method remains to be elucidated, most recent studies pointed out that SWE improves the specificity of B-mode ultrasound^[33-36] and provides a good diagnostic performance during breast ultrasound^[32,34,36,37]. Interestingly, SWE increased the speci-

ficity of breast mass assessment from 61.1% to 78.5% and the positive predictive value from 52.6% to 67.1% in a multicenter study with 939 breast masses, while the improvement in sensitivity was insignificant^[36]. Moreover, it is noteworthy that several studies demonstrated that SWE may have an important role in reducing the number of unnecessary breast biopsies^[34] and that could be useful to assess the cystic content of a breast lesion^[35] and axillary lymph node status^[38].

WHO SHOULD HAVE BREAST MRI FOR SCREENING?

Potential use of breast magnetic resonance imaging (MRI), a specialized non-invasive test is extensively studied nowadays. This method uses radio waves and strong magnets in order to determine the morphology of the inner breast. Latest studies, indicated that breast MRI is a valuable screening modality in women with a family history suspicious for inherited predisposition to BC^[39,40]. In fact, from these women, annual MRI in accordance with mammography is the current recommendation of several organizations such as American Cancer Society^[41], National Institute for Health and Care Excellence^[42] and European Society of Mastology-EUSOMA^[43]. Specifically, according to the recent guidelines, the main indication for annual MRI screening is the existence of BRCA1 or BRCA2 gene mutation. Moreover, there is some suggestion that women who have a first-degree relative (parent, brother, sister or child) with a BRCA1 or BRCA2 gene mutation, but personally have not been genetic tested, ought to be screened by MRI once a year^[41]. Similar recommendation applies for women who have a strong family history of BC^[42]. The prevalent age for starting breast MRI screening ranges from 25 to 30 years^[41,43]. However, several organizations recommend to women with family history of BC, MRI starting 10 years earlier than the age of diagnosis of the youngest affected relative^[11]. According to all aforementioned reasons and the limitation of evidence about the best age in which to start screening^[41], this decision should be tailored to women's unique situation. As an example, in women with Li-Fraumeni syndrome [an autosomal dominant disorder associated with abnormalities in the tumor protein p53 gene (TP53)], breast surveillance with breast MRI should be considered beginning at 20 years of age^[44]. Similarly, consensus recommendations for BC surveillance in women with Cowden syndrome [an autosomal dominant disorder associated with abnormalities in the phosphatase and tensin homolog (PTEN) gene] include annual mammogram and/(or) breast MRI starting at age 30 to 35 or 5 to 10 years before the earliest known BC in the family^[45]. Nowadays, another main debate is about the possibility of moving from the old recommendation of "MRI as an adjunct" to the new one "MRI alone"^[46]. Currently, MRI is not generally recommended as screening tool by itself, despite the fact that it has better sensitivity than mammography (especially in young women), it still has more false positive recalls^[39,41].

Furthermore, MRI is a quite expensive procedure^[47] and has no evidence on reducing BC mortality^[48].

DOES PRESURGICAL BREAST MRI INFLUENCE OVERALL SURVIVAL?

According to general belief, breast MRI is an extremely sensitive imaging assessment tool, which is able to detect BC^[40]. However, the integration of MRI into breast surgical operations remains debatable. Specifically, whether presurgical breast MRI has some impact on overall survival is a controversial and complex subject^[49]. Some investigators who support the use of breast MRI pre-operatively argue that it may have an influence in overall survival rates^[50]. This view is supported because of the potential benefits of MRI in decrease of recurrence rates^[51,52]. Conversely, recent available data has shown that this approach does not improve patient's outcomes^[53]. Interestingly, a meta-analysis which conducted in 2013 pointed out that MRI leads to overtreatment with probably unnecessary mastectomies^[54], a different conclusion than that of Killelea *et al*^[52]. Furthermore, a United Kingdom randomized trial (COMICE) indicated that preoperative MRI did not change the re-operation rates^[55]. In conclusion, there is a lack of randomized clinical trials showing a benefit of presurgical breast MRI in overall survival. Thus, in order to exist a definitive answer to this issue, additional studies are required.

PRESURGICAL DIAGNOSIS: FNA OR CORE BIOPSY?

Both fine-needle aspiration (FNA) and core biopsy (CNB) are the current procedures of choice for the detection of BC. FNA is executed with the use of a 10 or 20 mL plastic syringe and a 23 to 27 gauge needle. The syringe can adapted to a special device, which brought negative pressure. As keeping negative pressure, syringe makes reciprocating movements into the mass, while rotating physician's wrist^[56]. Also, in order to succeed nipple aspiration, a specially constructed syringe can be applied by Zervoudi's technique^[57]. On the other hand, CNB is a method that removes small solid samples of tissue using a needle with wide lumen. Both of these aforementioned procedures have advantages and disadvantages, as it is shown in Table 1^[58-61]. In recent years, there is a shift toward the use of CNB. However, whether FNA or CNB is better remains contentious and there is a lack of consensus among different BC centers. Specifically, some investigators summarized that FNA has superiority over CNB and that may be useful and reliable as a first diagnostic step for the detection of palpable breast lesions^[62,63]. Moreover, they found that FNA had a same predictive value with CNB^[64]. Conversely, other researchers demonstrated that CNB offers a more definitive histologic diagnosis in contrast to FNA, which has limitations in diagnostic accuracy, sensitivity and specificity^[56,58].

A main disadvantage of FNA cytology is the "inability" to distinguish between *in situ* and invasive cancer^[65]. On the contrary, CNB may permit the distinction between *in situ* and invasive cancer. As a result, CNB has gained popularity widely, but the final decision on whether to use one or another is based on a number of factors, such as the clinical features of the lesion, the likelihood of achieving an indicative diagnosis and the experience of the operator^[58].

FOLLOW-UP TO DETECT METASTASIS: CT SCAN AND BONE SCINTIGRAPHY OR PET/CT?

Currently, if computed tomography (CT) scan and bone scintigraphy could be used as a standard practice in BC follow up or whether PET/CT is more efficient, is controversial. Most published scientific studies, indicated that whole body PET/CT has greater sensitivity and specificity in detecting metastasis, compared to other approaches^[66]. In other words, recent available data revealed that PET/CT is superior to CT scan and bone scan and provides better accuracy in bone metastases detection, in patients with BC^[67-69]. However, an individual multicenter study concluded that bone scintigraphy, which is inexpensive^[68], is more effective in bone metastases determination than PET/CT^[70]. Moreover, PET/CT is related with low sensitivity in identification of tumors, smaller than 1 cm^[71]. Furthermore, in asymptomatic patients, it is noteworthy that none of the imaging tests, including CT scan, bone scintigraphy and PET/CT provides survival improvement^[72]. According to the above, imaging studies (apart of mammography and breast MRI in special occasions) are not recommended as a routine practice in people with no symptoms of metastases^[72-74]. However, in symptomatic patients, there is not enough evidence whether PET/CT could be replaced CT scan plus bone scintigraphy.

AFTER CONSERVATIVE SURGERY, IN PATIENTS WITH POSITIVE SENTINEL LYMPH NODES, SHOULD AXILLARY DISSECTION BE PERFORMED OR NOT?

Axillary dissection was considered as the gold standard practice for many years in patients with a positive sentinel lymph node. Nowadays, in accordance with the counterintuitive results of many studies, there is a key controversy on whether this approach is always necessary after a positive sentinel lymph node^[75]. In fact, both the ACOSOG Z0011 randomized trial and the IBCSG 23-01 controlled trial indicated that the routine use of axillary dissection could be safely omitted in women with early BC who have only one or two positive sentinel nodes^[76,77]. Interestingly, they showed that there is no statistical difference in overall survival and in disease free

Table 1 Comparison between fine needle aspiration and core biopsy

	FNA	CNB
Ability to distinguish invasive from <i>in situ</i> lesions	No	Yes
Accurate for palpable lesions	Yes	Yes
Accurate for non palpable lesions	No	Yes
Useful for hypocellular and sclerotic lesions	No	Yes
Diagnosis of papillary lesions	Low	Moderate
Distinction of low grade lesions	Very difficult	Difficult
Suitable for difficult or superficial sites	Yes	No
Appropriate for patients with coagulation abnormalities	Yes	No
Complication rate	Very low	Low
Minimal invasiveness	Yes	No
Special experience required	Yes	No
Rapid (initial) diagnosis	Yes	No
Patient discomfort	No	Yes
Long tissue processing time	No	Yes
Cost	Inexpensive	More expensive than FNA
Requirement of anesthesia	No	Yes

FNA: Fine needle aspiration; CNB: Core biopsy.

survival between patients who underwent axillary dissection and those that did not, but who received systemic therapy and radiation therapy (RT). These results were also confirmed by AMAROS study, which found that radiotherapy may be sufficient for most patients with a positive sentinel node^[78]. Indeed, the 2013 St. Gallen Consensus Conference recommended that in patients with macrometastasis in 1-2 sentinel lymph nodes, completion of axillary dissection can be avoided in patients who receive RT^[79]. On the other hand, individual studies pointed out that the omission of axillary dissection in women with sentinel node micrometastases is related to an increased 5-year recurrence rate^[80]. Summarizing all the above data and taking into account a recent review, a complete axillary node dissection is suggested in patients with positive sentinel node undergoing a mastectomy without RT^[81]. Furthermore, for patients with micrometastases (> 0.2 mm and no greater than 2.0 mm) or macrometastases in three or more nodes, after sentinel lymph node dissection, completion of axillary dissection is recommended for staging purposes and to ensure local control^[82]. In conclusion, according to the above data, the recent tendency is the shift from axillary dissection to axillary conserving strategies in selected patients with positive sentinel lymph nodes.

WHICH IS THE IMPACT OF MICROMETASTASIS IN SENTINEL NODE ON DFS AND OS?

The presence of micrometastasis in sentinel lymph nodes has raised the issue on whether has some impact on disease free survival (DFS) and overall survival (OS). Several

studies indicated that women with micrometastasis in sentinel lymph node did not have significant difference in DFS and OS *vs* node negative patients^[83]. Remarkably, in a study published by Hansen *et al.*^[84], patients with micrometastasis, pN0(i+) [regional lymph node(s) with (≤ 200) malignant cells in an area ≤ 0.2 mm] and pN1mi [regional lymph node(s) with malignant cells in an area > 0.2 mm but ≤ 2.0 mm (and/or with > 200 cells in an area ≤ 2.0 mm)] did not appear to have a worse 8-year DFS or OS in comparison with patients who were sentinel node negative^[85]. The latter was also confirmed by another population based study in which has been proved that there is hardly any impact on OS during the first years after diagnosis in patients with sentinel node micrometastasis. In contrast to all aforementioned studies, other studies concluded that the appearance of sentinel node micrometastasis has been associated with shorter positive DFS and OS rates^[86,87]. Summarizing, the influence of micrometastasis on BC outcomes remains uncertain, enhancing plenty of controversy among investigators.

IS SENTINEL NODE AFTER NEOADJUVANT CHEMOTHERAPY ACCURATE?

Patients who are candidates for neoadjuvant chemotherapy (NACT) and have a clinically negative axillary examination at presentation (cN0) may have a sentinel lymph node biopsy (SLNB) either prior to or after neoadjuvant chemotherapy. The timing is often determined by preferences of the treating physician, and in the absence of data suggesting a preferred strategy, either is reasonable. It is suggested that if the SLNB is negative (pN0), before or after NACT, no further axillary evaluation is required^[88]. Candidates for nodal evaluation who are about to undergo NACT are initially either clinically node-negative or clinically node-positive patients. However, the application of SLN surgery for staging the axilla, following NACT, for women who initially had clinically node-positive (cN1) BC [and, after NACT, clinically node-negative (cN0) BC] is unclear because of high false-negative rates (FNR) of SLNB reported in previous studies. Actually, considering that FNR is $> 10\%$, changes in approach and patient selection that result in greater sensitivity would be necessary to support the use of SLN surgery, after NACT, as an alternative to axillary lymph node dissection (ALND)^[89]. In addition, it seems “rationale” that SNDB is a more reliable diagnostic method before NACT and that after NACT, SLNB has a lower detection rate and a higher FNR compared with SLNB done before NACT. However, based on the results of the American College of Surgeons Oncology Group (ACOSOG) Z1071 trial and the SENTINA (SENTinel NeoAdjuvant) study, a prospective, multicenter cohort study, a clear relationship was found between the number of SLNs and false negative rates^[90]. Clearly, as much SLNs are removed, as low the false-negative rate is^[89-91]. For patients initially presenting with clinically node positive disease who then

received NACT, it was convincingly demonstrated that only when ≥ 3 nodes were harvested during SLNB, the FNR was comparable to that of patients initially presenting with clinically node negative disease^[91]. Furthermore, it seems that the false-negative rate of SLNB after NACT is roughly comparable to the one of SLN biopsy in general (10.5%)^[92,93], albeit it was suggested that there is insufficient evidence to recommend SLNB after NACT as a standard procedure^[92]. As for the “accuracy”, there are studies which confirm that SLN remains an accurate tool after NACT in selected patients with operable BC^[94,95] while in contrary others conclude that the diagnostic reliability is better before the systematic treatment^[90]. In conclusion, the accuracy of SLN after NACT remains a conflict through the published studies and further evaluation is needed.

IS SENTINEL NODE IN SECOND BC SURGERY (PRIOR CONSERVATIVE SURGERY) ACCURATE?

Approximately 10 to 15 percent of the patients with early BC, who had undergone breast-conserving surgery (BCS), will develop loco-regional recurrence disease within 10 years^[96,97]. Axillary staging in these patients is important for obtaining locoregional control and predicting prognosis^[98]. Nowadays, the concept of repeating sentinel node biopsy (SNB) is a potential clinical scenario. Inquiring into published data, the dominant aspect is that SNB is technically feasible and accurate and can be successfully performed^[99-101]. In similar assumptions ended a recent systematic review and meta-analysis of the literature published by Maaskant-Braat *et al.*^[99] after taking into account all studies on repeat SNB in locally recurrent BC. The main conclusions of the above review were that repeat SNB has a low false-negative rate, spares patients an unnecessary axillary lymph node dissection and its information can lead to a change in adjuvant treatment strategy. Nonetheless, more studies are required to determine the optimal interval before repeat SNB^[82].

INTERNAL MAMMARY NODE SAMPLING IN CENTRAL AND INTERNAL QUADRANT BC: USEFUL OR NOT?

Even if axillary sentinel lymph node (SLN) biopsy is a standard procedure for staging clinically node negative patients with BC, the value of sentinel lymph node biopsy for the internal mammary chain (IMC) remains marginally controversial^[102]. As for the tumor location and the internal mammary node (IMN) involvement, Paredes *et al.*^[103] reported that the predictive factor for the IMC involvement was location of the tumors in the inner quadrants ($P < 0.001$), while Cserni and Szekeres pointed out that data from extended radical mastectomy series cannot be extrapolated to patients suitable for SLN^[103,104]. Indeed, SLN biopsy does not reliably identify IMN involvement

because of interference from radioactivity at the primary tumor site and there is a high rate of technical failure^[82]. In addition, the axillary lymph node (ALN) involvement has been noticed as a predictive factor for IMN involvement^[105]. It is rarely found IMN metastasis without ALN metastasis according to Ramsay *et al.*^[106]. Prognosis for patients with axillary and IM involvement is worst while axillary node negative patients will be found to have regional metastasis to the IMN in 8 to 10 percent of cases^[82,104]. In case of positive diagnosis of IMN involvement, the treatment decisions may be affected regarding adjuvant systemic therapy and regional irradiation^[82,105]. However, randomized trials show no evidence that IMN resection through extended mastectomy compared with radical or modified radical mastectomy improves survival^[107,108]. Thus, the IMN dissection was abandoned. All these boils down to the fact that IM SLN biopsy is not routinely recommended (considered investigational) and further studies need to be undertaken^[82,102,109,110].

CAN PARTIAL BREAST RADIOTHERAPY BE SELECTED IN BIFOCAL CANCERS?

Accelerated partial breast irradiation (APBI) is used as an alternative technique to conventional whole breast irradiation (WBI) in selected patients with early BC after breast conserving surgery (BCS)^[111]. Recommendations for the selection of patients have been published from the American Society of Breast Surgeons (ASBS), the American Brachytherapy Society (ABS), the American Society for Radiation Oncology (ASTRO) and the European Society for therapeutic Radiology and Oncology (ESTRO)^[112-115]. The criteria for the selection conducted according to the published clinical evidence so as the APBI be effective. Polgár *et al.*^[115] argued that the relatively poorer results of early APBI studies with high local recurrence rates exceeding 1% per year could be attributed to inadequate patient selection criteria and/or suboptimal treatment technique and lack of appropriate QA procedures^[116]. Particularly, APBI should be limited to patients between 45 (ABS ≥ 50) and 70 years of age, with small (≤ 3 cm), unifocal, unicentric and lymph node negative tumors resected with negative margins and without adverse histologic features (including lobular carcinoma, *in situ* ductal carcinoma and extensive intraductal carcinoma). Consequently, a patient with a bifocal tumor cannot be selected for partial breast irradiation.

WHICH IS THE IMPACT ON RECURRENCE IN IMMEDIATE OR DELAYED RECONSTRUCTION AFTER MASTECTOMY?

Immediate (IBR) or delayed breast reconstruction (DBR) stipulates the time of reconstructive surgery after mastectomy. Even if the impact of loco-regional recurrence comparing IBR and DBR has not been evaluated, nu-

merous studies compare the recurrence ratio of IMR and DBR with mastectomy alone. Particularly, a published meta-analysis in 2012 demonstrates no evidence for increased frequency of local breast recurrence with IBR compared to mastectomy alone (OR: 0.98; 95%CI: 0.62-1.54) while another study reports that IBR had an acceptable 5-year local recurrence rate of 2.9% (95%CI: 0.1-5.7)^[117,118]. In case of DBR, Lindford *et al*^[119] (2013) concluded that delayed autologous reconstruction after mastectomy doesn't appear to adversely influence disease progression when compared to patients treated with mastectomy only. The appropriate time should be settled on minimizing the potential complications and optimizing the postoperative outcome. Nonetheless, in case of women who require postmastectomy radiotherapy (RT) the best option of reconstruction is controversial although need for postoperative RT is considered a relative contraindication to IBR^[120]. On one hand, based in a retrospective study, DBR should be proposed to these women as the loco-regional recurrence rate is lower when RT is given before reconstruction and patient demise may be increased when radiation therapy is performed following breast reconstruction^[121]. On the other hand, this was not proven by other data showing that mastectomy with immediate expander-implant reconstruction was associated with acceptable 5-year locoregional control, distant metastasis-free survival and overall survival^[122]. All these boils down to the fact that there is no evidence cancelling IBR or DBR based on recurrence. There is a tendency more and more using IBR over DBR considering, among others, that several studies revealed that women undergoing IBR experienced significant psychosocial benefits^[120].

WHICH IS THE OPTIMAL TIME TO START CHEMOTHERAPY AFTER BC SURGERY AND WHICH SEQUENCE OF RADIOTHERAPY AND CHEMOTHERAPY SHOULD BE ADMINISTERED?

Radiotherapy (RT) and chemotherapy (CT) are used to improve local control and reduce the risk of dying from BC. Nevertheless, for women with early stage BC who have been treated surgically, it remains marginally uncertain whether both treatments should be given at the same time (concurrently) or one after the other (sequentially) and in which order^[123]. Four schemes of sequencing RT and CT have been tried or adopted: administering CT before RT (more frequently used), administering CT and RT concurrently with an overlap of at least 21 d^[124], using a "sandwich" treatment schedule by administering three cycles of CT followed by RT and then administering three more cycles of CT^[125] and administering RT before CT. Adjuvant chemotherapy can be administered within 4-6 wk after the surgery while a delay of more than 12 wk could be detrimental^[126]. Abbas *et al*^[127], in a total of 267 patients divided into 3 groups, found that disease free

survival (DFS) at 2.5 years was 83.5%, 82.3% and 80% for patients receiving radiation before chemotherapy, sandwich and after finishing chemotherapy respectively concluding that DFS is not altered by treatment sequence. Pooling data of three randomized trials in women with early stage BC, Hickey concluded that local control and overall survival was similar comparing concurrent CT and RT, RT followed by CT and CT followed by RT when RT was commenced within seven months after surgery (as this was the maximum delay in the included studies). However, RT followed by CT was associated with an increased risk of neutropenic sepsis compared with CT followed by RT and concurrent chemoradiation increased anaemia, telangiectasia and pigmentation^[123]. Similarly, a randomized trial including 2396 women with early stage BC who received CMF with or without an anthracycline and who were treated with concomitant or sequential radiation therapy, concluded that in concomitant therapy there was a significant increase in acute skin toxicity (25 *vs* 16 percent)^[128]. It seems that concurrent chemoradiation is more toxic than sequential therapies. Taking everything into account, the concomitant use of RT and CT hasn't gain universal acceptance while the clinical practice uses CT before RT^[129].

HORMONOTHERAPY IN POSTMENOPAUSAL WOMEN: WHICH ONE AND FOR HOW LONG?

Undoubtedly, hormonotherapy constitutes a principal component in treatment of hormonal positive BC. Selective estrogen receptor modulators (*e.g.*, tamoxifen and toremifene), estrogen receptor downregulators (*e.g.*, fulvestrant) and aromatase inhibitors (*e.g.*, anastrozole, exemestane and letrozole) are all different types of hormonal therapy medicines^[41]. It is noteworthy that despite tamoxifen was the previous established therapy, it was replaced by the usage of aromatase inhibitors (Als) in postmenopausal women. This shift is based on the positive findings in studies which compared Als to tamoxifen^[130]. Notably, a meta-analysis indicated that Als significantly decrease the risk of recurrence and improve outcomes^[131]. However, tamoxifen remains an option of therapy, particularly in women with contraindication to Als, but not as a first choice^[132]. For many years, the ideal duration of tamoxifen treatment was 5 years. Nevertheless, recent randomized trials, such as ATLAS study demonstrated that the use of tamoxifen over 10 years has superiority in recurrence and mortality, compared to a 5-year therapy^[133]. On the other hand, there are many unanswered questions that generate plenty of controversy regarding the use of Als, which is the initial treatment in postmenopausal women. Firstly, it is unclear which of aromatase inhibitor is better. However, all Als appear to have similar efficacy, as it is shown by MA.27 study^[134]. Secondly, it is still uncertain which is the ideal duration of Als therapy. The standard treatment lasts 5 years, but

more studies are required in order to prove whether therapy with an AI could be efficient for more than 5 years. Thus, until now, for postmenopausal women, it is recommended by several organizations to begin treatment with an AI for 5 years, or with tamoxifen for 5 years followed by an AI for 5 years, or treatment with tamoxifen for 2 to 3 years followed by an AI in order to complete a 5-year therapy^[41,72,132]. In conclusion, the choice of suitable hormone therapy should be depend on patient's unique situation.

TAMOXIFEN-RALOXIFENE: WHICH IS BETTER FOR BC PREVENTION?

Focusing on tamoxifen and raloxifene, many trials have been conducted in order to point out which one is the most effective for BC prevention. The STAR trial (Study of Tamoxifen and Raloxifene) compared tamoxifen with raloxifene in 19490 high-risk postmenopausal women for a 5-year period. The initial results were almost equal with both drugs reducing the risk of BC approximately 50%. In the long-term follow-up, tamoxifen had a greater chemoprevention effect than raloxifene [1.24, 95%confidence interval (CI), 1.05-1.47]. Actually, long-term raloxifene retained 76% of the effectiveness of tamoxifen in preventing invasive BC^[135]. However, there are other trials which compared tamoxifen and raloxifene with placebo. In MORE (Multiple Outcomes of Raloxifene Evaluation) trial, 13 cases of BC were confirmed among the 5129 women assigned to raloxifene *vs* 27 among the 2576 women assigned to placebo [relative risk (RR), 0.24; 95%CI: 0.13-0.44]^[136]. In CORE (Continuing Outcomes Relevant to Evista) trial, the 4-year incidences of invasive BC and estrogen receptor (ER)-positive invasive BC were reduced by 59% [hazard ratio (HR) = 0.41; 95%CI = 0.24 to 0.71] and 66% (HR = 0.34; 95%CI = 0.18 to 0.66), respectively, in the raloxifene group compared with the placebo group^[137]. Finally, in Raloxifene Use for the Heart (RUTH) trial, in 10101 postmenopausal women with coronary heart disease or multiple risk factors for this disease, raloxifene reduced the incidence of invasive BC by 44% (HR = 0.56; 95%CI = 0.38-0.83)^[138]. Similarly, after 7 years of follow-up, the cumulative rate of invasive BC was reduced from 42.5 per 1000 women in the placebo group to 24.8 per 1000 women in the tamoxifen group (RR = 0.57, 95%CI = 0.46 to 0.70) in the National Surgical Adjuvant Breast and Bowel Project P-1 (NSABP-1) study. Furthermore, in the International Breast Cancer Intervention Study (IBIS-I), after a median follow-up of 96 mo after randomization, 142 BCs were diagnosed in the 3579 women in the tamoxifen group and 195 in the 3575 women in the placebo group (4.97 *vs* 6.82 per 1000 woman-years, respectively; RR = 0.73, 95%CI = 0.58 to 0.91). Although this study showed a somewhat "smaller" reduction of the risk of BC, the risk-reducing effect of tamoxifen appeared to persist for at least 10 years and, equally important, most side effects of tamoxifen did not continue after the 5-year treatment period^[139]. The

rates of BC were much lower in the tamoxifen group among women at high risk for BC (placebo, 6.26 per 1000 women-years, tamoxifen, 1.50 per 1000 women-years; RR = 0.24, 95%CI = 0.10 to 0.59) in the Italian Randomized Tamoxifen Prevention Trial^[140]. On the contrary, an interim analysis of the Royal Marsden Hospital tamoxifen randomised chemoprevention trial, with 2494 healthy women, the overall frequency of BC was the same for women on tamoxifen or placebo [tamoxifen 34, placebo 36, RR=1.06 (95%CI = 0.7-1.7)]^[141]. Summarizing the facts (not all included above) for the comparison of tamoxifene *vs* raloxifene, it can be concluded that postmenopausal women can choose the most effective tamoxifen (accepting its toxicities), or they can choose the (slightly) less effective (but more tolerable) raloxifene^[142]. Furthermore, according to recent data, anastrozole effectively reduces incidence of BC in high risk postmenopausal women^[143]. Finally, it must be emphasized that United States Preventive Services Task Force (USPSTF) recommends against the routine use of medications for risk reduction of primary BC in women who are not at increased risk for BC^[144].

DO BISPHOSPHONATES DECREASE THE RISK OF BONE METASTASIS?

Bone metastasis is the most common metastasis in women with BC^[145]. The effects of bisphosphonates in women with early-stage BC (EBC) have been evaluated after several meta-analyses as an adjuvant therapy with aromatase inhibitors (AI). In 2010, a meta-analysis, which included data from 13 eligible trials involving 6886 patients randomized to treatment with bisphosphonates or either placebo or no treatment, concluded that there is no significant reduction in bone metastasis (BM) and overall disease recurrence. Only in a subgroup analysis, use of zoledronic acid (ZOL) was associated with a statistically significant lower risk for disease recurrence (OR, 0.675; 95%CI: 0.479-0.952, *P* = 0.025)^[146]. Furthermore, another meta-analysis and systematic review published in 2012, reports that the use of bisphosphonates did not reduce the incidence of BM when compared with placebo^[147]. In contrast, a recent meta-analysis demonstrates that the use of ZOL improves overall survival (OS) compared with placebo (HR,0.81, 95%CI: 0.70-0.94)^[148]. Moreover, there are three international randomized studies, Z-FAST, ZO-FAST, and E-ZO-FAST, which were performed to evaluate the bone-protective effects of ZOL^[149]. After the analyses of the potential disease recurrence effects of ZOL, a significant activity in preventing bone loss during adjuvant AI therapy in postmenopausal women with EBC was noticed. However, heterogeneity between the trials for disease-free survival (DFS) and OS parameters resulted in statistically significant interaction *P* value, meaning that pooling of the data between studies would not be statistically valid^[149]. Last but not least, according to recent presented studies in the San Antonio Breast Cancer Symposium, the use of bisphosphonates

remains controversial. Coleman *et al.*^[150], after selecting 11036 postmenopausal women, demonstrated that those who were on bisphosphonate therapy experienced distant recurrences in 18.4% while women who were not in 21.9% with high statistically significant difference ($P = 0.0003$) and distant bone metastases in 8.8% and 5.9% ($P < 0.0001$) respectively. In addition, Susman *et al.*^[151] reported that BC specific mortality was reduced by 3.1% from 18.3% in women who were not treated with bisphosphonates to 15.2% for those who were on treatment ($P = 0.004$)^[150,151]. In contrast, in the other related to bisphosphonates presentation based on Neo-Adjuvant Trial Add-On (NATAN), von Minckwitz concluded that there was no difference in DFS and OS^[152]. However, even if bisphosphonates are used as an adjuvant therapy, they should be in addition with nutritional (calcium 1000 mg and 400 international units vitamin D), physical and lifestyle modifications^[153].

OPTIMAL FOLLOW-UP IN BC SURVIVORS: WHAT SHOULD BE DONE, UNTIL WHEN?

The number of BC survivors has improved within the last decades due to earlier diagnosis and effective treatments in order to prevent recurrence^[154,155]. In follow up guidelines, routine physical examination with a careful taking history has been the most valuable means of detecting BC recurrence^[156,157]. The European Society for Medical Oncology (ESMO) recommends regular visits every 3 to 4 mo in the first 2 years, every 6 mo from years 3 to 5 and annually thereafter^[72]. "In contrast", the American Society of Clinical Oncology (ASCO) recommendation for physical examinations is every 3 to 6 mo for the first 3 years, every 6 to 12 mo for years 4 and 5 and annually thereafter^[73]. Based on the evidence, mammographic surveillance remains the principal examination in detecting curable recurrences and improving survival^[158]. ESMO suggests ipsilateral (after breast-conservation surgery) and contralateral mammography every 1 or 2 years and ASCO recommends a post-treatment mammogram 1 year after the initial mammogram and at least 6 mo after completion of radiation therapy. According to ESMO, in the follow-up of patients on endocrine therapy, routine blood tests are usually indicated due to the potential side-effects of these drugs namely in the lipid profile. Furthermore, for patients on tamoxifen, an annual gynaecological examination (by an experienced gynaecologist) is recommended^[72]. However, routine ultrasound assessment of endometrial thickness is not suggested^[65]. Finally, for patients on aromatase inhibitors (AIs), regular bone density evaluation is advised^[72]. According to ASCO, in asymptomatic patients, other laboratory or imaging tests (*e.g.*, blood counts, chemistry tests, chest X-rays, bone scans, magnetic resonance imaging, liver ultrasound exams, CT scans or any tumor markers) are not recommended for routine BC follow-up^[73]. Last

but not least, the follow up should not only focus in cancer surveillance but also in late-treatment complications such as psychosocial issues^[157].

ARE MARGINS FOR DCIS AS IMPORTANT AS WE THOUGHT?

Since the treatment decision for patients with DCIS was difficult, a prognostic tool has been created. In 1996, Silverstein *et al.*^[159] have been developed the Van Nuys Prognostic Index (VNPI) by combining three significant parameters (tumor size, margin width, pathologic classification). However, in 2003 the University of Southern California added the patient age as a fourth parameter. The score ranges for 4 to 12 and the final goal was the prediction of local recurrence^[160]. The scores which were given to the four parameters range from 1 to 3. In case of margins, the score 1 is given for margin width ≥ 10 mm, the score 2 for 1 to 9 mm and the score 3 to less than 1 mm.

Even if this classification includes margins, it remains controversial the specific margin width which eliminates the risk of ipsilateral breast tumor recurrence (IBTR). Thus, the Society of Surgical Oncology (SSO) and the American Society for Radiation Oncology (ASTRO) examined the relationship between margin width and IBTR after taking into consideration systematic review and metaanalysis of the literature by including 28162 patients^[161]. They concluded that wider margin widths do not lower the risk for IBTR and consecutively wider negative margins, known as no ink on tumor, are not required. As a result, this new clinical recommendation has changed the way of thinking about negative margin widths. Even if, this was something new in clinical practice, for some others this was just a vindication^[162]. An updated version of VNPI could be proposed without the margins as a graded parameter and/or the substitution of margins with the hormone receptors status [anecdotal proposal of profs G Iatrakis and S Zervoudis (co-researchers A. Bothou and E Tomara)].

CONCLUSION

Clearly, there is much more evidence needed to clarify which answer is the correct one in the twenty-one aforementioned issues. The lack of recommended guidelines and reliable studies which include enough patients and give the possibility to generalize the results, are the main reasons why clinicians still have not consensus in clinical practice. Thus, multicentric studies and meta-analyses are required in order to clear up the less "acceptable" interventions and established the more "approved".

Key words: CYP2D6; Tamoxifen; Breast cancer; Adjuvant treatment

Core tip: Currently, routine cytochrome P450 (CYP)2D6 testing among women with breast cancer is not recommended and the significance of CYP2D6 phenotype in decision making regarding the administration of tamoxifen is unclear. The present study summarizes current literature regarding clinical studies on CYP2D6*4, particularly in terms of response to tamoxifen therapy and breast cancer outcome.

Abstract

Biotransformation of tamoxifen to the potent antiestrogen endoxifen is performed by cytochrome P450 (CYP) enzymes, in particular the CYP2D6 isoform. CYP2D6*4 is one of the most frequent alleles associated with loss of enzymatic activity. The incidence of CYP2D6*4 among Caucasians is estimated up to 27%, while it is present in up to 90% of all poor metabolizers within the Caucasian population. The hypothesis under question is whether the presence of one or two non-functioning (null) alleles predicts an inferior outcome in postmenopausal women with breast cancer receiving adjuvant treatment with tamoxifen. The numerous existing studies investigating the association of CYP2D6 with treatment failure in breast cancer are inconsistent and give rather conflicting results. Currently, routine CYP2D6 testing among women with breast cancer is not recommended and the significance of CYP2D6 phenotype in decision making regarding the administration of tamoxifen is unclear. The present study summarizes current literature regarding clinical studies on CYP2D6*4, par-

INTRODUCTION

Tamoxifen (TAM) is a selective estrogen receptor modulator (SERM) and 5 years of Tamoxifen treatment is considered as “standard of care” in the adjuvant setting in most cases of premenopausal patients with estrogen receptor positive (ER+) breast cancer, as well as in postmenopausal patients in different treatment strategies, alone or in combination with aromatase inhibitors. Recently, it was shown that, for women with ER-positive disease, continuing Tamoxifen to 10 years rather than stopping at 5 years produces a further reduction in recurrence and mortality, particularly after year 10. These results, taken together with results from previous trials

Figure 1 Tamoxifen metabolism pathways.

of 5 years of Tamoxifen treatment *vs* none, suggest that 10 years of tamoxifen treatment can approximately halve breast cancer mortality during the second decade after diagnosis^[1].

Tamoxifen has also been used as prophylactic treatment for those women considered being in high risk for developing breast cancer due to positive family history or the presence of atypia or lobular neoplasia *in situ* in a breast biopsy. Major side effects associated with tamoxifen use are hot flashes, as well as increased incidence of endometrial cancer and deep venous thrombosis. Besides acting as SERMs, it has been found that some of tamoxifen's metabolites also act as aromatase inhibitors *in vitro*^[2].

Norendoxifen consists the main metabolite of tamoxifen which is the most potent aromatase inhibitor of the tamoxifen metabolites. It causes the same decrease *in vitro* in aromatase activity as letrozole, an exclusive aromatase inhibitor.

Tamoxifen is actually a pro-drug with a weak affinity to ER that exerts its therapeutic action after been transformed in the liver. Tamoxifen metabolism mostly occurs *via* two pathways, 4-hydroxylation and N-demethylation, both of which result in the very potent secondary metabolite, endoxifen (Figure 1).

CYP2D6, a member of the cytochrome P450 mixed-function oxidase system, is one of the most important enzymes involved in the metabolism of xenobiotics in the body. CYP2D6 is highly polymorphic, as 93 alleles with varying functions and distribution among the nations have been reported. In particular, CYP2D6 is responsible for the metabolism and elimination of approximately 25% of clinically used drugs^[3]. This enzyme also metabolizes several endogenous substances such as hydroxytryptamines and neurosteroids^[3].

There is considerable variation in the efficiency and amount of CYP2D6 enzyme produced between individu-

als. Hence for drugs that are metabolized by CYP2D6 (that is CYP2D6 substrates), certain individuals will eliminate these drugs quickly (extensive metabolizers) whilst others will do that slowly (poor metabolizers). If a drug is metabolized too quickly then drug's efficacy might be reduced, while if the drug is metabolized too slowly, toxicity may result^[4]. Therefore, the dose of the drug might have to be adjusted in order to balance the speed at which it is metabolized by CYP2D6^[5].

CYP2D6*4 is the most frequent allele associated with loss of enzymatic activity within the Caucasian population (incidence reaching 27%); meaning that its significance in decision making regarding the administration of tamoxifen in breast cancer patients across Europe might be crucial. The clinical efficiency could be even stronger in small countries with a more consistent and homogeneous population.

The numerous existing studies investigating the relevance of CYP2D6 in the treatment of breast cancer are not unique and give conflicting results. The purpose of the present article is to focus especially on studies involving the CYP2D6*4, as this allele is present in up to 90% of all PMs in Caucasians^[6].

LITERATURE SEARCH

We performed a preliminary data search in PubMed which revealed 307 abstracts under the general terms "CYP2D6" and "tamoxifen". Consequently, we tried to narrow our research by excluding abstracts that were outside of clinical trials and the new approach revealed 23 abstracts that met the last criteria. We choose those with exact match in our review, especially involving CYP2D6*4 genotype, while we also selected original articles focused in the treatment of breast cancer with tamoxifen correlated with the CYP2D6 genotype in retrospective series among ER+ patients. We finally selected and took under consideration 31 abstracts as they appear to our references including general articles in order to explain the enzyme that correlates with our review along with tamoxifen usage.

RESEARCH

Clinical impact of CYP2D6*4 on breast cancer outcome was the main subject of our review. There are numerous studies performed that provide conflict results to support or not this assumption. Goetz *et al*^[7] performed a retrospective randomised phase III study in postmenopausal women with ER+ breast cancer. They concluded that tamoxifen- treated patients being homozygous for CYP2D6*4 had shorter relapse-free time and decreased DFS but not OS compared to *4/wt and wt/wt carries ($P = 0.030$, $P = 0.020$ and $P = 0.360$ respectively). The same conclusions could be extracted in a follow study for the same cohort evaluating the role of co-administration of CYP2D6 inhibitors^[8].

A further retrospective study by Schroth *et al*^[9], com-

pared 206 patients receiving adjuvant tamoxifen and 280 patients not receiving tamoxifen. They tried to extend the assessment of patients with poor metabolic status and assigned more CYP2D6 alleles with impaired activity (*4, *5, *10 and *41). They showed a significant association between CYP2D6-PM and -IM and an unfavourable outcome (more recurrences, shorter relapse-free time and reduced DFS) in patients receiving adjuvant tamoxifen therapy. The incidence of allele *4 has not been reported by the authors. A larger study from the same author refers to results from retrospective analysis of German and US cohorts of 1325 total patients treated with adjuvant tamoxifen. All women were genotyped for CYP2D6 alleles associated with reduced (*10, *41) or absent (*3, *4, *5) activity. Although no difference in overall survival could be observed heterozygous EM/IM and PM had significant higher recurrence rates and worse event-free and disease-free survival. CYP2D6*4 was present in 20% of study cases^[10]. A small series of 84 patients under adjuvant treatment with tamoxifen from Spain focused exclusively in allele *4. The authors concluded that combined genotype wt/*4 plus *4/*4 was significant associated with higher risk of disease relapse. This patient group had clearly lower benefit of tamoxifen treatment^[11]. Another retrospective study from Spain with 91 patients receiving tamoxifen in the adjuvant setting gave similar results. The genotyping was performed for 11 common CYP2D6 alleles. CYP2D6*4 was present in 22 cases, in 12 of which there was heterozygous in combination with a functional allele (*1, *2 or *35). Poor metabolizers were found to have worse DFS^[12]. A further population-based study from the Netherlands examined 85 patients for the clinical affection of allele *4 in breast cancer survival among tamoxifen users. The breast cancer mortality was also found to be significantly increased in patients with *4/*4 genotype^[13]. The report of Thompson *et al*^[14], is also of great interest. They genotyped 33 CYP2D6 alleles (including *4) in 618 tamoxifen-treated patients, using a pool of two cohorts from United Kingdom. Patients with at least one reduced function CYP2D6 allele showed a tendency for worse DFS, although not statistically significant. However, analysis restricted to four common variant alleles *4, *5, *10 and *41 showed no significant differences regarding DFS. In a sub-group analysis of post-menopausal women only, decreased metabolizers had a clear higher risk of disease recurrence. The influence of CYP2D6*4 on chemoprevention with tamoxifen was evaluated in a small subset of 46 patients with breast cancer and 136 controls pooled from a large Italian trial. The authors concluded that patients homozygous for allele *4 may be less likely to benefit from tamoxifen in the course of chemoprevention, as the cancer events were significantly higher in this study arm^[15]. The effect of variation in CYP2D6 activity on the clinical course of patients with familial breast cancer was approached in another study from United Kingdom. The 115 enrolled patients were genotyped for the CYP2D6 *wt, *3, *4, *5 and *41 alleles. Poor metabolizers showed a significantly

worse overall survival, a condition that was also observed in the subset analysis considering only CYP2D6*4, especially in BRCA2 carriers^[16]. Karle *et al*^[17] analysed the effect of the CYP2D6 genotyping in a palliative setting, enrolling 88 patients with ER positive advanced breast cancer. Co-medication with known CYP2D6 inhibitors was an exclusion criterion. The overall survival was significantly shorter for the poor or intermediate metabolizers when compared to an extensive group. Allele *4 was the most frequent non-functional variant, being detected in 37 cases. The authors concluded that CYP2D6 testing in advanced breast cancer is reasonable, especially if administration of tamoxifen is considered^[17]. A retrospective genetic analysis of patients pooled from the Austrian prospective TIGER study, incorporated 493 women with ER positive tumours and focused exclusively in allele *4. The overall frequency of allele*4 was as high as 31%, with 5.7% of all patients being genotyped as CYP2D6*4/*4. Overall, no significant difference in tumour free survival was reported; however, a subgroup analysis of patients treated with concomitant chemotherapy showed that CYP2D6*4 poor metabolizers had a shorter mean time interval to disease progression. However, It has to be reported that information on co-medication were not available^[18]. The impact of CYP2D6 in the outcome of breast cancer was further studied in a population-based cohort trial of 313 women that were adherent to tamoxifen therapy for at least one year (Table 1). It should be mentioned that 22.4% of enrolled patients were premenopausal, while administration of adjuvant chemotherapy was reported in 19,5% of the cases. Ninety seven women were heterozygous and 8 were homozygous for CYP2D6*4 respectively. This incidence was in accordance to the Hardy-Weinberg equilibrium. DNA for genotyping was extracted exclusively from patients' peripheral blood. CYP2D6 was shown to be an independent predictor of outcome, as its reduced activity was associated with recurrence and breast cancer specific survival. These results were more prevalent in the premenopausal subgroup of this cohort. As a possible explanation for this relationship, the authors proposed the higher endogenous estrogen levels in premenopausal ages that require efficient transformation into anti-estrogenic metabolites^[19].

In contrast to the studies mentioned above, Abraham *et al*^[20] published results in the opposite direction. In a large cohort of 3155 patients with confirmed treatment with tamoxifen from United Kingdom, the metabolic status of CYP2D6 was associated with breast cancer survival. In 587 of these patients additional chemotherapy had been administered, while for 1041 patients no data concerning concomitant chemotherapy were available. The authors could prove the absence of relevance between survival and variable CYP2D6 variants and argue therefore against CYP2D6 genetic testing in a clinical setting. A separate subset analysis for allele *4 showed also no statistically significant association regarding breast cancer specific- or overall-survival^[20].

Table 1 The impact of CYP2D6*6 genotype in clinical parameters

Ref.	Parameter	Extensive metabolisers	Intermediate metabolisers	Poor metabolisers

On the other hand, some published studies report a protective effect of CYP2D6*4. The relation between CYP2D6*4 genotype and tamoxifen therapy was validated in a cohort of 226 postmenopausal patients participating in the Stockholm Breast Cancer Group clinical trial. Nine patients were genotyped to be homozygous carriers of allele *4, while further 55 were wt/*4. Comparison was made among arms with and without tamoxifen therapy. Tamoxifen-treated patients with at least one CYP2D6*4 allele had a significantly longer survival time than those being homozygous for wildtype genotype^[21]. In a different and larger study by the same authors, data of 677 patients from Sweden, all treated with tamoxifen for stage II and III breast cancer, have been analysed. Patients homozygous for allele *4 showed a significant survival advantage when compared to the other two genotype patterns (wt/*4 or wt/wt)^[22]. Nowell *et al*^[23] investigated 337 breast cancer patients registered in the Arkansas Cancer Research Center of the USA, performing a CYP2D6*4 genotyping. 162 patients were under tamoxifen treatment, while the remaining 175 received no hormonal therapy. The number of patients with either one or two alleles *4 in the tamoxifen and the non-tamoxifen arm was 48 and 49 respectively. No remarkable impact of CYP2D6*4 on recurrence or overall survival in both study arms could be detected. The authors did actually mention that in all subgroups, the CYP2D6*4 variant seemed to have a slight beneficial role as it was associated with decreased risk of recurrence or death^[23]. A case-controlled study in a subgroup of patients enrolled in the Women's Environment Cancer and Radiation Epidemiology (WECARE) study investigated the association between CYP2D6 polymorphisms and risk for contralateral breast cancer among patients receiving tamoxifen. The authors failed to detect such an association in a cohort of 119 and 312 women with contra- and unilateral disease respectively. It should be mentioned that 39 patients had ER negative tumour status, while a small proportion of patients with ER positive cancers was treated with ad-

ditional chemotherapy. This observation was also issued among CYP2D6*4 carriers^[24]. The Arimidex, Tamoxifen Alone or in Combination (ATAC) study was a double-blind randomized clinical trial in which postmenopausal women with early-stage breast cancer were randomly assigned to receive anastrozole alone, tamoxifen alone, or a combination of both agents in a double-blind fashion. Rae *et al*^[25], designed a genetic substudy including 588 patients who enrolled in the tamoxifen group of the ATAC trial only in the United Kingdom. All these women were genotyped for CYP2D6, while 544 of them had hormone receptor-positive cancers. The investigators could not detect any statistically significant association between CYP2D6 activity (EM, IM or PM) and breast cancer outcomes for patients with ER+ early-stage breast cancer treated with adjuvant tamoxifen. They reported that their results could not be ascribed to any clinical pathological factors such as tumor size, grade, nodal status, and age. The Breast International Group (BIG) 1-98 study was a randomized, phase 3, double-blind trial that compared five years of treatment with various adjuvant endocrine therapy regimens in postmenopausal women with ER+ breast cancer. Regan *et al*^[26] investigated the clinical relevance of CYP2D6 phenotype by obtaining tissue samples from 4861 of 8010 postmenopausal women who enrolled in this prospective trial. A specific correlation for allele *4 has been also performed. The CYP2D6 results are interestingly very similar to these from ATAC. Patients who were homozygous (PM phenotype) or heterozygous (IM phenotype) for CYP2D6*4 variant had risk of breast cancer events that were not statistically significantly different from patients who were homozygous for wild-type alleles. CYP2D6*4 status did not influence the outcome in patients under tamoxifen therapy. According to these findings, CYP2D6 genetic testing is not recommended prior to adjuvant administration of tamoxifen. The results of the BIG 1-98 trial have been presented as recommendation at the 33rd annual San Antonio Breast Cancer Symposium, 2010. The results of another large

prospective multicenter randomised trial (Austrian Breast and Colorectal Study 8 - ABCSG trial 8) have been newly published. In this cohort 3901 postmenopausal patients with resected ER+ early cancer were randomised to receive either five years tamoxifen or two years tamoxifen followed by anastrozole administration over three more years. The incidence of negative events between carriers of one or two poor alleles (*3, *4, *6, *10, *41) vs patients with two extensive alleles was compared. The possibility of such an event was significantly higher when poor alleles were present and only during the period of tamoxifen administration. It should be noted that *4 was present in 58.45% of all non-EM cases^[27].

DISCUSSION

The advisory Committee for Pharmaceutical Science (Clinical Pharmacology Subcommittee) recommended in 2006 that CYP2D6 variations influence the levels of endoxifen and that patients with ER+ breast cancer who are poor metabolizers (due to genotype or drugs co-administration) have an increased risk for breast cancer recurrence. Contrary to this statement and due to lack of strong evidence, the American Society of Clinical Oncology (ASCO)^[28] and the St. Gallen's expert consensus (2011) do not recommend the routine use of CYP2D6 genotyping in the setting of decision making about administration of tamoxifen.

The analysis of existing literature regarding the clinical importance of CYP2D6 polymorphism in the outcome of breast cancer actually leads to conflicting results. Notably, the contradictory findings on this topic might also be due to the heterogeneity across the studies in terms of data collection, analysis and interpretation.

Interestingly and contrary to the main hypothesis, there are three reports that support improved outcome in patients who are carriers of CYP2D6*4^[21-23]. Although the interpretation of these findings remains unclear, these studies do actually support the effectiveness of tamoxifen in the group of intermediate and poor metabolizers. Since then, no other large study could confirm such a favourable impact of allele*4 in the clinical course of ER+ breast cancer.

A large number of published studies show a clear negative relationship between CYP2D6*4 genotype and breast cancer outcome. In five of them the investigation focused exclusively on allele*4, while in the study of Newmann *et al*^[16] performed in patients with familial breast cancer, a subanalysis for *4 alone has also been performed^[7,8,11,13,15]. In six other, the analysis included a larger pool of intermediate/poor metabolizers based on a combined basis of common non-functional alleles, including allele*4^[6,7,9,11,14,16]. All of them were unique regarding the worse clinical course of ER+ breast cancer under tamoxifen therapy in non-extensive metabolizers. In the study of Thompson, a higher recurrence risk could be proven, in a sub-group analysis of only post-menopausal women, while Margolin *et al*^[19] described this association

mainly in premenopausal subjects.

Furthermore, there are numerous studies supporting the strong relation of CYP2D6 genotype on the circulating serum levels of tamoxifen metabolites. A recent work of Zafra-Ceres *et al*^[29] studied 90 Spanish women with ER positive breast cancer concluded that the CYP2D6*4/*4 genotype was associated with statistically significant lower 4-OH tamoxifen and endoxifen levels. Irvin *et al*^[30] examined a brighter combination of CYP2D6 alleles and reported similar results. It could be additionally demonstrated that a daily dose adjustment from 20 to 40 mg could sufficiently increase the endoxifen concentration in patients with impaired CYP2D6 function. Although this data indirectly support the main hypothesis, there is no strong evidence about the influence of endoxifen levels on the clinical course of breast cancer^[30].

On the other hand, a large population based case-cohort study from the United Kingdom showed no association between any CYP2D6 variants and breast cancer specific survival in the setting of tamoxifen therapy. A sub-group analysis regarding allele*4 alone gave consistent results. However, it should be mentioned that a large proportion of included cases had received concomitant chemotherapy^[20]. Furthermore, Brooks *et al* investigated a cohort of breast cancer patients, pooled from the WECARE study, and showed that the CYP2D6*4 variant is not associated with higher risk of contralateral breast cancer, in the setting of tamoxifen treatment.

All these reported studies implicating allele*4 are retrospective and partially refer to limited cohort numbers. It is reasonable to assume that due to the small number of subjects, the proportion of poor metabolizers is unavoidably limited, a fact that influences the level of evidence of any extracted results regarding this group.

The comparison groups within the existing studies varies, as the heterozygous genotypes wt/*4 (IM) are not consistently stratified in one comparison group. Although most published studies classify them together with the homozygous *4 genotype, in three studies they are incorporated in the homozygous wt arm^[7,13,22].

The function of CYP2D6 can be altered or inhibited by several pharmaceutical substances. Agents such as fluoxetine, paroxetine, bupropion, quinidine and cinalcact act as strong inhibitors of CYP2D6 and should therefore be cautiously prescribed in combination with tamoxifen^[31]. Unfortunately, there is little and inconsistent data within the majority of available studies, regarding the co-administration of a CYP2D6-inhibitor. This fact strongly insults the reliability and the evidence level of any statistically significant result.

Another important aspect is the adherence of examined population to therapy. It is known that the long lasting administration of tamoxifen is associated with various adverse effects, such as hot flashes, that strongly impair the quality of life of the treated patients. Due to possible side effects, incompliance or therapy discontinuation, especially between extensive metabolizers or non-trial women, remains relatively high^[32]. Although data over the

adherence to tamoxifen therapy should be known in order to safely validate the existing results, this information is absent in nearly all relevant studies^[22].

The estrogen-receptor status of breast malignancies clearly affects the outcome of the administered hormonal therapy. Many of all existing studies analyse cohorts that include a number of patients with ER-negative disease^[15,16,20,23,24], while two other provide no sufficient data regarding the hormonal status of the enclosed population^[11,13]. This condition represents a strong limitation in the interpretation of the published results.

It is important to mention that the three latest large studies refer exclusively to postmenopausal women with ER positive breast cancer disease^[25-27]. Goetz *et al*^[27], have proven a statistically important incidence of negative events within carriers of poor CYP2D6 variants, while the two other studies failed to confirm such an association. Although they favour against a CYP2D6 genetic testing prior to tamoxifen therapy, it should be mentioned that both studies showed a substantial departure from the Hardy-Weinberg equilibrium regarding the frequency of allele*4^[25,26].

An important bias of most published trials is the followed genotyping procedure, as the estimation of CYP2D6 variant was performed at paraffin-fixed cancer tissue and not at hosts' blood-or buccal-derived DNA. However, tumor DNA may show significant differences from germline DNA, considering the frequent occurrence of "loss of heterozygosity" in cancer biology. A possible misclassification leads to a smaller arm of intermediate metabolizers (IM) in favour of extensive metabolizers (EM), a fact that strongly insults the final results and conclusions.

Furthermore and in order to safely evaluate the influence of CYP2D6 genotype on tamoxifen therapy, any performed study should actually enclose patients treated with tamoxifen monotherapy.

These two last conditions are unfortunately not satisfied in all three large prospective trials. It should be mentioned that the examined DNA was extracted from formalin-fixed paraffin-embedded tumor tissue, while concomitant chemotherapy is reported in a large proportion of the cohorts. These strong limitations set the reliability of the various results in doubt.

As a final comment, it remains questionable whether the possible ethnic heterogeneity of the examined population within the existing cohorts has an influence on any extracted results. This assumption makes the evaluation of all this data extremely difficult.

CONCLUSION

CYP2D6*4 consists the most frequent allele with poor metabolizing function among Caucasians, that possibly affects the clinical course of breast cancer. At present there is an ongoing debate, whether a dose or duration adjustment of administered tamoxifen could guarantee a better outcome in carriers of CYP2D6*4.

The current recommendations regarding breast cancer treatment do not include the routine use of CYP2D6 genotyping in the adjuvant setting of tamoxifen. On the other hand, there is strong evidence supporting a negative impact of allele*4 in the outcome of the disease, that should not be ignored. Large prospective trials, limited exclusively to postmenopausal women with ER positive breast cancer, have been newly completed and offer a huge bank of data eligible to further assessment. These three latest studies lead to conflicting results and are all amenable to criticism due to numerous limitations. In European countries with consistent and homogeneous population the frequency of CYP2D6*4 is expected to be quite high. For this group of patients, the question about the clinical importance of CYP2D6*4 in the course of breast cancer remains practically unanswered. Future research should explore prospectively the role of CYP2D6 activity in patients receiving tamoxifen, in particular in premenopausal patients for which tamoxifen represents the standard of care in the adjuvant and metastatic setting.

Abstract

The biological characteristics of the tumour are used to estimate prognosis and select appropriate systemic therapy for patients with (breast) cancer. The advent of molecular technology has incorporated new biomarkers along with immunohistochemical and serum biomarkers. Immunohistochemical markers are often used to guide treatment decisions, to classify breast cancer into subtypes that are biologically distinct and behave differently, and both as prognostic and predictive factors. Steroid hormone receptors, markers of tumour proliferation, and factors involved in angiogenesis and apoptosis are of scientific interest. In this review we will provide information on the immunohistochemical markers used in the management of breast cancer patients using available data from the literature. We consider the utility of established immunohistochemical markers, and discuss the challenges involved in integrating novel molecular markers into clinical practice.

Key words: Breast cancer; Immunohistochemistry; Markers

Core tip: Immunohistochemistry has an important role in the pathology of breast disease, as well as in other benign or malignant tumours. There is a growing list of avail-

able products (antibodies) or antigen retrieval techniques, which all contribute to the broader utility of immunohistochemistry for solving diagnostic problems or for determining prognosis and response to therapy in breast pathology. Myoepithelial markers are useful in helping to distinguish benign lesions from malignant lesions. The most common immunohistochemical breast cancer prognostic and therapeutic markers used include: estrogen receptor, human epidermal growth factor receptor-2, Ki-67, progesterone receptor, and p53. In addition, markers of angiogenesis and apoptosis are also important.

Zaha DC. Significance of immunohistochemistry in breast cancer. *World J Clin Oncol* 2014; 5(3): 382-392 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i3/382.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i3.382>

INTRODUCTION

Immunohistochemistry (IHC) is used to characterize intracellular proteins or various cell surfaces in all tissues. Individual markers or more often panels of various marker proteins can be used to characterize various tumour subtypes, confirm tissue of origin, distinguish metastatic from primary tumour and provide additional information which may be important for prognosis, predicting response to therapy or evaluating residual tumour post-treatment. There is a growing list of available products (antibodies) or antigen retrieval techniques, which all contribute to the broader utility of immunohistochemistry for solving diagnostic problems or for determining prognosis and response to therapy in breast pathology. Diagnostic and prognostic markers are described although some of them can be included in both.

DIAGNOSTIC MARKERS

The most important diagnostic problems that occur in

Table 1 Diagnostic markers

Marker	Staining pattern	Useful for
Smooth muscle actin	Cytoplasmic staining	Myoepithelial differentiation
Calponin	Cytoplasmic staining	Myoepithelial differentiation
p63	Nuclear	Myoepithelial differentiation
Smooth muscle myosin heavy chain	Cytoplasmic	Myoepithelial differentiation
CD10	Membranous staining	Myoepithelial differentiation
S100	Cytoplasmic	Myoepithelial differentiation
High-molecular-weight cytokeratins (14 and 5/6)	Cytoplasmic	To distinguish invasive carcinoma from benign proliferations; expressed by lobular carcinomas
Cytokeratin 8	Peripheral cytoplasmic	Ductal carcinoma cells
Cytokeratin 8	Perinuclear staining	Lobular carcinoma cells
CK 7 and 20		Mammary origin of a metastatic carcinoma
E-cadherin	Membranous staining	Usual ductal carcinomas
Hormone receptors estrogen receptor, progesterone receptor	Nuclear	Identified subtypes, mammary origin
HER2 neu	Membranous staining	Identified subtypes
Gross cystic disease fluid protein 15	Cytoplasmic	Mammary origin of a metastatic carcinoma
Mammaglobin A	Cytoplasmic	Mammary origin of a metastatic carcinoma
Carcinoembryonic antigen, CEAD-14 clone	Cytoplasmic	Evaluation of metastatic mammary carcinoma

mammary gland tumor pathology are: the differential diagnosis of various types of benign lesions and carcinoma; differentiating between carcinoma *in situ* and invasive carcinoma, diagnosis and differentiation of microinvasion and its imitating lesions and confirming the breast as the primary site in metastatic carcinoma. In the absence of advanced molecular biological techniques, IHC can be used to identify histologic subtype or molecular phenotype. Some of these problems can be solved using IHC markers (Table 1). It is well known that normal glandular breast tissue is composed of three cell types which express different subsets of proteins: luminal, basal and myoepithelial. The luminal cells express cytokeratins (CK 7, 8, 18, 19), epithelial membrane antigen (EMA), milk fat globule membrane antigen (MFGM), α -lactalbumin, estrogen receptor (ER), and progesterone receptor (PR). Myoepithelial cells express basal cell type CKs and specific markers: smooth muscle actin, calponin, S100 and p63, while basal cell types express different cytokeratins (5/6, 14, 17)^[1-3].

Myoepithelial markers: SMA, Calponin, p63, SMMHC

Myoepithelial markers are useful in helping to distinguish invasive carcinoma from benign proliferations with a similar morphological appearance, benign proliferative lesions and most preinvasive lesions with an intact myoepithelium. Invasive carcinomas lack the myoepithelial cell layer that normally surrounds benign breast glands. There is an exception, microglandular adenosis, a benign proliferative lesion which lacks the myoepithelial cell layer^[3-5]. In the same context, to assess intraductal proliferative lesions, high-molecular-weight cytokeratins (cytokeratin 14 and cytokeratin 5/6) can be helpful in distinguishing ductal hyperplasia from low-grade ductal carcinoma *in situ* (DCIS). Atypical ductal hyperplasia or *in situ* carcinoma can arise in otherwise benign papillary lesions and is defined as a type of ductal hyperplasia that morphologically simulates DCIS. Characteristically, atypical ductal hyperplasia has a uniform population of cells and most lesions

are small and focal, involving only a portion of a duct or only a few small ducts measuring less than 2 mm. Using IHC, positive myoepithelial staining is seen in the benign area with attenuated or absent staining in areas of atypia or *in situ* carcinoma. It is possible that the area of atypia or *in situ* carcinoma may not even be represented in the limited sample from a core needle biopsy.

Smooth muscle actin (SMA) has long been used as a myoepithelial marker in breast pathology diagnosis as a sensitive marker of myoepithelial differentiation, even if it is not specific, because any cell with substantial expression of actin is positive for SMA (myofibroblasts and blood vessels are positive for SMA).

This becomes problematic in lesions where there are either myofibroblasts or blood vessels in close proximity to the epithelial lesion. One pitfall is the presence of myofibroblasts within desmoplastic stroma adjacent to nests/glands of invasive carcinoma being misinterpreted as myoepithelial cells, resulting in a false-negative diagnosis. This is why the use of a panel of markers (p63, calponin, smooth muscle myosin, CD10, S100) or a more specific marker such as p63 are recommended.

One option is calponin, a protein belonging to the contractile apparatus in smooth muscle cells, which is considered to have the same sensitivity as SMA, however, similar to SMA, staining of myofibroblasts and smooth muscle in blood vessels can be obtained. As with SMA, cytoplasmic staining of myoepithelial cells tends to encircle the nucleus as opposed to the staining pattern of myofibroblasts. Compared to other markers (p63 or smooth muscle myosin heavy chain (SMMHC)), it tends to show more complete staining of the myoepithelial layer.

p63 is a homolog of p53, and has been shown to be expressed exclusively in myoepithelial cells in normal breast and can be very useful in differential diagnosis involving benign lesions such as sclerosing adenosis, radial scars and papillary lesions. The advantage of using p63 is its nuclear localization and absence of staining in smooth

muscle cells, such as myofibroblasts and blood vessels. Thus, it provides almost 100% specificity, however, its sensitivity has been reported to be approximately 90%. This is demonstrated by the so-called “focal gaps” in staining in the myoepithelial layer, partly due to the plane of section. In addition, it has now been shown that about 10% to 15% of invasive tumors, particularly high-grade and metaplastic carcinomas, express p63, although the staining is usually weaker than that seen in myoepithelial cells. Similarly, foci of squamous differentiation stain positively.

Like other smooth muscle markers, SMMHC is associated with contractile elements and is present in all cells with such properties. It is expressed primarily in myoepithelial cells, but is also expressed in blood vessels. An advantage of SMMHC is that it demonstrates less cross-reactivity in myofibroblasts than calponin and SMA. Overall, the studies so far suggest that among smooth muscle markers, SMMHC provides the best results, in terms of both sensitivity and specificity.

When inflammation or reactive fibrosis obscure the interface between involved ducts and adjacent stroma in some cases of DCIS, IHC can help to clarify the integrity of the duct wall. Usually ductal carcinoma cells are negative for myoepithelial cells markers: S100, SMA, SMMHC, calponin, CK5, CK14, CK17, CD10, and p63^[3,6-14]. The specific markers among these are SMMHC, calponin, and p63, these as well as some basal CKs have an advantage in that they do not stain myofibroblasts. Is this correct?

In most laboratories, however, the choice between these markers depends on individual experience, preference or financial resources. A combined approach, a nuclear and a cytoplasmic myoepithelial marker is the best option to increase the diagnostic utility of these markers. Pitfalls in the use of myoepithelial markers include those related to interpretation, fixation and technical aspects, and possible biological effects. Interpretative issues include the possibility of mistaking myofibroblasts for myoepithelial cells due to cross-reactivity of cytoplasmic epitopes (in particular, SMA and calponin). Fixation and technical issues include underfixed tissue not immunostaining optimally; in such situations, entrapped benign glands may be mistaken for invasive carcinoma due to lack of staining of myoepithelial cells, resulting in a false-positive diagnosis of carcinoma. The key to solving these issues is to include adequate internal controls.

Lobular or ductal carcinoma: E-cadherin, CK8

Determining whether an *in situ* lesion is lobular carcinoma or ductal carcinoma has clinical management implications and is another situation in which IHC proves its worth. Generally, ductal and lobular carcinomas, either invasive or *in situ* can be distinguished in hematoxylin-eosin-stained sections. In cases with non-specific morphologic characteristics, categorization can be performed through IHC, and E-cadherin is currently used to differentiate

between the two. The majority of ductal carcinomas express cytoplasmic E-cadherin, whereas most lobular carcinomas lack expression of E-cadherin^[3,15,16]. In addition, the differences in CKs expression may be used: high-molecular-weight CK (clone 34βE12) is usually expressed by lobular carcinomas, but is absent or expressed at low levels in most cases of DCIS^[3,17,18]. In the same context, CK 8 is stained in ductal carcinoma cells in the peripheral cytoplasm, while perinuclear staining is characteristic of lobular carcinoma^[19].

Identification of subtypes of breast cancer

Analysis of both adjuvant and neoadjuvant trials has shown that not all chemotherapeutics have equal effects on breast cancer patients, therefore, further individualization of chemotherapy may be required. Data on differences in chemotherapy sensitivity to taxanes and anthracyclines suggest that there are significant differences across disease subtypes, which if further validated, could be used to guide the best decision-making in patient treatment^[20]. The St Gallen expert panel which met at the 12th International Breast Cancer Conference held at St Gallen (Switzerland) in March 2011, identified four subtypes of breast cancer according to oestrogen and progesterone receptors, and overexpression and/or amplification of the human epidermal growth factor receptor 2 (HER2) oncogene. The four subtypes were luminal A, luminal B, Erb-B2 overexpression and basal-like. The expert panel provided systemic treatment recommendations for the subtypes including endocrine therapy alone for luminal A, endocrine ± cytotoxic therapy for luminal B (HER2 negative); cytotoxics + anti-HER2 + endocrine therapy for luminal B (HER2 positive); cytotoxics + anti-HER2 for HER2 positive (non luminal); and cytotoxics for triple negative.

Markers for mammary origin in metastatic carcinoma: GCDFP15, mamaglobin, CEA

In the case of small metastasis of infiltrating lobular carcinomas, false negative results are far more frequent than those in infiltrating ductal carcinoma^[21]. Medullary carcinoma metastasis or other subtypes of mammary carcinoma (lobular, sarcomatoid) can often be mistaken for malignant lymphoma (with “signet ring” cells, clear cells, with carcinoma pattern, sarcomatoids). In these situations, a positive reaction for CK and lack of reactivity for lymph markers suggest a diagnosis of metastasis. In as many as 24% of lymph nodes reported metastasis-free by standard histological examination, various authors found metastasis when multiple or serial sections were cut. Immunohistochemical markers also improve the specificity and accuracy of cell detection; therefore it is important to evaluate their utility in improving standard histological procedures. In the case of large metastasis in the axillary lymph nodes, IHC can demonstrate by a positive reaction for epithelial markers the carcinomatous nature of cells, difficult to appreciate as epithelial, in particular, in

the case of axillary metastasis of infiltrating lobular carcinoma (relatively uniform appearance of tumor cells and low mitotic activity). For small metastasis of infiltrating lobular carcinoma, false negative results are much more common than in infiltrating ductal carcinoma^[21]. In addition, medullary carcinoma metastasis or other subtypes of breast carcinoma can sometimes be confused with malignant lymphoma (cells in the so-called “signet ring”, clear cell); in these situations, a positive reaction for CK and lack of reactivity for lymphoma markers suggest a diagnosis of metastasis.

The identification of metastatic carcinoma of the breast may be difficult in the absence of a previous history of breast cancer. Various immunophenotypic markers have been introduced to aid in this process. Markers for mammary origin include receptors for hormones, such as androgen receptors (ARs) and gross cystic disease fluid protein 15 (GCDFP-15)^[3]. GCDFP-15 is present in the liquid of breast cysts and any apocrine cells: mammary glands, salivary glands, sweat, Paget’s disease, *etc.* Therefore, carcinoma of the breast and others show reactivity to GCDFP-15. Even in these conditions, the positive predictive value and specificity for the detection of breast cancer is 98%-99%^[22], but moderately sensitive (50%-74% for breast carcinoma), which is why it is important to add other markers to the diagnostic panel such as ER, PR, AR, and HER-2/*neu*, mammaglobin, and CKs (7 and 20). In this context, ARs and/or HER-2/*neu* are given additional value in a great number of ER-negative high-grade ductal carcinomas^[3].

Lately, mammaglobin has been described as a breast cancer-specific gene, and its utility as a novel breast cancer marker has been confirmed^[3,23,24]. Mammaglobin A and B identified in breast cells are overexpressed in breast cancer. Mammaglobin A is more specific for breast and gynecologic organs, while mammaglobin B may be found in a number of other tumors, especially gastrointestinal malignancies. Many studies have suggested that elevated mammaglobin levels in breast cancer are associated with clinical and biological features defining a less aggressive tumor phenotype. Mammaglobin expression is not changed at the metastatic or lymph node site. It can help, in combination with other markers, to establish the correct diagnosis of metastatic breast carcinoma. Although many carcinomas would not be included in the differential diagnosis of breast carcinoma, the specificity of this marker was 92%^[25].

In the same study, when the immunohistochemical staining pattern of mammaglobin was compared with GCDFP-15 in the breast carcinomas, mammaglobin had higher sensitivity than GCDFP-15. In addition, the mammaglobin antibody cocktail stained deeper than GCDFP-15, and among positive cases, the number of cells stained with mammaglobin was higher than with GCDFP-15. Despite some non-specificity of the mammaglobin antibody, these data provide convincing evidence for the inclusion of mammaglobin in a panel for the workup of carcinoma of an unknown primary site.

During the diagnosis of breast carcinoma, it should be taken into consideration that the sensitivity of mammaglobin is better than that of GCDFP-15^[25-27].

Carcinoembryonic antigen (CEA) is a well-known tumour marker glycoprotein of 180 kDa. The polyclonal antibody reacts strongly and diffusely with ductal mammary carcinomas, lung and large intestine carcinomas; CEAD-14 clone reacts with a small subset of mammary carcinomas, usually high grade, which is useful in the evaluation of metastatic mammary carcinoma in the lung, liver, brain and lymph nodes; 13% of breast carcinomas are positive for CEAD-14, with a focal reaction, but diffuse in high-grade carcinomas. A negative CEAD-14 pulmonary tumour is more likely to be a metastasis and not a primitive lung tumour, which is positive for other specific markers (such as thyroid transcription factor-1, TTF1)^[28].

MARKERS OF PROGNOSIS AND RESPONSE TO THERAPY

The most common immunohistochemical breast cancer prognostic and therapeutic markers used include: ER, HER2, Ki-67, PR, and p53. In addition markers of angiogenesis and apoptosis are used.

Hormone receptors

Nowadays, immunohistochemical detection of ER and PR is part of the routine work-up of breast cancer, and in some cases of DCIS the presence of ERs is an indication for tamoxifen therapy. There are many scoring systems and many studies have compared their ability to predict treatment response and correlations with outcome. The first scoring system counted the percentage of positive cells and ignored staining intensity^[29,30]. When we determine the proportion of positive stained cells, at least 1% is considered a hormonally treatable state. According to the International Breast Cancer Study Group scheme which is the basis of the most recent St Gallen treatment guidelines, breast cancer is divided into three groups based on the percentage of positive cells: responsive (10%), response uncertain (1%-9%), and nonresponsive (0%). In other words, a threshold of 1% positive cells indicates the option for hormonal therapy. These guidelines are widely followed in many countries from Europe and the United States, but they seem to be insufficient.

Many users report results as an Allred score, which comprises both the percentage of positive cells and staining intensity^[31]. A total score of 3 or more, corresponding to 1% to 10% positive cells, characterises the lowest positive result and corresponds to the St Gallen endocrine response uncertain category in which case adjuvant hormone treatment can be recommended, but has an uncertain benefit^[3,32,33]. Immunohistochemical staining for ER in DCIS, without associated invasive lesions has a role in estimating the potential positive effect of tamoxifen. The National Surgical Adjuvant Breast and Bowel Project

Protocol B-24, in patients with DCIS treated with partial mastectomy and then irradiation, who received placebo or tamoxifen for five years showed a conclusive reduction in both ipsilateral and contralateral breast cancer in the adjuvant tamoxifen group^[3,34,35].

HER-2/Neu expression

HER-2/neu was one of the first oncogenes studied in samples of invasive breast cancer and it is identified in 10%-20% of breast cancer patients. It is a marker for sensitivity to Herceptin (trastuzumab), and resistance to tamoxifen^[36]. Although Her-2/neu can be detected using many methods, only two are currently approved and recommended for its detection: IHC and fluorescence *in situ* hybridization (FISH). Standardized immunohistochemical techniques exhibit a very good correlation with FISH methods. Such standardization requires the use of 10% neutral-buffered formalin as a fixative allowing at least 6-8 h of tissue fixation, and not more than 48 h. IHC evaluates overexpression of the receptor protein at the surface of the cells, while FISH evaluates the status of the *HER2* gene in the nucleus. In the majority of *HER2*-positive cancers, *HER2* protein overexpression is the result of gene amplification, thus both methods should be highly correlated.

Immunohistochemistry reactions for HER-2 are scored by HercepTest where 0 and 1+ scores are negative, 2+ is weakly positive and 3+ is positive. A positive HER-2 result consists of a uniform and intense membrane staining of more than 30% of tumour cells and further evaluation is unnecessary for invasive cancers that stain definitely positive or negative. Weakly positive or equivocal or 2+ cases should be tested for gene amplification by FISH. A positive result using this method indicates more than 6 HER-2 gene copies per tumour cell nucleus or a HER-2 gene to chromosome 17 ratio of more than 2.2^[3,36-38].

Selection of the best treatment, especially if the patient is a candidate for HER2-targeted therapy, depends on accurate laboratory results of the assessment of HER2 status. All aspects of the test are performed in a highly standardized fashion with good quality control and the quality controls must be continuously monitored. The standardization includes aspects of pre-analytical sample tissue handling, the type and duration of fixation, tissue processing, assay performance, interpretation, and reporting^[37].

Due to the intrinsic subjectivity of the results of the two techniques (IHC and FISH), the identification of new methods with less subjectivity is necessary. Recently, the chemiluminescent technique has been used as a quantitative assay^[39,40]. It has many benefits such as high sensitivity and accuracy, stability of reagents, easy-to-use protocols, non-photodegradable products, and a good correlation between IHC and immunohistochemiluminescence results.

Markers of apoptosis and cell proliferation: Ki-67 proliferation index, BCI-2, p53

Ki-67, a non-histone protein, involved in the early steps of polymerase I-dependent ribosomal RNA synthesis is a predictive and prognostic marker in cancers and has been extensively studied. When Ki-67 level is above 10%-14%, breast cancer patients are defined as high-risk^[41,42]. According to the St. Gallen Consensus (2009), the Ki-67 index is useful for selecting patients with hormone receptor-positive breast cancers for the addition of chemotherapy to endocrine therapy. Thus, breast tumours are classified as low, intermediate, and highly proliferating according to a Ki-67 labelling index of under 15%, 16%-30%, and over 30%, respectively. Data from the Clinical Cancer Registry Regensburg showed that Ki-67 expression was associated with common histopathological parameters, especially grading and survival, but is an additional independent prognostic parameter for disease-free survival and overall survival in breast cancer patients^[43].

The neoadjuvant setting is useful for analyzing the value of Ki67 as a predictive and prognostic tool. The majority of studies investigating complete pathological response have identified a high Ki67 proliferation rate as a predictive factor for a higher rate of complete pathological response^[44,45]. However, it was found that patients in whom progression occurred had a higher proliferation rate than those who responded to neoadjuvant chemotherapy. This suggests a nonlinear effect of Ki67 on treatment response and probably on prognosis as well^[44,45].

Ki-67 expression has been used to determine the effects of different doses of tamoxifen on breast cancer proliferation^[42,46]. The change in Ki-67 expression induced by lower doses of tamoxifen was comparable to that achieved with the standard dose, indicating that tamoxifen retains antiproliferative activity at low doses^[46,47]. Dowsett *et al*^[48], in a small study, showed that a higher Ki-67 labelling index after two weeks of neoadjuvant therapy with tamoxifen was associated with shorter recurrence-free survival, whereas higher Ki67 expression at baseline was not. According to Ellis *et al*^[49], a significant reduction in the Ki-67 index after a short period (a few weeks) of hormonal treatment may be a simple and affordable way to select patients with ER-positive breast cancer who may not benefit from adjuvant chemotherapy.

Another proliferation marker in tumour tissue is the Ki-S2 antibody. This antibody recognises a proliferation-specific nuclear protein expressed exclusively in the cell cycle phase S, G₂, and M. Therefore, actively proliferating cells that constitute a subset of the population recognised by Ki-67 were specifically labelled. The cycling ratio was defined as the ratio of the Ki-S2 labelling index to the Ki-67 labelling index and represents the relative fraction of cells in proliferation. Alterations in cell cycle regulation at the G₁-S transition strongly influence breast can-

cer progression^[42,50]. Prognosis is probably indicated by the percentage of cells in S through M phases of the cell cycle and measurement of the Ki-S2 index may also improve to allow an accurate prognosis and to identify patients with a low risk of recurrence who may not require adjuvant therapy^[42,51].

With regard to the molecular breast cancers, high Ki-67 proliferation index can be used to classify triple negative breast cancer into subtypes with different prognoses or responses to treatment. For this purpose, the number of Ki-67 positive cells among the total number of counted tumour cells was determined and the high expression of Ki-67 was defined as $\geq 10\%$. It is known that patients with triple negative breast cancer have a poor survival, despite their high response rate to neoadjuvant chemotherapy, and those with high Ki-67 have more aggressive clinical features^[52].

The use of adjuvant chemotherapy in early breast carcinoma is controversial, with many advocating its use in high-risk patients as defined by specific pathologic parameters. Both BCL2 and p53, which are involved in apoptosis and cell proliferation, play an important role in determining tumour growth and may help to define high-risk patients more accurately. In breast cancer patients, BCL2 expression is significantly associated with hormone receptor status and p53 is an important prognostic marker in early breast cancer^[53].

BCL2 belongs to a group of protein key regulators of apoptosis or programmed cell death. The tumorigenic potential of inappropriate BCL2 protein expression associated with an adverse outcome was first described in subsets of non-Hodgkin's lymphoma as a result of the chromosomal translocation $[t(14,18)]$ ^[54,63].

Overexpression of BCL2 protein has been identified in a variety of solid organ malignancies, but in contrast to non-Hodgkin's lymphoma, BCL2 protein expression in breast cancer is associated with a nonaggressive phenotype of low-grade, slowly proliferative ER+ breast tumours^[55-57]. This favourable prognostic effect of BCL2 in breast cancer is explained by its non-apoptotic functions^[55,58]. BCL2 is expressed in normal breast glandular epithelium and is upregulated by oestrogen, possibly as a direct result of transcriptional induction^[55,59]. Its amplification or copy number gain is a rare condition and correlation between transcript and protein levels in breast cancer is nonlinear, involving post-transcriptional regulation^[55,60]. Moreover, many studies have demonstrated that expression of BCL2 is associated with improved survival in breast cancer, however, this was attributed to its correlation with ER status^[55,61,62]. If we compare patients with ER+/BCL2- disease to those with ER-/BCL2+ disease, the former have been found to have a worse prognosis than the latter^[61,62].

The prognostic value of BCL2 is present across molecular subtypes, and is independent of parameters such as stage, grade and tumour size. BCL2 can be used to prevent patients undergoing unnecessary cytotoxic therapy and provides additional prognostic information^[55].

The other marker, p53 is well studied in cancers, but its value in predicting clinical outcome in breast cancer is debatable. The p53 gene is located on the short arm of chromosome 17 and encodes a 375 amino acid nuclear phosphoprotein that prevents propagation of genetically modified cells^[64]. Wild-type p53 is a tumour suppressor protein and plays an essential role in regulating genomic stability by controlling the cell cycle and inducing apoptosis when cell damage cannot be repaired^[65-67]. In normal cells, p53 has a very short half-life due to ubiquitylation and proteasome degradation^[68,69]. IHC can be used, as wild-type p53 protein is rapidly degraded, while TP53 mutations (18%-25% of primary breast carcinomas) are often associated with the production of a stable protein. In addition, sequencing of the p53 gene in all breast cancers would be expensive and time-consuming for routine practice^[70,71,73]. A higher tumour grade, negative ER and PR status, and the more aggressive basal subtype were associated with abnormal p53 immunohistochemical expression or p53-positive status^[70,72,73]. With regard to early breast cancers, some scientists have reported that a p53 mutation has no influence on the outcome and therefore, the value of p53 status is too weak to be recommended as a routine marker in clinical practice^[74].

Angiogenesis markers

Tumor growth and metastasis are dependent on tumour angiogenesis and this complex process involves a delicate balance between angiogenic and antiangiogenic factors. Numerous studies have investigated the relationship between tumour angiogenesis, prognosis and response to antiangiogenic drugs. Analysis of these factors in tumour or serum of breast cancer patients by IHC or multiplex protein assay (FASTQuant® Microspot Assays) can improve diagnosis and prognosis of the disease. There is a large list regarding angiogenesis markers: Angiogenin, Ang2, keratinocyte growth factor (KGF), fibroblast growth factor basic, intercellular adhesion molecule (ICAM)-1, platelet-derived growth factor-BB and the vascular endothelial growth factor family. With regard to these markers, it has been observed that patients with breast cancer exhibited high levels, as well as high serum levels when compared to patients with benign breast diseases. When some of these markers were evaluated either in tumour or serum in breast cancer patients, they showed an association with standard clinical parameters, ER status and intratumoural microvessel density of tumours^[75].

The commonly used method to determine angiogenesis is counting intratumoral blood vessels (MVD) stained with factor VIII related antigen or anti CD31 or CD34 using light microscopy. The main difficulty is the significant variability in density between different areas of tumor and among observers. Counting newly formed stained microvessels is a useful tool in the early detection of metastatic potential and in the selection of patients for whom anti-angiogenesis drugs might be beneficial. The reactivity level of CD34 antigen was assessed by IHC

in all types of invasive ductal breast cancer and its level seems to be a useful predictor for the development of local lymph node metastasis and can indicate the benefit of antiangiogenic treatment^[76,77].

Anti-angiogenic drugs have been approved recently for the therapy of advanced cancers, including breast cancers. These drugs, alone or in combination with chemotherapy, are able to improve overall or progression-free survival in cancer patients. Unfortunately, the lack of validated biomarkers to allow the selection of patients who are most likely to benefit from targeted drugs such as bevacizumab, sunitinib, sorafenib and pazopanib, limits the rational use of these drugs and the ability to determine optimal dose and scheduling of these drugs^[78].

Most of the biological and clinical activity of the anti-angiogenic drugs currently approved for cancer therapy is against the VEGF-related pathways. The VEGF system is part of the platelet-derived growth factor gene family, and interacts with its specific receptors; VEGFR-1 (flt-1) and VEGFR-2 (flt-2) for VEGF-A, a very potent angiogenic growth factor. VEGF-B, interacting with VEGFR-1, seems to have an important role in the maintenance of existing vessels, but this protein is not well studied. VEGF A and B, their receptors VEGFR-1 and 2 are expressed in a variety of normal cells, and overexpression has been described in malignant tumors^[79-82].

There are different techniques used to assess VEGF-A, IHC being the most convenient in routine diagnosis as well as research, as it allows single cell analysis combined with morphology. The results are currently based on visual examination of IHC-stained tissue slides and several different scoring systems have been used^[79,83,84]. Some of these scoring systems evaluate the intensity of immunoreactivity, while others combine the examination of intensity score with the percentage of cells stained resulting in a semiquantitative scoring system. Unfortunately, such scoring is defined by subjectivity and debatable intra- and interobserver reproducibility. Therefore, using the same tumour sections, some laboratories also introduced an automated method for analyzing VEGF expression and obtained the AI score. Methods for computer-assisted image analysis of VEGF-A improved reproducibility by reducing some of the variation between measurements^[79,85,86].

The prognostic importance of VEGF in invasive breast cancer is associated with tumour stage and ER status, and inversely correlated with tumour grade and measurement of tumour VEGF, as an indicator of angiogenesis, which is more reliable prognostically than measurement of microvessel density or serum VEGF^[87,88]. In addition, tamoxifen treatment was associated with higher circulating and platelet-derived VEGF levels^[88].

CONCLUSION

IHC has become an integral part of the pathology laboratory. It is a more mature technology and accessible to the majority of pathology laboratories. IHC can be used

for diagnostic issues, estimating prognosis or predicting response to therapy. The best approach in the use of immunohistochemical markers is to combine them with the examination of standard hematoxylin-eosin slides and use panels of markers. Once the potential value of a new immunohistochemical method is appreciated, the burden will be to ensure standardization of the test protocol to maintain conformity and minimize interlaboratory variation. Results may vary widely depending on the choice of fixative, choice of antibody manufacturer, and the type of immunostaining methods. A scoring system for test results should be regularly adopted and properly reported. IHC testing is cost-effective and can be carried out in parallel with other tests. In the event of equivocal results, a back-up test using multigene assays or others methods should be made available. Once these parameters are standardized, IHC will assume a better and well-defined role in the management of patients with cancer.

It is clear that the role of IHC in detecting biomarker expression in pathology largely depends on research studies which demonstrate differential immunohistochemical expression and other studies that show good correlation between positive expression and response to new therapy. Although a gene study is a sensitive technique, it lacks specificity in distinguishing different cells, and may be contaminated by other cells. In addition, gene profile analysis is complex and inconvenient for routine clinical use.

With regard to subtypes, while the majority of scientists were against the requirement of multi-gene expression array profiling for subtype definition, approximately half the panel of St. Gallen 2013 opted for the use of a clinic-pathologic definition as sufficient for subtype definition. In conclusion, only ER, PR, Ki-67 and Her-2/neu are recommended for clinical use.

it has a more positive effect on serum lipids than does tamoxifen. Toremifene is therefore effective and safe in the treatment of breast cancer. It provides not only a useful therapeutic alternative to tamoxifen, but may bring specific benefits.

Key words: Breast cancer; Toremifene; tamoxifen; Adjuvant treatment; Advanced breast cancer

Core tip: Toremifene is safe and effective in the treatment of breast cancer. Toremifene and tamoxifen are equivalently effective in the treatment of breast cancer, although some studies show an advantage for toremifene. Safety and tolerability is also broadly equivalent, although toremifene may cause fewer uterine neoplasms, serious vascular adverse events and has a more beneficial effect on plasma lipids than does tamoxifen.

Abstract

Although more widespread screening and routine adjuvant therapy has improved the outcome for breast cancer patients in recent years, there remains considerable scope for improving the efficacy, safety and tolerability of adjuvant therapy in the early stage disease and the treatment of advanced disease. Toremifene is a selective estrogen receptor modifier (SERM) that has been widely used for decades in hormone receptor positive breast cancer both in early and late stage disease. Its efficacy has been well established in nine prospective randomized phase III trials compared to tamoxifen involving more than 5500 patients, as well as in several large uncontrolled and non-randomized studies. Although most studies show therapeutic equivalence between the two SERMs, some show an advantage for toremifene. Several meta-analyses have also confirmed that the efficacy of toremifene is at least as good as that of tamoxifen. In terms of safety and tolerability toremifene is broadly similar to tamoxifen although there is some evidence that toremifene is less likely to cause uterine neoplasms, serious vascular events and

INTRODUCTION

Despite improvements in screening and treatment, breast cancer remains a significant cause of morbidity and mortality; accounting for almost one-third of all cancer diagnoses in the US and is second only to lung cancer as a cause of cancer mortality^[1]. Over a million women are diagnosed each year worldwide and almost half a million deaths due to breast cancer are recorded each year^[2]. Whilst incidence rates are considerably higher in developed than in developing countries, survival rates are low in developing countries, probably due to the lack

of screening and systematic use of adjuvant therapy^[2]. Historically low rates of breast cancer in, for example, the Eastern World have shown a rapid increase in recent years^[3,4]. Although typically a disease of later life, breast cancer among younger, pre-menopausal women appears to be more common than in the Western World^[5,6]. Breast cancer among young women, although comprising only around 7% of diagnosed cases, is associated with later presentation, high grade tumors, hormone receptor negativity and human epidermal growth factor receptor 2 (HER2) overexpression; factors that lead to a poorer overall prognosis^[7].

The place of estrogen receptor modifiers (SERMs) in the treatment of breast cancer is now well established. Survival in breast cancer patients in the developed world has increased considerably over the past several decades, due principally to more widespread screening and the systematic use of adjuvant therapy^[8,9]. Whilst adjuvant therapy with SERMs, aromatase inhibitors, cytotoxic agents, monoclonal antibodies and other agents has transformed the outlook for breast cancer patients, there remains considerable unmet need for improvements in both efficacy and tolerability.

Toremifene

The first SERM to be introduced, tamoxifen, provided a revolutionary new treatment option for patients with hormone receptor positive breast cancer. With more than 30 years of experience now available this treatment modality has shown itself to be effective and physicians have learned how to manage its side effects. The mixed agonist/antagonist properties of SERMs define both their therapeutic effects and their undesirable effects. The different structural properties of different SERMs appears to influence their oncogenicity in both laboratory^[10,11] and clinical studies^[12-19].

The structure of toremifene differs from that of tamoxifen in that a chlorine atom replaces one of the hydrogen atoms in the ethyl side chain. This difference may modify the metabolism of toremifene such that the production of DNA adducts may be prevented or reduced compared with tamoxifen^[20,21].

Almost 25 years have elapsed since the first marketing authorization of toremifene and during that time considerable clinical experience has accumulated indicating its efficacy, safety and good tolerability. Indeed, so good was the safety and tolerability that the initially registered dose (60 mg per day) has been widely increased to 240 mg per day.

Toremifene dosage

As shown in Tables 1 and 2 a variety of doses of toremifene are, or have been, in common use. Although some early dose finding studies failed to distinguish between a wide range of doses from 20 mg to 200 mg^[22], 60 mg was chosen as the most appropriate balance between anti-estrogenic effects and tolerability in Phase II studies; significant side effects being observed at the highest

doses tested (680 mg)^[23]. Dose finding and other studies suggested that 60 mg was safe and effective in breast cancer^[24-26] and more effective than 20 mg^[27,28]. However, extrapolation from animal studies suggested that even higher doses would be well tolerated; phase I studies showed that 460 mg daily for five consecutive days was the highest fully tolerated dose^[23]. A conservative approach led to 240 mg being chosen for the high dose formulation. Subsequent phase III clinical trials appear to bear out the enhanced efficacy of the higher dose formulations of toremifene^[29-31].

Randomized studies with toremifene

There have been ten randomized controlled studies comparing toremifene with tamoxifen^[29-38]. Collectively, these studies, which include a total of more than 5500 patients show rather clearly that toremifene is not less effective than tamoxifen. These studies are summarized in Table 1.

Toremifene in advanced breast cancer

An early double-blind, Japanese study in 114 women with advanced or recurrent breast cancer found toremifene 40 mg and tamoxifen 20 mg resulted in similar response rates (26.3% *vs* 28.1%) and duration of response (155.0 *vs* 154.5 d)^[39]. However, the time to onset of complete response was significantly shorter with toremifene than with tamoxifen (91 *vs* 169 d; $P < 0.05$).

A Nordic study compared toremifene 60 mg with tamoxifen 40 mg in 415 postmenopausal women with advanced breast cancer in a double-blind randomized manner^[32]. Response rates were similar in toremifene and tamoxifen groups (31.5% *vs* 37.3%). Time to treatment failure and median overall survival were also similar.

An open study conducted in Eastern Europe compared toremifene 60 and 240 mg, with tamoxifen 40 mg in 463 postmenopausal women with advanced breast cancer^[31]. Response rates of 20.4% and 20.8% were achieved with toremifene 60 mg and tamoxifen, respectively. Although the response rate with the higher dose of toremifene was slightly higher (28.7%), it did not differ significantly from the other treatments. The findings were similar for time to progression and overall survival, quality of life, as assessed by changes in the Eastern Cooperative Oncology Group (ECOG) scale, was better with toremifene 60 mg than with tamoxifen.

A four-way randomized study was undertaken in 541 women in Russia comparing two doses of toremifene (60 mg and 240 mg) with tamoxifen (20 mg) and letrozole (2.5 mg)^[30]. Objective responses were most frequent in the toremifene 240 mg group (41.5%); objective responses were lower (though not statistically significantly so) in the toremifene 60 mg and letrozole groups (33.0% and 35.4% respectively). The proportion of responses in the tamoxifen group was statistically significantly lower than in the other three treatment groups. Similarly, the median duration of remission was longest in the toremifene 240 mg group (14.5 mo), shortest in the tamoxifen group (9.2 mo) and intermediate in the toremifene 60 mg and

Figure 1 Time from randomization to recurrence in estrogen-receptor positive invasive breast cancer patients receiving adjuvant toremifene or tamoxifen^[33].

letrozole groups (11.3 and 13.1 mo, respectively), the difference between tamoxifen and the other treatments was statistically significant.

Another open study, carried out in the United States, compared toremifene 60 mg and 200 mg with tamoxifen 20 mg in 648 post- or peri-menopausal women with metastatic breast cancer^[30]. As in the previous studies, there were no significant differences between the treatments with regard to response rates (21%, 23% and 19% with toremifene 60 mg, toremifene 200 mg and tamoxifen, respectively), time to progression, response duration or overall survival. There was again a suggestion that the 60 mg dose of toremifene resulted in the greatest improvement in quality of life, although the differences were not statistically significant. Compared with tamoxifen, more patients given toremifene 60 mg reported an improvement in enjoyment of life, pain and mood.

A Spanish double-blind, randomized study in 217 postmenopausal women with advanced breast cancer reported a somewhat higher response rate with toremifene 60 mg than with tamoxifen 40 mg (64% *vs* 52%), although the difference did not achieve statistical significance^[34]. Time to progression and overall survival rates were similar in the two groups.

The most recent randomized study reported in 2013 and compared toremifene 120 mg with the aromatase inhibitor exemestane in 91 post-menopausal women with non-steroidal aromatase inhibitor-resistant breast cancer^[37]. After a median 16.9 mo follow-up there were advantages for toremifene over exemestane in clinical benefit [41.3% *vs* 26.7% respectively (ns)], objective response rate [10.8% *vs* 2.2% respectively (ns)], progression-free survival (7.3 mo *vs* 3.7 mo respectively; $P = 0.045$) and overall survival [32.3 *vs* 21.9 mo respectively (ns)].

Toremifene in early stage breast cancer

The International Breast Cancer Study group combined the results from two studies with almost identical protocols in which a total of 1035 peri- or post-menopausal

women with breast cancer received either toremifene 60 mg or tamoxifen 40 mg^[31]. In common with other similar studies the efficacy of toremifene and tamoxifen were approximately equal; 5-year disease-free survival was 72% and 69% respectively and 5-year overall survival was 85% and 81%. Likewise, in an even larger randomized study in [North American Fareston *vs* Tamoxifen Adjuvant (NAFTA) trial] 1813 peri- or post- menopausal women with invasive breast cancer toremifene 60 mg and tamoxifen 20 performed similarly (5-year disease-free survival 92.2% in both groups)

After a median follow-up of 3.4 years a Finnish study found a number of efficacy parameters showing advantages for toremifene compared with tamoxifen, although none achieved statistical significance. Overall, time to recurrence, recurrence rate, recurrence at distant sites and the number of patients dying during follow-up were similar in toremifene- and tamoxifen- treated patients. Although the Kaplan-Meier analysis of the time to recurrence or the time to progression or disease free survival in this study (Figure 1) appears to show a separation between toremifene and tamoxifen from 3 years onwards, the difference is not statistically significant (hazard ratio toremifene:tamoxifen 0.88 (95%CI: 0.70-1.09). The respective 5-year survival rates were 70.3% *vs* 65.6% (also not statistically significantly different)^[33].

Whilst most randomized controlled studies of toremifene have been performed in patients with advanced or metastatic disease, another small study has been undertaken in an adjuvant setting in women with early stage breast cancer; 91 post-menopausal women with early stage, lymph node negative breast cancer were randomized to adjuvant treatment with toremifene 120 mg or tamoxifen 20 mg^[36]. Five-year survival (97% and 96.7% respectively), cumulative disease-free survival (97.5% and 97.3% respectively) and cumulative disease-free survival (88.5% and 90.6% respectively) were very similar between the two groups after 66.5 mo follow-up.

Non-randomized trials

Whilst there are at least 14 published non-randomized studies of toremifene in advanced breast cancer many include rather few patients or have imperfect methodologies. However, there are two recent retrospective studies that merit further description

The study of Gu *et al*^[40] reviewed the records of 810 women with early invasive breast cancer and identified 240 eligible patients who had received tamoxifen and 212 who had received toremifene. Following median follow-up times of 50.8 mo, although 5-year overall survival rates were similar (100% for toremifene and 98.4% for tamoxifen), recurrence-free survival was significantly longer in the toremifene group than in the tamoxifen (97.2% and 90.4% respectively, $P = 0.022$).

Another retrospective study, this time including 1847 pre-menopausal women who had undergone surgery followed by chemotherapy toremifene or tamoxifen similarly found no significant differences between the

Figure 2 Disease-free survival and overall survival in patients receiving adjuvant toremifene and tamoxifen: meta-analysis of the Finnish Breast Cancer Group^[30] and International Breast Cancer Study Group^[34] (data on file). DFS: Disease-free survival; OS: Overall survival; IBCSG: International Breast Cancer Study Group; FBCG: Finnish Breast Cancer Group.

treatments^[41]. All survival figures were identical between toremifene and tamoxifen; disease-free survival (10.3 years in both groups). Five-year disease-free survival (87% *vs* 85%, respectively) and 5-year overall survival (94.3% *vs* 93.5%, respectively).

META-ANALYSES

Whilst individual clinical trials can provide invaluable data on the efficacy of a medication in restricted populations, meta-analysis can provide information about more generalized patient populations and increase statistical power. The randomized clinical trials described above have been the subject of several meta-analyses. The earliest combined two randomized studies comparing toremifene (200 or 240 mg) and tamoxifen (20 or 40 mg) and included a total of 733 patients with advanced breast cancer^[42]. Response rates were higher in toremifene patients than in tamoxifen patients (25.2% *vs* 19.8%), but not statistically significantly ($P = 0.87$). Disease progression and survival also showed no statistically significant differences between toremifene and tamoxifen.

A subsequent meta-analysis in 1999 included results from the five randomized studies completed to that date^[43]. This meta-analysis represented 1421 postmenopausal patients with previously untreated, locally advanced or metastatic breast cancer that were treated with either toremifene 40-60 mg ($n = 725$) or tamoxifen 20-40 mg ($n = 696$). As in the previous meta-analysis toremifene and tamoxifen proved to be broadly equivalent in terms of response rate (24.0% *vs* 25.3%, respectively),

time to treatment failure (4.9 *vs* 5.3 mo) and survival (31.0 *vs* 33.1 mo).

Another meta-analysis has been performed on the disease-free and overall survival findings from two pivotal randomized studies comparing toremifene and tamoxifen in an early breast cancer^[31,33] (data on file, Orion). As shown in Figure 2, there are indications that toremifene may be superior to tamoxifen, most notably in estrogen-receptor-positive patients. In this subgroup of patients, the combined data showed a significant ($P = 0.037$) benefit for toremifene with regard to disease-free survival, although the difference with regard to overall survival did not achieve statistical significance ($P = 0.059$).

A more recent meta-analysis using somewhat more restrictive criteria for inclusion analyzed three eligible randomized comparisons with tamoxifen^[44]. However, the overall results were similar in that no significant differences in efficacy between toremifene and tamoxifen were identified with risk ratios close to unity for overall survival and disease-free survival.

A recent meta-analysis identified 23 randomized clinical trials comparing toremifene with tamoxifen involving a total of 7242 patients with breast cancer^[45]. This large study found that although for most efficacy parameters there were no significant differences between toremifene and tamoxifen, toremifene was significantly more effective in terms of 5-year survival [odds ratio (OR) 1.25; 95%CI: 1.04-1.50] among patients with early stage breast cancer.

A Cochrane review on toremifene *vs* tamoxifen for advanced breast cancer compared randomized controlled comparisons providing data on objective response rate,

Table 3 Incidence of adverse events among 1847 women with invasive breast cancer treated with tamoxifen or toremifene^[41]

Adverse event	Adverse event incidence (%)		P value

Bilirubin	27 (1.9)	8 (2.0)	1

time to progression and overall survival^[46].

The review identified 2061 patients from seven studies (1226 patients received toremifene and 835 patients received tamoxifen). The pooled risk ratio for the objective risk ratio was 1.02 suggesting that there was no statistically significant difference between toremifene and tamoxifen [objective risk ratios (ORR) were 25.8% *vs* 26.9%, respectively]. Similarly the hazard ratio for time to progression was 1.08, again, implying no statistically significant difference between toremifene and tamoxifen (time to progression 6.1 mo and 5.8 mo respectively). Overall survival also showed equivalence between the two medications [hazard ratio (HR) 1.02; overall survival 27.8 mo and 27.6 mo, respectively]. The authors conclude that toremifene and tamoxifen are equally effective in the first-line treatment of patients with advanced breast cancer.

The results of the randomized clinical trials are remarkably consistent and supported by both meta-analyses and retrospective studies; toremifene is at least as effective as tamoxifen in the treatment of breast cancer. Rather few studies find significant differences between the two SERMS, those that do differentiate between the two treatments find significant differences in favor of toremifene^[31,37,38]. None find significant advantages for tamoxifen.

Safety and tolerability

Toremifene and tamoxifen have similar adverse event profiles and are well tolerated, both in women with advanced breast cancer and in those receiving adjuvant therapy. Hot flushes, sweating, nausea and vaginal dis-

Table 4 Frequency of subjective adverse events among 499 patients with invasive breast cancer randomised to adjuvant toremifene or tamoxifen therapy^[33]

	Toremifene		Tamoxifen	
	Number of patients	%	Number of patients	%

Weight increase	23	5.0	19	4.3

charge are among the most common adverse effects and serious adverse events are rare.

A large retrospective analysis of 1847 breast cancer patients treated with toremifene or tamoxifen showed the expected pattern of adverse events with sweating and nausea/vomiting as the most common undesirable effects (Table 3). Although the great majority of adverse effects occurred at similar rates in toremifene- and tamoxifen-treated patients, irregular menses were significantly more common in the tamoxifen group (10% *vs* 6.3%, $P = 0.025$)^[40].

In the largest randomized study comparing tamoxifen and toremifene there were few differences in thromboembolic, gynecological and ocular adverse events between the two treatment groups. Fever and chills were significantly more common among tamoxifen-treated patients^[35].

A safety analysis in the Finnish Breast Cancer Study Group data also illustrates the similar tolerability and safety profiles of toremifene; sweating and hot flashes being observed in more than half of the patients, followed by vaginal dryness and discharge with itching and depression observed in more than 20% of patients^[32]. (Table 4) In no case were significant differences between toremifene and tamoxifen observed. There was similarly little difference in the incidence or pattern of serious adverse events between toremifene and tamoxifen (Table 5).

The above described studies were conducted with the low dose toremifene (60 mg), however high dose toremifene 200 or 240 mg is not associated with a significantly increased incidence, or different profile, of adverse events compared with the 60 mg dose^[30,31]. For example, in a randomized study that involved 648 women with metastatic breast cancer, with the exception of a slightly greater incidence of nausea in the high dose group, the incidence of the most common side effects was similar with toremifene 60 mg and 200 mg^[30]. Similarly, there were no significant differences between the incidence of side effects with toremifene 60 mg and 240 mg in a randomized study of 463 women with advanced breast can-

cer^[31]. In a pooled-analysis of two studies involving 733 women with advanced breast cancer^[41], high-dose toremifene 200 or 240 mg was tolerated as well as tamoxifen 20 or 40 mg.

In a meta-analysis of five studies significantly more tamoxifen- than toremifene-treated patients discontinued treatment prematurely (19.6% *vs* 13.7%; $P = 0.007$), predominantly due to greater non-compliance and protocol violations in the tamoxifen group^[42]. Not every study shows identical tolerability; in the Nordic study^[32], the percentage of patients discontinuing treatment prematurely was significantly lower with toremifene than with tamoxifen (14% *vs* 20% respectively; $P = 0.011$), mainly due to fewer adverse events/patients' refusals, loss to follow-up and deaths.

The recent meta-analysis of Chi *et al*^[45] however, showed that compared with tamoxifen, toremifene was associated with more vaginal discharge in patients with early stage breast cancer and more vaginal bleeding in patients with advanced disease, although the both drugs had a similar overall effect on quality of life.

Lipids

As the long-term prognosis for breast cancer patients improve, increasing attention has been focused on continuing quality of life and morbidity from other causes. This is particularly important when SERMs are used in an adjuvant setting in early-stage breast cancer where the probability of long-term survival is high. In this context, an attractive property of SERMs is their ability to improve cardiovascular risk factors. Toremifene reduces

**Figure 3** Percentage change in lipid parameters after one year with toremifene and tamoxifen^[47]. 1: Total cholesterol; 2: low-density lipoprotein (LDL) cholesterol; 3: high-density lipoprotein (HDL) cholesterol; 4: Triglycerides; 5: LDL:HDL; 6: Apo lipoprotein-B.

both total and low-density lipoprotein (LDL) cholesterol and increases high-density lipoprotein (HDL) cholesterol (Figure 3)^[47-50]. Particularly persuasive are the results from a crossover trial in which 197 women receiving adjuvant therapy with toremifene or tamoxifen were monitored for lipid levels^[51]. After one year of treatment the total cholesterol had decreased in both groups, but HDL-cholesterol increased only in the toremifene group ($P < 0.001$); indeed, HDL cholesterol significantly decreased in the tamoxifen-treated patients ($P < 0.001$). After one year of therapy patients who still had abnormal lipid levels were switched to the other medication. In patients switched from tamoxifen to toremifene total- and HDL-cholesterol increased and triglycerides decreased to pre-treatment levels whilst in the patients switched from toremifene to tamoxifen total cholesterol decreased and triglycerides increased. The authors conclude that the lipid profile changes associated with toremifene are better than those associated with tamoxifen^[50]. This finding was supported by the results of a recent meta-analysis of 23 clinical trials in which toremifene and tamoxifen were compared^[44]. In an early stage breast cancer patients' triglyceride levels were reduced more and HDL-cholesterol levels increased more by toremifene than by tamoxifen, although tamoxifen was more effective in reducing LDL-cholesterol. In patients with advanced disease toremifene also reduced triglyceride levels more than tamoxifen. Similar beneficial changes have also been reported from an extended randomized controlled investigation of the effects of toremifene *vs* the aromatase inhibitor anastrozole on lipid profile^[52].

The evidence seems rather clear that the effect of toremifene on patients' lipid profile is generally positive and better than that of the comparator treatments so far investigated.

Bone mineral density in breast cancer patients

Toremifene improves bone mineral density (BMD) and helps prevent osteoporosis in postmenopausal breast cancer patients. These effects are similar to those of

Figure 4 Incidence of serious vascular events in patients randomized to toremifene or tamoxifen adjuvant therapy in post-menopausal women^[17]. 1: Total cerebrovascular events; 2: Stroke; 3: Transient ischaemic attack; 4: Total thromboembolic events; 5: Pulmonary embolism; 6: Deep vein thrombosis.

tamoxifen. Comparative studies have shown that both toremifene and tamoxifen prevent reductions in BMD in the lumbar spine and proximal femur, and that these effects are reflected by changes in a wide range of bone biochemistry markers such as pyridinoline, deoxypyridinoline and urinary cross-linked aminoterminal telopeptide of type I collagen^[53-55]. Toremifene and tamoxifen have also been used successfully in combination with the bisphosphonate clodronate, with no significant differences between them^[56,57].

Some beneficial effects on BMD have been observed in premenopausal women at high risk for developing breast cancer taking toremifene 60 mg as chemoprevention, therefore making an attractive alternative to tamoxifen. A double-blind, placebo-controlled pilot study in 259 healthy premenopausal and postmenopausal women at high risk for breast cancer found a trend for a sustained increase in lumbar spine BMD after one year of toremifene therapy in premenopausal women^[58].

LONG TERM SAFETY

The long-term safety profile of toremifene was evaluated in detail in a review of all preclinical and clinical safety data from 1978 to 2004 and comparative clinical safety data between October 1995 and the end of 2004^[59]. At the time of this review, information was available from more than 350000 patient treatment years. The evidence indicated that toremifene has good long-term safety, with a lower incidence of endometrial cancer, stroke, pulmonary embolism, deep vein thrombosis and cataracts than tamoxifen.

A 3-year study specifically designed to compare the gynecological effects of toremifene 40 mg and tamoxifen 20 mg in 167 postmenopausal breast cancer patients showed that the incidence of proliferative endometrium was increased to a significantly ($P < 0.0001$) lesser extent by toremifene (from 20.0% to 32.2%) than by tamoxifen (from 20.4% to 46.8%)^[60].

Endometrial cancer

The finding that tamoxifen at high doses caused liver tumors in rats^[61] raised concern that it may be mutagenic in humans. The mechanism of this effect in laboratory animals was believed to be due to DNA adduct formation by metabolites of tamoxifen, although this has more recently been questioned^[62]. Nevertheless, endometrial cancer rates are increased in women taking tamoxifen^[13]. The chlorine substitution in the structure of toremifene alters its metabolism such that DNA adducts are much less likely to form^[13,63-66] and a case-control study based on records of 38000 Finnish breast cancer patients appears to suggest that toremifene is considerably less frequently associated with endometrial cancer than is tamoxifen [OR 2.9; 95%CI: 0.3-3.9 *vs* 0.9; 95%CI: 0.3-3.9]^[17]. However, a recent meta-analysis of studies involving a total of 7242 patients with early or advanced breast cancer found no difference in the number of endometrial cancers between patients treated with toremifene or tamoxifen, although the follow-up was relatively short in the majority of studies. There is clearly still much to be discovered concerning the oncogenicity of SERMs, but both laboratory and clinical evidence suggests an advantage for toremifene over tamoxifen in this regard.

Thromboembolic effects

A retrospective analysis of the serious vascular events reported in the manufacturer's Drug Safety Database^[67] revealed that cerebrovascular and thromboembolic events overall were significantly higher in tamoxifen than in toremifene-treated patients (Figure 4).

Other evidence suggests that toremifene may be associated with a lower risk of such thromboembolic events^[59]. A retrospective analysis of adjuvant treatment trials with toremifene 40 or 60 mg and tamoxifen 20 mg in more than 2500 postmenopausal women revealed a significantly lower incidence of ischemic stroke, total cerebrovascular events and total thromboembolic events with toremifene compared with tamoxifen.

DISCUSSION

For obvious ethical reasons the great majority of randomized clinical trials of toremifene have been undertaken with tamoxifen as the comparator, rather than placebo. The results of these studies, and the several meta-analyses that are based upon them, appear to characterize toremifene as being at least as effective as tamoxifen in the treatment of breast cancer both in the adjuvant setting and in patients with advanced and metastatic disease. Of the ten randomized controlled trials described in Table 1 all found toremifene to be at least as effective as tamoxifen. In some studies and for some parameters there was a statistically significant advantage for toremifene over tamoxifen; a shorter time to onset of complete response in Nomura *et al*^[39] 1993, a higher rate of objective response in Zejnalov *et al*^[30] 2006 and a longer progression-free survival in Yamamoto *et al*^[38] 2013. There

were no statistically significant efficacy advantages for tamoxifen in these studies. However, whilst it is tempting to claim at least a trend for better efficacy for toremifene, some statistically significant differences are likely to arise by chance when a large number of parameters are compared in several studies (68 individual parameters are represented in Table 1 far more were examined in the studies cited). So far as the efficacy of toremifene is concerned, the conclusion is that it is at least as effective as tamoxifen is reasonable seems conservative and reasonable. In addition, toremifene has been the subject of a number of meta-analyses using different criteria for inclusion of studies and all have come to the same conclusion that the efficacy of toremifene and tamoxifen are not statistically significantly different.

Modern hormonal treatment for breast cancer emphasizes continuing therapy with an anti-estrogen, or an anti-estrogen followed by a switch to an aromatase inhibitor after longer or shorter periods. Whilst toremifene appears to behave similarly to tamoxifen, there is a relative dearth of information on its use in these switch or extended adjuvant contexts.

So far as safety and tolerability are concerned, the simple substitution of a chlorine atom for a hydrogen atom appears to make a considerable difference. The altered pattern of metabolite formation with its strongly reduced DNA adduct formation is reflected in a lower incidence of endometrial cancer—a recent meta-analysis of studies involving a total of 7242 patients with early or advanced breast cancer found no difference in the number of endometrial cancers between patients treated with toremifene or tamoxifen, although the follow-up was relatively short in the majority of studies^[44]. On the other hand, the pattern of serum lipids is more favorably affected by toremifene with lower triglycerides, and an improved HDL/total cholesterol ratio. Thromboembolic events also show benefits in favor of toremifene. Overall, toremifene is well tolerated and the pattern of adverse events reported in clinical trials is rather similar between the two SERMs.

Taken together, the findings of clinical trials, meta-analyses and studies on specific aspects of the pharmacology of toremifene suggest that it is an effective and well tolerated agent for the treatment of early and advanced breast cancer. In comparison with tamoxifen, toremifene is at least as effective in all therapeutic contexts so far investigated and may have tolerability and safety advantages.

Abstract

Breast cancer is the most common type of cancer in women, but fortunately has high survival rates. Many studies have been performed to investigate the effects of exercise in patients diagnosed with breast cancer. There is evidence that exercise after the diagnosis of breast cancer improves mortality, morbidity, health related quality of life, fatigue, physical functioning, muscle strength, and emotional wellbeing. Based on scientific data, breast cancer patients should be recommended to participate in rehabilitation programs including aerobic and strength training. The aim of this article is to review the recently published data on the effect of exercise in patients with breast cancer in order to present the current perspective on the topic.

Key words: Breast cancer; Exercise; Rehabilitation; Physical activity; Cancer

Core tip: Exercise is not merely safe and feasible for breast cancer patients, but is moreover a complemen-

INTRODUCTION

Breast cancer is the most frequent cancer in females, with an estimated more than 2.8 million breast cancer survivors in the United States alone^[1,2]. For many years, breast cancer has been incredibly difficult for both patients and health care providers due to its high mortality and morbidity rates^[3]. However, due to recent advances in the diagnosis and treatment of breast cancer, survival rates have increased^[3]. Overall, the 5-year survival rate for breast cancer in all stages has been reported as 89% by the American Cancer Society^[2]. Despite this successful increase in the rate of survival, there are still many problems arising from either the disease itself or relating to its treatment in patients living with the disease.

Due to the high prevalence of breast cancer, especially in developed countries, the increased rates of survival and high expectations in the quality of life for women with breast cancer ultimately led patients and health care providers to seek alternative or additional approaches in the management of the disease^[4]. All of these factors created a greater interest in the physical activity of cancer patients over time. Thus, there has been much research on the effect of exercise on breast cancer patients and survivors within the medical community in the last few

decades^[5].

The effect of exercise might be evaluated in some items according to the disease stage, which may all be considered different major topics of interest. Among them, the preventive effects of exercise for breast cancer and effectiveness of exercise in breast cancer patients are the most covered areas in the current literature. The preventive effect of exercise for breast cancer has been shown in epidemiological studies^[6,7]. Risk reduction with physical activity for breast cancer in females is estimated to be up to 25%-30%^[1,6]. To achieve such an effect, women are recommended to follow a 150-min per week exercise regime of moderate to vigorous intensity consisting of sports or other physical activity^[4].

Fortunately, in many cases, cancer patients are no longer considered isolated people in many aspects of life. The traditional approach of clinicians advising rest and the avoiding of physical activity to breast cancer patients and survivors has changed over time, and both patients and the medical community are seeking the ideal level, type, and intensity of physical activity^[8]. This brings us to the other aspect researched: the effect of exercise in breast cancer patients.

Although the additional effect of exercise in breast cancer has been investigated in numerous studies throughout the last few decades, due to the wide variety in the status of patients in such areas as disease stage, associating co-morbid conditions, and physical function, to date there has been no clear consensus or standard approach that has been agreed upon in terms of exercise in breast cancer patients^[5,8], despite recent systematic reviews and meta-analyses published on the effect of exercise interventions^[5,9,10]. Considering the quickly accumulating amount of literature on the subject, we felt the need to overview the effects of exercise specifically for breast cancer and discuss the need for research for future trials. Therefore, the aim of this article is to review the recently published data on the effect of exercise in patients with breast cancer in order to present the current perspective on the topic.

POSSIBLE MECHANISMS OF EXERCISE

A variety of robust studies have clearly showed the beneficial effects of exercise in a healthy population, with a varying spectrum of positive changes in physiological and psychological effects^[11]. Hence, it is important to determine how these positive effects of exercise impact breast cancer patients.

The effect of treatment of cancer on immune functions and the positive effects of good immune function on survival and morbidity in cancer patients have been linked^[12]. Scientific data has suggested cancer and its treatment are related with a disruption of immune functions^[12,13]. Pro-inflammatory cytokines are found in higher levels in advanced stage, metastatic, and recurrent disease compared with non-metastatic, non-recurrent, and early stage disease^[14]. Although researchers have investigated

the relation between inflammatory markers and exercise in cancer patients, there is no significant data showing the effects of exercise on immune system markers in cancer patients^[13,15]. Recently, a few studies have showed some positive results in cytokine and insulin levels with Tai Chi exercises in breast cancer patients^[16,17].

Angiogenesis and apoptosis are related to the progression and metastasis of tumors, with vascular endothelial growth factor being the most studied angiogenic molecule^[18]. Ergun *et al*^[19] have showed the positive effects on levels of angiogenic molecules with supervised and home exercises in breast cancer patients compared to an education-only-group. Unfortunately, many studies investigating the relationship between immune functions and exercise in breast cancer patients are limited (*e.g.*, due to a small sample size), and so should be investigated further in future randomized clinical trials (RCT) with large populations.

Being overweight/obese is clearly associated with an increased risk of developing many cancer types, including breast cancer in postmenopausal women^[4,20]. The mechanism underlying obesity and breast cancer is considered to be immune function, inflammation, and levels of estrogen and IGF-1^[21,22]. However, there are studies exploring the effects of reducing breast cancer risk with intentional weight loss^[23,24]. The American Cancer Association recommends a healthy diet and advises against gaining weight due to its negative effects on treatment success and recurrence^[25]. The established ways for losing weight are to reduce dietary intake and/or increase physical activity. Besides obtaining a healthy diet, regular exercise in breast cancer patients would be helpful in maintaining their ideal weight.

Hahn *et al*^[26] showed that disruption of the circadian rhythm, such as by performing night shift work, might have an association with the progression of breast cancer. Exercise also acts as a regulator on the circadian rhythm and sleep; therefore regular exercise might hypothetically have an indirect effect on preventing the progression of breast cancer. However, this theory needs be proven with clinical studies in breast cancer patients.

One descriptive study showed that the prevalence of fibromyalgia might be high in hospitalized breast cancer patients^[27]. Fibromyalgia symptoms additional to typical cancer symptoms, such as fatigue, might inversely influence the patients' quality of life. Thus, taking fibromyalgia into account when prescribing exercise to patients diagnosed with breast cancer should be considered.

EFFECTS OF EXERCISE IN BREAST CANCER

There is a growing interest among cancer patients in searching for alternative options in order to achieve a better life quality. If the effect of practicing exercise in breast cancer patients on mortality as well as morbidity were well understood, that would create an important clinical impact in the future.

Prospective observational studies have demonstrated that physical activity after cancer diagnosis is associated with a reduced risk of cancer recurrence and improved overall mortality among multiple cancer survivor groups, including breast, colorectal, prostate, and ovarian cancer^[25,28-30]. Several studies in breast cancer survivors have demonstrated that being physically active after the diagnosis of breast cancer led to a 24%-67% reduction in the risk of total deaths and a 50%-53% reduction in the risk of breast cancer deaths when compared to a sedentary lifestyle^[31-33]. Some studies have also shown that physical activity is inversely related with co-morbidities in patients diagnosed with breast cancer^[34].

Fatigue is an important symptom that occurs frequently in breast cancer patients and has a negative impact on the quality of life^[35]. Studies have reported a prevalence of fatigue in cancer patients of up to 96%^[36]. A Cochrane review published in 2006 concluded that aerobic and resistive exercise in breast cancer patients on adjuvant therapy had significant positive effects on cardiorespiratory fitness and non-significant effects on fatigue and weight gain^[37]. A meta-analysis published by McNeely *et al.*^[5] also showed the significant positive effect of exercise on symptoms of fatigue in breast cancer patients. An updated Cochrane review in 2012 showed the benefits of aerobic exercise in combating fatigue in breast cancer patients during or adjuvant to chemotherapy treatment^[38].

The literature suggests that exercise in breast cancer survivors or in patients receiving therapy improves cardiorespiratory fitness, physical function, and muscular strength^[5,37-39]. However, there is a need for long-term studies for a better interpretation of these results.

Studies show that exercise and physical activity improve depression and anxiety in breast cancer patients receiving adjuvant therapy^[38-40]. Carayol *et al.*^[40] suggested that, according to their meta-analysis, relatively low doses consisting of 90-120 min of weekly moderate physical exercise is efficacious for such improvements in patients receiving adjuvant therapy.

A meta-analysis performed for trials on the effect of exercise in breast cancer patients showed a significant pooled effect of exercise on patients' quality of life^[5]. Confirming this data, recent Cochrane reviews evaluating the effects of exercise on health-related quality of life in cancer patients and survivors in randomized and controlled trials have suggested that cancer patients may benefit from exercise in some domains, including physical function, role function, social function, and fatigue^[38,39].

INDICATIONS AND CONTRAINDICATIONS

Indications for exercise treatment in this patient population include regaining or improving physical functions, aerobic capacity, strength, flexibility, body image, body composition, quality of life, the ability to physically and psychologically withstand to any current and/or future

cancer treatments, and to withstand anxiety due to living with current or recurrent disease^[41]. Indications also include the reduction of long-term and late effects of cancer treatment, and the potential delay in any recurrence or progress of the disease^[41].

Contraindications for exercise prescription in breast cancer patients include, but are not limited to: acute post-operative period (up to 8 wk); acute arm and shoulder problems for upper body exercises; patients with extreme fatigue, anemia, or ataxia; and general cardiovascular and respiratory contraindications for an exercise regimen^[41].

Traditionally, upper extremity exercises were avoided in breast cancer patients with lymph node dissection and radiotherapy. However, some recent studies have shown that upper body exercises do not have a negative impact on lymphedema^[42].

EXERCISE TYPE AND CONTENT

There is no standard approach to exercise regimens for breast cancer patients. This is mainly due to the wide spectrum of such patients in terms of age, stage of the disease, co-morbid situation, physical function, etc. Considering this variety, it seems impossible to ever have a standard approach for each individual patient. In addition, the prior functional status and exercise habits of each patient should always be taken into account when an exercise program is being prescribed.

There are various studies concerning the effects of different types of exercise on breast cancer patients. Types of exercises studied in breast cancer patients range from regular aerobic exercise to such activities as Tai Chi^[16,17,42]. The most frequently studied in these patient populations are aerobic exercises (*i.e.*, group, home, walking, and cycling), resistive exercises, and special types of exercise like Pilates, Tai Chi, and Yoga^[17,42-44]. Exercise regimens can be prescribed as either group exercises instructed by a trainer or self-practiced home exercises.

Resistance exercises in breast cancer patients are gaining more attention due to their ability to decrease muscle waste and fatigue^[45]. A combined Aerobic and Resistance Exercises (CARE) trial has investigated standard dose aerobic (25-30 min per session of 3 d per week), high dose aerobic (50-60 min per session of 3 d per week), and combined aerobic and resistive exercise (standard aerobic in addition to standard resistance training; 3 d per week, 2 set of 10-12 repetitions) schemes in breast cancer patients. The results showed that higher intensity and resistance exercises are safe in this population, and that high and combined resistive-aerobic exercise regimens are superior to standard aerobic ones in terms of certain domains such as muscle strength, endocrine symptoms, and quality of life aspects like bodily pain^[45].

Pilates exercises improve physical strength, flexibility, and postural control, and it is commonly-accepted by women as a fitness activity in developed countries^[43]. In a randomized clinical trial, it was shown that Pilates exercises have significant effects in females with breast cancer

in terms of functional capacity, fatigue, flexibility, and quality of life compared to the control group.

Tai Chi exercises are respected as exercises of mindfulness, and are known to improve physical and psychological well-being. Some studies demonstrated that Tai Chi exercises for 10-12 wk improved fatigue, body composition, and quality of life, as well as muscular, memory, and cognitive functions, in breast cancer survivors^[16,17].

Yoga is another type of meditative physical activity including breathing, posture, flexibility, and core strength exercises that can be used in breast cancer patients. In 2013, Sudarshan *et al*^[46] published a study on breast cancer patients which reported that weekly Yoga therapy improved physical function.

According to the data pooled from cancer studies, the American Cancer Society recommends that cancer survivors engage in regular physical activity, avoid inactivity, and exercise for at least 150 min per week, including strength-training for at least 2 d per week, to obtain a healthy weight^[25].

Kirkham *et al*^[47] compared different intensity arrangement methods for the precise prescription of aerobic exercise regimens. The American College of Sports Medicine's metabolic equation for treadmill walking and heart rate reserve are found to be the most accurate methods for exercise intensity prescription in breast cancer patients and survivors^[47].

Enjoyable exercises like Pilates, Tai Chi, Yoga, Nordic walking, and dance may be chosen according to the expectations and motivations of patients by carefully adjusting intensity on an individual-by-individual basis.

ADVERSE EVENTS

In most clinical trials that evaluate different types of exercises, adverse events are not even reported^[38,39]. In the clinical studies that have reported safety associated with exercise, most of them either reported no adverse events at all or only those that are very rare and usually non-serious. The reported exercise-related adverse events are mainly dizziness, dyspnea, musculoskeletal injuries, or lymphedema, which were similar to the control group in terms of numbers^[38-39]. In general, no differences whatsoever were observed regarding recurrence, disease progression, or increased mortality in exercise *vs* control groups. Although limited, these studies show that appropriate exercise regimens in breast cancer patients are quite safe to implement. However, the adverse events of exercise regimens in this patient group should be further studied and reported more thoroughly in future trials.

LIMITATIONS AND RECOMMENDATIONS

Although many studies have investigated the effects of exercise in breast cancer patients, there is still a need for randomized controlled trials for the clarification of exercise type, duration, and intensity for program standardization.

Most reported trials are conducted in small groups

and for short-term periods. Therefore, the results of these trials are difficult to implement for a long-term period and large populations. While advantageous that most cancer trials on the impact of exercise are researched in breast cancer survivors, it is unfortunate that very few of these are powered randomized controlled trials with large enough sample sizes^[9,10].

Considering the heterogeneity of breast cancer patients, individualized programs according to disease stage, treatment status, and co-morbid situation should be tailored and addressed in future research questions. Along with RCTs, long-term real life data from registries and databases on the outcome of exercises in female breast cancer patients might help in directing these questions.

Additionally, compounding factors that would have an effect on exercise and its outcome, such as the patients' previous exercise habits, co-morbid situation (*i.e.*, lymphedema), and functional status need to be evaluated.

Lack of knowledge on the effects of exercise and physical activity among the medical community and fear in creating an exercise regimen with regards to the seriousness of the disease is a social burden that results in unnecessary avoidance from physical activity in patients diagnosed with breast cancer. Therefore, in order for this substantial issue to be settled, the mindset of physicians should be changed, which should happen naturally over time as the evidence-based data accumulates.

Raising awareness and improving information in this area for patients, caregivers, and healthcare providers would have a great impact in approaching these patients' exercise needs. This emphasizes the importance of a multidisciplinary approach in overcoming the barriers in this area and helps patients get the best outcome from treatment. Little to no data is available on the cost-effectiveness of exercise treatment for breast cancer patients, which in the long-term needs to be evaluated.

Despite the crucial need for physical activity and exercise in this patient population, patients' demand for physical treatment greatly varies from 2%-81%^[3,48]. Patient awareness about physical activity after diagnosis can be a vital factor in determining this variation.

CONCLUSION

Exercise is not merely safe and feasible for breast cancer patients, but is moreover a complementary treatment for one to achieve physiological and psychological improvements. There is increasing evidence that regular exercise after the diagnosis of breast cancer might have a substantial positive impact in mortality, morbidity, prognosis, and quality of life. We advise a multidisciplinary approach in order to encourage breast cancer survivors into engaging in rehabilitation programs combining both strengthening and aerobic exercises for the most beneficial results.

Abstract

Breast cancer is a heterogeneous complex of diseases, a spectrum of many subtypes with distinct biological features that lead to differences in response patterns to various treatment modalities and clinical outcomes. Traditional classification systems regarding biological characteristics may have limitations for patient-tailored treatment strategies. Tumors with similar clinical and pathological presentations may have different behaviors. Analyses of breast cancer with new molecular techniques now hold promise for the development of more accurate tests for the prediction of recurrence. Gene signatures have been developed as predictors of response to therapy and protein gene products that have direct roles in driving the biology and clinical behavior of cancer cells are potential targets for the development of novel therapeutics. The present review summarizes current knowledge in breast cancer molecular biology, focusing on novel prognostic and predictive factors.

INTRODUCTION

Breast cancer is a heterogeneous complex of diseases, a spectrum of many subtypes with distinct biological features that lead to differences in response patterns to various treatment modalities and clinical outcomes. Traditional classification systems regarding biological characteristics, such as tumor size, lymph node involvement, histological grade, patient's age, estrogen receptors (ER), progesterone receptors (PR) and human epidermal growth factor receptor 2 (HER2 or c-erbB2) status, may have limitations for patient-tailored treatment strategies. Furthermore, the histological appearance of the tumors may not be sufficient to establish the underlying complex genetic alterations and the biological events involved in cancer development and progression. Tumors with similar clinical and pathological presentations may have different behaviors. Therefore, recent studies have

focused on defining more detailed biological characteristics to improve patient risk stratification and to ensure the highest chance of benefit and the least toxicity from a specific treatment modality. Global gene expression profiling (GEP) studies have provided evidence for classifying breast cancer into distinct biological classes associated with patient survival, based on gene expression patterns^[1,2].

Population based screening programs have resulted in a significant shift to early stage disease and increased the interest in studying biological prognostic and predictive factors^[3]. Novel molecular studies have opened a broad field in cancer research that allows basic and translational researchers to look for new potential targets. Analyses of breast cancer with new molecular techniques now hold promise for the development of more accurate tests for the prediction of recurrence. Gene signatures have been developed as predictors of response to therapy and protein gene products that have direct roles in driving the biology and clinical behavior of cancer cells are potential targets for the development of novel therapeutics^[4]. The present review summarizes current knowledge in breast cancer molecular biology, focusing on novel classification, prognostic and predictive factors.

IDENTIFICATION OF BREAST CANCER SUBTYPES BY GEP STUDIES

Gene expression microarray studies have identified distinct molecular tumor classes based on simultaneous expression analyses of thousands of genes in a single experiment. Perou *et al*^[5] first analyzed gene expression patterns in grossly dissected normal or malignant human breast tissues in 65 tumor samples from 42 individuals with locally advanced breast cancer treated with neoadjuvant doxorubicin, using complementary microarrays representing 8102 human genes. The authors selected 496 genes based on the criteria of significantly greater variation in expression between different tumors and minimum variation between paired samples from the same patient and these genes were termed the intrinsic gene subset. Samples and genes were aggregated according to the similarity to each other (unsupervised clustering). Subset cluster analysis revealed a dendrogram with two main branches that were clinically described as *ER-positive* and *ER-negative*. The tumors in the *ER-positive* group were characterized by the relatively high expression of many genes expressed by breast luminal cells (ER-responsive genes, luminal cytokeratins and other luminal associated markers), so they were termed the *luminal* group. The *ER-negative* group was further divided into *basal-like*, *ErbB2-positive* and *normal-like* subclasses. *Basal-like* tumors expressed many of the characteristics of breast basal epithelial cells that did not express ER and showed staining with basal keratins. Another cluster of tumors was characterized by the expression of high levels of HER2 oncogene, which also showed low levels of ER expression and other genes associated with ER expression. Eventu-

ally, the authors identified four groups of samples using the intrinsic gene set that might be related to different molecular features of mammary epithelial biology and they named them *ER-positive luminal-like*, *basal-like*, *ErbB2-positive* and *normal-like*. These results were confirmed in follow up experiments using larger numbers of cases^[6].

Subsequent studies revealed that similar molecular subtypes of breast cancer could be identified in multiple cohorts of breast cancers and that *luminal* cancers could be subclassified into 2 or 3 groups and different molecular subtypes were shown to have distinct clinical outcomes. Sørlie *et al*^[7] investigated the clinical relevance of gene expression profiles in 78 breast carcinoma patients. Of these patients, 51 were part of a prospective study with locally advanced (T3-T4 and/or N2) tumors and had received doxorubicin based chemotherapy before the surgery. The authors showed a highly significant difference in overall survival between the subtypes. Both the *basal-like* and *ErbB2-positive* subtypes were associated with the shortest survival times. The authors subclassified the *luminal-like* breast cancer into three subclasses comprising *luminal-A*, *luminal-B* and *luminal-C* and identified *luminal-A* subgroup of *ER-positive* tumors as being associated with the best outcome. Van't Veer *et al*^[8] also investigated node-negative breast cancer patients and found 231 genes significantly associated with disease outcome, as defined by the presence of distant metastasis at the 5th year. These data revealed that each breast tumor has its own unique molecular portrait, providing the basis for an improved molecular taxonomy of the disease.

SUBCLASSIFICATION OF LUMINAL LIKE BREAST CANCER

Approximately 75% of breast cancers are positive for ER and/or PR. The *ER-positive* tumors express ER, PR, ER responsive genes and other genes that encode typical proteins of luminal epithelial cells so they are termed the *luminal* group. Characterization of *luminal-like* breast cancer varied between various studies, probably due to the identification and use of distinct intrinsic gene sets for cluster analysis. Hu *et al*^[9] evaluated an intrinsic gene set derived from three independent studies (Sørlie *et al*^[7], 2001; Van't Veer *et al*^[8], 2002; Sotiriou *et al*^[10], 2003), joined them together into a combined data set and identified two main *luminal-like* subclasses corresponding to *luminal-A* and *luminal-B*. Most subsequent studies have supported the concept of two *luminal-like* subclasses^[10-12].

Luminal-A

The *luminal-A* is the most common subtype and represents 50%-60% of all breast cancers. These tumors frequently have low histological grade, low degree of nuclear pleomorphism, low mitotic activity and include special histological types (*i.e.*, tubular, invasive cribriform, mucinous and lobular) with good prognosis. *Luminal-A* is characterized by higher levels of ER and lower levels of proliferation related genes. It is characterized by the

expression of luminal epithelial cytokeratins (CK) 8 and 18, other luminal associated markers including ER1, genes associated with ER function such as *LIV1* (zinc transporter ZIP6 or *SLC39A6*; solute carrier family 39 zinc transporter, member 6), *hepatocyte nuclear factor 3 alpha* (*FOXA1*), *X-box binding protein 1* (*XBPI*), *GATA binding protein 3* (*GATA3*), *B cell lymphoma 2* (*BCL2*), *erbB3* and *erbB4*^[13]. *Luminal-A* subtype is defined as ER-positive and/or PR-positive tumors with negative HER2 and low Ki67 (proliferating cell nuclear antigen) index by immunohistochemistry^[14].

Patients with *luminal-A* breast cancer have a good prognosis; the relapse rate is significantly lower than the other subtypes. Recurrence is common in bone, whereas liver, lung and central nervous system metastases occur in less than 10% of patients and treatment is mainly based on hormonal therapy^[15,16].

Luminal-B

Luminal-B tumors comprise 15%-20% of breast cancers and have a more aggressive phenotype, higher histological grade, proliferative index and a worse prognosis^[17]. This subtype has a higher recurrence rate and lower survival rates after relapse compared to *luminal-A* subtype^[18].

The main difference between both *luminal* subgroups is increased expression of proliferation-related genes such as *avian myeloblastosis viral oncogene homolog (v-MYB)*, *gamma glutamyl hydrolase (GGH)*, *lysosome-associated transmembrane protein 4-beta (LAPTMB4)*, *nuclease sensitive element binding protein 1 (NSEP1)* and *cyclin E1 (CCNE1)* in *luminal-B* breast cancers. *Luminal-B* tumors also demonstrate increased expression of growth receptor signaling genes^[19]. Approximately 30% of *HER2-positive* tumors defined by immunohistochemistry are assigned to the *luminal-B* subtype^[20].

It should be noted that expression levels of proliferation related genes in ER-positive disease form a continuum; therefore, the cutoffs to define *luminal-A* and *luminal-B* cancers are set in an arbitrary manner rather than emerging from a bimodal distribution of these genes' expression levels^[21]. Various studies conducted to differentiate *luminal-A* and *luminal-B* subtypes defined more pragmatic criteria that can be broadly applied to clinical practice. The Ki67 index is suggested as a potential proliferation marker that could successfully differentiate *luminal-B* tumors from *luminal-A* in clinical practice. Cheang *et al*^[22] studied 357 breast cancer subtypes by using microarray based gene expression profiling and the Ki67 hormone receptor and HER2 status by immunohistochemistry. The authors determined the Ki67 cut off point (14%) that distinguishes *luminal-A* from *luminal-B* tumors, then applied it to an independent microarray series of 4046 breast cancers and concluded that the two subtypes could be distinguished by the Ki67 index. However, Ki67 immunohistochemistry has known limitations, such as low intra- and inter-laboratory reproducibility, arbitrary selection of optimal antibodies for testing and different methods of cell counting (manual

vs automated) in addition to potential problems resulting from tumor heterogeneity^[23]. There is also an urgent need to standardize the Ki67 expression analysis and validate its clinical utility.

From the immunohistochemical point of view, *luminal-B* subtype is defined as ER-positive, HER2-negative and Ki 67 high or ER and HER-2 positive tumors, but this definition does not include all *luminal-B* tumors as up to 6% of them are negative for both ER and HER2. Moreover, the Ki67 cut off point to distinguish *luminal-A* and *-B* has not been standardized^[24].

Overall survival in untreated *luminal-B* breast cancers is similar to the *basal-like* and *HER2-positive* subtypes which are widely recognized as high-risk tumors^[9]. *Luminal-B* tumors have poorer outcomes with hormone therapy. Several studies have suggested that *luminal-B* breast cancer was relatively insensitive to endocrine therapy compared to *luminal-A* breast cancer and to paclitaxel- and doxorubicin-containing preoperative chemotherapy compared with *HER2-positive* and *basal-like* breast cancers. However, *luminal-B* breast cancer responds better to neo-adjuvant chemotherapy than *luminal-A* subtype, achieving higher pathological complete response rates^[25-29]. Increased relapse rates observed in *luminal-B* tumors are limited to the first 5 years after diagnosis^[30].

Recent evidence suggests that certain alternative growth factor pathways, such as *fibroblast growth factor receptor 1 (FGFR1)*, *HER1*, *phosphoinositide 3 kinase (PI3K) catalytic alpha polypeptide*, and *sarcoma proto-oncogene (Src)*, may contribute to the higher proliferation and poorer prognosis of *luminal-B* breast cancer and related therapeutic agents are in active clinical development^[31].

In breast cancer, changes to fibroblast growth factor signaling are considered important for oncogenesis, mainly through amplification of *FGFR1* and *FGFR2*. *FGFR1* is amplified in 10% of all breast cancers. Recent data suggest that the *luminal-B* subtype is enriched for *FGFR1* gene amplification^[32]. Studies suggested that *FGFR1* gene amplification might be a contributor to the poor prognosis observed in *luminal-B* breast cancer through increased proliferation and resistance to endocrine therapy. Several antibodies and small molecule inhibitors of *FGFR* are currently under clinical study processes.

In breast cancer, the PI3K pathway is frequently activated. Amplification of upstream receptors such as HER2, loss of negative regulators such as PTEN, amplification of downstream targets such as protein kinase B (PKB or Akt) and activating mutations or genetic amplification of the alpha catalytic subunit of PI3K have all been described in breast cancer. Targeting the PI3K pathway appears promising, although more extensive studies are required^[33].

HER2-positive

Human epidermal growth factor receptor-2 is a member of the family of four membrane tyrosine kinases. The HER2 receptor is encoded by the HER2 gene, which is a proto-oncogene mapped in chromosome 17q21. Upon

ligand binding to their extracellular domains, HER proteins undergo dimerization and transphosphorylation of their extracellular domains. HER2 does not have a ligand and relies on heterodimerization with another family member or homodimerization with itself to be activated when expressed at very high levels. These phosphorylated tyrosine residues interact with numerous intracellular signaling molecules, leading to activation of downstream second messenger pathways and crosstalk with other membrane signaling pathways. Transcription factors activated by the pathway regulate many genes involved in cell proliferation, survival, differentiation, angiogenesis, invasion and metastasis^[34-37].

HER2-positive cancer accounts for 15-20% of breast cancer subtypes. HER2 positivity confers more aggressive biological and clinical behavior. These tumors are characterized by high expression of the HER2 gene and other genes associated with the HER2 pathway and/or HER2 amplicon located in the 17q12 chromosome. Morphologically, these tumors are highly proliferative, 75% have a high histological and nuclear grade and more than 40% have p53 mutations^[38]. Nearly half of *HER2-positive* breast cancers are positive for ER but they generally express lower ER levels.

The immunohistochemical profile of *ER-negative* and *HER2-positive* does not correspond perfectly with the intrinsic subtype since only 70% of HER2 tumors by microarray have the protein overexpressed on immunohistochemistry. Conversely, all tumors with HER2 amplification or overexpression are not included in the HER2 cluster by microarray analysis^[39,40].

Staaf *et al.*^[41] identified three separate subtypes of *HER2-positive* tumors, one with a clearly poor prognosis with a 12% 10 year survival compared to the 50-55% survival in the other two groups using HER2 derived prognostic predictor (HDPP) gene analysis. The HDPP was not directly related to the expression of proliferation gene and HER2 pathway but was mostly associated with genes related to immune response to tumor invasion and metastasis.

In the absence of treatment, *HER2-positive* tumors have a poor prognosis. They have increased sensitivity to certain cytotoxic agents such as doxorubicin, relative resistance to hormonal agents and a propensity to metastasize to the brain and visceral organs. Doxorubicin sensitivity is possibly due to coamplification of the topoisomerase-2 gene which is near the HER2 locus on chromosome 17 and is the target of this drug^[42,43]. Advances in translational science have led to the development of a large spectrum of HER directed therapies.

Basal-like

The *basal-like* subtype represents from 8% to 37% of all breast cancers, depending on the proportion of poorly differentiated G3 cases included in the population studied^[44]. *Basal-like* cancers are associated with high histological and nuclear grade, poor tubule formation and the presence of central necrotic or fibrotic zones,

pushing borders, conspicuous lymphocytic infiltrate and medullary features with exceptionally high mitotic and proliferative indices. Most of these tumors are infiltrating ductal tumors with solid growth pattern, aggressive clinical behavior and high rate of metastasis to the brain and lung^[45].

Tumors belonging to the *basal-like* subgroup express high levels of basal myoepithelial markers, such as CK5, CK 14, CK 17 and laminin, and do not express ER, PR and HER2, hence referred to as *triple-negative*. They also overexpress P-cadherin, fascin, caveolins 1 and 2, alpha-beta crystallin and epidermal growth factor receptor (EGFR). *Basal-like* cancers present with frequent mutations in the *tumor protein 53* (TP53) gene, evidence of genomic instability and inactivation of the *retinoblastoma* (Rb) pathway. Deregulated integrin expression has also been detected and may contribute to aggressive cell behaviors and progression in this subtype^[45].

It is important to clarify that the terms *triple-negative* and *basal-like* are not completely synonymous and there is approximately 20%-30% discordance across studies. The term *triple-negative* refers to the immunohistochemical classification of breast tumors lacking ER, PR and HER2 protein expression, whereas the *basal-like* subtype is defined *via* gene expression microarray analysis. The *basal-like* classification is available only in the research setting to date and thus the *triple-negative* phenotype currently is a reliable surrogate in the clinical setting^[46].

There are several reported biomarkers associated with the *basal-like* group as well as putative candidates suitable for immunohistochemical screening. However, currently there is no specific international consensus on complementary biomarkers that can define *basal-like* cancers^[47].

Several genes related to the *basal-like* subtype have been implicated in promoting cellular proliferation, cell survival, cell migration and invasion. Despite the wide diversity of the involved pathways, signaling molecules, such as the mitogen activated protein kinase (MAPK), PI3K, Akt and nuclear factor kappa B (NF- κ B), are commonly deregulated as seen in other breast cancer subtypes. Other alterations such as cytoplasmic and nuclear accumulation of beta catenin were also observed in *basal-like* cancers, being the marker suggested as a potential therapeutic target for this cancer^[48].

Microarray and immunohistochemical analyses demonstrated that basal-like subtype constitute approximately three quarters of *breast cancer 1* (BRCA1) gene related breast cancers. This gene, often termed the *caretaker of the genome*, is located on chromosome 17 and is related with both inherent DNA damage sensing processes and DNA repair mechanisms. Breast cancers related to BRCA1 often express *triple-negative* phenotype and are frequently positive for Ki67 basal cytokeratins, TP53, EGFR and P cadherin and X chromosome abnormalities. Outcomes for women with *basal-like* tumors and BRCA1 related breast cancers are similar, in particular for early relapse and pattern of metastatic disease^[49]. *Basal-like* cancers with deficient BRCA1 pathway may respond to specific

Table 1 2013 St. Gallen - intrinsic subtypes of breast cancer

Intrinsic subtype	Clinicopathological surrogate definition	
Luminal-A	"Luminal-A-like" all of: ER and PgR positive HER2 negative Ki-67 "low" ^a Recurrence risk "low" based on multi-gene-expression assay (if available) b	a A level of < 14% best correlated with the gene-expression definition of Luminal A based on the results in a single reference laboratory ^b PgR cut-point of ≥ 20% to best correspond to Luminal A subtype
Luminal-B	Luminal-B-like (HER 2 positive) ER positive HER2 negative and at least one of: Ki-67 "high" PgR "negative or low" Recurrence risk "high" based on multi- gene-expression assay (if available) Luminal-B (HER 2 negative) ER positive HER2 over-expressed or amplified Any Ki-67 Any PgR	
Erb-B2 overexpression	HER 2 positive (non-luminal) HER2 over-expressed or amplified ER and PgR absent	
Basal-like	Triple negative (ductal) ER and PgR absent HER2 negative	There is an 80% overlap between "triple-negative" and intrinsic "basal-like" subtype

therapeutic regimens such as poly-ADP ribose polymerase (PARP) enzyme inhibitors. Also, BRCA1 deficient cells have defects in DNA double strand break repair mechanisms that could render them particularly sensitive to therapeutic agents that generate DNA double strand breaks such as PARP enzyme inhibitors^[50]. As often overexpressed in *basal-like* cancer, EGFR may also be another potential therapeutic target. Dong *et al.*^[51] identified notch pathway as one of the mechanisms of resistance to EGFR inhibition in *basal-like* breast cancer as valuable information to overcome this resistance. Dual pathway inhibition may be a viable clinical strategy in *basal-like* cancers.

As one of the *triple-negative* subtypes, *claudin-low* breast cancer was described by Herschkowitz *et al.*^[52]. This subtype is characterized by low expression of genes involved in tight junctions and cell-cell adhesions including claudins 3, 4 and 7, occludin and E cadherin showing high expression of epithelial to mesenchymal transition genes and stem cell features. Currently, it has been reported that patients with *claudin-low* tumors also have poor clinical outcomes like other *triple-negative* tumors.

Normal breast-like

These tumors account for about 5%-10% of all breast carcinomas. They are poorly characterized and have been grouped into the classification of intrinsic subtypes with fibroadenomas and normal breast samples. They express gene characteristics of adipose tissue presenting an intermediate prognosis between *luminal* and *basal-like* cancers and usually do not respond to neoadjuvant chemotherapy. As they lack the expression of ER, PR and

HER2, these tumors can also be classified as *triple-negative* but they are not considered to be *basal-like* cancers as they are negative for CK5 and EGFR. There are few studies on this subtype and their clinical significance remains undetermined. There are doubts about their existence as a breast cancer subtype and some researchers believe they could be a technical artifact from high contamination with normal tissue during the microarrays^[53]. In fact, in a large series of samples where the neoplastic cells were isolated by microdissection, no cases of *normal breast-like* subtype were found, supporting this hypothesis.

The implications of the molecular classification in the therapeutic era have been accepted by international panels. In the 2011 and the latest 2013 St. Gallen International Breast Cancer Conferences, the expert panel members agreed that therapeutic decisions should be made based on the recognition of the intrinsic subtypes of breast cancer. Panel members agreed that the different breast cancer subtypes can be defined only by genetic array testing but approximation to this classification can be made by immunohistochemistry^[54,55] (Table 1).

Although molecular taxonomy of breast cancer has attracted great attention, to date, actual practical adaptation seems limited. Certain critical issues have been raised, such as validation, reproducibility and clinical utility. The four main molecular classes frequently reported can be considered an oversimplification of a novel molecular classification system and add little to our understanding of the biology and behavior of breast cancer. Sub classification of the largest *luminal* class remains unresolved. Most *luminal* tumors are hormone receptor positive and can be identified in routine practice using immunohisto-

chemistry. Hormone receptor expression in *luminal* phenotype is recognized as a validated predictor to hormonal treatments. The difference between *basal-like* and *triple-negative* is disputed, with triple negativity in clinical practice providing a more practical and routinely applicable classification. Similarly, strongly *HER2-positive* breast cancer patients by immunohistochemistry are likely to be offered anti-HER2 therapy, especially if their tumors show evidence of HER2 gene amplification, regardless of their molecular classification. Furthermore, the *normal breast-like* class is not well defined and the proportion of some classes defined by GEP varies substantially. Finally, the contribution of this molecular taxonomy to current clinical practice is just the modification of treatment protocols related to ER, PR, HER2 and Ki67 status of breast cancer. Molecular classification based on combination of the classical well-defined immunohistochemical markers can be considered a simpler and more practical approach and it is expected to remain as such unless novel target molecules driving individual classes are identified.

BIG 1-98 is a randomized, phase III study that compared five years of tamoxifen or letrozole and their sequences in post-menopausal women with ER positive early breast cancer. Metzger *et al.*^[56] updated benefit of endocrine treatment among *Luminal* subgroups in this trial. ER positive subtypes were defined as *Luminal-A* (ER+ and/or PR+ HER2- and Ki67 < 14%) or *Luminal-B* (ER+ and/or PR+, HER2- and Ki67 ≥ 14%). In the invasive ductal carcinoma subset, 1436 (44%) and 1163 (36%) were classified as *Luminal-A* and *Luminal-B*, while in the invasive lobular carcinoma subset, 237 (59%) and 87 (22%) were classified as *Luminal-A* and *Luminal-B*, respectively. In lobular carcinoma patients, disease free survival hazard ratios for letrozole *vs* tamoxifen were 0.51 (95%CI: 0.33 to 0.79) for *Luminal-A* and 0.35 (95%CI: 0.21 to 0.56) for *Luminal-B* subtypes. The disease free survival hazard ratios for letrozole *vs* tamoxifen were 0.93 (95%CI: 0.74 to 1.77) for invasive ductal carcinoma *Luminal-A* and 0.64 (95%CI: 0.52 to 0.78) for invasive ductal carcinoma *Luminal-B*. A greater reduction in risk of a disease free survival event was shown in women with Luminal B for both invasive ductal carcinoma and invasive lobular carcinoma^[56].

Currently, the available molecular tests have offered the opportunity to challenge the molecular complexity of breast cancer but do not provide sufficiently robust information to modify established treatment schemes. These tests require validation in large series and comparison with traditional classification systems in the context of comprehensive clinical trials.

CLINICAL GENE EXPRESSION BASED ASSAYS

Although up to 70% of patients with early breast cancer currently receive adjuvant chemotherapy, only a specific subgroup of these patients derive benefit from this treatment. Therefore, in parallel with the advances in the

molecular sub classification of breast cancer, several multigene predictors of outcome have been developed (Table 2). It was conceived that microarray based gene signatures were able to identify a subgroup of patients sufficiently with a good prognosis that would not be treated with adjuvant chemotherapy. Currently, many classifiers have been generated by using various technologies such as cDNA and oligonucleotide arrays and multiplex polymerase chain reaction (PCR) analysis. These genomic tests assess expression of different but sometimes overlapping sets of genes. Despite differences in candidate genes in each of the assays, most of them can quite reliably predict the biology of tested tumors. In fact, when some of these tests were compared with each other, they were found to be quite similar in their abilities to predict metastases-free and overall survivals. Five different prognostic signatures were shown to have a high correlation, even among tests utilizing expression of very few genes in common. One important finding from analyses of various genomic tests is the fact that they assign almost all patients with hormone receptor negative disease as high risk. Therefore, most of these tests are more applicable to patients with ER-positive cancers who constitute a more heterogeneous group for prognosis and probability of response to chemotherapy. Given this distinction, the utility of these tests in practice will still depend on clinical and histological assessments to identify specific patients who would then be appropriate for additional testing with gene expression signatures.

PAM 50

PAM 50 is a 50 gene expression assay based on microarray and quantitative real time (qRT)-PCR that was developed by analyzing 189 breast tumor samples to separate them into four molecular breast cancer subtypes (*luminal-A*, *luminal-B*, *HER2-positive* and *basal-like*)^[57].

PAM 50 assay can provide a risk of relapse score that predicts relapse-free survival for node-negative breast cancer patients who had not received adjuvant systemic therapy. The validation study revealed that patients with *luminal-A* subtype had better prognosis in contrast to the other types and were less responsive to chemotherapy^[58].

The most well described, albeit investigational, classifier for the intrinsic subtypes that can be performed on the fixed tissue available in most pathology laboratories is the PAM 50 assay; however, this assay requires further validation for routine clinical practice^[59].

MammaPrint

MammaPrint is a microarray based gene expression profiling assay that was developed after analyzing data from 78 patients with ER-positive, node-negative breast cancer patients who had not received adjuvant systemic therapy. Of the 78 patients, 34 developed distant metastasis and 44 were disease free at the 5th year. The tumors' mRNA was extracted for reverse transcription into cDNA, which was tested on microarray containing 25000 human genes. Seventy genes that had the strongest association with

Table 2 First generation gene expression signatures

Gene signature	MammaPrint	OncotypeDX	MapQuantDX	Breast cancer index	PAM 50 assay
Starting material	FF or stabilized RNA, FFPE	FFPE	FFPE, FF	FFPE	FFPE
Analytical platform	Microarray, RT-PCR	qRT-PCR	Microarray, qRT-PCR	qRT-PCR	nCounter
Number of genes	70	21	97/9	7	50
Indications	Stage I / II, 5 cm, ER (+), Node (-)/[1-3 Node (+)]	ER(+), Node (-)	ER (+), G2	ER (+)	All, Node (-) untreated
Application	Clinical outcome	Clinical outcome, benefit from chemotherapy	Molecular grading prediction of response to TMX	Clinical outcome, prediction of response to TMX	Subtype definition, risk of relapse without treatment
FDA approved	Yes	No	No	No	No
ASCO and NCCN recommendation	No	Yes	No	No	No

FF: Fresh frozen; FFPE: Formalin fixed paraffin embedded; G: Grade; TMX: Tamoxifen.

outcome *i.e.*, predicted good and poor risk disease were accurately selected^[60]. The genes that comprise the MammaPrint assay are proliferation genes and genes associated with invasion and angiogenesis. This test is based on microarray results and hence requires high quality RNA from freshly collected tissues^[61]. The expression of the selected genes defines a prognostic classification of patients as having a good or poor prognosis. This test was approved by Food and Drug Administration (FDA) for lymph node-negative breast cancer patients younger than 61 years of age with tumors smaller than 5 cm in size.

The microarray-prognostics-in-breast-cancer (RASTER) study is the first study designed to prospectively evaluate the performance of the 70-gene signature. 427 patients with cT1-3N0M0 breast cancer were treated based on the Dutch CBO 2004 guidelines, the 70-gene signature and doctors' and patients' preferences. Five year distant recurrence-free interval probabilities were compared between subgroups based on the 70-gene signature and Adjuvant! Online. Fifteen percent (33/219) of the 70-gene signature low risk patients and 81% (169/208) of the 70-gene signature high risk patients received adjuvant chemotherapy. The 5 year distant recurrence-free interval probabilities for 70-gene signature low risk ($n = 219$) and high risk ($n = 208$) patients were 97.0% and 91.7%. The 5 year distant recurrence-free interval probabilities for adjuvant online low risk ($n = 132$) and high risk ($n = 295$) patients were 96.7% and 93.4% respectively. For 70-gene signature low risk adjuvant online high risk patients ($n = 124$), of whom 76% ($n = 94$) had not received adjuvant chemotherapy, 5 year DRFI was 98.4%. In this prospective community-based observational study, the 5 year distant recurrence-free interval probabilities confirmed the additional prognostic value of the 70-gene signature to clinicopathological risk estimations^[62].

MammaPrint has not yet been sufficiently evaluated as a predictive tool. MINDACT (microarray in node negative and 1 to 3 lymph node-positive disease may avoid chemotherapy) is a large prospective randomized trial designed to document when chemotherapy can be omitted if genomic information and conventional clinical risk

assignment system are discordant^[63].

Oncotype DX

Oncotype Dx is the most widely used prognostic and predictive clinical 21 gene qRT-PCR based assay for women with hormone receptor positive, node-negative breast cancer^[64]. The test is based on qRT-PCR technology that utilizes short and homogeneous amplicons. This method accurately measures gene expression even in the presence of mRNA fragmentation that occurs in archived formalin fixed paraffin embedded tissues. The test is based on 21 selected genes essentially related to proliferation, ER and HER2 signaling and was developed and validated through a retrospective analysis of formalin fixed paraffin embedded materials from three independent clinical trials^[65,66]. The gene expression pattern was translated into a quantitative recurrence score used as a continuous variable to estimate the probability of recurrence. Recurrence score divided patients into 3 groups as low, intermediate and high risk categories. The 21 gene signature has been subsequently evaluated in other cohorts of breast cancer patients and was shown to be an independent prognostic parameter in patients with ER-positive tumors with up to 3 positive nodes receiving adjuvant chemotherapy and in postmenopausal patients with ER-positive tumors treated with anastrozole^[67].

Multiple retrospective validation studies in various clinical settings established the prognostic and predictive accuracy of Oncotype Dx assay. Examination of the genes of the 21 gene profile by intrinsic subtype suggests that virtually all *luminal-B* tumors would have high recurrence scores, whereas 29% of *luminal-A* tumors would have high recurrence scores due to relative endocrine resistance^[68]. A high recurrence score is able to predict poorer outcome among hormone receptor positive tumors despite endocrine therapy and also predicts sensitivity to a variety of adjuvant cytotoxic regimens^[69]. For this reason, the recurrence score is thought to predict general chemosensitivity in hormone receptor positive breast cancer and is a reasonable assay for decision making on chemotherapy, particularly in the node-negative popula-

tion.

Oncotype DX is suggested by the American Society of Clinical Oncology and the National Comprehensive Cancer Network for the decision of adjuvant chemotherapy in ER-positive, node-negative breast cancer patients^[70,71]. Tailor X is a large prospective randomized trial set to validate OncotypeDX in clinical practice by better defining the intermediate risk stratum^[72].

GENOMIC GRADE INDEX

MapquantDx is a predictor test that defines the tumoral histological grade by gene expression features, used to assign a grade index to ER-positive breast cancers in attempt to refine their molecular classification. It was derived by identifying 97 genes from grade 1 and 3 breast tumors. The test was able to classify grade 2 tumors into low and high genomic grades with a statistically significant difference in relapse free survival^[73,74]. Most of the genes in this signature are involved in cell cycle regulation and proliferation. Genomic grade index (GGI) was strongly associated with recurrence risk among patients with grade 2 tumors. This assay is microarray based and requires freshly prepared tissues.

BREAST CANCER INDEX

The breast cancer index (BCI) prognostic assay provides an assessment of the likelihood of distant recurrences in patients diagnosed with ER-positive, node-negative breast cancer. This assay has been developed from the combination of two indices: the ratio of HOXB13/IL17BR genes, which predicts distant recurrence in ER-positive patients treated with tamoxifen, and a proliferation related five gene molecular grade index, which discriminates grade 1 from grade 3 disease. The test is based on qRT-PCR using RNA from paraffin embedded tissues^[75,76].

The biological roles of the genes included in most of these tests are not completely understood and it is often unclear which clinical or tumor characteristics are being measured. Although proliferation related genes are essential components of most classifiers, there is little overlap and instabilities exist among different gene series.

These prognostic profiles have been far better examined in the node-negative population as estimating the risk according to signature may be more difficult in node-positives. The expression patterns of hormone receptors and Ki67 may especially show differences in the tumor cells at the lymph nodes and the primary lesion, probably due to tumor cell heterogeneity in parallel to increased tumor burden^[77].

Although research results indicate that these multi-gene molecular assays can reclassify some breast cancer patients who are ranked as high risk using the traditional classification systems into low risk (*i.e.*, reducing the number of patients who might unnecessarily undergo chemotherapy) and vice versa, available data are insufficient to challenge classical classification systems and to

justify withholding chemotherapy for high risk patients if classified as low risk using multigene assays. However, it should be realized that these assays can potentially provide important prognostic information in clinically indeterminate subgroups and, in such situations, combining these tests with conventional predictors may yield valuable information. For instance, high grade but small (10 mm) sized, node-negative breast cancer may be offered systemic therapy if it is classified as high risk using multigene assays as staging information in such cases may be insufficient to reflect the behavior of these early detected tumors.

NEXT GENERATION SEQUENCING

Gene expression profiling and microarray analysis led to new molecular classification systems in breast cancer. In recent years, research has moved from gene expression profiling to a more detailed overview through the biological mechanism of carcinogenesis and tumor progression by mutational profiling. Technological advances such as array comparative genomic hybridization (array-CGH), single nucleotide polymorphism (SNP) and high throughput screening (HTS) are applied to further *in vitro* and *in vivo* research in order to improve knowledge on breast cancer biology and understand the complex process of metastasis^[78].

Next generation sequencing is based on deep sequencing which produces billions of short sequences at a time. It is quantitative and can analyze the entire genome at base pair resolution without the limitations of microarrays^[79].

Sanger sequencing was the first approach for sequencing the genome but it was both expensive and time consuming. Next generation sequencing (NGS), known as massive parallel sequencing, can be applied to study the whole genome (exons, introns and intergenic regions for about 22000 genes) more specifically to whole exome or to the 200-400 potentially targetable exons. High sensitivity of this technique allows the evaluation of single nucleotide variants, small insertions, deletions, copy number alternations (gain and losses) and structural variations (translocations, inversions). NGS can also be applied to the RNA for expression level analysis and to alternative splicing, RNA editing and fusion transcripts. NGS can be applied to the tumor to identify somatic mutations compared to normal tissues or to the peripheral blood samples to investigate germ line alterations. The study of germ line aberrations may give more information about germ line actionable mutations, toxicity susceptibility, drug metabolism and familial disease susceptibility^[80].

Application of NGS has led to the extension of knowledge to produce a comprehensive catalogue of likely genomic drivers of the most common breast cancer subtypes. The Cancer Genome Atlas Network analyzed more than 800 primary breast cancers using all the cutting edge technologies. They demonstrated four main breast

cancer classes, each of which shows significant molecular heterogeneity. They showed that somatic mutations in only three genes (TP 53, PIK3A and GATA 3) occurred at 10% incidence across all breast cancers. There were numerous subtype associated novel gene mutations, including the enrichment of specific mutations in GATA3, PIK3CA and MAP3K1 with the *luminal-A* subtype^[81].

Although NGS creates a massive amount of information, each mutation/alteration is not a good candidate to become a target for specific therapeutics. Molecular Taxonomy of Breast Cancer International Consortium (METABRICK) study revealed ten different subtypes, each characterized by common genetic alterations such as PPR2A, MAP2K4 and MTAP deletions that are potentially targetable and linked to survival^[82]. Alterations in the gene expression landscape can also be useful to guide treatments with conventional and experimental therapeutics.

Recently, the prospective multicenter molecular screening trial SAFIR 01 (High Throughput Technologies to Drive Breast Cancer Patients to Specific Phase I / II Trials of Targeted Agents) analyzed 423 patients with metastatic breast cancer. Metastatic sites were biopsied and profiled using the copy number changes array and Sanger sequencing PIK3CA (exon 10/21) and AKT1 (exon 3). A targetable genomic alteration was identified in 204 patients. The most frequent genomic alterations were PIK3CA mutations, CCND1, FGF4 and FGFR1 amplifications. In this study, 46 out of 277 (17%) patients with genomic analyses received a targeted therapy matched to the genomic alteration, covering twelve different targets^[83].

The clinical applications of NGS have many difficulties. Searching for every single gene alteration or pathway abnormality is uncertain. There are biological issues due to tumor heterogeneity, clonal evolution and the difficulty of discriminating between driver and passenger mutations. There are also some technical problems in terms of tumor tissue availability, stromal interference and laboratory reproducibility of the results.

CONCLUSION

One of the main contributions of the breakthrough in cancer research is the integration of molecular studies into clinical trials. Advances in molecular biology of breast cancer over the past decade have led to the classification of the disease from a molecular point of view. Incorporation of multigene molecular classifiers to conventional breast cancer classification systems seems more realistic and practical to support more effective tailoring of therapy. These multigene classifiers can complement traditional methods through provision of additional biological prognostic and predictive information by identifying important, clinically relevant, biological processes better than that determined using morphological factors or individual molecular markers.

New molecular techniques hold promise for improv-

ing diagnosis and sub typing, better assessment of recurrence risk, careful selection of therapy and identification of targets involved in carcinogenesis and function of tumor cells, leading to the discovery of selective drugs. Understanding the pathways regulating the processes involved in neoplastic development helps in the design of clinical trials aimed at patients with specific characteristics that are candidates to benefit from specific treatments. Protein gene products that have direct roles in driving the biology and clinical behavior of cancer cells are potential targets for the development of novel therapeutics. Research efforts have focused on the investigation and identification of new molecular factors, which can improve the predictability of risk of metastasis and the likelihood of response to therapies.

Probably in the near future, the tumoral key mechanisms of regulation will be identified individually and treatments will be more specific and effective, with minimal toxicity. Numerous agents targeting various biological pathways are currently under clinical development to achieve an ideal, personalized medical therapeutic approach in breast cancer.

Key words: Breast cancer; Radiotherapy; Intensity modulated radiotherapy; Partial breast irradiation; Hypofractionation

Core tip: Several randomized trials provided evidence for the feasibility of modern radiotherapy techniques in the management of breast cancer. Current review will provide an up-to-date evidence based data on the role of modern radiotherapy techniques in the management of breast cancer.

Abstract

Breast cancer is the most common type of malignancy in females. Advances in systemic therapies and radiotherapy (RT) provided long survival rates in breast cancer patients. RT has a major role in the management of breast cancer. During the past 15 years several developments took place in the field of imaging and irradiation techniques, intensity modulated RT, hypofractionation and partial-breast irradiation. Currently, improvements in the RT technology allow us a subsequent decrease in the treatment-related complications such as fibrosis and long-term cardiac toxicity while improving the loco-regional control rates and cosmetic results. Thus, it is crucial that modern radiotherapy techniques should be carried out with maximum care and efficiency. Several randomized trials provided evidence for the feasibility of modern radiotherapy techniques in the management of breast cancer. However, the role of modern radiotherapy techniques in the management of breast cancer will continue to be defined by the mature results of randomized trials. Current review will provide an up-to-date evidence based data on the role of modern radiotherapy techniques in the management of breast cancer.

INTRODUCTION

Radiotherapy (RT) has a major role in the management of breast cancer for many years. It significantly reduces the risk of loco-regional recurrences after surgery by at least 70%^[1]. RT has been shown to improve overall survival both for early stage breast cancer after breast-conserving surgery (BCS) and locally advanced disease after mastectomy^[1]. However, its use is usually limited by late toxicity. In patients with a long life expectancy, only modern RT techniques could obtain survival benefit that is mostly dependent on the radiation dose to the cardiac structures^[1-4].

During the past 15 years, several developments took place such as imaging and irradiation techniques, hypofractionation and partial-breast irradiation (PBI). Improvements in the RT technology now frequently allow us a subsequent decrease in treatment-related complica-

tions such as fibrosis and long-term cardiac toxicity while improving the loco-regional control rates and cosmetic results^[5-7]. Computed tomography (CT) simulators, modern-day linear accelerators, three-dimensional (3D) planning techniques and treatment verification modalities provides improved targeting and smaller irradiated volumes of normal tissue.

Depending on the type of surgery and pathology reports, traditionally, conventional two-dimensional (2D) beams were used for whole-breast or chest wall irradiation^[8]. The first important challenging step in the RT technique came with the introduction of the CT-based treatment planning and 3D conformal RT (3DCRT) that provides us precise target volume definition, dose distribution calculation, and virtual simulation. Optimal shielding of organs at risk (OARs), including the heart, lungs, brachial plexus, esophagus, trachea, thyroid, and spinal cord decreased normal tissue exposure. Additionally, more homogeneous dose distribution in the clinical target volume could be obtained.

INTENSITY MODULATED RADIOTHERAPY

Intensity modulated RT (IMRT) is an advanced form of 3DCRT that became increasingly available for breast cancer. Several important studies has been carried out on the use of IMRT for breast cancer patients requiring

complex breast treatments^[9]. Patients with larger breasts are more likely to have dose inhomogeneities and most likely to benefit from IMRT. It can also be the best alternative for left-sided breast cancers to decrease cardiac dose, re-irradiation, contralateral breast irradiation, PBI, and deeply seated tumor bed irradiation.

The modulation of beam intensities could be determined by allowing sculpting the dose to fit a patient's anatomy. The major goal for IMRT technique is providing more homogenous dose distribution throughout the breast and concave structures such as the chest wall^[10,11]. This technology also allows better conformity of dose to the target and better sparing of OARs compared to non-IMRT plans^[7,10,12-17]. However it has some drawbacks, including decrease in surface build up dose which could adversely affect local control and increase risk for secondary malignancies^[18-20].

For each individual case, adequate coverage of the primary tumor site and most of the breast can be achieved by changing the gantry angle, the collimator angle, or shaping [with small cardiac blocks or multileaf collimator (MLC) leaves] the borders of the medial and/or lateral tangential fields while the heart and lung can be excluded from the high dose region at the same time. The normal tissue anatomy, the location of the primary tumor bed, and the contour of the breast should be taken into consideration when applying treatment field modifications for each individual patient. Forward planning by using the "field-in-field" technique provides excellent dose homogeneity in the irradiated areas. Thus, it is the most widely used technique in breast IMRT^[10,21] (Figure 1). There are also other methods, including forward-planned step-and-shoot breast IMRT, and an inversely planned breast IMRT technique, which can all improve dose homogeneity (Figure 2).

IMRT planning should be performed based on 3D visualization of contours delineated on planning CT images. Proper patient positioning, immobilization, target localization, and management of breathing-related motion are essential for IMRT due to sharp dose gradient changes^[22]. Also, sophisticated technical resources and longer period of time are required both for planning and quality assurance tests. In addition, radiation delivery turns out to be more complex. It requires specialized software to automate the process to reduce treatment time and the risk of delivery error. As a result of longer beam-on time, whole body and contralateral breast doses may increase.

Image-guided RT (IGRT) is required to precise localization of both target and normal tissues during planning and treatment procedure. The main advantage of IGRT is that it allows more accurate targeting in breast cancer by providing correct target volume delineation, obtaining simulation images, and set-up correction using images with the patient in the treatment position immediately prior to or during the treatment. A variety of imaging methods are used: (1) gantry-mounted systems [MV-electronic portal imaging device (EPID), kV/MV cone

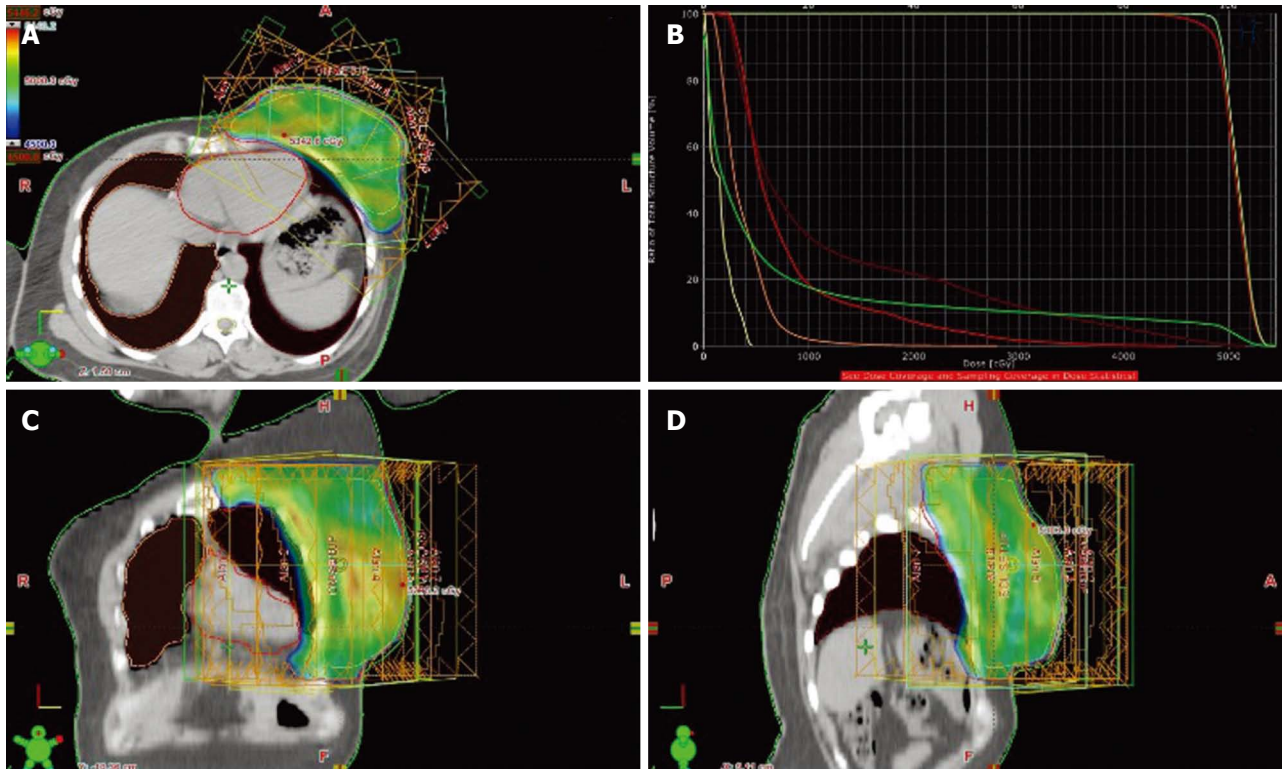

Figure 2 Treatment fields and dose distribution of inverse-planned intensity modulated radiotherapy: Axial section (A), dose-volume histogram (B), coronal section (C) and sagittal section (D).

beam CT, MV systems-tomotherapy]; (2) room-mounted systems; and (3) non-ionizing systems (ultrasound, video-based systems)^[23]. Besides, breath-holding techniques (using “active breathing control” devices or unassisted) and respiratory gating can effectively limit motion and decrease the dose to the heart and lungs, especially in cases in which the tumor bed is very close to the heart^[24-26].

There are several IMRT techniques; dynamic or static MLC based IMRT, arc therapy, tomotherapy, and topotherapy^[27,28]. Radiation is delivered to the patient as gantry rotates continuously around the patient in intensity modulated arc therapy. In tomotherapy, there is a helical radiation delivery that continues during treatment couch movement and binary MLC motion creates fluency. Topotherapy is performed with static gantry while as the patient translates through the treatment field instead of rotational delivery^[28].

TREATMENT OUTCOMES AND TOXICITY AFTER IMRT

IMRT has changed our RT practice and it is used for palliative and curative indications throughout several tumor types. The highest level of evidence by using IMRT exists particularly for breast and nasopharyngeal carcinomas^[29]. Although the clinical outcome of IMRT in breast cancers came mainly from retrospective studies, it has been assessed in three prospective randomized studies^[30-33] (Table 1). The primary aim of these studies was to investigate treatment-induced toxicity and patients’ quality of life

(QOL). They showed that IMRT increased the dose homogeneity and decreased the frequency and severity of toxicity in early-stage breast cancer after BCS. However, larger sample size and longer follow-up is required to see long-term clinical outcomes and evaluate for late deleterious effects.

There is only one randomized study of treatment efficacy comparing IMRT and non-IMRT^[33]. Mukesh *et al*^[33] reported 5-year results of 815 patients randomized to either standard wedged-based tangential fields or forward-planned IMRT. In this study, there was no statistically significant difference in 5-year loco-regional recurrence (2.56% and 1.35%) or overall survival (92.5% and 91.7%) rates. Additionally, there has been two reported trial designed to investigate breast cancer-related outcomes, the retrospective cohort study ($n = 240$) by McDonald *et al*^[34] and the prospective cohort study ($n = 332$) by Morganti *et al*^[35]. Findings did not show a statistically significant differences between IMRT and non-IMRT techniques for breast cancer related outcomes like survival, disease-specific survival and freedom from contralateral breast cancer recurrence.

Conventional RT causes acute skin toxicity, specifically moist desquamation in 30%-50% of patients^[36,37]. An inhomogeneous dose distribution and consequential hot spots of whole breast irradiation increases the rate of acute and late skin toxicity including erythema, edema, desquamation, pain, telangiectasia and fibrosis, and effects negatively cosmetic results and patient’s QOL^[32,38,39]. Large breast size and dose inhomogeneities > 10% as-

sociated with a poorer clinical outcomes^[40-42]. IMRT significantly improved dose homogeneity with a median of 0.1% of the treatment volume receiving ≥ 110% of the prescribed dose *vs* 10% with conventional wedge-based breast RT^[10,11]. Therefore, IMRT has been established as an effective treatment for adjuvant RT after BCS with a decrease in moderate or severe skin reaction of up to 44% and better cosmetic results as compared with the standard wedged tangential field techniques^[30-32,34,42,43].

There are eight studies reported on acute radiation toxicity of IMRT^[30,34,35,42-44]. Vicini *et al*^[10] reported a prospective trial of breast IMRT and demonstrated a reduction in acute skin reactions. Similarly, Freedman *et al*^[43] reported the results of a matched-pair analysis of 131 patients treated using either breast IMRT (*n* = 73) or standard wedge-based RT (*N* = 58). This study found a significant reduction in the rate of acute desquamation using IMRT compared with the wedge-based treatment. Harsolia *et al*^[42] reported toxicity results of 172 patients at a median follow-up of 4.7 years, and demonstrated that the use of IMRT resulted in significantly less acute ≥

Grade 2 toxicity for dermatitis (41% *vs* 85%, *P* < 0.001), breast edema (1% *vs* 28%, *P* < 0.001), and hyperpigmentation (5% *vs* 50%, *P* < 0.001), compared with patients treated with conventional wedge-based plans (2D RT)^[42]. In patients with larger breasts (≥ 1600 cm³, *n* = 64), use of IMRT was associated with a statistically significant decrease in ≥ Grade 2 acute breast edema (0% *vs* 36%, *P* < 0.001), and hyperpigmentation (3% *vs* 41%, *P* = 0.001), and chronic long-term edema (3% *vs* 30%, *P* = 0.007) compared with conventional wedge-based plans. McDonald *et al*^[34] reported cohort analysis on long-term outcomes of IMRT (*n* = 121) with conventional RT (3D RT) (*n* = 124)^[34]. Median dose to the whole breast was 50 Gy, and median total dose to the tumor cavity was 60 Gy for both IMRT and conventional RT patient groups. IMRT resulted in reduced Grade 2 or 3 dermatitis compared with conventional RT (39% *vs* 52%, *P* = 0.047) at median 6.3 years of follow-up. Pignol *et al*^[30] reported the first multicenter randomized trial demonstrating a successful reduction an acute radiation skin toxicity using IMRT^[30]. Three hundred and fifty-eight patients

were randomized to forward-planned IMRT or standard conventional wedge technique after complete excision of an early-stage breast cancer. IMRT significantly reduced the occurrence of moist desquamation anywhere in the breast and in the inframammary fold, with an absolute reduction of 16.6% ($P = 0.002$) and 17% ($P = 0.001$), respectively. Smaller breast size ($P < 0.001$) and use of IMRT ($P = 0.003$) strongly associated with a decreased risk of moist desquamation. Despite no statistically significant difference in the QOL or pain between the two treatment arms, there was a highly significant correlation between the development of moist desquamation and grade 2 to 3 pain score ($P < 0.0001$), a decrease in the global health status scale ($P = 0.0019$), and an increase in the breast symptoms scale ($P = 0.0028$). The retrospective cohort study reported by Morganti *et al.*^[35] found that all skin-related acute toxicity reduced when standard 3D wedges were compared to simplified step and shoot IMRT technique ($P < 0.05$), despite with a lower total dose in the IMRT group^[35]. Only the retrospective cohort study by Freedman *et al.*^[44] reported on the proportion of treatment time with acute dermatitis, finding a significant benefit for IMRT compared with conventional wedged-based plans (18% *vs* 71%, $P < 0.0001$)^[44]. In that trial, 405 patients treated with conventional RT and 399 patients treated with IMRT. A subgroup analysis demonstrated that the time spent with radiation induced Grade 2-3 dermatitis was decreased in IMRT for all patients regardless of breast size (all $P < 0.05$). Barnett *et al.*^[31] reported the randomized trial demonstrating no significant differences were found in the incidence of any acute toxicity and development of any photographically assessed breast shrinkage between the IMRT or standard RT groups [odds ratio (OR), 1.51; 95% confidence interval (CI): 0.83-1.58; $P = 0.41$]^[31].

The decrease in acute toxicity achieved with IMRT translates into a decrease in late toxicity. There are two randomized trials showing a beneficial effect of forward-planned IMRT on late toxicity^[31-33]. The first prospective randomized clinical trial testing the role of forward-planned IMRT in terms of 5 year outcome for adverse effects was reported by Donovan *et al.*^[32]. They randomized 306 patients after BCS to standard 2D wedge-based RT or to IMRT (either IMRT with “step-and-shoot” fields or a physical 3D compensator). All were treated with a dose of 50 Gy in 25 fractions followed by a 10-Gy boost with electrons. Forward-planned IMRT significantly decreased dose inhomogeneity ($\geq 105\%$ of the prescribed dose) comparing standard 2D wedge-based plans (19% *vs* 92%). Results of treatment were evaluated using photographic assessment performed before RT and at 1, 2, and 5 years follow-up. The standard arm patients were 1.7 times more likely to have a change in breast appearance than the IMRT arm patients after adjustment for the year of photographic assessment (95%CI: 1.2-2.5, $P = 0.008$). However, there were no significant differences in outcome between randomized groups in any of the self-assessed parameters, including breast pain, discomfort,

hardness, body image, or QOL as measured by EORTC QLQ C30 and BR23 modules. The highest levels of dose inhomogeneity in the 2D RT were seen in the upper and lower third of the breast. This suggested that dose inhomogeneity in the breast increases late adverse events. The second one designed to investigate the effect of forward-planned IMRT on the incidence of late radiation toxicity reported by Barnett *et al.*^[31] from Cambridge. In their study, 815 patients with early stage breast cancer were randomized to either standard wedged-based tangential fields or forward-planned IMRT. Patients were randomized if $\geq 2 \text{ cm}^3$ receiving $> 107\%$ of prescribed dose. In this study, breast dosimetry was significantly improved with the forward-planned IMRT. All patients were treated to a dose of 40 Gy in 15 fractions. The patients in the standard RT group were more likely to develop telangiectasia than those in the IMRT group at early follow-up of only 2 years after RT completion (OR, 1.68; 95%CI: 1.13-2.40; $P = 0.009$). In patients who had good baseline surgical cosmesis, those randomized to IMRT were less likely to deteriorate to a moderate or poor overall cosmesis than those in the standard RT group (OR, 0.63; 95% CI: 0.39-1.03, $P = 0.061$). Recently, Mukesh *et al.*^[33] reported 5-year results of this study^[33]. On univariate analysis, patients receiving IMRT had superior overall cosmesis (OR, 0.68; 95%CI: 0.48 to 0.96; $P = 0.027$) and reduced skin telangiectasia (OR, 0.58; 95%CI: 0.36 to 0.92; $P = 0.021$) as compared with patients receiving standard RT arm. However, no significant difference was observed in the development of photographically assessed breast shrinkage or clinically assessed breast edema, tumor bed induration, or pigmentation. On multivariate analysis, use of IMRT was significantly associated with improved overall cosmesis (OR, 0.65; 95%CI: 0.44 to 0.98; $P = 0.038$) and decreased risk of skin telangiectasia (OR, 0.57; 95%CI: 0.34 to 0.95; $P = 0.031$). Large breast volume, poorer baseline surgical cosmesis, and tumor bed boost were also associated with suboptimal overall cosmesis on multivariate analysis. Patients with moderate to poor baseline surgical cosmesis more frequently developed suboptimal final cosmesis, tumor bed induration, and photographically assessed breast shrinkage at 5 years in the study.

Late toxicity results have been reported in only two retrospective cohort studies and one prospective study^[34,42,45]. The study by Harsolia *et al.*^[42] ($n = 172$) showed a significant difference between IMRT and conventional wedged-based plans in favor of IMRT for \geq Grade 2 breast edema (1% *vs* 25%, $P < 0.001$), with no differences in hyperpigmentation, fat necrosis, induration/fibrosis or overall cosmetic score^[42]. The study by McDonald *et al.*^[34] ($n = 240$) found a trend towards a reduction in lymphedema rates (0% *vs* 4%, $P = 0.06$), with no differences in the reported occurrence of radiation pneumonitis, fat necrosis or second malignancies^[34]. Freedman *et al.*^[45] reported the 5-year results of a phase II study of IMRT. Seventy-five patients were treated with simultaneous integrated boost (SIB)-IMRT; the whole

breast received 2.25 Gy per fraction for a total of 45 Gy and the tumor bed received 2.8 Gy per fraction for a total of 56 Gy in 20 treatments over four weeks. After a median follow-up of 69 mo, the 5-year rate of local recurrence was 2.7%. There were no significant differences over time in patient-reported cosmesis, pain and arm function and physician-reported cosmesis through the 5-year period of the study.

ACCELERATED PARTIAL BREAST IRRADIATION

Multiple prospective randomized trials have demonstrated that BCS followed by whole breast RT (WBRT) as a standard treatment approach in early stage breast cancer^[46-51]. A large meta-analysis showed that a reduction in ipsilateral breast tumor recurrence (IBTR) translated into a survival benefit of 5.4% after 15 years in early stage breast cancer patients treated with BCS^[1]. This treatment allows preservation of the breast with equivalent survival to mastectomy. In WBRT, entire breast is treated with a standard fractionation, which consists of 45-50 Gy, daily Monday to Friday over a 5- to 6-wk period. Despite being well tolerated and good cosmetic results, some patients does not receive WBRT due to long treatment duration, limited geographical access, and cost of the treatment^[52]. To address some of these issues accelerated partial breast irradiation (APBI) has gained popularity in selected patients. However, more data are needed about the use of different methods of APBI defining the optimal patient selection criteria, technique, dose and fractionation, side effects, and long-term outcomes.

APBI is a reasonable alternative to WBRT in patients with BCS who have more favorable tumor characteristics. Published studies indicated that 70%-90% of IBTRs after breast conservation therapy occurred at or in close proximity to the lumpectomy cavity^[49,50,53]. Multiple phase II and several phase III trials confirmed that APBI may offer equivalent local control to WBRT with shortening conventional treatment duration from 5 to 6 wk to a single fraction or few days (1-3 wk). In APBI, only the lumpectomy cavity treated with a limited margin for potential microscopic spread. Potential advantages of APBI include shorter treatment interval, improved cosmesis due to the decreased volume of breast tissue treated, decreased heart and lung volume, and reduced cost compared with standard fractionation^[54]. Additionally, decreased volume allows acceleration and hypofractionation which might be has some theoretical radiobiological advantages.

A consensus group by American Society for Radiation Oncology (ASTRO) and the European GEC-ESTRO Cancer Working Group developed guidelines for patient selection to APBI on the basis of a variety of clinical and pathologic factors (Table 2)^[55,56]. These guidelines categorized patients into three groups: Low-risk or suitable, intermediate-risk or cautionary group, and high risk or un-

suitable group. ASTRO defined suitable group which was include patients age ≥ 60 years, without BRCA mutation, T1 (≤ 2), > 2 mm surgical margins, no lymphovascular space invasion, ER positive, unicentric, invasive ductal or other favorable histology, no extensive intraductal component, and lymph node negative optimally as part of a clinical trial. Application of APBI to intermediate or cautionary group is considered acceptable only in the context of prospective clinical trials^[57]. It is compatible with GEC-ESTRO recommendations except that tumor size (T1-2; ≤ 3 cm) and age (≥ 50 years).

Modalities for APBI include brachytherapy; interstitial brachytherapy (multi-catheter interstitial implant), intracavitary brachytherapy [one balloon catheter (MammoSite®), multiple balloon catheter (Contura®), hybrid BRT (SAVI®)], intraoperative RT (IORT); intraoperative electrons (Liac®, Mobetron®, or Novac-7®; 3-10 MeV) or low energy X-rays (Intrabeam®; 50 kV), external beam RT; 3DCRT and IMRT.

Multicatheter interstitial brachytherapy

The most mature follow-up and experience of all APBI technique is multicatheter interstitial brachytherapy (MIB) which is commonly used as a boost treatment^[55-58]. It is an invasive approach that multiple interstitial catheters (up to 20) are placed surrounding the tumor bed at the time of surgery or postoperatively under ultrasound guidance. The number of the catheters may vary according to the size and the shape of the target volume. After catheter placement, tumor bed plus a 1-2 cm margin is treated with LDR, HDR or PDR devices. Radioactive sources are inserted temporarily into the catheter during treatment and then removed. Most commonly used regimen is 34 Gy in 10 fractions (twice daily) over 5 d. This modality only performed at a few institutions because of the specialized training required, costly equipment, and more complex technical support needed for the procedure. It is well tolerated but dose heterogeneity within the target volume can potentially lead to fat necrosis and subcutaneous toxicity^[59]. Acute complications include pain and infection. Often oral antibiotic treatment is required and rarely requires removal of the catheters.

Intracavitary brachytherapy: Intracavitary brachytherapy is the most common form of brachytherapy for APBI because of the less invasive, simple, and requires less experience. It can be applied with a single-lumen (MammoSite®) or multilumen (Contura®) balloon catheter, and elliptically shaped cluster of catheters such as SAVI®^[60]. It can be inserted into the lumpectomy cavity either at the time of surgery or postoperatively using ultrasound guidance^[61]. The balloon is then filled with saline, and an HDR radioactive source (commonly ¹⁹²Ir) is inserted. After the balloon is inflated, it should be symmetric and conform to the cavity. Dose is usually prescribed to 1 cm from the balloon surface. The minimum distance between the balloon and the skin/chest wall should be ≥ 5 mm, with a shorter distance leading to a poorer cosmesis.

Table 2 American Society for Radiation Oncology and GEC-ESTRO recommendations on patient selection criteria for Accelerated Partial Breast Irradiation

Factor	ASTRO Suitable	GEC-ESTRO Low-risk	ASTRO Cautionary	GEC-ESTRO Intermediate-risk	ASTRO Unsuitable	GEC-ESTRO High-risk

Therefore, this technique may not be suitable for small breast size. The most commonly used regimen is 3.4 Gy per fraction, given twice daily, total of 34 Gy over 5 consecutive days^[58]. Potential advantage of this technique is that final pathology is known. Multi-lumen balloon catheters are more suitable for irregularly shaped lumpectomy cavities^[62]. The morbidity rates were significantly higher in patients treated with intracavitary brachytherapy with reported infection rates of 9.5% and seroma formation of 26.8% than IORT which were 1.3% and 12.9%, respectively^[63,64]. Fat necrosis was observed less compared to interstitial brachytherapy^[65,66].

External beam radiotherapy: The newest of the three major techniques with the most amounts of ongoing randomized studies is APBI with 3DCRT or IMRT. Potential advantages include noninvasiveness, knowledge of final pathology, a more homogenous dose distribution, widespread availability, less user experience, less seroma formation and infection. Additionally irregular cavities can be treated without concern for distance from the skin^[55,67]. The most common regimen is 38.5 Gy in 10 fractions given twice daily over 5 d. Shortcomings are the delivering more radiation to uninvolved quadrants of the breast and critical organs compared to other forms of APBI, short follow-up, uncertainty regarding the optimal dose and fractionation, and patient set-up requirement before each fraction.

Intra-operative radiotherapy: The least prevalent

technique is IORT using electrons (Liac[®], Mobetron[®], or Novac-7[®]; 3-10 MeV) or low energy X-rays (Intrabeam[®]; 50 kV). This technique is most commonly used in Europe and firstly used as a boost treatment. Most commonly applied after quadrantectomy and sentinel lymph node biopsy. A single fraction treatment can be delivered with either electrons (21 Gy in one fraction) or low energy photons (20 Gy in one fraction) immediately after surgery in the operating room^[68]. Direct visualization of the operative bed before treatment delivery reduces the likelihood of missing the target. This modality allows shielding of the skin. The potential disadvantages include increased operating times, the lack of final pathological result before delivering the RT, technical expertise and limited availability of this technique. Long-term radiobiological and cosmetic effects of such a single high fraction dose to the breast are largely unknown; however, an acceptable toxicity is achieved based on a randomized trial and a large, nonrandomized cohort studies^[63,69]. The risk of toxicity was low: 1.3% infections, 12.9% seroma formation, and 4.2% fat necrosis^[63].

Accelerated partial breast irradiation trials: Multiple modern phase II studies regarding APBI have reported promising local control and excellent cosmetic results^[57,70-77]. These studies showed 3%-6% of patients with 5-year local recurrence rates and 56%-99% of patients with good or excellent cosmesis. However, many Phase III studies have not been completed and primary

Table 3 Prospective randomized phase III trials of Accelerated Partial Breast Irradiation

Institution/trial	Number of patients	Inclusion criteria	Control arm	Experimental arm
National Institute of Oncology, Budapest, Hungary ^[80]	258	Wide local excision, > 40 yr, Tm ≤ 20 mm, Invasive ductal carcinoma (non-lobular), Node negative, Margin negative	WBRT (50 Gy in 25 fx)	(1) MIB (36.4 Gy in 7 fx) (2) Electrons (50 Gy in 25 fx)
European Institute of Oncology ELIOT ^[63,82]	1305	Quadrantectomy, ≥ 48 yr, Tm ≤ 2.5 cm, Invasive carcinoma, Node negative	WBRT (50 Gy in 25 fx) ± 10 Gy boost	IORT (21 Gy in 1 fx, electrons up to 9 MeV)
TARGIT-A ^[69,81]	3451	Lumpectomy, ≥ 45 yr, Invasive ductal carcinoma (non-lobular), Node negative	WBRT 40–56 Gy ± 10–16 Gy boost	IORT (20 Gy in 1 fx, low-energy X-rays)

Tm: Tumor; WBRT: Whole breast radiotherapy; fx: Fraction; MIB: Multicatheter interstitial brachytherapy; IORT: Intraoperative radiotherapy; DCIS: Ductal carcinoma *in situ*; 3DCRT: Three dimensional conformal radiotherapy; Gy: Gray.

outcome data of the largest randomized trial of WBRT *vs* APBI with the longest follow-up (NSABP B-39/RTOG 0413) is not yet reported. Regarding the efficacy of APBI in a higher risk population of patients, this trial including patients with > 18 years of age, DCIS, 1–3 positive lymph nodes, and ER negative tumors will provide valuable data on literature. This trial also allows comparison of the efficacies and toxicities of three most common techniques of APBI: MammoSite®, MIB and 3DCRT.

So far, only 5 randomized controlled trials have presented the final results of a completed trial^[69,78–81] (Table 3). The first two published studies from the United Kingdom have important limitations including patient selection criteria and variety of techniques^[78,79]. At 8-year follow-up, local recurrence was increased using APBI. However, surgical margins and axillary nodal status were not evaluated and larger tumors (< 4 cm) were included in the Christie Hospital study^[78]. Similarly, in the Yorkshire Hospital trial, surgical margin status was not assessed^[79]. After the publication of these trials, there has been growing interest and published studies on APBI using more strict patient selection criteria and modern radiation technique. The first of these studies was Hungarian trial compared WBRT with APBI using either HDR MIB or electrons in 258 patients with early stage breast cancer^[80]. At a median follow-up of 66 mo, the 5-year local recurrence rate was 4.7% for APBI and 3.4% for WBRT arm ($P = 0.50$). Excellent to good cosmesis was noted in 77.6% and 62.9%, respectively ($P = 0.009$). There were no significant differences in disease-free or overall survival. Since another study opened with the same patients group covering GEC-ESTRO trial, this study was stopped early. The second completed randomized trial, the TARGIT-A trial ($n = 2232$), compared WBRT with single dose IORT with or without boost after BCS^[69]. With a median follow-up of 2 years, the estimated 4-year local recurrence rate was 1.2% for IORT group and 0.95% for WBRT group ($P = 0.41$). The incidence of major toxicities were 3.9% and 3.3%, respectively ($P = 0.44$). Fourteen percent of patients received WBRT in addition to IORT according to the final pathology report. Five-year results of this trial recently published^[81]. Supplemental WBRT after IORT was applied in 15.2% of patients who received IORT in

the prepathology stratum. The 5-year risk for local recurrence in the conserved breast was 3.3% for IORT *vs* 1.3% for WBRT ($P = 0.042$). Overall, breast cancer mortality was similar between two groups (2.6% *vs* 1.9%, $P = 0.56$) but there were significantly fewer non-breast cancer deaths with IORT (1.4% *vs* 3.5%, $P = 0.0086$). Grade 3–4 skin complications were significantly reduced with IORT ($P = 0.029$). The last randomized trial was reported by Veronesi *et al*^[82] in 2013. They randomized 1305 patients after BCS to WBRT or IORT with electrons (21 Gy). After a median follow-up of 5.8 years, 35 patients in the IORT group and four patients in the WBRT group had had an IBTR ($P < 0.0001$). Five-year overall survival did not differ between the groups (96.8% in the IORT *vs* 96.9% in the WBRT, $P = 0.59$). Skin complications were significantly reduced with IORT ($P = 0.0002$). However, longer follow-up is required before routinely adopting these modern radiation techniques into clinical practice.

With regard to cosmesis, the analysis of all major studies shows conflicting data about the outcomes with APBI. Vicini *et al*^[83] reported the long-term experience of APBI with Mammosite A total of 1440 patients were treated. With a median follow-up of 4.5 years, 5-year local recurrence rate was 3.8% and 91% of patients had a good or excellent cosmetic result. The prospective study by Jaggi *et al*^[84] reported an early closure of an APBI study with IMRT. They showed unacceptable cosmesis in 7 of 34 patients with a median follow-up of 2.5 years. Toxicity of 3DCRT APBI was reported by Hepel *et al*^[85] in accordance with the technique and dose-volume constraints of the NSABP/RTOG 0413 protocol. At 15 mo, grade 2–4 late toxicity was observed in 10% of patients. The preliminary results of the RAPID study was presented at American Society for Radiation Oncology (ASTRO) 2012 and showed that the toxicity with 3DCRT APBI (32%) was more severe than WBRT (19%) at 3 years^[86]. In another prospective study ($n = 50$), 54% of incidence of moderate to severe fibrosis and 35% of fat necrosis was seen with long-term follow-up after the use of interstitial brachytherapy^[65]. The total dose was significantly correlated with the poor cosmetic results. Livi *et al*^[87] detected significant improvements in acute grade 1–2 skin toxicity, favoring APBI with IMRT over convention-

Table 4 Prospective randomized phase III trials of whole breast radiotherapy vs conventional fractionation radiotherapy

Institution/trial	N	Median F/U	Eligibility criteria	Treatment arms	Primary endpoint	Secondary endpoint
Royal Marsden Hospital/ Sutton and Gloucestershire Oncology Centre ^[90,91]	1410	5 yr ¹	Invasive breast cancer, T1-3N0-1M0, < 75 yr, BCS (complete macroscopic resection), Level II / III AD	50 Gy in 25 fx 39 Gy in 13 fx 42.9 Gy in 13 fx	Late changes in breast appearance	Palpable breast induration Ipsilateral tumor recurrence

ally fractionated WBRT. The preliminary results of the NSABP B-39/RTOG 0413 trial also have been reported equivalence of cosmesis to WBRT^[88].

Veronesi *et al.*^[63] reported on 1822 patients treated with IORT (electron, 21 Gy) after quadrantectomy. With a mean follow-up of 36.1 mo, the local recurrence rate and the recurrence rate outside the treatment area were 2.3% and 1.4%, respectively. Recently, ELIOT study was evaluated regarding GEC-ESTRO recommendations and local recurrence rates were reported^[89]. They found that 5-year local recurrence was 1.9% for good candidates, 7.4% for possible candidates, and 7.7% for contraindication groups. It clearly shows for this technique that accurate patient selection is so important. In order to reach a conclusion that APBI is an acceptable alternative to WBRT, further studies with longer follow-up are needed. Until this date; when treating patients with APBI, consensus guidelines should be considered.

HYPOFRACTIONATED WHOLE BREAST RADIOTHERAPY

Hypofractionated RT involves fewer treatments, delivers a higher dose per treatment, and shorter overall treatment time (approximately 5 wk) compared to conventional RT. The role of hypofractionated WBRT after BCS has been clearly defined by four prospective randomized trials (Table 4)^[90-95]. The Royal Marsden Hospital and Sutton and Gloucestershire Oncology Centre trial randomizing patients in the same 5-wk length of treatment between conventional RT (50 Gy in 25 fractions) and hypofractionated WBRT (39 Gy or 42.9 Gy in 13 fractions)^[90,91]. There was a significant reduction in the rate of local recurrence using hypofractionated WBRT (12.1% for 50 Gy, 14.8% for 39 Gy, and 9.6% for 42.9 Gy; $P = 0.027$). However,

there was a statistically significant change in breast appearance with the largest daily fraction size to 42.9 Gy compared with 39 Gy and 50 Gy. START trials (A and B) reported the experience of WBRT and hypofractionation^[92,93]. Trial A compared 50 Gy in 25 fractions, 41.6 Gy in 13 fractions, or 39 Gy in 13 fractions within same 5 wk length of treatment^[92]. Trial B compared 50 Gy in 25 fractions over 5 wk *vs* 40 Gy in 15 fractions over 3 wk^[93]. The 5-year local control, disease free survival, and overall survival with the hypofractionation arms similar to conventional RT arm. Ten-year results of these studies have been published recently and similar breast cancer related outcomes have been reported^[94]. In trial A, moderate or marked breast induration, telangiectasia, and breast edema were significantly less common in the 39 Gy group than in the 50 Gy group. Normal tissue effects did not differ significantly between 41.6 Gy and 50 Gy groups. In trial B, breast shrinkage, telangiectasia, and breast edema were significantly less common in the 40 Gy group than in the 50 Gy group. Whelan *et al.*^[95] randomized 1234 patients to either 42.5 Gy in 16 fractions over 22 d *vs* 50 Gy in 25 fractions over 35 d. At 10 years, a non-significant trend was seen for a lower local recurrence in the hypofractionated arm than in the conventional RT arm (6.2% and 6.7%, respectively). There were no differences in the survival, breast cancer mortality, and cosmetic outcomes. Additionally, ongoing UK FAST trial comparing 50 Gy in 25 fractions *vs* 28.5 or 30 Gy in 5 once-weekly fractions of 5.7 or 6 Gy, respectively^[96]. Preliminary results of this study showed inferior outcome for the ultra short fractionation regimen.

In a meta-analysis of the START A and B trials and pilot study from the Ontario Clinical Oncology Group found no significant difference between the hypofractionated WBRT and conventional RT for grade 3 tumors^[97].

Cochrane review comparing the major trials of hypofractionated WBRT with conventional RT have shown that there is no difference in local recurrence rate (RR, 0.97; $P = 0.78$), breast appearance (RR, 1.17; $P = 0.09$), or 5-year survival (RR, 0.89; $P = 0.16$)^[98]. However, acute skin toxicity was significantly lower with conventional RT (RR, 0.21; $P = 0.007$).

Despite the successful outcomes of hypofractionated WBRT, there are many unanswered questions regarding this issue. Firstly, all of these randomized studies did not have routine boost irradiation which was standard after WBRT for invasive breast cancer. Therefore, the optimal boost method after hypofractionated WBRT is still unknown. However, three phase I - II studies have reported favorable early local control and cosmesis of hypofractionated WBRT with a concurrent boost for early-stage breast cancer^[99-101]. Grade 3 or higher skin toxicity was not reported in these trials. Secondly, patients who underwent hypofractionated WBRT are often low risk patients, and have small breast size and small chest wall separation. Especially, application of this technique to high risk patients whom required chemotherapy remains investigational until mature data from IMPORT and RTOG 1005 can provide efficacy and safety of hypofractionated WBRT in this group. Finally, Coles *et al.*^[102] suggested that hypofractionated WBRT should be applied to only right-sided breast cancer to reduce the RT doses per fraction received by the heart and coronary arteries.

Nowadays, the ASTRO has published guidelines for the implementation of hypofractionated WBRT in early-stage breast cancer^[103]. Hypofractionated WBRT can be an acceptable treatment option outside of a clinical trial including patients with pT1-2 tumors, N0 nodal disease, age > 50 years old, patients who do not receive chemotherapy, and patients who do not require tumor bed boost.

CONCLUSION

Currently, phase III randomized trials demonstrated superiority of IMRT over conventional techniques in terms of both acute and late complications after breast conserving surgeries. Dosimetric trials showed that IMRT also improves breast and regional lymphatic coverage while decreasing radiation doses to heart, lungs, and contralateral breast tissues compared to old-fashioned radiotherapy techniques.

Hypofractionated regimens such as APBI may improve therapeutic index after breast conserving surgery. Furthermore, the duration of therapy will be shorter, and the workload in radiotherapy department will be minimized by those hypofractionated regimens. However, current standard of care after breast conserving surgery is still whole breast irradiation, not APBI. The role of hypofractionated regimens will be defined by mature results of both completed and ongoing randomized trials in the next decade.

Finally, it is noteworthy that quality assurance is cru-

cial for the application of those challenging radiotherapy techniques. Even minor errors may result in catastrophic outcomes. Therefore, planning and implementing of modern radiotherapy techniques in breast cancer should be carried out with maximal care.

Abstract

During the last 15 years we have witnessed an unprecedented expansion in the drugs developed to target human epidermal growth factor receptor-2 (HER-2) positive breast cancer. Trastuzumab, pertuzumab, ado-trastuzumab emtansine and lapatinib are currently food and drug administration (FDA)-approved for the treatment of breast cancer patients with HER-2 over-expressed. However, given the amount of information gathered from years of uninterrupted clinical research, it is essential to have periodic updates that succinctly recapitulate what we have learnt over these last years and help us to apply that information in our daily practice. This review will pursue that objective. We will summarize the most relevant and updated information

related to the state of the art management of HER-2 positive breast cancer in all the clinical scenarios including the adjuvant, neoadjuvant and metastatic settings. But we will also critically appraise that literature in order to highlight some key clinical concepts that should not be overlooked. Lastly, this review will also point out some of the most promising strategies that are currently being tested and may soon become available.

Key words: Breast cancer; Human epidermal growth factor receptor-2; Trastuzumab; Pertuzumab; Ado-trastuzumab; Lapatinib

Core tip: This is a review manuscript with the most updated information regarding the state of the art management of human epidermal growth factor receptor-2 positive breast cancer. It summarizes the most relevant and updated information derived from more than 40 phase II and III clinical trials that constitute the theoretical framework to support our daily practice. It also highlights some key clinical concepts that should not be overlooked by critically appraising the current literature. Finally, it gives the reader with a compilation of potential new agents that are currently being tested and may soon become the next step in the battle against this disease.

INTRODUCTION

Breast cancer is the most prevalent cancer in women, representing approximately 25% of all new cancers worldwide and accounting for one sixth of the total cancer-related deaths^[1]. Human epidermal growth factor receptor-2 (HER-2) positive breast cancer represents a special subtype that has clear epidemiological, clinical, molecular and prognostic differences that make it a separate entity with recognized worse prognosis and poor response to conventional chemotherapy agents alone.

The epidermal growth factor receptor (EGFR) family is composed by four different receptors: EGFR (ErbB1/HER-1), ErbB2 (HER-2/Neu), ErbB3 (HER-3) and ErbB4 (HER-4)^[2]. These membrane receptors have an intracellular domain with tyrosine kinase activity. Following the union of its ligands, ErbB receptors are activated by dimerization which can happen between identical or different type of receptors, a process named homo- and hetero-dimerization, respectively^[3]. Following dimerization, multiple tyrosine residues located in the membrane receptors become phosphorylated, ultimately leading to activation of downstream signaling pathways. EGFR activation has been linked to the regulation of key processes involved in tumor growth, proliferation, differentiation, adhesion, motility and migration. Multiple intracellular substrates participate in essential pathways such as Ras, Raf, mitogen-activated protein kinase (MAPK) and PI3K/AKT^[4-6]. To understand the role of HER-2 in breast cancer, it is important to highlight that this is a ligand-free receptor. HER-2 is always present in an active configuration and prepared to dimerize with any other family member. In breast cancer cells, HER-2 and EGFR are frequently over-expressed, conferring an aggressive tumor behavior and consequently, increased mortality in this population^[7]. HER-2 can be amplified in 20%-25% of breast cancers and is associated with adverse prognostic outcomes in early and advanced disease. The study of HER-2 and its intracellular and extracellular domains has led us into a deeper understating of the tumor biology and helped to develop pharmacological agents able to block this pathway.

Trastuzumab (Herceptin[®], Genentech, United States/Hoffman-Roche, Switzerland) was the first monoclonal antibody approved for breast cancer treatment directed against HER-2. It binds to HER-2 in its extracellular domain. Pertuzumab (Perjeta[®], Genentech, United States/Hoffman-Roche, Switzerland) is a humanized recombinant monoclonal antibody that binds HER-2 at a different extracellular domain than trastuzumab. Trastuzumab blocks homo-dimerization but cannot inhibit hetero-dimerization. Pertuzumab prevents also hetero-dimerization, resulting in more potent growth inhibition^[8]. Ado-trastuzumab emtansine (Kadcyla[®], Genentech, United States/Hoffman-Roche, Switzerland) is a conjugation of trastuzumab with a potent microtubule inhibitor agent, derivative of maytansine (DM-1)^[9]. This molecule has 3 properties, anti-HER-2 inhibition by trastuzumab, cytotoxic effect by DM-1 and certain level of tissue specific-

ity by directing the cytotoxic agent only to those cells that express HER-2. It has recently being approved for refractory metastatic disease. Lapatinib (Tykerb TM, GlaxoSmithKline, Research Triangle, NC, United States) is the only intracellular blocker approved. It is a dual reversible tyrosine kinase inhibitor of HER-2 and EGFR. It acts on both receptors simultaneously, achieving greater inhibitory effects^[10].

Given the enormous amount of information accumulated from almost 20 years of continuous basic and clinical research, it is important to have periodic updates in this topic that can succinctly recapitulate what we have learnt over the last years and help us to apply that information in our daily practice. This review will pursue that objective and also will allow the reader to envision some of the promising agents that may soon become part of our armament against this disease.

STATE OF THE ART ANTI-HER-2 THERAPY

In this section we will summarize all those relevant clinical trials that constitute the theoretical framework to support our daily practice. For practical reasons we will subdivide this section according to the clinical setting: adjuvant, neoadjuvant and metastatic disease. Also, given the breadth of this topic we will mainly focus only on phase III and some phase II clinical trials. Tables 1-3 recap the most important published clinical trials.

Adjuvant treatment

In the adjuvant scenario, treatment with trastuzumab is the standard of care for patients with HER-2 over-expressing breast cancer. Trastuzumab can be administered in combination with paclitaxel or docetaxel following an anthracycline-based chemotherapy (*i.e.*, doxorubicin and cyclophosphamide) or be given concurrently with carboplatin and docetaxel. Several phase III trials have consistently validated trastuzumab as the cornerstone of adjuvant chemotherapy. The question of the optimal therapy duration has been addressed and even though the answer is still pending, the actual evidence suggests that treatment for one year is probably the most appropriate. Cardiac toxicity is a major concern since anti-HER-2 therapy can result in decreased left ventricular ejection fraction (LVEF) and symptomatic heart failure. However, this is usually reversible after treatment discontinuation.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31 and the North Central Cancer Treatment Group (NCCTG) N9831 were two pivotal studies^[11]. The NSABP B-31 compared four cycles of doxorubicin and cyclophosphamide (AC) followed by four cycles of paclitaxel every three weeks to the same regimen plus trastuzumab given for 52 wk starting concurrently with paclitaxel. The NCCTG N9831 randomized patients to receive four cycles of AC followed by weekly paclitaxel for 12 cycles with or without trastuzumab, administered concurrently or sequentially

Table 1 Selected clinical trials in the adjuvant setting for human epidermal growth factor receptor-2 positive breast cancer

Drug or study name	Population included	No. of patients	Comparison	Median follow-up	DFS	OS	CHF/ Drop LVEF	Ref.

LN: Lymph nodes; AC → T: Adriamycin cyclophosphamide paclitaxel; FEC: 5-FU epirubicin cyclophosphamide; ED: Epirubicin docetaxel; Std QT: Standard chemotherapy; OS: Overall survival; DFS: Disease free survival; CHF: Cardiac heart failure; LVEF: Left ventricular ejection fraction.

Table 2 Selected clinical trials in the neo-adjuvant setting for human epidermal growth factor receptor-2 positive breast cancer

Study	Neo-adjuvant chemotherapy	No. of patients	Pathological complete response (%)	Comments	Ref.
Trastuzumab (H)					
MD Anderson Group	T → FEC <i>vs</i> T → FEC + H	19 <i>vs</i> 23	26% (95%CI: 9%-51%) <i>vs</i> 65% (95%CI: 43%-84%)	Probably the first study to emphasize better pCR with H	Buzdar <i>et al</i> ^[24]
The NOAH Trial	A + T → T → CMF <i>vs</i> A + T → T → CMF + H	117 HER-2 (+) <i>vs</i> 118 HER-2 (+)	22% (95%CI: not reported) <i>vs</i> 43% (95%CI: not reported)	Not originally designed to test the effects of neoadjuvance	Gianni <i>et al</i> ^[26]
The TECHNO Trial	EC → TH	217	38.7% (95%CI: 32%-45%)	Suggest pCR correlate with DFS	Untch <i>et al</i> ^[27]
The Z1041 Trial	FEC → TH <i>vs</i> T + H → FEC + H	138 <i>vs</i> 142	56.5% (95%CI: 48%-65%) <i>vs</i> 54.2% (95%CI: 46%-62%)	Concurrent use of H with anthracyclines is not better	Buzdar <i>et al</i> ^[28]
The HannaH Trial	Doc + H (SQ) → FEC + H <i>vs</i> Doc + H (IV) → FEC + H	260 <i>vs</i> 263	45.4% (95%CI: 39%-52%) <i>vs</i> 40.7% (95%CI: 35%-47%)	H can be administered subcutaneously	Ismael <i>et al</i> ^[30]
Lapatinib(L) +/- (H)					
The GeparQuinto Trial	ECH → TH <i>vs</i> ECL → TL	309 <i>vs</i> 311	30.3% (95%CI: 25%-36%) <i>vs</i> 22.7% (95%CI: 18%-28%)	Lapatinib is less effective than H	Untch <i>et al</i> ^[31]
The NeoALLTO Trial	TH <i>vs</i> TL <i>vs</i> THL	149 <i>vs</i> 154 <i>vs</i> 152	29.5% (22%-37%) <i>vs</i> 24.7% (22%-37%) <i>vs</i> 51.3% (43%-59%)	Suggested that combination H + L could be quite effective	Baselga <i>et al</i> ^[32]
The NSABP B-41 Trial	AC → TH or TL or THL	181 <i>vs</i> 174 <i>vs</i> 174	52.5% (50%-59.5%) <i>vs</i> 53.2% (45%-60%) <i>vs</i> 62.0% (54%-69%)	H + L no better. All patients received anthracyclines	Robidoux <i>et al</i> ^[33]
Pertuzumab (P)					
The NeoSphere Trial	Do + H <i>vs</i> Do + P + H <i>vs</i> Do + P <i>vs</i> P + H	107 <i>vs</i> 107 <i>vs</i> 107 <i>vs</i> 96	29.0% (21%-38.5%) <i>vs</i> 45.8% (36%-56%) <i>vs</i> 24.0% (16%-34%) <i>vs</i> 16.8% (10%-25%).	Combination P + H result in better pCR.	Gianni <i>et al</i> ^[34]
The Tryphaena Trial (Abstract Only)	FEC + HP → Do + HP <i>vs</i> FEC → Do + HP <i>vs</i> TCHP	223 patients in total	62% <i>vs</i> 57% <i>vs</i> 66%	TCH + P is an active combination	N/A

T: Paclitaxel; F: 5-FU; E: Epirubicin; C: Cyclophosphamide; A: Adriamycin; M: Methotrexate; Do: Docetaxel; TC: Docetaxel carboplatin.

Table 3 Selected clinical trials in metastatic human epidermal growth factor receptor-2 positive breast cancer

Drug or study name	Population included	No. of patients	Comparison	Median OS (mo)	Median TTP (mo)	ORR	1-yr Survival	Ref.
Single agents								
Trastuzumab (H)	Phase II, first line, MBC	114	None-2 doses of H used	24.4	3.8	26% (18%-34%)	N/A (approximately 65%)	Vogel <i>et al</i> ^[45]
Ado-trastuzumab	Phase II, refractory MBC	110	None	N/A	6.9 (4.2-8.4)	34% (26%-44%)	N/A	Krop <i>et al</i> ^[48]
Anti-HER-2 + QT H + Paclitaxel (T)	Phase III, first line, MBC	469	QT (AC or T) + H vs QT	25.1 vs 20.3	7.4 vs 4.6	50% vs 32%	78% vs 67%	Slamon <i>et al</i> ^[44]
Cont. Anti-HER-2 after failing 1st line								
Lapatinib (L)	Phase III, failed to H	324	Cape + L vs Cape alone	N/A	8.4 vs 4.4	22% vs 14%	N/A (approximately 60%)	Geyer <i>et al</i> ^[54]
EMILIA Trial (Ado-trastuzumab)	Phase III, MBC who failed TH	991	Ado-T vs Cape + L	30.9 vs 25.1	9.6 vs 6.4	43.6% vs 30.8%	85% vs 78%	Verma <i>et al</i> ^[55]
Dual Anti-HER-2 CLEOPATRA	Phase III, first line, MBC	808	Do + H + P vs Do + H	Not reached	18.5 vs 12.4	80% vs 69%	N/A (approximately 90%-95%)	Baselga <i>et al</i> ^[57]
Lap + Trastuzumab	Phase III, failed to H	296	L + H vs L alone	11.8 vs 8.9	2.75 vs 1.85	10% vs 7%	70% vs 36%	Blackwell <i>et al</i> ^[59]
H + Pertuzumab (P)	Phase II, failed to H	66	None-H + P single arm	N/A	5.5	24.20%	N/A	Baselga <i>et al</i> ^[61]
Anti-HER-2 + AI Anastrozole + H	Phase III, HR and HER-2 positive, 1 st line in MBC	207	Anastrozole + H vs Anastrozole alone	28.5 vs 23.9	4.8 vs 2.4	20% vs 6.8%	N/A (approximately 78%)	Kaufman <i>et al</i> ^[63]
Letrozole + L	Same	219	Letrozole + L vs Letrozole alone	33.3 vs 32.3	8.2 vs 3.0	28% vs 15%	N/A	Johnston <i>et al</i> ^[64]

QT: Chemotherapy; AI: Aromatase Inhibitor; MBC: Metastatic breast cancer; HR: Hormones receptor; Do: Docetaxel; AC: Adriamycin cyclophosphamide; T: Paclitaxel; OS: Overall survival; TTP: Time to progression; N/A: Not available or not reported.

to paclitaxel, for 52 wk. A joint analysis of these clinical trials was first presented in 2005. Initially both trials were designed to include patients with node positive breast cancer. But later on, the NCCTG trial included patients with high-risk node negative disease defined as tumors ≥ 2 cm and positive for hormone receptors or tumors larger than 1 cm with negative hormone receptors. The primary endpoint of these trials was disease-free survival (DFS) and overall survival (OS) was part of the secondary endpoints. On the initial report with a median follow-up of two years the hazard ratio (HR) for DFS was 0.48 (95%CI: 0.39 to 0.59; $P < 0.001$). At four years, 85.3% of patients treated with trastuzumab were alive and free of disease compared to only 67.1% in the control group. Mortality was reduced by 33%. Updated results were consistent with previous observations^[12]. The final analysis of these studies was presented at the 2012 San Antonio Breast Cancer Symposium (SABCS) and reported a 10-year DFS of 73.7% vs 62.2% ($P < 0.001$) and a OS of 84% vs 75.2% ($P < 0.001$) all favoring trastuzumab^[13]. Overall, treatment with trastuzumab resulted in a 40% risk reduction benefit in terms of 10-year DFS and 37% in OS. The NCCTG trial compared, as well, the efficacy of concurrent vs sequential administration of trastuzumab, showing a trend toward improvement in DFS in the concurrent arm^[14]. However, sequential was still better

than placebo ($P < 0.001$).

Published simultaneously, the Herceptin Adjuvant Trial (HERA), a randomized phase III trial designed to compare adjuvant treatment with trastuzumab for one or two years vs observation reported similar results. At the first interim analysis DFS was superior in the trastuzumab treated population^[15]. An absolute 8% difference between arms in DFS events was achieved ($P < 0.001$). Unlike other studies, patients included in this trial had already undergone adjuvant (90%) or neoadjuvant treatment and could have nodal involvement. Following the interim analysis, 52% of patients in the observation arm crossed over to trastuzumab before an event had occurred^[16]. At a median follow-up of 8 years, the HRs for DFS and OS in the trastuzumab arm compared to observation were 0.76 for both outcomes. Importantly, given the persistent benefits in terms of DFS and OS found even after a mean time from randomization to crossover of 22.7 mo, in clinical practice trastuzumab must be used even in delayed scenarios. This study also proved that 2-year adds no benefit to 1-year of treatment, but adds a slight increment in cardiologic adverse events.

The Finland Herceptin (FinHer) trial aimed to determine the role of vinorelbine compared to docetaxel in the adjuvant setting in patients with node positive and high risk node negative breast cancer^[17]. A total of 1010

patients were randomized to treatment with vinorelbine or docetaxel for 3 cycles followed by three cycles of 5-FU, epirubicin and cyclophosphamide. A group of 232 patients with HER-2 amplified tumors were again randomized to receive nine weekly cycles of trastuzumab concurrently with docetaxel or vinorelbine. The primary end point was distant DFS and with a median follow-up of 5 years, it favored treatment with docetaxel over vinorelbine ($P = 0.010$)^[18]. OS also tended to be better in patients treated with docetaxel compared to vinorelbine (39 *vs* 55 death, respectively; $P = 0.086$). In HER-2 positive patients, trastuzumab arms had favorable recurrence free survival irrespectively of the chemotherapy used (80% *vs* 73%; $P = 0.12$). This benefit was maintained when adjusted for nodal involvement and in patients treated with docetaxel over vinorelbine. The main limitation of this trial is the small number of patients with HER-2 positive tumors included, undermining the study power to detect a statistically significant benefit with trastuzumab. Also, even though the results suggested a benefit in patients treated with trastuzumab in combination with chemotherapy, the short course of treatment might have underestimated the real efficacy of the drug in this population.

Cardiotoxicity is the most important adverse effect derived from treatment with trastuzumab, which is worse when combined with anthracyclines. Therefore, there has been a special interest in studying anthracycline-free regimens in order to avoid synergistic deleterious cardiac toxicities. The BCIRG 006 study was designed to provide information on this matter^[19]. This phase III clinical trial randomized 3222 patients with HER-2 positive and node positive or high-risk node negative tumors to treatment with doxorubicin, cyclophosphamide and docetaxel (AC \rightarrow T), the same regimen plus trastuzumab (AC \rightarrow TH) or docetaxel, carboplatin and trastuzumab (TCH). The primary end-point was DFS and secondary end-points were OS, safety and cardiac toxicity. With a median follow-up of 65 mo, 5-year DFS was 84% ($P < 0.001$) in the ACTH arm, 81% ($P = 0.04$) in the TCH arm and 75% in the ACT arm (control). OS was also improved with trastuzumab (92% with ACTH, 91% with TCH and 87% in the ACT; $P < 0.001$ and 0.04, respectively). ACTH was slightly better than TCH, though this study was not designed to compare efficacy between these two regimens. The incidence of cardiac toxicity was five times more with ACTH (2%) compared with TCH (0.4%). Reductions in LVEF, over 10% from basal measurements, were more frequently associated with ACTH than with TCH (18.6 *vs* 9.4%; $P < 0.001$). As well, the rate of symptomatic congestive heart failure favored treatment with TCH ($P < 0.001$). According to these results, anthracycline-free chemotherapy is efficient and is a valid treatment option in patients at high risk of cardiac toxicity. Although the combination of doxorubicin and trastuzumab resulted in better DFS and OS, the difference seemed to be insignificant. To confirm that one regimen is better than the other, further evidence is required.

The French PACS 04 was the only negative study re-

ported^[20]. A total of 3010 patients with early stage breast cancer were randomly assigned to adjuvant treatment with anthracycline-based chemotherapy with or without docetaxel. Patients with HER-2 over-amplified tumors ($n = 528$) were subsequently randomized to receive trastuzumab sequentially every 3 wk. The primary endpoint was DFS. Treatment with trastuzumab resulted in a non-significant 14% reduction in the risk of relapse ($P = 0.41$) and there was no difference in OS. However, 10% of the patients assigned to trastuzumab were never treated and 25% of patients discontinued before the 16th cycle. Also, sequential use seems to be inferior to concurrent.

Duration of adjuvant treatment in HER-2 positive breast cancer is a matter of current discussion. Based on the previously analyzed HERA trial, two years of treatment with trastuzumab is not superior to one year. There is a special interest in investigating whether treatment duration could be shortened. The PHARE trial is a non-inferiority study designed to answer this question. This study evaluated adjuvant treatment length with trastuzumab for 6 mo compared to one year^[21]. A total of 1691 patients were treated with trastuzumab for 12 mo and 1693 for 6 mo after receiving at least 4 cycles of adjuvant chemotherapy. Patients were stratified according to sequential or concurrent treatment and ER status. The primary endpoint was DFS and with a median follow-up of 42.5 mo, 2-year DFS was 93.8% for the 12-mo group and 91.1% for the 6-mo group (HR = 1.28; 95%CI, 1.05-1.56), concluding that 6 mo of treatment did not reach the non-inferiority criteria. However, cardiac events were more common in the 12 mo treatment arm (5.7% *vs* 1.9%; $P < 0.001$). Two other ongoing phase III trials, SHORT-HER (NCT00629278) and PERSEPHONE (NCT00712140), will contribute to clarify this issue. Nonetheless, on the basis of the current available evidence, 12 mo of adjuvant treatment with trastuzumab remains the standard of care.

Lapatinib is currently approved for metastatic disease but its use in the adjuvant setting could be interesting due to its oral bioavailability. The TEACH trial studied the efficacy of lapatinib in trastuzumab-naïve patients as adjuvant treatment^[22]. A total of 3147 patients were randomized to 12 mo of treatment, or until progression, with lapatinib or placebo. DFS was non-significantly prolonged in patients treated with lapatinib (87% *vs* 83%; $P = 0.09$). In patients with centrally confirmed HER-2 status the HR was 0.92 ($P = 0.94$). In conclusion, single agent lapatinib seems to be quite ineffective in the adjuvant treatment. The ongoing ALTO trial is evaluating the efficacy of lapatinib in combination with trastuzumab and lapatinib sequential to trastuzumab *vs* trastuzumab alone. A treatment arm with single agent lapatinib was prematurely closed by an independent data and safety committee (NCT00490139).

Neo-adjuvant treatment

The original rationale behind the use of neo-adjuvant chemotherapy was to attempt tumor volume reduction

whenever the tumor size precluded an optimal surgical resection. However, clinical researchers rapidly understood that pre-surgical chemotherapy could represent an excellent way to assess the real *in vivo* response of the tumor, a fact obviously impossible to achieve in the adjuvant setting. Moreover, it is at least theoretically feasible that the response obtained in the primary tumor could be a good surrogate to what happens with the invisible micrometastases. In that sense, if some cells remain viable in the primary site, then the chances of having resistant micrometastases are higher. On the contrary, complete pathological response (pCR) should correlate with fewer future relapses. This concept has been more strongly established in triple negative breast tumors and though quite appealing intellectually, there are some caveats in this assumption that requires further discussion (see later)^[23].

Probably the first evidence addressing the role of anti-HER-2 therapies in the neo-adjuvant scenario came from a small randomized trial published by the MD Anderson group^[24]. With only 42 patients randomized, the addition of trastuzumab to sequential paclitaxel followed by FEC (P x 4 → FEC x 4) resulted in an impressive 2.5 times higher rate of pCR than chemotherapy alone (66.7 *vs* 25%; *P* = 0.02). Given the small sample, the confidence intervals were wide and also no clinical endpoints were reported. An updated version of the study confirmed the findings^[25]. The results of the NOAH trial, a randomized phase III study, helped to give further enthusiasm to this approach^[26]. The study was originally designed to compare neoadjuvant chemotherapy plus trastuzumab followed by 1-year trastuzumab to neoadjuvant chemotherapy alone in patients with locally advanced or inflammatory HER-2 positive tumors. But with the approval of trastuzumab all patients were allowed to receive this drug as adjuvant therapy. From 238 patients originally randomized to neoadjuvant treatment with or without trastuzumab, the addition of anti-HER-2 therapy improved the pCR from 22% to 43% (*P* < 0.001). Trastuzumab also resulted in a 40% risk reduction of recurrence, progression or death when compared to chemotherapy alone, but this was already known due to the adjuvant studies. Moreover, in 2011 German investigators published the results of an open label, phase II study - TECHNO trial - where 217 patients with HER-2 positive and ≥ 2 cm tumors received four cycles of epirubicin and cyclophosphamide, followed by four cycles of paclitaxel and trastuzumab before surgery^[27]. Complete pathological response was achieved in 38.7% of the cases. However, the most relevant observation from this study was that pCR correlated with better 3-year DFS (88% *vs* 71%; *P* = 0.003) and 3-year OS (96% *vs* 85%; *P* = 0.007). Obviously, the small number of patients and the fact that this was a phase II study limited the generalization of these findings but sparked the idea the pCR could correlate with harder clinical endpoints. Also, the American Z1041 trial randomized 282 women with similar inclusion criteria as the TECHNO study to receive trastuzumab and paclitaxel concurrently with FEC-75 or after this regimen^[28]. Both arms showed a high propor-

tion of pCR (54% and 56%) but the concurrent use of anthracyclines and trastuzumab resulted in a greater drop in the cardiac ejection fraction (2.9 % *vs* 0.8% at 12 wk, respectively). Lastly, similar rates of pCR were described in patients treated with chemotherapy and trastuzumab in the GeparQuattro study (32%) as well as in the HannaH trial (41% and 45% for intravenous *vs* subcutaneous trastuzumab, respectively)^[29,30].

In an attempt to improve the efficacy of anti-HER-2 therapies, some researchers started exploring the use of lapatinib or its addition to trastuzumab. Recently, at least three randomized phase III clinical trials were published testing that hypothesis. In the German GeparQuinto study, 620 patients received four cycles of epirubicin and cyclophosphamide (EC) followed by docetaxel and were randomized to have trastuzumab or lapatinib^[31]. All patients received standard of care trastuzumab for 1-year after surgical resection. Primary outcome was pCR and trastuzumab showed approximately 7% more complete responses than lapatinib (30.3% *vs* 22.7%; *P* = 0.04). Given these results and the significant number of adverse events described in this study, it is unlikely that lapatinib could replace trastuzumab in the neoadjuvant setting; however, dual HER-2 inhibition seems to be a better option. The NeoALLTO international, randomized, phase III study compared the use of single agent lapatinib, trastuzumab or the combination of both in addition to paclitaxel for neo-adjuvant treatment^[32]. Interestingly, the combination arm showed a remarkable improvement in pCR almost duplicating the two other single agent anti-HER-2 arms (51% *vs* 29.5% trastuzumab *vs* 24.7% lapatinib; *P* < 0.001). As expected the addition of lapatinib resulted in worse side effects, mainly related to diarrhea and rash. However, in contraposition to the NeoALLTO, the freshly published NSABP B-41 study showed no statistical difference with the combination of trastuzumab and lapatinib when compared to either drugs used as single agent^[33]. Two issues though deserves further discussion. First, even though the population included in both trials was similar, the chemotherapy regimens were not. In the NSABP study all patient received four cycles of AC and then they were randomized to paclitaxel plus trastuzumab, lapatinib or both. Second, the rates of pCR in all three arms were unusually high (62% for the combination, 53% for trastuzumab and 52.5% for lapatinib).

Up to this date, lapatinib has not received FDA approval to use in the neoadjuvant setting. Nonetheless, the FDA has recently granted accelerated approval to pertuzumab for its use before surgery when combined with trastuzumab and chemotherapy. This controversial decision was based on the results of two phase II clinical trials. The already published NeoSphere trial was a multicenter, open-label, randomized phase II study where 417 patients were randomized to one of four possible arms: pertuzumab (P) + trastuzumab (T) + docetaxel (Do); T + Do; P + Do or P + T alone^[34]. All eligible patients then underwent surgical resection followed by adjuvant FEC and 1-year of trastuzumab. The primary

endpoint was pCR and no information regarding harder clinical outcomes (*i.e.*, DFS, OS, *etc.*) was reported. The three drug arm (P + T + Do) showed the maximal rate of pCR (46%) and was statistically different from T + Do (29%; $P = 0.014$). Pertuzumab + docetaxel resulted in a 24% pCR and the chemotherapy-free arm had a 17% pCR. Importantly, the addition of pertuzumab did not produce any significant drop in the cardiac function (4-5% EF drop across all groups). The second study - TRYPHAENA trial - is only available as an abstract but its importance relies on the fact that it incorporates the trastuzumab + pertuzumab combination to an anthracycline-free regimen^[35,36]. One of its three arms use the very popular TCH regimen (carboplatin, docetaxel and trastuzumab) with pertuzumab for six cycles before surgery followed by one year of trastuzumab. Even though more information will be available when the study become fully published, preliminary data suggest that all three arms achieved > 55% pCR.

The preceding paragraph served to describe the current available evidence supporting the use of anti-HER-2 drugs as a neoadjuvant treatment. But, how should we apply all this information? In our own opinion, there are a couple of important points to emphasize. First, dual blockage of the HER-2 receptor, even without chemotherapy, results in an at least 15% pCR (NeoSphere Trial), meaning that 1 in 6 patients may not need chemotherapy. This certainly represents an attractive option for patients who cannot tolerate more than targeted agents. Second, the addition of chemotherapy leads to a more robust effect with values between 40%-50% when trastuzumab alone is used or even more than 50% when dual blockage is applied. Moreover, anthracyclines seem to play a significant role in HER-2 positive tumors; however, results from NeoALLTO and TRYPHAENA trials suggest that when dual blockage is used, anthracyclines toxicity might be spared. In this regard clinicians have now two options; to follow the NeoSphere protocol that requires the use of FEC post-surgically or to use TCH + pertuzumab (TRYPHAENA). Until further information is available, the anthracycline-free option might better serve the lower risk tumor (*i.e.*, small tumors with negative lymph nodes) or in patients with serious cardiovascular comorbidities and leave the anthracyclines for more advanced disease and younger women. Third, in all of the clinical trials available pCR is markedly diminished in tumors expressing hormone receptors in addition to HER-2.

Nonetheless, probably the most important question to ask ourselves is how reliable is pCR as a valid surrogate for real clinical outcomes. It is important to consider that these drugs are utilized in potentially curable disease and there are still some doubts about whether pCR always correlates with DFS and OS. It has been established by many authors, including the FDA, that pCR is a surrogate of survival in patients with localized breast cancer previously treated with chemotherapy^[37]. This may well be the case for anti-HER-2 therapy when used in this fashion. A Cochrane meta-analysis evaluating preoperative with

postoperative chemotherapy evidenced that the risk of dying among patients who had a pCR was approximately 50% less than that in patients with residual disease^[38]. The FDA has presented in SABCS 2012 and is in process to publish a meta-analysis with 12900 patients enrolled in randomized neoadjuvant trials, with the objective to identify those patients in whom a pCR was most likely to predict survival^[39]. There was a marked correlation between pCR and relapse free survival in all the subgroups analyzed. However, a recent German study showed that pCR was correlated with OS in triple negative breast cancer (TNBC) as well as HER-2 positive and non-luminal tumors but was not the case in the cohort of HER-2 positive and luminal patients^[40]. In this last group pCR may not be a good surrogate for survival; but, from a hypothetical view, it is also true that ER positive disease tends to progress more slowly. It is possible that more events would be needed to have mature results. Perhaps, with longer follow-up curves might separate, becoming more consistent with the meta-analysis presented in SABCS 2012 by Cortazar and colleagues. Up for today, neoadjuvant with anti-HER-2 agents is a valid and approved option especially in those patients with locally advanced, unresectable tumors. Its use in small resectable cancer is probably appropriate but has to be balanced with the practical consideration as well as the patient's own preferences.

Lastly, some studies have also reported on different biomarkers which could predict pCR after neoadjuvant chemotherapy. They include estrogen receptor status, the PI4K pathway and p95HER-2 among others. However, no one is currently validated and available to use. An interesting niche where the use of biomarkers could be tremendously useful would be on patients with residual cancer cells at surgery after optimal neoadjuvant therapy. Since these patients have a poor prognosis, the analysis of the residual tumor cells for predictive biomarkers could unfold potential targets^[41].

Metastatic disease

It has now been close to 15 years since the first publications reporting the use of trastuzumab for metastatic breast cancer^[42-44]. Since those seminal studies, we have made major progress in our understanding of the anti-HER-2 therapies and some concepts should be highlighted.

Anti-HER-2 therapies are active even as single agents: Single agent anti-HER-2 molecules seem to have a modest but consistent activity even when used alone. This has been well proven for the case of trastuzumab (ORR = 15%-25%)^[45], but also for pertuzumab (ORR = 5%)^[46], lapatinib (ORR = 5%-7%)^[47] and ado-trastuzumab emtansine (ORR = 35%)^[48]. For the newer drugs, this holds true even after failing first line trastuzumab containing regimens. The vast majorities are only partial response, but some patients experience sustained stable disease which also adds to the clinical benefit.

The addition of conventional chemotherapeutics maximizes the efficacy of anti-HER-2 drugs: The addition of chemotherapy to anti-HER-2 agents increases the ORR up to 60%-70%. Paclitaxel is probably the most frequently used drug, but the benefit is seen regardless of the type of chemotherapy administered and there is solid evidence to support the combination of trastuzumab with vinorelbine or docetaxel^[49] and even carboplatin^[50]. Lapatinib is also frequently combined with capecitabine^[51].

The HER-2 target should remain blocked even after progression: Patients seem to achieve considerable clinical benefit if the HER-2 axis remained blocked even after experiencing progression from regimes containing anti-HER-2 therapies. This was categorically proven by the German Breast Group in the BIG 305 trial where 146 patients were randomized to capecitabine or capecitabine plus trastuzumab after having progressed to a trastuzumab containing regimen^[52]. The median progression-free survival (PFS) was 3 mo longer (8.2 *vs* 5.6; $P = 0.033$) and there was better ORR (48% *vs* 27%; $P = 0.015$) in the trastuzumab continuation arm. However, updated results showed no significant difference in OS^[53]. These results are somehow comparable with the earlier tested combination of capecitabine and lapatinib. In the study reported by Geyer and colleagues in 2006, patients with locally advanced or metastatic disease who had failed trastuzumab regimens (> 95% of the population enrolled) were randomly assigned to either capecitabine alone or combined with lapatinib^[54]. Time to progression (TTP) was similar in both trials, BIG 305 and the lapatinib study, in terms of the control arm (single agent capecitabine 4.5 and 5.5 mo, respectively) as well as the experimental arm (8.2 mo in trastuzumab + capecitabine and 8.5 mo in lapatinib + capecitabine). Irrespectively of the obvious difference in side effects of each drug and some intrinsic disparities in these two studies, the proof of concept brought by these investigations was the fact that the HER-2 target must continue to be attacked probably indefinitely. In accordance to this principle, a new molecule has recently gained FDA approval for trastuzumab refractory cases. Ado-trastuzumab emtansine, an interesting conjugation between the trastuzumab antibody and the chemotherapy agent DM-1, proved to be better than lapatinib and capecitabine combination. The EMILIA trial randomized 991 patients with metastatic (84%) or locally advanced (16%) disease, who have been previously treated with trastuzumab and a taxane, to T-DM1 or lapatinib plus capecitabine^[55]. PFS, the primary endpoint of the study, was significantly improved with T-DM1 (9.6 *vs* 6.4 mo; $P < 0.001$) as it was OS (31 *vs* 25 mo; $P < 0.001$) and ORR (44 *vs* 31%; $P < 0.001$). Currently, ado-trastuzumab emtansine is considered the best option for patient progressing after first line trastuzumab. Nonetheless, early data from phase II studies showed promising results with ado-trastuzumab as a front line option^[56]. What happened

after progression with T-DM1? Options will include either switching to trastuzumab + lapatinib (see below) or to consider lapatinib and capecitabine. But irrespectively of the option selected, the HER-2 targeted therapy should continue.

Two different anti-HER-2 therapies could be combined to exploit the benefit: Apparently, the conjunction of two different anti-HER-2 agents could result in better outcomes. Three combinations are particularly important: (1) Pertuzumab + trastuzumab + docetaxel; (2) Trastuzumab + lapatinib; and (3) Pertuzumab + trastuzumab alone. The CLEOPATRA study randomly assigned 808 patients with metastatic and chemotherapy naïve HER-2 positive breast cancer to either what was up to that moment the standard of care (trastuzumab + docetaxel) or the same combination plus pertuzumab^[57]. The study was strongly positive with almost 50% prolongation in PFS favoring the experimental arm (18.5 *vs* 12.4 mo; $P < 0.001$). Updated results also confirmed a significant improvement in OS^[58]. Currently, pertuzumab, trastuzumab and docetaxel are considered the standard of care for first line treatment in metastatic disease. Notably, this regimen takes advantage of two of the previously mentioned concepts: dual HER-2 blockage and addition of a chemotherapy agent. However, even without adding a chemotherapeutic, dual blockage is still an active alternative especially on those heavily pretreated patients who may not tolerate chemotherapy. The EGF104900 was an open-label, phase III study where women vastly treated with trastuzumab-containing schemas (median 3 prior regimens) were randomly assigned to single agent lapatinib or lapatinib and trastuzumab^[59]. The dual blockage arm showed longer PFS (12 *vs* 8 wk; $P = 0.008$) as well as OS (14 *vs* 9.5 mo; $P = 0.026$)^[60]. Another appealing strategy tested in phase II setting is the combination of pertuzumab and trastuzumab with no chemotherapy agents. Baselga and colleagues reported a 24% ORR and a median PFS of 5.5 mo in 66 patient with previous trastuzumab-based therapy failure, using this combination alone^[61].

Triple positive patients (ER/PR positive and HER-2 positive) benefit from dual blockage: This is a very relevant issue because close to 50% of the tumors that over-expressed HER-2 also have some expression of ER and there is significant cross-talk between them^[62]. Moreover, chemotherapy-free alternatives are always appealing. Two phase III trials have been reported testing the hypothesis that dual blockage is better than anti-hormonal therapy alone. In the TAnDEM study, 207 patients with no brain metastases and no prior chemotherapy received either anastrozole alone or combined with trastuzumab^[63]. The primary efficacy point was PFS which was extended by 2.4 mo with the use of trastuzumab (4.8 *vs* 2.4 mo; $P = 0.0016$). OS was not statistically different but crossover was allowed. Importantly, up to 15% of the patients in the combination arm did not experience relapse for up

to 2 years, suggesting that for at least a small proportion of patients this regimen was quite useful. The second study (EGF 30008 trial) compared letrozole alone or with lapatinib^[64]. No prior therapy for metastatic disease was allowed and 219 of the total 1286 patients randomized were HER-2 positive. In the HER-2 positive subgroup the experimental arm showed a significant extension in PFS (8.2 *vs* 30 mo; $P = 0.019$) but once again no benefit was seen in terms of OS and there were more serious adverse events (8% *vs* 4%) compared with letrozole alone ($P < 0.05$). Lastly, the small eLEcTRA trial was discontinued due to slow enrollment with only 57 patients analyzed^[65]. The cohort was similar to the TAnDEM trial but letrozole was used instead of anastrozole. The authors reported a trend towards improvement in TTP (14.1 *vs* 3.3 mo; $P = 0.23$). Lack of significance, though, could be due to a type 2 error (false negative) based on less than expected accrual. These studies support the use of HER-2 targeted treatments combined with non-steroidal aromatase inhibitors, in post-menopausal patients, as a valid chemotherapy-free option for triple positive patients^[66].

Central nervous system metastases are probably different than the rest: A recent meta-analysis showed a higher risk of brain metastases as initial-only site of recurrence in patients relapsing after receiving adjuvant treatment with trastuzumab *vs* chemotherapy alone^[67]. As expected given its molecular structure, most of the currently available anti-HER-2 drugs - trastuzumab, pertuzumab and ado-trastuzumab - have probably limited access into the central nervous system (CNS). Small molecules have in theory better chances to obtain therapeutic concentrations within the brain sanctuary. The combination of lapatinib and capecitabine has been correlated with a lower rate of CNS relapse compared with capecitabine as a single agent^[68]. Nonetheless, the recent CEREBEL study showed no difference in the rate of CNS relapse as a first-site of disease progression (3.0% *vs* 5.0%; $P = 0.360$) between trastuzumab + capecitabine and lapatinib + capecitabine treatment^[69]. However, the low incidence of CNS metastases might have undermined the ability of the study to show a significant difference. Also, a recently published French phase II trial showed that in patients with previously untreated HER-2 positive diffuse CNS metastases the combination of capecitabine and lapatinib lead to an impressive high response rate (ORR = 66%) when given as initial approach. The regimen was effective in treating both, CNS and extra-CNS disease, and delayed whole brain radiotherapy by a median of 8 mo^[70]. The conclusions from a planned randomized study evaluating capecitabine plus lapatinib plus whole brain radiotherapy are expected soon^[66].

NEW TARGETS

Since this field is quite dynamic and the frontiers are in continuously expansion, it will be appropriate to discuss some of the new strategies that are currently being inves-

tigated for HER-2 positive breast cancer.

Afatinib

Afatinib is an oral small molecule that irreversibly inhibits HER-1, 2 and 4^[71]. A phase II study in trastuzumab-resistant metastatic patients showed 4 out of 35 partial responses^[72]. Adverse events included diarrhea and rash. LUX-Breast 1 is a phase III study of vinorelbine plus trastuzumab or afatinib for metastatic patients who progressed to one chemotherapy regimen containing trastuzumab (NCT01125566)^[73]. A phase II trial is also evaluating afatinib with or without vinorelbine in patients with inflammatory or metastatic breast cancer (NCT01325428).

Neratinib

Neratinib is also an oral, irreversible inhibitor of HER-1, -2 and -4^[74]. A phase II trial evaluated neratinib in 136 HER-2-positive patients^[75]. In pretreated as well as trastuzumab-naïve patients, median PFS were 22.3 and 39.6 wk and ORR were 24% and 56%, respectively. Diarrhea was the most common grade 3/4 adverse effect. Another phase I - II trial combined neratinib plus trastuzumab in 45 metastatic and trastuzumab-resistant patients showing an encouraging 27% ORR^[76]. Finally, a phase I - II trial evaluated neratinib plus vinorelbine in trastuzumab or lapatinib pretreated patients ($n = 77$)^[77]. ORR was 42% in lapatinib-treated and 51% in lapatinib-naïve patients. Open label phase II trials are currently testing neratinib monotherapy in patients with HER-2 positive metastatic brain tumors (NCT01494662). Also a phase III trial (ExteNET) in the adjuvant setting is ongoing (NCT00878709).

MM-11

MM-11 is a bi-specific monoclonal antibody that reversibly targets the HER-2 and -3 heterodimer^[78]. A phase I - II study is currently evaluating its efficacy as single agent in HER-2 positive advanced breast cancer patients who have received prior trastuzumab or lapatinib therapy (NCT00911898)^[79]. Another phase I trial is studying MM-11 plus trastuzumab in HER2-positive, heregulin-positive, advanced and refractory breast cancer (NCT01097460).

HER2-targeted vaccines

Cancer vaccines designed to induce specific anti-HER-2 immunity are being investigated. Different strategies include protein-based vaccines, plasmid DNA-based vaccines, and vaccines that deliver HER-2 in a viral vector. HER-2 peptide-based vaccines have been tested in patients with metastatic HER-2 positive breast cancer^[80,81]. Patients immunized developed delayed-type hypersensitivity reactions and strong CD8⁺ cell responses specific for HER-2^[82]. A dendritic cell based vaccine was also tested in a small group of patients with stage IV breast cancer^[83]. One patient showed a partial response and three had stable disease for ≥ 12 mo. Using a different

strategy, cell-based GM-CSF secreting vaccines were tested in combination with trastuzumab^[84,85].

Pi3k/Akt/mTOR blocking drugs

PI3K/Akt/mTOR is an intracellular signal pathway that is frequently deregulated in breast cancer and mediates primary or secondary resistance to anti-HER-2 agents^[86]. A phase I study tested the combination of everolimus plus weekly paclitaxel and trastuzumab in 33 patients with heavily pretreated metastatic disease^[87]. Encouraging activity was reported, with an overall disease control rate at 6 mo of 74%. There are currently two ongoing phase III trials of everolimus in this setting: BOLERO-1 which assesses the combination of everolimus, trastuzumab, and paclitaxel as first-line therapy and BOLERO-3 which explores the addition of vinorelbine to everolimus plus trastuzumab in patients previously treated. With 569 patients completing the BOLERO-3 study, median PFS was 7.0 vs 5.78 mo in the placebo arm ($P = 0.0067$)^[88].

Histone deacetylase inhibitors

Histones acetylation status regulates the access of transcription factors to DNA and influences gene expression. Histone deacetylase (HDAC) activity reduces acetylation of histones. HDAC inhibitors induce growth arrest and apoptosis of tumor cells. Vorinostat is approved for cutaneous T-cell lymphoma. A phase II trial of vorinostat together with tamoxifen in patients with hormone therapy-resistant breast cancer showed that the combination is reasonably tolerated and exhibits activity in reversing hormone resistance^[89]. Clinical trials combining vorinostat with chemotherapy, EGFR inhibitors and bevacizumab are ongoing.

Heat shock protein 90 pathway

Heat shock protein 90 (Hsp-90) is a molecular chaperone that provides stability and supports the functionality of several proteins. Many of these proteins (*i.e.*, Bcr-Abl, c-Kit and PDGF- α) are pro-oncogenic. Sustained inhibition of Hsp-90 chaperone induces proteosomal degradation of the free proteins. HER-1 and HER-2 require chaperoning by Hsp-90 for their stability^[90]. Clinical data from a phase I trial with the Hsp-90 inhibitor tanespimycin used in combination with trastuzumab as second-line therapy showed evidence of antitumor activity in 63% of patients^[91]. A phase II trial enrolled 31 patients with HER-2 positive metastatic breast cancer whose disease has progressed on trastuzumab. Patients were administered weekly treatment with tanespimycin and trastuzumab. The ORR was 22% and the clinical benefit reached 59%^[92].

Other exploratory anti-HER-2 blocking strategies

Ongoing trials combining anti-HER-2 agents with drugs blocking other signaling pathways hold the promise of further improvement. An auspicious approach seems to be the combination of anti-HER-2 therapy with insulin growth factor receptor (IGFR-1) blocking agents.

IGFR-1 inhibition has been shown to restore sensitivity to trastuzumab in animal models^[93]. Another potential combination is the dual blockade of HER-2 and SRC which was recently shown to work as a central node downstream of multiple trastuzumab-resistance mechanisms^[94]. Finally, HER-3 is another strong activator of PI3K/Akt signaling pathway that has been demonstrated to be up-regulated after HER-2 blockade^[95]. Although still in early phases of development, Rb disruption strategies and the use of CDK-4/6 inhibitors may be clinically useful^[96].

CONCLUSION

We have recently witnessed an unprecedented expansion in the drugs developed to target HER-2 positive breast cancer. Transcendental advances were made and substantial improvements in all relevant outcomes and in all the clinical scenarios for either early or advanced disease were accomplished. However, patients still progress and cure for metastatic disease is still a utopia. We can only envision the arrival of newer and more sophisticated weapons to keep on fighting this lethal disease and we can already start asking ourselves some questions. Would neratinib, for example, soon become available? Could adotrastuzumab be ever used as a first line treatment? Can we make an anti-HER-2 drug with no cardiac effects? We will soon have some answers to these and many other questions, but up to that moment comes the state of the art management of HER-2 positive breast cancer relies on the more than 40 phase III and II clinical trials that were concisely described in the preceding pages.

Abstract

The population tends to consume foods that in addition to their nutritional values can offer some benefits to their health. There are many epidemiological evidences and research studies in animal models suggesting that diet plays an important role in breast cancer prevention or progression. This review summarized some of the relevant researches about nutrition and cancer during the last years, especially in breast cancer. The analysis of probiotics and fermented products containing lactic acid bacteria in cancer prevention and/or treatment was especially discussed. It was observed that a balance of fatty acids similar to those of traditional Mediterranean diet, the consumption of fruits and vegetables, dietary fiber intake, vitamin supplementation are, along with the intake of probiotic products, the most extensively

studied by the negative association to breast cancer risk. The consumption of probiotics and fermented products containing lactic acid bacteria was associated to reduce breast cancer risk in some epidemiological studies. The use of animal models showed the modulation of the host's immune response as one of the important effects associated to the benefices observed with most probiotics. However; future assays in human are very important before the medical community can accept the addition of probiotic or fermented milks containing lactic acid bacteria as supplements for cancer patients.

INTRODUCTION

The population tends to consume foods that in addition

to their nutritional values can offer some benefits to their health.

The WHO reported that approximately 30% of cancer deaths are due to five behavioral risk factors and diet, such as high body mass index, low fruit and vegetable intake, lack of physical activity, tobacco use, alcohol use^[1]

Breast cancer is a type of tumour in which there are many reports about the influence of nutrition^[2,3].

Lactic acid bacteria (LAB) represent a heterogeneous group of microorganisms that are present in the normal diet of many people and also in the gastrointestinal and urogenital tract of animals, and some of these claimed to be probiotics. Probiotics are defined as live microorganisms which when administered in adequate amounts, confer a health benefit on the host^[4]. These microorganisms and fermented foods containing LAB were growing in their popularity due to increasing numbers of studies proving that certain strains present health promoting properties, among them the prevention or treatment in the early stages of some types of cancers^[5,6].

The use of experimental animal models has a number of advantages in that the environmental conditions and genetics can be either controlled or defined. The value of the models is the insight they can provide into the complex, multi-faceted processes and mechanisms that can result in cancer development. *In vitro* assays are also important to understand the mechanisms of action involved in the LAB or other dietary effects. However, the application of dietary modifications against cancer needs to be ultimately tested in human trials.

This review summarizes some of the relevant researches about nutrition and cancer during the last years, especially in breast cancer. The analysis of probiotics and fermented products containing LAB in cancer prevention and / or treatment will be discussed separately, with emphasis in the possible mechanisms involved.

NUTRITION AND CANCER

Several studies have been demonstrated a relationship (either beneficial or harmful) between diet and development of different types of cancer^[7-9]. High fat diet, fiber consumption and vitamins are among dietary habits more reported by their association with cancer along with probiotic supplements, that will be discussed in a separately section.

Calorie restriction without malnutrition was associated to cancer prevention^[10]. This effect was related to the reduction in the activity of pro-aging pathways, inflammation in the pre-cancerous cells, and to the increase in the apoptosis of damaged cells.

Several epidemiological studies have been shown the relationship between increase consumption of high fat diet and the risk to develop cancer, such as kidney, stomach, lung, esophagus, colon and breast cancer. Colorectal cancer (CRC) is a tumour for which there are many studies that associate obesity with increased risk, especially in men^[11]. The exact mechanisms of this relationship

are still unknown, but metabolic syndrome, insulin resistance^[12], modifications in levels of adipocytokines^[13] seem to be implicated. The role of the microbiota in the maintenance of intestinal homeostasis, and its relationship with intestinal inflammation and colon carcinogenesis was also extensively studied^[14-16].

Dietary fat intake was also related to risk of ovarian cancer. It was suggested that higher intake of omega-3 may be protective, whereas high consumption of trans fat may increase risk of this cancer^[17].

The fiber consumption is another important component of the diet that was associated inversely with cancer risk, such as CRC^[18], nasopharyngeal carcinoma^[19], oesophageal cancer^[20].

The consumption of vitamins and mineral supplements are commonly used to prevent chronic diseases such as cancer. It was demonstrated that vitamin C (ascorbate) was selectively toxic to some types of tumor cells^[21]. Recently, it was reported a case in which the consumption of this vitamin decreased chemotherapy associated side effects^[22]. As regard to vitamin D, Bikle^[23] revised its relationship with different cancers and described that animal and cellular studies supported a role for vitamin D in the prevention and treatment of cancer, but the same conclusion was not arrived from clinical studies.

Folate is essential for DNA synthesis and methylation and its role against cancer is controversial, even against one type of cancer, such as for prostate cancer^[24]. Some studies implicated folates with tumour progression, such as the work reported by Dixon *et al*^[25] showing evidences that folate intake affects ovarian cancer survival. On other hand, the chemopreventive effect of folic acid was evaluated *in vivo* using rat as model for liver carcinogenesis. This effect was observed in association with tributyrin and was related to the potential to inhibit tumour angiogenesis^[26]. A recent review and meta-analysis showed that dietary folate intake was associated with a decreased risk of esophageal and pancreatic cancer, but not gastric cancer^[27].

NUTRITION AND BREAST CANCER

There are many epidemiological evidences and research studies in human and animals suggesting that diet plays an important role in breast cancer prevention or progression^[2,3]. Diet represents one of the most modifiable risk factors for breast cancer^[28]. Changes in the dietary patterns are not only related to less risk but also patients diagnosed and treated for breast cancer who pursue healthier dietary habits can improve their health and survival.

The relationship between obesity and breast cancer was reviewed in many articles because the high incidence and prevalence of both diseases. Overweight and obesity at the time of diagnosis were associated with a worse prognosis in breast cancer patients^[29]. A study in Italy showed that a diet high in glycemic load was associated with increased breast cancer risk^[30].

A systematic review showed that there are some strat-

egies to prevent weight gain that may decrease the risk of breast cancer or improve cancer outcomes in women with breast cancer^[31].

de Lorgeril and Salen suggested that a high omega-3 to omega-6 ratio, such as the case of traditional Mediterranean diet, reduce the risk of cancer, especially breast cancer^[32]. A cohort study of breast cancer survivors showed that intake of marine fatty acids EPA (eicosapentaenoic) plus DHA (Docosahexaenoic) was associated with improved prognosis^[33]. Omega-3 fatty acid, in particular EPA and DHA found principally in oily fish have been demonstrated to exert anti-angiogenic effects inhibiting production of different angiogenic mediators^[34]. The beneficial effect of EPA and DHA intakes was also associated by reducing inflammation through different mechanisms such as the suppression of NF- κ B, and the alteration of the plasma membrane micro-organization (lipid rafts)^[35].

Canola oil has also been associated with a reduced risk of breast cancer. The inhibition of cancer cells *in vitro* and the reduction of tumour volume in rats with chemical induced mammary tumour that consumed canola oil was reported^[36]. It was also suggested that canola oil can be used as prenatal nutritional strategies to reduce breast cancer risk in humans^[37]. This suggestion was based in results obtained *in vivo* using a chemical induced mammary tumour in offspring rats of canola-fed dams. These animals showed significantly decreased tumor volume with increased survival rate comparing to the control group whose mothers received control diet with soybean oil during pregnancy and lactation.

Diets rich in fruits and vegetables are also implicated in breast cancer risk reduction. A meta-analysis including fifteen prospective studies that reported decreased risk of breast cancer associated with fruit and vegetable intake, showed that high intake of fruits, and fruits and vegetables combined can be associated with reduction in risk of breast cancer^[38]. Similar results were obtained in a meta-analysis of prospective studies of blood concentrations of carotenoids and breast cancer risk^[39]. Carotenoid concentrations in blood can be used as biomarkers of fruit and vegetable intake and in this sense; the authors showed that blood concentrations of carotenoids were strongly associated with reduced breast cancer risk. Recently, an inverse association between citrus fruits intake and the risk of breast cancer was suggested^[40].

Dietary fiber intake was also inversely associated with breast cancer risk^[41]. The ingestion of dietary phytoestrogens may increase risk of estrogen receptor alpha (ER α)-positive breast cancer and this effect was associated with their estrogenic effects observed *in vitro* and *in vivo*. The proliferative effect of soy isoflavones was mainly observed in animal models of tumours. However; paradoxically, consumption of phytoestrogens has also been associated with reduced risk of breast cancer^[42-46]. This controversy with regard to the effect of soy isoflavones on breast cancer risk was analyzed and it was demonstrated that soy isoflavone phase II metabolism differs

between humans and rodents, and this should be taken in count to understand the value of the use of these rodents for investigate the effects of isoflavones in humans^[47]. Epidemiologic data indicate that soy intake is associated with a decreased breast cancer risk in Asia. A systematic review among women showed the possible protective effect of isoflavones on breast cancer risk^[48]. It was also demonstrated that soy isoflavone intake was associated with lower risk of recurrence among post-menopausal patients with breast cancer and those who were receiving adjuvant endocrine therapy^[49].

The understandings of the hormonal and non-hormonal mechanisms by which isoflavones can exert the beneficial effects were subject of many researches. The chemical structure of soy isoflavones is similar to that of estrogens. They are therefore considered to be possible selective estrogen receptor modulators (SERMs), which may bind to estrogen receptors and selectively stimulate or inhibit estrogen-like action in various tissues^[50]. It was demonstrated that sera of adult mice consuming soy isoflavone genistein (GEN) or blueberry (BB) polyphenol-containing diet altered mammosphere formation *in vitro* using receptor-positive and estrogen receptor-negative human breast cancer cell lines^[51]. Recently, this group demonstrated that breast cancer prevention by GEN was related to the regulation of mammary adiposity^[52]. The cytotoxic action of GEN against breast cancer cells involved mobilization of endogenous copper ions and generation of reactive oxygen species^[53].

Vitamin supplementation is another strategy, as was explained above, used to reduce cancer risk. With regard breast cancer, there was no found clear evidence of cancer prevention for vitamin supplements^[54]. Folates and folic acid were evaluated in breast cancer patients and also *in vivo* using animal models, and as was explained, the role of folates is controversial. There are epidemiological studies suggesting an inverse association between folate status and the risk of breast cancer^[55,56]. Some studies have also suggested that with alcohol consumption, folate supplementation reduces the risk of breast cancer^[57,58]. The beneficial effect associated to folate intake in some populations was associated to genetic polymorphisms of folate-metabolizing enzyme, methylenetetrahydrofolate reductase (MTHFR)^[59]. A population-based case-control study in Saudi Arabia showed that the MTHFR C677T polymorphism may modify the association between dietary folate intake and breast cancer risk^[60]. Similar results were obtained from the Shanghai Breast Cancer Study^[61] and in a case-control study in the Jiangsu Province of China^[62]. A recent work suggested that intake of natural folates can be inversely associated with breast cancer risk, but this association may vary by race, menopausal status or estrogen receptor status^[63]. The authors also observed an increased risk in European American women with the highest intake of synthetic folate from fortified foods. In this sense, a systematic review analyzed the effect of high folate intake post fortification, especially when folic acid was used, and demonstrated a higher risk of breast can-

cer in these populations^[64]. The authors showed the need to be cautious with high intakes of folic acid, especially in countries with mandatory food fortification, as Chile.

Animal models were used to understand the mechanisms by which folates and folic acid exert their effects, especially in breast cancer patients. Mammary tumors were chemically induced in rats and then, the animals received a diet containing different levels of folic acid^[65]. Folic acid supplementation was associated with significantly higher volume of mammary tumors and increased expression of BAX, PARP, and HER.

Riboflavin intake was also analyzed and an inverse association with breast cancer risk was documented^[66].

Selenium (Se) is an essential micronutrient having high anticancer properties in different animal models^[67,68]. As regard to breast cancer, it was demonstrated, using an animal model, that organic Se supplementation may reduce breast cancer metastasis, while selenite exacerbated it^[69].

Another dietary component (even though is minor in our diet) that was reported as effective against cancer is the inorganic sulfur. It was showed that inorganic sulfur significantly decreased proliferation of MDA-MB-231 human breast^[70]. This effect was due to reduction of ErbB2 and ErbB3 protein and mRNA expression, affecting the he ErbB-Akt pathway. Previously, it was reported that inorganic sulfur reduced cancer cell motility and invasion by inhibiting activity and mRNA expression of matrix metalloproteases (MMP-2 and MMP-9)^[71].

PROBIOTICS AND CANCER

Probiotic microorganisms and fermented foods containing LAB have been growing in popularity due to increasing numbers of studies proving that certain strains present health promoting properties, among them the prevention or treatment in the early stages of some types of cancers^[5,6,72].

The effects of probiotics and fermented products on intestinal disorders have been the most extensively studied considering that these microorganisms enter the organism orally and can positively modulate the intestinal microbiota involved in many of these disorders. The benefits of probiotics on the gut immune system in the prevention of cancer has also been previously described^[73,74]. There are many different mechanisms by which probiotics and fermented products containing viable LAB may lower the risk of colon cancer; among them, the modulation of the intestinal microbiota^[75-80], the inactivation of carcinogenic compound^[81-83], anti-oxidant effects^[84-86], and the modulations of the host's immune response^[87-89]. Recently, the administration of probiotic Dahi containing *Lactobacillus* (*L.*) *acidophilus* LaVK2 and *Bifidobacterium bifidum* BbVK3 alone or in combination of piroxicam showed anti-neoplastic and anti-proliferative activities in a model of DMH-induced CRC in rats^[90].

It was also demonstrated that oral administration of probiotic microorganisms can influence mucosal sites

different to the intestine due to the existence of the common mucosal immune system. In this sense, after intestinal stimulation, both B and T cells can migrate from Peyer's patches to mucosal membranes of the respiratory, gastrointestinal and genito-urinary tract, as well as to exocrine glands such as the lacrimal, salivary, mammary and prostatic glands^[91]. The oral administration of *L. casei* CRL 431 to mice induced an immune stimulation not only at the intestinal level, but also in bronchus and mammary glands^[92].

Beneficial effects of probiotic LAB administration were reported for non-intestinal tumors. The antitumor activity of *L. casei* CRL 431 was studied against a fibrosarcoma induced by methylcholantrene in mice. The administration of the probiotic strain inhibited tumor growth in a dose-dependent form^[93,94], stimulated the immune system with high levels of macrophage activation (the main infiltrative cells in the tumor), high levels of TNF α and with a remarkable decrease in tumor volume.

The effect of LAB or fermented products containing these microorganisms in non-intestinal tumours reported during the last years (2011-2014) were obtained searching the words "probiotic and cancer" in PubMed database.

It was reported the beneficial effect against cervical cancer. A pilot study suggested that probiotic promotes the clearance of HPV-related cytological abnormalities^[95]. Common vaginal lactobacilli exerted cytotoxic effects on cervical tumour cells independently of pH and lactate^[96]. *L. casei* displaying E7 antigen at its surface protected mice against human papillomavirus type 16-induced tumours^[97].

As regard hepatocarcinoma, the administration of probiotic fermented milk containing *L. rhamnosus* GG and, *L. casei* strain Shirota with chlorophyllin reduced liver pre-carcinogenic events in rat AFB1 induced liver carcinogenesis. This effect was attributed to an increased antioxidant status and decreased expression of oncogenes^[98].

The beneficial effects of LAB were also reported in animal models of oral cancer^[99], and skin carcinogenesis^[100].

PROBIOTICS AND BREAST CANCER

Breast cancer is another tumour in which there are reports about the beneficial effects of probiotic administration. Many reports analyzed, as was explained above, the association of soy based products and especially soy isoflavones with breast cancer risk. In this context, soy isoflavone ingestion was studied accompanied with the co-administration of probiotic bacteria, and it was observed that high concentrations of probiotics may alter the metabolism of isoflavones^[101]. Recently, the consumption of beverages containing *L. casei* Shirota and soy isoflavone was inversely associated with the incidence of breast cancer in Japanese women when they were consumed regularly since adolescence^[102]. The cooperative prevention mechanism of soymilk and *L. casei* Shirota was evaluated

Table 1 Examples of breast cancer animal models that have demonstrated the beneficial effects of lactic acid bacteria

Model	Results	Mechanisms	LAB	Ref.
4T1 tumour bearing mice	Significant decrease of tumour growth	Modulation of the host's immune response	<i>L. acidophilus</i> isolated from traditional home-made yogurt and from neonatal stool	[113]
Mice bearing invasive ductal carcinoma	Decrease of tumour growth rate and prolongation of mice survival	Modulation of the host's immune response	<i>L. casei</i> spp. <i>casei</i> ATCC 39392	[114]
4T1 breast cancer bearing mice	Tumor volumes of mice treated with Se nanoparticle-enriched probiotic were decreased and their survival rate increased compared to mice that received probiotic alone or control mice.	Modulation of the host's immune response	<i>L. plantarum</i> strain enriched with selenium nanoparticles	[115] [116]
Swiss mice fed a Westernized chow and FVB strain erbB2 (HER2) mutant mice	Inhibition of mammary neoplasia in both models.	LAB triggered CD4+CD25+ lymphocytes that convey transplantable anti-cancer protection.	<i>L. reuteri</i> ATCC-PTA-6475	
4T1 breast cancer bearing mice	Decrease of tumour growth in mice fed preventively with LAB and also in mice fed probiotic after tumour detection	Modulation of the host's immune response and decrease of tumour angiogenesis	<i>L. casei</i> CRL 431	[117]

LAB: Lactic acid bacteria.

using a rat carcinogenic model. It was observed that soy-milk prevented the development of mammary tumors and that *L. casei* Shirota suppressed tumor growth^[103].

In the West diet, fermented milks are more common as probiotic foods than soy based products. Milks fermented by different LAB and bifidobacteria strains (*B. infantis*, *B. bifidum*, *B. animalis*, *L. acidophilus* and *L. paracasei*) were evaluated *in vitro*, and the inhibition of the growth of a breast cancer cell line was reported^[104]. Other studies performed in humans, showed a negative association between yogurt consumption and breast cancer development^[105]. van't Veer *et al.*^[106] showed similar results in The Netherlands, and suggested that these effects would be related to changes in the intestinal microbiota (which could alter the metabolism of estrogen) and to the modulation on the immune system.

In addition to containing LAB, fermented milks can possess non-bacterial components produced during fermentation that may contribute to their anti-tumor activities^[107]. Thus, cultured dairy products can be proposed to inhibit the growth of many types of cancers, including breast tumors. In this context, milk fermented by *L. helveticus* R389 (a strain with high proteolytic activity) was studied comparatively with the milk fermented by a proteolytic deficient mutant, and both were able to delay tumour growth in an experimental breast cancer model using BALB/c mice^[108,109]. This effect was related to the immunoregulatory capacity of the fermented milks that decreased IL-6 levels, modulating the relationship between immune and endocrine systems. The important increase of IL-10 in mice fed with milk fermented by *L. helveticus* R389 could explain the difference between both fermented milks, attributed principally to the components released into the milk after the fermentation with the proteolytic strain, where the regulation of the immune response was observed in serum, mammary gland and also in the tumour infiltrating immune cells.

Kefir was another fermented product also evaluated in a breast cancer model in mice. Kefir and its cell-free fraction (KF) possess several substances that can exert beneficial effects on the immune system and prevent certain types of cancer^[110]. It was observed that mice receiving 2 d cyclical feeding with whole kefir diminished tumour growth, and the same cyclical feeding with KF showed the most significant delay of the tumour growth^[111]. This effect was related principally to a decrease in IL-6. KF caused not only a decrease of this cytokine but also a regulatory response with increased levels of IL-10 in all the samples studied. The results also demonstrated that the most important effect in this tumour model was due to substances released during milk fermentation (and not the microorganisms themselves)^[112].

Table 1 summarizes the effects reported for different LAB against breast cancer during the last years (2012-2014).

It was reported that *L. acidophilus* isolated from traditional home-made yogurt and also from neonatal stool induced a significant decrease in breast tumour growth pattern using a mouse model^[113]. This effect was associated to the alteration of cytokine production into a Th1 protective pattern.

L. casei spp. *casei* ATCC 39392 was also analyzed in a model of invasive ductal carcinoma in mice, and its administration decreased the growth rate of tumor and prolonged the survival of the animals. This effect was associated to the improvement of the host immune response by inducing Th1 cytokine profile and natural killer cells^[114].

The administration of selenium nanoparticle-enriched *L. plantarum* induced an efficient immune response in 4T1 breast cancer bearing mice. This effect was caused by the elevation of the pro-inflammatory cytokines IFN- γ , TNF- α and IL-2 levels and increased NK cell activity^[115].

The importance of the stimulation of host immune

cells by LAB and their beneficial effect against mammary carcinoma was analyzed using two mice models^[116]. In one model, mice were fed a Westernized chow increasing risk for development of mammary tumors. The other model consisted of FVB strain erbB2 (HER2) mutant mice, genetically susceptible to mammary tumors. Animals received *L. reuteri* ATCC-PTA-6475 in drinking water. It was observed that LAB oral supplementation inhibited features of mammary neoplasia in both models. The protective mechanism was associated to triggered CD4⁺CD25⁺ lymphocytes because when they were isolated and transplanted into other subjects conferred anti-cancer protection in the cell recipient animals.

Recently, our research group evaluated the effect of milk fermented by the probiotic bacterium *L. casei* CRL 431 on a murine breast cancer model. It was observed that the administration of this probiotic fermented milk stimulated the immune response against this breast tumour, avoiding or delaying its growth when it was preventively administrated and also when the administration started after tumour cells injection^[117].

CONCLUSION

There are many epidemiological evidences and research studies in animal models suggesting that diet plays an important role in breast cancer prevention or progression. A balance of fatty acids similar to those of traditional Mediterranean diet, the consumption of fruits and vegetables, dietary fiber intake, vitamin supplementation are, along with probiotic products, the most extensively studied. Although controversial data about isoflavones, epidemiological studies showed that the intake of soy based products in Asia was associated with decrease of breast cancer risk.

Probiotics and fermented products containing LAB have awakened the interest of many researches related to cancer and especially with breast cancer. Some epidemiological studies showed negative association between the consumption of these products and breast cancer development. Animal models were used to understand the possible mechanisms by which probiotic can exert the beneficial effects, and the modulation of the host's immune response was associated to the effects observed with most probiotics.

However, there are not enough human trials where the application of probiotics as biotherapeutics against breast cancer was tested. These assays are very important before the medical community can accept the addition of probiotic or fermented milks containing LAB as supplements for cancer patients.

Abstract

This critical review of the literature assembles and compares available data on breast cancer clinical stage, time intervals to care, and access barriers in different countries. It provides evidence that while more than 70% of breast cancer patients in most high-income countries are diagnosed in stages I and II, only 20%-50% patients in the majority of low- and middle-income countries are diagnosed in these earlier stages. Most studies in the developed world show an association between an advanced clinical stage of breast cancer and delays greater than three months between symptom discovery and treatment start. The evidence assembled in this review shows that the median of this interval is 30-48 d in high-income countries but 3-8 mo in low- and middle-income countries. The longest delays occur between the first medical consultation and the beginning of treatment, known as the provider interval. The little available evidence suggests that access barriers and quality deficiencies in cancer care are determinants of provider delay in low- and middle-income countries. Research on specific access barriers and deficiencies in quality of care for the early diagnosis and treatment of breast cancer is practically non-existent

in these countries, where it is the most needed for the design of cost-effective public policies that strengthen health systems to tackle this expensive and deadly disease.

Key words: Breast cancer; Early diagnosis; Delays; Time intervals; Clinical stage; Access; Health care delivery

Core tip: This review assembles the available data on breast cancer clinical stage for 10 high-income and 13 low-income countries and the time intervals from symptom discovery to cancer diagnosis and treatment for 33 countries. Most breast cancer patients in low-income countries suffer very long delays and are diagnosed in advanced stages. The scant available evidence for low and middle-income countries suggests that access barriers and quality deficiencies in cancer care are determinants of these delays.

Unger-Saldaña K. Challenges to the early diagnosis and treatment of breast cancer in developing countries. *World J Clin Oncol* 2014; 5(3): 465-477 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i3/465.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i3.465>

INTRODUCTION

The World Bank classifies countries according to their gross national income as low income, lower-middle income, higher-middle income and high income. Low- and middle-income countries (LMICs) are also sometimes referred to as “developing” economies, while high-income countries (HICs) are referred to as “developed”^[1]. The term does not imply either that all developing countries

Table 1 Countries with the highest breast cancer incidence and mortality rates^[3]

Country	Incidence rate	Country	Mortality rate
1 Belgium	111.9	1 Fiji	28.4
2 Denmark	105	2 Bahamas	26.3
3 France	104.5	3 Nigeria	25.9
4 The Netherlands	99	4 Pakistan	25.2
5 Bahamas	98.9	5 New Caledonia	24.4
6 Iceland	96.3	6 Armenia	24.2
7 United Kingdom	95	7 Lebanon	24.0
8 Barbados	94.7	8 Trinidad and Tobago	23.5
9 United States	92.9	9 Ethiopia	23.0
10 Ireland	92.3	10 Uruguay	22.7

21 Israel	80.5		
22 Sweden	80.4		

Incidence and mortality rates are number of cases and number of deaths, respectively, per 100000 women. Both measures are age-standardized.

are actually in the process of developing or that those in the developed group have necessarily reached some final stage of development^[1]. For global health care, this classification provides a useful framework to assess how the countries' available resources should be allocated to address the most relevant health issues^[2].

Breast cancer is the most frequent cancer in women worldwide, with 1.67 million new cases diagnosed in 2012^[3]. It is also the leading cause of cancer death among women, with approximately 500000 annual deaths^[3]. The highest incidence rates occur in the most developed regions of the world, with 74.1 new cases per 100000 women in comparison to the 31.3 new cases per 100000 observed in less-developed regions^[3]. Nevertheless, the mortality rates are actually higher in developing countries. Table 1 presents the countries with the highest breast cancer incidence rates (above 80 per 100000 women) and those with the highest mortality rates (above 20 per 100000 women) in 2012. As shown, the majority of countries with the top incidence rates are high-income countries (HICs), while the majority of those with the highest mortality rates are low- and middle-income countries (LMICs).

Cancer survival data are extremely scarce for developing countries, but the few data available are in line with the observed incidence/mortality differences. The 5-year survival rates for breast cancer are much worse for low- and low-middle income countries such as Gambia (12%), Algeria (38.8%), India (52%) and Brazil (58.4%) in comparison to HICs such as the United States of America (83.9%), Sweden (82.0%), Japan (81.6%) and Australia (80.7%)^[4,5].

The higher breast cancer mortality rates in LMICs are thought to be due to diagnosis in advanced stages and

access barriers to medical care^[6]. The limited data available for developing countries have made it difficult to determine how many more cases of advanced breast cancer are actually diagnosed in LMICs than in HICs. Even more rare are data from LMICs on time to care and access barriers. The purpose of this review was to assemble and compare the available data on the clinical stage, time intervals and access barriers across different countries to identify the main challenges in the early treatment of breast cancer in developing countries.

A critical review of the literature was conducted of quantitative studies published in English, Spanish, or Portuguese in the last 15 years that reported breast cancer clinical stage, time intervals and/or access and quality barriers associated with delayed cancer care. The PubMed and SciELO electronic databases were searched for "breast cancer" combined with each of the following terms: "clinical stages", "survival", "delay", "time intervals", "help seeking behavior", "access", "barriers"; plus one of the subsequent terms: "developing countries", "limited resource", "low income" or "middle income". For data on clinical stage, Google searches were also performed, using the terms "breast cancer" and "clinical stages". Additionally, references from relevant studies were used to trace other studies. The search was updated to December 2013. All articles relevant to clinical stage, time intervals and access and quality barriers were included, as they are scarce, particularly those performed in developing countries, which were the most relevant to this analysis.

This review presents information on clinical stage, which was collected from 20 studies or registries providing data for 10 HICs and 13 LMICs. Evidence on the time intervals to care is summarized for 33 studies that

gathered data for 10 HICs and 23 LMICs. Finally, the data from 26 studies on access barriers to care are presented, of which only three studies took place in LMICs.

ADVANCED CLINICAL STAGE OF BREAST CANCER IN LMICs

The clinical stage at breast cancer diagnosis remains one of the most important prognostic factors of survival^[7]. The most accepted classification is the TNM staging system developed by the American Joint Committee on Cancer (AJCC)^[8]. The estimated 3-year survival rates for high-income countries such as Canada, Sweden, Norway, Denmark and the United Kingdom are between 99.3 and 100.0% for patients diagnosed in stage I, 91.5% to 96.4% for stage II, between 69.0% and 83.0% for stage III, and 27.4% to 41.8% for distantly spread disease (stage IV)^[9]. Another staging classification that is sometimes used is that proposed by the United States National Cancer Institute of Surveillance, Epidemiology, and End Results (SEER) Program. This system considers three stages: (1) localized, for tumors confined to the breast with no extension to the lymph nodes (equivalent to TNM stages I and II A); (2) regional, when breast cancer has disseminated to the regional lymph nodes (equivalent to stages II B, III A, III B and III C); and (3) distant, when cancer has spread to distant organs (TNM stage IV)^[10]. The reported 5-year survival rates for 317340 patients who were diagnosed between 2003 and 2009 in the United States SEER regions were 98.6% for localized stage cancer patients, 84.4% for regional stage patients and 24.3% for distant stage patients^[10].

Table 2 summarizes the clinical stage data reported for different countries. As shown, while the majority of breast cancers are diagnosed in localized stages in HICs, most are detected in regionally spread stages in LMICs. In HICs, more than 70% of breast cancer patients are diagnosed in stages I and II; Sweden and Norway have proportions above 90%. In contrast, in LMICs, only between 20 and 60% of patients are diagnosed in these earlier stages, while between 30 and 80% are diagnosed in stages III and IV. The exceptions in the table are Porto Alegre in Brazil and white women in South Africa, who behave similar to women in developed countries, with 70% and 68% of breast cancer cases detected in stages I and II, respectively. The data presented for the different regions or subpopulations in Brazil, South Africa and India reveal tremendous disparities within each of these countries. Similar differences have been reported in the United States, the United Kingdom and other developed countries and have been shown to be a result of socioeconomic disparities, as will be discussed in detail later on. These inequities are revealed in this table only for these particular cases because the data available for developing countries come from country-regions or even hospitals, while the data for most HICs were gathered through national registries and thus constitute a single measure for the entire population.

The question remains as to why cancer patients are di-

agnosed in such advanced stages in developing countries. Research on this matter is scarce. Most study findings in the developed world show an association of advanced clinical stage of breast cancer with delays greater than three months between symptom discovery and treatment start (total delay)^[11-13]. Additionally, delays greater than three months are associated with reduced survival^[12,13]. A reasonable explanation of the relationship between delay and survival is that delay influences disease progression, which in turn affects survival. This hypothesis is supported by studies in which the association between delay and survival disappears once clinical stage is controlled for^[12,14].

TIME INTERVALS FOR BREAST CANCER CARE

Traditionally, breast cancer total delay has been defined as more than three months between symptom discovery and the beginning of cancer treatment and has been classified in two types: patient delay and provider delay^[15-18]. Patient delay refers to the lengthening of the interval between the discovery of symptoms and the first medical consultation, and the most accepted threshold to establish it is three months. Provider delay is that which takes place between the first medical consultation and the beginning of definitive treatment, and the threshold used to define it is highly variable between studies. Table 3 summarizes the data for the total, patient and provider intervals reported in different countries. The median lengths of the intervals are reported when available and, in the absence of medians, some mean intervals and/or percentages of delays greater than three months are reported.

Diverse classifications and names of the provider interval have been used. The most commonly used are the diagnosis and treatment interval classifications. The diagnosis interval is that from the first medical consultation to the confirmation of a cancer diagnosis. The treatment interval is the time between diagnosis and the beginning of oncologic treatment. Two other classifications have also been used: (1) the doctor (from first consultation with the primary physician to the first investigation of cancer) and system (from the first investigation to the beginning of cancer treatment) intervals; and (2) the referral (from the first medical consultation with the primary physician to the patient's referral to the specialist) and specialist care (from the patient's referral to the beginning of cancer treatment) intervals^[19]. These two last classifications (doctor/system, and referral/specialist) are rarely used, although the names are commonly used interchangeably in reference to the provider interval. They have been properly used only in health systems with well-organized primary and secondary care services, such as those of the United Kingdom and Denmark. They would be extremely difficult to measure in the context of fragmented health services or a lack of registries and electronic medical records, as is the case for the majority of developing countries. For the sake of clarity, despite the delay

Data are population-based, except for the following countries where data is hospital-based: Brazil, Colombia, Egypt, India, Iraq, Libya, Malaysia, Mexico, Nigeria, Peru, South Africa and Thailand. All percentages were corrected to exclude Non-Staged cancers.

nomenclature used in each study, the terms presented in Table 3 are those that correspond to the definition that was used. When this was not possible, only the definition is shown and not the term used by the researchers.

To further complicate things, a wide range of methods has been used to measure time points and intervals, with the majority of existing studies lacking methodological rigor^[20,21]. As a result, research findings are not easily comparable between studies and countries. Nevertheless, to obtain a rough idea of the differences in intervals of care between developing and developed countries, data from all the retrieved studies were included.

Among HICs, the median total intervals range between 30 and 48 d, and more than 60% of patients begin treatment less than 3 mo after symptom discovery (Table 3). In comparison, the median total intervals for LMICs are between 5.5 mo (Malaysia) and 8 mo (Brazil), and for countries with available data (Brazil, Libya, Mexico and Malaysia), it is striking that fewer than 30% of patients start treatment in less than three months after abnormal screening or

symptom discovery^[22-27].

The median patient interval is between 7 and 16 d for HICs and between 10 d and 3 mo for LMICs. The lengthiest median patient intervals have been reported for Iran (3 mo), Egypt (2.7 mo) and Malaysia (2 mo)^[26,28,29]. Among countries that report mean instead of median intervals, including Eastern European countries, India and Ethiopia, the average patient interval is between 24 d (Hungary) and 1.5 mo (India) for all except Ethiopia, which reports a striking 18-mo patient interval mean.

Finally, available provider intervals or subintervals are also presented in Table 3. It is hard to compare these because of the diverse definitions used. The full provider interval is only reported for one HIC, Germany, with a median duration of 15 d. In contrast, the median provider intervals in LMICs, which are available only for Brazil, Colombia, Mexico and Turkey, range between 2.6 mo and 6.5 mo. The median diagnosis intervals for the HICs of France and the United States are 7 and 32 d, respectively, while that for the LMIC Brazil is 6.5 mo^[24,30,31]. Notably,

¹These correspond to mean intervals, instead of medians. Patient interval is not defined in the table because studies coincide in the accepted definition: symptom discovery or abnormal screening to first medical consultation.

the median patient interval in LMICs is between 1.4 and 12.9 times longer than that observed in HICs, and the diagnosis interval is between 3.8 and 27.9 times longer. The patient interval prolongation is primarily influenced by the patients' help-seeking behavior, which varies according to different socioeconomic and cultural factors. In turn, the delayed provider intervals most likely reflect access barriers and quality deficiencies in cancer care in the LMIC health systems, as has been observed in some of the few available studies^[32-36].

ACCESS BARRIERS AND QUALITY OF CARE DEFICIENCIES ASSOCIATED WITH DELAYED BREAST CANCER TREATMENT

Access to health care is a multidimensional concept that has

been defined as the “degree of fit” between a patient's socioeconomic characteristics, the health system, and health services organization^[37], and it includes both financial and non-financial dimensions^[38-41]. Five different components of access have been described: affordability, acceptability, accessibility, accommodation, and availability^[37]. Availability refers to the adequacy of the supply of health providers, facilities and services in relation to the patients' health needs. Accessibility is the relationship between the geographical location of services and that of patients (*e.g.*, transportation resources, travel time, distance and cost). Accommodation is the relationship between the manner in which the supply resources are organized to accept patients (*e.g.*, operation hours, appointment systems, telephone services), the patients' ability to accommodate these factors, and the patients' perceptions of their appropriateness. Affordability is the relationship between

the prices of services and the patients' ability to pay and/or existing health insurance. Finally, acceptability refers to the patients' beliefs, perceptions and attitudes in regard to the characteristics of health personnel and facilities (*e.g.*, doctor's gender or ethnicity, clinic type), as well as the health personnel's attitudes about the acceptable personal characteristics of the patients.

Table 4 summarizes different factors related to access or quality of care deficiencies that have been associated with breast cancer provider delay. As shown, there is little research on this matter, and the vast majority of studies have taken place in developed countries. Furthermore, the predominating focus has been to quantify associations between the patients' socio-demographic characteristics and delays, without exploration of specific access and quality of care issues that could explain these relationships.

Socioeconomic status (SES) has long been linked to morbidity, mortality, illness behavior, health services utilization and access to care^[42-44]. SES differences in health are embedded in the larger problem of health disparities associated with social disadvantage^[44]. As SES decreases, breast cancer clinical stage has been shown to increase and 5-year survival rates to decline^[45,46]. These associations have been confirmed for several measures of SES, including income, education and occupation. SES has a direct impact on the access dimension of affordability^[37]. Therefore, a plausible explanation for the disparities of breast cancer clinical stage and survival is that people

with low SES suffer longer provider delays than people with high SES, as documented^[47,48], most likely because they face access barriers to health care that remain to be identified and are most likely specific to each health system.

The relationship between ethnicity and provider delay may also be mediated by lower socioeconomic status and reduced access to medical care. Black people in the United States have poorer breast cancer survival rates than whites (79.1% *vs* 91.7%), and these gaps persist within clinical stages^[10]. These ethnic disparities in breast clinical stage have been shown to dissolve when controlling for socioeconomic position^[49,50]. Additionally, the relationship between ethnicity and provider delay has been shown to disappear when poverty and insurance status are controlled for^[51]. Moreover, a study that examined the influence of ethnicity, socioeconomic position and gender on an individual's perception of the need for and urgency or seeking health care found that Black respondents and respondents from lower socio-economic groups were at least as likely to report immediate health care seeking as White respondents and those from higher socio-economic groups^[52]. These findings suggest that the ethnicity differences observed in provider delay are very likely due to socioeconomic disparities that influence access to care.

Access to health insurance is also related to socioeconomic position and has long been known to be one of the most relevant enabling factors for health care utilization^[39,53]. Therefore, it is not surprising that lack of health

insurance is related to provider delay for breast cancer care^[54]. This might be particularly important in countries with fragmented systems, where the uninsured population has access to only certain types of health services (availability and accommodation) and/or has to pay out-of-pocket for each consultation, medical study and treatment (affordability).

The relationship between age and delay is very interesting. Older age has been found to be associated with patient delay in several studies^[11,17], while younger age has been linked with provider delay^[47,55-58]. Several mechanisms have been proposed to explain the association between older age and patient delay. Studies conducted in developed countries have suggested that older women may attribute early breast cancer symptoms to other comorbid conditions or to normal aging^[11,16]. Likewise, older women may be more fatalistic, thinking they have lived long enough^[16]. Study findings have also confirmed that delay in these older patients could be a consequence of negative attitudes toward seeing their general practitioner and fears about the consequences of the diagnosis and treatment of cancer^[59]. The relationship between older age and provider delay has been less studied, and the plausible mechanisms of this relationship have not been explained^[54]. Nevertheless, some of the mechanisms discussed for patient delay might also occur after the first medical consultation has taken place, when the patient might decide to postpone studies and/or the beginning of treatment. Another possible mechanism includes the tendency for older people to be affected simultaneously by other chronic conditions in addition to cancer, such as hypertension or diabetes. In these cases, the physician might postpone cancer treatment until the other comorbidities are stable. Yet another mechanism that is particularly relevant for developing countries is that older women may face more access barriers to health care because of unemployment and its consequences on the lack of health insurance and socioeconomic problems.

The relationship between young patient age and provider delay is most likely a consequence of medical errors. The majority of studies that have found a significant association between young age and delay have failed to explore the mechanisms behind this relationship^[47,60]. Some studies, however, have suggested that young age increases the difficulty of a medical diagnosis^[58]. The sensitivity of mammography has been found to be significantly lower in young women than older women (68 vs 91 percent), and tumors have been found to be more ill-defined for palpation because of background mammary density or a diffuse growth pattern^[61]. Additionally, the suspicion of a cancer diagnosis may be less common among young patients than their older counterparts^[55]. The presentation of breast cancer is highly unlikely in women younger than 40 years, with an estimated risk for a 30-year-old woman of 0.44 to develop a breast cancer in the next 10 years in comparison with a risk of 3.84 for a 70-year-old woman^[10]. To further complicate things, breast benign conditions such as fibroadenoma and cysts

are very common in young women^[62,63].

Travel time to the hospital, distance from the patient's home to the hospital, long waiting times for medical appointments and the consultation of 3 or more different health services before arriving at a cancer hospital reflect different dimensions of access to care: accommodation, availability and affordability^[37]. The study of these types of specific access barriers is scarce and much needed in developing countries where delays for cancer treatment and other life-threatening conditions are very common. For each country's health system, and even each health service within countries and country regions, specific access barriers need to be identified in order to address them and improve time to care.

Finally, the associations found between provider delay and type of first health service contacted, the medical specialty of the first provider that was consulted and medical errors all reflect differences in the quality of care that patients receive. Medical errors in relation to provider delay have been studied in terms of the primary care physician's failure to suspect cancer at the initial consultation^[33,35], false-negative interpretations of mammography^[31,48,64,65] and false-negative biopsy interpretations^[48,64]. The relationships reported between the specialty of the first doctor consulted and provider delay as well as that of the primary care physician's failure to suspect cancer highlight the relevance of the role of the first medical professional consulted. This is very pertinent for developing countries, where highly specialized human resources are scarce and the first contact for the majority of the population is a general physician, that is, a recently graduated medical doctor (NOT a specialist in General Medicine). The majority of these doctors have never seen breast cancer and are typically not familiar with breast cancer screening and diagnostic guidelines.

IMPLICATIONS FOR PUBLIC POLICY IN LMICs

As the limited available data for LMICs presented here show, breast cancer is being treated in very advanced stages after long intervals of time. This is most likely because patients in these countries face significant access barriers to quality health care. The situation may be even worse for countries in which there are no data available. As Indraneel Mittra well points out in his interesting discussion about the global applicability of cancer screening recommendations, "the real unresolved problem of cancer control in developing countries is how to make accessible to the population at large the minimum level of cancer care that will reduce mortality and suffering^[66]". A common proposed solution is to enhance early detection through mammography screening. However, as I will argue, this is most likely not the right path to follow for LMICs.

Organized population-based mammography programs have been adopted as the gold standard of early detection in the majority of HICs. Many LMICs are

trying to follow this example, even if they lack the infrastructure and human and financial resources to implement programs of this magnitude. Therefore, they are typically ending up with opportunistic screening mammography programs that are not only inequitable^[67], more expensive and less effective than organized screening^[68,69] but also make it harder to assure test quality and access to adequate diagnosis and treatment^[70].

In recent years, the benefit of screening mammography has been seriously questioned^[71-74]. There is evidence from several HICs that most of the reductions in breast cancer mortality that have occurred since the national mammographic screening programs began are not attributable to mammographic screening but to improved adjuvant therapy^[75-81]. A recent Cochrane Systematic Review showed no effect of screening on either cancer mortality after 10 years or on all-cause mortality after 13 years^[74]. Additionally, over-diagnosis and consequent over-treatment have been reported to occur in approximately 30% of screen-detected breast cancers^[82,83].

If the benefit of screening mammography is questionable in HICs, it should be more so in LMICs. The World Health Organization has suggested that for a mammography screening program to be effective in the reduction of mortality, it needs to cover at least 70% of the population at risk^[84], which is a very difficult coverage to reach, even for HICs. Furthermore, for HICs, it has been estimated that for every 2000 women 50 years and older screened throughout 10 years, one breast cancer death will be avoided, and 10 healthy women who would not have been diagnosed if there had not been screening will be treated unnecessarily; more than 200 women will experience distress because of false-positive findings, and approximately half of them will undergo an unnecessary biopsy^[74,85]. These estimations were calculated considering HIC incidence rates and under the assumption that screening reduces breast cancer mortality in 15% of patients and has a 30% rate of over-diagnosis and unnecessary treatment. Considering that the incidence of breast cancer in LMICs is much lower and that the peak incidence occurs at a younger age, the benefits of screening mammography in LMICs are likely to be lower than in HICs, while the costs required to establish an organized screening program are most likely unaffordable for many LMICs^[70]. Some screening mammography pilot programs in LMICs have actually been shown to be ineffective and unsustainable on a larger scale because of a lack of resources^[86,87].

In the context I have presented here for breast cancer care in LMICs, with most breast cancer cases diagnosed at advanced stages and long times to diagnosis and treatment due to access barriers and substandard quality of care, the benefit of a screening program is even more questionable. Screening is useless if access to adequate diagnosis and treatment cannot be assured. The Breast Health Global Initiative Guidelines recommend that a population-based screening mammography program should not be implemented until access to the basic can-

cer diagnosis and treatment resources is guaranteed^[88].

A more cost-effective strategy could be early diagnosis or down-staging, which has been endorsed for LMICs by the World Health Organization and the Breast Health Global Initiative^[84,86,89]. The early diagnosis approach consists of the promotion of the awareness of early signs and symptoms among the public, the education of first-line health professionals and improved referral procedures to facilitate the prompt and adequate diagnosis and treatment of breast cancer in early stages.

A successful example of a down-staging program was performed in Malaysia^[90]. The program consisted of training 400 first-line health personnel in hospitals and rural clinics to improve their skills in early detection and of raising public awareness through visual information and sensitization by trained health personnel. After four years of program implementation, late-stage (III and IV) breast cancer cases were reduced from 60% to 35%^[90].

Although there is still not sufficient evidence regarding the benefits of down-staging programs, the World Health Organization and the Breast Health Global Initiative Guidelines recommend them as the most basic breast cancer early detection strategy to implement and strengthen in low-resource settings before moving on to consider mammography screening^[84,86,89]. After reviewing the evidence of advanced clinical stage and prolonged times to treatment in LMICs, it is evident that much more than just screening remains to be done to improve breast cancer mortality rates. There are serious problems in access to health services, the strength of the first level of care for the early detection of symptomatic patients, the regulation of establishments where breast imaging tests are performed, and the faulty or absent delineation of referral pathways to cancer care. Programs directed at improving these problems, which are widespread in LMICs, are likely to be much more cost-effective and have an impact in a shorter term than attempting to establish population-wide mammography screening programs in low-resource settings.

CONCLUSION

This review assembled sufficient evidence to argue that the lower breast cancer survival rates observed for LMICs in comparison to HICs are due to diagnosis in much more advanced stages. Although there is scant information on the length of care intervals, which are incomparable in many cases, the presented data provide sufficient evidence to state that breast cancer patients in LMICs suffer long diagnosis and treatment delays, and this is most likely why they present in such advanced stages. In contrast to what has usually been assumed, the greatest delays in LMICs are not attributable to patients delaying care. The longest delays appear to occur after the first medical consultation has taken place, and they are likely the result of access barriers and substandard quality of care. Research on access barriers and quality of care for the diagnosis and treatment of breast cancer is practi-

cally non-existent for LMICs, where it is most needed. To strengthen the capacity of each country's health system(s) and health services for the early diagnosis and treatment of cancer, specific barriers need to be identified throughout the entire cancer care trajectory. Such knowledge could enable individualized designs of public policies and programs for each country, region, city or even health facility that are likely to be more effective and affordable for LMICs than attempting to implement expensive and complex screening mammography programs, which are currently proving to be more harmful than beneficial, even in HICs.

Abstract

Nipple-sparing mastectomy (NSM) is a safe technique in patients who are candidates for conservation breast surgery. However, there is worry concerning its oncological safety and surgical outcome in terms of post-operative complications. The authors reviewed the literature to evaluate the oncological safety, patient selection, surgical techniques, and also to identify the factors influencing postoperative outcome and complication rates. Patient selection and safety related to NSM are based on oncological and anatomical parameters. Among the main criteria, the oncological aspects include the clinical stage of breast cancer, tumor characteristics and location including small, peripherally located tumors, without multicentricity, or for prophylactic mastectomy. Surgical success depends on coordinated planning with the oncological surgeon and

careful preoperative and intraoperative management. In general, the NSM reconstruction is related to autologous and alloplastic techniques and sometimes include contra-lateral breast surgery. Choice of reconstructive technique following NSM requires accurate consideration of various patient related factors, including: breast volume, degree of ptosis, areola size, clinical factors, and surgeon's experience. In addition, tumor related factors include dimension, location and proximity to the nipple-areola complex. Regardless of the fact that there is no unanimity concerning the appropriate technique, the criteria are determined by the surgeon's experience and the anatomical aspects of the breast. The positive aspects of the technique utilized should include low interference with the oncological treatment, reproducibility, and long-term results. Selected patients can have safe outcomes and therefore this may be a feasible option for early breast cancer management. However, available data demonstrates that NSM can be safely performed for breast cancer treatment in selected cases. Additional studies and longer follow-up are necessary to define consistent selection criteria for NSM.

Key words: Breast reconstruction; Skin-sparing mastectomy; Nipple-sparing mastectomy; Outcome; Complications; Silicone breast implants; Tissue expanders; Oncoplastic surgery

Core tip: In selected patients, nipple-sparing mastectomy (NSM) has allowed an adequate oncologic control with satisfactory aesthetic outcome. In addition, utilizing the native breast skin optimizes the aesthetic outcome of the reconstructed breast and minimizes post-mastectomy deformity. The satisfactory results are due to a close collaboration with the oncological surgical

team in terms of incision selection and mastectomy flap dissection. In general, choice of reconstructive procedure requires careful consideration of various patient related factors, including: breast volume, degree of ptosis, areolar size, patient preference and expectation, and surgeon experience. With careful patient selection and well-planned surgical technique, NSM can provide satisfactory outcomes with acceptable complication rates. However, available data demonstrate that NSM can be safely performed for breast cancer treatment in selected cases. Although NSM reduces the psychological trauma associated with nipple-areola complex resection, the oncologic safety as well as functional and aesthetic outcomes needs additional investigation. Thus, additional clinical studies and longer follow-up are necessary to define consistent selection criteria for NSM.

INTRODUCTION

Early breast cancer treatment has advanced greatly in recent years. The introduction of skin-sparing mastectomy (SSM) technique has improved the aesthetic outcome of oncological breast surgery and immediate reconstruction^[1]. In fact, breast reconstruction following mastectomy can result in a prominent scars and a paddle of skin that is of a different color. Thus, the SSM involves en-bloc resection of the glandular tissue, nipple-areola complex (NAC), and the skin overlying superficial tumours^[2-5]. Simultaneously, the native breast skin envelope and infra-mammary fold are preserved therefore facilitating the reconstruction procedure. Utilizing the breast skin envelope optimizes the contour of the breast, resulting in a satisfactory aesthetic outcome and minimizing scarring and post-mastectomy deformity^[6-9].

Recently, an argumentation has advanced about the opportunity of extending conservation of the skin to include the NAC^[10-29]. In fact, although breast reconstruction following SSM may offer aesthetic advantages over mastectomy, removal of the NAC significantly impacts on the aesthetic outcome. Some surgical techniques have been developed to repair the NAC, including local skin flaps, skin grafts, and nipple-sharing procedures^[30,31]. However, different surgical stages are usually necessary to achieve an acceptable aesthetic result and sometimes with an unpredictable outcome^[30-32]. In one clinical series, Jabor *et al.*^[32] evaluated the satisfaction following NAC reconstruction and observed that almost 36% of patients mentioned dissatisfaction.

First described by Freeman in the 1960s as a subcutaneous mastectomy with NAC sparing, the author indicat-

ed the technique for benign diseases, however he did not report the procedure for oncological objectives or as a risk-reduction alternative^[10,11]. Recently, there has been an increase in clinical experience studies of NSM for breast cancer prophylaxis or early cancer treatment, evidencing revived interest in this surgical procedure^[12-30,33-44]. In fact, there is evidence that NSM provides aesthetic advantages, with reduced need for further surgery and NAC reconstruction^[15,17,20-22,29,33-39,44-48]. However, it is important to emphasize that most of these clinical series do not have sufficient follow-up, thus definite conclusions based on the present data is precipitated. In addition, to date there have been no controlled clinical trials evaluating the oncological effectiveness of nipple-sparing mastectomy (NSM) *vs* traditional SSM surgery. In spite of the controversies involving risk of local relapse, some current clinical studies have shown that the NSM is a safe procedure for selected cases^[11,14-16,18,23-27,29,30,33-39,44,47,48].

LITERATURE SEARCH/DATA EXTRACTION

Two independent reviewers have evaluated titles and abstracts without language restrictions to assess eligibility in terms of outcome measures and study design. A literature search was carried out up to October 2013 to identify studies of breast cancer patients submitted to NSM and determine if any technique of immediate reconstruction was recorded. In an attempt to minimize the omission of potentially relevant clinical studies, we also reviewed the reference lists of included studies and relevant reviews for additional eligible articles. Potential studies were identified by searches of MEDLINE and PubMed databases using the terms “Nipple-Areola Sparing Mastectomy”, “Total Skin-Sparing Mastectomy”, “Subcutaneous Mastectomy” and “Immediate Reconstruction”. Studies identified were screened for those that focused on techniques, surgical and oncological outcomes after NSM reconstruction and references of each study were further investigated to include all relevant published data. All types of reconstruction techniques were included (tissue expander, implant, autologous tissue, and combination of methods) and compared.

A total of 440 potential articles were identified during the primary evaluation. After appraisal of the inclusion criteria, 265 articles were identified for potential inclusion and reviewed in detail. A total of 150 articles were excluded, leaving 109 articles to form the basis of this review.

ONCOLOGICAL ASPECTS

Oncological safety/patient selection

The main criteria include the clinical stage of breast cancer and tumor aspects^[11,15,27,37-39]. From the oncological point of view, the NAC is resected because of the traditional concept that the adjacent ducts may contain tumor cells and the possibility of local recurrence^[40,41].

In addition, some clinical series observed that nipple involvement in mastectomy specimens ranges from 0% to 58%^[12,38,42-54] (Table 1). One might surmise that this wide range is chiefly due to divergences in techniques used for pathology tests of the breast specimens, differences in technique and subgroup of patient populations. In fact, early anatomical studies proposed by Sappey described a centripetal lymphatic drainage toward the areolar plexus, thus justifying the rationale of NAC resection^[15,44]. Contrarily, recent anatomical studies demonstrated a lymphatic drainage to the deep pectoral plexus^[44,55,56].

Concerning the clinical aspects, recent studies have noted that the risk of tumor involvement of the NAC has been magnified^[38,41-43]. Thus, some clinical series have demonstrated that the NSM is a safe technique for some group of patients^[11,14-16,18,19,23-27,29,30,33-39,44,57]. In fact, some studies have considered NSM safe in patients with peripherally located tumors, small, without multicentricity, or for risk reduction^[24]. Although there is no unanimity regarding the selection criteria, the major part of studies include tumor size up to 3 cm, lack of clinical involvement of the NAC and tumor to nipple distance greater than to 2 cm. In addition, patients with clinical axillary node involvement; whose tumors are centrally located; who have inflammatory breast cancer, or Paget disease are not candidates for NSM.

In a clinical experience of 286 SSM specimens, Laronga *et al*^[38] observed that 5.6% were found to contain tumor in the NAC and did not define significant differences between groups regarding tumor size and histological subtype. However, sub-areolar tumor location and multicentricity were important risk factors for NAC involvement. Based on these findings, the authors observed that in patients with negative axilla and tumors situated on the periphery, the probability of an occult tumor is less than 2%. Similarly, Vyas *et al*^[42] in a clinical series of 140 mastectomies analyzed whether NAC correlated with areola-tumor distance, tumor size, nodal status and lymphatic embolization. In this sample, the authors also observed tumour size and nodal positivity as a potential risk factor for NAC involvement. Correspondingly, Simmons *et al*^[43]

analyzed 217 mastectomy specimens and evaluated tumor involvement of the NAC. Concerning the NAC involvement, the overall frequency was 10.6% and comparisons of patients with tumors < 2 cm with tumors ≥ 2 cm did not present a significant difference. The authors observed that only 6.7% of small tumors with up to two positive lymph nodes only had NAC involvement. For tumors located in central quadrants, the NAC was involved in 27.3% of cases. Contrarily, for those located in any of the four quadrants, the NAC was compromised in only 6.4% of cases. Gerber *et al*^[57] in a series of 112 NSMs, evaluated patients whose tumors were more than 2 cm from the NAC. The frozen sections of the subareolar tissue were negative for tumor in 54.5% of cases, thus enabling NAC preservation. During the follow-up, 5.4% local recurrences (LR) occurred in patients who underwent SSM compared with 8.2% of 134 patients who had undergone conventional mastectomy during the same follow-up. Regolo *et al*^[19] in a clinical study of 219 mastectomies observed that 20% of NACs were compromised by tumor, consisting of 9.4% of stage 1-2 tumors and 30% of stage III tumors. Concerning the tumor location, the NAC was compromised in 2.5% of peripheral tumors and in 68% of central quadrants. The authors failed to observe any cases of local relapse in patients undergoing NSM after an average of 16 mo follow-up (Table 2).

Caruso *et al*^[16] indicated NSM in patients with tumors that were peripherally situated. Their study included 50 patients with a 12% overall recurrence rate. Similarly, Sacchini *et al*^[18] evaluated patients who had NSM with reconstruction for either risk reduction, treatment of cancer, or both. With a median follow-up of 24 mo, two breast cancer patients and two patients who had NSM for prophylaxis presented a local recurrence outside of the NAC. Based on this clinical experience, the authors concluded that the risk of local relapse is low and the procedure is feasible in the risk-reducing and breast cancer-treatment.

Munhoz *et al*^[33] evaluated 158 consecutive patients submitted to NSM. In almost 35% of patients the procedure was indicated for cancer prophylaxis including high-risk lesions, prophylactic, familial history and carriers of the *BRC11* or *BRC42* mutation. In the remaining breast cancer patients, almost 75% of tumors measured 2 cm or less (T1) and the majority were stage 0 and I. Similarly as observed by other authors, the present study also included a few stage III breast carcinomas; however in the preoperative period these patients were staged as earlier-stage carcinoma^[9,58]. Additionally, the authors excluded patients with NAC infiltration, NAC bleeding or with the tumor at less than 5 cm from the NAC. Considering these parameters, the authors believe that NSM is feasible with low local recurrence. With a mean follow-up of 65.6 mo, local recurrence rate was 3.7% and the incidence of distant metastases was 1.8%.

In a comprehensive review, Tokin *et al*^[24] observed that the local recurrence following NSM was between 0%-20%, with studies varying widely in inclusion criteria and follow-up period. Boneti *et al*^[26] reported in a series

Table 2 Clinical outcome and local recurrences following nipple-sparing mastectomy

Babiera <i>et al</i> ^[107]	2010	54	0-III	15	0	0
Benediktsson <i>et al</i> ^[105]	2008	216	0-III	156	0	8.5
Munhoz <i>et al</i> ^[33]	2013	158	0- II	65.6	0	3.7

of 281 NSM with 25.3 mo mean follow-up, a 4.6% local recurrence rate. Jensen *et al*^[27] published results from 149 patients without local recurrences at a mean 5-years follow-up.

In a recent review, Mallon *et al*^[59] quantified the incidence of occult NAC cancer and identified the factors influencing occult nipple malignancy, local recurrence rates, and complication rates. According to the authors, the overall nipple (0.8%) and flap (3.4%) recurrence rates were similar to those reported after mastectomy and conservative breast surgery. However, care must be taken to distinguish that follow-up periods for NSM clinical studies are briefer than those for mastectomy and partial mastectomy. For definitive conclusions, a longer and similar follow-up is necessary, as the greater part of recurrences occur within 5 years.

Therefore, it would appear oncologically safe to perform NSM, provided the tumor is not close to the NAC, small, peripherally located, without multicentricity and a frozen section protocol is performed. Although various clinical series including SSM and NSM aided in the selection of patients for NSM using tumor to NAC distance values, the ideal tumor to NAC distance has yet to be clarified, since the total number of patients analyzed in these clinical series is insufficient and requires validation^[41,59]. Additionally, patients must be informed that NAC resection may still be necessary if residual tumor is identified on frozen sections of the subareolar tissue or definitive histology.

Timing: One stage x two stage approach

NSM may be planned in one setting with immediate reconstruction (one-stage approach)^[39,57,60], or in two settings with partial glandular resection or NAC autotomization followed by additional breast tissue resection and total reconstruction weeks to months afterwards (two-stages approach)^[30,34,39,61-65].

Preoperative planning should include the breast ptosis and volume and mostly addressing singular reconstructive requirements, enabling each patient to receive an individual “custom-made” planning. In addition, an in-depth discussion concerning alternatives for NSM reconstruction should be undertaken with the patients and her family, including the risks and positive aspects of one vs

two-stages approaches.

One-stage approach: With one-stage approach both procedures (breast cancer treatment/risk reduction and reconstruction procedures) are associated in one operative setting. Additionally, the emotional benefit of having begun reconstruction at the time of NSM procedure may decrease the impact of the loss of the breast. In fact, Sahin *et al*^[60] in a series of 21 bilateral prophylactic NSM due to higher risk for cancer indicated the one stage approach and simultaneous breast reconstruction using submuscular silicone implants. According to the authors, better projection and shape may be achieved with serial expansion of the submuscular pocket, but this has to be weighed against the morbidity associated with two surgical procedures. In their clinical experience, a one-stage procedure using high-profile implants resulted in very good projection while avoiding the morbidity of a second surgery.

Other centers indicated both approaches according to the quality and the width of the remaining breast skin flap. Chen *et al*^[30] in a series of 115 NSM evaluated the risks and benefits of the procedure associated with immediate breast reconstruction. In all patients, reconstruction with tissue expander or silicone implant was performed immediately following the NSM. Of the 66 patients, 58 underwent tissue expansion followed by implant placement in a two-stage reconstruction (87.9%) and eight patients underwent one-stage reconstruction (12.1%). According to the authors, nineteen patients had wound-healing problems. Full and partial necrosis of the NAC was not associated to initial expander volume but was more prevalent in thin flaps and larger breasts.

Although NSM and immediate implant reconstruction can be accomplished in a single stage, this is not the first option in some cancer centers^[30]. In fact, Chen *et al*^[30] emphasized that with two the stage approach it is possible to have a better control over the NSM skin flap. First, some aspects relating to implant asymmetry can be treated at the time of the second stage. Second, by limiting the volume of the expander such that the skin flap is not redundant but also not under tension, the risk of necrosis is reduced. Finally, patients usually desire a volume change, and starting the reconstruction with a two stage

approach allows the surgeon to customize the outcome to patient preference.

In spite of these aspects, for some group of patients the one-stage approach can be advantageous. In fact, patients with small breasts, without ptosis and cardiovascular clinical diseases are the best candidates for one-stage NSM. Caruso *et al.*^[16] considered NSM in patients with small to moderate-sized breasts with moderate to minimal ptosis and a healthy breast skin. Similarly, in a systematic review Endara *et al.*^[39] examined current trends with NSM, including selection criteria, incision choice, and reconstructive techniques. In the major part of the cases, NSM requires no skin resection, however with increasing breast volume (> 500 g) or breast ptosis, higher rates of NAC or breast skin flap necrosis are expected. In addition, low BMI and minimal ptosis were consistently used to screen patients for NSM in these studies.

Conversely, with the one-stage approach the surgical time can be lengthened and potential complications of the NSM (*e.g.*, skin/NAC necrosis, dehiscence, infection) can adversely influence the postoperative outcome. In addition, the procedure can be compromised by positive margins, especially in the sub-areolar region. In fact, Mallon *et al.*^[59] in a recent comprehensive review demonstrated that the greater part of the NSM studies performed biopsy of the retroareolar tissue separately from the mastectomy specimen. Concerning the technique, some studies used frozen section analysis, however, this technique has a false-negative rate as high as 8.7% according to the present review. Therefore many cancer centers await definitive pathologic evaluation of sub-areolar specimens before deciding on NAC resection. Thus, it is advocated that all patients submitted to one stage therapeutic NSM have a retroareolar sampling. In addition, these patients must be informed that the NAC may need to be ultimately resected if result of the retroareolar biopsy is compromised.

Two-stage approach: With two-stage approach, the surgical process is less extensive than NSM and immediate reconstruction in one operative setting. Some patients are so distressed by their cancer diagnosis, that they are not able to cooperate in reconstructive decisions. Additionally, some potential complications of the NSM and reconstruction techniques (*e.g.*, skin necrosis, dehiscence, infection) can unfavorably defer the adjuvant therapy. However, while the rationale for this approach is reasonable, the addition of a different surgical stage may introduce possibilities for complications^[65].

First proposed by Palmieri *et al.*^[66], the two-stage concept of delayed NSM had the objective of complete removal of all breast tissue, including the lactiferous ducts. According to the authors, the first stage involves NAC autonomization by performing a periareolar incision to detach the ductus from the nipple. The second stage is then performed 2-3 wk later. The authors observed one case of NAC necrosis that occurred during the NAC autonomization, delaying the NSM for 6 wk to allow

complete revascularization with a satisfactory outcome. Similarly, Jensen *et al.*^[67] indicated the two-stage approach with NAC surgical delay in 20 patients who were at high risk for NAC necrosis following NSM. The authors performed the delay technique 7-21 d prior to NSM mastectomy. Sub-areolar biopsy was performed at the time of the delay procedure and if the biopsy revealed malignancy, the NAC was removed at the time of NSM. All of the NAC survived and in 2 patients the subareolar biopsy was positive and 3 NAC were removed.

Another important point is related to the possibility of another stage to improve the aesthetic outcome^[30,34]. In fact, Blechman *et al.*^[34] in a series of 55 NSM performed in 29 consecutive patients evaluated the technical aspects and outcome. After tissue expansion the implant volume can be selected during the second stage without causing flap tension. Also, this strategy provides an opportunity to refine the breast contour such as by fat grafting.

In the greater part of the clinical series, NSM are related to patients with relatively small, minimally ptotic breasts or for risk reduction^[14,39,61,62]. However, the NSM reconstruction of large and/or ptotic breasts poses a more troublesome challenge than the NSM of small sized breasts because of an excessively large skin flap^[33]. In addition, the Wise-pattern skin excision best addresses this excess skin but is associated with a high incidence of flap necrosis with subsequent reconstruction failure^[22,33]. Munhoz *et al.*^[33] in a series of 158 patients submitted to NSM observed a significantly higher incidence of complications in the obese and larger specimen group. This aspect can be partially explained by a decreased perfusion of the relatively large skin flaps that result from SSM in much larger breasts. According to the authors, after adjusting for other risk factors (BMI, weight of breast specimen), the probability of complications tends to be higher for the Wise pattern with superior pedicle incision approaches.

Although large breasts and severe ptosis may represent a contraindication for NSM, surgical strategies based on the two-stage concept were planned to correct the ptosis followed by NSM in a second stage. Introduced by Spear *et al.*^[61] the NSM staged procedure includes patients with large or ptotic breasts and candidates to NAC preservation. In fact, the authors observed that although there are breasts that are too large to be considered for a NSM, it is possible to extend the indications by using the two stage approach and reducing the breast volume and ptosis previously. Thus, the main objective in these sub-group of patients is to preserve the oncological objective of the NSM (therapeutic or risk reduction) while expanding the aesthetic outcome and minimizing complications. For this objective, some authors divided the one-stage Wise-pattern skin excision into a two-stage procedure^[61,63,64]. In the first stage, the mastopexy or reduction mammoplasty is performed, keeping periareolar dermis preserved to maintain the adequate NAC blood supply at the time of the future definitive NSM. At the time of the

Figure 1 Schematic representation of nipple-sparing mastectomy incisions. A: Radial lateral incision; B: Periareolar with lateral extension; C: Hemi-periareolar (superior and inferior); D: Transareolar; E: Circumareolar (periareolar total); F: Periareolar with vertical extension; G: Circumareolar (periareolar total) with vertical extension; H: Wise-pattern mastectomy.

second stage, care must be taken to guarantee consistent flap thickness in order to avoid damage to the skin flap blood supply.

Liu *et al.*^[63] in a series of 12 patients achieved successful outcome using the two staged Wise-pattern excision. In the first stage, the NSM and reconstruction were performed using a vertical excision. In the second stage, the redundant skin at the inframammary fold was excised, tightening the breast skin envelope vertically. According to the authors, the addition of the two staged incisions recreates the Wise pattern, breaking up the T point into two straightforward primary closures. Similarly, Spear *et al.*^[61] reported a successful two-stage NSM in 15 patients (24 breasts). All patients underwent NSM after mastopexy or reduction (71% prophylactic and 29% therapeutic) with an average follow-up of 13 mo. Four of the 24 operated breasts (17%) presented a complication. Besides the satisfactory outcome, it is important to emphasize that although the two-stage NSM is acceptable in the prophylactic group, patient selection is somewhat more complex in the group with breast cancer. Thus, the two-staged procedure must be correctly planned so that it does not significantly delay the oncological treatment in this patient population. Yacoumettis^[64] in a retrospective study of 52 patients evaluated the results of bilateral subcutaneous mastectomy for breast cancer prophylaxis. All reconstructions were completed in two-stages with tissue expanders followed by textured gel filled silicone implants. According to the authors and during the average follow-up of 7.2 years, no cases of invasive cancer were observed, and the aesthetic outcome was considered satisfactory.

Thus, the two-stage concept can be, in theory, advan-

tageous when compared to the one stage NSM. However, as we observed in any procedure this approach can present some limitations. The main negative aspects are related to some technical difficulties, *i.e.*, scar tissue and fibrosis. Additionally, the procedure can be time consuming and demanding additional costs, which can represent some limitations to the insurance coverage and resource implications for community hospitals.

Incision selection

Numerous incisions have been described by a variety of designs incorporating a periareolar approach, or other variations in the shape around the NAC^[11-16,18-22,30,33-37,39,59,61,63,66-68]. Although the incision types vary with configuration, the impasse of the access incision with no complications has drawn attention in the great part of the studies^[20,25-28,30,33] (Figure 1).

A critical survey shows that the procedure is normally performed by numerous approaches, but the greater part more than one type of incision is performed^[11-16,18-22,30,33-37,39,59,61,63,66-69]. In fact, Endara *et al.*^[39] analyzed 48 NSM studies, of which 41 described details related to the type of NSM incision. A total of 15 diverse approaches were described and the greater part of the studies (70%) more than one type of incision was indicated. According to the authors, the most common incision described were radial, followed by periareolar, inframammary, mastopexy, and transareolar (Figures 2-4).

The radial incision is one of the most performed techniques for NSM. Endara *et al.*^[39] reported that this incision represented almost 46% of all incisions performed. Stoler *et al.*^[20] in a series of 82 NSM for risk reduction and cancer treatment described that the most

Figure 2 Nipple-sparing mastectomy/inframammary incision. A and B: A 44-year-old patient with an invasive ductal carcinoma in the right breast (1.4 cm) and a familial history of breast cancer; C and D: Nipple-sparing mastectomy preoperative planning was based on a bilateral through a inframammary approach and immediate reconstruction with biodimensional implant-expander (Allergan 150 SH, 285 cm³). Intraoperative frozen sections demonstrated nipple-areola complex free of tumor; E and F: Five years postoperative appearance with a very good outcome.

common incisions utilized were related to the radial incision and a lateral incision beginning from outside the NAC. According to the authors, this incision allowed an adequate exposure to all regions including the axillary tail and the internal thoracic vessels for free flap anastomosis. Colwell *et al*^[70] performed an inferolateral approach with the incision located in the lateral quadrant. Similarly, Chung and Sacchini evaluated NSM incisions, which the greater part associated the periareolar to the radial incisions^[65]. The same group reported NSM through different incisions and the periareolar incision with lateral extension was used in 42% of cases^[11]. The authors mentioned a satisfactory exposure as advantages of the use of the radial extensions. Compared to other incisions, complications were observed in 67% of cases with an inferior lateral incision (inframammary fold extended

laterally). Wijayanayagam *et al*^[71] in a series of 64 NSMs performed in 43 patients evaluated the technical aspects and surgical outcome. Using different types of incisions, the authors observed that the radial incision provided the best approach and had the greatest likelihood of maintaining viable NAC without necrosis, which was observed in almost 97% of the sample. Despite the benefits, some authors do not advocate this approach due to aesthetic disadvantages. In fact, this technique creates a scar that is especially visible in the oblique and profile views^[60].

The periareolar incisions are the second most performed techniques for NSM. In fact, Endara *et al*^[39] reported that the periareolar approach represent almost 27% of all incisions performed for NSM. The main benefits are related to scar camouflage with a more satisfactory outcome. Despite its advantages, the periareo-

Figure 3 Nipple-sparing mastectomy/superior periareolar incision. A and B: A 52-year-old patient with *in situ* multifocal carcinoma in the right breast (4.8 cm) and atypical hyperplasia in the left breast; C and D: The patient underwent a bilateral nipple-sparing mastectomy through a superior periareolar incision and sentinel lymph node biopsy; E and F: The oncological procedure was immediately followed by a bilateral pedicled transverse rectus abdominis myocutaneous flap reconstruction. lar incision is not adequate for all patients candidate to NSM. In fact, the more suitable indication is in patients with small breasts with an adequate areola diameter. A limited exposure and difficulty in breast flaps dissection are commonly observed in small areola patients and inexperienced breast surgeon. For patients with large areola diameter without breast ptosis, a hemicircumareolar incision is usually indicated. Another important indication is the presence of a marked color transition between the NAC and the breast skin and small/medium volume breasts (cup size A-B). Sahin *et al*^[60], in a series of prophylactic NSM usually indicated the periareolar incision for small-breasted patients. According to the authors, the NSM and the reconstruction are performed through this incision, extending circumareolar or semicircular in the lower half of the NAC. Rivolin *et al*^[35] in a series of

22 patients submitted to NSM evaluated the benefits of the periareolar approach associated with mastopexy for patients with ptotic breasts. All patients in the periareolar group were submitted to a one-stage reconstruction, while a two-stage approach was selected in 20% of patients. The complication rate was higher in the periareolar group, although the difference did not reach significance. Despite the satisfactory outcome, the mastopexy technique was inadequate if repositioning the NAC was more than 3 cm or in sufficiently large reductions to reduce excess skin. In women with larger and more ptotic breasts, Chen *et al*^[30] advocated the omega-type elliptical incision. Similar to the periareolar incision with lateral extension, the omega-type approach gave the surgeon wide access to the breast regions and axilla.

Besides the limited exposure, the periareolar incision

Figure 4 Nipple-sparing mastectomy/superior periareolar incision. A and B: A 56-year-old patient with invasive ductal carcinoma of the left breast (2.3 cm); C and D: The patient underwent a left nipple-sparing mastectomy with a superior periareolar incision and sentinel lymph node biopsy. The oncological procedure was immediately followed by a free deep inferior epigastric perforator flap reconstruction; E and F: Five years postoperative appearance with a very good outcome. The superior periareolar incision was converted to a total circumareolar incision in order to achieve a better symmetry during the second stage of reconstruction.

can result in an impairment to blood supply, which can induce NAC necrosis. In fact, Regolo *et al*^[19], in a series of 32 NSM utilizing the periareolar incision observed a high rate of complications of the NAC (60%). Consequently, Munhoz *et al*^[21] developed an approach to improve the surgical exposure based on total circumareolar incision. This technique was based on the double concentric periareolar incision to resect the glandular tissue, while maintaining the vascularization of the NAC through the subdermal vascular plexus. In addition, the authors advocated de-epithelializing the whole periareolar incision to allow for triple-layer closure of the wound. Therefore, no part of the suture lines present only one layer, thus lessening the risk of breast implant exposure.

The inframammary incision is the third most performed approach for NSM. According to Endara *et al*^[39]

the inframammary technique represents almost 20% of all incisions performed for NSM. Blechman *et al*^[34] in a clinical series of 55 NSM through a lateral inframammary incision performed in 29 consecutive patients evaluated the technical aspects and outcome. The authors indicated the lateral IMF approach for a variety of breast volumes, and were able to place different volumes of implants. According to the authors, the benefits are related to hiding the scar and the incision is the furthest from the NAC and thus it is the least likely to threaten its vascular stability. In addition, rotating the IMF incision laterally facilitates easier access to the sentinel lymph node biopsy. Contrarily, Chen *et al*^[30] in their review of a series of 115 NSMs evaluated the risks and benefits of the procedure associated with immediate breast reconstruction. The IMF approach was indicated for patients with smaller

breasts. Stoller *et al*^[20] observed that the inframammary fold incision was uncertain. According to the authors, surgical access to the recipient vessels may be problematic, making this incision more adequate to implant reconstruction. In addition, they reported an inaccurate dissection around the NAC and in the upper quadrants. Similarly, Wijayanayagam *et al*^[71] in a series of 64 NSMs performed in 43 women observed that the inframammary incision provided a large exposure. However, they were concerned about the ability to access the upper quadrants in patients with large breasts and limited this incision to patients with very small breasts. Thus, the authors recommended using an incision of at least 10 cm because the larger incision enables easier eversion of the skin for improved visualization of sub-areolar region. Saliban *et al*^[30] analyzed 118 NSMs in 80 consecutive patients and observed that patients with different breast sizes underwent inframammary approach, except those patients who had very large breasts or those who requested a breast lift.

Contrarily, some authors avoid the inframammary fold incision due to the technical limitation to dissect the upper pole breast tissue and inadequate resection^[20,30,33,36,60,70]. In fact, Chen *et al*^[30] observed that although the inframammary incision allows a better final position of the scar, the resection of glandular tissue superiorly could be more challenging. Additionally, in some cases the authors believe that it is difficult to place the incision on the right position once the final implant volume is decided at the end of the surgery^[33]. Besides these limitations, some authors believe that the inframammary incision could impair the inframammary blood supply^[36,72]. Proano and Perbeck compared skin blood supply in patients having either an inframammary approach or a lateral lazy S incision using laser Doppler and fluoresceinometry^[72]. In a series of 69 patients, they observed a significant reduction in flow to an area of skin 2 cm below the NAC in the group submitted to inframammary approach.

The mastoplasty incision has been previously described for planning SSM/NSM in ptotic breasts^[1]. Classified by Carlson *et al*^[5,6] as a Type IV, it involves breasts that require a reduction of the skin flap and offers a wide exposure^[22,33,39,73-76]. According to Endara *et al*^[39] the mastoplasty approach represents almost 4% of all incisions performed for NSM. The main benefits are related to a better surgical access in patients with large breast and moderate/severe ptosis. Another potential advantage is related to reduction of the skin envelope and the dead space between the skin and the implant. Rusby observed that a limited volume of fluid collecting between skin flaps and reconstruction allows the preserved skin to redrape over the breast mound to a variable and uncontrolled extent^[75]. In fact, by reducing the skin flap, such that it is closer to the breast mound size, movement is reduced.

Munhoz *et al*^[33] reported that almost 35% of the patients were submitted to the mastoplasty incision. The superior pedicle and inferior pedicle techniques were indicated for moderate ptosis and severe ptosis cases respec-

tively. In spite of the main benefits, this technique has some limitations since the lateral and medial skin flaps that close down to the inframammary fold may become ischemic, and implant exposure can be observed^[33,74,75]. Another negative aspect is related to the relative lack of space in the inferior and medial aspects of the submuscular pocket. It is possible to release the inferior aspect of the pectoralis muscle, however a subcutaneous pocket could become an implant exposed, in the situation of an ischemic NSM flap^[22]. According to Toth and Lappert^[1], this aspect is critical and not rare if the general surgeon during dissection needs to leave very thin poorly vascularized NSM flaps. Thus, the technique requires close collaboration between the oncologic and reconstructive surgeons. In higher risk patients or severe breast ptosis, Munhoz *et al*^[33] preferred the inferior pedicle technique since the well-vascularized pedicle provides a stable soft-tissue cover for the implant, which protects against exposure. Similarly, Nava *et al*^[22] in a series of 28 patients with ptotic breasts proposed a combined flap technique to reconstruct by use of anatomical silicone implants. After preoperative planning, a large area in the lower half of the breast was deepithelialized according to the conventional Wise pattern.

Skin flap and NAC complications

In spite of the NSM advantages, the outcome is not always predictable. Surgical concerns are related to increased complications such as wound healing problems or ischemic necrosis^[19,24-29,33]. In fact, one of the most problematic complications of NSM is skin flap and NAC necrosis, which can lead to unsatisfactory aesthetic result (Table 3) (Figure 5).

Early reports on the NSM technique described high rates of complications^[18,28,30,57]. Gerber *et al*^[57] in one of the first clinical series of NSM evaluated the NAC outcome in 61 patients. The authors observed that 9.8% of patients presented partial nipple necrosis with no cases of total necrosis. Komorowski *et al*^[28] observed a 7.9% incidence of total nipple necrosis and a 5.3% of partial nipple loss. In 2006, Sacchini *et al*^[18] observed necrosis of the nipple in 11% of the sample and it was judged minimal in 59% of patients. Munhoz *et al*^[33] identified patient and breast related factors that increased complication rates. Concerning the NAC outcome, the majority of NAC demonstrated some degree of immediate ischemia manifested by coolness. However, the NAC skin survived in almost 95% of cases and partially survived in 4.4%. In these cases, the NAC developed epidermolysis/partial-thickness necrosis and most of these healed conservatively.

Previous studies have reported some risk of skin flap/NAC necrosis^[20,24-30,33,36,39]. Although comparing NAC necrosis rates between different populations, techniques and experiences can be challenging, most studies report rates from 0 to 19.5%^[23,25]. As techniques have improved, the rates of local complications have been reduced to satisfactory levels^[19-22,24-27,33]. Some authors advo-

Figure 5 Local complications following nipple-sparing mastectomy. A: Inferior periareolar incision with partial wound dehiscence; B: Superior periareolar incision with partial nipple areola complex necrosis; C and D: Wise pattern incision with partial mastectomy and nipple areola complex necrosis; E and F: Inframammary incision with partial mastectomy necrosis.

cate the use of lateral incisions, avoidance of periareolar incisions which require more skin traction, limiting dissection beyond the lateral aspect of the anterior axillary line and over the sternum to preserve blood supply to the skin flap, and the use of scissors to avoid thermal lesion^[11,44]. In addition, the option of the adequate surgical approach is critical and depends on previous scars, tumor location, breast volume, degree of ptosis and NAC anatomy. Although large studies are necessary to evaluate the best incision type, reduced NAC necrosis have been described with radial areolar incisions^[20,36,39,71,76].

In a recent review, Endara *et al.*^[39] evaluated the incision type and outcome following NSM. Based on 48 clinical studies in a pooled analysis, the authors reported similar rates of NAC necrosis between radial and inframammary incisions (8.83% and 9.09%, respectively) but an increased rate of necrosis following periareolar

approaches (17.81%). In this review, the transareolar incision presented the highest incidence of nipple necrosis (81.82%). Based on the results of this review, the preferred incision is either the inframammary fold or the radial with a lateral extension.

Contrarily, Munhoz *et al.*^[33] observed that the type of incision was not significantly predictive of complications in univariate analysis. However, after adjusting for other risk factors (BMI and weight of specimen), the probability of complications tends to be higher for hemipariareolar and Wise-pattern superior pedicle incision. In addition, they observed a lower incidence of NAC necrosis with the double circle incision technique. This aspect is probably due to the full access along the inferior border of NAC, which seems to allow adequate blood supply to the NAC. The authors believed that besides the limited access, the hemipariareolar technique can

Munhoz <i>et al</i> ^[33]	2013	158	1	8

potentially result in vascular impairment to blood supply due to traction, which can induce partial necrosis. In fact, Regolo *et al*^[19] in a series utilizing the periareolar incision observed a high rate of necrotic complication of the NAC, which they abandoned in favor of a lateral incision. Similarly, Stoller *et al*^[20] reported no cases of nipple necrosis when using a lateral or radial incision and Chung *et al*^[65] found adequate postoperative NAC viability by using a periareolar and lateral skin incision or an inframammary approach.

Some authors suggest that clinical co-morbidities are relevant risk factors for complications^[5,6,28,33,77-82]. Komorowski *et al*^[28] analyzed such factors and concluded that age below 45 years is associated with a reduced risk of necrosis. Contrarily, Munhoz *et al*^[33] did not observe age as a significant factor for NAC necrosis. However, in an univariate analysis the authors showed a significantly higher incidence of complications in the obese, hypertensive and larger specimen group. In fact, the deleterious effect of obesity on breast reconstruction was previously studied^[77,78,80]. One might suppose that increased BMI may predispose the flap necrosis due to the compromised sub-dermal plexus brought about by the increased surface of the flap^[83]. In addition, obese patients are likely to have additional complications due to associated vascular disease. Similarly as observed by Wooderman *et al*^[79], the authors observed that specimen weight more than the mean weight seems to be associated with statistically significant odds ratios to develop complications^[33]. This aspect can be partially explained by a decreased perfusion of the relatively large skin flaps that result from SSM in much larger breasts.

RECONSTRUCTIVE ASPECTS

In general, the NSM reconstruction are related to autologous and alloplastic techniques and sometimes include contra-lateral breast surgery. Various reconstructive techniques have been described, and aesthetic outcomes of NSM reconstruction continue to be met with variable satisfaction rates. Choice of reconstructive technique requires consideration of numerous patient related factors, including: breast volume, degree of ptosis, areola size, pa-

tient preference and expectation, clinical factors, smoking and surgeon experience. In addition, tumor related factors include size, location and proximity to the skin and NAC. Regardless of the fact that there is no unanimity regarding the best procedure, the criteria are determined by the surgeon's experience and the anatomical aspects of the breast. The main advantages of the technique utilized should include low interference with the oncological treatment, reproducibility and long-term outcome.

During a NSM, the NAC is preserved and incisions are located in more aesthetically regions. The breast volume, consisting of the breast tissue and fat, is entirely removed and reconstruction of the breast skin is not necessary. Thus, the objectives are to repair contour, volume and position.

In a recent systematic review, Endara *et al*^[39] examined current trends with NSM, including the reconstructive options. Based on 48 clinical studies that met the inclusion criteria, yielding 6615 NSM, the authors observed that 2373 (45.5%) were two-stage expander to implant, 2126 (40.7%) were one-stage direct to implant, and 719 (13.8%) were autologous tissue.

Autologous reconstructions involve pedicle flaps such as the latissimus dorsi myocutaneous (LDMF) or transverse rectus abdominis myocutaneous (TRAM) flaps. Although these techniques presents positive aspects some limitations have arisen regarding the muscle resection^[83-88]. Thus, alternatively free tissue transfer including the deep inferior epigastric perforator (DIEP), pedicled thoracodorsal perforator flap (TAP), free TRAM or the gluteal artery perforator (GAP) flaps can be indicated with a lower donor site morbidity. In fact, the DIEP flap diverges from abdominal myocutaneous flaps with maintenance of well-vascularized tissue and total abdominal muscular and aponeurotic layer preservation^[89-94]. Mosahebi *et al*^[83] in a series of 61 NSM reconstructions compared alloplastic and autologous tissue in terms of aesthetic outcome and satisfaction survey. According to the authors, all three reconstruction methods (implant, LDMF and DIEP) achieved good evaluation scores. However, in patients who had adjuvant radiotherapy, tonometry demonstrated that the breast remained softer in DIEP flap reconstruction.

In spite of the positive aspects, the outcome following SSM and NSM reconstruction with autologous tissue is not frequently predictable^[39,95-97]. Utilizing autologous tissue and particularly free flaps require special considerations in terms of recipient vessels and a monitoring skin flap. Preoperatively the plastic surgeon should evaluate the incision approach, the recipient vessels and the width of the remaining skin flaps for adequate skin preservation. Munhoz *et al*^[8] in a series of SSM DIEP reconstructions utilized five different incision approaches. According to the authors, the criteria decision was based on the breast anatomy (volume, ptosis and areola), the biopsy incision and the tumor location. The periareolar incision was the second most common incision selected and the restricted surgical exposure and difficulty in DIEP

anastomosis were the main negative technical aspects. Thus, a correct selection of a suitable recipient pedicle is decisive for a successful outcome^[90,92-94]. In NSM, the use of internal thoracic recipient vessels can be troublesome since the surgical exposure is restricted^[8,95]. Thus, longer instruments and the use of endoscopic lighting are necessary^[95]. In this situation, some authors advocated the peri-areolar approach with a lateral extension to obtain a better exposure^[94,95]. In addition, some authors advocate that use of the internal thoracic vessels may result in a higher rate of NAC necrosis compared with using the thoracodorsal vessels^[39,95]. Yang *et al.*^[95] in a series of 92 NSM free flap reconstructions utilized the internal mammary vessels if the mastectomy flap did not restrict the access. The authors observed that the thoracodorsal vessels were indicated in 59 cases, and internal mammary vessels in 33 cases including 4 cases with perforators of the internal thoracic vessels. In a selected group of patients, the internal thoracic branches can be used as an alternative to the internal mammary pedicle. The main advantages are sparing the internal mammary vessels and decreasing the operative time by limited dissection. However, Munhoz *et al.*^[92] reported that the internal thoracic branches are potentially available in only 55% of patients, therefore, this should not be the first option as recipient site.

Although autologous tissue presents advantages, it is not adequate in all cases especially in those without donor areas. In these cases, alloplastic techniques are usually indicated, and involve two-stage approach with tissue expanders followed by silicone gel implant replacement or one-stage reconstruction with conventional silicone implants. Although NSM reconstruction can be performed in a single stage, this is not the standard practice in several cancer centers^[39]. Enthusiasts of single-stage reconstruction promote lower costs, however supporters of the two-stage approach advocate a second operation to improve symmetry and the unpredictability of the NSM flaps. Chen *et al.*^[30] evaluated reconstruction with tissue expander or silicone implant performed immediately following the 115 NSM. Of the 66 patients, 58 patients underwent tissue expansion followed by subsequent implant placement in a two-stage reconstruction (87.9%) and eight patients underwent one-stage reconstruction (12.1%). The authors advocate that with two-stage reconstruction, it is possible to achieve the maximum control over the skin flap and by limiting the volume of the tissue expander such that the skin envelope is not redundant, the risk of ischemia is reduced. In addition, future aspects relating to NAC position, asymmetry and implant asymmetry can be managed at the time of the replacement of the tissue expander with a silicone implant. Starting the reconstruction with a tissue expander allows the reconstructive surgeon to customize the results to patient preference. Endara *et al.*^[39] has demonstrated that the incidence of NAC necrosis is little increased with one-stage approach (4.50% x 3.90%), however the overall complication rates were higher in the two-stage group (52.4% x 18.6%). The authors emphasized that there is

no ideal algorithm for reconstruction and the decision to proceed with reconstruction and the technique should be made by the surgeon based on assessment of skin flap viability.

The introduction of biodimensional implant-expander system (BIES) has proved increasingly popular over the last years^[9,21,33,97-102]. Designed with the objective of combining the advantages of the silicone gel implant and tissue expander into one system, it may present a superior breast form compared with what might be achieved using unshaped implants or expanders. The system design permits postoperative adjustments in implant volume and contra-lateral symmetry^[9,97-102].

In spite of the positive aspects, complications can be expected and are best avoided by placing the BIES under a submuscular pocket. Regardless of the good results observed with total muscular coverage, in some patients this technique is not free of unpredictable outcome^[9,21,74,101,102]. Total muscular coverage can limit lower pole expansion and can result in a high-riding device^[74,102]. Mahdi *et al.*^[99] in a series of BEIS reconstructions, observed that some patients failed to develop adequate lower pole projection and 35% required inferior muscular release to obtain a satisfactory result. Munhoz *et al.*^[33] advocated performing only minimal immediate expansion of the skin flaps in order to avoid tissue tension^[29,33]. In fact, in a series of patients submitted to NSM reconstruction, Peled *et al.*^[29] observed that NAC necrosis greatly decreased after the technical refinements of incision selection and performing implant reconstruction in a two-stage fashion.

Another option for implant coverage in NSM reconstruction is the use of acellular dermal matrices (ADM). Boneti *et al.*^[26] in a series of 281 NSM reconstructions utilized the alloplastic tissue situated in a partial muscular pocket, with ADM bridging the lateral and inferior edge of the muscle and the chest wall. The authors observed an overall complication rate of 7.1% (20 of 281) and the most frequent complication was breast skin flap ischemia. Spear *et al.*^[61] described a successful two staged NSM in 15 patients (24 breasts) utilizing the ADM. According to the authors, four of the 24 operated breasts (17%) experienced a complication, in that 2 patients (8%) developed flap necrosis and two patients developed partial NAC necrosis. Endara *et al.*^[39] in a systematic review could not assess the impact of acellular dermal matrix on reconstructive outcomes following NSM. According to the authors, the studies either did not report acellular dermal matrix use, or did indeed place acellular dermal matrix for all cases in only three studies, totaling NSM reconstructions. Given the insufficient number of patients comparison of complication rates between the two groups was not possible.

CONCLUSION

NSM is not a new concept but is becoming increasingly accepted by breast surgeons. In selected patients, this approach has allowed an adequate oncologic control with

satisfactory aesthetic outcome. Although NSM requires more intraoperative care, the concept can optimize the aesthetic result in early-stage breast cancer patients.

The satisfactory outcome are due to a close collaboration with the oncological surgical team in terms of incision selection flexibility and skin flap dissection. Alternately, care must be taken during the oncological procedure with meticulous surgical technique and gentle handling of tissues to avoid complications. In general, choice of reconstructive procedure requires careful consideration of various patient related factors, including: breast volume, degree of ptosis, areolar size, patient preference and expectation, clinical factors, and surgeon experience. Regardless of the fact that there is no consensus concerning the best technique, the criteria are determined by the surgeon's experience and the anatomical aspects of the breast. Probably, all these objectives are not achieved by any single procedure and each technique has advantages and limitations. With careful patient selection and well-planned surgical technique, NSM can provide satisfactory outcomes with acceptable complication rates. However, available data demonstrate that NSM can be safely performed for breast cancer treatment in selected cases. Additional studies and longer follow-up are necessary to define consistent selection criteria for NSM.

phenotype which limits the activity of effector T cells and supports tumor growth and progression. Various factors and signaling pathways have been implicated in the immunosuppressive functioning of DCs in cancer, and researchers are working on resolving processes that can circumvent tumor escape and developing viable therapeutic interventions to prevent or reverse the expression of immunosuppressive DCs in the tumor microenvironment. A better understanding of the pattern of DC response in patients with BC is fundamental to the development of specific therapeutic approaches to enable DCs to function properly. Various studies examining DCs immunotherapy have demonstrated its great potential for inducing immune responses to specific antigens and thereby reversing immunosuppression and related to clinical response in patients with BC. DC-based immunotherapy research has led to immense scientific advances, both in our understanding of the anti-tumor immune response and for the treatment of these patients.

Abstract

Breast cancer (BC) is the most common malignant neoplasm and the cause of death by cancer among women worldwide. Its development, including malignancy grade and patient prognosis, is influenced by various mutations that occur in the tumor cell and by the immune system's status, which has a direct influence on the tumor microenvironment and, consequently, on interactions with non-tumor cells involved in the immunological response. Among the immune response cells, dendritic cells (DCs) play a key role in the induction and maintenance of anti-tumor responses owing to their unique abilities for antigen cross-presentation and promotion of the activation of specific lymphocytes that target neoplastic cells. However, the tumor microenvironment can polarize DCs, transforming them into immunosuppressive regulatory DCs, a tolerogenic

Key words: Breast cancer; Dendritic cells; Tumor microenvironment

Core tip: Breast cancer is a worldwide major public health problem, and dendritic cells are of crucial importance for activating an effective antitumor immune response. Deepening our understanding of the tumor microenvironment can enable the development of new therapies that will make it possible to induce an efficacious antitumor response. Given the search for effective means with which to induce such a response *via* dendritic cell (DC) immunotherapy, the study of the mechanisms involved in the DC pattern of response in the tumor microenvironment is important.

dratic cells in the tumor microenvironment and breast cancer. *World J Clin Oncol* 2014; 5(3): 495-502 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i3/495.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i3.495>

INTRODUCTION

Breast cancer (BC) is the most common cancer among women and the second most prevalent form of terminal cancer in this population^[1]. Cancer is characterized by accelerated and uncontrolled proliferation of normal cells due to specific genetic mutations that alter the cell cycle^[2,3]. These genetic changes can culminate in the expression of mutant proteins, that in theory, should be recognized as foreign by the immune system^[4]. Within the immune system, dendritic cells (DCs) play a distinct role wherein they are essential both to innate and to acquired immunity^[5]. They have the unique ability for antigen cross-presentation for T helper lymphocytes (CD4⁺) and cytotoxic T lymphocytes (CD8⁺)^[6] in secondary lymphoid organs, a process that activates a sophisticated and specific immunological response^[7].

Although they perform the functions of antigen capture and processing in peripheral tissues, DCs are initially immature. They mature when interactions with Toll like Receptors (TLRs) or inflammatory cytokines convert immature DCs into mature DCs that present a specific antigen to naïve T cells, thereby activating them^[8]. DCs with differing maturation stimuli upregulate the expression of the cell surface and intracellular molecules required for their journey to secondary lymphoid tissues. However, the activation and maturation of DCs depend on the local microenvironment and can be blocked or polarized by a combination of specific local factors, resulting in the formation of DCs with tolerogenic or immunosuppressive activities^[9].

Various types of cells and factors present in tumor microenvironment generate a range of stimuli for DCs, that affect all aspects of their biology and thus control their functionality and longevity^[10]. It's known that immunotherapy with CDs is currently being studied and used as therapy for a large variety of tumors, solid or not. We have chosen to study the mechanisms involved in the pattern of response of the CDs in the tumor microenvironment, specifically in the BC because it is considered major public health problem. The knowledge of these cells response will be the basis for developing an effective immunotherapy. In this work, we provide an up-to-date review of the pattern of DC response in the BC tumor microenvironment and the use of immunotherapy with a DC vaccine.

ROLE OF DCs IN TUMOR IMMUNITY

DCs are key regulators of immunity by B and T lymphocytes because of their superior ability to capture, process and present tumor-associated antigens^[11]. They

are derived from a hematopoietic line with cell subsets that differ in terms of their morphology, phenotype and function depending on the particular conditions and the tissue in which they reside. However, the various DC subsets generally have the ability to stimulate T cells^[12]. DCs have different co-stimulatory molecules, such as B7, intercellular adhesion molecule 1 (ICAM-1), lymphocyte function-associated antigen-1 (LFA-1), lymphocyte function-associated antigen-3 (LFA -3) and CD40 on their cell surfaces. As a set, these proteins generate a chain of secondary signals essential to reinforcing the T cell activation, with the resultant immune response initiation, programming and regulation being directed specifically at the tumor^[13].

The DC maturation process determines the presentation of processed tumor antigens and the subsequent activation of CD4⁺ and CD8⁺ T cells^[14]. Their migration from tissues to the lymph nodes is fundamental to this process, since it provides the period during which expression levels of co-stimulatory molecules as class II MHC molecules, adhesion molecules and the C-C motif chemokine receptor (CCR7) are increased. This process is accompanied by a reduction in CCR6^[15,16], which coincides with increase in the expression of particular C-C motif chemokine ligands (CCLs)-namely CCL19 (a.k.a. EBI1 ligand chemokine) and CCL21 (a.k.a. secondary lymphoid-tissue chemokine)-within the lymph nodes as well as increased CCR7 binding^[17]. The expression of molecules on the DC membrane and the migration of DCs to T-cell populated areas in the lymph nodes, where drainage occurs, during this process are fundamental to specific immune response by the T lymphocytes^[7,18]. Nevertheless, depending on microenvironment conditions, which involve the cells present in the tissue as well as the presence of mediators, DCs can present alternative phenotypes that are implicated directly in an immunogenic to tolerogenic change of function^[19].

PROGRESSION OF BC, ITS RELATIONSHIP WITH THE TUMOR MICROENVIRONMENT AND THE PROCESS OF DC MATURATION AND ACTIVATION

If found in an early stages, BC has a good cure rate, though the metastatic or recurrent form of the disease has a poor prognosis. BC consists of a heterogeneous group of neoplasms derived from the ductal epithelium. The majority of BCs (80%) are ductal (including medullary, papillary, tubular and mucinous subtypes), and the remaining 20% are lobular cancers. The normal mammary gland consists of a layer of luminal epithelial cells, myoepithelial cells and a continuous basal membrane. The stroma contains fibroblasts, immune system cells (*e.g.*, macrophages, DCs and lymphocytes) and vasculature surrounded by the extracellular matrix and adipocytes, which maintain the structure of normal tissue^[20].

The evolution of malignant breast tumors beings with

epithelial hyperproliferation and progressing to *in situ*, invasive ductal and metastatic carcinomas^[21]. In *in situ* ductal carcinoma, epigenetically and phenotypically changed myoepithelial cells, which are surrounded by a basal membrane that is still mostly continuous, are incapable of contributing to the polarization and organization of normal cellular processes. In invasive ductal carcinoma, there has been a loss in the continuity of the basal membrane, loss of function of the myoepithelial cells and an invasion of the epithelial cells into the stroma and vasculature. During conversion from *in situ* to invasive carcinoma, there is an increase in the production of extracellular proteases that degrade the stromal matrix and cells^[22]. Concomitantly, tumor cells in the stroma produce proteolytic enzymes; while chemokines and cytokines continue to attract leukocytes, modulate tumor remodeling, and facilitate tumor cell invasion of distant organs, leading to metastasis. Infiltrating fibroblasts and leukocytes are induced to increase the secretion of growth factors, cytokines, chemokines and matrix metalloproteinases (MMPs) which produce an immune-evasion mechanism that enables the tumor to progress and achieve angiogenesis^[23].

We now know that the tumor microenvironment is the main regulator of carcinogenesis and is responsible for the course of tumor progression, including how tumors respond to various types of treatment^[24,25]. The development and progression of a tumor to a malignant phenotype is highly dependent on interactions between the tumor cells and normal cells present in the tumor microenvironment^[23,26]. There are extensive changes in genetic expression in all cell types during BC progression. Genetic changes detected in cancerous epithelial cells have been tied to the overexpression of particular C-X-C motif ligand (CXCL) chemokines, namely CXCL14 by myoepithelial cells and CXCL12 by myofibroblasts. These chemokines bind receptors in cancerous epithelial cells, resulting in increases in their proliferation, migration, and invasion, thus favoring tumor remodeling, as well as their ability to migrate to and induce metastasis in distant organs. Chemokines and cytokines produced by tumor cells and infiltrating cells continue to attract more leukocytes, further facilitating tumor progression^[27]. Abnormal matrix remodeling in BC tumor progression is attributable to MMPs, which can also activate chemokines, cytokines, adhesion molecules, and growth factors that support tumor progression. Angiogenic factors are activated by MMPs 1, 2, 9 and 14^[28].

The tumor microenvironment promotes BC initiation, growth, migration, metastasis, and therapeutic resistance. The mediators and enzymes produced can induce important genetic changes in tumor-associated cells, such as fibroblasts, endothelial cells, adipocytes, and leukocytes. These cells are critical components of the tumor stroma and can damage the microenvironment, enabling malignancy as shown in Figure 1^[25]. Tumor occurrence has been shown previously to be associated with DNA methylation and histone modifications in fibroblasts^[29]. We also know that germinal mutations in *BRC A1* and

BRC A2 confer increased risk of BC and ovarian cancer and reduced risk of other types of cancer; *TP53* and *PTEN* mutations are also found in BC cells^[30-32]. Mature adipocytes influence tumor behavior by producing hormones, growth factors, and cytokines, as well as a heterogeneous group of molecules known as adipokines, which can change the phenotype of the epithelial cell, increasing its mobility. Interestingly, these molecules provide a link between obesity and BC risk^[33,34].

The endothelial cells that form tumor neovessels are distinct from normal endothelial progenitor cells^[35,36]. Under the influence of proteins in the tumor microenvironment, such as macrophage colony-stimulating factor (M-CSF), monocytes can differentiate into endothelial cells that provide angiogenesis within the tumor^[37]. This process, which can also be mediated by components of the extracellular matrix (*e.g.*, fibronectin), leads to the phenomenon of monocyte-epithelial cell differentiation^[38].

Tumor-associated macrophages are a major component of the leukocyte infiltrate; when activated, they exercise a tumoricidal action^[39]. However, the presence of tumor-associated vascular leukocytes has been shown to be linked directly with tumor growth through increased expression of the cytokine tumor necrosis factor (TNF)-alpha^[38]. Release of TNF-alpha in the tumor microenvironment promotes the differentiation of tumor-associated monocytes towards a myeloid-epithelial pro-angiogenic phenotype *via* positive regulation of the fibronectin receptor $\alpha 5\beta 1$.

In a study of tumors obtained from patients with invasive BC^[40], we found that differences in T and B lymphocytes, in terms of peritumor/intratumor infiltrate, were related to tumor size. Specifically, small tumors (≤ 2 cm) had relatively lower levels of intratumor B lymphocytes, whereas large tumors (2-6 cm) had relatively low levels of peritumor T lymphocytes. We know that tumor-infiltrating B cells can subserve an antibody response to breast tumors. In a study analyzing the presence of B lymphocytes (CD20⁺) in 1470 invasive breast carcinomas, Mahmoud and colleagues documented that B lymphocytes were diffuse in areas at a marginal distance from the carcinoma (average distance, 12 cells) compared to their more dense presence within the carcinoma and in stromal compartments adjacent to the tumor. Total B-cell counts correlated with a higher tumor grade and a basal phenotype, as well as with estrogen receptor (ER)/progesterone receptor (PR) negativity^[41].

Regulatory T lymphocytes (Tregs) and cytokines have also been implicated in the immune cell infiltration of tumors. Invasive BC tumors have been reported to exhibit elevated levels of intratumoral Tregs, with ER/PR negativity and HER2 overexpression being associated with an unfavorable prognosis^[42]. Furthermore, enrichment of Tregs in invasive ductal carcinoma of the breast correlates with upregulation of interleukin (IL)-17A expression and augmented invasive ability^[43].

In a letter to the editor about an article entitled "cancer stage and local immune response," the researcher^[44]

Figure 1 Changes to the tumor microenvironment seen in a mammary gland with breast cancer, consisting of a layer of luminal epithelial cells surrounded by myoepithelial cells, bordered by a continuous basal membrane, with adipocytes external to the mammary gland. In the stroma, there are tumor-associated fibroblasts immune cells surrounded by the extracellular matrix that maintains the tissue structure. In ductal carcinoma, the myoepithelial cells are changed epigenetically and phenotypically. The number of fibroblasts, monocytes and macrophages associated with the tumor are increased in the stroma, elevating secretion of growth factors, cytokines and chemokines, which promotes tumor progression. Dendritic cells (DCs) have plastic characteristics, showing distinct phenotypes depending on their mature state.

Murta reiterated and defended the idea that the BC stroma and peri- or intratumoral lymphocyte infiltrates are important to the development of and prognosis for BC and that immunotherapy for breast cancer is still under investigation. Moreover, the tumor microenvironment has innumerable escape mechanisms and ways to favor tumor progression, even using the cells themselves and mediators of the immune response in its favor.

INFLUENCE OF THE TUMOR MICROENVIRONMENT ON DENDRITIC CELLS

DCs can change their phenotype in response to tumor microenvironmental factors and contribute to angiogenesis. This cellular plasticity characteristic seems to be exploited by tumors that repress DC maturation, thereby inhibiting specific antitumor immune responses^[45]. Tumors can induce the generation and accumulation of immunosuppressive cells (*e.g.*, Tregs) in the tumor microenvironment, improving tumor's ability to evade immunological defenses^[42]. Tumor-associated cytokines such as vascular endothelial growth factor (VEGF), IL-10, and prostaglandin E₂ (PGE₂) can affect the phenotype of DCs^[46]. Liu *et al.*^[47] placed DCs in co-culture with isolated Lewis lung carcinoma cells to simulate the tumor micro-

environment. The co-cultured DCs were induced to differentiate into regulatory DCs with a CD11c^{low} CD11b^{high} Ia^{low} phenotype and elevated expression of IL-10, nitric oxide, VEGF, and arginase I. These regulatory DCs inhibited T-cell proliferation both *in vitro* and *in vivo*, with PGE₂ being the major inducer of arginase I in the regulatory DCs^[47]. Corroborating this idea, several studies have shown that tumor-associated DCs can induce Treg expansion and become not only incapable of inducing specific immune responses but also immunosuppressive^[45,48,49]. Furthermore, BC tumors have been reported to promote the differentiation of DCs into a phenotype that expresses IL-10 and tumor growth factor (TGF-β), which, in turn, induce the expansion of Tregs (CD4⁺CD25⁺FOXP3⁺)^[50].

Tumor-associated DCs can produce pro-angiogenic factors in the tumor microenvironment. Rapid tumor growth factors are associated with the infiltration of immature DCs that promote angiogenesis and tumor growth, whereas mature DCs are known to suppress angiogenesis^[51]. BC cell-secreted IL-6 determines whether monocytes in the tumor stroma will differentiate into DCs or macrophages. *In vitro*, activated monocytes placed in contact with fibroblasts (common in tumor stroma) induce the fibroblasts to release IL-6. IL-6 regulates the expression of M-CSF receptors in functional monocytes and enables them to become reactive to autocrine M-CSF.

Interaction between IL-6 and M-CSF favors monocyte differentiation into macrophages, rather than DCs. Like fibroblasts, Hs578T BC cells modulate monocyte differentiation into macrophages *vs* DCs depending on the presence of IL-6^[52].

DCs are a specialized group of antigen-presenting cells with extraordinary functional plasticity. They have the potential to stimulate or suppress immunity, depending on the sequence and combination of microenvironmental stimuli present^[12]. DCs cultivated *in vitro* in the presence of tumor factors can have some characteristics of epithelial cells, such as low-density lipoprotein absorption, leptin binding^[53], and even suffer a process of endothelialization characterized by loss of CD14/CD45, loss of the endothelial markers CD31 and CD34, and loss of the von Willebrand factor, vascular endothelial growth factor receptor 2 (VEGFR-2), and vascular endothelial (VE)-cadherin^[54].

By means of a literature review, Curiel^[55] defends the need of a reduction in the function of Treg cells in the microenvironment tumor recurrence in patients with cancer, either individually or in combination with other therapies. According to this study the reduction may be clinically beneficial and potentially effective as an immunotherapy against cancer. In his work, he highlights other studies in which the function of Treg cells can be decreased, as an indirect effect, after the use of other immunotherapeutic agents, as the use of Denileukin diftitox (DAB389IL-2), a fusion protein of interleukin 2 (IL-2) and diphtheria toxin^[56], and doses of diftitox denileukin, in combination with a recombinant vaccine poxviral can increase the immune responses in an antigen-specific normal murine model. The authors noted that Treg cells in spleen, peripheral blood and bone marrow of the animals were variously reduced after a single intraperitoneal injection of denileukin diftitox, evident reduction in 24-h effect after around 10 d. Similarly, in another study^[57] examined the effects of a single dose of low dose cyclophosphamide (CTX) on immunogenicity of DC vaccines in animals with tumors of the colon and melanoma. As a result there was an increase in IFN- γ produced by lymphocytes in the spleen and significantly reduce CD4⁺ CD25⁺ FoxP3⁺ Treg cells, thus establishing a proposal for an immunotherapy strategy by combining low dose CTX with DC.

In the study^[58] an antiangiogenic therapy was used in clinical trials of patients with BC through Sunitinib and Bevacizumab and demonstrated that there is a significant induction of hypoxia in the tumor microenvironment, with increased of stem cell cancer population.

MATURE DCs AND THE TUMOR MICROENVIRONMENT IN BC

As shown in Figure 1, the BC tumor microenvironment is highly immunosuppressive due to the presence of growth factors (*e.g.*, VEGF) and cytokines (*e.g.*, IL-10), and the infiltration of Tregs and immature DCs. Infiltration

of mature DCs into primary tumor lesions is associated with prolonged patient survival and reduced risk of metastasis^[59]. These findings reinforce the importance of DCs in antitumor immunological oversight, including the migration of DCs into regional lymph nodes where they present specific tumor antigens to naïve T cells.

In 2008, Dieu-Nosjean and colleagues reported a study^[60] that indicated that the density of tumor-infiltrating lymphocytes (CD4⁺, T-bet⁺ Th1 T cells, in particular) was reduced in tumors that had weak infiltration by mature DCs. The authors interpreted the findings as indicating that the density of mature DCs was a better predictor of clinical evolution than the other parameters tested.

The therapeutic potential of mature-DC vaccines remains of great interest. Research probing the benefits of DC immunotherapy has demonstrated safety with few adverse secondary effects as well as interesting results in terms of efficacy for stimulating immune cells^[61,62]. Current strategies to curtail immune evasion by tumors include a combination of DC vaccination with Treg depletion by way of administration of anti-CD25 antibodies^[63], and blockade of endothelin receptors in endothelial cells to facilitate the infiltration of cytotoxic T cells into the tumor microenvironment^[64]. Stimulation of an immune response by DC immunotherapy has been evidenced by increases in the percentages of IL-2-, TNF-alpha-, and IL-10-expressing T-helper (CD4⁺) cells. A similar result was observed for IL-2 expression by cytotoxic T (CD8⁺) cells. The percentage of total T (CD3⁺) cells remained elevated during immunotherapy. Counts of Treg (CD25⁺/FOXP3⁺) cells remained significantly lower than the pre-treatment baseline count throughout the treatment period^[65].

Vaccines made from DCs pulsed with autologous tumor lysates induced secretion of Th1 cytokines and an increase in natural killer cells and CD8⁺ IFN-gamma⁺ T lymphocytes in the peripheral blood of BC patients. This finding suggests that a vaccine of DCs pulsed with tumor lysates may be an effective source of tumor antigens, capable of inducing effective immune responses^[66]. In another study, a vaccine of DCs pulsed with HER-2 was reported to be well-tolerated and to attenuate expression of HER-2/neu, enabling an immune response to invasive cancer to be mounted^[67]. Finally, in a clinical trial, an antitumor DC vaccine administered together with IL-2 was found to induce specific cellular immunity in patients with BC that was accompanied by a reduction in TGF-beta levels, an increase in IL-12 secretion, and a reduction in CD4⁺ CD25⁺ T cells^[68]. Based on these promising findings, we believe that DC-based therapies designed to disrupt a tumor-promoting microenvironment should be investigated with the aim of developing more powerful DC vaccines that can generate an intense and long-lasting anti-BC immune response^[69].

In conclusion, growing evidence shows that the BC tumor microenvironment is immunosuppressive, at least in part through modification of DCs toward a Treg phenotype, *i.e.*, mature DCs are not functional in the tumor

microenvironment in patients with BC. DC maturation is critical for enabling specific molecular identification of BC antigens and DC vaccine immunotherapies have the potential to induce specific immunity against tumor antigens. Importantly, changes in immunological parameters that favor a specific antigen immune response, together with a reduction in immunosuppression, correlate with a positive clinical response in patients treated with a DC vaccine. Clarification of the microtumor environment, the mediators involved, interactions with immune response cells, and immune-evasive mechanisms may lead to new forms of immunotherapy.

Abstract

The thyroid hormones (THs), triiodothyronine (T3) and thyroxine (T4), are essential for survival; they are involved in the processes of development, growth, and metabolism. In addition to hyperthyroidism or hypothyroidism, THs are involved in other diseases. The role of THs in the development and differentiation of mammary epithelium is well established; however, their specific role in the pathogenesis of breast cancer (BC) is controversial. Steroid hormones affect many human cancers and the abnormal responsiveness of the mammary epithelial cells to estradiol (E2) in particular is known to be an important cause for the development and progression of BC. The proliferative effect of T3 has been demonstrated in various types of cancer. In BC cell lines, T3 may foster the conditions for tumor proliferation and increase the effect of cell proliferation by E2; thus, T3 may play a role in the development

and progression of BC. Studies show that T3 has effects similar to E2 in BC cell lines. Despite controversy regarding the relationship between thyroid disturbances and the incidence of BC, studies show that thyroid status may influence the development of tumor, proliferation and metastasis.

Key words: Thyroid hormone; Triiodothyronine; Breast cancer; Mammary gland and metabolism

Core tip: Breast cancer (BC) is a malignant tumor occurring much more frequently in women than in men; worldwide, the incidence of BC has increased markedly in recent years. It is estimated that 1.7 million women will be diagnosed with BC in 2020, marking an increase of 26%, compared to the current incidence: 1.35 million new cases annually. Countless environmental risk factors, pathological conditions, and physiological agents, as well as thyroid hormones (THs), have been involved in the development of BC. Various lines of evidence suggest tumor-promoting effects of THs. The literature contains controversial reports regarding the relationship between thyroid diseases and BC; furthermore, studies reporting both an excess of and a lack of THs may affect breast development and progression to cancer. Epidemiologically, many studies suggest that hyperthyroidism is a factor in the development of BC. Furthermore, experimental studies have shown that high levels of THs reduce the interval of multiplication of BC cell lines. Therefore, the influence of THs on BC is unclear. However, the majority of BC research suggests a relationship, primarily, when the molecular aspects of these hormones are considered in the progression of this type of tumor.

INTRODUCTION

Thyroid hormones (THs), 3,5,3',-triiodothyronine (T3) and thyroxine (T4), play critical roles in the differentiation, growth, metabolism, and physiological function of nearly all mammalian tissues^[1,2]; in addition, they are required for amphibian metamorphosis^[3]. Multiple biological effects of THs depend on intracellular levels of T3, which binds to the thyroid hormone receptor (TR) and is for the most part generated in peripheral tissues by outer-ring deiodination of T4^[4]. TH is a key metabolic regulator that coordinates short-term and long-term energy needs^[5]. Significant metabolic changes are seen with variations in human thyroid status^[6].

Hypothalamus-secreted thyrotropin-releasing hormone (TRH) and thyroid stimulating hormone (TSH), secreted by the anterior pituitary (hypophysis), act in the thyroid gland where THs^[7,8] are produced (Figure 1A). TRH and TSH are negatively regulated by T4 and T3 (negative feedback), acting directly on the TSH receptor (TSH-R), expressed on the thyroid follicular cell basolateral membrane^[9].

THs regulate a wide range of genes after activation from the prohormone (T4), to the active form (T3)^[10]. The signaling pathway is complex and highly regulated because in cells and tissue there is an expression of TH transporters, multiple TR isoforms, as well as interactions with corepressors and coactivators^[11,11] (Figure 1B). The functional TR complex consists of a heterodimer with retinoid X receptor (RXR) that binds to a TH response element (TRE) to modulate gene expression. Liganded TR stimulates genes that are positively regulated by triiodothyronine (T3), whereas unliganded TR binds to a TRE to repress those genes. The repressive actions of unliganded TR act in metabolic regulation, particularly in antagonizing the action of other nuclear receptors^[12].

TH action has been substantially altered by recent clinical observations of thyroid signaling defects in hormone resistance syndromes and in a broad range of conditions, including profound mental retardation, obesity, metabolic disorders, and a number of cancers^[13]. However an uncontrolled study of 3,3'-diiodothyronine (3,3'-T2), iodothyronines as T3 and T4, administration to humans for 4 weeks by an unspecified route was associated with increased metabolic rate and reduced body weight^[14], no specific role of 3,3'-T2 in humans has been demonstrated^[15]. Animal studies, however, suggest that the 3,5-diiodothyronine and 3,3'-T2 increase metabolic rate^[15,16], by acting at the mitochondrial level to increase hepatic cytochrome oxidase activity^[17] and supraphysiological dose of T3 causes genotoxicity and potentiates oxidative stress^[18].

T3 can influence the mammary gland; this involves

the activation of TR present in the mammary gland inducing differentiation and lobular growth in an estrogen-like manner. However, there is controversy regarding the relationship between thyroid disorders and breast cancer (BC) incidence^[19].

In this chapter, the influence of T3 on BC will be reviewed. The physiological role of THs in the normal breast will be discussed.

MAMMARY GLAND DEVELOPMENT

Mammary glands are composed of conjunctive tissue and adipose tissue; the latter may vary according to the size of the breast. The development of these glands begins in the embryo phase *via* the extension of ectoderm tissue^[20]. This extension is due to allometric growth, which represents the relationship between growth of the ectoderm and the metabolic profile of the epithelial cells^[21]. The maintenance and regulation of breast epithelial cells are also controlled by the complex interaction of various hormones including estrogen, progesterone, glucocorticoids, insulin and prolactin^[22]. At the onset of puberty, some hormones in the ovary influence the maturation of the mammary glands. They act on the glands by filling a system of branches and lateral ducts surrounding the layer of fat. During pregnancy, mammary glands produce milk due to the high level of estrogen secreted by the placenta. This milk is stored in alveolar secretory units to be supplied later for breastfeeding^[21].

During lactation, lipoprotein lipase activity decreases in the adipose tissue and increases in the breast tissue. This indicates an increase in the capture of fatty acids in this tissue^[23]. Therefore, the quantity of milk produced is also influenced by the hormone levels; as a result, the physiological process of the epithelial cells is modified^[22].

Regarding cell proliferation, studies conducted on human breast tissues report that cell multiplication in mammary epithelium is constant following the complete development of the mammary glands. This mitotic state of proliferation during the luteal phase of the ovarian cycle may coincide with the increase in secretion of estrogen and progesterone^[22].

Thus, at this phase, the epithelial cells of the mammary glands may be stimulated by the presence of progesterone or in its synergy with estrogen. After several days of peak cell proliferation, and at the end of the luteal phase, these cells undergo apoptosis. This apoptotic peak coincides with the decrease in estrogen and progesterone secretion from the ovaries; furthermore, a low level of apoptosis occurs in the entire mammary lobule^[22].

Based on the foregoing, it is noteworthy that breast tissue constantly undergoes marked physiological cell renovation. This process is due to a response to the levels of estrogen and progesterone secreted by the ovaries. It is also evident that the proliferation and cell replacement of the mammary epithelial cells, after complete development of the breast, plays an important role in the maintenance and tissue function of the normal breast^[17].

Figure 1 Production and action of thyroid hormone. The key components required for thyroid hormone action are shown, demonstrated by a range of clinical observations. (1) Thyroid hormones (T4 and T3) are produced by the thyroid gland and are regulated by thyroid stimulating hormone (TSH) produced by the hypophysis, which is stimulated by thyrotropin-releasing hormone (TRH). Once released, T4 and T3 exert a negative feedback mechanism on the production of TRH and TSH; and (2) The effects of T4 *in vivo* are mediated via T3. T4 is converted to T3 in target tissues by deiodinases 1 and 2 (D1 and D2). Deiodinase 3 (D3) converts T3 to the inactive rT3. Unliganded TR heterodimerizes with RXR and binds to a TRE and then to a corepressor, such as a nuclear receptor corepressor (NcoR); thus, repressing gene expression. T3 binding to the ligand-binding domain results in movement of the carboxyterminal helix 12, disruption of corepressor binding, and promotion of coactivator binding, which then leads to recruitment of polymerase III and the onset of gene transcription. Adapted from Ref.[13].

TRIIODOTHYRONINE EFFECT IN THE MAMMARY GLAND

The hormones that regulate breast development have been known since the 1930s^[24] and the involvement of THs in the development and differentiation of normal breast tissue has been established^[25-27]. Breast growth and development require the coordinated action of many hormones, such as prolactin, estrogen, progesterone, adrenal steroids, insulin, growth hormone, and THs^[28,29]. THs exert a wide variety of biological effects in vertebrate animals; however, their most noteworthy actions may be found in the regulation of cell development and differentiation^[30]. From the onset of embryologic devel-

opment, the mammary glands in women go through a process of ductal development, which supports the creation of alveolar structures during pregnancy, before the onset of lactogenesis. This development includes various stages of proliferation and morphogenesis, which are largely driven by simultaneous changes in the main hormones and growth factors in various reproductive states. Ductal extension is driven by estrogen, growth hormone, growth factor similar to insulin I, and epidermal growth factor; however, ductal branching and alveolar budding are influenced by additional factors, such as progesterone, prolactin, and THs^[27].

THs are not essential for the development of the breast ducts; however, they appear to stimulate the development of the lobules of these glands^[25]. It is also thought that, in states of excess or lack of this hormone, the process may be negatively affected^[31]. In 1986, Vonderhaar *et al.*^[26] verified that THs influence the development of epithelial cells of the mammary glands in rats. In regard to cell differentiation, the responsiveness of the breast tissue to prolactin in the rat increases *via* the activation of prolactin receptors. In rabbit breast tissue, THs stimulate the synthesis of casein induced by prolactin^[32].

BREAST CANCER

This cancer is characterized by a multiphasic process in which a series of genetic and epigenetic changes take place in sequence, leading to the cells' loss of control of the proliferation, differentiation, apoptosis, and repair of DNA^[33]. Worldwide, BC is the most common malignant neoplasm in women^[34]. It is characterized by epithelial cells and by the tendency to metastasize to distant locations. Most of the tumors are adenocarcinomas, derived from the terminal ductal lobular unit^[35].

In Brazil, the estimated incidence in 2012 was 53 thousand new cases, according to the National Cancer Institute^[36]. The estimated incidence in the United States for 2011 was 231 thousand cases of BC^[37]. The etiology of BC is complex and involves endogenous and exogenous factors that make up the risk factors of the disease^[38]. These factors are associated with the onset and development of the tumor; furthermore, they confer a significant histopathologic, genetic, and prognostic variability to this disease^[39,40].

Endogenous factors include: family history; an excessive number of ovulatory cycles due to early menarche and/or late menopause; high-density breasts (primarily in post-menopausal women); and genetic mutations (such as BRCA1 and BRCA2). Some examples of exogenous factors are the use of oral contraceptives, hormone replacement therapy, diet, physical exercise, and socioeconomic factors^[39,40].

Family history is one of the main risk factors for the development of BC. However, 80%-95% of cases do not have any familial relationships; they are sporadic, resulting from mutations, epigenetic changes, or even the polymorphism of genes involved in metabolism. BC can also

arise from genes that codify components of the paths of hormonal signaling and growth factors or from DNA repair genes. Despite the foregoing causes, BC is primarily related to the exposure of breast tissue to estrogen^[41-43].

Epidemiologic studies have shown a possible association between thyroid dysfunction and BC. Postmenopausal BC patients have been reported to have a significant increase in THs, suggesting that an imbalance between estradiol (E2) and T3 fosters the development of BC^[44-46]. Conversely, hyperthyroidism has been associated with a reduction in the incidence of BC^[47]. The literature describes an increase in survival in hyperthyroid patients with BC, suggesting that hyperthyroidism may protect against the development of BC by increasing steroid hormone binding globulin and by reducing estrogen stimulation of the breast tissue^[48].

Despite advances in the knowledge of the pathogenesis and molecular aspects of the disease, little is known about the mechanism whereby T3 modulates its receptor in tumor tissue. Studies are contradictory regarding the type of thyroid pathology and how this influence may take place^[48,49].

TRIIODOTHYRONINE AND BREAST CANCER

Experimental studies have shown that THs influence both the differentiation of normal breast cells^[44] and the proliferation of BC cells^[44,50,51]. The proliferative effect of T3 has been demonstrated in various types of cancer. In BC cell lines, T3 may foster tumor proliferation and increase the effect of cell proliferation by E2; thus, T3 may play a role in the development and progression of BC^[52,53]. Apart from this, THs appear to have a stimulating effect on the angiogenesis of certain types of cancer^[54,55]. TH levels are related to the risk of BC. As shown by Tosovic *et al.*^[56], high levels of T3 in postmenopausal women positively correlate with the risk of BC in a dose-response manner. In the case of hyperthyroidism, this correlation was found in postmenopausal women but not in premenopausal woman who had BC^[44]. These postmenopausal women with BC had a significant increase in their thyroid/estradiol ratio, suggesting that an imbalance between E2 and T3 fosters the development of BC^[44]. Conversely, hyperthyroidism has been associated with a reduction in the incidence of BC^[47].

Many *in vitro* and *in vivo* studies have related THs to human cancer since Beatson^[57] described the use of thyroid extracts for treating metastatic BC in 1896. Abundant data indicate that the thyroid status affects the formation of a tumor, its growth, and metastasis in both laboratory animals and humans^[45]. However, the relationship between thyroid status and the pathogenesis of human BC is currently not elucidated^[45].

EXOGENOUS TRIIODOTHYRONINE THERAPY AND BREAST CANCER RISK

The relationship between THs and BC is a controversial

topic. The topic was first addressed in 1896 when Beatson used thyroid extract as a treatment for BC^[57]; however, some studies reported that THs increased the risk of BC^[57,58]. In addition, other studies reported an increase in survival of BC patients who had high TH levels^[48]. Some studies that evaluated thyroid pathology reported that BC rarely occurred in hyperthyroid women^[58], while others reported that primary hyperthyroidism is associated with a reduced incidence of primary BC^[47].

TH replacement therapy primarily entails administering doses of levothyroxine sodium ranging from 1.6 to 1.8 µcg/kg per day^[59]. An inhibitory effect of iodine on BC was suggested to be attributable to its antioxidant role^[60-62]; however, some *in vitro* experiments have shown a proliferative effect of triiodothyronine on BC cell lines^[63,64].

A recently conducted meta-analysis found no statistically significant association between TH replacement and BC risk^[19]. One of these studies demonstrated primary hyperthyroidism as a strong protective factor against BC after adjusting for clinical parameters including TH replacement therapy^[47].

The literature contains a few studies that show a correlation between TH replacement therapy and BC, despite a tendency towards a non-statistical association between the two. Laboratory studies have demonstrated the ability of triiodothyronines to induce BC proliferation in an estrogen receptor-dependent manner, possibly through crosstalk between the THs and estrogen pathways^[50,63,65]. Others THs should be studied in relation to BC, as 3,3'-T2, because Jonklaas *et al.*^[66] found in their study that the concentrations of 3,3'-T2, T3 and T4 were higher in patients with thyroid cancer, patients who had undergone thyroidectomy, and those who were taking levothyroxine (LT4), than patients without.

A large prospective study should be conducted on women who are undergoing TH replacement therapy to clarify any association with BC.

CONCLUSION

The relationship between THs and the mammary gland can be viewed from various aspects, such as from the influence of these hormones in differentiation and lobular growth in a manner similar to estrogen and even with research that identifies its participation in the development of BC. Thus, it is apparent that controversy is present in the literature in regard to the relationship between thyroid diseases and BC, with research showing that both an excess of and a lack of THs may affect breast development and progression to cancer.

Many epidemiologic studies suggest that hyperthyroidism is a factor that leads to BC. However, experimental studies have shown that high TH levels can reduce the time of multiplication of BC cell lines, pointing, inclusively, to a possible crossing of pathways between the molecular action of THs and estrogen. Research that attempts to determine a relationship between TH replacement therapy and BC found no relationship between the two factors. Thus, a relationship between THs and BC is

not clear. However, a significant amount of research on this topic indicates that there is a relationship, principally when molecular aspects of these hormones are considered in the progression of this type of tumor.

Abstract

To review the present status of breast cancer (BC) screening/early detection in low- and middle-income countries (LMICs) and identify the way forward, an open focused search for articles was undertaken in PubMed, Google Scholar and Google, and using a snowball technique, further articles were obtained from the reference list of initial search results. In addition, a query was put up on ResearchGate to obtain more references and find out the general opinion of experts on the topic. Experts were also personally contacted for their opinion. Breast cancer (BC) is the most common cancer in women in the world. The rise in incidence is highest in LMICs where the incidence has often been much lower than high-income countries. In spite of more women dying of cancer than pregnancy or childbirth related causes in LMICs, most of the focus and resources are devoted to maternal health. Also, the majority of women in LMICs present at late stages to a hospital to initiate treatment. A number of trials have been conducted in various LMICs regarding the use of clinical breast examination and mammography in various combinations to understand the best ways of implementing a population level screening/early detection of BC; nevertheless, more research in this area is badly needed for different LMIC specific contexts. No-

tably, very few LMICs have national level programs for BC prevention *via* screening/early detection and even stage reduction is not on the public health agenda. This is in addition to other barriers such as lack of awareness among women regarding BC and the presence of stigma, inappropriate attitudes and lack of following proper screening behavior, such as conducting breast self-examinations. The above is mixed with the apathy and lack of awareness of policy makers regarding the fact that BC prevention is much more cost-effective and humane than BC treatment. Implementation of population level programs for screening/early detection of BC, along with use of ways to improve awareness of women regarding BC, can prove critical in stemming the increasing burden of BC in LMICs. Use of newer modalities such as ultrasonography which is more suited to LMIC populations and use of mHealth for awareness creation and increasing screening compliance are much needed extra additions to the overall agenda of LMICs in preventing BC.

Key words: Breast cancer; Screening; Early detection; Mammography; Clinical breast examination; Breast self examination; Ultrasonography; Awareness; Developing countries; Low- and middle-income countries

Core tip: Implementation of population level breast cancer (BC) screening/early detection programs will prove to be most cost-effective for low- and middle-income countries (LMICs). Accompanying awareness creation regarding BC among women, more research and change in policy are also necessary to reduce the burden of BC in LMICs.

INTRODUCTION

Breast cancer (BC) is the most common cancer among women in all parts of the world, be it high income countries (HICs) or low- and middle-income countries (LMICs), accounting for 1/10th of all malignancies detected in both men and women^[1]. HICs and LMICs have been defined by the World Bank as having per capita incomes of \$12616 or more and \$12615 or less respectively^[2]. In general, there is a 10-fold difference in BC incidence across the world, with HICs having a higher incidence compared to LMICs^[3]. Moreover, BC is also the primary cause of cancer death among women worldwide, accounting for about 375000 deaths in 2000^[1]. Mortality due to BC is higher in LMICs than HICs, mostly due to lack of timely detection and treatment^[3]. However, the incidence of BC is rising in all parts of the world, whether in HICs or LMICs^[3], with higher rates of increase observed in LMICs^[4].

Screening and early detection of BC has been well established in HICs due to concerted efforts through many decades. As a consequence of mammographic screening for women aged 50-69, a decrease in BC mortality has been clearly depicted^[5,6]. This is based on observations in the United Kingdom, Northern Europe and Australia of an increasing incidence of early stage and *in situ* BCs after implementation of screening programs, followed by decline in advanced BC and mortality^[7-10]. The estimates are that 10 years after screening began in the United Kingdom, about one-third of the overall 21% reduction in BC mortality was directly due to screening^[11].

The situation in LMICs is in contrast to that of HICs. Although BC has become a health priority for most LMICs due to increasing incidence, lack of early detection and adequate treatment^[12], BC control strategies are hardly in place^[13], resulting in most women presenting with late stage disease when very little can be done^[14]. It is increasingly being realized that detecting BC early and efficiently must be the cornerstone of preventing morbidity and mortality due to BC in LMICs^[15]. In spite of this, the evidence base for implementing early detection/screening of BC in LMICs is extremely thin^[16]. This is unacceptable given the rising populations and the demographic and epidemiological shifts seen in LMICs. It is apparent that along with such changes, an accompanying increase in cancer burden is to be expected in the coming decades in LMICs^[17]. If we were to limit the impact of rising cancer burden in LMICs, it is of utmost importance that there be adequate application of existing knowledge regarding cancer prevention as well as generation of new evidence^[17]. This is also imperative in the light of strong evidence that demonstrates that diagnosing BC early can reduce BC mortality rates, mainly through initiation of appropriate and adequate treatment in the disease's natu-

ral history^[18-20].

As a part of this review, an attempt has been made to consolidate the evidence that exists regarding prevention of BC in LMICs in terms of screening and/or early detection, along with exploring ways to implement the existing evidence and identifying loopholes in research and implementation. The immediate need for prevention of BC in LMICs cannot be emphasized enough.

LITERATURE SEARCH

For the purposes of this focused review, an open search for articles was undertaken in MEDLINE (www.pubmed.com) or the PubMed database, Google Scholar and Google search using keywords like BC, prevention, control, screening, early detection, low- and middle-income countries, LMICs, developing countries, mammography, clinical breast examination (CBE), self breast examination (BSE), ultrasonography and ultrasound with their corresponding MeSH terms in combination with OR, AND where applicable. In addition, the reference list of the articles obtained from the preliminary search was used to further obtain relevant articles and so on *via* a snowball technique. The search was limited to English literature and there were no time limitations for the search. Apart from the search, a question was also put up on ResearchGate^[21] related to this topic, namely "What are the options for early detection and/or screening for BC in low- and middle-income countries (LMICs)?", to find out the opinion of various experts in the field, from both HICs and LMICs. The content of the responses was used to further obtain articles to be included in the review and also to understand the prevalent opinion regarding screening options for BC in LMICs. In addition, experts in the field were also contacted for more references and opinions.

STATUS OF BREAST CANCER PREVENTION IN LMICs-THE REAL

BC, the most common neoplasm in women worldwide, is on a fast and steady rise in LMICs^[1,22]. Mortality caused by BC is also rising quickly^[1,22]. This trend of increasing incidence and mortality due to BC is a common occurrence in LMICs in various parts of the world, be it Latin America, Asia or Africa^[19]. In most of these countries, the rising incidence is most probably due to changing lifestyle patterns, change in reproductive risk factors and increasing obesity due to improving affluence^[23-26]. The contribution of exogenous hormonal influences cannot be ruled out^[27]. It is also quite apparent that most primary risk factors of BC and the ways in which they are changing are not easily modifiable since most of them influence the long term hormonal milieu in a woman's body^[23]. Thus, beneficial impact on BC mortality can only be created *via* implementation of population level screening/early detection and continued improvements in BC treatment^[23].

Among all forms of BC prevention, screening and early detection are the most important since they can have the maximum beneficial impact in lowering the morbidity and mortality due to BC. Consequently, a number of studies have highlighted the need for BC screening/early detection in LMICs to prevent early deaths of women presenting with late stage at diagnosis^[17,28-30]. However, many complex issues crop up in the context of planning and implementation of BC screening in LMICs. One of the important issues is the occurrence of estrogen receptor negative (ER-) BC at earlier ages in LMICs^[31]. It has been suggested that the younger age of BC in LMICs is due to the age distribution of the population^[31], although there is a possibility that the aggressive ER- BC seen in younger ages in LMICs might be a different disease subtype, as has been suggested in Asia and Africa^[32,33].

Status of mammography in LMICs

Thus far, mammography has remained the main modality of BC screening throughout the world. Adequate evidence exists from some randomized controlled trials (RCTs) that mammography screening is associated with significant reductions in BC mortality^[34-36]. Also, to be most beneficial, mammographic screening programs must be of high quality, with appropriate targeting and of sufficient frequency^[37]. Mammography itself does not lead to any excess deaths^[38], although that is currently being debated, with certain researchers suggesting that for every 10000 women invited for screening, 3-4 deaths were avoided, while 1-3 deaths were from other causes for every BC death avoided^[39]. In addition, there is data emerging from HICs that apparently denotes that implementation of screening mammography at the population level has led to probable overdiagnosis while only marginally reducing the rate at which women presented with advanced cancer, consequently having only a small effect on rate of death due to BC^[40]. Similar evidence has been accumulated from multiple other studies^[41,42] and adds to the ongoing discourse regarding the usefulness of population level BC screening using mammography^[43].

Adding to the above scenario is the fact that in LMICs, BC incidence is lower and occurs more in younger age groups when breast tissue is dense. Also, there is a lack of resources for implementing any population level screening programs using mammography. Given the above, implementation of a mammographic screening program becomes quite close to impossible since the costs are too high while the benefits are negligible. There have been very few studies that have focused on cost-effectiveness of BC screening in LMICs^[44,45]. Treating Stage 1 disease and having an extensive BC screening program were found to be most cost-effective by Groot *et al*^[44], while Okonkwo *et al*^[45] suggested CBE to be as cost-effective as mammograms for India. However, maximum cost-benefit can only occur if screening is done in an age group which has a sufficiently high incidence of BC and sufficient high longevity^[46], criteria which are very difficult to fulfil in the case of LMICs. If we look at the list

of countries with any form of population level screening program involving mammography, there are hardly any LMICs, with the exception of China where such a program was begun only in 2009^[47].

Status of CBE and BSE in LMICs

In the absence of mammography as a screening option, the other options for BC screening have been CBE and BSE. Of the two, CBE is more effective than BSE with the ability to detect much smaller tumors. CBE and BSE are more important for LMICs since the screening priorities differ between LMICs and HICs. Mostly, screening programs in HICs focus on finding asymptomatic tumors, while for most LMICs the primary issue is early detection of palpable tumors^[48]. Thus, the choice of an ideal screening program for any given LMIC needs to be based on evidence generated for each of those country settings which, however, is limited due to the paucity of data being generated regarding disease burden and cost-effectiveness of screening modalities. As has been noted by Anderson *et al*^[49], it is necessary to look very closely in any given country to best direct that particular country's screening program. As a consequence, a number of attempts have been made in various LMICs for determining a BC screening solution. Numerous evaluations of such pilot studies or national programs exist in countries such as India^[50], Egypt^[51], Colombia^[52], Lebanon^[53], Palestine^[54], Philippines^[55], Taiwan^[56], Mexico^[57], Brazil^[58], Pakistan^[59] and Nepal^[60]. The results of the above pilots have been varied due to the different combinations of screening modalities and varying compliance rates, with the most effective results being observed in studies where some degree of community penetration was possible, such as in Egypt with home visits by social workers^[61] or *via* mobile units in Brazil^[62]. Results from Taiwan and Egypt were most promising with the use of a two-phase screening, starting with CBE and continuing with mammography^[56,63]. In fact some of the earliest evidence regarding combining various screening modalities come from the breast screening trial set within the Health Insurance Plan of New York where mammography was combined with CBE and almost 70% effect was estimated to be due to CBE^[64]. The Canadian Breast Screening Study among women aged 50-59 (CNBSS 2) found no benefit from adding mammography to CBE and BSE^[65], with around 20% mortality reduction achieved due to CBE and BSE^[66].

The evidence regarding the usefulness of BSE is more indirect, with evidence observed in CNBSS 2^[66]. Furthermore, a nested case-control study discovered depicted benefits from BSE among women aged 40-49 and 50-59 in CNBSS^[67]. Similar benefits were observed in Finland^[68] with randomized trials not showing any benefits of BSE^[69,70], although these trials had limitations and BSE probably would not have led to additional benefits^[61]. In fact, our studies in LMICs have clearly shown that BSE can have a significant impact on stage reduction^[71]. It has been estimated that in India, up to 55%

reduction in mortality from BC can be attained over a 5 year period by detecting tumors of 3 cm in size in the community^[72] which is possible *via* raising awareness regarding BC and BSE. In addition, studies have indicated that women can detect 95% of BCs and 65% of early minimal BCs by themselves^[73]. Along with awareness of risk factors, the health belief model (HBM) suggests that if a woman knows about BC risks, then she is more likely to practice BSE^[74]. Evidence predicts that BSE can reduce mortality up to 18%^[75] and this figure might be higher with regular BSE practice^[76]. Thus, overall it can be said that, in the absence of mammography, CBE is a good tool to begin with at the population level for early detection. In addition, knowledge of BSE among women can also be a major factor for downstaging BC tumors.

Role of knowledge and awareness in BC prevention in LMICs

The importance of awareness when it comes to tackling cancer emerges in the quote of the title of an article in one of the recent bulletins of the World Health Organization (WHO)-“Awareness is the first step in battle against BC”^[77]. This is indeed truer for developing countries where awareness continues to be low among lay women as well as physicians and nurses. In LMICs, women present with late stage tumors which could have been detected at the primary level by physicians or nurses, but primary care physicians and nurses have not been trained to be vigilant about signs and symptoms of cancer and therefore they do not look for them^[77]. In addition, stigma and discrimination become major barriers for women who might detect a lump in their breast but hesitate in seeking medical help in time due to the fear of being abandoned by their partners or losing their jobs^[77]. It is especially important for women with cancer to have a champion or role model who has survived BC^[77]. With respect to cancer awareness interventions, there are broadly two types: one is individual-level interventions and the other community-level interventions. Evidence suggests that both individual-level and community-level interventions may increase cancer awareness. In addition, community-level interventions might increase early presentation although the evidence is limited for that^[78]. In our studies in other LMICs, we definitely found that increased individual awareness of BSE had a significant impact on early presentation^[71]. Increasing awareness also has long term impact on early presentation, as has been suggested by studies in the United Kingdom^[79].

In fact, low levels of cancer awareness have been found to be a very important risk factor for delay in presentation by the patient^[80,81]. However, studies depict that most of the research on cancer in LMICs is related to treatment with miniscule amounts of research devoted to BC prevention, awareness, early detection and palliation^[16]. Such lack of evidence on the interventions to promote cancer awareness and improve early presentation has been dampening the development of policy and action^[78], especially in LMICs.

Policy implications of BC screening in LMICs

Implementation of BC screening programs in LMICs involves complex policy implications. One of the most fundamental problems related to formulating policy making regarding BC screening in LMICs is the lack of good surveillance and monitoring systems that can provide accurate data regarding the magnitude of burden of cancer apart from cancer risk factors^[82]. Added to that is the lack of various system level factors, such as lack of trained personnel and cancer services to support screening services, which further complicates creation of effective policy^[82].

Other aspects affecting policy making includes low incidence of BC in LMICs, which means that a much larger number of women (than in HICs) need to be screened in order to find true cases of BC. Thus, implementation of screening for cancers are considered too expensive^[83]. Also, communicable diseases (CDs) are still prevalent in LMICs due to which there is reluctance to divert resources from CDs to non-communicable diseases (NCDs) like cancer, especially when there are well developed vertical programs in place in the health systems for CDs^[83]. Experts also put forth the opinion that it is unethical to screen people for cancers since treatment is unaffordable or inaccessible after screening. Thus, the final effect is that cancer screening remains accessible to a small affluent section of the population who also generally have health insurance^[83]. This situation is further aggravated by the fact that the economic evidence for implementation of BC screening strategies remains limited and of poor quality^[84]. Thus, although BC screening strategies may be economically attractive in LMICs, the evidence to create specific recommendations regarding choices such as mammography and/or CBE, frequency of screening, target population etc. remains inadequate in both quantity and quality^[84].

In general, one of the most important forces that has tried to influence policy regarding BC overall in LMICs has been the Breast Health Global Initiative (BHGI). Begun in 2002, BHGI has tried to form a global alliance for creating evidence based guidelines to improve BC outcomes according to levels of resources (basic, limited, enhanced and maximal)^[85]. Their recommendations regarding BC screening/early detection according to different resource strata are provided in Table 1^[46]. However, these recommendation need to be adapted for each country according to the various factors affecting policy in a particular country, as has been discussed before.

POSSIBLE IMPROVEMENTS IN BREAST CANCER PREVENTION IN LMICs UNDER PRESENT CIRCUMSTANCES-THE ALMOST REAL

Best possible screening strategy for BC in LMICs

Based on the evidence so far, it is becoming apparent that every country needs to customize and create its own BC

Table 1 Recommendations for breast cancer screening/early detection and public education/awareness according to the resource level of a country^[46]

Level of resources	Public education and awareness	Detection methods	Evaluation goal
Basic	Developing culturally sensitive and linguistically appropriate local education programs for target populations to convey value of early detection, BC risk factors and breast health awareness (education and self examination)	Clinical history and CBEs	Breast health awareness regarding value of early detection in improving BC outcome
Limited	Culturally and linguistically appropriate targeted outreach/education encouraging CBE for age groups at higher risk administered at district level using healthcare provider in the field	Diagnostic breast USG and/or diagnostic mammography if CBE + Mammographic screening of high risk target groups	Downsizing of symptomatic disease
Enhanced	Regional awareness programs regarding breast health related to general health and women's health programs	Mammographic screening every 2 yr in women aged 50 or older Consider mammographic screening (or USG) every 12-18 mo in women aged 40-49	Downsizing and/or downstaging of asymptomatic disease in highest yield target groups
Maximal	National awareness campaigns regarding breast health using mass media	Annual mammographic screening in women aged 40 or more	Downsizing and/or downstaging of asymptomatic disease in women in all risk groups

CBE: Clinical breast examination; USG: Ultrasonography; BC: Breast cancer.

screening and/or early detection strategy. When it comes to LMICs, most of them fall in the strata of having basic or limited resources, with only a few having enhanced resources. Considering BHGI guidelines (Table 1)^[46], it can be seen that the best that LMICs can wish for with regards to BC is downstaging of the disease. Based on the how much the health system and health expenditures of a country can allow, a LMIC can aim for CBE, CBE in combination with mammography or mammography at a population level. However, the most important factor to be considered before advocating any form of population based BC screening and/or early detection is a way to identify high risk groups of women based on their life and family history. This will ensure that any population based BC control program will be cost-effective and have maximum impact. Moreover, BC screening and/or early detection must be offered at the primary care level and primary care level workers must be properly trained in conducting CBEs. Also, proper referral and diagnostic services must be available as a part of BC screening/detection programs. A BC control program targeting prevention can be viewed as a “best buy” investment opportunity for reducing health expenditures^[86]. The above also needs to be coupled with strategies for increasing the knowledge and awareness of women regarding BC and BC screening/early detection, as emphasized below.

Education and awareness enhancement for improving BC outcomes

The majority of studies from LMICs clearly indicate that the knowledge and attitude of women regarding breast screening does not correlate well with the actual screening behavior^[87-90], with regular screening behavior such as conducting BSE ranging from 10% to 80% based on ed-

ucation, occupational and socioeconomic status^[91-93]. On average, less than 50% of women aware of BSE actually practised it, with the majority of women practising incorrect techniques. Contrary to the expected view, healthcare providers were not knowledgeable about screening techniques, neither did they encourage women to implement screening behavior^[87,94]. Healthcare providers were also not at the top of the list in terms of their importance as source of information. Instead, electronic media and television (TV) was noted to be the most important source of information on BC^[95]. For less educated women, it was relatives and friends who were the most important source of information^[96]. Also, it is important to note that, despite the low levels of awareness of women in LMICs regarding BC, very few studies exist regarding evaluating methods for increasing awareness^[97-101].

However, given the importance placed by the WHO^[77] and BHGI^[49] on the importance of awareness in controlling and preventing BC, it is of utmost importance that organized methods be applied in LMICs regarding spreading awareness of BC, especially *via* the use of electronic media and TV. There must be increased public awareness regarding disease risk factors, symptoms and screening behaviors leading on to the detection of BC at earlier stages. The impact of practising breast screening behaviors on downstaging of BC has been clearly observed in our studies in LMICs^[71].

Need for more research regarding BC prevention

As has been stressed before in this work, research on BC prevention remains highly inadequate and significant improvement is required in both quantity and quality in order to reduce morbidity and mortality due to BC. A recent review of the literature suggests a very significant

role of research in adapting the findings and experience of HICs in LMICs^[102]. A most important need in LMICs is to study “structural violence” as defined by Paul Farmer: the diffuse and indirect oppressive societal forces that routinely limit the choices that individuals have to make in LMICs^[103]. Another important area of research is to clearly define the varying etiology of BC in various LMICs, as has been delineated in some of our studies with regards to hormone receptor status^[31,104]. In fact, significant differences have been observed with respect to hormone receptor status in populations of various LMICs, such as Bangladesh, Taiwan, Philippines, Vietnam and India, relative to HIC populations^[105-107]. Similarly, differences between LMICs and HICs exist when it comes to host metabolism of systemic treatment agents, one of the cases in point being tamoxifen^[108,109]. Other differences lie in mediating effects of social and cultural factors on impact of BC interventions in LMICs, including personal representations^[110,111]. Another important area of research in LMICs is health systems which can be highly complex and thus, interventions and strategies developed for HICs may be inappropriate for LMICs with competing interests such as communicable diseases^[112] and affordability gaps^[113,114]. Overall, more research is required in various LMICs to provide the evidence base required to develop customized BC prevention strategy for each LMIC, as has also been reiterated by BHGI^[49].

Policy changes required for implementing BC screening in LMICs

It is quite apparent by now that cancer screening/early detection is not a high priority in terms of policy for LMICs. In fact, most LMICs are focused on maternal health policies based on Millennium Development Goals (MDGs). This is in spite of the fact that 200000 more women die each year due to breast and cervical cancer than from complications due to pregnancy and childbirth^[115-117]. The rising incidence of cancer in women in LMICs is quite in line with “cancer transition” described by Bray *et al*^[118]. According to these projections of cancer trends until 2030, it is plausible that cancers caused due to infections (*e.g.*, cervical cancer) will be offset due to a rise in cancers associated with NCD risks (*e.g.*, breast cancer)^[118]. Thus, overall the burden of women’s cancer will continue unabated unless the right policies are made to counteract such trends by building capacity for basic cancer services, especially screening/early detection.

Premature death and disability from cancer has maximum economic impact compared to other causes of death worldwide. Despite this, only 5% of global resources are being spent in LMICs on cancer, while 80% of the cancer burden is being borne by LMICs^[119]. With such low spending in LMICs and even without direct medical expenditures, cancer still costs approximately 895 million USD, or 1.5% of global GDP, which is 20% higher than that for cardiovascular disease^[120]. According to Knaul *et al*^[121], much of this spending can be reduced. Especially for breast and cervical cancer, the cost savings by the

“prevention/early detection and treatment approach” are much greater than by the “treatment only” approach followed currently by LMICs. The scenario is changing gradually, although with few and far between examples of implementation of cancer screening/early detection in LMICs. For example, the state of Tamil Nadu in India is the first state to launch cervical cancer screening using the VIA/VILI method^[122]. However, what is still lacking in India and most other LMICs is an overarching nationwide policy that implements screening, early detection and prevention of cancer. Thus, the need of the hour for most LMICs is the formation of a national cancer control policy which also has inbuilt strategies for increasing knowledge and awareness of people regarding cancer.

FUTURE REQUIREMENTS AND POSSIBILITIES FOR BREAST CANCER PREVENTION IN LMICS-THE SURREAL

New inventions of the future for BC screening

Although the main modalities of BC screening/early detection are still a trio of mammography, CBE and BSE, new modalities are emerging for BC prevention that may become the cornerstone of BC screening/early detection in future with greater benefits and cost-effectiveness for LMICs. One such method for BC screening/early detection has been the use of ultrasonography (USG) and there have been limited trials in LMICs^[123,124] that have proven their utility, especially when dealing with small or dense breasts, as is common with BC occurring in younger premenopausal women in LMICs^[124]. Similar trials of USG as a screening modality are required in other LMICs to evaluate its benefits as a more cost-effective and easily available way of conducting BC screening/early detection. A number of other modalities are also gradually becoming available apart from mammography and USG, such as low-dose mammography, contract-enhanced mammography, tomosynthesis, molecular imaging and magnetic resonance imaging (MRI)^[125]. MRIs are more sensitive than mammograms in picking up tumors in asymptomatic women^[46]. However, once again more trials are necessary in LMIC specific contexts to decide the best suitable technologies according to age, risk and breast density^[125]. The main issue when it comes to widespread use of better imaging technologies such as MRI is to bring down the costs to levels that can be afforded by health systems of LMICs^[126].

Use of mobile health (mHealth) for better spread of education and awareness

It will also be ideal in future if the full potential of mHealth is utilized for enhancing knowledge and changing the attitudes of women in LMICs regarding cancer and screening behaviors to limit the impact of “structural violence”^[103]. Technological interventions have gained much popularity ever since the phenomenal growth observed in Asia, Africa and Latin America in the use of

new information and communication technologies (ICTs), especially the cell phone and internet^[127]. If we look at the most recent figures, 41% of the world's households were using the internet, ranging from 7% in Africa to 77% in Europe^[127,128]. More astounding is the number of global mobile phone users which has grown to 6.8 billion, or 96% of the world's population, with the greatest growth occurring in Asia, Middle East and Africa^[127,129]. All this has become the bedrock for the growth of ICTs in health, eHealth systems or mHealth.

Mobile phone based ICTs have been used in multiple ways globally in the context of LMICs. Also termed mHealth, individuals around the world are increasingly integrating mobile technologies to access health care services and information while health professionals are integrating mobile technologies into public health and clinical activities^[130]. The main advantages of a mobile or cell phone platform has been its capability of transferring information quickly for both literate and illiterate populations. With relatively low start-up cost and flexible payment plans, mobile technology is accessible by most strata of the population^[131]. Various uses of mobile phones in health have included using SMS or even voice-recorded messages for things like reminders to take medication or dates for appointments. With further development of health-related software in mobile phones, such platforms can provide real-time feedback, pre-programmed automated message services and support an increasingly decentralized health system^[132]. Several studies from LMICs, such as Bangladesh, Laos and Egypt, have shown that introduction of mobile phones led to a more direct link between clients and health care workers, causing an increase in demand for health services and health-related information^[131,133]. Such mHealth strategies can be made a part of the cancer control programs in various LMICs for easy dissemination of information, for reminding women about appropriate screening behavior, and for scheduling appointments for screenings.

CONCLUSION

In conclusion, it can be pointed out that in spite of more women dying from cancer than from pregnancy or childbirth related complications, most LMICs are focused mainly on maternal health in terms of resources, while cancer overall and BC takes a backseat. That apart, policy maker awareness remains low in LMICs regarding BC screening/early detection being cost-effective and the "best buy" opportunity to reduce health costs. This coupled with a lack of research regarding cost-effective screening/early detection methods and little community awareness about BC being a treatable disease results in most LMICs losing a large number of women at an early age, a situation that is unfair from a human rights perspective while also creating "cancer orphans"^[86]. While creating new options for pathological diagnosis and treatment, the main focus of LMICs must be on developing national level programs that emphasize screening/early

detection of BC along with effective use of ICT for changing knowledge, attitudes and practices of women. In addition, greater encouragement for research in various aspects of public health ranging from use of newer screening methods and improving health systems cannot be emphasized enough. For the moment, the best option ahead for LMICs is to begin with ways of opportunistic screening after assessing a woman's risk using a combination of CBE followed by mammography at select centers. As a next step, such methods must be rolled out for the larger population with guidelines developed regarding frequency of screening based on the BC epidemiology in a particular LMIC. Further research regarding use of USG and development of screening guidelines regarding use of USG as a screening modality in LMICs is eagerly awaited.

Abstract

Breast cancer is the most common cancer among women. In recent years, many *in vitro* and *in vivo* studies indicate that green tea possesses anti-cancer effects. The epidemiological studies, however, have produced inconclusive results in humans. Likewise, results from animal models about the preventive or therapeutic effects of green tea components are inconclusive. The mechanisms by which green tea intake may influence the risk of breast cancer in humans remain elusive mechanisms by which green tea intake may influence. Here, we review recent studies of green tea polyphenols and their applications in the prevention and treatment of breast cancer. Furthermore, we discuss the effect of green tea components on breast cancer by reviewing epidemiological studies, animal model studies and clinical trials. At last, we discuss the mechanisms by which green tea

components suppress the development and recurrence of breast cancer. A better understanding of the mechanisms will improve the utilization of green tea in breast cancer prevention and therapy and pave the way to novel prevention and treatment strategies for breast cancer.

Key words: Breast cancer; Green tea; Epigallocatechin-3-gallate; Chemoprevention; Treatment

Core tip: Green tea components, especially epigallocatechin-3-gallate, possess anti-breast cancer effects. However, their effects on breast cancer prevention and therapy are still inconclusive. The anti-tumor mechanisms of green tea remain elusive. This review focuses on epidemiological and animal studies on green tea components against tumorigenesis, as well as possible mechanisms involved.

INTRODUCTION

Breast cancer is a malignant proliferation of epithelial cell lining the ducts or lobules of the breast. Breast cancer is still the most common cancer among women^[1]. According to the National Cancer Institute, 232340 new cases of female breast cancer and 2240 new cases of male breast cancer were reported in the United States in 2013, as well as about 39620 deaths caused by this disease. While there has been a steady decrease in breast cancer incidence and mortality since the early 90s^[1], due largely to improvements in the early detection and treatment of breast

tumors^[2], the social and economic impact of this malignancy continues to be enormous^[3]. Many risk factors can impact on a woman's likelihood of developing breast cancer^[4]. For those who are at a high risk for breast cancer, chemoprevention may be an alternative intervention to inhibit or delay carcinogenesis.

Green tea is the distinctive “liquor” produced from the evergreen plant *Camellia sinensis* leaves and is the most ancient beverage in the world. Traditional Chinese medicine has recommended drinking green tea for the prevention of disease. In recent years, many scientific and medical studies suggested that green tea possesses antiproliferative, antimutagenic, antioxidant, antibacterial, antiviral and chemopreventive effects^[5]. Green tea contains large amounts of various flavonoids. A major class of flavonoids is catechins, which include epicatechin (EC), epigallocatechin (EGC), epicatechin-3-gallate (ECG), and epigallocatechin-3-gallate (EGCG)^[6]. EGCG is the most abundant catechin and accounts for 50%-75% of the total amount of catechins. Also, EGCG appears to be the most effective constituent of green tea^[7]. Green tea polyphenols, and its major constituent EGCG, have been tested in tissue culture, animals and more recently in clinical trials^[5]. In this review, we will highlight the recent studies on tea polyphenols and their applications in the prevention and treatment of breast cancer.

GREEN TEA AND BREAST CANCER PREVENTION: EPIDEMIOLOGICAL STUDIES

Over the past three decades, green tea has attracted increasing attention for its health benefits, especially anti-cancer effects^[8]. As early as 1997^[9], there was an epidemiological study showed that increased consumption of green tea had a potentially preventive effect on breast cancer in a Japanese population, especially among females drinking more than 10 cups a day. Since then, the association between green tea consumption and breast cancer risk has been extensively investigated. To date, three meta-analyses^[10-13] have been published on the association between green tea and breast cancer risk and/or recurrence.

The most recent meta-analyses included two studies of breast cancer recurrence and seven studies of breast cancer incidence^[11,14-20]. Among the two studies of breast cancer recurrence, both found a non-significant reduction in recurrence among heavy green tea drinkers (> 3 cups a day)^[14,15]. There was no significant heterogeneity among the studies ($P = 0.65$, $I^2 = 0\%$). This analysis suggested a marginally significant reduction of 27% in recurrence among heavy green tea drinkers (> 3 cups a day) (summary RR = 0.73, 95%CI: 0.56-0.96) when compared to non-drinkers. Among the breast cancer incidence studies, two were cohort studies and five were case-control studies^[16-20]. Overall, there was a statistically significant reduction of 19% among women with high green tea

intake (summary RR = 0.81, 95%CI: 0.75-0.88). Case-control studies suggested an identical effect as the overall analysis with a 19% reduction in risk among green tea drinkers (summary RR = 0.81, 95%CI: 0.75-0.88). However, when cohort studies were analyzed separately, no association between green tea consumption and breast cancer incidence was observed (summary RR = 0.85, 95%CI: 0.65-1.22). In the second meta-analysis, seven studies were included for analyses^[16-18,21,22]. The pooled RR of developing breast cancer for the highest levels of green tea consumption in cohort studies was 0.89 (95%CI: 0.71-1.1, $P = 0.28$, $I^2 = 0\%$), and in case control studies, the odds ratio was 0.44 (95%CI: 0.14-1.31, $P = 0.14$, $I^2 = 47\%$). In summary, these meta-analyses did not find a significant effect of green tea on breast cancer prevention. For the 2 studies that assessed risk of breast cancer recurrence in relation to green tea consumption, both were cohort studies ($n = 1632$)^[15,23]. The pooled RR for breast cancer recurrence in all stages was 0.75 (95%CI: 0.47-1.19, $P = 0.22$, $I^2 = 37\%$). A subgroup analysis of recurrence in stage I and II disease showed a pooled RR of 0.56 (95%CI: 0.38-0.83, $P = 0.004$, $I^2 = 0\%$). These data indicate that high intake of green tea may be associated with a relative risk reduction in stage I and II breast cancer recurrence.

The epidemiological studies on the association between green tea and breast cancer remain inconclusive^[24,25]. Remarkably, green tea may also interact with other bioactive dietary components, such as those in soy and mushroom, to affect breast cancer risk. A study in Asian-American women demonstrated a statistically significant inverse association between green tea and breast cancer risk among women with low soy intake, but not among women with high soy intake^[26]. A case-control study indicated that higher dietary intake of mushrooms decreased breast cancer risk in pre- and postmenopausal Chinese women, and an additional decreased risk of breast cancer from joint effect of mushrooms and green tea was observed. These data suggested that combined green tea composition with other bioactive dietary components may be an appropriate way to improve its effects in cancer prevention. However, additional studies are required to elucidate the potential mechanisms of action.

GREEN TEA COMPONENTS AND BREAST CANCER: *IN VIVO* EXPERIMENTAL STUDIES

Green tea components and breast cancer prevention in animal models or clinical trials

“Cancer chemoprevention” was first introduced by M. Sporn, who defined it as the prevention of the occurrence of cancer by the oral administration of one or multiple compounds^[27]. In 1987, the chemopreventive effect of EGCG was first reported when the inhibitory effects of EGCG on teleocidin-induced tumor promotion in mouse skin was observed^[28]. There is an increasing

amount of evidence that has been presented, indicating that green tea may be chemopreventive^[29]. Here, we focus on several recent studies about the effects of green tea components on breast carcinogenesis in animal models or clinical trials (Table 1).

Kavanagh *et al.*^[30] showed that a green tea extract significantly increases mammary tumor latency and decreases tumor weight and metastases in dimethyl-benzanthracene (DMBA) treated rats. Sakata and co-workers showed that green tea, alone or in combination with other anticancer components, may have significant chemopreventive effects on carcinogen-induced mammary tumorigenesis^[31]. In the DMBA-induced mammary cancer rat models, the number of tumors per rat and the time latency to tumor development were estimated. However, animals exposed throughout life to EGCG in the drinking water showed no significant difference compared with the control group with respect to second and third tumor latency, although there was a decrease in the latency to first tumor development. Furthermore, the number of tumors per rat in EGCG-exposed rats was not significantly different from that in the controls. The authors suggested that the lack of effect of EGCG was because of the low bioavailability of pure EGCG. In 2012, Crew *et al.*^[32] reported results from a phase Ib clinical trial using EGCG over a 6-mo period, which was conducted to determine the maximum tolerated dose (MTD)^[32,33]. During the treatment period no changes in breast tissue proliferation were observed. Overall, the agent was well-tolerated, with toxicity data establishing a 600 mg twice daily MTD for polyphenon E (Poly E). A phase II trial testing the cancer preventive effects of 1 year of EGCG in postmenopausal women with high mammographic is currently ongoing, and the results are expected.

Green tea components and breast cancer therapy in animal models

So far, numerous studies have investigated the therapeutic effects of green tea on breast cancer using different rodent models and a variety of green tea products including green tea mixtures as well as specific catechins^[38]. The recent studies of green tea catechins for breast cancer treatment in animal models are summarized in Table 2.

One recent study showed that treatment with EGCG at 50 to 100 mg/kg per day in drinking water significantly inhibited the progression of breast cancer in female mice. A further study suggested that the effect of EGCG on tumour size was mediated by the inhibition of hypoxia-inducible factor 1 α (HIF-1 α) and nuclear factor κ B (NF- κ B) activation as well as vascular endothelial growth factor (VEGF) expression^[39]. Another study demonstrated that EGCG significantly reduced tumor volume in a xenograft mouse model developed using stem-like SUM-149 breast cancer cells^[40].

Remarkably, one study showed that high-dose green tea extracts strongly activated HIF-1 in T47D human breast carcinoma cells, and increased the expression of HIF-1 target genes including glucose transporter

(GLUT)-1, VEGF, and p21/CDKN1A^[41]. These results suggest that intended cancer chemoprevention with high-dose green tea extracts may be compromised by the ability of tea catechins to promote tumor cell survival pathways associated with HIF-1 activation. Therefore, the possibility of antagonistic interactions must be taken into account in the development of new cancer therapy strategies based on drug-EGCG co-treatments.

In breast cancer, EGCG has been shown to interfere with estrogen receptor function, inhibit estrogen-induced breast cancer cell proliferation, and sensitize hormone responsive tumors to drugs that target steroid receptors (*e.g.*, tamoxifen)^[44-46]. The combination of EGCG and curcumin was efficacious in both *in vitro* and *in vivo* models of ER α - breast cancer. Also, our study showed that EGCG overcame paclitaxel-induced 78 kDa glucose-regulated protein (GRP78) expression and potentiated paclitaxel-induced Jun N-terminal kinase (JNK) phosphorylation in 4T1 cells both *in vitro* and *in vivo*^[47]. When tumor-bearing mice were treated with paclitaxel in combination with EGCG, tumor growth was significantly inhibited, whereas the single-agent activity of paclitaxel or EGCG was poor. In addition, a clinical trial conducted recently in breast cancer patients undergoing radiotherapy showed that EGCG could potentiate the effect of ionizing radiation^[48]. After two to eight weeks of EGCG plus radiotherapy administration, serum levels of angiogenic factors VEGF, hepatocyte growth factor, and active matrix metalloproteinase (MMP)-2 and MMP-9 were lower compared to those in patients receiving only radiotherapy. In addition, the antioxidant and anti-inflammatory activities of green tea catechins have been suggested to contribute to the potential protective role of EGCG against chemotherapy and radiotherapy side effects^[49]. The use of green tea components, especially EGCG, could enhance the effect of conventional cancer therapies through additive or synergistic effects as well as through amelioration of deleterious side effects. Further research, especially at the clinical level, is needed to ascertain the potential role of EGCG as an adjuvant in breast cancer therapy.

MECHANISMS OF ACTION OF GREEN TEA COMPONENTS IN BREAST CANCER

To better understand the preventive and therapeutic activities of green tea components on breast cancer found in animal studies, substantial research has been conducted to uncover the mechanisms at cellular and molecular levels. Experimental studies collectively show that green tea components lead to wide range of responses in animal models or breast cancer cells.

Anti-angiogenesis

Induction of new blood vessel growth, known as angiogenesis, is required for tumor growth and metastasis^[50]. Angiogenesis permits rapid tumor growth by providing an exchange of nutrients, oxygen, and paracrine stimuli to the tumor. A recent study showed that EGCG treat-

Table 1 Studies of green tea catechins on mammary tumorigenesis in animal models or clinical trials

Ref.	Model	Intervention	Main results
Kavanagh <i>et al</i> ^[30] , 2001	4-wk-old female Sprague-Dawley rats	Treated with green tea catechins after exposure to DMBA	Green tea extract given after initiation significantly increases mammary tumor latency and decreases tumor weight and metastases in DMBA-treated rats
Hirose <i>et al</i> ^[34] , 2002	6-wk-old female F344 rats	PhIP alone or PhIP plus 1% green tea catechins for 52 wk	1% green tea catechins were associated only with reduced mean size of mammary tumors without affecting the total number of mammary tumors
Whitsett <i>et al</i> ^[35] , 2006	Female Sprague-Dawley CD rats	Treated with DMBA to induce breast cancer after previous exposure to green tea catechins or control diet throughout life	Animals exposed throughout life to EGCG in the drinking water showed a decrease in the latency to first tumor development, although there was no significant difference as compared with the control group with respect to second and third tumor latency. Furthermore, the number of tumors per rat in EGCG-exposed rats was not significantly different from the controls
Kaur <i>et al</i> ^[36] , 2007	C3(1)SV40T, t antigen transgenic multiple mammary adenocarcinoma mice	Mice received green tea catechins in drinking water at 0.01% (w/v) for 25 wk, with water as control	Green tea catechins delayed carcinogenesis as evidenced by a significant decrease in the volume and size of tumors in the mice exposed to green tea extract
Lubet <i>et al</i> ^[37] , 2007	50-d-old female Sprague-Dawley rats	Intravenous injection of methyl-nitrosourea (75 mg/kg bw) <i>via</i> the jugular vein. 5 d after treatment with the carcinogen, Poly E was given by gavage at 1000 and 333 mg/kg bw/d.	There was no effect of Poly E on the latency period of the mammary tumors. The high and low doses of Poly E decreased the number of mammary tumors by 14% and reduced the weight of the tumors by 30% and 21%, respectively
Sakata <i>et al</i> ^[31] , 2011	C3H/OuJ mice carrying preneoplastic lesions	Treated with EGCG and tamoxifen alone or in combination	The tumor incidences were decreased in the green tea extract, tamoxifen, and green tea extract and tamoxifen groups. Importantly, in the group treated with green tea extract and tamoxifen, no tumors developed
Crew <i>et al</i> ^[32] , 2012	Women with a history of histologically confirmed resected stage I-III, estrogen and progesterone receptor negative breast carcinoma.	Participants received either Poly E delivering 400, 600, or 800 mg of EGCG (2-4 capsules) twice daily with food or matching placebo for 6 mo	(1) The MTD for Poly E should be 600 mg twice daily; (2) There was about a 70% reduction in serum estradiol levels ($P = 0.05$) and a significant decrease in SHBG ($P = 0.03$) at 6 mo compared with baseline in the Poly E group. However, these changes did not differ significantly compared with the placebo group due to smaller numbers; and (3) No changes in breast tissue proliferation were observed.

DMBA: Dimethyl-benzanthracene; EGCG: Epigallocatechin-3-gallate.

ment reduced plasma VEGF levels over the control mice and the EGCG-treated tumor had lesser micro-vessels than the control tumor. The down-regulation of VEGF expression by EGCG was associated with the inhibition of HIF-1 α and NF- κ B activation^[39]. Consistently, administration of polyphenon E, a standardized green tea extract, at concentrations of 20 ng/ μ L or greater significantly decreased the formation of vascular structures. *In vivo*, quantification of micro-vessel density also indicated that polyphenon E drastically reduced angiogenesis in a dose-dependent manner^[51]. Another *in vitro* study showed that green tea extracts and EGCG decreased the RNA levels of VEGF in MDA-MB231 cells^[52]. Taken together, inhibition of VEGF transcription appeared to be one of the molecular mechanisms involved in the antiangiogenic effects of green tea, which may contribute to its potential use for breast cancer treatment and/or prevention.

Interaction with target proteins

The eight phenolic groups of EGCG can serve as hydrogen bond donors to many biomolecules. EGCG has been recently shown to bind with high affinity to several target proteins, including phosphoinositide 3 kinase (PI3K)^[53], 67-kDa laminin receptor^[54], Ras-GTPase activating protein (GAP) SH3 domain-binding protein

1 (G3BP1)^[55], Bcl-xL and Bcl-2^[56], vimentin^[57], Fyn^[58], GRP78^[59], 70 kDa zeta-associated protein (Zap-70)^[60], insulin like growth factor 1 receptor (IGF-1R)^[61] and so on. All these proteins have been demonstrated to be important for the inhibitory activity of EGCG in breast cancer cell lines or animal models.

Inhibition of cell signaling pathways

VEGF is the most significant regulator in the development of the vascular system and is commonly overexpressed in breast cancer. Green tea catechins, especially EGCG, inhibit tumor growth, proliferation, migration, and angiogenesis of breast cancer^[39,52]. Overexpression of Her-2/neu, the second member of epidermal growth factor receptor (EGFR) family, has been seen in about 30% of breast cancers and was associated with poor overall survival. EGCG treatment reduces basal phosphorylation and constitutive activation of the Her-2/neureceptor^[62,63]. Other investigators have demonstrated that EGCG blocks Wnt signaling through the HBP1 transcriptional repressor that was previously shown to inhibit Wnt signaling^[64]. In addition, Bigelow and Cardelli have investigated the effect of EGCG on inhibition of the hepatocyte growth factor signaling pathway. The results showed that EGCG (0.3 mmol/L) could completely

Table 2 Studies of green tea catechins on breast cancer treatment in animal models

Ref.	Model	Intervention	Effect on tumor size	Main mechanisms
Gu <i>et al</i> ^[39] , 2013	8-wk-old female C57BL/6 mice were inoculated with 10 ⁶ E0771 cells into the left fourth mammary gland fat pad	After cells were inoculated, mice received EGCG (around 50-100 mg/kg per day) in drinking water for 4 wk and 8 control mice received water only	(1) Tumor cross section area reduced 65% ($P < 0.01$); (2) tumour weight reduced 68% ($P < 0.01$); and (3) no difference in body weight, heart weight, kidney weight, or urinary protein	Inhibition of vascular endothelial growth factor (VEGF) expression and tumor angiogenesis <i>via</i> inhibiting hypoxia-inducible factor 1 α and nuclear factor κ B activation
Mineva <i>et al</i> ^[40] , 2013	6-wk-old female nonobese diabetic/severe combined immunodeficiency mice were implanted with 5 \times 10 ³ SUM-149 cells in the fourth inguinal mammary fat pad	After 25 d, mice were intraperitoneally injected with 16.5 mg/kg EGCG or control PBS five times a week for the first five weeks and daily for the last week	(1) Tumor volume decreased 37.7% \pm 4.4%; (2) tumor weight decreased 28.6% \pm 6.5%; and (3) the lymphatic vessel density at the periphery of tumors decreased in EGCG-treated mice	EGCG decreased levels of VEGF-D RNA and VEGF-D protein
Jang <i>et al</i> ^[42] , 2013	4T1 cells (10 ⁵) were injected subcutaneously into either side of the posterior flank of BALB/c mice	On the 7 th , 9 th , 11 th days after cell injection, mice were intraperitoneally injected with either EGCG (10 mg/kg) or PBS control	On day 30 after cell injection, a significant decrease of tumor volume and weight was observed in the EGCG-treated group <i>vs</i> the control group ($P < 0.0005$)	EGCG inhibited expression of CSF-1, CCL-2, IL-6 and transforming growth factor- β , and induced tumor necrosis factor- α expression
Thangapazham <i>et al</i> ^[43] , 2007	5-wk-old female athymic nude mice (NCR-nu/nu) were implanted with 5 \times 10 ⁶ MDA-MB-231 cells in the mammary fat pad	After cell inoculation, one group of animals received 1% polyphenols from green tea (GTP) as a sole source of drinking water and the other group received a dose of 1 mg/animal of EGCG or water as control	At the end of 10 wk, the tumor volume was reduced by 45% and 61% in the EGCG and GTP treated groups, respectively ($P < 0.05$). All animals appeared healthy with no loss of body weight	EGCG and GTP fed animals showed increased apoptosis and decreased proliferation

DMBA: Dimethyl-benzanthracene; EGCG: Epigallocatechin-3-gallate; VEGF: Vascular endothelial growth factor.

blocked phosphorylation of Met (HGF Receptor) and its downstream extracellular signal-regulated kinases 1 and 2 (ERK1/2), and Akt/protein kinase B (PKB)^[65].

Inhibition of enzyme activities

Numerous *in vivo* and *in vitro* studies have been published on the anti-tumour and anti-proliferative properties of green tea. EGCG has been reported to inhibit a number of enzymes. For example, Liang *et al*^[60] showed that cyclin-dependent kinase (CDK) 2 and CDK4 were inhibited by 30 μ mol/L EGCG in MCF-7 breast cancer lines, and this was associated with cell cycle arrest in G₀ and G₁. Also, EGCG increased the expression of the CDK inhibitor p21 in human breast carcinoma cells. Another study found that EGCG inhibited p38-regulated/activated protein kinase (PRAK; IC₅₀ = 1 μ mol/L) and dual-specificity tyrosine-phosphorylated and regulated kinase 1A (DYRK1A; IC₅₀ = 0.33 μ mol/L), but did not inhibit CDK2^[67]. A recent study shows that EGCG is an ATP-competitive inhibitor of both PI3K and mammalian target of rapamycin with *K_i* values of 380 and 320 nmol/L, respectively^[53].

Induction of cell cycle arrest and apoptosis

Dysregulated cellular proliferation and apoptosis are a hallmark of cancer. Green tea extracts and EGCG are capable of inhibiting cell growth and inducing apoptosis *via* a variety of mechanisms. Recent studies showed that EGCG suppressed proliferation and growth of triple negative breast cancer Hs578T cells^[68], estrogen and pro-

gesterone receptor positive human breast cancer cells^[69], MMTV-Her-2/neu mammary gland tumor NF639 cells^[63] and others^[70]. Also, EGCG induced apoptosis in estrogen receptor negative MDA-MB-468^[71] and MDA-MB-231 cells^[72]. Therefore, it is likely that EGCG induces cell cycle arrest and apoptosis in most, if not all, breast cancer cell lines. EGCG increases protein expression of p21 and p27^[73]. Green tea inhibited expression of Ki-67 in both benign and malignant cells^[74]. EGCG alters the activity of EGFR and its downstream targets^[75]. In addition, research showed that catechin hydrate increased the expression of pro-apoptotic genes caspase-3, -8, and -9 and TP53^[70,76]. In addition, EGCG can mediate the retinoblastoma (pRb)-E2F/DP pathway, an important regulator of cell cycle arrest and apoptosis^[77].

Effects on microRNAs

MicroRNAs (miRNAs) are small (about 22 bases), single stranded, endogenous, noncoding RNAs that negatively regulate the translation and/or stability of mRNAs. It could be affected by EGCG to cause subtle changes in multiple molecular targets and pathways. In 2010, the first global miRNA expression profile showed that there were 16 down-regulated and 7 up-regulated miRNAs in MCF-7 breast cancer cells treated with Polyphenon-60 green tea extract^[78]. Remarkably, among the miRNAs down-regulated by Polyphenon 60 treatment, MiR-27a was the most dramatic^[78]. MiR-27a directly targets FOXO1, a putative tumor suppressor, and regulates endogenous protein expression in MCF-7 breast cancer

cells^[79]. In addition, Jang *et al.*^[42] found that EGCG up-regulates MiR-16 in tumor cells, which down-regulates I κ B kinase α and subsequently induces I κ B accumulation in tumor associated macrophages, and inhibits M2 polarization. These studies suggest that the ability of green tea components to regulate miRNA expression may be one of potential mechanisms for green tea in breast cancer prevention and treatment.

Other potential mechanisms

In addition to mechanisms discussed above, there were other mechanisms involved in anticancer effects of green tea components including DNA methylation, metabolism, endoplasmic reticulum stress response and so on. Treatment of breast cancer cells with EGCG results in promoter demethylation of human telomerase reverse transcriptase, retinoic acid receptor β 2 and target of methylation-induced silencing 1^[80,81]. These studies demonstrated that EGCG has the potential to reverse epigenetic changes. A pilot study in overweight breast cancer survivors showed that intake of decaffeinated green tea for 6 mo was associated with a slight reduction in body weight and improved high-density lipoprotein and glucose homeostasis^[82]. Also, EGCG treatment inhibited the expression of fatty acid synthase in MCF-7 and AU565 human breast cancer cell lines by blocking heregulin^[83]. And our studies showed that EGCG potentiates quercetin-, taxol- and vinblastine-induced activation of pro-apoptosis arms of the endoplasmic reticulum stress response, such as JNK phosphorylation, caspase-7 and poly (ADP-ribose) polymerase (PARP) cleavage^[47,84,85]. In addition to these mechanisms discussed in breast cancer, there are other multiple mechanisms presented in colon, lung, prostate, ovarian and other cancers. It can be expected that further in-depth research on each of these specific mechanisms will uncover more details of the action of green tea in breast cancer prevention and therapy.

Abstract

Breast cancer continues to be one of the leading causes of cancer mortality in the world. The treatment generally involves multiple modalities including surgery, radiation and/or chemotherapy. Anthracyclines, one of the first chemotherapeutic agents introduced in the 1960s, has been the backbone for the last 30 years and has been used extensively so far. However, the cardiac toxicity and the concern for secondary hematological malignancy has always been a challenge. A better understanding of the tumor biology, role of Her2 expression and the discovery of trastuzumab and other anti-Her 2 agents along with other effective novel therapeutic options, have revolutionized the treatment for breast cancer. The role of anthracyclines has come under close scrutiny, especially in the adjuvant setting for patients with early stage breast cancer and those with low or intermediate risk of disease recurrence. Recent studies have highlighted such a shift in the use of anthracyclines in both the academic and community clinical practice. However, in patients with a high risk of relapse, anthracyclines still hold promise. Ongoing clinical trials are underway to further define the role of anthracyclines in such a patient population. This review highlights the development, clinical utility, limitations and potential future use of anthracyclines

in the adjuvant setting for patients with breast cancer. We consulted PubMed, Scopus, MEDLINE, ASCO annual symposium abstracts, and <http://clinicaltrials.gov/> for the purpose of this review.

Key words: Breast cancer; Adjuvant; Neoadjuvant; Chemotherapy; Anthracyclines

Core tip: A better understanding of the tumor biology along with other effective novel therapeutic options, have revolutionized the treatment for breast cancer. The role of anthracyclines has come under close scrutiny, especially in the adjuvant setting for patients with early stage breast cancer and those with low or intermediate risk of disease recurrence, as per the recent studies. However, in patients with a high risk of relapse, anthracyclines still hold promise. Ongoing clinical trials are underway to further define the role of anthracyclines in such a patient population.

INTRODUCTION

Approximately 230000 new cases of female breast cancer are diagnosed annually in the United States^[1]. The probability of developing invasive breast cancer in one's lifetime is one in eight^[2]. Breast cancer is a heterogeneous disease with common aspects to treatment including surgery, chemotherapy and radiation therapy. Systemic (neo)adjuvant chemotherapy, cytotoxic treatment before

or following primary surgery, is responsible in part for the reduction in cause-specific mortality from breast cancer^[3]. In the 1960s and early 1970s the anthracyclines emerged as a novel therapeutic agent against metastatic breast cancer and by the late 1970s the very first adjuvant trials with these agents were reported^[4-8]. By the 1980s, doxorubicin-based combination regimens established themselves as a primary class of chemotherapy regimens used in the treatment of early and advanced stage breast cancer^[5]. The introduction of new and effective therapeutic agents in combination with some of the irreversible and/or long term adverse events of the anthracycline group of drugs has now questioned their use in the (neo)adjuvant setting^[9].

PATIENT SELECTION/INDICATIONS FOR TREATMENT

Multiple components determine the necessity for patients requiring adjuvant chemotherapy. These include but are not limited to the tumor size, molecular subtype, histology and its grade. The axillary and regional lymph node status and the tumor hormone receptor expression are also important considerations. Finally, the patient's age, concomitant co-morbidities and their performance status play a significant role in determining the benefit of (neo)adjuvant chemotherapy. Other histologies require more information regarding size and nodal status to delineate the role of chemotherapy. Tumor size in the setting of regional disease is an independent prognostic factor with five-year overall survival (OS) for tumors ≤ 2 cm, 2.1 to 5 cm and ≥ 5 cm being 95, 82 and 63 percent, respectively^[10]. Nodal status also plays a role with any nodal involvement lowering the survival rate at five years^[11].

ESTIMATING THE BENEFIT/RISK RATIO

Despite all of the components above, selection of patients for adjuvant chemotherapy requires an individualized approach that has been enhanced by the use of benefit *vs* risk calculators. One of the most widely studied and validated tool is Adjuvant! Online^[12]. Adjuvant! Online is a web based program that aims to help health care professionals discuss the risk and benefits of getting additional therapy including chemotherapy, hormone therapy, or both after surgery for early stage cancer^[13]. The calculator uses resources such as Surveillance, Epidemiology, and End Results (SEER) database and data on adjuvant therapy from the Early Breast Cancer Trialists' Collaborative Group (EBCTCG), as well as data from several pivotal adjuvant clinical trials. It helps make approximations of the risk of a negative outcome (cancer related mortality or relapse) without systemic adjuvant therapy and calculates the estimates of the reduction of these risks afforded by therapy. These estimates are based on information entered about individual patients and their tumors (including patient age,

tumor size, nodal involvement, histologic grade, *etc.*)^[13]. In addition to the above risk calculator, the last decade has also witnessed the emergence of genomic profiling of the primary tumor with tests like Oncotype DX[®], Mammprint[®] and PAM50, which allows for better risk prognostication and in some of them a predictive benefit of adjuvant therapies^[14-16]. The review of these tools are beyond the scope of this article but needless to say, they have allowed to better define the population of patients that should consider adjuvant chemotherapy. This substantially helps both providers and patients to better assess the worthiness of the potential benefits of chemotherapy as compared to their known probable short and long term side effects.

DATA SUPPORTING ADJUVANT THERAPY WITH ANTHRACYCLINES

The EBCTCG meets every five years to review data from global breast cancer trials. The 2011 EBCTCG meta-analysis included an analysis of the utility of adjuvant chemotherapy. One analysis compared no treatment to the combination of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) compared to an anthracycline containing regimen. Compared to no treatment, the use of CMF in 5253 women resulted in a significant improvement in the risk of recurrence at 10 years [risk ratio (RR), 0.70, 95%CI: 0.63-0.77], which translated into an absolute gain of 10.2 percent. There was also a significant reduction in breast cancer mortality (RR, 0.76, 95%CI: 0.68-0.84), validating a complete benefit of 6.2 percent. Lastly, there was a significant reduction in overall mortality (RR, 0.84, 95%CI: 0.76-0.93), thereby demonstrating an absolute gain of 4.7 percent^[17]. Comparatively the use of an anthracycline containing regimen compared to no treatment in 8575 women established a significant improvement in the risk of recurrence at 10 years (RR, 0.73, 95%CI: 0.68-0.79), which resulted in a total gain of 8.0 percent. There was also a significant reduction in breast cancer mortality (RR, 0.79, 95%CI: 0.72-0.85), ensuing an absolute improvement of 6.5 percent and a significant reduction in overall mortality (RR, 0.84, 95%CI: 0.78-0.91), confirming an absolute benefit of 5.0 percent^[17].

The 2011 EBCTCG meta-analysis also compared the dosing regimens of anthracyclines *vs* CMF. The standard dose of anthracyclines was defined as a cumulative dose of doxorubicin of 240 mg/m² *vs* the high dose defined as doxorubicin > 240 mg/m² or epirubicin > 360 mg/m²^[17]. The 10 year results of this analysis in 5122 women showed that standard dosing of anthracyclines was equivalent to CMF with no improvement in the risk of recurrence, breast cancer mortality or overall mortality^[17]. An analysis of 9527 women receiving either higher cumulative doses of anthracyclines or CMF were compared at 10 years with a reduction in the risk of recurrence (RR, 0.89, 95%CI: 0.82-0.96), which translated into an absolute gain of 2.6 percent. There was also a reduction in breast cancer mortality (RR, 0.80, 95%CI: 0.72-0.88) with

an absolute gain of 4.1 percent and a reduction in overall mortality (RR, 0.84, 95%CI: 0.76-0.92) with an absolute gain of 3.9 percent^[17]. These results suggest standard dosing anthracycline regimens are equal to CMF but slightly inferior to regimens including higher cumulative doses of anthracyclines, *i.e.*, 6 cycles of an anthracycline-based regimen being better than 4 cycles. No single regimen has been defined as the absolute gold standard treatment but based on well conducted prospective trials and meta-analyses conducted by the EBCTCG, anthracycline-based regimens have been recommended for more than 2 decades^[17-19].

The 2011 EBCTCG meta-analysis also included taxanes such as docetaxel and paclitaxel in its analysis of adjuvant therapy. Incorporation of taxanes into an anthracycline containing regimen resulted at 8 years in the reduction of the risk of recurrence, risk of breast cancer mortality, and overall mortality. This benefit was present independent of age, nodal status, tumor size, tumor grade or estrogen receptor (ER) status^[17].

Studies have also examined the dose intensity of the adjuvant regimens. A meta-analysis of dose dense therapy *vs* standard therapy in 10 trials of over 11000 women reported an improvement in disease free survival (DFS) with dose dense therapy in women with estrogen receptor (ER)-negative disease (HR, 0.71, 95%CI: 0.56-0.98), but not in women with ER-positive disease (HR, 0.92, 95%CI: 0.75-1.12)^[18]. Another analysis of three randomized trials involving 6644 women with node positive breast cancer and variable hormone receptor status demonstrated that women with ER-negative breast cancer had a larger reduction in the risk of recurrence compared to women with ER-positive breast cancer at 5 years, (55% *vs* 26%, respectively). There was also a higher absolute improvement in DFS (23% *vs* 7%) and higher absolute improvement in OS (17% *vs* 4 %)^[19].

PROBLEMS WITH THE ANTHRACYCLINES

Cardiotoxicity and secondary MDS/AML are two significant long-term toxicities of anthracycline use. Anthracycline cardiotoxicity is believed to be derived from damage to the myocardium from free reactive oxygen radicals, direct DNA damage, interference with DNA repair, and induction of immune reactions leading to cardiomyocyte apoptosis^[20-22]. This damage leads to a decrease in the left ventricular ejection function, and although could be reversed with good medical management, in many cases could be an irreversible long term problem. The risk of MDS/AML remains rare at 0.5%-1% but it carries a high mortality rate due to its association with poor cytogenetics and refractory nature to standard treatment^[23,24].

ANTHRACYCLINE TOXICITY

Cardiotoxicity

Anthracyclines are associated with cardiovascular tox-

icities including abnormal electrocardiogram (sinus tachycardia and transient arrhythmias), cardiomyopathy, acute and late-onset congestive heart failure (CHF), myocarditis, pericarditis and myocardial infarction^[25,26]. The incidence of cardiomyopathy and heart failure secondary to anthracyclines has been shown to be dose dependent and generally occurs at higher doses than the dosages administered in the adjuvant setting. However, some of the other acute cardiac events are often not dose related and could occur as soon as after the first dose^[27,28]. The risk of chronic cardiomyopathy and CHF increases substantially at cumulative doses of doxorubicin greater than 400-500 mg/m²^[28] and epirubicin greater than 800-1000 mg/m²^[28]. It is estimated that the overall risk of cardiac toxicity using standard dose anthracyclines in the general population is approximately 1%-3%, however, such risk varies greatly depending on the population of women studied. Older studies that included patients who received higher cumulative doses of anthracyclines report a higher incidence rate whereas newer clinical trials have an insufficient follow up time to accurately assess the long-term incidence of CHF^[29]. An older but long-term prospective trial of 120 patients with advanced breast cancer showed that those patients receiving high cumulative doses of epirubicin (850-1000 mg/m²) had the highest risk of CHF with 11% at 1 year, 14% at 2 years and 20% at 5 years^[30]. Also of note, those patients receiving long term treatment with an angiotensin converting enzyme inhibitor had a significant and long term recovery in cardiac function^[30].

Certain populations including older women are at increased risk with a retrospective study of 12500 women with invasive breast cancer showing a 5-year cumulative incidence of CHF of 6 percent among women aged 65 to 74 and 11 percent among women aged ≥ 75 years^[31]. This was in stark contrast to younger women with a cumulative incidence of 1-2 percent. With the addition of biologic agents including trastuzumab there is a concern for additive cardiotoxicity. In women treated with an anthracycline plus trastuzumab, there was a cumulative CHF incidence of 20 percent which represented an increased risk compared to patients who did not receive an anthracycline or trastuzumab [hazard ratio (HR), 7.19, 95%CI: 5-10.4]^[31]. The risk was also increased among patients treated with trastuzumab without an anthracycline (HR, 4.12, 95%CI: 1.11-1.76)^[31]. Of note in this study only 11.2 percent of women over the age of 65 received an anthracycline based therapy^[31]. Another study supporting the increased risk in older women reviewed 43338 patients with breast cancer treated with chemotherapy through the SEER database^[32]. The authors concluded women aged 66 to 70 years who received adjuvant anthracyclines had significantly higher rates of CHF, 38.4% of the anthracycline-treated group compared with 32.5% of the patients who received non-anthracycline chemotherapy and 29% in the no-chemotherapy group^[32]. The difference in rates of CHF continued to increase through more than 10 years of follow-up^[32].

There has also been data that have not supported long term cardiac adverse effect of adjuvant anthracycline therapy. Patients treated on the Southwest Oncology Group (SWOG) protocol S8897 were randomly assigned to adjuvant chemotherapy with or without the anthracycline doxorubicin. A retrospective study evaluated the left ventricular ejection fraction (LVEF) at 5 to 8 years and 10 to 13 years after treatment randomization^[33]. A total of 93 breast cancer survivors from a potential sample of 1176 patients completed the longitudinal assessment of LVEF^[33]. In the longitudinal analysis, there was no significant deterioration in LVEF concluding that the exposure to doxorubicin did not increase the likelihood of adverse cardiac effects^[33]. However, as noted the studied population was very small.

Risk of MDS and AML

Another well-known serious and concerning adverse event from the use of anthracycline is the development of myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML). Multiple cytotoxic agents have been implicated including those more commonly used in breast cancer including cyclophosphamide, doxorubicin, daunorubicin and epirubicin. The incidence among breast cancer patients varies among different retrospective studies. In a review of 6 adjuvant National Surgical Adjuvant Breast and Bowel Project (NSABP) breast cancer trials (B-15, B-16, B-18, B-22, B-23, and B-25) the incidence of AML/MDS was sharply elevated in patients receiving standard dose doxorubicin ($60 \text{ mg/m}^2 \times 4$) plus higher doses of the alkylating agent cyclophosphamide. In this study, those regimens with two or four cycles of cyclophosphamide at 2400 mg/m^2 (with granulocyte colony-stimulating factor (G-CSF) support) had a cumulative incidence of AML/MDS at 5 years of 1.01% (95%CI: 0.63% to 1.62%), compared with 0.21% (95%CI: 0.11% to 0.41%), for patients receiving 4 cycles of standard doxorubicin/cyclophosphamide (AC) chemotherapy^[34]. Also patients who additionally received breast radiotherapy experienced more secondary AML/MDS than those who did not (RR, 2.38, $P = 0.006$)^[34]. This study also suggested that the use of G-CSF may be an independent factor associated with increased risk of MDS/AML but this may be secondary to the use of higher doses of leukemogenic chemotherapy agents.

Therapy related myeloid neoplasms (t-MN) have on average a latency period of five to seven years^[35]. Praga and colleagues reviewed the incidence of AML/MDS in 19 randomized trials involving 7110 patients who had received adjuvant epirubicin and cyclophosphamide^[24]. Patients with administered cumulative doses of both epirubicin and cyclophosphamide in standard regimens ($\leq 720 \text{ mg/m}^2$ and $\leq 6300 \text{ mg/m}^2$, respectively) had an 8-year cumulative probability of developing AML/MDS of 0.37% (95%CI: 0.13% to 0.61%) compared with 4.97% (95%CI: 2.06% to 7.87%) for patients administered higher cumulative doses of both epirubicin and cyclophosphamide^[24]. Patients most commonly present

with persistent hematologic abnormalities such as macrocytic anemia or pancytopenia in peripheral blood and bone marrow evaluation reveals changes consistent with MDS or AML. Cytogenetics plays an important role in the prognosis of AML. In patients with t-MN there is a higher incidence of unfavorable cytogenetics compared to de novo AML (46.2% *vs* 20.4%)^[36]. Unfavorable genetics affect OS even more in treatment related AML compared to de novo AML (10 mo *vs* 15 mo, $P < 0.001$)^[36].

ANTHRACYCLINE VS NON-

ANTHRACYCLINE ADJUVANT REGIMENS

The MA.5 trial directly compared an anthracycline to a non anthracycline regimen^[37]. The trial enrolled 710 pre and peri-menopausal women with node positive breast cancer. Patients were randomly assigned to receive cyclophosphamide, epirubicin, and fluorouracil (CEF) or cyclophosphamide, methotrexate, and fluorouracil (CMF). The 10-year relapse free survival was 52% for patients who received CEF compared with 45% for CMF patients (HR for CMF *vs* CEF = 1.31; stratified log-rank, $P = 0.007$). The 10-year OS for patients who received CEF and CMF are 62% and 58%, respectively (HR for CMF *vs* CEF = 1.18; stratified log-rank, $P = 0.085$). These results support the previous 5 year follow up data with CEF being superior to CMF^[38]. This trial was not powered for comparison of treatment regimens in subgroups based on nodes or hormone receptor status, however, the HRs favored CEF in patients with one to three nodes and four or more nodes^[37].

The National Surgical Adjuvant Breast and Bowel Project (NSABP) 23 trial was another direct comparison of an anthracycline to a non-anthracycline containing regimen^[39]. 2008 patients were randomly assigned to CMF or AC with or without tamoxifen. In contrasting results a comparison between all CMF and all AC treated patients demonstrated no significant differences in relapse free survival (RFS) (87% at 5 years in both groups, $P = 0.9$), event free survival (EFS) (83% and 82%, $P = 0.6$), or OS (89% and 90%, $P = 0.4$)^[39].

As noted above, the CMF regimen has been a well-established non-anthracycline-containing regimen but its lack of superiority and longer duration of therapy led to its relative abandonment by the oncologic community in the 1990s. However, it still has an important role for patients who are not candidates for anthracycline and/or taxane-based regimens. Capecitabine, an oral prodrug that is converted to 5-fluorouracil, and approved for the treatment of metastatic breast cancer, has been evaluated in the adjuvant setting as a possibly more convenient and less toxic chemotherapy for older women. The Cancer and Leukemia Group B study CALGB 49907 was a randomly assigned trial comparing standard chemotherapy (AC or CMF per patient/provider's choice) *vs* oral chemotherapy with capecitabine in patients age 65 years or older with early-stage breast cancer^[40]. Unfortunately the

study demonstrated that capecitabine therapy was highly likely to be inferior to standard chemotherapy and patients who were randomly assigned to capecitabine were twice as likely to have a relapse and almost twice as likely to die as compared to patients who were randomly assigned to standard chemotherapy ($P = 0.02$).

Docetaxel plus cyclophosphamide has become one of the most popular adjuvant regimens of the last decade. This is based on the long term results of the US Oncology adjuvant trial 9735, which enrolled 1016 patients, age 18 to 75 years, with stage I–III breast cancer (irrespective of nodal, hormonal or HER2 status) and reported a statistically significant superiority of docetaxel-cyclophosphamide (TC) over doxorubicin-cyclophosphamide (AC)^[41]. At a median of 7 years follow-up, there was a statistical improvement in disease-free survival between TC and AC (81% TC *vs* 75% AC; $P = 0.033$; HR, 0.74; 95%CI: 0.56–0.98) as well as an OS (87% TC *vs* 82% AC; $P = 0.032$; HR, 0.69; 95%CI: 0.50–0.97). Benefit was observed irrespective of hormone-receptor status or HER-2 status. TC was noted to be superior in all age groups with the caveat that more febrile neutropenia (FN) was observed in the older population defined by a cutoff of 65 years (for TC, the rate of FN was 8% for the older population and 4% for younger patients compared with 4% in older and 2% in younger patients who received AC). Notably, the use of prophylactic granulocyte colony-stimulating factor to stimulate neutrophil production was not utilized in this study. Of concern is that 4 late deaths were observed in patients without relapse and all occurred in the AC group: a young woman died of cardiomyopathy and CHF, two older women died of complications related to myelodysplasia and myelofibrosis respectively, and 1 other patient died of acute leukemia 10 years after AC. The US Oncology group is now involved in a new study (USO 06090 phase III trial), that will further evaluate the need for anthracyclines by comparing six cycles of TC (plus/minus bevacizumab) against six cycles of TAC (docetaxel/doxorubicin/cyclophosphamide) for 3900 patients with HER2-negative resected breast cancer. We are eagerly awaiting the results of this trial.

The CALGB 40101 trial enrolled 3171 women with early stage breast cancer who were randomized in a 2 × 2 factorial design to AC once every 3 wk for four (12 wk) or six (18 wk) cycles *vs* paclitaxel (T) weekly for 12 or 18 wk (3 wk of T was considered one cycle)^[42]. So far, what has been reported is the comparison of 4 *vs* 6 cycles of therapy. The 4-year RFS was 90.9% for patients randomly assigned to six cycles of therapy and 91.8% for patients randomly assigned to four cycles. The 4-year OS for patients randomly assigned to six cycles of therapy was 95.3% as compared to 96.3% for patients randomly assigned to four cycles of therapy. The conclusion of the study established that six cycles of therapy was not superior to four cycles for either RFS or OS after adjusting for the effects of tumor size, number of positive nodes, hormone receptor status, and menopausal status. There

were a total of 28 patients in the AC arms that developed grade 3 or 4 (G3–G4) left ventricular systolic dysfunction (LVSD) and 1 G5. There was also 1 patient in the AC × 4 cycles that died of acute myocardial infarction. This is in stark contrast with no cases of LVSD in the T × 4 cycles arm and only 3 G3–4 LVSD in the T × 6 cycles arm. Six patients were diagnosed with AML/MDS between 11 and 28 mo after initiation of treatment; 5 in the AC × 6 arm and 1 in the AC × 4 arm. Patients were between 44 and 62 years of age at the time of study enrollment. No cases of AML/MDS occurred in patients treated with T. The study's data safety monitoring board has not yet released data for the efficacy comparison of AC *vs* T, but we presume that it is likely that no major differences will be noted as this trial enrolled all of these patients several years ago, between May 2002 and February 2008.

EARLY STAGE HER2 POSITIVE TUMORS

It has been hypothesized that a specific population of patients who may benefit from the use of anthracycline is that of patients with HER2 positive tumors^[43]. The National Surgical - Breast and Bowel Project 31 (NSABP B-31) trial included women with HER2 positive, node positive breast cancer. Patients were assigned to treatment with doxorubicin and cyclophosphamide (AC) followed by paclitaxel (T) with or without trastuzumab (H) therapy. In conjunction with this trial was the North Central Cancer Treatment Group (NCCTG) intergroup trial N9831 which enrolled women with HER2 positive node positive or high-risk node negative breast cancer. The women were treated with AC and T followed by no treatment, AC and T followed by sequential H or AC followed by concurrent T and H. From these two trials at a median follow up of 3.9 years, chemotherapy plus adjuvant trastuzumab compared to treatment without trastuzumab resulted in significantly superior DFS (86% *vs* 74%, HR 0.52) and OS (93% *vs* 86%, HR 0.61)^[44].

Anthracycline *vs* non-anthracycline based therapy was compared during the Breast Cancer International Research Group 006 (BCIRG-006) trial of 3222 women with HER2-positive, node-positive or high-risk node negative disease. Patients were randomly assigned to adjuvant treatment with AC-T (doxorubicin and cyclophosphamide followed by docetaxel), ACTH (AC followed by T plus trastuzumab) or TCH (docetaxel, carboplatin and trastuzumab)^[45]. With a median follow up of 65 mo patients treated with an anthracycline (ACTH) compared to treatment without an anthracycline (TCH) demonstrated a trend towards an improvement in DFS, rates at 5 years were 84% and 81%, respectively. Estimated rates of OS were 92%, and 91%, respectively. These rates for DFS and OS did not reach statistical significance but the study was actually not powered or designed to compare equivalence between the two trastuzumab-containing groups (ACTH *vs* TCH)^[45]. Conversely, patients receiving ACTH had significantly higher rates of adverse events including CHF, neuropathy and severe neutropenia^[45].

The incidence of symptomatic congestive heart failure in the two trastuzumab-containing regimens was higher in the group receiving ACTH than in the TCH group (2.0% *vs* 0.4%, $P < 0.001$)^[45]. In addition, a significant difference in sustained, subclinical loss of mean LVEF (defined as $> 10\%$ relative loss) was observed in the group receiving ACTH, as compared with the TCH group (18.6% *vs* 9.4%, $P < 0.001$)^[45]. Neuropathy was significantly worse in patients receiving ACTH (49.7% *vs* 36%, $P < 0.001$) as was neutropenia (71.5% *vs* 65.9%, $P = 0.01$)^[45].

The evaluation of whether HER-2 positivity is associated to anthracycline sensitivity has been attempted in a number of adjuvant trials. A pooled analysis of eight of such trials revealed that, for those women randomized to anthracycline *vs* non-anthracycline regimens, the DFS and OS HRs for women with HER-2 positive tumors were markedly superior, at 0.71 (95%CI: 0.62-0.85) and 0.73 (95%CI: 0.62-0.85), respectively^[46]. However, such differential benefit seems to be lost when trastuzumab is added to the adjuvant regimen^[45]. Additionally, a higher incidence of cardiotoxicity has been noted when trastuzumab is used with regimens containing an anthracycline^[47].

In evaluating HER2 positivity and anthracycline sensitivity, topoisomerase 2- α (TOP2A) has been evaluated as well to see whether TOP2A gene alterations could predict incremental responsiveness to anthracyclines in some breast cancers. Some studies have supported the concept that TOP2A co-amplification is the clinically useful target of the anthracyclines and its co-amplification in tumors could be used as a predictive marker of responsiveness to anthracyclines^[48]. A 2011 meta-analysis evaluated the relationship of HER2 and TOP2A status in patients who received either a non-anthracycline based regimen (CMF) *vs* anthracycline based regimens in the adjuvant setting of early stage breast cancer. Tumors from 3452 patients were analyzed for HER2 status (amplified *vs* non-amplified), and from 3102 patients for TOP2A (normal, amplified, or deleted) by fluorescent *in-situ* hybridization (FISH). Although there was a significant improvement in event-free survival (but not OS), for patients with HER2 overexpression treated with anthracyclines compared to CMF and for both outcomes in patients with TOP2A alterations (*vs* TOP2A normal), treated with anthracyclines, the authors concluded that there was not enough evidence to restrict the use of anthracyclines only in patients with HER2-amplified or TOP2A-altered tumors. The main reasons for this conclusion were that women with non-HER2 amplified and non-TOP2A altered tumors also derived benefits when treated with anthracyclines, and because problems exist with the reproducibility of TOP2A gene status assessment by FISH^[49]. Jones and colleagues completed a recent phase 2, single group study of adjuvant therapy with docetaxel, cyclophosphamide, and trastuzumab in HER2-amplified patients with early breast cancer and a low risk of recurrence (node negative or 1-3 positive nodes)^[50]. They enrolled 493 patients with HER2 positive tumors, that were TOP2A gene positive or negative, to receive four 21-d cycles of docetaxel (75

mg/m²) and cyclophosphamide (600 mg/m²), plus intravenous trastuzumab (4 mg/kg [loading dose] on day 1 and 2 mg/kg on days 1, 8, and 15 during chemotherapy, followed by trastuzumab 6 mg/kg every three weeks for the rest of 1 year). Follow up at 2 years revealed DFS was 97.8% (95%CI: 94.2-99.2) in the 190 TOP2A-amplified patients and 97.9% (94.9-99.1) in the 248 patients without amplified TOP2A and OS was higher than 98% in both groups. Investigators found a low occurrence of cardiotoxicity. The investigators concluded that a short course of adjuvant chemotherapy with docetaxel and cyclophosphamide plus trastuzumab might be an option in patients with lower risk HER2-amplified early breast cancer irrespective of TOP2A status as an alternative to an anthracycline containing regimen.

Targeted therapy

New agents are constantly being developed against known and novel targets. Currently such novel agents, such as VEGF (vascular endothelial growth factor), PARP (poly ADP ribose polymerase), mTOR (*mammalian target of rapamycin*) and HDAC (histone deacetylase) inhibitors, are being studied in the neo-adjuvant, adjuvant and metastatic setting, along with anthracycline and non-anthracycline containing regimens^[51]. These clinical trials will provide information on whether they can improve the outcome of patients with breast cancer and their interaction with the different standard chemotherapy agents. The targeted agent most studied has been bevacizumab, but a discussion of its potential benefits or of any of the other agents are beyond the scope of this review.

DISCUSSION

In accordance to all the data reviewed in this manuscript, the indiscriminate use of anthracyclines in the adjuvant setting has become very controversial. Humans are creatures of habit and change is often uncomfortable. Physicians are no exception and it is well known that changes in patterns of practice can take a long time. The use of (neo)adjuvant chemotherapy has certainly contributed to the decline in disease relapse and improvement in survival as noted in the last 30 years in patients with all types of early stage breast cancer. The anthracyclines have been the backbone of most adjuvant chemotherapy regimens since the 1980s and it certainly has served us well. However, emerging evidence demonstrates that anthracyclines may not be critical to the adjuvant treatment of breast cancer and such a change is being observed in practice overall. Additionally, the current evidence also suggests that the specific benefits of anthracyclines are very difficult to substantiate for HER2 positive tumors in the era of the great equalizer trastuzumab and other targeted anti-HER2 agents.

Investigators at the University of California, San Francisco Breast Cancer Center examined the charts of 1116 patients treated for breast cancer between 2000 and 2010^[52]. They examined the use of anthracycline contain-

ing chemotherapy regimens against the non-anthracycline containing. From 2000-2005, 95% of chemotherapy regimens included an anthracycline compared to 65% from 2005-2010. Another study from Giordano *et al.*^[53], looking at claims from 4458 Medicare beneficiaries and 30422 privately-insured population (Marketscan), demonstrated that a sharp increase in the use of taxane-based chemotherapy and a decline in anthracycline-based chemotherapy had occurred during the study period (1998-2009). Such change seemed to appear in late 2005 and the crossover occurred in late 2007. By the end of the study period, 51% of patients in the Medicare cohort received taxane-based and only 32% received anthracycline-based chemotherapy. A similar pattern of care was noted in the privately insured population. An additional important observation was seen among trastuzumab recipients, in the private market, use of docetaxel increased from 34.4% of women in 2005 to 61.7% of women in 2008, and for patients who did not receive trastuzumab, the use of docetaxel changed from 42.6% in 2005 to 59.4% in 2008. Similar findings were also noted in the Medicare cohort. In the trastuzumab recipients, the rate of docetaxel increased from 62.5% of patients in 2005 to 74.5% of patients in 2008, and in patients who did not receive trastuzumab, docetaxel increased from 44.2% in 2005, to 88.8% in 2008. These changes likely reflect the increasing popularity of the docetaxel/cyclophosphamide (TC) regimen for patients with HER2 negative disease and of the docetaxel/carboplatin/trastuzumab (TCH) regimen for patients with HER2 positive disease. Also of relevance is that, patients who underwent the 21-gene recurrence score testing Oncotype DX[®] were more likely to receive a taxane-based chemotherapy.

Based on the emerging data it seems that patients felt to be at lower or intermediate risk of relapse are being treated with non-anthracycline regimens in the adjuvant setting. But is there a population that should still receive an anthracycline based-regimen? We personally believe that the anthracyclines still have an important role in the (neo)adjuvant care of patients with early stage breast cancer. Anthracyclines plus taxanes are important components of what is called today “third generation regimens”^[13]. These include regimens such as 3 cycles of CEF followed by 3 cycles of docetaxel (CEF-D) as developed in the PACS 01 trial^[54]; 4 cycles of AC followed by paclitaxel or docetaxel as used in the CALGB 9741 and ECOG 1199 clinical trials^[55,56]; 6 cycles of doxorubicin, cyclophosphamide and docetaxel (TAC) as in the BCIRG 001 trial^[57] and the trastuzumab containing regimens from the NCCTG 9831, NSABP B-31 and BCIRG 006 studies previously discussed^[44,45]. These regimens have demonstrated in large prospective randomized trials to yield the best relative risk reduction in breast cancer relapse, especially for those patients with high recurrence risk (large primary tumors, presence of nodal metastasis, estrogen receptor negative tumors, HER2 positive tumors), and almost all of them were built with a backbone of anthracyclines. Until new trials, such as USO 06090

and/or others comparing the use of anthracycline *vs* non-anthracycline regimens, are able to show either the lack of superiority of the anthracycline regimen or the non-inferiority of the non-anthracycline regimen, there is still a role for its use in high-risk patients. The only high risk sub-group that could certainly obviate the use of an anthracycline is the population with HER2 positive disease. However, patients should be made aware of the small differences in 5-year DFS between the AC-T and trastuzumab *vs* the TCH regimen (84% *vs* 81% respectively), and that although this was not “statistically different”, as it wasn’t the difference in 5-year OS (92% *vs* 91% respectively), the study was not powered to detect equivalence between these 2 regimens. That 3% DFS difference may be considered clinically significant by the patient and her provider.

CONCLUSION

The current role of adjuvant anthracycline-based chemotherapy in early-stage breast cancer is very much in question. It is very reasonable to substitute such for well-established non-anthracycline regimens for patients considered at lower or intermediate risk of disease recurrence. However, for those at high risk we need more comparative studies to totally abandon a family of drugs that contributed to the decline in breast cancer relapse and improvement in related survival over the last 3 decades. Most importantly, the increasing prospectively conducted research using genomic profiling, will hopefully allow for better risk prognostication and predictive benefit of adjuvant therapies and lead us to spare many from the adverse events of any type of chemotherapy.

Abstract

Cancer clusters have long been a focus of interest because of the possibility of identifying etiologic agents. Only on rare occasions, however, have such cluster investigations been successful. One major difficulty in cluster investigations, particularly in the area of breast cancer, is the long latent period. There have been a number of publications providing a discouraging picture regarding cancer cluster investigations. The possibility of learning from a cluster investigation, however, is greatly increased if the cancer involved is relatively rare and if it has a short latent period. Inflammatory breast cancer (IBC) fits these criteria and is worth pursuing because of the strong evidence that environmental factors play a major role. In this report we describe our experience with several clusters and the lessons

learned which are now being utilized to improve investigation of future IBC clusters. The first IBC cluster that we evaluated was in 2000, when we were asked to investigate an apparent cluster of IBC in Castro Valley, California where three women in an office setting of 24 people were diagnosed with IBC in a ten month period from May 1999 to March 2000. Our investigation of this striking cluster did not yield a specific trigger for this cluster but it did indicate that the women involved all had at least two IBC risk factors that may well have made them susceptible to getting IBC. We are now investigating another apparent cluster in Texas and are aware of several others requiring careful consideration. We see a need for a consistent protocol for the evaluation of IBC clusters focusing on the laboratory investigation of environmental triggers, primarily infectious agents and chemical carcinogens.

INTRODUCTION

Cancer clusters have long been a focus of interest because of the possibility of identifying etiologic agents. Only on rare occasions, however, have such cluster investigations been successful^[1-4]. In Goodman *et al.*'s^[5] review of 428 cancer cluster investigations in a particular geographic area or community, they found a confirmed increased incidence for only 72 investigations, of which only three were linked to the exposure, and in only one of those, the pleural cancer investigation in South Carolina, was there clear evidence that there was an exposure to some chemical in the naval shipyard^[3]. In the other two investigations in which there was an association, there was statistical uncertainty. In the leukemia investigation in Woburn, Massachusetts, the association with contaminated water was not statistically significant and the association was found only in the boys and not the girls^[1,6]. In the pediatric cluster in Dover Township, New Jersey^[2], which was a superfund site, there were elevated incidences of leukemia and central nervous system cancers in children. However, a statistically significant association was found only with leukemia and for females only.

One major difficulty in cluster investigations, particularly in the area of breast cancer, is the long latent period. There have been a number of publications providing a discouraging picture regarding cancer cluster investigations^[5,7-10]. The possibility of learning from a cluster investigation, however, is greatly increased if the cancer involved is relatively rare and if it has a short latent period. Inflammatory breast cancer (IBC) fits these criteria and is worth pursuing because of the strong evidence that environmental factors play a major role^[11-13]. The evaluation of each cancer cluster is a separate experiment in which the outcome, while usually not identifying a specific etiologic factor, is a learning experience which can assist in preparing a more definitive evaluation when another cluster is identified. In this report we describe our experience with several clusters and the lessons learned which are now being utilized to improve investigation of future IBC clusters.

FOLLOW UP OF THE NILES, ILL. LEUKEMIA CLUSTER

The first cancer cluster we investigated was in 1967 when we were asked to obtain biological samples from the only survivor (JB) of a well described acute leukemia cluster in Niles, Ill.^[14]. This cluster was the first of a series investigated by the Centers for Disease Control and involved acute leukemia occurring among children primarily in one Catholic school 1957-1963. These early studies were primarily descriptive although some biospecimens, primarily blood samples, were provided to the Viral Leukemia Section of the National Cancer Institute (NCI)^[17]. The serologic tests available at that time were less specific than those in use today. In 1967 we learned that a survivor of the Niles, Ill. cluster, now 13 years old, was having

a tonsillectomy and the virologists in the National Cancer Institute who were involved in the original cluster investigation hoped to obtain biospecimens from the tonsillectomy to isolate a leukemia virus. One of us (PHL) traveled to Chicago and obtained blood, bone marrow and tonsillar tissue placed in fresh media and brought them back to NCI for the laboratory studies. While no human leukemia virus was isolated from this patient, this and similar projects involving collection of biospecimens for NCI's Virus Cancer Program (VCP) proved to be valuable for years to come, providing reagents for research investigators, such as Robert Gallo, who credited the VCP with accelerating his discovery of human lymphotropic virus type I (HTLV-I) by providing appropriate biospecimens (Gallo, personal communication).

A CLUSTER OF CHRONIC FATIGUE SYNDROME ASSOCIATED WITH NON-HODGKIN'S LYMPHOMA IN NORTHERN NEVADA

A second cancer-related cluster that provided useful experience, although not IBC, was an outbreak of chronic fatigue syndrome (CFS) in 1984-6 in Incline Village, NV^[15] which was focused on a single internal medicine practice since the two primary physicians were recognized as the regional experts on this controversial disorder. These physicians suspected an excess of cancer in their CFS patients, particularly non-Hodgkin's lymphoma and brain cancer, and asked for our epidemiologic assistance^[16]. To investigate this possibility, we worked with the Nevada Cancer Registry and compared the cancer patterns in Washoe County in northern Nevada (which contains Reno) where the cluster was focused, to the patterns in Clark County in southern Nevada (which contains Las Vegas) which was selected as a control county. NHL and brain cancer were the targeted malignancies, and the control cancers chosen were breast and lung cancer. An abrupt relative increase in NHL was noted in 1986 in Washoe County compared to Clark County and a more sustained increase in brain cancer followed^[17,18].

AN IBC CLUSTER IN CASTRO VALLEY, CALIFORNIA

The first IBC cluster that we evaluated^[19] was in 2000, when we were asked to investigate an apparent cluster of IBC in Castro Valley, California where three women in an office setting of 24 people were diagnosed with IBC in a ten month period from May 1999 to March 2000.

The office had major environmental concerns. It was located one floor above a mammography and MRI imaging center and employees were concerned about the bad air and water quality in the office as well as the potential radiation exposure from the floor below. File boxes were stacked in front of windows that did not open in an area

where the ventilation system did not operate adequately when in use and was turned off at night. In addition, the office stored billing records printed on carbonless copy paper at a temperature above 68 degree Fahrenheit in the same area where the employees worked.

Although the complaints about the air and water quality and possible exposure to radiation began in 1986, the air quality studies and a water sampling study did not begin until 1988 and the radiation leakage studies began in 1999 when new mammography equipment had replaced the old units. The water sampling studies indicated that the only organic compounds detected were present at allowable California maximum contaminant levels. The radiation leakage studies found no radiation despite the absence of concrete between the two floors. The indoor air quality studies showed that the office had poor air circulation and higher levels of CO and CO₂. All three cases had their offices located on the side of the office that had the worst air circulation according to the studies.

All employees were interviewed by telephone using a structured questionnaire that obtained demographic information and information on IBC and breast cancer risk factors, such as pregnancy history, family history of breast cancer, oral contraceptive and hormone replacement therapy use, medical history, and exposure to possible oncogenic agents and tumor promoters.

The three cases did not live in the same residential area and therefore did not share the same residential environmental exposures. While the sample was too small to do statistical analyses, there were some interesting differences between the cases and the controls. The cases had a higher BMI, higher oral contraceptive and hormone replacement therapy use, and were exposed to pesticides and herbicides for a longer period of time. The one case that had children had her first child at age 19 and did not breast feed her children. Two of the cases had a family history of breast cancer, and the third case's mother was adopted.

All three cases were seen by the same oncologist and all cases had pathologically confirmed IBC with invasion of the dermal lymphatics. Although IBC is a clinical diagnosis and pathologic confirmation is not necessary, the surgeon believed documentation was important and obtained skin biopsies. It required 15 skin biopsies before a positive skin biopsy was obtained for one of the cases. We obtained tissue samples for all three cases.

Our attention was focused on the environmental exposures because of the concerns of the office workers and at that time infectious agents were not considered.

AN IBC CLUSTER IN FRIENDSWOOD, TEXAS

In 2011, a possible IBC cluster in Harris and Galveston counties in Texas was brought to our attention by a patient advocate/IBC survivor as part of our recruitment of cases for the IBC Registry and a biospecimen repository, which we established in 2002^[20]. The registry links

epidemiologic information with laboratory studies from our biospecimens. We were referred to an IBC Google map (www.terrismap.org) that reports IBC cases in the United States and is constantly updated. The IBC map showed approximately fifteen cases diagnosed between 1998 and 2011, nine in Harris County and six in Galveston County. All women in this apparent cluster were diagnosed at major cancer centers in the Houston area, including the MD Anderson Medical Center.

We were encouraged by the patient advocate/IBC survivor to enroll these patients in our Registry which only enrolls patients who contact us first and complete Informed Consent forms as per our Institutional Review Board (IRB) approval. Based on information from concerned patients, one focus of research was a hazardous waste site designated by the Environmental Protection Agency (EPA) which allegedly had waste draining into a stream going through the community. In order to investigate possible environmental triggers for this IBC cluster, we tried to identify the potential hazardous waste sites in the region utilizing the National Priorities List (NPL) developed by the Environmental Protection Agency (EPA)^[21]. Harris County with its largest concentration of chemical manufacturing and refining facilities has 27 EPA regulated Superfund Sites out of 31 for both counties. Key concerns regarding the quality of outdoor air include elevated levels of ozone and particulate matter. Two seafood advisories have been issued in the past for the Galveston bay system, tributaries of which run through parts of both the counties. The first was based on dioxin contamination. The second advisory was based on the three toxic compounds, namely dichloromethane, trichloroethane (carcinogens) and carbon disulfide discovered in fish from Clear Creek, a principal tributary of the Galveston bay. The contaminated fish were found in the vicinity of an EPA Superfund site. A study of the map showed two cases in the Friendswood city where the Clear Creek flows and which also includes a former refining site. Four cases were also concentrated near Clear Lake in Galveston County.

As this cluster was being investigated, the possibility of an infectious trigger was raised by a report suggesting infectious agents as possible etiologic factors in a series of IBC patients in Pennsylvania^[22] and our observation of a seasonal incidence of IBC in the northeastern United States^[13]. We therefore investigated infectious agents prevalent in Harris County where this IBC cluster appeared, and noted that Saint Louis encephalitis (SLE) is endemic and occasionally epidemic in that particular region. In 2002, West Nile virus (WNV) appeared in Houston and quickly spread throughout that region. Both SLE and WNV are transmitted by a particular species of mosquitoes, called *Culex quinquefasciatus* which is the prevalent species in Harris County. It is also a dominant vector of lymphatic filariasis, a disease caused by thread like parasitic worms. This raises the possibility of a parasite or a virus transmitted by mosquitoes. *Culex quinquefasciatus* larvae breed and thrive abundantly in stagnant dirty

water. The elaborate drainage system of Harris County creates ideal biotic and abiotic conditions conducive for mosquito larval development, particularly during relatively dry periods when stagnant water remains in the storm sewer system. Approximately 99% of the mosquitoes that develop in these storm sewers are *Culex quinquefasciatus*. These mosquitoes use the storm drains as daytime resting sites as well as for larval development. Outbreaks of *Vibrio* diseases have also been reported. Out of 176 *Vibrio* infections reported statewide between May of 1981 and September of 1991, 68 were reported in counties surrounding Galveston Bay which also includes Harris County. Contact recreation and consumption of molluscan shellfish, primarily oysters, were roughly equal sources of *Vibrio* infections, which accounted for 75% of the reported cases. The consumption of oysters, especially raw, can pose a significant health risk since oysters can concentrate pathogens in their gut as they feed. Of particular concern is *Vibrio Vulnificus*, which can cause severe infection with exposure of open wounds to sea water, especially in those with underlying chronic diseases or who are immunocompromised. This particular bacterium showed a greater genetic diversity in Galveston Bay water and oysters. An interesting feature of this organism is its response to low temperature stress where it goes into a viable but non-culturable state during winter months (December to February). These observations are intended to show the feasibility of infectious agents as a trigger to the Texas cluster but no evidence for such a link currently exists.

An attempt has been made to confirm the reported IBC cases and to get updated information from the Texas Cancer Registry, comparing the incidence of IBC in the Houston area with other metropolitan areas, such as Dallas and Austin. These studies are in progress.

DISCUSSION

Cancer clusters are notoriously difficult to evaluate, and we have tried to take advantage of our experience and those of others to develop a hypothesis consistent with the information currently available on IBC. One hypothesis that we believe is tenable is based on our studies of CFS and NHL where a cluster of CFS showed an ecologic association to NHL^[16,17,23] and the link was subsequently documented by a linkage of population-based registries of CFS patients in Medicare and cancer patients in SEER^[24], where NHL was the only malignancy with a statistically significant association with CFS. The virus most closely linked to CFS is EBV, which is consistently reactivated in those patients with acute onset CFS presenting with an infectious illness^[25], and, not infrequently, is a long term sequel of infectious mononucleosis which is the most common clinical manifestation of primary EBV infection. EBV is a ubiquitous virus, however, and more than 90% of the population has been infected early in life and is therefore immune to new infection. Therefore EBV is unlikely to trigger a cluster of CFS. Since CFS can be trig-

gered by a variety of infectious agents^[26], we hypothesize that a new agent struck the community and in certain susceptible individuals, perhaps those with a predisposing susceptibility to an autoimmune disorder, CFS developed. Clusters of CFS (initially described as epidemic neuromyasthenia)^[27,28] have been well documented^[29] and occasionally the precipitating agent has been identified, including EBV, herpes simplex-1, herpes zoster and giardia^[26,30]. We therefore postulate that for IBC, it is feasible that a precipitating agent, either chemical or infectious, could strike a community and those individuals with a predisposition (possibly a combination of factors such as obesity, family history, and/or infection with the proposed human tumor virus with sequences similar to mouse mammary tumor virus^[31-34], subsequently develop IBC. While we were successful utilizing the Nevada Cancer Registry to show the clustering of NHL after CFS, similar efforts investigating IBC is very problematic. NHL is a defined disease histologically and should be captured by a cancer registry in virtually 100% of cases. IBC, however, is a far more difficult problem for two reasons. First, the diagnosis has been evolving, and, although the situation has improved since we first documented the conflict between two major institutions, the American Joint Committee on Cancer and NCI's the Surveillance, Epidemiology, and End Results program (SEER), who used different case definitions^[20], the situation is far from satisfactory. Our clinical experience in Tunisia and with the IBC Registry indicates even the current criterion of clinical involvement of one third of the breast is too restrictive and the diagnosis should be made in any patient with acute onset of erythema, induration, and/or peau d'orange regardless of the size. This suggestion is supported by research efforts documenting the similar outcome and laboratory findings in IBC regardless of the extent of erythema^[35,36]. Second, there are many reasons why IBC may not be recorded in the cancer registry even though the physician has the diagnosis in his office records because it may not be noted by the abstracter reviewing the final hospital diagnoses. Attempts are being made to investigate the degree of "slippage" between the number of cases identified by practicing physicians and the number of cases recorded in the central registry^[37]. In addition to the concern that many IBC cases are not appropriately coded in cancer registries, there are constraints that hinder the collection of data on IBC in small geographic areas, even counties, since registries often will not release data where less than 50 patients are included because of concerns about confidentiality being maintained.

Although the extensive experience of the Centers for Disease control^[7] and others have often been disappointing, investigation of clusters of rare aggressive cancers such as IBC should not be completely neglected. For optimal pursuit of such clusters, several items should be considered to bring optimal results.

The importance of a coordinating physician(s)

Coordinating physicians were extremely important in the

success of cluster evaluations in Niles, Ill (the patient's internist), Incline Village, NV (the two internists in the practice) and Castro Valley, California (the three patients' medical oncologist). These physicians facilitated the signing of the informed consent forms, documentation of diagnosis, collection of good historical data, and collection of biospecimens. In contrast, thus far the absence of a coordinating physician in Texas has made interviews of the patients and collection of biospecimens in the Texas cluster extremely difficult.

Preservation of biospecimens

Obtaining biospecimens is critical. Techniques for utilizing a variety of biospecimens, including formalin fixed paraffin embedded tissues, in molecular studies continue to improve. We have been able to use the biospecimens in our repository for a number of projects^[36,38-40] and several hypotheses can be proven with these samples, such as the detection of organochlorines should chemical toxicity be responsible for the Friendswood clusters. In future studies, blood samples on cases and controls should be obtained to investigate the possibility of infectious agents as triggers of clusters. Other hypotheses might require other biospecimens, such as saliva or urine.

The importance of moving quickly

Early investigation is critical because of the frequently poor outcome in IBC. For example, our prompt investigation of the Castro Valley cluster allowed us to obtain a critical positive family history not recognized by clinicians from a patient who died shortly after our interview. Ideally one should obtain the biospecimen before treatment as neoadjuvant chemotherapy may affect the tumor biology.

Identification of appropriate laboratory support

The thorough evaluation of biological specimens requires experienced laboratory support that is primarily found in large research institutions. As noted below, it will be useful to have consistent protocol for the evaluation of IBC clusters to allow an exchange of relevant information among various investigators. We are currently attempting to develop a protocol focusing on infectious agents and environmental toxins with potential carcinogenic properties but we expect this protocol to change as laboratory techniques improve and additional information is obtained from other cluster investigations. Our latest studies are taking advantage of available molecular techniques allowing identification of bacterial pathogens in paraffin blocks of tumors but we expect eventually to explore viral pathogens and collect blood samples for antibody studies. The identification of potential toxins will be difficult because they are rapidly metabolized and/or excreted but we hope to identify some persistent chemical byproducts, such as organochlorines, which may be useful.

The issue of statistical significance

Statistical analysis of cancer clusters has been addressed

in several publications^[41,42] and various analytic methods have been used, but it is important to recognize that biological significance can be independent from statistical significance. Statistical significance is particularly problematic because of the small number of IBC cases compounded by changes in the case definition and Registry coding. Occasional misdiagnosis or unusual presentations have been encountered^[43-47], but these are uncommon and are unlikely to deter epidemiologists from focusing laboratory studies on the typical cases. We suggest that the identification of a cluster of IBC cases in a short period of time, such as the three women in a small office within ten months, deserves investigation regardless of whether or not it is statistically significant.

CONCLUSION

In summary, the apparent importance of environmental factors on the etiology of IBC and the identification of clusters of this relatively rare aggressive malignancy indicate the need to investigate these clusters for possible etiologic triggers. A variety of biospecimens should be collected for immediate testing but also for storage as future hypotheses and technology may provide clues not initially apparent. Tissue samples could be examined for toxic chemicals or infectious agents, blood samples could be used to identify adducts signifying exposure to carcinogens or antibodies to infectious agents, and DNA (saliva or white blood cells) could be used to identify genetic markers of susceptibility. Detailed histories could not only reveal potential important exposures but systemically applied questionnaires such as those used by the IBC Registry could identify predisposing factors that could add to our understanding of risk factors for IBC.

Abstract

The clinical significance of pleomorphic lobular carcinoma *in situ* (PLCIS) is a subject of controversy. As a consequence, there is a risk of providing inconsistent management to patients presenting with PLCIS. This review aims to establish whether the current guidelines for the management of PLCIS are consistent with current evidence. A systematic electronic search was performed to identify all English language articles regarding PLCIS management. The data was analysed, specifically looking at: incidence of concurrent disease, recurrence rates, long-term prognosis and PLCIS management. A search was also performed for PLCIS management guidelines for the United Kingdom, United States, Canada, Australia, Germany and pan-European. The results of the evidence analyses were compared to the guidelines in order to establish whether the recommended management is consistent with the published evidence. Nine studies (level 3-4 evidence), involving a total of 176 patients and five management guidelines

(from United Kingdom, United States, Australia and pan-European) were included in the review. From the evidence, 46 of 93 (49%) patients were found to have PLCIS with concurrent invasive disease on excision specimen analysis. Regarding recurrence rates, 11 of 117 (9.4%) patients developed a recurrence of PLCIS. There were no instances of invasive disease or ductal carcinoma *in situ* (DCIS) on recurrence histology. There were no studies assessing long-term outcomes in PLCIS cases. With regards to the management guidelines, the Association of Breast Surgery (United Kingdom) and the National Breast and Ovarian Cancer Care (Australia) do not mention PLCIS. The National Comprehensive Cancer Network (United States) suggest considering excision of PLCIS with negative margins. The NHS Breast Screening Programme (United Kingdom) and the European Society of Medical Oncology (pan-European) recommend PLCIS should be treated as with DCIS. We conclude that high quality evidence to inform guidance is lacking, thus recommendations are relatively vague. However, based on the available evidence, it would seem prudent to treat PLCIS in a similar manner to DCIS.

Key words: Pleomorphic lobular carcinoma *in situ*; Breast cancer; Breast carcinoma; Carcinoma *in situ*; Guideline; Excision margin; Recurrence rate

Core tip: Pleomorphic lobular carcinoma *in situ* (PLCIS) is a breast lesion, the clinical significance of which is a subject of controversy. To date, this systematic review is the largest pooled series of clinical data regarding PLCIS. We aimed to establish whether current guidelines for management are consistent with the evidence. The results demonstrate a lack of high quality data and guidelines for management are variable. Analysis revealed a high incidence of concurrent invasive disease with PLCIS (49%) and following excision, a recurrence rate of 9.4%. We conclude that it would seem prudent

to manage PLCIS as with ductal carcinoma *in situ*, although there is a dire need for long-term outcome studies.

Pieri A, Harvey J, Bundred N. Pleomorphic lobular carcinoma *in situ* of the breast: Can the evidence guide practice? *World J Clin Oncol* 2014; 5(3): 546-553 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i3/546.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i3.546>

INTRODUCTION

The pleomorphic subtype of lobular carcinoma *in situ* (PLCIS) was first described by Frost *et al*^[1] in 1996. Frost described the lesion as being composed of one or multiple distended lobules with enlarged and dyscohesive cells, irregularly shaped nuclei and abundant eosinophilic cytoplasm^[1]. PLCIS is also regularly associated with comedo necrosis and calcification and hence is often mammographically detectable, in contrast to classical LCIS (CLCIS)^[1-5]. The clinical significance of PLCIS is a subject of controversy. It is generally accepted to be a risk factor for invasive disease, as with CLCIS. However, there is a suspicion that PLCIS may carry a higher risk of progression to invasive disease due to its more aggressive molecular and histopathological features, which are more consistent with those of ductal carcinoma *in situ* (DCIS) than CLCIS^[1,2]. There is an acceptance that PLCIS should be considered a non-obligate precursor to invasive disease and managed in a similar way to DCIS, though this is largely based on the histopathological similarities rather than studies providing evidence on clinical outcomes^[1,6].

It has historically been difficult to differentiate PLCIS from DCIS due to the similarities in their histomorphology. Due to recent advances in immunohistochemical staining differentiating PLCIS from DCIS has become much more achievable. Use of E-cadherin immunohistochemistry can differentiate between DCIS and LCIS^[7,8]; E-cadherin is a cell adhesion molecule, expression of which is lost in lobular neoplasia but retained in ductal. As a consequence, there has been an increase in the number of PLCIS cases reported^[9].

There are multiple reviews relating to PLCIS in the literature, but they are predominantly narrative in nature^[6,9-14]. Hussain *et al.* published the only systematic review to date that includes clinical data regarding PLCIS^[12]. However, this review included only 22 PLCIS cases. Compared to CLCIS and atypical lobular hyperplasia (ALH), they demonstrated that PLCIS is the most likely to have concurrent malignancy on excision specimen (41% of PLCIS being associated with malignancy compared with 19% in ALH ($P = 0.003$). Since the Hussain *et al*^[12] systematic review there has been a large increase in the published literature for PLCIS. Guidance on the management of PLCIS may be historical, based on a small number of reported cases. The aim of this systematic re-

view is to compare the current evidence base for PLCIS with international guidance on its management.

SEARCH STRATEGY: EVIDENCE

This systematic review was conducted in line with the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) Guidelines. Electronic literature search of Medline, Embase, the Cochrane database, and the WHO International Clinical Trials Registry Platform were performed by a single author (AP). Search terms were “pleomorphic lobular carcinoma *in situ*”, “pleomorphic lobular carcinoma *in-situ*” and “PLCIS”. Articles were then selected based on title and abstract and then on the full text manuscript. A manual search of the references from key articles was also performed to identify any articles potentially missed by the systematic search.

The search was limited to human studies published in English, from 1996 onwards. The search was conducted in October 2013. We excluded editorials, case reports, reviews and letters or comments, and case series with less than five patients. Small studies (less than five patients) were excluded to focus the review on studies that would more likely influence practice.

SEARCH STRATEGY: GUIDELINES

In order to obtain a global representation of management guidelines for PLCIS, searches were performed for the United States, Canada, United Kingdom, Germany, pan-European and Australia. Electronic literature search of Medline and Embase were performed by a single author (AP). Search terms were “guideline” AND “breast cancer” AND the respective country (“United States”, “Great Britain”, “Canada”, “Australia” and “Europe”). National oncology, pathology and surgical societies, colleges, associations and governing bodies were also manually searched for each country. Independent organisations’ websites were searched for guidelines for breast cancer management. For the United Kingdom, the National Institute for Health and Care Excellence^[15], the Association of Breast Surgery^[16] and the National Health Service Breast Screening Program^[17] sites were searched. For the United States, the American Society of Clinical Oncology^[18], the College of American Pathologists^[19], the National Comprehensive Cancer Network^[20], the American College of Surgeons^[21] and the Society of Surgical Oncology^[22] websites were searched. For Canada, the Royal College of Physicians and Surgeons of Canada^[23], the Breast Cancer Society of Canada^[24], the Canadian Cancer Society^[25] and the Cancer Care Ontario (CCO)^[26] websites were searched. For Australia, the Cancer Australia and National Breast and Ovarian Cancer Care^[27] site was searched. For Germany, the German Cancer Society^[28] website was searched. Pan-European guidelines were searched for on the European Society of Medical Oncology^[29] website. Google search engine was used and Google Translate was used for non-English websites.

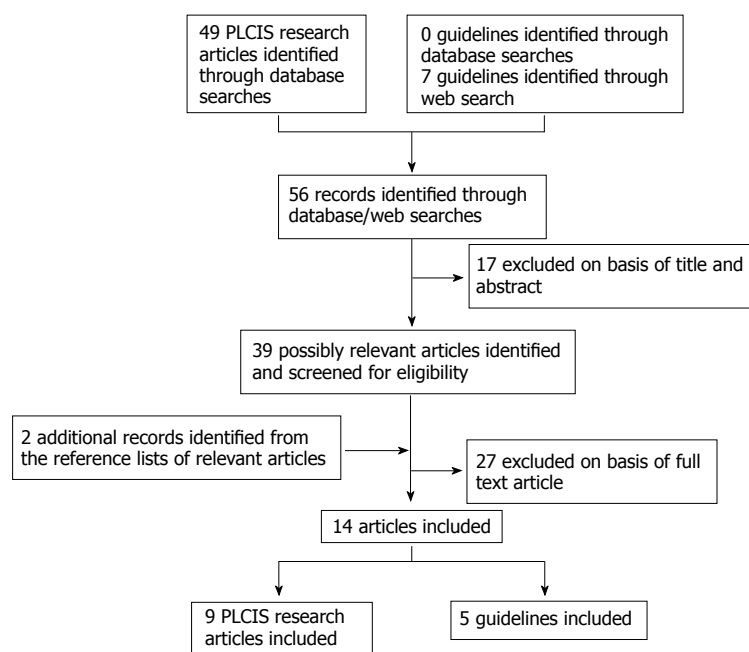

Figure 1 Study selection. PLCIS: Pleomorphic lobular carcinoma *in situ*.

Guidelines that did not have a version available in English were excluded. Guidelines that were specific to invasive disease (*i.e.*, did not give recommendations regarding *in situ* disease) were excluded.

DATA ANALYSIS

AP extracted data and JH and AP assessed its quality. Disagreements were resolved by discussion and study review. The following topics were specifically considered: incidence of concurrent invasive disease, recurrence rate of disease, long-term prognosis and the management of PLCIS alone.

DESCRIPTION OF STUDIES AND GUIDELINES

There were nine research articles and five guidelines that met the inclusion criteria (Figure 1). The nine studies involve a total of 176 patients. There were no meta-analyses, randomised control trials or cohort studies. All studies were case series, with data collected retrospectively. The dates of publication ranged from 2000 to 2013. Seven of the studies (93 patients) aimed to determine the risk of concurrent invasive carcinoma or DCIS on excision specimen, following a core needle biopsy diagnosis of PLCIS. Three studies (117 patients) documented recurrence rates in PLCIS. There are no studies published to date that investigate comparative treatment options, or oncological outcomes such as local and systemic recurrence disease in PLCIS patients.

Guidelines for “*in-situ*” breast disease management were found for the United Kingdom (Association of Breast Surgery and NHS Breast Screening Programme), United States (National Comprehensive Cancer Network), Canada (Cancer Care Ontario), Australia (National

Breast and Ovarian Cancer Care), Germany (German Cancer Society) and pan-European (European Society of Medical Oncology). An English version of the German guidelines could not be found and thus was excluded. The Canadian guidelines were pertaining to invasive disease only and thus were excluded.

INCIDENCE OF CONCURRENT INVASIVE DISEASE

The risk of concurrent invasive disease was based on the pooled data from seven studies, involving 93 patients^[3,4,30-34]. All patients were women, with a mean age of 58.4 years at PLCIS diagnosis (age range 35-84 years). Of those with a documented mode of presentation, 40 (91%) patients presented after a screen-detected abnormality and 4 (9%) had a symptomatic lump. Initial core biopsy results showed PLCIS as the most significant lesion in 58 (62%) cases and PLCIS with DCIS or invasive carcinoma in 35 (38%) cases. The breakdown of number of patients diagnosed with concurrent PLCIS with DCIS, and PLCIS and invasive carcinoma on core biopsy are not specified. After core biopsy, all patients went on to have surgery: 2 had a diagnostic biopsy, 67 had a wide local excision, 8 had a segmental mastectomy, 15 had a mastectomy and 1 patient had a bilateral mastectomy (reason not stated). On surgical specimen histology, 34 (37%) patients had PLCIS alone and 59 (63%) patients were found to have concurrent DCIS or invasive carcinoma (Table 1). Of these patients with DCIS or invasive disease; 13 (22%) were DCIS, 7 (12%) were invasive ductal carcinoma, 26 (44%) were invasive lobular carcinoma and 13 (22%) were invasive carcinoma with type not specified. The risk of concurrent invasive disease was 49% (46 of 93 patients). Looking specifically at the risk of upstaging from a core biopsy result of PLCIS only,

Table 1 Risk that ductal carcinoma *in situ* or invasive carcinoma is found on subsequent surgical excision pathology following a core biopsy diagnosis of pleomorphic lobular carcinoma *in situ*

Ref.	No. of PLCIS cases	Diagnosis on core biopsy	Surgical procedure	PLCIS alone on surgical specimen	Concurrent DCIS or invasive carcinoma on surgical specimen	Concurrent DCIS (%)	Concurrent invasive cancer (%)

At initial assessment PLCIS is diagnosed on a core biopsy specimen, this table details the subsequent histology from a surgical resection of the area, demonstrating how many of the core biopsies are upgraded to invasive carcinoma or DCIS. PLCIS: Pleomorphic lobular carcinoma *in situ*; DCIS: Ductal carcinoma *in situ*; ILC: Invasive lobular carcinoma; IDC: Invasive ductal carcinoma; IC: Invasive carcinoma (with type not specified); DB: Diagnostic biopsy; WLE: Wide local excision; Mx: Mastectomy; SMx: Segmental mastectomy; BMx: Bilateral mastectomy.

to invasive disease on surgical specimen, data from five of the studies were used (in two studies, the correlation between core biopsy specimen and respective surgical specimen is unclear^[30,31]). Of 42 patients with PLCIS only on core biopsy, 14 were upstaged to invasive carcinoma on surgical specimen histology (33%).

RECURRENCE RATE OF DISEASE

There are three articles reporting recurrence rates following excision of PLCIS^[5,30,35]. Downs-Kelly *et al*^[5] report a retrospective series of 26 patients with PLCIS on surgical excision. They included both patients with PLCIS alone (20 cases) and patients with PLCIS and concurrent invasive disease where excision margin for the invasive component was more than 10 mm (6 cases). Patients were offered adjuvant chemoprevention and/or radiotherapy. The article does not state which chemoprevention agents were used. Of the six PLCIS cases with concurrent invasive disease, one had adjuvant radiotherapy and five had both chemoprevention and radiotherapy. Of the 20 cases of PLCIS alone, three patients received radiotherapy, six had chemoprevention and one received both chemoprevention and radiotherapy. The authors state that three of the cases of PLCIS alone had been misdiagnosed as DCIS at the time of treatment and thus received adjuvant therapy. The rationale for the remaining seven cases of PLCIS alone whom received adjuvant treatment is unclear. Downs-Kelly *et al*^[5] report one episode of recurrent PLCIS at 19 mo (3.8% recurrence rate). The recurrence was biopsy-diagnosed following a mammogram with new suspicious calcification at the surgical site (patient had

previous normal mammograms at 7 and 12 mo). Of note at initial excision, PLCIS was present at the margin. The patient had received adjuvant chemotherapy after the initial excision but no radiotherapy (Table 2).

Khoury *et al*^[35] report a series of 57 PLCIS cases and compare their recurrence rate to that of 615 cases of DCIS, who had presented over the same 12-year period. Their data shows 7 episodes of recurrent PLCIS with no invasive disease (12.3% recurrence rate). This series reports that the recurrence rate was higher in younger women and in cases where the margin remained positive for CLCIS ($P = 0.02$ and 0.01 respectively). PLCIS had a higher rate of recurrence than low and intermediate grade DCIS cases observed in the study ($P = 0.06$ and 0.04 respectively). It is not stated as to whether margin clearance was the same for DCIS and PLCIS cases. The margin status for PLCIS recurrences and the time to recurrences are not reported. Fasola *et al*^[30] consider the role of radiotherapy in PLCIS, comparing 13 patients with a diagnosis of PLCIS alone and 21 patients with PLCIS in the setting of invasive carcinoma. Patients with PLCIS alone were more frequently treated with lumpectomy as opposed to mastectomy (85% *vs* 43%, $P = 0.03$) and none of the PLCIS only patients received adjuvant radiotherapy or chemotherapy compared to 16 (76%) of the patients with PLCIS and invasive disease receiving radiotherapy and/or chemotherapy. They report that local recurrence rate in the PLCIS only group is 15% compared with 5% in the PLCIS and carcinoma group ($P = 0.8$). The comparative adequacy of margin clearance is not stated for the two groups. However, they conclude that this increased rate of recurrence may be a result of the

Table 2 Rate of recurrent disease after surgical excision of pleomorphic lobular carcinoma *in situ*

Ref.	No. of PLCIS cases	PLCIS at margin	Histology of recurrence	Time to recurrence	Local recurrence rate
Downs-Kelly <i>et al</i> ^[5]	26	13 cases ≤ 1 mm 4 cases 1.1-2 mm 9 cases > 2 mm	1 PLCIS	19 mo	3.8%
Khoury <i>et al</i> ^[35]	57	Not stated	7 PLCIS	Not stated	12.3%
Fasola <i>et al</i> ^[30]	34	Not stated	3 PLCIS	≤ 5 yr	8.85

This details the number of cases of histologically diagnosed recurrence following a previous excision of PLCIS. PLCIS: Pleomorphic lobular carcinoma *in situ*.

less aggressive adjuvant therapy and there may be a role for radiotherapy in PLCIS. They report an overall 5-year recurrence rate of 8.8% (3 of 34 patients) for PLCIS.

Combining the data from the three studies gives a PLCIS recurrence rate of 9.4% (11 of 117 cases) regardless of margin (not reported in all cases). There were no cases reported where invasive disease was found on recurrence specimens in any of the three studies.

REVIEW OF NATIONAL GUIDELINES FOR MANAGEMENT

A total of 5 national guidelines (United Kingdom, United States, Australian and pan-European) were found that met the inclusion criteria and are summarised in Table 3. Associated guidelines for management of CLCIS and DCIS by the same organisations are included in the Table for comparison.

There is no mention of PLCIS in the Association of Breast Surgery and National Breast and Ovarian Cancer Care guidance. The National Comprehensive Cancer Network suggest considering resection of PLCIS with negative margins. The European Society of Medical Oncology recommend that PLCIS should be managed as with DCIS and similarly, the NHS Breast Screening Programme recommend grading PLCIS on core biopsy as B5a, *i.e.*, non-invasive carcinoma (in contrast to CLCIS which is graded as B3 indeterminate) and excising with negative margins.

EVIDENCE QUALITY

There are significant limitations to this review, currently there is a lack of quality evidence supporting the management of PLCIS, the majority being level 3-4 evidence^[36]. There are no management comparison studies measuring long-term survival and very limited data on recurrence rates. Nonetheless, there are significant findings within the data available. This is the only systematic review to focus specifically on PLCIS management and with 173 cases, this is the largest pooled series of clinical data regarding PLCIS.

ASSOCIATION OF PLCIS WITH INVASIVE DISEASE

PLCIS is associated with invasive lobular carcinoma on

excision in at least 28% of cases (26 of the 93 cases, but in 13 more cases of associated invasive carcinoma, the type is not reported). When DCIS is diagnosed on core biopsy there is a 10%-20% risk of associated invasive carcinoma on subsequent excision^[37-40]. By comparison with DCIS, this study demonstrates PLCIS to have a higher association with its invasive counterpart. Reis-Filho *et al*^[41] identified that invasive pleomorphic carcinoma and its *in situ* counterpart share the same genetic changes, supporting the argument that PLCIS is a precursor lesion (rather than simply a risk factor) of invasive disease. The high rate of upstaging of PLCIS to invasive disease seen in this review further supports the “non-obligate precursor” hypothesis. These findings suggest that it would not only be advisable to perform a surgical biopsy for PLCIS to look for associated malignancy, but to ensure excision with margins negative for PLCIS. Thus, a grading of pre-invasive (B5a) similar to DCIS would seem appropriate.

SENTINEL NODE BIOPSY AND PLCIS

For pure DCIS on core biopsy, the Association of Breast Surgery recommend that sentinel lymph node biopsy should be considered in cases where there is a high risk of finding invasive disease on the subsequent excision specimen^[42]. They state that this would include patients undergoing surgery for: an extensive area of microcalcification; a palpable mass; or high grade disease. In this review, the overall rate of concurrent invasive disease associated with PLCIS was found to be 49%. In 67% of these cases, the invasive component was missed on core biopsy and thus wasn't diagnosed until analysis of the surgical specimen. Given the high risk of upgrading PLCIS to invasive disease after definitive surgery, combined with the fact that histologically, PLCIS is considered to have a similar appearance and characteristics to high grade DCIS, sentinel node biopsy should be considered in PLCIS.

ADJUVANT THERAPY FOR PLCIS

There are no studies that consider the role of adjuvant chemoprevention in PLCIS. Fasola *et al*^[30] assessed whether there is a potential role for radiation therapy in PLCIS by looking at the comparative recurrence rates^[30]. However, they demonstrated no significant difference between the radiation therapy and non-radiation therapy groups.

Table 3 Summary of guidelines for the management of *in situ* breast disease

Guideline source	Recommendation-PLCIS	Recommendation-CLCIS	Recommendation-DCIS
ABS, 2009 ^[16] (United Kingdom)	PLCIS not mentioned	Should consider diagnostic biopsy Clear margins not required Post-op surveillance is appropriate (No adjuvant treatment mentioned) (No lymph node surgery required)	Resection with clear margins (> 1 mm) required (WLE or Mx) Intra-op radiography should be used for all DCIS as majority impalpable Lymph node surgery not usually required but may be considered in high risk cases
NCCN, 2013 ^[20] (United States)	"Consider excision with negative margins"	Diagnostic biopsy Risk reducing treatment discussion with patient (options: risk reducing surgery, hormone therapy, no further treatment) Surveillance indicated	Consider MRI WLE or Mx Margin controversial but certainly > 1 mm SLNB usually not required but may be considered in high risk cases Consider RTx
ESMO, 2013 ^[29] (pan-European)	"May behave similarly to DCIS and should be treated accordingly"	Risk factor for future development of invasive cancer and does not require active treatment	Resection with clear margin (≥ 2 mm) required (WLE or Mx) SLNB usually not required but may be considered in high risk cases
NBOCC, 2003 ^[27] (Australia)	PLCIS not mentioned	Consider surgical biopsy Surveillance ≥ 15 yr No role for clear margin excision established	Clear margin excision Usually adjuvant RTx Consider hormone therapy
NHSBSP "In situ lobular neoplasia: overview and recommendations" [pending publication] ^[17] (United Kingdom)	Should be classified B5a (as with DCIS) and excised with negative margins	Merits MDT discussion and usually diagnostic biopsy	

ABS: Association of Breast Surgery; NCCN: National Comprehensive Cancer Network; ESMO: European Society of Medical Oncology; NBOCC: National Breast and Ovarian Cancer Care; NHSBSP: National Health Service Breast Screening Programme. PLCIS: Pleomorphic lobular carcinoma *in situ*; DCIS: Ductal carcinoma *in situ*.

ARGUMENT FOR MRI IN PLCIS CASES

Invasive lobular carcinoma is associated with over a quarter of the PLCIS cases, it is more frequently multifocal and bilateral compared with ductal carcinoma^[43,44]. Consequently, MRI is often performed pre-operatively in known lobular carcinomas in order to better assess the extent of disease and thus reduce re-excision rates. MRI may have a future role in imaging of patients with PLCIS due to the high rate of upstaging from PLCIS to invasive lobular carcinoma.

RECURRENCE RATES AFTER PLCIS EXCISION

Safety of PLCIS management ultimately can be determined by recurrence rates. No conclusions could be drawn from a small sample size of 173 cases, especially given the heterogeneous mix of margin management and adjuvant therapies. Information on recurrence is also not stated in all series. Using DCIS again as a comparator, Boyages *et al* reported that after excision, 43% of local recurrences were invasive, not *in situ*^[45]. In this review, there were no episodes of invasive disease on recurrence - only PLCIS.

PLCIS MANAGEMENT GUIDELINES

Looking at the guidelines for management, PLCIS is not mentioned in the Association of Breast Surgery or the

National Breast and Ovarian Cancer Care publications. These guidelines were last updated in 2009 and 2003 respectively and thus pre-date the majority of the evidence regarding PLCIS. Thus, it is no surprise that PLCIS does not feature. The National Comprehensive Cancer Network publication (2013) states that PLCIS may have a similar behaviour to DCIS, and proposes that negative margin excision should be considered. Qualification of this statement is made by explaining that the outcome data regarding the efficacy of surgical excision to negative margins is lacking. This guidance is certainly consistent with the data reviewed. The NHS Breast Screening Programme (pending publication) and the European Society of Medical Oncology (2013) make similar statements that PLCIS may behave similarly to DCIS and should be excised with negative margins. The European Society of Medical Oncology also states, with regards to *in situ* lobular neoplasia, "radiotherapy is not warranted, perhaps with the exception of the pleomorphic subtype". This statement is presumably made, based on the histomorphological similarities between DCIS and PLCIS, thus using DCIS-based data as surrogate evidence, but there is no data regarding the clinical efficacy of radiotherapy for PLCIS directly. The lack of guidance from many National and International organisations on the management of PLCIS reflects the lack of data on which to support treatment guidance. The few guidelines that do pertain to PLCIS generally recommend excision with no clear definition of margin width.

CURRENT VARIATIONS IN PRACTICE

Blair *et al.*^[46] recently published a survey completed by surgeons in the United States, regarding the management of positive margins in PLCIS cases. They report considerable heterogeneity in the management. Only 24% felt they would always wish to re-excite PLCIS at the margin. The survey did not address the reasons for the varied responses, but they postulate that it may be due to a lack of familiarity with this unusual variant of LCIS or an active decision to await better evidence to inform further intervention. Either way, such diversity in responses suggests a requirement for clearer evidence and guidance.

PLCIS has historically been a rarely diagnosed phenomenon. In the past, some cases will undoubtedly have been diagnosed as DCIS due to its histological similarities. However, due to the relatively recent universal use of E-cadherin immunostaining, combined with the ever-growing numbers in breast screening programs, PLCIS is likely to become a more frequent diagnosis. Its clinical characteristics remain largely unknown, but are not entirely consistent with either DCIS or CLCIS. Thus independent, clear guidelines for the management of PLCIS are required, although there remains a need for quality evidence on a national and international scale, to inform practice.

CONCLUSION

There is a lack of quality evidence to inform guidance on the management of PLCIS. The limited data demonstrates a high rate of concurrent invasive disease associated with PLCIS. Based on the available evidence, it would seem safe to surgically excise PLCIS in a similar manner to DCIS. There is no evidence on the efficacy of adjuvant treatments. As with high grade DCIS, a sentinel lymph node biopsy may be considered at the time of excision.

Abstract

Exercise and rehabilitation approaches in palliative care programs for cancer patients affect patients' symptoms, physical functioning, muscle strength, emotional well-being, psychological symptoms, functional capacities, quality of life, mortality and morbidity positively. Based on scientific data, palliative cancer patients should be recommended to participate in exercise programs. There is no standard approach to recipe an exercise regimen for a palliative cancer survivor. Studies for demonstrating the positive effects of exercising in palliative care patients are increasing in number day by day. At this point, increasing awareness about exercising in the entire team monitoring the patient and our efforts in this matter seems to be very important.

INTRODUCTION

Cancer and intensive medical therapies administered due to cancer affect the physical, functional, emotional, psychological and social statuses of patients^[1]. There are many factors that cause disability in cancer patients. These factors include fatigue, treatment complications, malnutrition, neurological and musculoskeletal problems, pain, intestinal and bladder dysfunctions, thromboembolic disease, depression, and presence of comorbid diseases^[2-9]. The resulting physical disability leads to depression, decreased quality of life, and increased need for care and health expenditures^[2,10-12]. Right at this point, we, rehabilitation physicians assume great responsibility. The first study that documented the need for cancer rehabilitation was published by Lehman *et al*^[5]. In that study, 805 cancer patients were examined and 438 patients were found in need of rehabilitation; this need was reported to be as high as 70% in patients with breast, lung, and head-neck tumors. There was functional loss associated with physical weakness in 35% of the assessed patients, a need for an assistive device to be able to perform daily living activities in 32% of them, difficulty in ambulation in 23% and inadequacy in transfers in 7%^[5]. Despite the crucial need for physical activity and exercise in this patient population, patients' demand for physical treatment varied from 2% to 81%^[13]. It has been stressed that terminal cancer patients also have significant functional incapacity^[4,6]. Although emphasizing its importance date back to many years ago in the literature, utilization of these study results in clinical practice has not unfortunately reached the desired level.

Physical strength, time spent in bed during the day, ability to do something intended and being dependent on others are important factors for cancer patients and their

loved ones in terms of their quality of life. It is stressed in the literature that progressive disability and the feeling of being dependent on others are among the reasons that deplete the desire to live in cancer patients^[14,15]. In another study made in a nursing home with terminal-stage cancer patients, it was found that the desire to be physically active came first even during the last three days of life. In that study, 88% of the patients wished to have increased mobility and 50% of them complained about the problems in their daily living activities^[16].

Rehabilitation in cancer patients is very important in that it ensures maintenance of their functional capacity and particularly their mobility^[17,18]. Although cancer patients are in great need of physiotherapy and rehabilitation, this is often ignored by health professionals^[19,20]. For this reason, the role of physiotherapy and rehabilitation during palliative care in cancer patients is limited in both clinical practice and literature^[21]. Especially in terminal-stage cancer patients, we see assumptions that rehabilitation is useless with the underlying thought that death is approaching. On the contrary, patients we see in our clinical practice seem to have a desire for exercising even if they will be lost (death) in a day. Treatment approaches for protecting and restoring physical functioning particularly in patients with diminished life expectancy have started to appear in small numbers in the literature related to palliative care^[22]. Physical functions appear to be the major factor determining the length of life and quality of life^[22,23]. Although, the additional effect of exercise in palliative care has been investigated in numerous studies throughout the last decades, there have been no clear consensus or a standard approach yet.

EFFECT OF EXERCISE IN PALLIATIVE CARE

It has been found in recent studies that exercise has a positive effect on life expectancy in cancer patients during their palliative care^[22,24-26]. Prospective-observational studies have demonstrated that physical activity after cancer diagnosis is associated with a reduced risk of cancer recurrence and improved overall mortality among multiple cancer survivor groups, including breast, colorectal, prostate and ovarian cancer^[27]. In a multi-center, randomized and controlled study made by Courneya *et al*^[28], resistance and aerobic exercises were prescribed for 17 wk to 242 patients with breast cancer who had been started adjuvant chemotherapy. Although the exercises given did not affect the individuals' quality of life associated with cancer, they improved their physical conditions, body compositions and general well-being^[28]. There is increasing evidence that exercise therapy is beneficial during palliative care of cancer patients. Studies have reported that 30% of total cancer deaths are associated with lack of exercise and malnutrition and 250000 early deaths occur every year due to inactivity^[29,30].

Exercises have positive effects on energy use, insulin

resistance, inflammation, and on many tissues and organs. The cardiovascular capacities and quality of life of the cancer patients who exercise increase, their fatigue, sleeping problems, body structures and immune responses improve and therefore a general well-being occurs^[18,19,31-34]. Exercise has been shown to have positive effects not only on physical and functional condition but also on psychological symptoms in cancer patients^[35,36]. This positive effect on both physical and psychological symptoms may explain the increase in life expectancy in these patients.

QUALITY OF LIFE

Although quality of life decreases in patients with advanced cancer, this decrease is less in those who receive exercise therapy^[37]. There are only a few studies investigating the effect of rehabilitation in terminal-stage cancer patients. In one of those studies, 301 people who have been staying in a nursing home and who have exercised for 6 years were examined. They had an average of 27% improvement in their Barthel mobility indexes after their rehabilitation. Forty-nine patients gained their independence in their mobility and daily living activities^[11,12]. In the study of Porock *et al*^[38] where they investigated the effect of exercise on palliative care patients, fatigue, anxiety and quality of life improved in patients who received an exercise therapy for 28 d^[38]. In another study, fatigue and quality of life improved in patients who received an intensive exercise therapy for 6 wk^[22]. Montagnini *et al*^[39] also evidenced that exercising resulted in an improvement in the scores of the daily living activities scale in 56% of the palliative care patients within 2 wk^[39].

FATIGUE

Fatigue is a very frequently seen symptom in palliative care patients (80%-90%). Fatigue is argued as being associated with anxiety, depression, pain, dyspnea, insomnia, loss of appetite, nausea, and dizziness. It is an important symptom in that it affects daily living activities of people and lowers their quality of life. Exercising is known to have positive effects on fatigue^[40]. It is stressed that group exercises, energy protection techniques and regular physical activities are significant in reducing cancer-related fatigue^[41]. A 20-30 min daily progressive walking exercise program was administered 4-5 times a week to patients with breast cancer who were receiving radiotherapy and a decrease was seen in fatigue^[42]. A bicycle exercises program was administered for 30 min to 50% of the patients after bone marrow transplantation and fatigue and physiologic stress levels were found to be lower in the exercising group than in those who did not exercise^[43]. In a study where fatigue and its causes as well as the efficacy of rehabilitation were investigated, 32 cancer patients were included in a rehabilitation program consisting of aerobic and muscle strengthening exercises, sports activities and psychological support. After the rehabilitation activities which lasted fifteen weeks, improvement was

seen in physical parameters and a marked decrease in fatigue^[44]. There are not adequate data as to how exercise reduces fatigue or its role in decreasing cancer risk.

It should be borne in mind that aerobic exercises must be employed when fighting against fatigue in cancer patients. In many studies, light and moderate walking and bicycle exercises have been administered a few times a week to activate large muscle groups and to increase oxidative muscle fibers. In view of the data available to us, it can be said that a less intense exercise program should be administered to patients whose cancer treatment actively continues and more intense exercises can be prescribed to those whose cancer treatments have been completed.

MUSCLE MASS AND MUSCLE STRENGTH

Cancer cachexia is a multifactorial condition that cannot be fully reversed with conventional food supplements; it leads to progressive functional impairment and progresses with loss of muscle mass^[45]. There are very few treatment options for patients with advanced cancer. Loss of muscle mass and muscle strength in cancer cachexia results in unintentional weight loss. Due to the potential effect of exercising on muscle mass and muscle strength, exercise is recommended as a treatment method that can be chosen before and during cachexia in advanced cancer cases^[46-52]. In a meta-analysis that evaluated the effect of physical exercise on muscle mass and muscle strength during an active cancer treatment and that reviewed 16 studies, it was demonstrated that aerobic and resistance exercises administered during an active cancer treatment could prevent muscle mass loss^[53]. Therefore, exercise therapy in cancer patients is effective for patients in sustaining their daily living activities^[8,26,53].

Measuring muscle mass objectively requires experienced staff and expensive equipment. There is not a clear consensus about the dose and type of exercise that has to be performed for the recovery of muscle mass^[53]. For this reason, it is difficult to comment on the changes an exercise therapy makes in muscle mass. There is a need for further studies evaluating muscle strength in advanced cancer cases.

The importance of protecting and increasing muscle mass for daily living activities has been stressed. There are also studies on the positive effects of muscle strengthening exercises^[26,48,50-53].

TREATMENT PLAN AND COMPLIANCE

A rehabilitation program should be custom made. When planning the rehabilitation, disease location, its stage, previous and present treatments received by the patient, their previous functional condition, their life expectancy, comorbidities, pain, medications used, the patient's cognitive and emotional status, their nutrition, physical capacity and potential limitations should all be considered^[54]. The patient's neurological and musculoskeletal examinations

should be performed thoroughly and their motor deficits, range of motion (ROM), walking patterns and risk of falling should be inquired. Indications for the exercise treatment in this patient population include to regain or improve physical functions, aerobic capacity, strength, flexibility, body image, body composition, quality of life, ability to withstand physically and psychologically to any current and future cancer treatments and to withstand the anxiety associated with the current or recurrent disease^[55].

For example, while the main target is the restoration of arm and shoulder mobility in a patient who was administered a curative surgery due to breast cancer, mobility and daily living activities come first for a patient who had a hip metastasis associated with breast cancer and who developed a pathologic fracture. In rehabilitation, targets should be objective and realistic; education and psychosocial consultation facilities should be provided. The patient's family and loved ones should be active participants of the rehabilitation process.

Adherence to treatment in cancer patients and our efforts in this matter also become very important. Generally speaking, compliance of patients with the treatment is quite high. The reasons patients discontinue an exercise therapy include lack of interest in the therapy, medical complications, exercising time and intensity, program being too long, disease stage, and transportation problems. The intensity and length of the exercise program should be adjusted in a way not to tire or bore the patient especially when terminal-stage cancer patients are in question^[54].

When exercising with palliative care patients, the patient groups are kept small and there is no definite standard in treatment programs. This is why it is difficult to determine what type of exercise will be given to what patient group and how. There is no agreement about the type, frequency, intensity and length of exercises to be given to cancer patients, nor is there an agreement as to at what stage of the disease it should be given and how. The exercise types usually given are exercises performed by the patient in bed with the help of a caregiver, exercises performed by the patient alone in line with the directives given, exercises involving simple support devices and weights, strengthening and aerobic exercises such as walking and swimming. Patients often prefer walking and home exercising programs^[20].

A rehabilitation or exercise program which disregards the patient's general condition and in which expectations are kept high will make patient compliance difficult and will demoralize the patient. For example, it would certainly not be appropriate to give 2 tours of walking exercise in the corridor mornings and evenings to a patient who can only walk from the bed to the patient room door due to fatigue. To give only ROM and breathing exercises to a patient who can hardly move in bed will be more relaxing for both the patient and his/her family. Patient compliance is better when the patient is able to do and comply with the programs.

Workouts involving resistance exercises are usually

less common; the majority of workouts involve aerobic exercises^[31,56]. Resistance exercises increase muscle strength and overall body mass^[57]. Although there are data that resistance exercises are more effective in increasing muscle mass and muscle strength than aerobic exercises, there are no strong evidences yet^[28,53].

According to the data pooled from cancer studies, the American Cancer Society recommends cancer survivors to engage in regular physical activity avoiding inactivity, to exercise for at least 150 min per week including strength-training for at least 2 d per week and to keep a healthy weight^[27]. Joyful exercises like Pilates, Tai Chi, Yoga, Nordic walking and dance may be chosen according to the expectation and motivation of the patient by carefully adjusting the intensity to the abilities of the individual.

CONCLUSION

Exercise and rehabilitation approaches in palliative care programs for cancer patients affect patients' symptoms, functional capacities, quality of life and length of life positively. Studies for demonstrating the positive effects of exercising in palliative care patients are increasing in number day by day. Exercise in palliative care should definitely be considered since it is easily administered and safe and is beneficial for the patient. We, rehabilitation physicians, must certainly be a major part of this team, because patients can benefit from this facility only when they are directed to us. At this point, increasing awareness about exercising in the entire team monitoring the patient and our efforts in this matter seems to be very important.

Abstract

Lung cancer, is the most common cause of cancer death in men and second only to breast cancer in women. Currently, the first line therapy of choice is platinum-based combination chemotherapy. A therapeutic plateau has been reached with the prognosis for patients with advanced non-small cell lung cancer (NSCLC) remaining poor. New biomarkers of prognosis as well as new therapies focusing on molecular targets are emerging helping to identify patients who are likely to benefit from therapy. Despite this, drug resistance remains the major cause for treatment failure. In this article we review the role of apoptosis in mediating drug resistance in NSCLC. Better understanding of this fundamental biological process may provide a rationale for overcoming the current therapeutic plateau.

INTRODUCTION

Lung cancer is the leading cause of cancer death in the United Kingdom accounting for 24% of all male related cancer deaths and 20% in females^[1]. Similar trends are seen in the United States with lung cancer representing the most common cause of cancer death in men and women, recently overtaking breast cancer in the latter^[2]. In the United States, more than 213000 new cases were diagnosed in 2007 with a total of 1.61 million cases worldwide in 2008^[2,3]. The majority of these cancers (75%-80%) are non-small cell lung cancers (NSCLC)^[4].

Surgery is the mainstay of treatment for early stage and localised disease (Stage I and II and selected IIIA). Multimodal therapy is the norm for regionally advanced disease in the form of adjuvant chemotherapy. Palliative chemotherapy forms the mainstay of treatment in patients with advanced metastatic disease^[5]. Five year survival rates following lung resection for NSCLC are I A-73%, I B-54%, II A-48%, II B-38%, IIIA-25%^[6]. The majority of patients have advanced disease at the time of

diagnosis and therefore are not surgical candidates. This is illustrated by the fact that in the United Kingdom only 14% of patients diagnosed go on to have surgical resection^[7]. In those patients that are surgical candidates, more than 50% will develop a recurrence. Adjuvant chemotherapy has been used with limited success to decrease the recurrence rates but this has only yielded a survival benefit of 5%-15%^[8].

For patients not suitable for surgery due to advanced disease or those who have suffered recurrence following resection, chemotherapy forms the mainstay of treatment with evidence that platinum based therapies are most effective in the first line setting^[9,10]. Despite this, in a recent trial of platinum combination therapies in advanced NSCLC, only 30% of patients showed objective disease response and a significant proportion suffered toxic side-effects such as neutropenia (27%), anaemia (10%), thrombocytopenia (13%), alopecia (21%) and nausea (4%). During the trial, deaths due to study drug toxicity were in the region of 1%^[11]. This demonstrates the major problem of drug resistance in NSCLC to standard platinum based therapies and the associated toxicities.

MOLECULAR TARGETED THERAPY

A recent major advance in the management of NSCLC has been the identification of activating mutations in the tyrosine kinase domain of the epidermal growth factor receptor (EGFR)^[12]. These mutations, found in 10% of NSCLC specimens in the United States and Europe, are associated with increased sensitivity to EGFR tyrosine kinase inhibitors erlotinib and gefitinib^[13]. EGFR mutations are often accompanied by gene amplification^[14]. Mutation of the EGFR can lead to signal transduction independent of ligand stimulation, relaying signals to the PI3K-AKT-mTOR pathway involved in cell survival, or to the RAS-RAF-MEK-ERK pathway involved in cell proliferation^[15]. The fact that kinase inhibition leads to apoptosis in cells with mutant EGFR supports the notion that these cells are "addicted" to signalling *via* the mutant proteins^[16]. This explains the dramatic response to EGFR tyrosine kinase inhibitors in EGFR mutated NSCLC with associated improvement in survival^[17,18].

Molecular profiling in NSCLC has revealed a number of other mutations such as EML4-ALK translocation^[19]. This is associated with extreme preclinical sensitivity to respective ALK kinase inhibition in both preclinical and clinical settings^[20,21]. Additional molecular subclasses with associated somatic gene alterations have been discovered, predominantly in lung adenocarcinomas and include mutations of BRAF^[22], Her2^[23] and PIK3CA^[24]. The continual discovery of new molecular subclasses represents significant progress in the treatment of NSCLC but they should not necessarily be viewed as a panacea as resistance to these novel targeted therapies are being reported^[25]. The above molecular subclasses still only account for less than half all new cases of the disease. The majority of patients still rely on standard combination

chemotherapy of platinum based doublet regimens.

In addition to molecular tumour markers, there is increasing interest in developing biomarkers associated with NSCLC. These may be predictive for response to treatment or prognostic. An area of interest in our unit relates to the link between plasma fibrinogen and NSCLC. In early stage disease amenable to surgical resection, raised fibrinogen is associated with increased risk of incomplete resection and correlates with T stage of tumour^[26]. More recently, serum fibrinogen has been shown to be an independent predictor for both disease recurrence and overall survival in both resectable and advanced disease^[27,28]. The mechanism by which fibrinogen acts as a marker is not fully understood. Its role as an extracellular matrix, in promoting angiogenesis and metastasis has been proposed^[29-32].

APOPTOSIS AND DRUG RESISTANCE

Cisplatin (*cis*-diamminedichloroplatinum II) is the most effective platinum based therapy in the first line setting for NSCLC^[33]. It forms DNA-platinum covalent adducts resulting in inhibition of DNA replication, suppression of RNA transcription and protein translation, attempted DNA repair as well as disturbance of the cell cycle and the activation of apoptosis^[34].

Apoptosis serves as a natural barrier to cancer development^[35]. Normally the accumulation of genetic mutations required to drive uncontrolled cell cycle progression and tumorigenesis would result in triggering of apoptosis within a cell^[36]. The ability of cancer cells to evade apoptosis is, therefore, an essential hallmark of cancer^[37]. Defects in apoptosis, harboured by cancer cells, not only underpin tumorigenesis but also drug resistance^[38]. Resistance of NSCLC cells to a diverse range of cytotoxic therapies suggests a defect in apoptosis signalling^[39]. Further understanding of the mechanisms by which apoptosis resistance occurs and how this can be overcome will be important in order to administer a more rational approach to anticancer drug design and therapy.

APOPTOSIS

Apoptosis, a genetically encoded programme of cell death, was originally defined based on the morphological features observed as the cell died; nuclear condensation, nuclear and cellular fragmentation, membrane blebbing and phagocytosis of the dying cell in the absence of inflammation^[40]. The process of apoptosis is conserved in a wide range of multicellular organisms from worms to humans and plays a key role in normal development and homeostasis. The apoptosis phenotype is produced through the activity of cysteine-aspartic proteases, a family of cysteine proteases termed caspases. A hierarchical cascade of activation occurs which results in apoptosis. Two groups of caspases have been classified; the initiator caspases and the effector caspases.

The initiator caspases, caspase-8, -9 and -10, are ac-

tivated early in apoptosis signalling and have restricted cleavage targets, limited to self cleavage, the effector caspases and BID (caspase-8). In contrast, the effector caspases, caspase-3, -6 and -7, have hundreds of cleavage sites broadly distributed throughout the cell^[41]. The effector caspases are held in the cytosol as inactive dimers. The activating event, catalyzed by the initiator caspases, involves conversion to catalytically active enzymes by cleavage in the linker region between the large and small active subunits. This allows intramolecular rearrangements to form an enzymatically active dimer^[42]. Caspase-3 and -7 display highly similar substrate specificity and carry out redundant but essential functions in apoptotic cell death as mouse embryonic fibroblasts lacking both enzymes are resistant to intrinsic and extrinsic apoptotic stimuli^[43].

Caspase-8 and -10 are involved in the death receptor signalling pathway whereas caspase-9 is involved in mitochondrial apoptosis.

It is clear caspase activation is a critical step in the execution of apoptosis and is generally a terminal event for the cell. Regulation of the process occurs through the extrinsic, death receptor apoptosis pathway and the intrinsic mitochondrial apoptosis pathway.

EXTRINSIC APOPTOSIS PATHWAY

Apoptosis occurs via the extrinsic apoptosis pathway as a result of signalling through death receptors expressed on the surface of mammalian cells. In the 1970's it was identified that certain products of lymphocytes and macrophages caused the lysis of certain types of cells, especially tumour cells. This product was termed 'tumour necrosis factor (TNF)'^[44,45]. It has been established that TNF has its effect via cell surface receptor binding and activation. At least 18 TNF family ligands and 29 receptors have been identified in humans^[46]. In cancer research, interest has grown around the use of TNF-related apoptosis-inducing ligand (TRAIL) and targeting its receptors, members of the TNF superfamily, since the observation that recombinant human (rh) TRAIL induces apoptosis in various tumour cells but not in normal cells^[47].

TRAIL activates apoptosis by binding to specific transmembrane receptors TRAIL-R1 (DR4) and TRAIL-R2 (DR5)^[48,49]. It can also bind truncated, non-functional receptors TRAIL-R3 and TRAIL-R4 known as decoy receptors (DcR1 and DcR2)^[50]. Upon binding TRAIL to the death receptors (DR4, DR5), trimerization of the receptors occurs and a complex is formed termed the death-inducing signalling complex (DISC). This is the key step for subsequent initiator caspase activation to occur.

INTRINSIC APOPTOSIS PATHWAY

The other major apoptosis pathway leading to caspase activation and cell death is the Intrinsic (mitochondrial) apoptosis pathway. As DISC formation is the key step

in extrinsic (death receptor) signalling so mitochondrial outer membrane permeabilization (MOMP) is the key requirement for caspase activation and apoptosis via the mitochondrial apoptosis pathway. As the name suggests, this apoptosis pathway is engaged primarily as a result of internal cellular stresses such as DNA damage, ER stress^[41].

MOMP during apoptosis is primarily controlled by the BCL2 family of proteins^[51]. The pro-apoptotic members, BAX^[52] and BAK^[53], contain BH1-3 domains. BAX and BAK are often referred to as effector proteins as there is an absolute requirement for their activation at the outer mitochondrial membrane for MOMP to occur^[54].

A diverse range of death signals caused by eg DNA damage, growth factor deprivation leads to a shift in the balance of anti- and pro-apoptotic BCL2 family members with signals produced to engage MOMP. Activation of a "multidomain" proapoptotic member, BAX or BAK, is an essential gateway to mitochondrial dysfunction required for cell death in response to these diverse stimuli^[54].

Upon receipt of a death signal, BAX translocates to the mitochondrial surface where BAK already resides^[55,56]. A detailed sequence of events from BAX translocation to the OMM, subsequent activation and MOMP has been described recently^[57]. The requirement for activated BAX and/or BAK for MOMP to occur is clear, the mechanism by which they bring about MOMP is not. The key feature of MOMP in bringing about caspase activation and apoptosis is cytochrome C release. This is clear from evidence that cells lacking cytochrome C fail to activate caspases in response to UV irradiation, serum withdrawal, or staurosporine^[58]. The primary function of cytochrome C is in oxidative phosphorylation as it is a key component of the electron transport chain and it is found loosely associated with the mitochondrial inner membrane. The other important mitochondrial intermembrane space protein released during MOMP is second mitochondria-derived activator of caspase (SMAC) also termed DIABLO (direct IAP binding protein with low pI). It binds XIAP's, antagonising their ability to inhibit caspases^[59,60].

APOPTOSIS BLOCK IN CANCER

Having outlined how apoptosis proceeds, the mechanisms by which cancer cells evade this process will be explored. Block in mitochondrial apoptosis has been broadly divided into three groups^[61]: (1) Class A block occurs when normal generation of proapoptotic activators by aberrant behavior is inhibited. The mechanisms by which aberrant behaviour, such as genomic instability and oncogene activation, generate death signals via BH3-only proteins is as yet poorly understood. This is an area of ongoing study; (2) Class B block occurs when there is a significant loss of the BCL2 family effectors, BAX and BAK; and (3) Class C block occurs when increased expression of an anti-apoptotic BCL2 family protein is present, thereby inhibiting or sequestering pro-apoptotic BH3-only proteins. In this scenario, the cell has generated

an appropriate BH3-only death signal but it is inhibited by opposing anti-apoptotic expression. Cells in this state are referred to as “primed for death” and are “addicted” to the overexpression of the anti-apoptotic protein^[62].

Apoptosis blocks such as described above may determine the sensitivity of a cancer cell to a wide range of diverse chemotherapy agents and explain frequently observed phenomenon of multidrug resistance^[51]. The fact that being primed for death (class C block) is apparently more common in tumours than in normal cells may help explain why chemotherapy is often more toxic to cancers^[51].

Having classified apoptosis block in tumours, a new technique for determining what type of block a given cell employs has been developed termed BH3 profiling^[61,62]. The basic method involves incubation of mitochondria isolated from tumour cells with a panel of BH3 peptides. By assessing the pattern of response, the type of apoptosis block present can be identified. This may be used in the future to select drugs targeting anti-apoptotic proteins as a strategy for improving efficacy of drug treatments.

EXPRESSION OF BCL2 FAMILY MEMBERS IN NSCLC

Much focus has been placed on the role of BCL2 as a prognostic predictor in NSCLC. Many studies over the last 15-20 years have assessed its expression in many differing solid tumours. Given its function as an antiapoptotic protein, it would be predicted that overexpression would result in a more aggressive and treatment resistant phenotype. The published data is mixed with regard to its role as a prognostic marker.

A meta-analysis from 2003 compiled 28 studies from 1993 to 1999 which report the expression of BCL2 in NSCLC and the prognostic value of its expression in the primary tumour^[63]. Immunohistochemistry was used to detect expression in all studies. Of the 28 studies included, 11 concluded BCL2 expression was a good prognostic marker, 14 concluded it was not prognostic for survival with only 3 linking BCL2 expression to poor prognosis. Having performed the meta-analysis, the authors concluded that BCL2 positive tumours had a significantly better survival than those with BCL2 negative tumours. Given its function in the apoptotic pathway this would appear a paradoxical conclusion. One theory suggests that loss of BCL2 expression correlates with tumour de-differentiation and therefore a more aggressive phenotype^[64]. As discussed above, increased expression of BCL2 would likely confer a class C block in apoptosis and as such these tumours would be primed for death perhaps explaining the increased survival. This should be interpreted with caution as a result of heterogenous treatment patients in these studies received. Given the highly complex interplay between BCL2 and its other family members in regulating apoptosis, it is not surprising that the study of one anti-apoptotic member yielded such a result. As knowledge about the interplay between BCL2

family members improves, other targets or combination of targets may be more relevant to study rather than a single protein in isolation.

The crucial role the proapoptotic multidomain proteins BAX and BAK play in mitochondrial outer membrane permeabilisation warrants further study as prognostic markers. Loss of both proteins would confer a class B apoptosis block. Many studies exist reporting the status of BAX and BAK expression in NSCLC but again only report in isolation and each is considered separately as prognostic markers.

Altered BAX expression is frequently reported in NSCLC^[65-68]. None of these studies conclude that altered BAX expression has significant value as a prognostic marker, although none have investigated the expression of BAK together with BAX. Fewer studies report the incidence of altered BAK expression^[69,70]. These studies report the incidence of BAK loss at 42% and 59%. They also include data on BAX expression with loss reported in 34% and 47%. Neither study reports the incidence of double loss. Both conclude that no prognostic value is attributed to BAX or BAK expression in NSCLC but again each protein is analysed in isolation. Data from the International Adjuvant Lung Cancer Trial (IALT) suggests a trend toward increasing chemosensitivity with increasing BAX level^[71]. The converse effect of BAX negativity was not reported.

STRATEGIES TO OVERCOME MITOCHONDRIAL APOPTOSIS BLOCK

Given the frequent loss of expression of each protein, it is likely a significant portion of patients with NSCLC will have BAX and BAK double loss and given the evidence that this results in a highly apoptosis resistant phenotype it would be important to assess the impact on double loss on both survival and response to standard chemotherapy and radiotherapy in NSCLC.

Given what is known about the mitochondrial apoptosis pathway, class B block in apoptosis is likely to prove resistant to a range of targeted therapies. BH3 mimetics would be predicted to be ineffective due to absence of effector proteins BAX and BAK. Alternative strategies will be required to treat these potentially multidrug resistant cancers. *In vitro* evidence exists to show that in the absence of BAX and BAK, detachment of hexokinase from mitochondrial VDAC can lead to cytochrome C release and therefore mediate cell death^[72]. This can be achieved using either a competitive peptide, or by inhibiting AKT (which in turn regulates hexokinase interaction with VDAC) and prove a rational approach to treating cancers exhibiting Akt activation or an imbalance in the expression of antiapoptotic and proapoptotic members of the BCL2 family.

CONCLUSION

NSCLC presents a major health burden worldwide. Plati-

num based chemotherapy is the mainstay of treatment in the clinic today, although denovo and acquired drug resistance has resulted in a therapeutic plateau since its introduction over 30 years ago. Novel targeted therapies are beginning to emerge that induce apoptosis in certain molecular subclasses. Apoptosis resistance underpins tumorigenesis and drug resistance. Understanding how apoptosis resistance occurs in NSCLC will allow tailoring of therapy and development of novel targets to overcome this problem.

APPENDIX I-V Instructions to authors

ABOUT COVER Editorial Board Member of *World Journal of Clinical Oncology*, Bruna Scaggiante, PhD, Assistant Professor of Molecular Biology and Aggregate Professor of Molecular Biology, Department of Life Sciences, University of Trieste, Via Licio Giorgeri, 1, 34127 Trieste, Italy

AIM AND SCOPE *World Journal of Clinical Oncology* (*World J Clin Oncol*, *WJCO*, online ISSN 2218-4333, DOI: 10.5306) is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJCO covers a variety of clinical medical topics, including etiology, epidemiology, evidence-based medicine, informatics, diagnostic imaging, endoscopy, tumor recurrence and metastasis, tumor stem cells, radiotherapy, chemotherapy, interventional radiology, palliative therapy, clinical chemotherapy, biological therapy, minimally invasive therapy, physiotherapy, psycho-oncology, comprehensive therapy, and oncology-related nursing. Priority publication will be given to articles concerning diagnosis and treatment of oncology diseases. The following aspects are covered: Clinical diagnosis, laboratory diagnosis, differential diagnosis, imaging tests, pathological diagnosis, molecular biological diagnosis, immunological diagnosis, genetic diagnosis, functional diagnostics, and physical diagnosis; and comprehensive therapy, drug therapy, surgical therapy, interventional treatment, minimally invasive therapy, and robot-assisted therapy.

We encourage authors to submit their manuscripts to *WJCO*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great clinical significance.

INDEXING/ABSTRACTING *World Journal of Clinical Oncology* is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

molecular mechanisms of resistance and the options for clinical management of disease progression. Promising investigational strategies for overcoming TKI resistance are highlighted.

Becker K, Xu Y. Management of tyrosine kinase inhibitor resistance in lung cancer with EGFR mutation. *World J Clin Oncol* 2014; 5(4): 560-567 Available from: URL: <http://www.wjgnet.com/2218-4333/full/v5/i4/560.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i4.560>

Abstract

The identification of driver mutations and drugs that inhibit their activity has been a major therapeutic advance for patients with advanced lung adenocarcinoma. Unfortunately, the success of these drugs is limited by the universal development of resistance. Treatment failure can result from inadequate drug exposure or selection of resistant malignant clones. Clinically distinct mechanisms of disease progression have been identified and can inform treatment decisions. Investigations into the biochemical mechanisms of tyrosine kinase inhibitor resistance may provide additional therapeutic targets by which the efficacy of targeted therapy can be improved.

Key words: Epidermal growth factor receptor mutation; Tyrosine kinase inhibitor; Lung cancer; Adenocarcinoma; Resistance; Targeted therapy

Core tip: The causes of epidermal growth factor receptor tyrosine kinase inhibitor (TKI) treatment failure including pharmacokinetic failure, intrinsic resistance and acquired resistance are discussed. We review the

INTRODUCTION

In the treatment of lung adenocarcinoma, drugs that inhibit unique driver mutations have proven superior to conventional chemotherapy in molecularly-defined subgroups, altering treatment paradigms and research agendas. The observation that dramatic responses to erlotinib or gefitinib occurred in patients with epidermal growth factor receptor (EGFR) mutations affirmed the concept of “oncogene addiction^[1]” in non-small cell lung cancer: despite the complexity of genetic and epigenetic changes in malignant cells, interfering with the activity of a single dominant oncogene can induce tumor regression. Translating this concept into clinical benefit required identification of the driver mutations to which the cancers are “addicted” and the development of drugs capable of selectively blocking their activity. Mutually exclusive driver mutations can be detected in approximately 60% of lung adenocarcinomas through multiplexed testing techniques^[2]. Single agent anti-tumor activity has been reported with drugs that inhibit the kinase activity of EGFR, EML4-ALK, ROS1, HER-2, BRAF, RET and MET^[3-9]. Moreover, targeted therapy with afatinib, gefitinib or erlotinib in EGFR-mutated lung cancer and crizotinib in lung cancer harboring EML4-ALK translocations have dem-

onstrated clinically significant improvements in response rates, progression-free survival (PFS) and quality of life when compared with standard chemotherapy^[3,4,10-12]. In the LUX-Lung 3 trial, for example, afatinib produced longer PFS (11.1 mo *vs* 6.9 mo) and higher response rates (56% *vs* 23%) compared with pemetrexed and cisplatin in the first-line treatment of patients with EGFR mutations^[3]. Based on these results, practice guidelines recommend targeted therapy as first-line treatment for lung cancers with EGFR mutations or ALK translocations^[13]. Unfortunately, this therapeutic success is invariably temporary as all patients ultimately develop resistance to currently available targeted therapies. The goals of this review are therefore to (1) examine the mechanisms of failure of tyrosine kinase inhibitors (TKIs); and (2) discuss the strategies for preventing or overcoming resistance that are currently in development. We will focus on resistance to targeted therapy in lung cancers harboring EGFR mutations where these concepts are best characterized, though some concepts may be applicable to targeted therapy in general.

DIFFERENTIATING DRUG RESISTANCE FROM PHARMACOKINETIC FAILURE

The first step in identifying the mechanism of treatment failure is to differentiate pharmacokinetic failure from true drug resistance. Pharmacokinetic failure refers to disease progression due to inadequate drug exposure. True drug resistance occurs when malignant cells survive and divide in the presence of therapeutic drug levels and can be further characterized as intrinsic or acquired. In cases of pharmacokinetic failure, interventions to achieve therapeutic drug levels may effectively halt or prevent disease progression.

Interactions

Gefitinib and erlotinib are metabolized by the cytochrome p450 system and therefore have the potential for numerous interactions (Table 1). Concurrent medications and homeopathic remedies that induce p450 enzymes may lower systemic drug levels of these targeted therapies. The clinical significance of such interactions is demonstrated in the published case of a patient with advanced EGFR-mutated lung cancer that did not respond to initial treatment with erlotinib while concurrent medications included fenofibrate, a CYP3A4 inducer^[14]. Serum trough levels of erlotinib were sub-therapeutic and disease regression was achieved after dose escalation re-

sulting in therapeutic drug concentrations. Furthermore, current smokers have increased clearance of erlotinib, likely due to induction of CYP1A2 and CYP1A1^[15] and similar interactions are possible with gefitinib based on pharmacokinetic studies^[16]. In a study to determine the maximum tolerated dose of erlotinib in patients currently smoking at least 10 cigarettes daily, the trough plasma concentration and toxicity profile at 300 mg daily was similar to the standard dose of 150 mg in non-smokers^[15]. In patients taking erlotinib who cannot achieve smoking cessation, dose escalation to 300 mg daily as tolerated is recommended^[17]. Afatinib undergoes minimal metabolism by the cytochrome P450 system but is a substrate of p-glycoprotein. P-glycoprotein inducers may therefore lower systemic drug concentrations of afatinib^[18]. As oral drugs, gastric contents and pH may also impact bioavailability. Afatinib absorption is reduced when taken with a high fat meal whereas erlotinib absorption is increased and patients are directed to take both medications on an empty stomach. Drugs that increase gastric pH can reduce absorption of erlotinib and gefitinib, and have been shown to lower drug levels^[17,19]. When patients require antacid therapy, twice-daily histamine receptor blockers are recommended over proton pump inhibitors when possible and patients are advised to take erlotinib ten hours after the last dose and two hours prior to the next dose to minimize the effect on absorption^[17].

Blood-brain barrier

Central nervous system (CNS) involvement in the form of brain or leptomeningeal metastases is common in patients with advanced non-small cell lung cancer, either at the time of diagnosis or as a site of disease progression. The blood-brain barrier restricts most large and hydrophilic substances from passing from the circulation into the CNS. The cerebrospinal fluid (CSF) to plasma concentration ratios for erlotinib and gefitinib have each been shown to be less than 0.01^[20,21]. While confirming the reduced penetration of these drugs into the CNS, these measurements likely underestimate the exposure of brain metastases to each of these drugs due to local disruption of the blood-brain barrier in abnormal tumor vasculature. Despite CSF concentrations that would predict sub-therapeutic drug exposure, radiographic responses have been observed in brain metastases treated with erlotinib, gefitinib and afatinib at standard doses^[22,23]. Moreover, dose escalation of gefitinib or high-dose weekly erlotinib can increase drug levels in the CSF and reverse CNS disease progression that occurred during standard dosing. In one case report, a patient with an exon 19 mutation exhibited progressive brain and leptomeningeal metastases despite systemic disease control on gefitinib. The gefitinib concentration in the CSF was found to be less than that required to inhibit the growth of a cell line derived from the patient's tumor. After dose escalation to 1000 mg daily, the CSF concentration of gefitinib exceeded the half maximal inhibitory concentration and the patient experienced radiographic and symptomatic improvement

with clearing of malignant cells from the CSF^[20]. Since sustained escalated doses of erlotinib are poorly tolerated, high-dose weekly administration was investigated as a strategy to improve erlotinib CNS penetration. In a retrospective series of nine patients with CNS progression while on standard dose erlotinib, the CNS response rate to 1500 mg once weekly was 67%^[24].

DEFINING MECHANISMS OF DRUG RESISTANCE

True drug resistance, the survival and proliferation of malignant cells in the presence of therapeutic drug levels, is observed to varying degrees in all EGFR-mutated lung cancers. The complete response rates for currently available agents are less than 5% suggesting the presence of intrinsic resistance in a population of tumor cells of most patients at the time of treatment initiation. Furthermore, disease progression after initial response occurs due to emergence of acquired resistance with median PFS ranging from 9 to 13 mo in clinical trials. Given that some factors present at the time of diagnosis can predict both reduced probability of response and shorter duration of response, there is clearly overlap between the mechanisms of intrinsic and acquired resistance.

The response to EGFR-targeted therapy varies according to EGFR mutation

Both the probability and the duration of response to EGFR-targeted therapy vary according to the specific EGFR mutation. Activating EGFR mutations occur within exons 18-21 of the tyrosine kinase binding domain. Exon 19 deletions and L858R point mutations in exon 21 comprise 85%-90% of EGFR mutations and most reliably predict response to EGFR-targeted therapy^[25]. For this reason, FDA approval for first-line therapy with erlotinib or afatinib is limited to cancers harboring these mutations. However, differential sensitivity within this group has been observed: patients harboring exon 19 deletions show longer progression free survival compared with patients with L858R mutations^[26,27], despite similar *in vitro* activity^[28]. The reasons for the differences in clinical activity observed are not clear.

The efficacy of EGFR TKIs in the treatment of uncommon EGFR mutations is less predictable, in part due to their relative rarity. This is a heterogeneous group that includes exon 20 mutations, exon 19 insertions, exon 21 missense mutations (other than L858R), and exon 18 point mutations^[25]. The data on TKI efficacy in these cancers is limited to subset analyses of larger trials, small series and case reports. No partial responses were observed in patients with uncommon EGFR mutations in a phase II trial of first-line gefitinib, although some patients achieved prolonged stable disease^[29]. In the LUX-lung 3 trial of first-line treatment with afatinib *vs* pemetrexed and cisplatin, the progression free survival of patients treated with afatinib was improved when less common mutations were excluded from the analysis, sug-

gesting a higher prevalence of intrinsic or acquired resistance in this group^[3]. Exon 20 mutations in particular are generally associated with clinical resistance to all currently available EGFR TKIs. However, even within the group of tumors bearing exon 20 mutations there is heterogeneity and responses to EGFR TKIs have been observed with selected mutations^[30].

EGFR mutation abundance and heterogeneity

EGFR activating mutations occur *de novo* during tumor development and heterogeneity with regard to EGFR mutation status in a particular tumor nodule has been reported^[31,32]. While conventional DNA sequencing can detect an EGFR mutation present in at least 10% of tumor cells, a more sensitive method, the Scorpion amplification refractory mutation system (ARMS; DxS, Manchester, United Kingdom) uses unimolecular fluorescent probes to detect mutations present in 1%-10% of cells^[33]. In a retrospective study of 100 randomly selected archived cases, treatment with EGFR TKIs achieved a longer progression free survival of 11.3 mo in patients whose tumor demonstrated high EGFR mutation abundance (more than 10%) than those with low EGFR mutation abundance (1%-10%, PFS 6.9 mo) and the PFS in both cases were longer than that in patients with wild type tumors (PFS 2.1 mo)^[34]. This notion that higher EGFR mutation abundance in the tumor correlates with treatment effect in prolonging tumor control requires prospective validation. The heterogeneity of EGFR mutation status is not only observed in the primary tumor, but also between the primary and the metastatic lung nodules, with a discordance rate as high as 24%^[35]. The cases with discordance appear to show mixed response to EGFR TKIs^[35]. Therefore, genetic heterogeneity could be another mechanism for apparent TKI resistance at tumor progression.

Additional pathways that modulate response to targeted therapy

Several additional pathways appear to influence the depth and duration of response to TKIs in patients with EGFR-mutated tumors and provide new targets for improving therapeutic efficacy. The pro-apoptotic protein BIM has been shown to be necessary for EGFR TKI-induced apoptosis and tumor regression in EGFR-mutated cell lines and xenograft models^[36,37]. In a small retrospective series, treatment with an EGFR TKI was associated with a higher response rate (57% *vs* 29%, $P = 0.04$) and longer PFS (13.7 mo *vs* 4.7 mo, $P = 0.007$) in patients whose tumors showed higher pre-treatment levels of BIM RNA^[38]. An intronic deletion polymorphism of BIM found in 12% of East Asian patients and associated with reduced anti-apoptotic activity correlated with inferior response to EGFR TKIs^[39]. In cell lines and xenografts with this polymorphism, restoration of BIM function with BH3-mimetic drugs or HDAC inhibition overcame TKI resistance^[39,40]. This suggests that therapeutic strategies to augment BIM function, particularly in low-BIM expressing tumors, may reduce the problem

of TKI resistance in oncogene-addicted tumors. In addition, activation of the NF- κ B pathway has been shown to confer *in vitro* resistance to erlotinib in EGFR-mutant cell lines. Patients whose tumors showed high expression of the NF- κ B inhibitor I- κ B were more likely to respond to treatment with erlotinib and had longer progression free and overall survival, suggesting that NF- κ B signaling may have a clinically significant role in EGFR TKI resistance^[41]. Therefore, combined EGFR and NF- κ B inhibition presents another potential opportunity for improving the efficacy of targeted therapy.

Acquisition of secondary EGFR mutations

An important strategy for defining mechanisms of resistance to EGFR TKIs has been to re-biopsy the tumor at the time of disease progression. In two reported series comprising 192 patients treated with erlotinib or gefitinib, a distinct histologic change or molecular mechanism of resistance could be identified in the majority of cases^[42,43]. Importantly, all TKI-resistant tumors retained the original EGFR mutation. In over half of tumors analyzed, a second EGFR point mutation, T790M in exon 20, was newly detected. T790M mutations are thought to reactivate EGFR signaling by increasing the receptor's affinity for ATP over TKIs^[44]. Though a systematic analysis of the mechanisms of resistance to afatinib has not yet been published, resistance due to emergence of T790M has been reported^[45].

EGFR-independent mechanisms of acquired resistance

Signaling through alternate oncogenic kinases can bypass EGFR inhibition to re-activate proliferation and survival pathways in EGFR-mutated cells. Amplifications of MET and HER2 were identified in a minority of resistant tumors examined in the two re-biopsy series mentioned above^[42,43,46]. In one of the studies, PIK3CA mutations were also identified in two patients^[42]. Furthermore, an analysis of a large tissue database identified BRAF mutations as a possible mechanism of resistance in 2% of specimens^[47]. In addition, histologic changes such as transformation to small cell histology and epithelial to mesenchymal transition have also been observed, though the mechanisms by which they develop and lead to resistance are incompletely understood^[42,43]. So far, mechanisms of resistance have been studied in a limited number of tumors and therefore the prevalence of each resistance mechanism is likely to change as more data accrues.

CLINICAL MANAGEMENT OF TKI-RESISTANT DISEASE

When a patient who previously responded to a TKI develops progression of disease, acquired TKI resistance occurs due to the various mechanisms described above. Although its clinical utility is debated, re-biopsy at progression in selected cases could be critical to understanding the mechanism of TKI resistance and hence guide

management decisions. While it is standard practice to discontinue chemotherapy at the time of disease progression, there is definitely a rationale for TKI continuation as discussed below. Treatment options include adding local therapy or conventional chemotherapy, or TKI continuation alone. Two hypotheses guide current strategies for treatment of TKI-resistant disease: (1) a population of TKI-sensitive clones remains at the time of disease progression; and (2) Resistant clones may be detected radiographically before widespread dissemination occurs.

As discussed above, the T790M secondary mutation is by far the most common mechanism of resistance, responsible for disease progression in more than half of patients treated with erlotinib or gefitinib. *In vitro* data has demonstrated that cells that acquire T790M second site mutations grow at a slower rate than parental cells without the mutations^[48]. Furthermore, the same study suggested that in the presence of TKIs, resistant cell populations are heterogeneous and consist of slow-growing cells harboring T790M along with quiescent cells without the secondary mutation. Clinical observations support these *in vitro* results. In two patients with acquired TKI resistance and T790M mutations, serial biopsies during treatment with and without TKIs showed that T790M becomes undetectable after a period without TKI treatment^[42]. Moreover, patients with T790M mutations identified at the time of disease progression have longer post-progression survival than those without the mutation^[49]. Presumably, continuation of the original TKI exerts selective pressure that inhibits more aggressive TKI-sensitive clones and allows only the indolent T790M-harboring cells to proliferate. Therefore, in patients with T790M-mediated resistance or asymptomatic patients with radiographic evidence of progression and limited overall increase in disease burden, immediate change of systemic therapy may not be necessary and continuation of targeted therapy may still provide some measure of disease control.

It is conceivable that TKI-resistant clones develop in a single site of disease and can be detected on imaging before widespread dissemination. Patients who initially achieve disease control with EGFR-targeted therapy may subsequently show signs of disease progression in only one or a few sites of disease while other sites remain suppressed. Several groups have described their experience with the use of local therapies such as radiation or surgery to these sites of limited disease progression and have observed prolonged disease control after local therapy without a change in systemic therapy^[50-52]. Progression-free-survival after local therapy of 6-10 mo^[50,51] has been reported and the time until change in systemic therapy in one study was 22 mo^[50]. Clearly, patient selection is key to the success of this strategy. Factors that might predict prolonged stable disease after local therapy include EGFR exon 19 deletions and longer duration of initial disease control on targeted therapy^[52]. These observational studies suggest that local therapy may be of benefit, though prospective trials are needed to determine

whether local therapy can truly alter disease course.

In patients with symptomatic or rapid radiographic progression, re-biopsy of a rapidly growing lesion should be considered. If transformation to small cell histology is discovered, small cell chemotherapy regimens are appropriate for those patients. The remaining majority of patients are generally treated with chemotherapy. In this group of patients, the question of whether the original TKI should be continued is under investigation. Although no benefit was observed with the addition of TKIs to chemotherapy in unselected non-small cell lung cancer populations^[53,54], several observations suggest benefit in the treatment of patients with EGFR mutations and acquired TKI resistance. A retrospective series reported higher response rates in patients who continued the original TKI after initiating chemotherapy, though no difference in progression-free survival was observed^[55]. Furthermore, accelerated disease progression or “disease flair,” defined by hospitalization or death attributable to disease progression, was observed in the short wash out period in some patients who stopped TKIs awaiting further chemotherapy^[56]. These results suggest that some clones remain sensitive to EGFR blockade at the time of disease progression and that maintaining EGFR suppression is beneficial. Clinical trials are underway to prospectively assess the benefit of continuing TKI when chemotherapy is initiated (NCT01544179, NCT01928160 clinicaltrials.gov). If the TKI is not continued during chemotherapy, re-responses to erlotinib can be seen after post-progression “drug holidays”^[57].

FUTURE DIRECTIONS

The identification of common recurring mechanisms of resistance to TKIs provides the opportunity for rationally designed treatment of resistant disease. One strategy is the development of new TKIs with activity against secondary resistance mutations. Though there was initial optimism based on preclinical data that afatinib, an irreversible TKI, would overcome resistance to erlotinib or gefitinib including T790M, the response rate was only 7% in a phase II b/III trial in patients with disease progression after initial disease control on erlotinib or gefitinib^[58]. CO-1686, a third-generation EGFR TKI, has shown *in vitro* and *in vivo* activity against cells and tumors harboring T790M mutations and is currently being studied in a phase 1/2 clinical trial of EGFR TKI-resistant disease^[59]. In addition, an alternate dosing regimen incorporating intermittent high-dose afatinib showed *in vitro* activity against T790M and is being studied in a phase Ib clinical trial (NCT01647711 clinicaltrials.gov). Furthermore, combination therapy with afatinib and cetuximab showed promising activity in erlotinib resistant disease including cancers harboring the T790M mutation^[60]. Other strategies to prevent or treat TKI-resistant disease include the addition of an inhibitor of one of the bypass pathways (MET, AKT, PI3K, IGF1R) and HSP-90 inhibitors, which may decrease signaling through EGFR by decreasing the

stability of the protein^[61].

The identification of driver mutations in lung adenocarcinoma and the subsequent development of drugs that inhibit their oncogenic activity has been a major therapeutic advance benefitting patients with advanced disease. An understanding of the reasons for drug failure enables the optimal use of currently available EGFR targeted TKIs and maximizes their clinical benefit. Current evidence to guide management of TKI-resistant disease is limited but suggests that new principles may apply in the era of targeted therapy. The field of targeted therapy of lung cancer is rapidly evolving and the full potential of this treatment strategy is yet to be realized.

Abstract

Protons interact with human tissue differently than do photons and these differences can be exploited in an attempt to improve the care of lung cancer patients. This review examines proton beam therapy (PBT) as a component of a combined modality program for locally advanced lung cancers. It was specifically written for the non-radiation oncologist who desires greater understanding of this newer treatment modality. This review describes and compares photon (X-ray) radiotherapy (XRT) to PBT. The physical differences of these beams are described and the clinical literature is reviewed. Protons can be used to create treatment plans delivering significantly lower doses of radiation to the adjacent organs at risk (lungs, esophagus, and bone marrow) than photons. Clinically, PBT combined with chemotherapy has resulted in low rates of toxicity compared

to XRT. Early results suggest a possible improvement in survival. The clinical results of proton therapy in lung cancer patients reveal relatively low rates of toxicity and possible survival benefits. One randomized study is being performed and another is planned to clarify the clinical differences in patient outcome for PBT compared to XRT. Along with the development of better systemic therapy, newer forms of radiotherapy such as PBT should positively impact the care of lung cancer patients. This review provides the reader with the current status of this new technology in treating locally advanced lung cancer.

INTRODUCTION

Lung cancer is the leading cancer killer in the United States and worldwide. It has been estimated that lung cancer has taken the lives of 159480 Americans in 2013^[1]. Lung cancer has been historically divided into 2 major histologic types: non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC).

Thoracic radiotherapy using photon (X-ray) radiotherapy (XRT) has been standard therapy for lung cancer since the 1960's when the Veterans Administration Hospital System performed a phase III trial in patients with unresectable lung cancer (including both SCLC and NSCLC)^[2]. Patients with localized but clinically inoperable tumors were assigned either XRT or a placebo. The median survival of patients given XRT was 142 d compared to 112 d ($P = 0.05$) for those who received a placebo. This study established the role of XRT in the treatment of unresectable lung cancer. XRT improved survival modestly in spite of the fact that many of these patients likely had distant metastatic disease that wasn't recognized because this trial was performed prior to the advent of modern imaging (computed tomography, magnetic resonance imaging, or positron emission tomography).

Standard therapy for locally advanced SCLC (stages II-III) and NSCLC (stage III) includes concurrent chemotherapy plus XRT^[3]. SCLC patients who complete chemotherapy plus RT and have achieved stable disease or a better response should also receive prophylactic cranial irradiation (PCI)^[3,4].

In spite of many years of investigation, the outcome for lung cancer patients remains poor due to the cancer's propensity to persist locally and metastasize widely^[5]. Local control rates have been poor when defined using post-chemo-RT tumor persistence on biopsy rather than radiologic imaging criteria^[6]. The overall 5-year survival rates for locally advanced NSCLC and SCLC range from approximately 15% to 25%^[3,4]. Concurrent chemotherapy plus XRT results in better survival than XRT alone or sequential therapy but with higher rates of severe toxicity^[7,8]. For example, The North Central Cancer Treatment Group (NCCTG) performed a phase III trial to determine whether chemotherapy (cis-platin and etoposide) plus either twice daily (BID) XRT or daily (QD) XRT achieved a better outcome for patients with stage III NSCLC. Severe, grade ≥ 3 (3+) and grade 4+ toxicity was very common, occurring in 87% and 67% of patients, respectively^[9]. Grade 3+ and 4+ hematologic toxicity occurred in 80% and 62%. Grade 3+ and 4+ esophageal toxicity occurred in 18% and 1%. Grade 3+ and 4+ pneumonitis occurred in 12% and 2%. The 5-year survival was 17%. These results form a reasonable standard for chemotherapy plus XRT to which other treatment programs can be compared. It is clear that

more research is needed to develop therapies that result in better survival and less toxicity.

PHYSICS, RADIOBIOLOGY, AND RATIONALE FOR PBT

One potential method to improve patient outcome is to optimize the radiotherapy. Historically, we have improved patient outcomes each time newer methods of radiation delivery were invented. First, radiotherapy was delivered with radio-isotopes placed directly into the tumor. This was problematic when treating lung cancer since the act of placing potential sources within a lung tumor would require physical damage to the lung. Low energy X-ray devices were then developed which delivered kilo-voltage X-rays. Unfortunately, these beams penetrated the tissues poorly and delivered the maximum dose on the skin with only a small fraction of the dose to a deep seated tumor. Kilovoltage X-ray beams were used in the VA study noted above. The isotope cobalt 60 was then used and produced a beam composed of gamma rays with two distinct energies of 1.17 and 1.33 million volts (MV) resulting in better skin sparing and improved depth-dose penetration. Linear accelerators were then developed which produced still higher energy MV X-rays or photons. These photon beams penetrated better but still delivered the maximal dose between 1.5 and 3.5 cm beneath the surface with the dose gradually decreasing as the beam penetrated straight through without stopping until exiting the body. The dose-distribution of X-rays within the body is due to their unique characteristics of having almost no mass and no charge.

Protons, in contrast, have mass (approximately 1800x that of an electron) and hold a positive elementary charge. These characteristics create a much different distribution of dose deposition within the body. First, the accelerated protons enter the body with a high momentum which carries them to a specific depth dependent on the initial kinetic energy imparted upon them by the accelerating device (generally a cyclotron or synchrotron). As the proton beam travels to that depth, there is a relatively small amount of energy transmitted to the tissues. As the protons slow down, more and more energy is transferred to the surrounding tissues. The energy lost per unit path length is almost inversely proportional to the square of the speed of the proton. Shortly before the entire energy of the proton is lost, the energy loss rate reaches a sharp peak. Once the kinetic energy of the proton is entirely dissipated into the tissue, the proton comes to rest within the body. The energy of the proton is dissipated in collisions with the electrons of the neighboring atoms in the surrounding tissues causing ionizations which produce radiation damage. The region in the body where the maximum energy loss and final stopping of protons occurs is narrow and is located at a specific depth depending on the initial energy of the proton beam. This sharp, well defined peak of maximal dose from charged particles is referred to as the "Bragg peak". Beyond this

Figure 1 Depth-dose comparisons of a single photon (X-ray) beam and a proton beam.

point, there is no radiation energy imparted upon surrounding tissues as the protons have stopped. So far we have only discussed mono-energetic proton beams, *i.e.*, proton beams in which all protons have the same initial energy. The peak of a mono-energetic proton beam is so narrow that in order to generate a clinically useful proton beam one has to spread it out by giving repeated mono-energetic beams of protons with successively lower energies to cover a mass or tumor within the high dose region otherwise known as the “spread-out Bragg Peak” (Figure 1).

Figure 1 reveals depth-dose comparisons of a single photon (X-ray) beam and a proton beam. Each beam enters the body at 0 cm depth on the left side of the graph and travels into the body traveling to the right. The depth within the patient is shown on the X-axis and the percent of the prescribed dose delivered on the Y-axis. The 18 MV photon beam delivers the greatest dose at 3.5 cm depth within the patient and then decreases in dose delivered as it enters and exits the tumor at depths of 11 and 22 cm, respectively. The photon beam then continues through the body until it exits. In contrast, the proton beam administers the maximum dose in the tumor stopping just beyond the deepest portion of the tumor. There is less dose delivered as the proton beam travels to the tumor and no exit dose beyond the tumor. The grey areas correlate to the excess dose delivered by photons to normal healthy tissue that would not be irradiated by the proton beam.

Protons are also different from photon irradiation in terms of killing power. The relative biological effectiveness (RBE) for proton RT is generally estimated at 1.1 X that for photons. Thus, one gets 10% more cancer kill power for each gray (Gy) of proton RT than photon RT. To simplify discussions, photon doses are described in Gy and proton doses described in Gy equivalence (GyE) to describe 2 beams with similar killing properties. One Gy is the addition of one joule of energy per kilogram of tissue. The energy absorbed results in free radical formation. The free radicals ionize and fracture DNA

molecules within the cells’ nuclei. These DNA fractures result in cell death especially in rapidly reproducing cells which are the most sensitive to radiotherapy.

The primary benefits of PBT compared to XRT are based on the above mentioned interactions with matter when traveling into a patient to treat a tumor. The fact that the proton beam stops results in no radiation exposure beyond the tumor allows for the sparing of distally placed tissues. In contrast, photons don’t stop and travel through the entire body from the entrance to the exit point.

If one has a tumor in the anterior portion of the chest, it would be desirable to treat from the anterior perspective with PBT. After the proton beam treats the tumor, it stops. This results in substantially less dose than X-rays to deeper structures including the spine (spinal cord and marrow), esophagus, lung, and heart. Each of these normal dose-limiting organs is sensitive to radiation and can be injured during treatment. As discussed earlier, the standard therapy of concurrent chemotherapy plus XRT to 60 Gy in 30 daily fractions results in severe (grade 3+) toxicity in the vast majority of patients^[9]. Thus, maximal sparing of these critical organs is important in potentially improving patient outcomes (survival, quality of life, and toxicity).

Detailed studies comparing the XRT plans using both 3-D planning and intensity modulated photon RT (IMRT) technology to proton TRT plans have been performed. Nichols *et al*^[10] examined the dose distributions (dosimetry) from 8 consecutive stage III NSCLC patients. In all patients, 3-D XRT, IMRT, and proton therapy plans achieved the dose goals for the tumor volumes. Compared with 3-D XRT plans, proton plans offered a median 29% reduction in normal lung V20 (total lung volume receiving > 20 Gy), a median 33% reduction in mean lung dose (MLD), and a median 30% reduction in the volume of bone marrow receiving a dose of > 10 Gy. The V20 and MLD have been established to correlate well with the risk of radiation pneumonitis^[11-14]. The 10 Gy dose to the bone marrow would be sufficient to suppress myelopoiesis within the irradiated marrow. Compared with the IMRT plans, the proton plans offered a median 26% reduction in normal lung V20, a median 31% reduction in MLD, and a median 27% reduction in the volume of bone marrow receiving a dose of > 10 Gy. They concluded that by reducing the volumes of normal structures irradiated, protons can potentially improve the therapeutic index for stage III NSCLC compared to with either 3-D XRT or IMRT. Similar results were found by Chang *et al*^[15] when they compared the RT plans that delivered high dose RT with either protons or photons. PRT reduced the dose to normal tissues significantly, even with dose escalation, compared with standard-dose photon therapy, either 3-D XRT or IMRT.

The dosimetric studies highlight significant differences in the dose distributions when comparing protons to photons in the treatment of lung cancer. Because the proton beam can stop just beyond the far end of the target, normal tissues beyond the tumor can be spared from

Figure 2 Dosimetric comparisons between photon [left (A, C, E) and proton right (B, D, F)] plans for a stage III lung cancer patient. Radiation doses shown as color washes warmer colors (red) represent higher doses compared to cooler colors (blue). The first pair of axial slices (A and B) are at a level superior to axial cuts C and D; It is apparent that more normal lung is irradiated on the left than the right; E and F are coronal cuts with dosimetry.

receiving radiation when compared to XRT. These differences can be used to produce potentially safer RT plans.

Clinical data is required to substantiate that the gains found dosimetrically translate into improvements in patient outcome. Newer proton facilities are employing scanned pencil beams instead of the broad passively scattered proton beams which are shaped with apertures and range compensators. Pencil beams are very narrow proton beams steered with magnetic fields which move in a raster pattern back and forth through the tumor volume. The intensity (or dose) can be modified as the beam moves allowing the delivery of intensity modulated proton beam therapy (IMPT). Zhang *et al.*^[16] was able to show that IMPT produced better dosimetric results than more conventional proton beam therapy. Figure 2 includes dosimetric comparisons between photon and proton plans for a patient with stage III lung cancer. The doses delivered shown as a color wash with lower doses denoted in blue and higher doses in red. On

the left is a rapid arc intensity modulated photon RT (IMRT) plan which included 6 MV photons which delivered IMRT while the gantry rotated around the patient. On the right are shown the same patient treated with intensity modulated proton RT. It is clear from figures that the IMPT plan delivers the same dose to the target (red outlined region) with less dose to the surrounding normal tissues.

Proton beams are more sensitive to a variety of uncertainties such as respiratory motion, changes in patient positioning, and tumor shrinkage. This creates more technical challenges in planning and delivery of radiotherapy. The term, “robust” is used to describe treatment plans which can accommodate these uncertainties.

RESEARCH

Results in patients with limited stage SCLC

Colaco *et al.*^[17] reported the first known series of limited

stage SCLC (L-SCLC) patients treated with PBT. All 6 patients also received chemotherapy and PCI. Five patients received 60–66 GyE in 30–34 daily fractions and one patient received 45 GyE in 30 BID fractions. With one year of median follow up, the one-year overall survival rates was 83%. Treatment was well tolerated; there were no cases of acute grade 3+ esophagitis or grade 2+ pneumonitis, and no other grade 3+ non-hematological toxicities were seen. Dosimetric comparison revealed better sparing of lung and esophagus with PBT than IMRT. They concluded that PBT merits further investigation as a method of reducing toxicity in L-SCLC.

Results of PBT in patients with stage III NSCLC

Clinical outcomes of phase I and II studies are available. Standard therapy for stage III NSCLC in fit patients is concurrent radiation and chemotherapy. As such, this summary focuses on the studies which delivered combined modality therapy. Chang *et al.*^[18] reported the early findings of a phase II trial of high-dose PBT that included 44 patients with stage III NSCLC treated with 74 GyE in 37 fractions with weekly carboplatin and paclitaxel. Protons were delivered as passively scattered beams and adaptive re-planning. The median overall survival time was 29.4 mo and no patients suffered grade 4 or 5 proton-related toxicity. The most common non-hematologic grade 3 toxicities were dermatitis ($n = 5.11\%$), esophagitis ($n = 5.11\%$), and pneumonitis ($n = 1.2\%$). Nine (20.5%) patients experienced local disease recurrence, four (9.1%) patients had regional lymph node recurrence, and 19 (43.2%) patients developed distant metastasis. Of the 44 patients, 9 (20%) had their original plans adapted to changes in their tumor volume^[19]. Changes in tumor volume due to response can sufficiently alter the proton stopping power of the tissues to require changing the plan in order to administer the prescription dose to the tumor and protect normal tissues. The authors concluded that concurrent high-dose PBT and chemotherapy were well tolerated and that the median survival was encouraging.

Hoppe *et al.*^[20] reported on 19 NSCLC patients ($n = 18$:stage III, $n = 1$:stage II b) treated with carboplatin, paclitaxel, and PBT to 74 Gy/37 fractions. There were only 1 (5%) acute grade ≥ 3 non-hematologic toxicity and 2 (11%) chronic non-hematologic toxicity with a median follow up of 16 mo. Oshiro compiled a series of 57 patients with stage III NSCLC treated with a median dose of 74 Gy with PBT and no chemotherapy^[21]. The median survival was 21.3 mo which was similar to many combined modality series. Toxicity was very modest with grade 3+ lung toxicity in 11% and no grade 3+ esophageal toxicity.

Comparative results of protons vs photons

Clinical comparisons of patients treated with either photon or proton therapy for lung cancer are rare. This is in part due to the relatively few clinical experiences with proton therapy for lung cancer. This is in part due to the

difficulty in getting lung cancer covered by insurance for PBT. Seijpal *et al.*^[22] reported a retrospective comparative analysis of the MD Anderson experience in patients with stage 3 NSCLC. Their rationale for the use of proton beam therapy was the recognition that concurrent chemotherapy plus XRT, the standard of care for stage 3 NSCLC, causes severe toxicity in most patients. Photon based TRT cannot be given at doses associated with a high chance of cure without excessive toxicity. They hypothesized that PBT could permit higher tumor doses with less normal-tissue toxicity than XRT delivered as 3-D XRT or IMRT. They compared the outcome of PBT + chemotherapy ($n = 62$), 3D-XRT + chemotherapy ($n = 74$) or IMRT + chemotherapy ($n = 66$). RT was delivered to the gross tumor volume with weekly paclitaxel and carboplatin. The median total radiation dose was 74 GyE for the proton group and 63 Gy for the other groups. Severe (grade 3+) pneumonitis and esophagitis in the proton group (2% and 5%) were lower despite the higher radiation dose (3-D XRT, 30% and 18%; IMRT, 9% and 44%; $P < 0.001$ for all). The median survival times were 17.7 mo for the 3-D XRT group, 17.6 mo for the IMRT group, and 24.4 mo for the proton therapy group ($P = 0.1$). They found that higher doses of PBT could be delivered to lung tumors with lower rates of esophagitis and pneumonitis.

The above findings were provocative enough to justify a randomized trial of IMRT *vs* PBT. This trial is entitled, “A bayesian randomized trial of image-guided adaptive conformal photon *vs* proton therapy, with concurrent chemotherapy, for locally advanced NSCLC.” The primary objective is to compare the incidence of grade 3+ treatment related pneumonitis (TRP) or local failure. In addition, the Radiation Therapy and Oncology Group (RTOG) is planning a phase III trial (RTOG 1308) comparing chemotherapy plus either XRT or PBT in doses of 60 to 70 Gy. The primary endpoint is overall survival. Other trials exist and can be found at: <http://clinicaltrials.gov> and are summarized in Table 1.

PBT offers stage III lung cancer patients potentially safer radiotherapy plans with significantly lower doses delivered to the lungs, esophagus, and bone marrow. This has resulted in less toxicity^[22] in retrospective comparisons. Safe dose escalation with photon therapy was not possible in stage III NSCLC patients treated on RTOG 0617 which compared chemotherapy plus either 60 Gy or 74 Gy of photon irradiation. The higher dose arm resulted in poorer survival which appears to be secondary to increases in normal tissue (pulmonary and/or cardiac) doses^[23]. PBT can better spare the normal surrounding organs at risk and, thus, offers investigators an opportunity to safely deliver higher tumor doses which may result in higher local control rates and improved survival.

One randomized study is being performed and another is being planned to further elucidate the potential clinical benefits of PBT compared to traditional XRT. Technology continues to improve and pencil beam PBT and IMPT may produce better clinical results than scat-

Table 1 Proton beam therapy trials for stage 3 lung cancer patients**Non-small cell lung cancer**

- 1 ClinicalTrials.gov identifier NCT00881712 (LU02: University of Florida): A phase II trial of 3-D proton radiotherapy with concomitant chemotherapy for patients with initially unresectable stage III non-small cell lung cancer:
 - (1) Arm 1: Concurrent chemotherapy and PBT (74 GyE/37 fractions) for unresectable stage 3 patients with nodes > 15 mm in diameter.
 - (2) Arm 2: Concurrent chemotherapy and PBT (60 GyE/30 fractions) for unresectable stage 3 patients with nodes < 15 mm in diameter.
 - (3) Arm 3: Resectable stage 3 diseases: preoperative PBT (50 GyE/25 fractions) and surgery.
- 2 ClinicalTrials.gov identifier NCT01993810: (RTOG1308) phase III randomized trial comparing overall survival after photon vs proton chemoradiotherapy for inoperable stage II-III B NSCLC:
 - (1) Arm I : XRT (70 Gy/35 fractions) and either paclitaxel and carboplatin or etoposide and cisplatin.
 - (2) Arm II: PBT (70 GyE/35 fractions) and either paclitaxel and carboplatin or etoposide and cisplatin.
- 3 ClinicalTrials.gov identifier NCT01770418 (Proton Collaborative Group): A Phase I / II study of hypofractionated proton therapy for stage II-III non-small cell lung cancer:
 - (1) Proton radiotherapy
 - Dose Level 1: 60 Gy (RBE) at 2.5 Gy (RBE) per fraction × 24 fractions
 - Dose Level 2: 60 Gy (RBE) at 3 Gy (RBE) per fraction × 20 fractions
 - Dose Level 3: 60.01 Gy (RBE) at 3.53 Gy (RBE) per fraction × 17 fractions
 - Dose Level 4: 60 Gy (RBE) at 4 Gy (RBE) per fraction × 15 fractions
 - (2) Paclitaxel and carboplatin or cisplatin and etoposide
- 4 ClinicalTrials.gov identifier NCT01565772 (MGH): A phase I trial of hypofractionated PBT with cisplatin and etoposide followed by surgery in stage III non-small cell lung cancer:

Radiation (PBR): 45-55 Gy total, 1.8-2.2 Gy × 25 fractions with cisplatin and etoposide followed by resection
- 5 ClinicalTrials.gov identifier NCT01165658 (MD Anderson) phase I study of Hypofractionated Proton Radiation Therapy in Thoracic Malignancies: The radiation prescription dose ranges from 45 Gy in 3 Gy fractions to 60 GyE in 4 Gy fractions. This is for patients ineligible for chemotherapy.
- 6 ClinicalTrials.gov identifier NCT00614484 (Loma Linda University): phase I / II study of combined chemotherapy and high dose, accelerated proton radiation for the treatment of locally advanced non-small cell lung carcinoma. Carboplatin and taxol and 5 wk of daily proton therapy.
- 7 ClinicalTrials.gov identifier NCT01629498 (MD Anderson): phase I / II trial of Image-guided, intensity-modulated photon or scanning beam proton therapy. Both with SIB dose escalation to the GTV with concurrent chemotherapy for stage II / III NSCLC
 - (1) Experimental. IMPT + SIB + chemotherapy phase I starting IMPT dose: 60 Gy (RBE) in 30 fractions; phase I starting SIB dose: (72-84) Gy (RBE). All patients receive standard concurrent chemotherapy.
 - (2) Experimental. IMRT + SIB + chemotherapy: phase I Starting IMRT dose: 60 Gy (RBE) in 30 fractions; phase I starting SIB Dose: (72-84) Gy (RBE). All patients receive standard concurrent chemotherapy
- 8 ClinicalTrials.gov identifier NCT00915005 (MD Anderson): A bayesian randomized trial of image-guided adaptive conformal photon vs proton therapy, with concurrent chemotherapy, for locally advanced NSCLC (treatment related pneumonitis and locoregional recurrence)
 - (1) Experimental group 1 (photon therapy): 74 Gy/37 fractions + carboplatin and paclitaxel
 - (2) Experimental group 2 (proton therapy): 74 Gy/37 fractions + carboplatin and paclitaxel
 - (3) Experimental group 3 (proton therapy): 66 Gy/33 fractions + carboplatin and paclitaxel
- 9 ClinicalTrials.gov identifier NCT01076231 (University of Pennsylvania) feasibility and phase I / II trial of preoperative PBR with concurrent chemotherapy for resectable stage IIIA or superior sulcus NSCLC: pbr over 5.5-7.5 wk plus concurrent chemotherapy comprising cisplatin and etoposide. Then, patients may undergo surgical resection or additional chemoradiotherapy
- 10 ClinicalTrials.gov identifier NCT01108666 (University of Pennsylvania): phase I dose escalation trial of PBR with concurrent chemotherapy and nelfinavir for inoperable stage III NSCLC. Determine MTD of nelfinavir and MTD of PBR when given with chemotherapy for stage III NSCLC.
- 11 ClinicalTrials.gov identifier NCT01808677 (MD Anderson): registry study of thoracic reirradiation for NSCLC utilizing PBT or intensity modulated radiation therapy. Primary objective to assess the prevalence of high-grade toxicity in patients being treated with thoracic re-irradiation with PBT or IMRT for NSCLC, with or without chemotherapy.
- 12 ClinicalTrials.gov identifier NCT01386697 (University of Pennsylvania): A prospective radiation oncology planning study for lung, gastrointestinal and lymphomatous malignancies using proton radiotherapy as compared to 3D conformal and intensity-modulated X-ray therapy for dosimetric evaluation of tumor coverage and dose to organs-at-risk. The overall objective is to estimate the actual or potential benefit of DIBH treatment in the context of proton radiotherapy as compared to 3DCRT and IMXT.

PBT: Proton beam therapy; RBE: Relative biological effectiveness; IMRT: Intensity modulated radiation therapy; NSCLC: Non-small cell lung cancer; SIB: Simultaneous integrated boost; GTV: Gross tumor volume; DIBH: Deep inspiration breath holding; IMXT: Intensity-modulated X-ray therapy; 3DCRT: Three dimensional conformal radiation therapy.

tered PBT. Along with the development of better systemic therapy, improvements in radiotherapy technology should positively impact on the care of unresectable lung cancer. Protons may allow the safe escalation of dose to levels considered to be tumoricidal while sparing the critical normal tissues^[24]. This was not possible using photons either with 3-D treatment planning or IMRT when tested in RTOG 0617^[25].

More research is needed to optimize proton administration especially for the newer pencil beam systems. This requires greater physics understanding in order to create plans which are robust in the face of uncertainty. Comparative studies will elucidate the potential value of this newer radiotherapy modality in terms of both clinical outcomes (survival, toxicity, and QOL) and cost effectiveness.

Key words: Lung cancer; Non-small cell lung cancer; Targeted therapies; Epidermal growth factor receptor; Epidermal growth factor receptor; Anaplastic lymphoma kinase; Anaplastic lymphoma kinase; Acquired resistance

Core tip: The development of oncogene-directed targeted therapies has significantly changed the treatment of non-small-cell lung cancer. We review the data demonstrating efficacy of small-molecule tyrosine kinase inhibitors against epidermal growth factor receptor, anaplastic lymphoma kinase, ROS1, and other oncogenes. We also discuss the challenge of acquired resistance to these therapies and review promising agents which may overcome resistance.

Abstract

The last decade has witnessed the development of oncogene-directed targeted therapies that have significantly changed the treatment of non-small-cell lung cancer (NSCLC). In this paper we review the data demonstrating efficacy of gefitinib, erlotinib, and afatinib, which target the epidermal growth factor receptor (EGFR), and crizotinib which targets anaplastic lymphoma kinase (ALK). We discuss the challenge of acquired resistance to these small-molecular tyrosine kinase inhibitors and review promising agents which may overcome resistance, including the EGFR T790M-targeted agents CO-1686 and AZD9291, and the ALK-targeted agents ceritinib (LDK378), AP26113, alectinib (CH/RO5424802), and others. Emerging therapies directed against other driver oncogenes in NSCLC including *ROS1*, *HER2*, and *BRAF* are covered as well. The identification of specific molecular targets in a significant fraction of NSCLC has led to the personalized deployment of many effective targeted therapies, with more to come.

INTRODUCTION

Lung cancer is the leading cause of cancer-related deaths around the world with approximately 1.3 million deaths per year and a poor prognosis for those with advanced stage disease treated with traditional chemotherapy agents^[1,2]. However, the last decade has witnessed the discovery of molecular changes that drive lung cancer in a substantial minority of patients and development of many targeted therapies that have significantly changed treatment in this setting. In this paper we review the data leading to approval of targeted therapies against the epidermal growth factor receptor (EGFR) and anaplastic lymphoma kinase (ALK), discussing the challenges of overcoming acquired resistance to these small-molecular tyrosine kinase

inhibitors (TKIs). We also review several other promising targeted therapies currently in development.

FIRST-GENERATION EGFR TKIS

The first available targeted therapies for advanced NSCLC were gefitinib and erlotinib, both of which are small-molecule TKIs against EGFR, also known as HER1 or ErbB-1. The dimerization of EGFR activates its tyrosine kinase, which in turn activates intracellular signal transduction pathways involved in many cellular processes. Early work on EGFR in lung cancer has shown that EGFR overexpression is commonly seen in NSCLC^[3,4], motivating the development of EGFR TKIs.

Phase II studies of gefitinib and erlotinib in the second- or third-line setting for advanced NSCLC in unselected patients were promising, showing a partial radiographic response rate of about 12% with symptomatic improvements^[5-7]. The first clinical trial to show an improved overall survival (OS) was the Canadian phase III BR.21 trial, which randomized patients with stage III B or IV NSCLC, neither clinically nor molecularly selected for EGFR mutations, who had received one or two chemotherapy regimens, to either erlotinib or placebo. Patients receiving erlotinib had a median OS of 6.7 mo, compared with 4.7 mo for those on placebo^[8]. Interestingly, a similar phase III study, the Iressa Survival Evaluation in Lung Cancer (ISEL) trial, comparing gefitinib to placebo in the second- or third-line setting failed to demonstrate an improved OS. However, subgroups of never smokers and Asians did have statistically significant survival advantage on gefitinib compared to placebo^[9]. That erlotinib apparently had greater efficacy than erlotinib might be due to the fact that erlotinib was dosed at its maximum tolerated dose (MTD)^[8] while gefitinib was dosed at one-third of its MTD^[9].

However, data from these clinical trials and others suggested that EGFR immunohistochemical staining intensity was not predictive of therapeutic benefit^[5]. Subsequently, somatic activating EGFR mutations, most commonly including exon 19 deletions and exon 21 L858R missense mutations, were discovered to be a dominant predictor of responsiveness to EGFR TKIs^[10-15]. It is estimated that these activating EGFR mutations are present in tumors from about 50% of Asian patients with NSCLC and 15% of Western patients^[16-19]. The cause for this difference in the prevalence rates of EGFR mutations among various ethnic groups remains unknown, yet EGFR mutations are also observed most frequently in women, patients with no or minimal history of smoking, and tumors of adenocarcinoma histology^[16,17,20].

More recent first line studies in advanced NSCLC attempted to enrich patients with activating EGFR mutations to compare EGFR TKI therapy with conventional chemotherapy. The pivotal Iressa Pan-Asia Study (IPASS) randomized over 1200 untreated patients who were never smokers or former light smokers to either gefitinib or the combination of carboplatin and paclitaxel. The progres-

sion-free survival (PFS) at 12 mo was 25% for gefitinib and 7% for chemotherapy. For patients with activating EGFR mutations, gefitinib was associated with a hazard ratio for progression of 0.48 ($P < 0.001$) compared to chemotherapy, while for patients who were negative for EGFR mutations, gefitinib was associated with shorter PFS with a hazard ratio for progression of 2.985 ($P < 0.001$). OS was similar between the two groups, presumably due to crossover^[18,19]. Similar results have been observed in other trials involving gefitinib conducted in Asia. The First-SIGNAL trial from the South Korea comparing gefitinib to cisplatin and gemcitabine in the first-line setting for advanced pulmonary adenocarcinoma in never smokers demonstrated a PFS benefit for gefitinib but also no OS difference. This study also had significant crossover. For the subgroup of patients with EGFR-mutant adenocarcinoma, gefitinib was associated with a higher overall response rate (ORR) (84.6% *vs* 37.5%; $P = 0.002$) and a trend toward longer PFS (HR = 0.544; 95%CI: 0.269-1.100; $P = 0.086$) compared to chemotherapy. For those patients with tumors harboring wild-type EGFR, the reverse was found: chemotherapy showed a trend toward higher ORR and longer PFS^[21]. Together, the IPASS and First-SIGNAL studies demonstrated that activating EGFR mutations are predictors of benefit with gefitinib and that wild-type EGFR patients do poorly with first-line gefitinib compared to platinum-based chemotherapy.

Instead of selecting patients by smoking status, subsequent studies included only patients with activating EGFR mutations. In randomized controlled trials, Japanese researchers confirmed the PFS superiority of gefitinib to chemotherapy as first-line treatment for patients with advanced EGFR-mutant NSCLC. In the West Japan Thoracic Oncology Group trial 3405, patients on the gefitinib arm had a median PFS of 9.6 mo, compared to 6.6 mo for those on cisplatin plus docetaxel^[22,23]. In a North-East Japan Study Group trial, gefitinib was associated with a PFS of 10.8 mo *vs* 5.4 mo for carboplatin-paclitaxel^[24]. In both Japanese trials, the differences in OS were not statistically significant^[23,24].

Similar to gefitinib, erlotinib has also demonstrated PFS advantages compared to chemotherapy in patients with EGFR-mutant NSCLC in the first-line setting. The Chinese OPTIMAL trial showed a PFS of 13.1 mo for erlotinib *vs* 4.6 mo for carboplatin and gemcitabine^[25]. The EURTAC trial demonstrated that EGFR TKIs were also effective for European patients with EGFR-mutant NSCLC in the first-line setting. In this study, patients receiving erlotinib had a PFS of 9.7 mo, compared to 5.2 mo for those receiving a platinum-based chemotherapy regimen^[26]. OS was not statistically different between the erlotinib and chemotherapy arms in either the OPTIMAL or EURTAC trial^[26,27].

More recent efforts have focused on newer-generation EGFR TKIs. Afatinib is an irreversible ErbB family inhibitor that, in preclinical models, has been shown to have activity against activating EGFR mutations as well

as the *EGFR* T790M mutation that confers resistance to erlotinib and gefitinib^[28]. The initial randomized studies of afatinib addressed its efficacy in the *EGFR*-TKI resistance setting. In LUX-Lung 1, patients with *EGFR*-mutant NSCLC who had received a first-generation *EGFR* TKI and chemotherapy were randomized to either afatinib or placebo. PFS was 3.3 mo for afatinib, compared to 1.1 mo for placebo ($P < 0.0001$)^[29]. The drug was then studied as a first-line treatment for *EGFR*-mutant NSCLC. The global LUX-Lung 3 phase III study randomized 345 patients to either afatinib or cisplatin-pemetrexed. The median PFS was 11.1 mo for afatinib and 6.9 mo for chemotherapy (HR = 0.58; 95%CI: 0.43-0.78; $P = 0.001$)^[30]. Similarly, the LUX-Lung 6 phase III study randomized 364 Chinese patients with *EGFR*-mutant NSCLC to either afatinib or cisplatin-gemcitabine in a 2 to 1 ratio. The median PFS of patients on the afatinib arm was 11.0 mo *vs* 5.6 mo for chemotherapy, HR = 0.28, $P < 0.0001$ ^[31]. In July 2013, nine years after the initial approval of erlotinib for treatment of advanced NSCLC (second or third line, regardless of *EGFR* mutation status) and only two months after the approval of erlotinib for first-line treatment of advanced *EGFR*-mutant NSCLC, the United States Food and Drug Administration (FDA) approved afatinib, for the first-line treatment of advanced NSCLC with activating exon 19 deletions and L858R *EGFR* mutations. A pooled subgroup analysis from trials of afatinib in TKI-naïve patients demonstrated good activity with a PFS of 10.7 mo in patients with other *EGFR* mutations that are classically sensitive to erlotinib, like L861Q and G719X^[32]. However, tumors initially harboring historically TKI-resistant alterations including T790M and exon 20 insertions appear markedly less sensitive, with PFS of under 3 mo in both groups. The ongoing clinical trial LUX-Lung 7 is comparing afatinib against gefitinib in the first-line setting for *EGFR*-mutant NSCLC to help determine relative efficacy of the two TKIs (ClinicalTrials.gov identifier: NCT01466660).

OVERCOMING RESISTANCE TO EGFR TYROSINE KINASE INHIBITORS

The discovery of *EGFR* TKIs has thus revolutionized treatment of NSCLC with activating *EGFR* mutations, with erlotinib, gefitinib, and afatinib approved for use in various countries. While a small minority of patients have disease control for years on these drugs, on average these TKIs have a median response duration seldom exceeding one year due to acquired resistance. The mechanisms of resistance vary, with the *EGFR* T790M point mutation in exon 20 being the most common cause of acquired resistance, accounting for about 50% of cases. The T790M “gatekeeper” mutation was initially thought to simply exclude binding of *EGFR*-TKI drugs by steric hindrance, but more importantly it appears to restore the *EGFR* affinity for ATP, thus decreasing the binding of the ATP-competitive TKIs^[33-35]. There is increasing evidence that a low level of the T790M mutation exists before treatment in many patients with *EGFR*-mutant NSCLC and pre-

dicts a worse PFS on erlotinib compared to those without pre-treatment T790M^[36]. Another clearly described cause of acquired resistance to TKI is the amplification of the mesenchymal epithelial transition (MET) proto-oncogene, which activates an AKT-mediated signaling pathway, bypassing *EGFR*^[37,38]. Several other *EGFR* mutations have also been implicated in conferring resistance to *EGFR* TKIs: D761Y^[39], T854A^[40], and L747S^[41], in addition to activating *BRAF* mutations^[42] and *HER2* amplification^[43]. Interestingly, some TKI-resistant tumors undergo histologic changes, including transformation from non-small-cell to small cell or epithelial-mesenchymal transition, leading to resistance through less direct mechanisms^[44].

Since half of acquired resistance is dependent on the T790M missense mutation, newer *EGFR* TKIs are in development to overcome resistance. The second-generation inhibitors afatinib and dacomitinib irreversibly inhibit both wild-type and mutant *EGFR* proteins, and to a lesser extent, T790M *EGFR*. In clinical trials designed to test activity in patients with acquired resistance, however, these drugs have not routinely induced reliable, robust responses. In the LUX-Lung 4 single-arm phase II study from Japan, patients were enrolled with *EGFR*-mutant NSCLC that had progressed on gefitinib/erlotinib and chemotherapy. Treatment with afatinib was associated with a modest response rate of 8.2%, and median PFS of 4.4 mo with median OS of 19.0 mo^[45]. Similarly, the larger placebo controlled trial of LUX-Lung 1 trial of afatinib after failure of chemotherapy and erlotinib or gefitinib evaluated 390 patients on afatinib and 195 patients on placebo. Compared with the afatinib group, the placebo group had an identical OS (10.8 mo *vs* 12.0 mo; HR 1.08; 95%CI: 0.86-1.35; $P = 0.74$). However, median PFS was statistically better in the afatinib group (3.3 mo *vs* 1.1 mo; HR 0.38; 95%CI: 0.31-0.48; $P < 0.0001$), yet the response rate was still unimpressive in this group (7%)^[29]. Dacomitinib (PF-00299804) is another irreversible TKI active against *EGFR*, *HER2*, and *HER4*. In a preliminary report of a phase II studying patients with NSCLC after failure of chemotherapy and erlotinib, responses were seen in 3 of 62 evaluable patients (5%)^[46]. To confirm the activity in this population, a large phase III study, the Canadian BR.26 trial, randomized 720 patients to dacomitinib or placebo for progressive disease after treatment with chemotherapy and an *EGFR* TKI (ClinicalTrials.gov identifier NCT01000025). According to a recent press release, however, this trial failed to meet its primary objective of prolonging overall survival *vs* placebo, with results to be reported in upcoming meetings^[47]. Another phase III study comparing dacomitinib *vs* gefitinib in treatment-naïve patients with *EGFR*-mutant NSCLC is still ongoing (ClinicalTrials.gov identifier NCT01774721). With other second-generation *EGFR* inhibitors including neratinib^[48] and XL647 (which also inhibits VEGFR)^[49], similarly low response rates were reported in trials of acquired resistance.

The strategy of combination therapy incorporating second-generation inhibitors has also been employed with

mixed success. Cetuximab, a monoclonal antibody against EGFR, adds little activity when added to erlotinib in the setting of acquired resistance^[50]. However, the combination of afatinib and cetuximab is surprisingly effective for acquired resistance. In a phase I b study, patients with acquired EGFR inhibitor resistance were given 40 mg daily of afatinib plus 500 mg/m² of cetuximab every other week. Of 61 reported patients at the recommended dose, 35% had confirmed response and 95% had stable disease or better, including patients with tumors with and without T790M mutations. Side effects including rash, diarrhea, and mucositis were significant^[51]. Follow-up trials of these agents for patients with *EGFR*-mutant NSCLC are currently in development. The strategy of combined EGFR and MET inhibition has also been employed in phase I / II trials. In a dose-finding trial of erlotinib plus the MET and VEGFR inhibitor cabozantinib (XL-184), 53 patients were evaluable and had a response rate of 8%. Interestingly, the two patients with confirmed *MET* copy number gain had disease shrinkage^[52]. Preliminary results from a phase I study using dacomitinib plus crizotinib (a MET and ALK inhibitor) noted a response rate of 5% in 20 patients who had previously had response or prolonged stable disease on an EGFR TKI^[53]. Further study of the infrequent *MET* amplification cohort will be of interest using this combination.

Although the second-generation agents do not appear to effectively combat acquired resistance, a novel class of third-generation EGFR inhibitors has been recently identified that much more potently inhibits mutant EGFR with T790M than wild type EGFR. The first such described molecules demonstrated impressive preclinical effectiveness in a mouse model of T790M-dependent acquired EGFR resistance^[54]. Since that time, two compounds with similar affinity for mutant, including T790M, EGFR protein, but minimal binding of wild-type EGFR, have early phase I results reported: CO-1686 and AZD9291. In a preliminary report of the CO-1686 clinical trial, 56 patients with *EGFR* activating mutations and failure of prior EGFR TKI therapy have been enrolled to a dose escalation trial. Of the 9 patients with tumors testing positive for T790M who were treated at the highest dose, 6 responded, 2 had stable disease (with slight decrease), and 1 patient progressed on therapy^[55]. In a similarly designed dose escalation study of AZD9291, 35 patients were treated with doses ranging from 20-80 mg. Fifteen of 35 patients (43%) had a confirmed or unconfirmed partial response, including those with and without documented T790M mutation. The majority of patients had some degree of tumor control, and only 4 patients progressed initially on treatment. Interestingly, wild-type EGFR toxicity for both agents appears quite mild, with rash and diarrhea infrequently reported^[56].

FIRST-GENERATION ALK TKI

Activating EGFR mutations are not the only actionable genetic alterations in NSCLC. In 2007, Japanese researchers working with NSCLC cells discovered an inversion

in chromosome 2p resulting in a novel fusion gene comprised of portions of the echinoderm microtubule-associated protein-like 4 (*EML4*) gene and the anaplastic lymphoma kinase (*ALK*) gene, including its entire intracellular tyrosine kinase domain. The *EML4* fusion partner mediates ligand-independent dimerization of ALK, leading to constitutive kinase activity. *EML4*-ALK fusion protein was tumorigenic in mice, and the Japanese researchers detected this transcript in about 5 out of 75 (6.7%) tumors from NSCLC patients^[57]. Subsequent published series have suggested that the frequency of *ALK* gene rearrangement in unselected NSCLC patients is about 3% to 6%^[58-63]. Besides *EML4*, several other fusion partners of *ALK*, *e.g.*, *KIF5B* and *TFG*, have been identified^[64,65]. Similar to activating *EGFR* mutations, *ALK* gene rearrangements are associated with younger age, never or light smoking status, and adenocarcinoma histology; however there is equal distribution by sex^[66,67].

Crizotinib, an oral, small-molecule inhibitor of ALK and c-Met, was originally developed as a potential therapeutic agent for *ALK*-positive anaplastic large cell lymphoma (ALCL)^[68]. The drug has indeed demonstrated activity in *ALK*-positive ALCL^[69] as well as *ALK*-positive diffuse large B cell lymphoma and inflammatory myofibroblastic tumors^[70,71]. However, crizotinib has been most widely applied in the treatment of NSCLC with *ALK* gene rearrangements after marked activity was noted in the patient population in the phase I trial, leading to FDA approval of the drug^[72]. In a phase III study, 347 patients with locally advanced or metastatic *ALK*-rearranged NSCLC who had received one prior platinum-based regimen were randomized to crizotinib or chemotherapy with either pemetrexed or docetaxel. The median PFS was 7.7 mo in the crizotinib group, significantly superior to the 3.0 mo in the chemotherapy group (HR for progression or death with crizotinib, 0.49; 95%CI: 0.37-0.64; *P* < 0.001). Common adverse events associated with crizotinib were visual disorders, nausea, diarrhea, vomiting, constipation, and elevated liver enzymes^[73]. Rare cases of esophageal ulceration associated with crizotinib have also been reported^[74]. In August 2011, only four years after the discovery of *ALK* gene rearrangements in NSCLC, the FDA granted accelerated approval to crizotinib for patients with *ALK*-positive NSCLC^[75]. An ongoing clinical trial seeks to demonstrate superiority of crizotinib compared to first-line platinum/pemetrexed chemotherapy for *ALK*-rearranged (ClinicalTrials.gov identifiers: NCT01154140 and NCT01639001). Accrual is complete and results are awaited, though crizotinib is commonly used in the first line setting without this evidence.

OVERCOMING RESISTANCE TO CRIZOTINIB

Unfortunately, many tumors with *ALK* gene rearrangements eventually acquire resistance to crizotinib, frequently within one year, similar to *EGFR*-mutant NSCLC

developing resistance to erlotinib or gefitinib. Researchers from Massachusetts General Hospital and collaborators analyzed 18 patients with crizotinib-resistant NSCLC and discovered that almost one-quarter of the patients had either secondary mutations in the *ALK* tyrosine kinase domain or *ALK* fusion gene amplification. About half of the patients were found to have tyrosine kinase activity via EGFR or KIT, thus bypassing the inhibited ALK-mediated pathway^[76]. The L1196M mutation has been shown to be a gatekeeper mutation in the *ALK* kinase domain, conferring resistance to crizotinib^[76-79], similar to the *EGFR* T790M mutation that confers resistance to erlotinib. Besides *EGFR* mutations^[76,78], *KRAS* mutations have also been identified as a possible mechanism of crizotinib resistance in a separate series of crizotinib-resistant patients from the University of Colorado^[78].

Multiple second-generation ALK inhibitors have been developed with increased potency and potential to overcome acquired resistance to crizotinib, including ceritinib (LDK378), AP26113, and alectinib (CH/RO5424802). Ceritinib has recently been shown to have efficacy against crizotinib-naïve as well as crizotinib-resistant *ALK*-positive lung cancer. In a multicenter phase I study, 131 patients with advanced malignancies harboring a genetic alteration in *ALK*, including 123 patients with *ALK*-rearranged NSCLC, received ceritinib orally at doses of 50 mg to 750 mg once daily. Among the 88 NSCLC patients who received ceritinib at 400-750 mg daily, the ORR was 70%. In the subset of 64 crizotinib-resistant patients, the ORR was similar at 73%, with responses observed in patients with different crizotinib resistance mutations, patients without detectable mutation, and even patients with untreated CNS metastases. In all 123 NSCLC patients, the median PFS was 8.6 mo (95%CI: 4.3-19.3). Ceritinib appeared to have more toxicities than crizotinib, however, with the most common adverse events, including all grades, being nausea (72%), diarrhea (69%), vomiting (50%), and fatigue (31%)^[80]. The drug has advanced to phase III clinical trials, being compared *vs* chemotherapy for *ALK*-rearranged NSCLC in the first-line setting (ClinicalTrials.gov identifier NCT01828099) or in the third-line setting for patients previously treated with chemotherapy and crizotinib (ClinicalTrials.gov identifier NCT01828112).

Another promising second-generation ALK inhibitor is AP26113, which exhibits activity against all 9 clinically-identified crizotinib-resistant mutants, including the L1196M gatekeeper, in preclinical experiments^[81,82]. Like most other ALK inhibitors, AP26113 also inhibits ROS1, an actionable target to be discussed later in this review, and selectively inhibits *EGFR* T790M without affecting the native receptor^[83]. In a phase I / II multicenter study, 55 patients with advanced malignancies, including 47 with NSCLC refractory to available therapies, received daily doses of AP26113. Of the 24 patients who had *ALK*-positive solid tumors, 15 responded. Among *ALK*-rearranged NSCLC patients with prior crizotinib only, 12 out of 16 (75%) responded. The drug appeared to

have activity in the CNS as well. Four out of 5 *ALK*-positive patients with untreated or progressing CNS lesions had evidence of radiographic improvement in the CNS, including 1 patient resistant to both crizotinib and LDK378. The most common adverse events were fatigue (40%), nausea (36%), and diarrhea (33%), generally at CTCAE grade 1/2^[84].

A third ALK inhibitor in development is alectinib, previously known as CH/RO5424802. In a phase I / II study of 58 patients with *ALK*-rearranged NSCLC and no prior ALK inhibitor therapy, the overall response rate for alectinib in 46 patients on the phase II part of the study was 93.5% (95%CI: 82.1-98.6) with 2 CRs and 41 PRs. With a median follow-up period of 12.6 mo, 47 out of 58 patients were still on study treatment, and the median treatment duration had passed 10.3 mo^[85]. Alectinib has been shown to have activity post crizotinib as well. In a phase I study of alectinib in 37 patients with *ALK*-rearranged NSCLC who progressed after crizotinib and chemotherapy, partial response (PR) was observed in 48% of all patients and 59.5% of the subgroup of patients receiving doses of 460 mg or higher twice a day. Median PFS had not been reached, with the median duration on study ranging from 39 d to over 347 d^[86]. Sixteen of these *ALK*-rearranged NSCLC patients had CNS metastases. Although PFS had not been reached by June 2013, alectinib demonstrated rapid benefit in brain metastases in a number of patients, including those resistant to crizotinib^[87]. The most common side effects of the drug were fatigue, myalgia, cough, liver enzyme elevation, peripheral edema and rash^[86,87].

There are also other second-generation ALK inhibitors in earlier stages of clinical development. For example, X-396, a potent and highly specific ALK TKI, demonstrated preclinical activity against the most common *ALK* fusions as well as against secondary *ALK* mutations that conferred resistance to crizotinib^[88]. X-396 is currently in phase I development (ClinicalTrials.gov identifier NCT01625234). PF-06463922 is a promising next-generation ALK/ROS1 inhibitor that has potent and selective inhibitory activity against all known acquired crizotinib-resistant mutations. PF-06463922 is also capable of penetrating the blood brain barrier in preclinical animal models^[89]. The drug is also currently in phase I development (ClinicalTrials.gov identifier NCT01970865). ASP3026 is another potent ALK inhibitor that also has activity against crizotinib-resistant tumors in mouse model^[90]. ASP3026 is currently in phase I development (ClinicalTrials.gov identifier NCT01401504).

OTHER "ACTIONABLE" MOLECULAR TARGETS

The discovery of the oncogenic alterations involving *EGFR* and *ALK* and their inhibitors has revolutionized the treatment of non-small cell lung cancer over the past decade. However, *EGFR*-mutant and *ALK*-rearranged cancers make up less than one-fifth of all NSCLC cases

Table 1 Selected current targeted therapies for non-small cell lung cancer and their stages of development

Drug	Company	Stage of development in NSCLC
EGFR activating mutations		
Gefitinib	AstraZeneca	Approved
Erlotinib	Roche	Approved
Afatinib	Boehringer Ingelheim	Approved
Dacomitinib	Pfizer	Phase III
CO-1686	Clovis	Phase I / II
AZD9291	AstraZeneca	Phase I / II
ALK gene rearrangements		
Crizotinib	Pfizer	Approved
LDK378	Novartis	Phase III
AP26113	ARIAD	Phase II
Alectinib	Chugai	Phase II
X-396	Xcovery	Phase I
PF-06463922	Pfizer	Phase I
ROS1 gene rearrangements		
Crizotinib	Pfizer	Phase II (approved for ALK-positive NSCLC)
LDK378	Novartis	Phase II
PF-06463922	Pfizer	Phase I
HER2 activating mutations		
Trastuzumab	Genentech	Phase II
Afatinib	Boehringer Ingelheim	No HER2-mutant NSCLC specific trial
Neratinib	Puma Biotechnology	Phase II
BRAF activating mutations		
Dabrafenib	GlaxoSmithKline	Phase II

NSCLC: Non-small-cell lung cancer; ALK: Anaplastic lymphoma kinase.

in the United States. Several other potentially actionable molecular targets have recently been found.

ROS1 gene rearrangements, involving the receptor tyrosine kinase *ROS1* and partners *CD74*, *SLC24A2*, and *FIG*, are the driver oncogenes in a small subset of NSCLC^[91-93] also responsive to crizotinib^[91]. An expansion cohort of the phase I crizotinib study PROFILE 1001 included 40 patients with *ROS1*-positive NSCLC. In the 35 patients who were evaluated, the ORR was 60% with 2 complete response (CR), 19 PR, and 10 stable disease (SD) cases. Six-month PFS probability was 76% (95%CI: 55-88). Median PFS had not been reached when the results were reported at the World Conference on Lung Cancer in October 2013^[94]. Unfortunately, acquired resistance to crizotinib in *ROS1*-positive patients has also been reported. A patient with the *ROS1-CD74* fusion oncogene initially responded dramatically to two mo of crizotinib treatment but then progressed in the third month. Her tumor was found to have a novel G2032R mutation in the *CD74-ROS1* fusion junction that had not been observed before crizotinib treatment^[95]. Recently a promising *ROS1* inhibitor, foretinib, has been shown to demonstrate efficacy against *ROS1*-rearranged tumor cells, including crizotinib-resistant cells. Foretinib, which also inhibits other kinases including *MET* and *VEGFR2*, is being studied in phase I and II studies in a variety of cancers.

About 1% to 2% of NSCLC tumors have mutations in *HER2* exon 20^[96,97], which is not clearly associated with *HER2* amplification. Although anti-Her2 therapies are in-

effective in *HER2*-amplified NSCLC^[98,99], *HER2*-mutant NSCLC has been shown to be responsive to trastuzumab plus chemotherapy, with an overall response rate of 50% and median PFS of 5.1 mo in one case series^[96]. Afatinib, the ErbB family inhibitor approved for *EGFR*-mutant NSCLC as discussed earlier in this review, also has clinical activity against *HER2*-mutant NSCLC in a small case series^[96,100]. As HER family members signal via the PI3K-AKT-mTOR cascade, recent attempts have been made to inhibit both *HER2* and mTOR in *HER2*-driven cancers. In a phase I study of the combination of neratinib (a small molecule pan-HER inhibitor) and temsirolimus (an mTOR inhibitor), 7 patients with *HER2*-mutant NSCLC were treated, with 2 showing partial responses^[101]. An ongoing phase II study compares neratinib *vs* neratinib plus temsirolimus in patients with *HER2*-mutant NSCLC (ClinicalTrials.gov identifier NCT01827267).

BRAF activating mutations can be observed in 1%-3% of NSCLC^[102,103]. In one case series, about half of these *BRAF* mutations are the V600E mutation that is also seen in melanoma. Unlike *EGFR*, *ALK*, and *ROS1* genetic alterations that are associated with light or never smoking status, *BRAF* mutations in NSCLC are often reported in current or former smokers^[103]. In a phase II study, 17 patients with *BRAF* V600E-mutant NSCLC received dabrafenib, which had previously shown activity in *BRAF* V600E-mutant melanoma. Seven patients out of 13 (54%) evaluable patients had PR, with 1 patient having stable disease. The drug was generally well tolerated, and the median duration of treatment was 9 wk, with the longest duration of response being 49 wk when the results were reported at the 2013 ASCO Annual Meeting^[104]. An ongoing phase II study tests dabrafenib *vs* dabrafenib and trametinib, an inhibitor of MEK that is downstream of BRAF, in patients with *BRAF* V600E mutation-positive NSCLC (ClinicalTrials.gov identifier NCT01336634).

Other rare genetic alterations in NSCLC have been found and have potentially therapeutic agents include *MET* amplification, *FGFR1* amplification, *RET* translocations, and *MEK1* mutations. Investigations using inhibitors of these oncogenic pathways are ongoing, with anecdotal responses reported in some cases. A detailed discussion of these targets is beyond the scope of this review. Table 1 summarizes the targeted therapies for NSCLC that have already been approved or are still in ongoing clinical trials.

CONCLUSION

Until several years ago, the only therapeutic option for advanced NSCLC was cytotoxic chemotherapy. The discovery of activating *EGFR* mutations and the unprecedented efficacy of erlotinib and gefitinib in *EGFR*-mutant NSCLC ushered in an era of truly personalized cancer care. There is increasing evidence that targeted therapies yield better outcomes than traditional chemotherapy in appropriate patients. The Lung Cancer Mutation Consortium recently reported that an actionable

driver was detected in 64% of patients with pulmonary adenocarcinoma and that among the 938 patients the consortium tracked, the median survival was 3.5 years for the 264 with an oncogenic driver treated with genotype-directed therapy, 2.4 years for the 318 with an oncogenic driver with no genotype-directed therapy, and 2.1 years for the 360 with no driver identified ($P < 0.0001$)^[105].

With the advance of next-generation sequencing, one can foresee a future in which every single tumor will be sequenced at the time of diagnosis to find potential driver mutations that can be therapeutically targeted. While some rare patients have had astounding disease remission, defined as long-term complete responses to EGFR TKI therapy^[106,107], these patients are still usually receiving active therapy and therefore cannot truly be considered “cured”. Therefore, challenges remain on how to overcome the seemingly inevitable acquired resistance to these therapies. The optimal sequence for the use of multiple inhibitors of the same target and the efficacy and tolerability of combinations of inhibitors of various oncogenic pathways are being actively studied. In addition, the emerging promise of immunotherapies such as PD-1/PDL-1 directed antibody therapy opens the door for studies of potential synergy with these drugs and tyrosine kinase targeted therapeutics. Even if a cure for advanced lung cancer still remains out of reach, one can hope that in the near future advanced NSCLC may be controlled like other chronic diseases with well-tolerated and effective therapies.

Abstract

Lung cancer, is the most common cause of cancer death in men and second only to breast cancer in women. Currently, the first line therapy of choice is platinum-based combination chemotherapy. A therapeutic plateau has been reached with the prognosis for patients with advanced non-small cell lung cancer (NSCLC) remaining poor. New biomarkers of prognosis as well as new therapies focusing on molecular targets are emerging helping to identify patients who are likely to benefit from therapy. Despite this, drug resistance remains the major cause for treatment failure. In this article we review the role of apoptosis in mediating drug resistance in NSCLC. Better understanding of this fundamental biological process may provide a rationale for overcoming the current therapeutic plateau.

Core tip: A therapeutic plateau has been reached with

INTRODUCTION

Lung cancer is the leading cause of cancer death in the United Kingdom accounting for 24% of all male related cancer deaths and 20% in females^[1]. Similar trends are seen in the United States with lung cancer representing the most common cause of cancer death in men and women, recently overtaking breast cancer in the latter^[2]. In the United States, more than 213000 new cases were diagnosed in 2007 with a total of 1.61 million cases worldwide in 2008^[2,3]. The majority of these cancers (75%-80%) are non-small cell lung cancers (NSCLC)^[4].

Surgery is the mainstay of treatment for early stage and localised disease (Stage I and II and selected IIIA). Multimodal therapy is the norm for regionally advanced disease in the form of adjuvant chemotherapy. Palliative chemotherapy forms the mainstay of treatment in patients with advanced metastatic disease^[5]. Five year survival rates following lung resection for NSCLC are I A-73%, I B-54%, II A-48%, II B-38%, IIIA-25%^[6]. The majority of patients have advanced disease at the time of

diagnosis and therefore are not surgical candidates. This is illustrated by the fact that in the United Kingdom only 14% of patients diagnosed go on to have surgical resection^[7]. In those patients that are surgical candidates, more than 50% will develop a recurrence. Adjuvant chemotherapy has been used with limited success to decrease the recurrence rates but this has only yielded a survival benefit of 5%-15%^[8].

For patients not suitable for surgery due to advanced disease or those who have suffered recurrence following resection, chemotherapy forms the mainstay of treatment with evidence that platinum based therapies are most effective in the first line setting^[9,10]. Despite this, in a recent trial of platinum combination therapies in advanced NSCLC, only 30% of patients showed objective disease response and a significant proportion suffered toxic side-effects such as neutropenia (27%), anaemia (10%), thrombocytopenia (13%), alopecia (21%) and nausea (4%). During the trial, deaths due to study drug toxicity were in the region of 1%^[11]. This demonstrates the major problem of drug resistance in NSCLC to standard platinum based therapies and the associated toxicities.

MOLECULAR TARGETED THERAPY

A recent major advance in the management of NSCLC has been the identification of activating mutations in the tyrosine kinase domain of the epidermal growth factor receptor (EGFR)^[12]. These mutations, found in 10% of NSCLC specimens in the United States and Europe, are associated with increased sensitivity to EGFR tyrosine kinase inhibitors erlotinib and gefitinib^[13]. EGFR mutations are often accompanied by gene amplification^[14]. Mutation of the EGFR can lead to signal transduction independent of ligand stimulation, relaying signals to the PI3K-AKT-mTOR pathway involved in cell survival, or to the RAS-RAF-MEK-ERK pathway involved in cell proliferation^[15]. The fact that kinase inhibition leads to apoptosis in cells with mutant EGFR supports the notion that these cells are "addicted" to signalling *via* the mutant proteins^[16]. This explains the dramatic response to EGFR tyrosine kinase inhibitors in EGFR mutated NSCLC with associated improvement in survival^[17,18].

Molecular profiling in NSCLC has revealed a number of other mutations such as EML4-ALK translocation^[19]. This is associated with extreme preclinical sensitivity to respective ALK kinase inhibition in both preclinical and clinical settings^[20,21]. Additional molecular subclasses with associated somatic gene alterations have been discovered, predominantly in lung adenocarcinomas and include mutations of BRAF^[22], Her2^[23] and PIK3CA^[24]. The continual discovery of new molecular subclasses represents significant progress in the treatment of NSCLC but they should not necessarily be viewed as a panacea as resistance to these novel targeted therapies are being reported^[25]. The above molecular subclasses still only account for less than half all new cases of the disease. The majority of patients still rely on standard combination

chemotherapy of platinum based doublet regimens.

In addition to molecular tumour markers, there is increasing interest in developing biomarkers associated with NSCLC. These may be predictive for response to treatment or prognostic. An area of interest in our unit relates to the link between plasma fibrinogen and NSCLC. In early stage disease amenable to surgical resection, raised fibrinogen is associated with increased risk of incomplete resection and correlates with T stage of tumour^[26]. More recently, serum fibrinogen has been shown to be an independent predictor for both disease recurrence and overall survival in both resectable and advanced disease^[27,28]. The mechanism by which fibrinogen acts as a marker is not fully understood. Its role as an extracellular matrix, in promoting angiogenesis and metastasis has been proposed^[29-32].

APOPTOSIS AND DRUG RESISTANCE

Cisplatin (*cis*-diamminedichloroplatinum II) is the most effective platinum based therapy in the first line setting for NSCLC^[33]. It forms DNA-platinum covalent adducts resulting in inhibition of DNA replication, suppression of RNA transcription and protein translation, attempted DNA repair as well as disturbance of the cell cycle and the activation of apoptosis^[34].

Apoptosis serves as a natural barrier to cancer development^[35]. Normally the accumulation of genetic mutations required to drive uncontrolled cell cycle progression and tumorigenesis would result in triggering of apoptosis within a cell^[36]. The ability of cancer cells to evade apoptosis is, therefore, an essential hallmark of cancer^[37]. Defects in apoptosis, harboured by cancer cells, not only underpin tumorigenesis but also drug resistance^[38]. Resistance of NSCLC cells to a diverse range of cytotoxic therapies suggests a defect in apoptosis signalling^[39]. Further understanding of the mechanisms by which apoptosis resistance occurs and how this can be overcome will be important in order to administer a more rational approach to anticancer drug design and therapy.

APOPTOSIS

Apoptosis, a genetically encoded programme of cell death, was originally defined based on the morphological features observed as the cell died; nuclear condensation, nuclear and cellular fragmentation, membrane blebbing and phagocytosis of the dying cell in the absence of inflammation^[40]. The process of apoptosis is conserved in a wide range of multicellular organisms from worms to humans and plays a key role in normal development and homeostasis. The apoptosis phenotype is produced through the activity of cysteine-aspartic proteases, a family of cysteine proteases termed caspases. A hierarchical cascade of activation occurs which results in apoptosis. Two groups of caspases have been classified; the initiator caspases and the effector caspases.

The initiator caspases, caspase-8, -9 and -10, are ac-

tivated early in apoptosis signalling and have restricted cleavage targets, limited to self cleavage, the effector caspases and BID (caspase-8). In contrast, the effector caspases, caspase-3, -6 and -7, have hundreds of cleavage sites broadly distributed throughout the cell^[41]. The effector caspases are held in the cytosol as inactive dimers. The activating event, catalyzed by the initiator caspases, involves conversion to catalytically active enzymes by cleavage in the linker region between the large and small active subunits. This allows intramolecular rearrangements to form an enzymatically active dimer^[42]. Caspase-3 and -7 display highly similar substrate specificity and carry out redundant but essential functions in apoptotic cell death as mouse embryonic fibroblasts lacking both enzymes are resistant to intrinsic and extrinsic apoptotic stimuli^[43].

Caspase-8 and -10 are involved in the death receptor signalling pathway whereas caspase-9 is involved in mitochondrial apoptosis.

It is clear caspase activation is a critical step in the execution of apoptosis and is generally a terminal event for the cell. Regulation of the process occurs through the extrinsic, death receptor apoptosis pathway and the intrinsic mitochondrial apoptosis pathway.

EXTRINSIC APOPTOSIS PATHWAY

Apoptosis occurs via the extrinsic apoptosis pathway as a result of signalling through death receptors expressed on the surface of mammalian cells. In the 1970's it was identified that certain products of lymphocytes and macrophages caused the lysis of certain types of cells, especially tumour cells. This product was termed 'tumour necrosis factor (TNF)^[44,45]. It has been established that TNF has its effect via cell surface receptor binding and activation. At least 18 TNF family ligands and 29 receptors have been identified in humans^[46]. In cancer research, interest has grown around the use of TNF-related apoptosis-inducing ligand (TRAIL) and targeting its receptors, members of the TNF superfamily, since the observation that recombinant human (rh) TRAIL induces apoptosis in various tumour cells but not in normal cells^[47].

TRAIL activates apoptosis by binding to specific transmembrane receptors TRAIL-R1 (DR4) and TRAIL-R2 (DR5)^[48,49]. It can also bind truncated, non-functional receptors TRAIL-R3 and TRAIL-R4 known as decoy receptors (DcR1 and DcR2)^[50]. Upon binding TRAIL to the death receptors (DR4, DR5), trimerization of the receptors occurs and a complex is formed termed the death-inducing signalling complex (DISC). This is the key step for subsequent initiator caspase activation to occur.

INTRINSIC APOPTOSIS PATHWAY

The other major apoptosis pathway leading to caspase activation and cell death is the Intrinsic (mitochondrial) apoptosis pathway. As DISC formation is the key step

in extrinsic (death receptor) signalling so mitochondrial outer membrane permeabilization (MOMP) is the key requirement for caspase activation and apoptosis via the mitochondrial apoptosis pathway. As the name suggests, this apoptosis pathway is engaged primarily as a result of internal cellular stresses such as DNA damage, ER stress^[41].

MOMP during apoptosis is primarily controlled by the BCL2 family of proteins^[51]. The pro-apoptotic members, BAX^[52] and BAK^[53], contain BH1-3 domains. BAX and BAK are often referred to as effector proteins as there is an absolute requirement for their activation at the outer mitochondrial membrane for MOMP to occur^[54].

A diverse range of death signals caused by eg DNA damage, growth factor deprivation leads to a shift in the balance of anti- and pro-apoptotic BCL2 family members with signals produced to engage MOMP. Activation of a "multidomain" proapoptotic member, BAX or BAK, is an essential gateway to mitochondrial dysfunction required for cell death in response to these diverse stimuli^[54].

Upon receipt of a death signal, BAX translocates to the mitochondrial surface where BAK already resides^[55,56]. A detailed sequence of events from BAX translocation to the OMM, subsequent activation and MOMP has been described recently^[57]. The requirement for activated BAX and/or BAK for MOMP to occur is clear, the mechanism by which they bring about MOMP is not. The key feature of MOMP in bringing about caspase activation and apoptosis is cytochrome C release. This is clear from evidence that cells lacking cytochrome C fail to activate caspases in response to UV irradiation, serum withdrawal, or staurosporine^[58]. The primary function of cytochrome C is in oxidative phosphorylation as it is a key component of the electron transport chain and it is found loosely associated with the mitochondrial inner membrane. The other important mitochondrial intermembrane space protein released during MOMP is second mitochondria-derived activator of caspase (SMAC) also termed DIABLO (direct IAP binding protein with low pI). It binds XIAP's, antagonising their ability to inhibit caspases^[59,60].

APOPTOSIS BLOCK IN CANCER

Having outlined how apoptosis proceeds, the mechanisms by which cancer cells evade this process will be explored. Block in mitochondrial apoptosis has been broadly divided into three groups^[61]: (1) Class A block occurs when normal generation of proapoptotic activators by aberrant behavior is inhibited. The mechanisms by which aberrant behaviour, such as genomic instability and oncogene activation, generate death signals via BH3-only proteins is as yet poorly understood. This is an area of ongoing study; (2) Class B block occurs when there is a significant loss of the BCL2 family effectors, BAX and BAK; and (3) Class C block occurs when increased expression of an anti-apoptotic BCL2 family protein is present, thereby inhibiting or sequestering pro-apoptotic BH3-only proteins. In this scenario, the cell has generated

an appropriate BH3-only death signal but it is inhibited by opposing anti-apoptotic expression. Cells in this state are referred to as “primed for death” and are “addicted” to the overexpression of the anti-apoptotic protein^[62].

Apoptosis blocks such as described above may determine the sensitivity of a cancer cell to a wide range of diverse chemotherapy agents and explain frequently observed phenomenon of multidrug resistance^[51]. The fact that being primed for death (class C block) is apparently more common in tumours than in normal cells may help explain why chemotherapy is often more toxic to cancers^[51].

Having classified apoptosis block in tumours, a new technique for determining what type of block a given cell employs has been developed termed BH3 profiling^[61,62]. The basic method involves incubation of mitochondria isolated from tumour cells with a panel of BH3 peptides. By assessing the pattern of response, the type of apoptosis block present can be identified. This may be used in the future to select drugs targeting anti-apoptotic proteins as a strategy for improving efficacy of drug treatments.

EXPRESSION OF BCL2 FAMILY MEMBERS IN NSCLC

Much focus has been placed on the role of BCL2 as a prognostic predictor in NSCLC. Many studies over the last 15-20 years have assessed its expression in many differing solid tumours. Given its function as an antiapoptotic protein, it would be predicted that overexpression would result in a more aggressive and treatment resistant phenotype. The published data is mixed with regard to its role as a prognostic marker.

A meta-analysis from 2003 compiled 28 studies from 1993 to 1999 which report the expression of BCL2 in NSCLC and the prognostic value of its expression in the primary tumour^[63]. Immunohistochemistry was used to detect expression in all studies. Of the 28 studies included, 11 concluded Bcl-2 expression was a good prognostic marker, 14 concluded it was not prognostic for survival with only 3 linking Bcl-2 expression to poor prognosis. Having performed the meta-analysis, the authors concluded that Bcl-2 positive tumours had a significantly better survival than those with Bcl-2 negative tumours. Given its function in the apoptotic pathway this would appear a paradoxical conclusion. One theory suggests that loss of Bcl-2 expression correlates with tumour de-differentiation and therefore a more aggressive phenotype^[64]. As discussed above, increased expression of BCL2 would likely confer a class C block in apoptosis and as such these tumours would be primed for death perhaps explaining the increased survival. This should be interpreted with caution as a result of heterogenous treatment patients in these studies received. Given the highly complex interplay between Bcl-2 and its other family members in regulating apoptosis, it is not surprising that the study of one anti-apoptotic member yielded such a result. As knowledge about the interplay between Bcl-2

family members improves, other targets or combination of targets may be more relevant to study rather than a single protein in isolation.

The crucial role the proapoptotic multidomain proteins BAX and BAK play in mitochondrial outer membrane permeabilisation warrants further study as prognostic markers. Loss of both proteins would confer a class B apoptosis block. Many studies exist reporting the status of BAX and BAK expression in NSCLC but again only report in isolation and each is considered separately as prognostic markers.

Altered BAX expression is frequently reported in NSCLC^[65-68]. None of these studies conclude that altered BAX expression has significant value as a prognostic marker, although none have investigated the expression of BAK together with BAX. Fewer studies report the incidence of altered BAK expression^[69,70]. These studies report the incidence of BAK loss at 42% and 59%. They also include data on BAX expression with loss reported in 34% and 47%. Neither study reports the incidence of double loss. Both conclude that no prognostic value is attributed to BAX or BAK expression in NSCLC but again each protein is analysed in isolation. Data from the International Adjuvant Lung Cancer Trial (IALT) suggests a trend toward increasing chemosensitivity with increasing BAX level^[71]. The converse effect of BAX negativity was not reported.

STRATEGIES TO OVERCOME MITOCHONDRIAL APOPTOSIS BLOCK

Given the frequent loss of expression of each protein, it is likely a significant portion of patients with NSCLC will have BAX and BAK double loss and given the evidence that this results in a highly apoptosis resistant phenotype it would be important to assess the impact on double loss on both survival and response to standard chemotherapy and radiotherapy in NSCLC.

Given what is known about the mitochondrial apoptosis pathway, class B block in apoptosis is likely to prove resistant to a range of targeted therapies. BH3 mimetics would be predicted to be ineffective due to absence of effector proteins BAX and BAK. Alternative strategies will be required to treat these potentially multidrug resistant cancers. *In vitro* evidence exists to show that in the absence of BAX and BAK, detachment of hexokinase from mitochondrial VDAC can lead to cytochrome C release and therefore mediate cell death^[72]. This can be achieved using either a competitive peptide, or by inhibiting AKT (which in turn regulates hexokinase interaction with VDAC) and prove a rational approach to treating cancers exhibiting Akt activation or an imbalance in the expression of antiapoptotic and proapoptotic members of the Bcl-2 family.

CONCLUSION

NSCLC presents a major health burden worldwide. Plati-

num based chemotherapy is the mainstay of treatment in the clinic today, although denovo and acquired drug resistance has resulted in a therapeutic plateau since its introduction over 30 years ago. Novel targeted therapies are beginning to emerge that induce apoptosis in certain molecular subclasses. Apoptosis resistance underpins tumorigenesis and drug resistance. Understanding how apoptosis resistance occurs in NSCLC will allow tailoring of therapy and development of novel targets to overcome this problem.

Abstract

Lung cancer represents the leading cause of cancer mortality worldwide. Despite improvements in preoperative staging, surgical techniques, neoadjuvant/adjuvant options and postoperative care, there are still major difficulties in significantly improving survival, especially in locally advanced non-small cell lung cancer (NSCLC). To date, surgical resection is the primary mode of treatment for stage I and II NSCLC and has become an important component of the multimodality therapy of even more advanced disease with a curative intention. In fact, in NSCLC patients with solitary distant metastases, surgical interventions have been discussed in the last years. Accordingly, this review displays the recent surgical strategies implemented in the therapy of NSCLC patients.

INTRODUCTION

Lung cancer represents the leading cause of cancer mortality worldwide, accounting for around 1.4-1.6 million deaths each year^[1-4]. While this tumor entity has by far the first place in incidence and mortality among other forms of cancer in males, it is the fourth most frequently malignant tumor in women after breast, cervical and colorectal cancer but it is also the second most common cause of death in the female population^[1]. Improving the survival of lung cancer patients is a major challenge for modern multimodality oncological treatment strategies, considering that the 5-year survival remains less than 15% across all stages of disease with fewer than 7% of patients alive 10 years after diagnosis^[5]. Even with improvements in preoperative staging, surgical techniques,

neoadjuvant/adjuvant options and postoperative care, there are still great difficulties in significantly improving survival, especially in locally advanced disease while early tumor stages theoretically represent the most consistent possibility of modifying the outcome of non-small cell lung cancer (NSCLC)^[5]. Indeed, similar to other malignant tumors, the therapy of NSCLC is stage related. At this, surgical resection is the primary mode of treatment for stage I and II NSCLC and an important component of the multimodality approach to stage IIIA disease with a curative intention. Standard resections include removal of the lobe involved with tumor and systematic evaluation of ipsilateral hilar and mediastinal lymph nodes. Moreover, even in NSCLC patients with solitary distant metastases, surgical interventions have been discussed in the last years. Therefore, the current review displays the recent surgical strategies implemented in the therapy of NSCLC (Figure 1).

NSCLC STAGE I + II (T1-2 N0-1, T3N0)

NSCLC stage I + II (T1-2 N0-1)

Patients with stage I and II NSCLC account for only 25%-30% of all patients presenting with the diagnosis of this malignant tumor^[6]. For medically operable patients, lobectomy, the surgical resection of a single lobe, with mediastinal lymph node dissection (MLND) or systematic lymph node sampling (SLNS), is generally accepted as the optimal procedure for this early tumor stage^[7,8]. Although the role of surgery has not been validated through randomized trials, the favorable results reported in surgical series and the relative infrequency of long-term survival in patients treated without surgery established this therapeutic approach as the treatment of choice^[9,10]. The current literature describes the prognosis for stage I and II NSCLC, undergoing primary surgical resection, expressed in terms of 5-year survival rates, as 60% to 80% for stage I and 30% to 50% for stage II NSCLC^[11].

In general, lung resections for NSCLC are performed through a lateral thoracotomy. However, in patients with early stage NSCLC, video-assisted thoracoscopic surgery (VATS) seems to be an acceptable alternative to the well-known open lobectomy in terms of complications and oncological value in patients with early stage NSCLC^[12].

In fact, in the last years a number of retrospective studies have shown that VATS lobectomy is associated with fewer complications, and shorter length of hospital stay compared to open surgery^[13-20]. These advantages were also described in elderly patients with NSCLC^[13,14,19,21-23]. Furthermore, two meta-analyses and two systematic reviews revealed that patients undergoing VATS lobectomy have reduced perioperative morbidity, mortality and less postoperative pain as short-term benefits compared to patients receiving open surgical resection while the long-term results (survival and recurrence rates) were not significantly different between the two surgical procedures^[12,22,24,25]. In addition, a recent study by

Park *et al.* with more than 6000 NSCLC patients undergoing either VATS or standard open lobectomy, showed not only that VATS lobectomy had fewer complications (38% *vs* 44%) and a shorter length of hospital stay (5 d *vs* 7 d) compared to open surgical resection but rather that patients undergoing VATS at high volume hospitals had a shorter median length of hospital stay (4 d *vs* 6 d) compared with patients receiving surgical resection at low-volume hospitals^[26].

However, the quality and efficiency of the lymphadenectomy (LAD) in NSCLC patients undergoing VATS lobectomy was controversially discussed for a long period of time. A review about 770 patients (VATS: 450 patients, open resection: 320 patients) with cN0-pN2 NSCLC by Watanabe *et al.* examined the total number of lymph nodes, lymph node stations and mediastinal nodes resected by VATS *vs* open lobectomy, and found no difference in any of these categories^[27]. Moreover, data from the recent American College of Surgery Oncology Group Z0030 trial (*n*: 752 patients, VATS: 66 patients; open: 686 patients) has also confirmed the efficacy of LAD by the VATS procedure with demonstrating similar number of lymph nodes removed and lymph node stations assessed by both surgical techniques^[18].

A point for discussion regarding VATS lobectomy in NSCLC patients might be the issue of smaller resection margins compared to the open procedure, as one might suggest that the extent of the bronchial margin has clinically relevant impact on disease-free and overall survival in early-stage non-small-cell lung cancer. However, recent studies showed that the complete surgical resection (R0 resection) but not the extent of the resection margin itself is of prognostic impact^[28].

Based on these findings VATS lobectomy is an appropriate surgical technique in the therapy of patients with early stage NSCLC in terms of morbidity, oncological value and survival compared to open surgery^[12].

It is generally accepted that the treatment of choice in stage I and II NSCLC patients with low surgical risk is the primary surgical tumor resection by excision of the whole affected lobe. However, especially due to the progress and development in CT imaging, a growing number of ground-glass opacities and small tumors are being detected^[29]. Therefore, there is an increasing number of studies dealing with the subject of a sub-lobar resection in such tumor cases. In fact, several retrospective studies have compared sub-lobar resection with complete lobectomy in patients with early NSCLC. For example, in the currently largest study performed by Whitson *et al.*^[30], using the American Surveillance Epidemiology and End Results (SEER) database, with data from 14,473 patients with stage I tumors treated by anatomical segmentectomy or lobectomy, the prognostic impact of both techniques was assessed. The authors demonstrated that the latter approach provides a statistically significant 5-year survival advantage, even after adjustment for other prognostic factors including tumour size.

Nevertheless, sub-lobar resection might be considered especially in the following patients: (1) Compromised

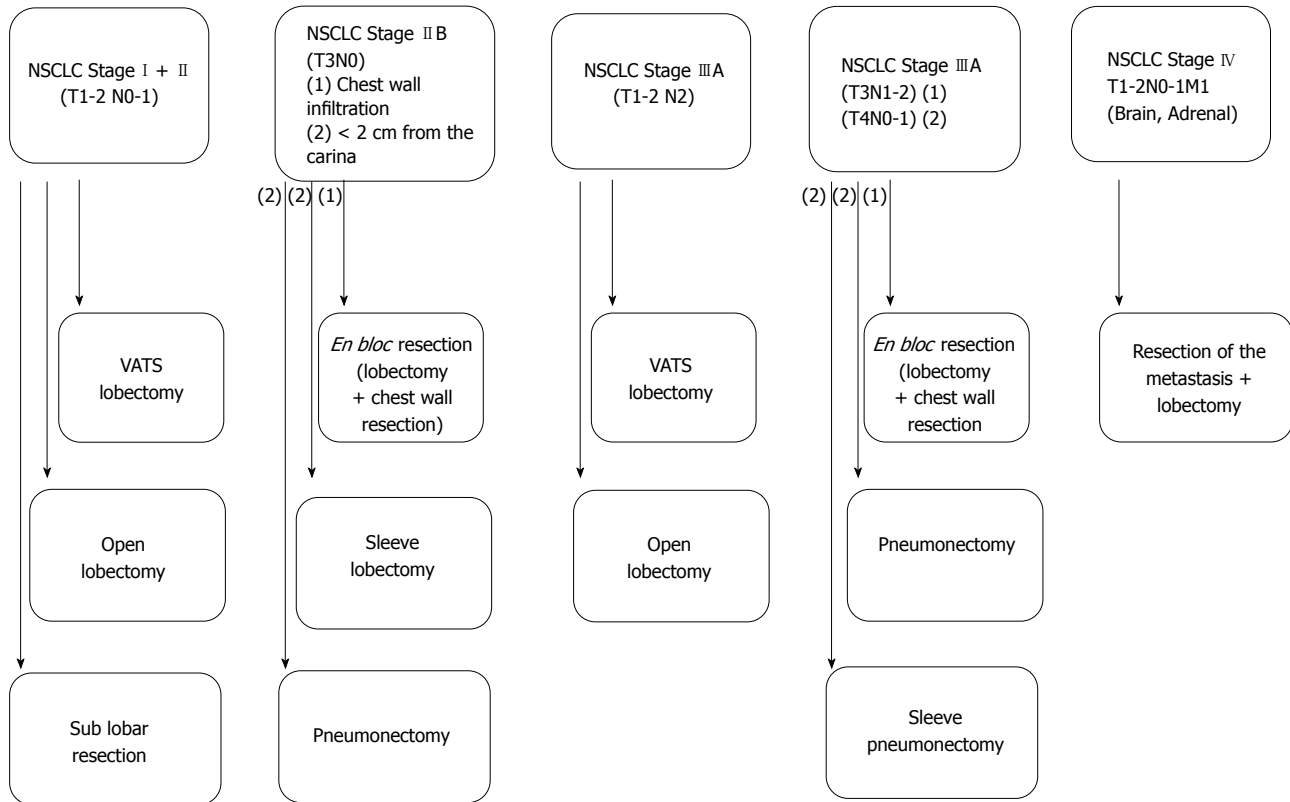

Figure 1 Clinical tumor stages in non-small cell lung cancer and possible surgical treatment options in operable patients. NSCLC: Non-small cell lung cancer; VATS: Video-assisted thoracoscopic surgery.

patients that might not tolerate a complete lobectomy; (2) Patients that could tolerate lobectomy but their tumor size itself might not demand a lobectomy.

As data from randomized trials (other than the LCSG trial^[31]) is still missing, currently it is not clear if sub-lobar resection is really safe enough in patients with contraindication for lobectomy and if it is associated with equivalent oncological long-term results. Perhaps there are some specific tumor characteristics in that a sub-lobar resection should be recommended in particularly. In addition, another point of discussion is the functional benefit achieved by sub-lobar resection compared to complete lobectomy. Interestingly, studies have shown that the difference in the mean reduction of the post-operative FEV1 and FVC ranges from 5%-6%, respectively 1%-6% (Table 1)^[31-33]. As long as it is not proven that the prognostic impact of sub-lobar resection in early stage NSCLC is really equivalent to complete lobectomy, the more invasive procedure should stay the treatment of choice. There are currently 2 randomised controlled trials that may clarify the role of limited resection, *i.e.*, the Cancer and Leukemia Group B 140503 trial (segmentectomy and wedge resection) and the Japan Clinical Oncology Group 0802/West Japan Oncology Group 4607L (segmentectomy) trial^[34,35]. In these trials, selection for limited resection includes tumors 2 cm or less in size, peripheral tumors close to the outer third of the lung and good functional status. Finally, sub-lobar resection should preferably be performed by a segment and not by a wedge

resection as current data in early stage NSCLC patients revealed that a segment resection is associated with a higher cancer-related survival and lower local recurrence rate compared with a wedge resection^[36].

Stage II B (T3N0M0)

Tumor invasion of the chest wall is an uncommon event in NSCLC with only around 5% of all patients. Interestingly, recent studies suggest that a long term survival rate after surgical *en bloc* R0 resection of 40%-50% in case of a T3N0M0 tumor stage can be achieved^[37]. Similar results (40% five-year survival rate in case of a T3N0 status) have been presented by Doddoli *et al.*^[38] in 212 patients with stage II B tumors. At this, the two most important prognostic factors affecting the survival of this patient subgroup are the complete tumor resection and the pathologic nodal status^[39,40].

STAGE III A (T1-2 N2, T3 N1-2, T4N0-1)

Stage III A (T1-2 N2)

Stage III NSCLC includes a heterogeneous population with disease presentation ranging from apparently resectable tumors with occult microscopic nodal metastases to unresectable bulky nodal disease. Patients with T1-2 pN2 tumor stage can be divided into 3 groups: (1) Patients with an unexpected intraoperative finding of a pN2 stage despite the preoperative staging. The reported incidence of an unexpected N2 lymph node status ranges from

Figure 2 Common anatomical tumor locations for bronchoplastic pulmonary resection. Figure from Faber^[91].

4.7% to 26 %^[41-43]. In this subgroup of patients, the surgical resection should be continued, with a lobectomy and LAD. Cerfolio *et al*^[44] reported a 5-year survival rate in patients with unexpected N2 disease who underwent complete resection followed by adjuvant therapy of 35% while patients with single station N2 disease had even a better outcome^[44]; (2) Patients with preoperative evidence of N2 disease based on the CT or PET-CT findings and histopathological confirmation. In this group of patients a multimodality therapy is preferable^[45]. Interestingly, Ripley and Rusch have recently published a review about the role of induction therapy in NSCLC patients. The authors suggest in this review that a multimodality therapy should be the standard care for stage IIIA (N2) NSCLC patients with resection being offered to patients suitable for complete resection^[46]; and (3) Bulky N2 disease. Patients with extensive (bulky) N2 disease should receive a combined radiochemotherapy and only selected cases with good tumor down-sizing should be evaluated for surgical resection. However, for this group of patients just little data about the optimal therapy is currently available^[47].

Stage IIIA (T3N1-2, T4 N0-1)

In case of a chest wall infiltration (T3) a N2 lymph node status should not be considered as a contraindication for surgical resection in terms of lobectomy with partial chest wall resection and MLND or SLNS. The reported 5-year survival rate after complete resection is 21% in T3N2 disease patients^[48].

In case of T4 tumors with invasion of the main carina a sleeve pneumonectomy can be considered and has become an established procedure in carefully selected patients in experienced centers^[49]. While in patients with a complete resection and a post-operative N0 lymph node status the 5-year survival rate ranges between 25%-45%, it is less than 15% in patients with a post-operative N2 disease^[50].

LUNG CANCER SURGERY IN PATIENTS WITH SOLITARY BRAIN OR ADRENAL METASTASIS

Several studies have shown that patients with T1-2 tumors

Table 1 Functional benefit after sub-lobar resection

Ref.	Patients (L/SL)	Mo (follow-up)	Postoperative reduction of FEV1		Postoperative reduction of FVC	
			L	SL	L	SL
Ginsberg <i>et al</i> ^[31]	85/71	12-18	-11%	-5%	-5%	+1%

and simultaneously solitary brain or adrenal metastases seem to benefit from a surgical resection^[51-55]. This special group of patients can undergo a removal of the solitary brain/adrenal metastasis followed by surgical resection of the primary lung tumor. For example, Read *et al*^[51] revealed in 92 NSCLC patients with solitary brain metastases that the 5-year survival rate after curative resection of the lung tumor and brain metastasis was 21%. Similar data were reported by Billing *et al*^[52] in a retrospective analysis of 28 NSCLC patients with solitary brain metastasis undergoing surgical removal of both tumor locations. Also in NSCLC patients with synchronous solitary adrenal metastasis a surgical treatment with resection of the adrenal and lung mass seems to be beneficial especially for patients with a negative lymph node status^[52,54,55].

BRONCHOPLASTIC LUNG RESECTION

Pneumonectomy has been associated with higher morbidity/mortality and a worse 5-year survival rate after resection for NSCLC, compared to lobectomy or less advanced resection techniques^[56-58]. This created the impression that limited anatomical resections in the form of single or double sleeve resections may be beneficial avoiding pneumonectomy related morbidity and mortality. Interestingly, two reviews indicate equivalent survival for patients undergoing either pulmonary sleeve resection or pneumonectomy^[59,60]. Furthermore, there was no difference in the recurrence rate but rather a survival benefit for patients with pN0/1 disease undergoing pulmonary sleeve resection. In fact, the most common anatomical locations for bronchoplastic pulmonary resection involve tumors of the right upper lobe and the left upper lobe orifices (Figure 2)^[61-63]. At this, the bronchial anastomosis is typically covered using pleura, pedicled pericardial fat or pedicled muscle flap to minimize anastomotic complications^[64]. Furthermore, patients undergoing sleeve resection may experience an improved postoperative quality of life compared to patients with a pneumonectomy which was described by Deslauriers *et al*^[65]. Finally, a recent study by Schirren *et al*^[66] showed even in patients with advanced nodal disease no significant advantage for pneumonectomy over sleeve resection.

LYMPHADENECTOMY

Although it is generally accepted that lymph node stag-

ing of NSCLC should be as accurate as possible, there is ongoing debate regarding the extent of mediastinal lymphadenectomy. Worldwide, surgeons use a variety of techniques including selective sampling (sampling involving only selected suspicious or representative lymph nodes), a SLNS (exploration and biopsy of a standard set of lymph node stations in each case) and MLND, which involves the removal of all node-bearing tissue within defined landmarks for a standard set of lymph node stations^[67]. As data have shown that the accuracy of staging in NSCLC patients is more effective with either MLND or SLNS compared with selective sampling alone^[68-70], existing guidelines recommend either one of the methods at the time of surgical resection. Studies have shown that MLND leads to a significant reduction of local and systemic recurrence^[71,72]. Furthermore, another potential advantage of MLND is a more accurate tumor staging through the detection of skip- and micro-metastases^[71,73-75]. Nevertheless, some researchers argue that the improved outcome after MLND is in fact just a stage migration phenomenon (“Will Rogers phenomenon”)^[76,77]. In a retrospective study by Doddoli *et al*^[72] the effect of MLND *vs* SLNS on overall survival of patients with stage I NSCLC was assessed and the working group demonstrated that MLND was a favorable independent prognostic factor. Similar results were reported by Lardinois *et al*^[71] showing a longer disease-free survival in stage I NSCLC patients who underwent MLND *vs* SLNS (60.2 ± 7 *vs* 44.8 ± 8.1 mo).

EXTENDED RESECTIONS, ANGIOPLASTY AND MARGINAL RESECTIONS USING EXTRACORPOREAL MEMBRANE OXYGENATION

It is hypothesized that the need for extended resection in patients with locally advanced NSCLC is associated with a higher morbidity and mortality rate. However, evidence suggests that the mortality rate is not significantly increased after extended resections^[78]. For example, Izbicki *et al*^[78] showed in patients undergoing extended resection for stage T3 or T4 NSCLC tumors that the study patients with no residual tumor had a 3-year survival rate of 33%. In addition, Spaggiari *et al*^[79] reported a 3-year probability of survival of 39% after extended pneumonectomy with partial resection of the left atrium for advanced lung cancer. Even a study from Hillinger *et al*^[80] revealed that patients with T4 tumors (infiltration of great vessels, trachea, esophagus, vertebral bodies, *etc.*) showed an increasing 5-year survival rate from 15 to 35% after radical resection with acceptable preoperative mortality if treated in experienced centres. Extended surgical resections seems also appropriate for patients with locally advanced lung cancer with limited invasion of the carina, left atrium, superior vena cava, or pulmonary artery^[81]. Furthermore, in case of advanced tumor removals with the need of additional pulmonary resection, extracorporeal

membrane oxygenation (ECMO) support is a considered to be a safe alternative to cardiopulmonary bypass after pneumonectomy or even carina resection after pneumonectomy^[82,83]. In the event of a tumor infiltration into the pulmonary artery, a major anatomical lung resection with angioplastic procedures may achieve a similar oncological radicality with sparing distal lung parenchyma. The long term outcomes in these cases are significantly influenced by the nodal status and are comparable to those of conventional lobectomy^[84,85]. Therefore, lung resections with bronchovascular reconstruction are invaluable for patients with central tumours, although they do demand more skill than pneumonectomies. The acceptable clinical results and oncological reliability promote this type of interventions, which always have to be considered for any central tumour in order to avoid pneumonectomy and its complications^[86].

DISCUSSION

Thoracic surgery is a dynamic field with many scientific and technical changes occurred in the last years. A prominent example is the use of less invasive approaches for major resection of NSCLC patients. In fact, it has been proven in early stage NSCLC patients that VATS lobectomy as a routinely performed technical procedure is a method with equal or even better long-term results compared to the well-established open surgical resection.

Sub-lobar resection has its value in the surgical therapy of NSCLC patients with limited lung function. Especially for patients with decreased pulmonary function or comorbid disease and clinical stage I NSCLC a sub-lobar resection should have priority over a conservative treatment. Possible criteria for sub lobar lung resection in early stage NSCLC patients seem to be: (1) limited lung function; (2) tumor diameter ≤ 2 cm; (3) N0 lymph node status; and (4) Frozen section with tumor free edge resection. In case of a sub-lobar resection, segmentectomy should always be preferred rather than a wedge resection. However, a lot of reports about sub-lobar resection combine segmental and wedge resection which seems in our opinion not appropriate as segmentectomy offers the potential advantage of complete resection of lymphatic and vascular drainage.

The ongoing debate about the efficacy of LAD during VATS lobectomy originates mainly from the lack of strict technical standards. The guidelines of the American National Comprehensive Cancer Network recommend the complete dissection of at least three mediastinal lymph node stations^[87]. The European Society for Thoracic Surgery (ESTS) has published similar guidelines advising the removal of at least three lymph node stations including the subcarinal station^[88].

Another issue is the debate about the role of radiation therapy in postoperative N2 disease. Even though some studies suggest that postoperative radiation in case of N2 disease can improve local control, it remains controversial whether it has a prognostic effect^[89]. Based on

the National Cancer Institute of Canada and Intergroup Study, the postoperative radiation may be considered in selected patients to reduce the risk of local recurrence, if any of the following are present: (1) involvement of multiple nodal stations; (2) extracapsular tumor spread^[90].

Finally, multimodality treatment options have been implemented for patients with locally advanced or limited metastatic disease offering more patients a potential complete surgical tumor resection as the operative therapy remains the most important and successful option to really cure NSCLC patients.

that have accumulated in the last ten years on the use of miRNAs as lung cancer biomarkers.

© 2014 Baishideng Publishing Group Inc. All rights reserved.

Key words: Lung cancer; Non-small cell lung carcinoma; MicroRNAs; Biomarkers

Core tip: Biomarkers able to stratify for the subtype of lung cancer, prognosticate the course of disease, or predict the response to treatment are in high demand. In the last decade, microRNAs (miRNAs), measured in resected tumor samples have emerged as biomarkers, due to the ease of their detection and in their extreme specificity. Moreover, miRNAs present in sputum, in plasma, in serum or in whole blood have increasingly been explored in the last five years as less invasive biomarkers for the early detection of cancers.

Abstract

Lung cancer is the leading cause of cancer mortality worldwide. Its high mortality is due to the poor prognosis of the disease caused by a late disease presentation, tumor heterogeneities within histological subtypes, and the relatively limited understanding of tumor biology. Importantly, lung cancer histological subgroups respond differently to some chemotherapeutic substances and side effects of some therapies appear to vary between subgroups. Biomarkers able to stratify for the subtype of lung cancer, prognosticate the course of disease, or predict the response to treatment are in high demand. In the last decade, microRNAs (miRNAs), measured in resected tumor samples or in fine needle aspirate samples have emerged as biomarkers for tumor diagnosis, prognosis and prediction of response to treatment, due to the ease of their detection and in their extreme specificity. Moreover, miRNAs present in sputum, in plasma, in serum or in whole blood have increasingly been explored in the last five years as less invasive biomarkers for the early detection of cancers. In this review we cover the increasing amounts of data

INTRODUCTION

Lung cancer is the leading cause of cancer mortality worldwide^[1]. About 270000 individuals were predicted to die of lung cancer in the European Union in 2013^[2]. This high mortality is due to the poor prognosis of the disease caused by a late disease presentation, tumour heterogeneities within histological subtypes, and the relatively limited understanding of tumour biology. Most lung cancer patients are diagnosed at an advanced stage of disease, and, although a small subsets of these patients can be treated with new drugs offering improved survival and reasonable quality of life, the majority of patients can only be treated with palliative chemotherapy. Overall survival remains poor, and many patients die within a few months

of diagnosis.

Lung cancer is not one, but rather a group of diseases: small cell lung carcinomas (SCLCs) are high grade neuroendocrine tumours (NET), metastasize earlier and are initially more chemosensitive than the so called non-small cell lung carcinomas (NSCLC). Over the past two decades it has become clear that NSCLC itself is a clinically and biologically heterogeneous group of lung cancers, and should not be treated as a single disease entity. The two main subgroups of NSCLC are adenocarcinoma (AD) and squamous cell carcinoma (SCC), with a remaining third class of carcinomas devoid of histological features of adeno- or squamous- differentiation, named LCC (large cell carcinoma)^[3]. The appearance of these tumours at light microscopy differs substantially, suggesting that their aetiology and biology differ as well. Importantly, the histological subgroups of NSCLC respond differently to some chemotherapeutic substances^[4-7] and side effects of some therapies appear to vary between subgroups^[8].

Beside SCLC, NETs include a spectrum of tumors from the low-grade typical carcinoid (TC) and intermediate-grade atypical carcinoid (AC) to the high-grade large-cell NE carcinoma (LCNEC). The distinction between these various entities may be sometimes difficult on histological grounds, but is of great therapeutic relevance.

Biomarkers able to stratify for the subtype of lung cancer, prognosticate the course of disease, or predict the response to treatment are in increasing demand. Lung cancer subtyping has traditionally relied on the histopathological observation of resected specimens, bronchoscopic biopsies, fine needle aspirations or sputum, which represent samples with decreasing invasiveness for the patient, but also of increasing challenge for the pathologist, as proportionally fewer tumour cells are captured^[9-11]. Recently, the introduction of several immunohistochemical markers has rendered lung cancer subtyping more accurate and clinically useful^[12].

In the last decade, microRNAs (miRNAs), measured either from tumour samples or in biofluids, have emerged as biomarkers for tumor diagnosis, prognosis and prediction of response to treatment. In the following pages we will review the increasing amounts of data that have accumulated in the last ten years on the use of miRNAs as lung cancer biomarkers.

MIRNAS AND CANCER

microRNAs (miRNAs or miRs) are small non-coding single-stranded RNAs, 19-25 nucleotides (nt) in length, acting as negative regulators of gene expression at the post-transcriptional level. More than 1000 miRNAs are transcribed from miRNA genes in the human genome. A single miRNA is able to modulate hundreds of downstream genes by recognizing complementary sequences in the 3'UTRs of their target mRNAs. It has been estimated that in humans about 30% of messenger RNAs (mRNAs) are under miRNA regulation, but this percent-

age is likely to grow in the future, as studies have shown that miRNAs can also bind target sequences located in the 5' UTR or in the open reading frame (ORF)^[13]. The biological functions of miRNAs are diverse and include several key cellular processes, such as differentiation, proliferation, cellular development, cell death and metabolism.

In a seminal paper the Croce laboratory showed in 2002 that the genes for miR-15 and miR-16 are deleted or down-regulated in the majority of chronic lymphocytic leukaemia cases^[14]. Scott Hammond, Gregory Hannon and collaborators demonstrated that miRNAs can modulate tumour formation and implicated the mir-17-92 cluster as a potential human oncogene in another fundamental paper^[15], in which they demonstrated that enforced expression of the mir-17-92 cluster acts with c-myc expression to accelerate tumour development in a mouse B-cell lymphoma model. Since then, evidences have accumulated to indicate that miRNAs play a role in the onset and progression of several human cancers^[16]. The transcription or processing of some miRNAs is altered in neoplastic tissues, in respect to their normal counterparts. miRNAs whose levels increase in tumors are referred to as oncogenic miRNAs ("onco-miRs"), sometimes even if there is no evidence for their causative role in tumorigenesis. On the other hand, miRNAs down-regulated in cancer are considered tumor suppressors. From the mechanistic point of view, it is important to understand how these variations may contribute to tumor progression.

In 2005, the Horvitz and Golub labs demonstrated the potential for miRNAs as diagnostic tumor markers, when they were able to indicate the tumor embryonic origin using miRNA expression profiles, successfully classifying poorly differentiated tumors, among which lung tumors^[17]. Subsequently, the Croce lab performed a large-scale miRNome analysis on 540 samples including lung, breast, stomach, prostate, colon, and pancreatic tumors, and identified a solid cancer miRNA signature composed by a large portion of over-expressed miRNAs. While some miRNAs were commonly dys-regulated in the six cancer types, several other miRNAs were associated to a particular type of cancer^[18]. The utility of miRNAs levels as diagnostic and prognostic biomarkers became clear already from these first studies^[19]. Moreover, the effectiveness of miRNAs as biomarkers for tracing the tissue of origin of cancers of unknown primary origin was demonstrated by Rosenfeld and colleagues^[20], who constructed a tissue classifier based on the measurement of 48 miRNAs on a microarray, to identify the tissue origin of metastatic tumors. These results were translated into a qRT-PCR platform, to develop a diagnostic test for the identification of tumour tissue origin^[21]. The classifier has been further implemented in a second-generation custom microarray based on the measurement of 64 miRNAs^[22] the usefulness of which as a diagnostic tool was very recently confirmed^[23].

A different 47-miRNA signature for the identification

of cancers with unknown primary tissue-of-origin was identified by other authors using a different microarray platform^[24].

MIRNAS AND LUNG CANCER

As far as lung cancers are concerned, the role of miRNAs in lung carcinogenesis was indicated as early as 2004, when the Croce lab demonstrated that more than half of the miRNA genes then known were located in cancer-associated genomic regions or in fragile sites and that several miRNAs located in this deleted regions have low expression levels in lung cancer cell lines as well as in chronic lymphocytic leukaemia samples^[25]. In the same year, Takamizawa and colleagues reported reduced expression of the let-7 microRNA in human NSCLC lung cancers^[26], followed by several independent studies^[27-29]. The let-7 family was later shown to have an onco-suppressor activity in NSCLC tumor development in mice xenografts^[30]. One of the consequences of let-7a down-regulation in lung cancer has been demonstrated to be the upregulation of RAS protein^[27]. A single nucleotide polymorphism (SNP) in a let-7 complementary site of KRAS mRNA was found to be associated with increased risk of NSCLC in moderate smokers^[31]. Based on *in vitro* experiments and analyses of patient samples the authors concluded that this SNP alters the ability of let-7 to regulate translation of KRAS, leading to overexpression of KRAS and increased lung cancer risk.

Other miRNAs may also interact with RAS. For instance, Wang *et al.*^[32] found that miR-451 is downregulated in NSCLC, and that low expression correlated with poor survival. The authors were able to show that miR-451 inhibits the expression of ras-related protein 14 (RAB14), suggesting that lower expression of miR-451 may allow this oncogene to escape regulation.

The oncogenic miR-17-92 cluster is markedly overexpressed in lung cancers, especially with SCLC histology and enhances cell proliferation *in vitro*, therefore possibly playing a role in the development of lung cancers^[33]. On the other hand, deletion of the miR-17-92 cluster, in mice, is lethal and causes lung and lymphoid cell developmental defects^[34].

The tumor suppressor protein p53 is mutated in a large number of lung cancer cell lines and tumour specimens from patients with lung cancer^[35,36]. There is growing evidence that p53 regulates the expression of several miRNAs^[37-42]. p53 directly regulates the expression of miR-34 family members, and the upregulation of these miRNAs result in the downregulation of genes associated with cell cycle control^[37] and promotion of apoptosis^[40] in cultured lung cancer cells. Further miRNAs, including miR-125a, have more recently also been linked to p53-regulated apoptosis in lung cancer cells^[41].

METHODS FOR THE QUANTIFICATION OF MIRNAS

The main advantage of the use of miRNAs as biomarkers

resides in the ease of their detection and in their extreme specificity. miRNAs are stable molecules well preserved in formalin fixed, paraffin embedded tissues (FFPE) as well as in fresh snap-frozen specimens, unlike larger RNA molecules as mRNAs^[43].

A range of methods has been used for the isolation and profiling of miRNAs. Purification of total RNA is obtained either through several commercially available column filtration protocols, implemented to guarantee recovery of miRNAs, or via the extraction of RNA by variously named "Tri-reagents" (acid phenol in combination with guanidinium-thiocyanate and chloroform), also available from vendors. Given that the interest is focused on the quantification of specific miRNAs in different conditions, the method of choice should exclude any bias in the purification of miRNAs from the samples. Importantly, the Kim laboratory has recently reported that, differently from what everybody in the field has thought for decades, in Tri-reagents-based RNA purification protocols, short structured miRNAs with low GC content are lost when a small number of cells are used^[44]. The finding raises warning flags about comparisons of miRNA levels between populations of cells at different densities.

Sequencing-, microarray- and quantitative reverse-transcription polymerase chain reaction (qRT-PCR)-based methods are currently used for miRNA profiling.

Next generation sequencing (NGS)^[45], providing accurate and sensitive miRNAs measurements, allows the identification of miRNAs differently expressed in tumor samples and matched healthy tissue. Furthermore, NGS enables scientists to discover novel miRNAs, as opposed to microarrays and qRT-PCR methods, which only can detect already known miRNAs. NGS techniques are rapidly evolving in power and multiplexing capacities, but they remain expensive and labor-consuming, both in sample preparation and data analysis.

The majority of miRNA profiling studies have been carried out so far using microarrays and have provided signatures consisting in few to several (5-30) distinct miRNAs^[46]. With time, it has become clear in the field that the use of microarrays for miRNA profiling presents with major problems of cross-hybridisation between members of miRNA families and discrepancies in comparing results obtained with different microarray platforms^[47-50]. A common strategy is to validate the microarray data by qRT-PCR, which warrants high sensitivity and specificity.

Additionally, the analysis of a great number of genes including ones whose changes are not directly or indirectly associated with cancer, in clinical settings is not necessary. Hence, the large amount of data obtained by microarray and NGS profiling needs to be transposed into clinical trials by developing an easily performed and serviceable assay that can analyze the cancer-specific miRNAs for cancer diagnosis and prognosis. Such an analysis has been so far relying on qRT-PCR assays.

Several methods for the analysis of miRNAs by qRT-PCR have been devised^[60] and companies are providing

multiwell plate-based qRT-PCR assays that promise to substitute microarrays in the high-throughput profiling of miRNAs. Additionally, qRT-PCR is the most easily performed and cost-effective technique and it is therefore the method of choice when it comes to measuring the levels of the restricted number of miRNA biomarkers in cancer samples, in the clinical setting.

qRT-PCR measures the relative levels of variable target miRNAs in comparison with one or more stably expressed reference genes (sometimes called housekeeping or endogenous control genes). This normalization is required to allow for variability in RNA quantity and quality and/or in the efficiency of cDNA synthesis. Despite miRNAs having been intensively studied in cancer research in the last years, suitable reference genes for relative quantification of miRNA levels in qRT-PCR assays have not been satisfyingly identified. Ribosomal RNAs (rRNAs) have been used as a reference RNA in miRNA studies^[26,61]. However, concerns have been raised regarding the use of rRNAs in normalization, as they can be expressed at much higher levels than the target RNA, making it challenging to quantify an rRNA and a rare transcript in the same RNA dilution. Moreover, there is evidence of rRNA deregulation in apoptosis^[62] and cancer^[63]. The most commonly used reference RNA in miRNA qRT-PCR experiments is the small nuclear RNA U6 (U6 snRNA)^[55,64]. However, using U6 snRNA to normalise miRNA levels is controversial because being much bigger in size (106-107 nt) it might differ from miRNAs with respect to efficiency of its extraction, reverse transcription and PCR amplification. U6 snRNA has been analysed as a reference gene for miRNA studies in several papers, and most of them came to the conclusion that the variance of U6 expression across tissues is high, therefore making U6 not a suitable reference gene for miRNA quantification^[65-67]. Further reference genes commonly used are snoRNAs but they too might be dys-regulated in cancer^[68]. Several authors have suggested to use as reference a combination of miRNAs whose levels do not vary in the specific tumor tissue under investigation. For example, in fresh-frozen lung cancer samples, Peltier and Latham^[65] suggest the use of a combination of miR-191 and miR-103.

The use of unvalidated and different reference genes makes it difficult to compare papers describing miRNA-expression cancer profiles and might represent one of the major reasons for the discrepancies in published studies regarding differentially expressed miRNAs in specific cancers.

A recent addition to the detection methods for miRNAs is droplet digital PCR (dPCR)^[69], a method especially useful for low abundance miRNAs. In droplet dPCR, single cDNA molecules are partitioned evenly among hundreds of individual droplets in which they are amplified to generate binary calls. With this method an absolute readout of total DNA copy number can be obtained, avoiding the need for an endogenous reference gene.

MIRNAS FROM RESECTED SPECIMENS

MiRNAs as biomarkers for the diagnosis of lung cancer and for stratifying lung cancer subtypes

In 2005, the Horvitz and Golub labs used a bead-based flow cytometric miRNA expression method to identify complex profiles consisting of approximately a hundred of dys-regulated miRNAs, able to classify 11 different tumor types, among which lung tumors^[17]. Subsequently, the Croce lab used a custom-made oligonucleotide miRNA microarray to compare lung carcinomas to normal tissue, and identified a group of three downregulated and 35 upregulated miRNAs. Among these, miR-21 was commonly up-regulated in the six cancer types analyzed (lung, breast, stomach, prostate, colon, and pancreatic tumors) and miR-17-5p, miR-128b, miR-155, miR-191 and miR-199a-1 were up-regulated in at least other two cancer types^[18].

In 2006 Yanaihara *et al.*^[28] compared the miRNAs expression profiles in 104 pairs of lung cancer tissues and corresponding non-cancerous lung tissue, by the same custom-made oligonucleotide miRNA microarray used by Volinia and colleagues. They identified a unique profile made of 43 differently expressed miRNAs (Table 1) allowing the distinction of lung cancer from the non-cancerous lung tissue. Of the 15 upregulated and 28 downregulated miRNAs, miR-21 and miR-205 are located in a chromosomal region amplified and miR-32, miR-126-5p and miR-126-3p in a region deleted in lung cancers, respectively. The authors next validated the microarray results by a solution hybridization detection method and by qRT-PCR, confirming that miR-21 and miR-205 are frequently up-regulated and miR-126-5p is often down-regulated in lung cancer tissues when compared with the corresponding noncancerous lung tissues.

Comparison analyses between ADC *vs* noncancerous tissues and SCC *vs* noncancerous tissues revealed 17 and 16 miRNAs with statistically different expression, respectively (Table 1). Six miRNAs (miR-21, miR-155, miR-191, miR-126-5p, miR-210 and miR-224) were shared in both histological types of NSCLC. Yanaihara and colleagues also directly compared the two most common histological types of NSCLC, identifying two miRNAs (miR-99b and miR-102) that were higher in ADC and 4 miRNAs (miR-202, miR-203, miR-205 and the precursor of miR-204) that were higher in SCC. However, the authors do not explore further the issue of distinguishing ADCs from SCCs, in this paper.

Decreased expression of miR-107, miR-185 and let7a, and the overexpression of miR-31a, was observed by qRT-PCR in lung cancer tissues and cell lines, compared to normal lung tissue^[70]. Landi *et al.*^[71] reported 34 miRNAs that significantly differentiated SCCs from ADCs in male smoker patients, of which 2 were downregulated and 32 upregulated in ADC *vs* SCC. Raponi *et al.*^[72] used Ambion microarrays to profile total RNA from 61 SCC samples and 10 matched normal lung samples and identified 15 miRNAs that were differentially expressed

between normal lung and SCC (Table 1). Two of these miRNAs were down-regulated in SCCs (miR-125a and let7e) while the remaining 13 miRNAs were upregulated (miR-17-5p, miR-20a, miR-20b, miR-93, miR-106a, miR-106b, miR-182, miR-183, miR-200a, miR-200c, miR-203, miR-210, miR-224). More recently, a 5-miRNA classifier was identified by microarray analysis (miR-30a, miR-140-3p, miR-182, miR-210, miR-486-5p) that could distinguish stage I-III SCC from normal lung tissues^[73]. This classifier had an accuracy of 94,1% in a training cohort (34 patients) and 96,2% in a test cohort (26 patients).

A panel of 16 miRNAs has been reported to differentiate between primary lung tumors and metastases to the lung of various origin (Table 1)^[74]. This miRNA profile was identified using microRNA microarray data generated from FFPE samples, and was confirmed by qRT-PCR. The panel includes miR-182, which was most strongly

over-expressed in the lung primary tumors, and miR-126, which was over-expressed in the metastatic tumors.

Researchers have also aimed at finding one or few miRNAs that can be used as a convenient tool for lung cancers diagnosis. Lebanony *et al.*^[75] used a microarray to measure miRNA levels in AD and SCC FFPE samples, and verified their findings by qRT-PCR. They identified miR-205 as a highly specific marker for SCC, when combined with the measured miR21 levels. The finding was confirmed by other papers^[76,77]. Moreover, an algorithm for accurate classification of NSCLC cases, diagnosed as LCC on purely morphologic grounds, was proposed by integrating immunohistochemical markers (Δ np63, DSC3, and napsin A) with miR-205 and miR-21 measurement^[78].

Evaluating by qRT-PCR FPPE specimens from NETs, Lee *et al.*^[79] found that the levels of miR-21 and

miR-155 were significantly higher in high-grade NET carcinomas (LCNECs and SCLCs) than in carcinoid tumors (TCs and ACs).

Two microRNA panels yielded high diagnostic accuracy in discriminating SCLC from NSCLC (miR-29a and miR-375) and in differentiating SCC from AD (miR-205 and miR-34a) in FFPE surgical lung specimens^[80]. Moreover, the same microRNA panels accurately differentiated SCLC from NSCLC and SCC from AD in bronchial brushing specimens.

Gilad *et al.*^[81] reported a single assay for the classification of the four main types of lung cancer (Table 1): carcinoid, SCLC, and squamous and nonsquamous NSCLC, based on the expression of eight miRNAs (miR-7, miR-21, miR-29b, miR-106a, miR-125a-5p, miR-129-3p, miR-205, miR-375). The assay was effective both on resected and on cytologic (fine-needle aspiration (FNA) and bronchial brushing and washing) lung cancer samples.

A recent study has also evaluated miRNAs in FNA NSCLC biopsies^[82]. miR-21, miR-155, and miR-7 showed a higher level in tumoral FNA than in normal FNA specimens, while let7a showed a lower level. A direct comparison of FNAs with resected specimens from the same patients indicated that the measured miRNAs had the same trend in the two types of specimens.

miRNAs as biomarkers for lung cancers prognosis

Reduced expression of the let-7 family has been correlated with poor postoperative survival in NSCLC^[26]. In a later study, AD patients with high expression of either miR-155, miR-17-3p, miR-106a, miR-93, or miR-21 and low expression of either let-7a-2, let-7b, or miR-145 were found to have a significantly worse prognosis (Table 2)^[28]. Overexpression of the precursor of miR-155 and reduced expression of let-7-a was especially predictive of poor survival.

Analyzing frozen resected specimens from NSCLC patients, Yu *et al.*^[83] identified a five-microRNA signature that can predict the survival and relapse of patients with lung cancer (Table 2). Two of these miRNAs (miR-221 and let-7a) were protective (*i.e.*, their down-regulation correlated with poor survival and high relapse probability), while the other three (miR-137, miR-182-3p, miR-372) were risky, and their up-regulation was predictive of poor survival and high relapse probability. The authors also demonstrated that miR-221, miR-137, miR-182-3p and miR-372 can alter the invasive ability of lung cancer cells in culture.

In the already described work by Raponi *et al.*^[72]. Twenty miRNAs were identified as having a significant association with overall survival in lung SCC patients (Table 2). Among these miRNAs, miR-146b alone was found to have the strongest prediction accuracy as the group with high miR-146b expression had significantly worse overall survival.

The p53-dependent miR-34 family was observed to be down-regulated in surgically resected NSCLC tumor

samples compared with normal tissue, and low levels of miR-34a expression were correlated with a high probability of relapse^[84]. MicroRNA expression profiles were also identified that may predict recurrence of localized stage I NSCLC after surgical resection^[85]. These profiles included miR-124-5p, miR-146b-3p, miR-200b-5p, miR-30c-1-3p, miR-510, miR-585, miR-630, miR-657 and miR-708 (Table 2).

High miR-16 levels, measured by qRT-PCR in resected NSCLC samples, were reported as a prognostic factor for poor disease-free survival and poor overall survival^[86]. Low miR-145 and high miR-367 are associated with shorter time to relapse (TTR) in resected NSCLC^[87]. Noteworthy, p53 regulates miR-145 expression, which, in turn, inhibits the translation of SRY-related HMG box (SOX)2 and octamer-binding transcription factor (OCT)4. These transcription factors control the expression of the miR-302-367 cluster.

In a panel of 27 miRNAs which were observed by microarray analysis to be deregulated greater than two-fold in NSCLC resected samples compared to normal lung tissue, Gao *et al.*^[88] identified three miRNAs whose levels (confirmed by qRT-PCR) were related to clinicopathologic characteristics or patient prognosis: low levels of miR-143 were significantly correlated with smoking status, high miR-21 expression and low miR-181a expression were associated with poor survival.

The lower expression level of a 5-miRNA signature (miR-25, miR-34c-5p, miR-191, let-7e, and miR-34a) correlated with poor overall survival among SCC patients (Table 2)^[71] and high expression of miR-31 was associated with poor survival in Chinese SCC patients^[73].

Eight miRNAs were confirmed to be significantly differentially expressed in NSCLC FFPE samples from patients with brain metastases compared with patients without brain metastases (Table 2)^[89]. In particular, in this work, the over-expression of miR-328 and miR-330-3p was indicated as a marker for patients at risk for brain metastases, and a role for miR-328 in conferring migratory potential to NSCLC cells was suggested.

miRNAs as biomarkers to predict response to therapy in lung cancer

miRNAs have also been used as biomarkers predictive of patient's response to therapy. miR-21 expression was significantly increased in platinum-based chemotherapy-resistant NSCLC patients and increased miR-21 expression was associated with the shorter disease-free survival^[90]. A single nucleotide polymorphism in *miR-196a-2* gene was reported to be associated with severe toxicity after platinum-based chemotherapy of advanced NSCLC patients in a Chinese population^[91].

Recent therapeutic advances for the treatment of NSCLC include the use of epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKIs) including gefitinib and erlotinib. MiRNA-128b was shown to directly regulate EGFR translation and miR-128b LOH was found to be frequent in NSCLC samples and cor-

Table 2 MiRNAs as biomarkers for the prognosis and to predict response to therapy

miRNA	Experiment	Scope	Sample	Ref.
let-7a family (DOWN)	lung cancer tissue <i>vs</i> normal	NSCLC poor postoperative survival	Solid, (not specified)	[26]
mir-155, mir-17-3p, mir-106a, mir-93, mir-21 (UP)	AD <i>vs</i> SCC	AD poor survival	Solid, (not specified)	[28]
let-7a-2, let-7b (DOWN)				
miR-221, let-7a (DOWN) miR-137, miR-182-3p, miR-372 (UP)	NSCLC <i>vs</i> normal	NSCLC poor survival	Solid, snap frozen	[83]
miR-146b, miR-191, miR-155, miR-15a, miR-511, miR-100, miR-10a, miR-21, miR-126 (UP) miR-206, miR-299-3p, miR-122a, miR-513, miR-184, miR-453, miR-379, miR-202, miR-494, miR-432, miR-370 (DOWN)	SCC <i>vs</i> normal	SCC Overall Survival	Solid, snap frozen	[72]
miR-34a (DOWN)	NSCLC <i>vs</i> normal	NSCLC Probability of relapse	Solid, (not specified)	[84]
mir-124-5p, mir-146b-3p, mir-200b-5p, mir-30c-1-3p, mir-510, mir-585, mir-630, mir-657, mir-708 (relative expression)	stage I NSCLC <i>vs</i> normal	Stage I NSCLC recurrence	Solid, formalin-fixed, paraffin-embedded (FFPE)	[64]
miR-16 (UP)	NSCLC <i>vs</i> normal	NSCLC poor survival	Solid, (not specified)	[86]
miR-143 (DOWN)	Lung cancer tissue <i>vs</i> normal	smoking status	Solid, snap frozen	[88]
miR-21 (UP) miR-181a (DOWN)	Lung cancer tissue <i>vs</i> normal	NSCLC poor survival	Solid, snap frozen	[88]
miR-25, miR-34c-5p, miR-191, let-7e, miR-34a (DOWN)	AD <i>vs</i> SCC	SCC survival	Solid, formalin-fixed, paraffin-embedded (FFPE)	[71]
miR-31 (UP)	SCC <i>vs</i> normal	SCC poor survival	Solid, snap frozen	[73]
miR-325, miR-326, miR-328, miR-329-2-pre, miR-330-3p, miR-500a-3p, miR-370, miR-650-pre (UP)	BM – NSCLC <i>vs</i> BM + NSCLC	NSCLC, risk for brain metastasis	Solid, formalin-fixed, paraffin-embedded (FFPE)	[89]
miR-21 (UP)		Platinum-based chemotherapy-resistant NSCLC patients	Solid, snap frozen	[90]
miR-196a-2 SNP	Treatment <i>vs</i> genotype	Severe toxicity after platinum-based chemotherapy of advanced NSCLC patients	Genomic DNA from peripheral leukocytes	[91]
miR-128b (UP)		NSCLC samples correlated with clinical response and survival following gefitinib treatment	Microdissected primary surgically resected NSCLC tumors	[92]
miR-30b, miR-30c		Regulated by EGFR and hepatocyte growth factor (MET) receptor tyrosine kinase	Solid, Lung tumor tissue samples	[93]
miR-30b, miR-30c		Prognostic predictors in NSCLC patients who underwent first line treatment with TKIs	Solid, formalin-fixed, paraffin-embedded (FFPE)	[94]

NSCLC: Non-small cell lung cancer; AD: Adenocarcinoma; SCC: Squamous cell carcinoma; BM: Brain metastasis.

related significantly with clinical response and survival following gefitinib treatment^[92]. miR-30b and miR-30c expression levels, which are regulated by EGFR and hepatocyte growth factor (MET) receptor tyrosine kinase^[93] have been reported to be prognostic predictors in NSCLC patients who underwent first line treatment with TKIs^[94].

MIRNAS IN SPUTUM AS NON-INVASIVE LUNG CANCER BIOMARKERS

An early diagnosis of cancer remains a challenge and, in this context, it is important to find a sensitive, non-invasive tool to detect early neoplastic changes. One relatively non-invasive source of miRNAs for the diagnosis of lung cancers is sputum^[95]. The Jiang laboratory demonstrated that endogenous miRNAs are stably present in sputum specimens. Using qRT-PCR, miR-21 and miR-155 were detected, of which miR-21 was significantly overexpressed in sputum of NSCLC patients as

compared with cancer-free subjects^[96]. Furthermore, elevated miR-21 expression was more sensitive (70%) than conventional sputum cytology (48%) in diagnosing lung cancer. The same research group defined miRNA signatures for different histologic types of lung cancer in studies of similar design^[97,98]. For the diagnosis of SCC, the combination of miR-205, miR-210 and miR-708 yielded 73% sensitivity and 96% specificity. A panel consisting of miR-21, miR-200b, miR-375 and miR-486 produced 81% sensitivity and 92% specificity in discriminating sputum of AD patients from controls. The authors found no association between miRNA expression and stage of lung cancer, suggesting that the miRNA signatures can be used as a tool in the detection of early lung cancer. The same group recently reported that combined quantification of miR-31 and miR-210 copy number by digital PCR in sputum of the cases and controls provided 65.71 % sensitivity and 85.00 % specificity for stage I NSCLC diagnosis^[99]. Very recently, the same authors also reported that combining miR-31 and miR-210 detection by qRT-

PCR and Computed Tomography they improved NSCLC diagnosis specificity^[100].

In an independent study, a five-miRNA profile (miR-21, miR-143, miR-155, miR-210, miR-372) performed by qRT-PCR on sputum samples detected NSCLC with 83.3% sensitivity and 100% specificity^[101].

CIRCULATING MIRNAS

First evidences

The finding that miRNAs have an exceptional stability in several tissues suggested that these tiny molecules were also preserved, detectable and quantifiable in the circulation and in other biofluids.

The first indication of circulating microRNAs with a potential as non-invasive diagnostic biomarkers for diffuse large B-cell lymphoma (DLBCL) and possibly other cancers was found by Lawrie *et al.*^[102]. These authors were the first to highlight that miRNAs could be reliably detected in serum and they demonstrated that high levels of miR-21, miR-210 and miR-155 could discriminate cancer patients with (DLBCL) from healthy individuals. Plasma miRNAs were observed to be present in a remarkably stable form that is protected from endogenous RNase activity^[103]. These papers established the measurement of tumor-derived miRNAs in serum or plasma as an important approach for the blood-based detection of human cancer. Further studies demonstrated that microRNAs are also preserved and detectable in other biofluids such as urine, saliva, cerebro-spinal fluid and amniotic fluid^[104] and their composition and concentrations are measurably different among these fluids^[105].

On the origin of circulating miRNAs

miRNAs can be released in the circulation by two different pathways: energy-free passive release or active and selective secretion in response to different stimuli. The first process does not need energy, it occurs after cell breakage in pathological conditions such as tissue damage, apoptosis, metastasis or inflammation but it does not play a major role in the generation of circulating miRNAs^[106]. miRNAs active secretion, differently from the passive leakage, is a process ATP- and temperature-dependent. It is similar to the release of hormones and cytokines, with or without cell stimulation^[106].

Circulating miRNAs can be packaged in microvesicles (MVs) or apoptotic bodies (ABs) or can be found as microvesicle-free miRNAs, associated with various multi-protein or lipoprotein complexes.

MVs are small vesicles derived from cells, generally including microparticles (MPs) and exosomes. These two kinds of MVs have quite different vesicular structures: exosomes (50-90 nm), with an endocytic origin, are released by fusion of multivesicular bodies (MVBs) with the plasma membrane^[107]. They have been identified in various body fluids such as blood, urine, malignant ascites, bronchoalveolar lavage fluid, synovial fluid, breast milk and saliva^[108]. MPs, on the other hand, are larger

than exosomes (> 100 nm diameter) and are shed from plasma membranes^[109]. Almost all cell types can release MVs under normal physiological or pathological conditions.

Larger in size than MPs, ABs are generated in response to apoptotic stimuli^[110] and implicated in tissue repair and angiogenesis.

It has been demonstrated that MVs and ABs are involved in the transport of circulating miRNAs^[111-114]. Gibbings *et al.*^[115] showed that miRNAs loading into exosomes is not a random event, but it is mediated by proteins as Argonaute protein Ago2, a part of RNA-induced silencing complex.

On the other hand, several studies suggested that a significant fraction of extracellular miRNAs resides outside of vesicles and acts in exosome-independent manner, by its association with RNA-binding proteins including Ago2 and Nucleophosmin 1 (NPM1) or lipoprotein complexes such as high-density lipoprotein (HDL). Arroyo *et al.*^[116] showed that miRNAs in plasma are predominantly free of exosomes or microvesicles. They demonstrated an association of miRNAs with Ago2 protein, showing that this binding protects and increases the stability of released miRNAs^[116]. Turchinovich *et al.*^[117] confirmed this hypothesis and demonstrated that also additional Argonaute proteins (Ago1, -3, -4) may be associated with cell-free circulating miRNAs. Wang *et al.*^[118] found that other RNA binding proteins, such as NPM1, can protect miRNAs from degradation, playing a role in the packaging and export of circulating miRNAs. Vickers *et al.*^[119] in 2011 revealed a potential new role for HDL in gene regulation and intercellular communication, showing that this lipoprotein transports and delivers miRNAs to recipient cells.

Circulating miRNAs as cancer biomarkers

It has been shown that miRNAs present in body fluids can reflect altered physiological conditions, representing new effective biomarkers^[104].

A perfect biomarker should have some important features: non-invasivity, specificity, early detection, sensitivity and ease of translatability from model systems to humans.

Proteins used as blood biomarkers (*e.g.*, troponin for cardiovascular conditions, carcinoembryonic antigen (CAE) for various cancers, prostate specific antigen (PSA) for prostate cancer, and aminotransferases for liver function) do not respect all these criteria and are difficult to use in this field. On the contrary, secreted miRNAs have many of these requisites: they are stable in various biofluids, the expression of some miRNAs is specific to tissues or biological stages, and their level can be easily detected by various methods.

However, several challenges have to be overcome in order to successfully use circulating miRNAs as cancer biomarkers. First, biofluids contain very low amount of RNA, and normal quantification methods are not suitable for these type of samples. Second, it is important

to avoid cellular contamination and hemolysis and third, biofluids contain inhibitors of reverse transcriptase and polymerase enzymes used for miRNAs quantification. All these factors are obstacles to consider when circulating miRNAs are isolated and quantified from biofluids such as plasma or serum. Another major challenge for the analysis of circulating miRNAs is the choice of an appropriate reference gene, since some of the small RNA species frequently used as reference genes (such as U6 RNA) are present in extremely low concentrations in serum and plasma as well as in other biofluids. Moreover, normalization controls used to remove variations and increase the accuracy of miRNAs quantification cannot ensure constant expression under all experimental conditions, underlining the importance of the selection of a proper reference gene.

Chen *et al.*^[120] reported that U6 and 5S rRNA are degraded in serum samples from lung cancer patients, and miR-16 is inconsistent, choosing to normalize the level of circulating miRNAs to total RNA. In a study on sera from Hepatitis B infected patients and matched controls, snRNA U6-1 is found to have high variability and snRNA U6-2 is not detectable. In this type of samples the combination of miR-26a, miR-221, and miR-22* is recommended as the most stable set of reference genes for circulating miRNAs evaluation^[121]. Similarly, U6-2 is inconsistent in serum from gastric cancer patients and healthy controls. In this study, authors recommend the combined use of miR-16 and miR-93 as suitable reference genes^[122]. On the contrary, in serum from uro-oncological patients, U6-2 is detectable and rather consistent^[123]. snoRNA U44 levels are similar in sera from breast cancer patients and from age-matched healthy women, differently from miR-16 and 5S rRNS that show remarkable variability in the same samples. Surprisingly, snRNA U6-1 serum levels are found consistently higher in breast cancer patients compared to healthy controls, not only confirming that U6 is not an appropriate reference gene, but also indicating an interesting new paradigm in cancer^[124]. Finally, Sourvinou and colleagues showed that a combined use of endogenous miR-21 and miR-16 and exogenous cel-miR-39, compensates differences in miRNAs recovery and differences in cDNA synthesis between samples. Using this normalization procedure and miR-21 as a biomarker, it seems possible to clearly discriminate healthy individuals from NSCLC patients^[125].

Circulating miRNAs as lung cancer biomarkers

The Jiang laboratory found that miR-155, miR-197 and miR-182 can be potential biomarkers for early detection of lung cancer with 81.33% sensitivity and 86.76% specificity (Table 3). The levels of these miRNAs in plasma of NSCLC patients are elevated compared with healthy controls^[126]. The same group demonstrated that another set of plasma miRNAs (miR-21, miR-126, miR-210, and miR-486-5p), had 86.22% sensitivity and 96.55% specificity in distinguishing NSCLC patients from the healthy

controls (Table 3). Furthermore, the panel of four miRNAs produced 73.33% sensitivity and 96.55% specificity in identifying stage I NSCLC patients. The miR panel had higher sensitivity (91.67%) in diagnosis of AD compared with SCC (82.35%)^[127]. Authors from the Jiang lab recently reported that quantification of the plasma miR-21-5p and miR-335-3p by digital PCR provided 71.8% sensitivity and 80.6% specificity in distinguishing lung cancer patients from cancer-free subjects (Table 3)^[128].

Tang *et al.*^[129] reported that higher plasma miR-21 and miR-155 and lower plasma miR-145 expression levels distinguish lung cancer patients from healthy smokers with 69.4% sensitivity and 78.3% specificity (Table 3). Levels of miR-361-3p and miR-625-3p might have a protective influence on the development of NSCLC, and the quantification of these miRNAs in serum could be useful for the diagnosis of NSCLC, in particular in smokers^[130]. A study reported that the expression of miR-146b, miR-221, let-7a, miR-155, miR-17-5p, miR-27a and miR-106a is significantly reduced in sera of NSCLC cases, while miR-29c is significantly increased (Table 3). Unexpectedly, no significant differences were observed in plasma of patients compared with controls^[131].

Bianchi *et al.*^[132] provided an evidence that some serum-circulating miRNAs are important to identify asymptomatic high-risk individuals with early stage lung cancer (Table 3). Between others, they highlighted the importance of let-7 family, members of miR-17-92 cluster, miR-126 and miR-486 in sera of NSCLC patients^[132].

Recently, qRT-PCR was used to assess miR-205-5p, miR-205-3p, and miR-21-3p expressions in serum and tissue samples (Table 3)^[133]. The relative expressions of miR-205-5p and miR-205-3p were significantly higher in NSCLC tissues compared with cancer-adjacent paired specimens. In the serum, significantly higher miR-205-5p, miR-205-3p, and miR-21-3p relative expressions were observed in the NSCLC group compared with healthy volunteers or patients diagnosed with a benign lung disease (pulmonary tuberculosis, pneumonia, chronic obstructive pulmonary disease, or interstitial pneumonia). The relative expressions of miR-205-5p and miR-21-3p in NSCLC tissues and serum were significantly correlated, while no significant correlation was observed for miR-205-3p. Expressions of miR-205-5p and miR-205-3p in SCC specimens were significantly higher than in lung adenocarcinoma specimens. Similarly, higher serum miR-205-5p and miR-205-3p levels were observed in SCC patients.

MiRNAs expression profile in whole-blood showed that miR-190b, miR-630, miR-942 and miR-1284 are present in a majority of the classifiers generated during the analyses to distinguish lung cancer cases from controls^[64]. In a different study, miR-22, miR-24, and miR-34a were found upregulated in RNA extracted from whole blood of NSCLC patients *vs* healthy controls (Table 3)^[134].

In a recent paper, Aushev *et al.*^[135] described a specific panel of miRNAs (miR-205, -19a, -19b, -30b, and -20a)

Table 3 Circulating miRNAs as biomarkers in lung cancer

MIRNA	Function	Scope	Sample	Ref.
miR-155, miR-197, miR-182 (UP)	Diagnostic	Lung cancer patients <i>vs</i> healthy controls	Plasma	[126]
miR-21, miR-210, miR-126, miR-486-5p (relative expression)	Diagnostic	NSCLC patients <i>vs</i> healthy controls	Plasma	[127]
miR-21-5p (UP) and miR-335-3p (DOWN)	Diagnostic	Lung cancer patients <i>vs</i> healthy controls	Plasma	[128]
miR-21, miR-155 (UP), miR-145 (DOWN)	Diagnostic	Lung cancer patient <i>vs</i> healthy smokers	Plasma	[129]
miR-361-3p, miR-625* (DOWN)	Diagnostic	Lung cancer patients <i>vs</i> healthy controls	Serum	[130]
miR-146b, miR-221, let-7a, miR-155, miR-17-5p, miR-27a and miR-106a (DOWN), miR-29c (UP)	Diagnostic	Early stage NSCLC <i>vs</i> healthy controls	Serum	[131]
miR-92a, miR-484, miR-486-5p, miR-328, miR-191, miR-376a, miR-342, miR-331-3p, miR-30c, miR-28-5p, miR-98, miR-17-5p, miR-26b, miR-374, miR-30b, miR-26a, miR-142-3p, miR-103, miR-126, let-7a, let-7d, let-7b, miR-22, miR-148b, miR-139 (DOWN), miR-32, miR-133b, miR-566, miR-432-3p, miR-223, miR-29a, miR-148a, miR-142-5p, miR-140-5p (UP)	Diagnostic	Asymptomatic NSCLC patients <i>vs</i> healthy smokers	Serum	[132]
miR-205-5p, miR-205-3p, and miR-21-3p (UP)	Diagnostic	NSCLC patients <i>vs</i> benign lung disease and healthy controls	Serum	[133]
miR-190b, miR-630, miR-942 and miR-1284 (relative expression)	Diagnostic	Lung cancer patients <i>vs</i> healthy controls	Whole-blood	[85]
miR-22, miR-24, and miR-34a (UP)	Diagnostic	NSCLC patients <i>vs</i> healthy controls	Whole-blood	[134]
miR-205, miR-19a, miR-19b, miR-30b, miR-20a (DOWN)	Diagnostic	Patients after lung cancer surgery <i>vs</i> healthy controls	Plasma	[135]
miR-7, miR-21, miR-200b, miR-210, miR-219-1, miR-324 (UP), miR-126, miR-451, miR-30a, miR-486 (DOWN)	Diagnostic	NSCLC patients <i>vs</i> healthy controls	Plasma	[137]
miR-101, miR-106a, miR-126, miR-133a, miR-140-3p, miR-140-5p, miR-142-3p, miR-145, miR-148a, miR-15b, miR-16, miR-17, miR-197, miR-19b, miR-21, miR-221, miR-28-3p, miR-30b, miR-30c, miR-320, miR-451, miR-486-5p, miR-660, and miR-92a (relative expression)	Diagnostic	NSCLC patients <i>vs</i> healthy controls	Plasma	[138]
miR-155, miR-197 (UP)	Prognostic	Lung cancer patients with metastasis <i>vs</i> patients without metastasis	Plasma	[126]
miR-486, miR-30d, miR-1, miR-499 (relative expression)	Prognostic	NSCLC patients <i>vs</i> healthy controls	Serum	[139]
let-7f, miR-30e-3p (DOWN)	Prognostic	NSCLC patients <i>vs</i> healthy controls	Plasma	[140]
miR-125b (relative expression)	Prognostic	NSCLC patients <i>vs</i> healthy controls	Serum	[141]
miR-21 (UP)	Response to treatment	Platinum chemotherapy-resistant patients <i>vs</i> non resistant patients	Plasma	[90]
miR-21 and miR-10b (UP)	Response to treatment	NSCLC patients with EGFR mutation <i>vs</i> patients without mutation	Plasma	[142]
miR-22 (UP)	Response to treatment	NSCLC patients <i>vs</i> healthy controls	Whole-blood	[134]

NSCLC: Non-small cell lung cancer.

decreasing in plasma of patients after SCC surgery (Table 3). Interestingly, high levels of these miRNA are found in tumor-specific exosomes^[135].

Also NGS has been used to depict the differential expression of miRNAs in peripheral blood of lung cancer patients detecting 76 previously unknown miRNAs and 41 novel mature forms of known precursors. In addition, the authors identified 32 annotated and seven unknown miRNAs that were significantly altered in NSCLC patients^[136].

A plasma-based 24-miRNA signature classifier with predictive, diagnostic, and prognostic value was described, whose use could reduce the false-positive rate of low-dose computed tomography (LDCT), thus improving the efficacy of lung cancer screening (Table 3)^[137,138].

Regarding the potential of circulating miRNAs as prognostic factors, the levels of miR-155 and miR-197 have been found higher in plasma from lung cancer patients with metastasis than in those without metastasis (Table 3)^[126].

Moreover, Hu *et al.*^[139] using NGS described that serum levels of miR-486, miR-30d, miR-1 and miR-499 are significantly associated with overall survival (Table 3). NSCLC patients and healthy controls differ in vesicle-related miRNAs in plasma: let-7f and miR-30e-3p levels decreased in plasma vesicles of NSCLC patients and the expression of these miRNAs is associated with poor outcome (Table 3)^[140]. Finally, serum miR-125b may represent a biomarker in NSCLC with an independent prognostic potential for overall survival (Table 3)^[141].

Circulating miRNAs have also been explored for their ability to predict response to treatment. miR-21 expression has trends similar in plasma and matched resected specimens and was significantly increased in platinum-based chemotherapy-resistant patients, in which increased miR-21 expression was associated with the shorter disease-free survival (Table 3)^[90].

The expression of miR-21 and miR-10b was much higher in plasma samples of patients with NSCLCs with EGFR mutation than without mutation (Table 3)^[142]. Patients who had up-regulated miR-21 expression had shorter overall survival, but a better response to gefitinib than patients who had low expression of the microRNA. Additionally, miR-10b is highly expressed in progressive disease compared with complete remission or stable disease.

Franchina *et al.*^[134] recently reported a correlation between high expression of miR-22 in whole blood and the lack of response in pemetrexed treated NSCLC patients (Table 3).

CONCLUSION

MiRNAs have increasingly been pointed as important players in carcinogenesis and cancer progression, but also as potential diagnostic and prognostic markers.

For the future, circulating miRNAs could open new opportunities in the field of diagnosis and prognosis in various types of human cancers. The difficulties found in traditional therapies, due to insufficient disruption of oncogenic pathways, drug resistance and drug-induced toxicity, require the development of novel therapeutic strategies. The ease, specificity and sensitivity of determining body fluid miRNAs profiles paves the way for several applications and provides hope to accomplish this task. However, from the technical and applicative point of view, there are still several limitations to consider. Further studies are necessary to find the best possible normalization control and to improve the technique, but also to establish panels of miRNAs specific to each type of tumor, taking into account early or advanced cancer stages, response to treatment, patient outcome and recurrence. After the complete validation for several candidates, miRNAs studies could open a new era in cancer treatments, providing improved targeted agents for the cure of patients^[143] and constituting the basis for the development of novel therapies.

carcinomas of the lung, *i.e.*, in bronchial hyperplasia/metaplasia and atypical adenomatous hyperplasia. In the stages leading to pulmonary squamous cell carcinoma, expression is sustained in dysplasia, carcinoma *in situ* and invasive carcinomas, and this pertains to the normal presence of C4.4A in squamous epithelium. In pulmonary adenocarcinomas, a fraction of cases is positive for C4.4A, which is surprising, given the origin of these carcinomas from mucin-producing and not squamous epithelium. Interestingly, this correlates with a highly compromised patient survival and a predominant solid tumor growth pattern. Circumstantial evidence suggests an inverse relationship between C4.4A and the tumor suppressor LKB1. This might provide a link to the prognostic impact of C4.4A in patients with adenocarcinomas of the lung and could potentially be exploited for predicting the efficacy of treatment targeting components of the LKB1 pathway.

Abstract

The high prevalence and mortality of lung cancer, together with a poor 5-year survival of only approximately 15%, emphasize the need for prognostic and predictive factors to improve patient treatment. C4.4A, a member of the Ly6/uPAR family of membrane proteins, qualifies as such a potential informative biomarker in non-small cell lung cancer. Under normal physiological conditions, it is primarily expressed in suprabasal layers of stratified squamous epithelia. Consequently, it is absent from healthy bronchial and alveolar tissue, but nevertheless appears at early stages in the progression to invasive

Core tip: C4.4A is a new biomarker with potential prognostic value in pulmonary adenocarcinoma. High levels of protein expression correlate with poor patient survival and a histological growth pattern of the solid type. Recent data suggest that C4.4A is negatively regulated by the tumor suppressor liver kinase B1 (LKB1), which is inactivated in a fraction of adenocarcinomas of the lung. Such an inverse association between C4.4A and LKB1 could possibly render C4.4A a candidate predictive biomarker for therapeutic intervention targeting components of the LKB1 pathway, such as mammalian target of rapamycin.

as a biomarker in pulmonary adenocarcinoma and squamous cell carcinoma. *World J Clin Oncol* 2014; 5(4): 621-632 Available from: URL: <http://www.wjnet.com/2218-4333/full/v5/i4/621.htm> DOI: <http://dx.doi.org/10.5306/wjco.v5.i4.621>

INTRODUCTION

Lung cancer is the most prevalent and most mortal form of cancer, with an estimated 1.6 million new cases and 1.375 million deaths every year^[1]. Survival is highly dependent on stage at presentation, decreasing drastically from localized (52%) to regional (25%) and distant disseminated disease (4%), yielding an overall relative 5-year survival of only approximately 15%^[2]. Despite these discouraging statistics, there have, with the advent of personalized medicine, been some improvements in the treatment of lung cancer^[3]. This pertains predominantly to an improved knowledge on tumor biology, which has uncovered a molecular rationale for different treatment efficacies. In this context, molecular and histologic parameters for prediction of drug responsiveness, in particular the identification of subsets of lung cancer harboring distinct targetable oncogenic driver mutations, have guided choice of therapy.

A striking example can be seen with small tyrosine kinase inhibitors (TKIs), for which activating mutations in exons 19 and 21 of the epidermal growth factor receptor (EGFR) gene are predictive of therapeutic efficacy^[4-7]. Consequently, activating *EGFR* mutations are now a validated biomarker for decisions regarding first-line treatment of advanced non-small cell lung cancer (NSCLC)^[4,8]. Response to the anaplastic lymphoma kinase (ALK)-TKI crizotinib similarly depends on the presence of the *echinoderm microtubule-associated protein-like 4 (EML4)-ALK* fusion gene in a subset of pulmonary adenocarcinoma (AC)^[9,10]. In addition to *EGFR* and *ALK* tests, the potential of other biomarkers is being validated in clinical trials, *e.g.*, ROS1, human epidermal growth factor receptor 2/neu (HER2), BRAF and mesenchymal-epidermal transition proto-oncogene (MET) primarily in AC, and fibroblast growth factor receptor 1 (FGFR1) and discoidin domain receptor 2 (DDR2) in squamous cell carcinoma (SCC)^[11]. Regarding NSCLC histology, there have been tolerance issues coupled to the inhibitor of angiogenesis, bevacizumab, which can cause life-threatening hemorrhage and hemoptysis in patients with SCC, and is thus contra-indicated in this subgroup^[12,13]. Another drug, the antifolate pemetrexed, inhibits three enzymes of the folate metabolism, thymidylate synthase (TS), dihydrofolate reductase, and glycinamide ribonucleotide formyltransferase, the consequence of which is a reduction in *de novo* purine and pyrimidine synthesis, thus interfering with DNA and RNA synthesis. Overexpression of TS might be associated with a reduced efficacy of pemetrexed, and this can explain why it is more efficient in advanced AC than in SCC^[14,15]. The fact that tumor histology and molecular features can influence the choice of treatment implies that different NSCLC histologic subtypes should be considered

as distinct disease entities, which in turn comprise distinct molecular subsets that should be managed individually for successful outcome.

Earlier detection of lung cancer, as well as assessment of the malignant potential of a resected tumor for decisions regarding adjuvant treatment, represent other promising avenues for reducing the high mortality of the disease. Continuously increasing our knowledge on the mechanisms involved in pathogenesis is crucial to further improve the rational targeting strategy that has been adopted for lung cancer treatment. New biomarkers of early disease, prognosis and prediction of response to targeted therapy are relevant in this context, to ameliorate patient survival^[16-18]. The protein C4.4A is a potential new biomarker in NSCLC.

C4.4A – A UROKINASE RECEPTOR PROTEIN HOMOLOG

C4.4A is a membrane protein anchored to the cell surface via a glycosylphosphatidylinositol (GPI) moiety, showing predicted structural homology to the other multidomain members of the Ly6/urokinase-type plasminogen activator receptor (uPAR) (LU) protein family, *i.e.*, the uPAR, Haldisin, TEX101, CD177 and *LYPD4*^[19-23]. The genes encoding these proteins are clustered in a small region of chromosome 19q13 (Figure 1A). After posttranslational processing, C4.4A consists of 278 amino acids distributed in 2 N-terminal LU domains and a serine, threonine, proline-rich region C-terminally (Figure 1B).

C4.4A IN NORMAL DIFFERENTIATION PROCESSES

Under normal physiological conditions, C4.4A is predominantly expressed in suprabasal layers of stratified squamous epithelia such as those of the skin, hair follicles, esophagus, oral and nasal cavity, vagina and cornea (Figure 1C). It is furthermore found in the cuboidal epithelium of human term placenta and sweat ducts, in the pigmented epithelium of the retina and in Hassall's corpuscle in the thymus^[19,24]. Remaining epithelia, including the alveolar and bronchial compartments of the healthy lung (Figures 2A and 3A; Table 1), are devoid of C4.4A, suggesting a tight regulation of its expression, possibly by the CCAAT/enhancer binding protein β (C/EBP β) or estrogen^[25,26]. This is clearly visualized at transition zones such as those present in the rodent stomach and at the ano-rectal junction, where the distinct C4.4A expression at the squamous side is abruptly terminated at the columnar side (Figure 1D). The stringent membrane-associated expression pattern of C4.4A would be in line with a putative role of this protein in cell adhesion^[19,27,28], but its biological function is still to be delineated.

C4.4A IN PATHOLOGICAL CONDITIONS

C4.4A was originally identified by two independent differ-

ential antigen screens as a candidate metastasis-associated protein^[29,30], the first in a rat pancreatic adenocarcinoma cell line, and the second in an *in vitro* urothelial wound response model. Rösel *et al.*^[29] furthermore reported on the capability of C4.4A-positive but not C4.4A-negative tumor cells to penetrate a matrigel, in the absence but not in the presence of a monoclonal C4.4A antibody. C4.4A has indeed been implicated in a range of human cancers, including lung^[31-35], esophageal^[27], bladder^[30] and colorectal^[36], as evaluated by immunohistochemistry, *in situ* hybridization, PCR, North-

ern blotting or microarray screening. In colorectal cancer^[36], esophageal squamous cell carcinomas^[27] and bladder transitional cell carcinomas (Jacobsen *et al.*^[33], manuscript in preparation), C4.4A is upregulated at the tumor invasive front as compared to the tumor core, suggesting a possible association of C4.4A to the invasive process. Whether this can be further translated to a direct involvement in the ability of a tumor cell to metastasize as initially proposed has not been verified experimentally *in vivo*, but the expression of C4.4A seen in primary tumors is at least in the case of the esopha-

gus and the lung recapitulated in corresponding lymph node metastases^[27,33].

One of the most well-studied diseases regarding C4.4A expression is NSCLC^[31,33,34]. The role of C4.4A in the progression to pulmonary SCC and AC is described in the following

C4.4A IN PULMONARY SQUAMOUS CELL CARCINOMA

Progression to malignancy through well-described premalignant lesions

Lung cancer is divided into two main histological types, where small cell lung cancer comprises around 15% of cases and NSCLC the remaining 85% of cases. The latter is further subdivided into AC, SCC and large cell carcinoma

(LCC), of which AC has become the most frequent type^[37-39].

Pulmonary SCCs most often originate in the bronchial compartment. There is a high degree of consensus concerning the stages that transform normal, pseudostratified columnar bronchial epithelium into invasive SCC^[40]. After an excessive proliferation phase resulting in hyperplasia of basal cells, metaplasia entails the transdifferentiation of bronchial cells resulting in the conversion of columnar epithelium to squamous epithelium. Dysplasia represents the first true premalignant stage and is followed by carcinoma *in situ* (CIS), which again can develop into malignant carcinoma. Morphologically, epithelial thickness, cell size and mitotic figures increase throughout this progression, which is also characterized by pleomorphism and loss of epithelial polarity^[37]. Molecularly,

Figure 3 C4.4A in pulmonary adenocarcinoma. Panels A-E: C4.4A expression as detected by immunohistochemistry with a polyclonal antibody in normal alveoli (A; reproduced with permission from Jacobsen *et al.*^[34], 2012), atypical adenomatous hyperplasia (B), invasive AC with predominant mucinous lepidic (C), non-mucinous lepidic (D), acinar (E), papillary (F) and solid (G) pattern. Panel H: Kaplan-Meier estimates for the survival of AC patients, which is correlated with C4.4A scores, here stratified by tertiles (red: Lowest level of C4.4A; blue: Intermediate level of C4.4A; green: Highest level of C4.4A). Modified from Jacobsen *et al.*^[33], 2013.

activation of oncogenes and inactivation of tumor suppressor genes occur, along with allelic losses^[41-43].

Morphologically normal bronchial epithelium is devoid of C4.4A (Figure 2A), but expression appears

already at the stage of hyperplasia (Figure 2B) and becomes prominent upon metaplastic (Figure 2C) and dysplastic conversion (Figure 2D, Table 1)^[34]. The protein is consistently present in invasive SCC (Figure 2E), with

high levels detected in approx. 75% of patients in two different cohorts^[31,33].

C4.4A expression mirroring normal squamous differentiation

Given that hyperplasia and metaplasia are not true pre-malignant lesions, but rather regarded as reactive changes primarily caused by chronic irritation such as cigarette smoking, they do not by themselves indicate an increased risk of developing into a manifest carcinoma, as contrasted to severe dysplasia and CIS^[43-45]. A consequence of the very early appearance of C4.4A in basal cell hyperplasia/early metaplasia is that it cannot reflect the subsequent malignant transformation *per se* and therefore cannot be used as an early biomarker for pulmonary SCC. It thus reports on the differentiation status of the cells rather than on their malignant potential, and this provides an explanation for the presence of C4.4A in nearly all cases of invasive SCC^[31,33,34]. With consistent high levels of C4.4A in both premalignant and malignant lesions, C4.4A cannot differentiate between individual cases, and this is furthered into a lack of prognostic information in SCC patients (Figure 2F)^[31,33].

The detection of C4.4A in squamous metaplasia and dysplasia aligns excellently with the normal expression of C4.4A, which is closely linked to squamous differentiation of epithelium, as exemplified by murine embryogenesis, where C4.4A and the differentiation-specific cytokeratin 10 appear simultaneously in the nasal cavity (day E13.5) and in the interfollicular epidermis of the vibrissae (day E14.5)^[24]. Due to the stringent regulation of C4.4A in squamous epithelia, as convincingly shown at squamo-columnar junctions (Figure 1D), the appearance of C4.4A in basal cell hyperplasia in the bronchial compartment is on the other hand an unexpected finding. This could suggest that C4.4A reports on the induction of the metaplastic conversion process, where pseudostratified columnar epithelium is replaced by stratified squamous epithelium, even before the emerging squamous differentiation is evident morphologically. It has indeed been demonstrated that genetic aberrations such as mutations, deletions and overexpression of p53, and loss of heterozygosity (LOH) at chromosomes 3p and 9p (p16^{INK4a} locus) occur in histologically normal respiratory mucosa of smokers and lung cancer patients^[40,42,45-47]. Respiratory basal cells have been reported to be progenitors of squamous metaplastic cells and presumably preneoplastic epithelium^[37,40,42,48,49]. Delineating the function of C4.4A might give an indication of its role in the transdifferentiation process occurring in the bronchial mucosa, setting the stage for ensuing neoplastic transformation. This would increase our knowledge on the very early pathogenesis of pulmonary SCC. Considering the complete lack of C4.4A in normal bronchial epithelium, it might be used in conjunction with other histopathological, molecular and genetic markers in risk assessment for identifying malignant clones of the bronchial mucosa before these are manifest morphologically^[40], which could

suggest a need for a closer patient follow-up.

C4.4A IN PULMONARY ADENOCARCINOMA

From atypical adenomatous hyperplasia to invasive adenocarcinomas

Most ACs of the lung originate peripherally, which in contrast to the central airways is much more challenging to image, rendering a delineation of the various stages of transformation from normal alveolar epithelium to invasive AC corresponding to the development to invasive SCC difficult^[37,40,46]. On the basis of clinicopathologic and molecular studies, atypical adenomatous hyperplasia (AAH) has nevertheless been identified as a precursor lesion, which subsequently transforms into adenocarcinoma *in situ* (AIS), formerly known as bronchioloalveolar carcinoma (BAC)^[38,40,42,50-56]. AAH and AIS thus represent the counterparts of squamous dysplasia and CIS, respectively. Evidence for the stepwise development from AAH to AC comes from longitudinal case studies by low-dose computed tomography imaging^[57,58], the similarity of molecular aberrations^[40,59-62] and a common expression pattern of markers of the suggested progenitor cells, Clara cells and type II pneumocytes, in AAH and AC^[40,42,63] as well as mouse models of pulmonary AC, targeting KRAS/p53^[64] or EGFR^[65,66].

With a view to the preferential expression of C4.4A in squamous epithelium, as described above, one would not expect C4.4A expression in the alveolar compartment. This is indeed the case for normal alveoli (Figure 3A), but unexpectedly, the protein is present in approx. 25% of investigated cases of AC, albeit at much lower expression levels than in SCC, when scoring C4.4A semi-quantitatively as a product of intensity (0-4) and frequency (0-4) of immunohistochemical staining (median of 1 vs 8 on a scale up to 16) (Figure 3C-G, Table 1)^[31,33]. Interestingly, a small fraction of atypical type II pneumocytes in AAH lesions is also positive for C4.4A (Figure 3B)^[34]. This might be coupled to the cuboidal nature of these cells, as C4.4A also is found in other cuboidal epithelia such as the placenta and sweat ducts^[19] (and Krieglbaum, unpublished).

Prognostic impact of C4.4A in adenocarcinomas

As compared to known prognostic factors, such as stage, performance status, completeness of resection, tumor differentiation grade, nodal status, age and gender, the translational value of proposed lung tumor markers and gene expression signatures has been disappointing^[16,67]. It is therefore of interest to find new biomarkers or a combination thereof that could allow a more accurate survival prediction and aid in the decision making regarding adjuvant therapy. The prognostic impact of C4.4A in NSCLC has been investigated by a specific and reproducible semi-quantitative immunohistochemical protocol with substantial inter-observer agreement in two independent patient cohorts (40 ACs/56 SCCs from Denmark^[31]

and 88 ACs/104 SCCs from Germany^[33]). These studies showed that increasingly higher levels of C4.4A in ACs correlated with a decreasing patient survival, as evaluated by Kaplan-Meier analysis, where C4.4A scores were grouped according to tertiles (Figure 3H). Univariate and multivariate analysis of overall survival including C4.4A scores and the clinical covariates pathological stage, performance status, gender, age and treatment, likewise revealed C4.4A to be a significant prognostic factor (Table 1), together with pathological stage. The validation of the observations obtained in the first study in a second, larger patient population emphasizes the robust correlation between C4.4A levels and prognosis of AC patients. This has been further substantiated by another study based on quantitative real-time PCR, where the gene encoding C4.4A, *LYPD3*, was selected as one of 91 signature genes for survival prediction of pulmonary AC patients^[68]. It could be interesting to use patient material from previously conducted large clinical trials to retrospectively test for superiority of C4.4A to current prognostic factors, with a view to future validation in a prospective, randomized trial.

Considering the sequential development from AAH to AC, it is tempting to speculate whether a C4.4A-positive AAH eventually could develop into a C4.4A-positive AC with an ensuing compromised patient survival. If this were the case, this would entail that there are subpopulations of C4.4A-positive AAH cells with higher malignant potential than the C4.4A-negative counterparts, with the possibility to be used as an early marker of a supposedly more aggressive subtype of AC. In addition, considering that only a minority of AAHs progresses to AC, it would be interesting to assess whether C4.4A-positive AAH cases are more prone to this malignant progression than C4.4A-negative AAH. Addressing these questions would, however, require prospective, longitudinal studies and advanced imaging techniques not yet available for proper visualization of both AAH lesions and C4.4A, or alternatively following the various stages of malignant progression in a suitable mouse lung cancer model^[69].

Correlation of C4.4A expression with solid growth type

Pulmonary ACs encompass a histologically, molecularly and genetically very heterogeneous group of tumors. The new multidisciplinary classification suggests that AC should be described according to histological subtype, which can be mucinous or non-mucinous lepidic, acinar, papillary, micropapillary or solid^[38]. Gene expression profiling clusters the different AC types according to morphological and molecular characteristics, which emphasizes that ACs cannot be classified in one homogeneous group^[70,71]. Interestingly, patient survival also differs significantly with subtype, with 5-year relative survival rates of 86%-90% and 39%-70% when the lepidic and solid components, respectively, are predominant^[72,73].

Detailed analysis of C4.4A in the fraction of positive ACs, with focus on histological subtypes, has revealed that C4.4A expression is tightly correlated with the solid

growth pattern^[33]. Whereas the protein is almost absent in cases with a predominant mucinous/non-mucinous lepidic, acinar or papillary pattern (Figure 3C-F), the median value in cases with solid growth is 4 on a scale ranging from 0 to 16. This places the majority of these patients in the upper tertile of C4.4A scores in the AC group (> 3.5), with an ensuing poor prognosis as illustrated by Kaplan-Meier survival curves (Figure 3H). Given that a solid component in itself predicts poor patient survival^[72,73], it could be assumed that this clear interaction between C4.4A and solid growth would explain the prognostic impact of C4.4A. This is, however, refuted by multivariate overall survival analysis using the Cox proportional hazards model including growth pattern and the C4.4A/solid interaction in addition to classical clinical factors, where C4.4A and pathological stage are the only significant independent parameters. Despite the interaction between C4.4A and solid growth pattern, C4.4A is thus a stronger prognostic factor than solid growth^[33]. Given that AC patients with a predominant solid growth pattern seem to benefit from adjuvant radiotherapy, this might be exploited in clinical decision-making regarding this form of treatment^[74].

By comparing gene expression profiles of independent lung cancer patient populations obtained by DNA microarray analysis, Hayes *et al.*^[75] identified three AC subtypes that were termed bronchioid, squamoid and magnoid, with reference to their resemblance to bronchioalveolar carcinoma, SCC and LCC, respectively. AC tumors in a differentiation state close to the SCC phenotype thus seem to exist. This is further substantiated by a study of ACs of mainly the solid pattern with signet-ring morphology, which co-express thyroid transcription factor 1 (TTF-1) and p63, being markers of AC and SCC, respectively^[76]. In the WHO classification from 2004, carcinomas with histological and immunohistochemical evidence of double differentiation are termed adenosquamous carcinomas^[37]. The squamoid ACs are characterized by moderate or poor differentiation, solid growth, invasion, and a poor patient survival^[75,77]. The fact that C4.4A is primarily expressed in AC of the solid type, coupled to its close association to squamous differentiation and prognostic impact in AC would suggest that the C4.4A-positive ACs according to this classification are of the squamoid type.

Regulation of C4.4A by the tumor suppressor LKB1

The normal stringent control of C4.4A expression as seen in squamous epithelia is apparently disrupted in pulmonary AC. Whether the unexpected expression of C4.4A in pulmonary AC has functional implications in the pathogenesis of AC remains unknown. It might also be reporting on an erroneous regulation of a signaling pathway that when activated in the lung results in highly malignant tumors. Circumstantial evidence suggests the involvement of the tumor suppressor liver kinase B1 (LKB1). Firstly, C4.4A is negatively regulated by LKB1 in esophageal cancer cell lines, where *LYPD3* was up-

regulated upon loss of LKB1. The migratory and invasive potential of these cells was reduced when *LYPD3* subsequently was knocked down^[78]. Secondly, LKB1 reconstitution in the LKB1-deficient AC cell line H2126 downregulates C4.4A at the mRNA level^[79]. Thirdly, 17%-54% of pulmonary AC patients present with LKB1 inactivating mutations, of which the majority is found in poorly differentiated cases^[80-84]. Fourthly, LKB1 is lost in a fraction of AAH lesions^[85]. If there is an inverse relationship between LKB1 and C4.4A, C4.4A-positivity with its ensuing worsened patient prognosis in pulmonary AC might be explained by LKB1 inactivation in the given cases. This would imply that C4.4A potentially could be used as a biomarker for the efficacy of treatment targeting the LKB1 pathway, including mammalian target of rapamycin (mTOR) signaling, which is activated upon LKB1 inactivation^[86]. The potential of mTOR inhibitors as therapeutic agents in NSCLC is currently investigated in a range of clinical trials^[87,88].

One of the most recent genetic murine lung cancer models exploits a combination of LKB1 inactivation and KRAS oncogene activation to obtain metastatic tumors of a mixed phenotype, including AC, SCC and LCC^[79]. Crossing a C4.4A-deficient mouse with the KRAS/LKB1 model would allow a simultaneous investigation of the consequences of the absence or presence of C4.4A in the progression of both AC and SCC, revealing if C4.4A is functionally involved in or is a reporter of a molecular mechanism that could be targeted therapeutically.

CONCLUSION

C4.4A induction is an early event in the progression of two very distinct histological subtypes of lung cancer, *i.e.*, AC and SCC, where expression is seen in the presumed precursor lesions AAH and hyperplasia/metaplasia, respectively. Nevertheless, the differential prognostic impact suggests that the protein plays distinct roles in the pathogenesis of these two entities, and this underscores the high heterogeneity of lung cancer and the concept of AC and SCC as two different diseases.

In the progression to SCC, C4.4A is inherently linked to the phenotype that arises following the transdifferentiation process that converts pseudostratified columnar respiratory epithelium to squamous epithelium, completely in line with its normal expression. The appearance already in basal cell hyperplasia is interesting from a biological point of view, indicating that C4.4A is such an early marker of squamous differentiation that it is present even before the phenotype is morphologically manifest. However, given that C4.4A consistently is expressed in reactive lesions even preceding true premalignant lesions, is sustained in the subsequent stages of malignant progression and is invariably present in invasive carcinomas, it cannot possibly provide any information on the survival of SCC patients.

In sharp contrast to this, C4.4A is a strong, independent prognostic indicator in AC patients, and it therefore

has clinical relevance in this lung cancer subtype, especially in cases with a solid growth pattern, for which C4.4A is a surrogate marker. As such, whereas C4.4A follows a normal differentiation pattern in SCC, its expression in AC reflects an abnormal differentiation program. Clarifying whether this has implications for AC pathogenesis or is reporting on a dysregulated signaling pathway awaits the delineation of the biological function of C4.4A. Either way, it is tempting to speculate that there is a link between C4.4A-positive AAH lesions and ACs with a solid pattern, which would make C4.4A a very early biomarker for a particularly malignant form of AC. It is, however, at present unclear if AAH actually develops into overt solid AC^[38,46,53]. It is furthermore of interest to investigate the putative inverse correlation between LKB1 inactivation and high C4.4A expression and the hypothetical candidacy of C4.4A as a predictive biomarker for therapy aimed at components of the LKB1 pathway. This is in line with the goal of supplementing traditional NSCLC management according to the TNM classification with personalized medicine^[18], which depends on predictive biomarkers reporting on biological and molecular tumor characteristics that can identify the patient populations benefitting from a given targeted treatment.

ACKNOWLEDGMENTS

The authors would like to thank John Post (Finsen Laboratory) for skilled assistance in figure preparation. Dr. Eric Santoni-Rugiu participates in Pfizer's Nordic Board for ALK in NSCLC, has received speaker's fees from Pfizer, Roche, and Novartis, and his institution receives research funding from Pfizer and Roche.

Abstract

Non-small-cell lung cancer remains a leading cause of death around the world. For most cases, the only chance of cure comes from resection for localised disease, however relapse rates remain high following surgery. Data has emerged over recent years regarding the utility of adjuvant chemotherapy for improving disease-free and overall survival of patients following curative resection. This paper reviews the clinical trials that have been conducted in this area along with the studies integrating radiation therapy in the adjuvant setting. The role of prognostic gene signatures are reviewed as well as ongoing clinical trials including those incorporating biological or targeted therapies.

Key words: Carcinoma; Non-small-cell lung; Chemotherapy; Adjuvant; Radiotherapy; Biological therapy; Biomarker

Core tip: Improvement in survivals of patients with

resected non-small lung cancer has been rather modest. Adjuvant systemic chemotherapy with high dose cisplatin and vinorelbine has been established to be beneficial in improving disease free and overall survival in stage II and IIIA but not stage I patients. This benefit is observed also in elderly patients. Post-operative radiation therapy has a deleterious effect on early stage tumour but appears to improve survival and reduce local recurrence in higher risk stage III or N2 disease with modern techniques. The availability of targeted biologicals and biomarker development may allow future selection of high risk groups who benefit from adjuvant treatments.

INTRODUCTION

Lung cancer remains the leading cause of cancer-related death, contributing 19.4% to the total number of cancer deaths worldwide in 2012^[1]. Between 1975 and 2008 the 5-year survival for this condition in the United States has only seen a modest rise from 12% to 17%^[2]. Non-small cell lung cancer (NSCLC) comprises approximately 80% of all lung cancers; despite surgery 5-year mortality ranges from 33% to 77% for stage I a and IIIa disease respectively, primarily from tumour recurrence^[3]. Over the last few decades adjuvant chemotherapy following curative surgery has been proven to decrease recurrence and improve patient survival, initially for node-positive breast cancer^[4] but subsequently to include other malignancies such as ovarian^[5], bowel^[6], gastro-oesophageal^[7] and pancreatic^[8] cancers. In addition, inhibitors of tumour growth signalling

pathways such as the anti-human epidermal growth factor receptor 2 (HER2) antibody trastuzumab for breast cancer^[9], are starting to be incorporated into adjuvant systemic therapies.

Patient selection for adjuvant therapy is mainly based on the odds of tumour recurrence. Generally, patients with high recurrence risk will derive the most benefit from adjuvant therapy. Conversely, patients who have a low risk of relapse may not derive a net benefit from adjuvant therapy, particularly if the marginal reduction in relapse risk is not offset against the risks and inconveniences of treatment. Adjuvant radiation can also confer a benefit although this advantage is generally restricted to preventing locoregional tumour recurrence. This article reviews the evidence for adjuvant therapy for NSCLC with a focus on systemic treatments.

CHEMOTHERAPY

Alkylating agents

Initial studies of adjuvant chemotherapy for NSCLC were not promising. In 1995 a meta-analysis of adjuvant chemotherapy by the NSCLC Collaborative Group showed that alkylating agents used in the earliest adjuvant studies had a detrimental effect on survival over surgery alone, with a HR of 1.15 ($P = 0.005$)^[10].

Early cisplatin trials

Despite the detrimental effect found with alkylating agents, the same meta-analysis suggested there may be a small survival benefit within the subgroup of trials that used cisplatin-based chemotherapy with a HR of 0.87 ($P = 0.08$); similarly there was a non-significant improvement in survival by 3% at 2 years, and 5% at 5 years, with treatment. The individual studies pooled to obtain this result were small, with sample sizes ranging from 28 to 332 patients.

Subsequent to this meta-analysis, the Eastern Cooperative Oncology Group (ECOG) 3590 study compared post-operative radiotherapy alone, to the same plus chemotherapy consisting of 4 cycles of cisplatin and etoposide on 488 patients^[11]. After a median follow-up of 44 mo, there was no improvement in median survival between the arms, being 38 mo for chemotherapy and 39 mo for observation. Only 69% of patients assigned chemotherapy received all 4 cycles of treatment, and this included patients who required treatment dose reductions.

The Big Lung Trial (BLT)^[12] was conducted to see if it could confirm the findings from the meta-analysis of a small survival advantage from adjuvant cisplatin-based chemotherapy. The design was pragmatic and clinicians could choose from 4 different cisplatin-based chemotherapy regimens; in addition chemotherapy could be administered either before or after surgery. This study closed early owing to slow accrual, reaching only 76% of the target of 500 patients. However even if full accrual were achieved, the sample size would still only have had 20% power to detect a 5% difference in survival.

The Adjuvant Lung Project Italy (ALPI) was the first large cisplatin-based adjuvant trial that had adequate statistical power to confirm the small benefits suggested by the 1995 meta-analysis^[13]. It recruited patients with resected stage I–III NSCLC between 1994 and 1999. Patients were randomised to receive 3 cycles of mitomycin, vindesine and cisplatin, or observation. Radiation was permitted in accordance with the policy of each treating institution.

After a median follow up of 64.5 mo, no advantage was seen in the chemotherapy arm for either overall survival or disease-free survival. Possible explanations for the negative result include the removal of 1 centre which recruited 108 of the total of 1209 patients owing to concerns over data integrity and low treatment compliance, with only 69% completing the 3 cycles of chemotherapy. Furthermore, about half of these patients required dose reductions. However, analyses adjusting for these effects still did not suggest that they were responsible for the negative result. Another possible explanation is the imbalance in radiation delivery favouring the control arm, as 26% of patients in the chemo arm had their radiation interrupted at an early stage compared to 11% of controls.

Recent cisplatin trials

The largest adjuvant lung cancer study to date is the International Adjuvant Lung Trial (IALT)^[14]. The study included 1867 patients with completely resected stage I–III NSCLC who were randomly assigned to 3–4 cycles of cisplatin-based chemotherapy or observation. This was a pragmatic study, with participating centres being allowed to choose from 4 chemotherapy regimens (details in Table 1). Post-operative radiotherapy was permitted in accordance to local institutional policy. At a median follow up of 56 mo, there was a statistically significant overall survival benefit from chemotherapy [hazard ratio (HR), 0.86; $P < 0.03$]. The 2-year survival rate was 70.3% in the chemotherapy group and 66.7% in the control group and at 5-years, this was 44.5% and 40.4%, respectively. Similarly, disease-free survival was significantly better in chemotherapy arm with a HR of 0.83 ($P < 0.03$).

An updated analysis of this study was published with a median follow up period of 7.5 years^[15]. The benefit seen earlier was maintained for overall survival (HR, 0.91; $P = 0.10$) and disease-free survival (HR, 0.88; $P = 0.02$). However there was an increase in late mortality seen after 5 years of follow-up (HR, 1.45; $P = 0.04$) with a positive test for interaction ($P = 0.006$). An increase in non-lung-cancer mortality was observed in the chemotherapy arm (HR, 1.34; $P = 0.06$), and probably explains the late mortality, as there was no evidence of an interaction between chemotherapy effect and the follow-up period. The statistically significant causes of non-cancer deaths were infections, circulatory and respiratory diseases.

The JBR.10 trial^[16] was a large North American

Table 1 Important randomised trials of adjuvant treatments for non-small cell lung cancer

CALGB 9633 ^[16]	344	I b	4 cycles of carboplatin AUC 6 plus paclitaxel 200 mg/m ² , every 3 wk	HR, 0.83 (<i>P</i> = 0.12)	HR, 0.80 (<i>P</i> = 0.065)

¹Control arms treated with observation. OS: Overall survival; DFS: Disease-free survival; HR: Hazard ratio; NR: Not reported.

Intergroup adjuvant study of stage I b and II NSCLC. Chemotherapy consisted of 4 cycles of cisplatin plus vinorelbine, and radiation was not permitted. The results of this study strongly favoured chemotherapy, with a 5-year survival rate of 69% compared to 54% in the control arm (*P* = 0.03). The HR for death was 0.69 (*P* = 0.04). Similarly, 5-year disease-free survival rates were 61% and 49% for the study and control arms, respectively (*P* = 0.08).

The results of this study were updated after a median follow up of 9.3 years^[17]. Reassuringly, the improvement in overall survival from chemotherapy was maintained with a HR of 0.78 (*P* = 0.04) and 0.73 (*P* = 0.03) for overall survival and disease-free survival, respectively. Five-year survival rates were 67% in the chemotherapy arm and 56 % in the control arm. The benefit was confined to stage II patients, with a HR of 0.68 (95%CI: 0.5-0.92, *P* = 0.01) compared to 1.03 (95%CI: 0.7-1.52, *P* = 0.87) for stage I b patients where there is no benefit, in addition there was a trend for interaction with disease stage (*P* = 0.09).

The Adjuvant Navelbine International Trialist Association (ANITA) conducted a very similar study with equally similar results^[18], thus validating the strongly positive findings from JBR.10. In contrast to the JBR.10 study, patients with stage III NSCLC were included in the ANITA trial in addition to stages I b and II. Patients were randomised to receive 4 cycles of chemotherapy with cisplatin plus vinorelbine, or observation. After a median follow-up of 76 mo, there was an improvement in overall survival (HR, 0.8; *P* = 0.017) with chemotherapy. Median survival in the chemotherapy group was 65.7 mo compared to 43.7 mo in the control group. There was an absolute benefit from chemotherapy on overall survival of 8.4% at 7 years, however stage I b patients did not benefit from treatment with a HR for survival of 1.1 (95%CI: 0.76-1.57). In parallel with the JBR.10 findings, the ANITA study also found a trend towards an interaction between tumour stage and chemotherapy (*P* = 0.07).

Individual patient data from the 5 largest randomised trials of cisplatin-based chemotherapy were pooled in another meta-analysis in an attempt to verify the small but not statistically significant improvement in survival seen earlier by the Collaborative Group. The Lung Adjuvant Cisplatin Evaluation (LACE)^[19] reassuringly confirms a significant survival benefit (HR, 0.89; *P* = 0.005) and disease-free survival benefit (HR, 0.84; *P* = 0.001) from adjuvant chemotherapy. The absolute benefit at 5 years was 5.4% and 5.8% for overall and disease-free survival, respectively. There was no heterogeneity of chemotherapy effect between the trials. In parallel with the updated IALT analysis, there was a similar increase in non-lung-cancer deaths in the chemotherapy arm, particularly in the first 6 mo of follow-up, with a HR of 2.41 (*P* < 0.001). Of these 74 deaths seen in the chemotherapy arm, 18 were from chemotherapy toxicity. Another 40 deaths in this arm were from pulmonary/ cardiovascular events, compared to 21 in the control arm. The authors hypothesized that some of these excess cardiovascular deaths seen in the chemotherapy arm could be a result of cisplatin, particularly as the under-reporting of cardiovascular complications from cisplatin has been described in the literature^[20].

The NSCLC Meta-analyses Collaborative Group updated their previous results^[10] by performing 2 further meta-analyses^[21]. The first examined the benefit of adding chemotherapy to surgery. Similarly, the second analysis explored the benefit of chemotherapy, but in the setting of surgery plus radiotherapy as the control. Both these meta-analyses showed a benefit from adjuvant chemotherapy, with good concordance in survival HRs (for surgery, HR, 0.86; *P* < 0.0001; for surgery plus radiotherapy, HR, 0.85; *P* = 0.009) and also the absolute improvement in 5-year survival (4% for both).

Uracil-tegafur

The antimetabolite uracil-tegafur (UFT) has been

studied in Japan for the treatment of NSCLC. It is an orally administered combination of uracil and tegafur (a pro-drug of fluorouracil) and demonstrated single-agent activity against NSCLC as well as in combination with cisplatin^[22]. A small adjuvant study performed by the West Japan Study Group for Lung Cancer reported improved survival for the 2 arms that received adjuvant UFT-based chemotherapy *vs* observation^[23] and paved the way to a large confirmatory trial by the Japan Lung Cancer Research Group^[24]. Recruitment was restricted to patients with stage I adenocarcinoma and chemotherapy consisted of 2 years of UFT. With a median follow up of 72 mo the 5-year survival for the chemotherapy arm was 88% in the chemotherapy arm *vs* 85% in the observational group ($P = 0.047$). This advantage was driven by an 11% absolute improvement in 5-year survival for patients with T2 tumours ($P = 0.005$), whereas the difference in 5-year survival for patients with T1 tumours was only 1%.

Not all trials of adjuvant UFT have been positive, hence the second Collaborative Group meta-analysis^[20] pooled the results of 7 adjuvant studies that used tegafur/UFT as a single agent and found a survival benefit from treatment with a HR of 0.76 ($P = 0.001$). It also found a benefit for tegafur/UFT in combination with platinum, where the results of 8 pooled studies showed a HR of 0.79 ($P = 0.005$). Another meta-analysis restricted to studies using UFT alone showed a similar survival HR of 0.74 ($P = 0.001$)^[25]. The absolute improvements in 5- and 7-year survival were 4.3% and 7.0%, respectively, however it should be noted that there is considerable overlap in the studies pooled between these meta-analyses.

UFT has only been widely studied for NSCLC in Japan, where ethnic differences in pharmacogenomics and tumour biology may mean that these findings may not be generalisable to NSCLC patients worldwide^[26]. This suspicion is also heightened by the knowledge that its analog, fluorouracil, is generally considered to be ineffective against NSCLC. Lastly, adjuvant UFT has only been studied in a population that is made up almost exclusively of patients with stage I NSCLC, where the benefits from adjuvant cisplatin-based chemotherapy are still controversial. For these reasons UFT should not be considered a standard treatment for this setting, outside Japan.

TARGETED THERAPY

The epidermal growth factor receptor (EGFR) forms part of a signalling pathway that regulates a large range of cellular functions, including proliferation, invasion, angiogenesis and metastasis. It is commonly overexpressed in NSCLC. Trials of EGFR inhibitors showed activity in advanced NSCLC^[27-29] and in 2002 the NCIC instigated the BR19 study to compare the EGFR inhibitor gefitinib with placebo in the adjuvant setting^[30]. However, this study was closed prematurely in 2005, after the large ISEL study failed to show an improvement in overall survival from gefitinib for advanced NSCLC^[31].

By then it had only accrued 503 patients out of a target of 1242. With a median follow-up period of 4.7 years, this study did not find a benefit in disease-free survival (HR, 1.22; $P = 0.15$) or overall survival (HR, 1.24; $P = 0.14$).

In light of current knowledge that activating mutations in the EGFR gene strongly correlate with responsiveness to gefitinib^[32,33], it is possible that the negative result of this study is related to the unusually low incidence of EGFR mutations found in this cohort, being detected in only 4% of the 359 tumour samples tested. The results of ongoing adjuvant studies of EGFR inhibitors in selected patients with EGFR-mutant tumours are awaited with interest, and are discussed towards the end of this article under "Ongoing studies". Targeted therapies will no doubt shape the future of oncology and are discussed further in that section. Table 1 summarises the important individual studies covered in this section and provides further details on their respective treatment regimens.

CHOICE OF REGIMEN

The 2 trials showing the largest magnitude of benefit from adjuvant chemotherapy to date are JBR.10^[16] and ANITA^[18], with treatment providing similar improvements in median survival of 21 and 22 mo, respectively. The use of nearly identical doses of chemotherapy (high-dose cisplatin plus weekly vinorelbine for 4 cycles) in these trials provides further validation of the effectiveness of this combination. Both studies used 100 mg/m² cisplatin per cycle; in ANITA this was given as a single dose on day 1 whereas it was divided into 2 doses of 50 mg/m² given on days 1 and 8 in JBR.10. Both studies used vinorelbine 30 mg/m² for 16 weekly doses at the onset, however the dose was subsequently reduced to 25 mg/m² in JBR.10 owing to a high incidence of treatment-related adverse events following the commencement of this study. While the efficacy of chemotherapy in both studies were comparable, the early treatment-related mortality in the ANITA trial was relatively high at 2% justifying the decision by the JBR.10 investigators to reduce the dose is justified. The incidence of clinically significant toxicities from cisplatin and vinorelbine in both these studies can be found in Table 2.

The Lung Adjuvant Cisplatin Evaluation (LACE) meta-analysis^[19] confirmed the superiority of cisplatin plus vinorelbine over 2 other chemotherapy regimen subgroups ($P = 0.04$), but only when these subgroups were pooled together. There was also a trend in favour of a total cisplatin dose above 300 mg/m².

PATIENT SELECTION

The modest survival benefit obtained from ACT means that most patients will not personally benefit from the treatment. For instance, the 5% survival benefit from chemotherapy seen in the LACE meta-analysis would

Table 2 Incidence of treatment-related World Health Organization grade 3-4 toxicity from adjuvant cisplatin and vinorelbine

Trial	JBR.10 (%) ^[16]	ANITA (%) ^[18]
Anaemia	14	7

mean that 20 patients would need to be treated with chemotherapy to prevent 1 lung cancer death, whilst the other 19 patients would not derive any individual benefit from the treatment. Furthermore patients and clinicians also have to weigh up the risks and inconveniences of ACT. Cisplatin is considered to be strongly emetogenic, even though the current availability of 5HT₃ and substance P neurokinin-1 receptor antagonists have substantially reduced the magnitude of this side-effect. It also has the potential to cause permanent neuropathy that can be disabling in a small percentage of patients. Cardiovascular complications have been identified from cisplatin^[19] and as mentioned above an increase in cardiovascular-related mortality has been identified in the chemotherapy cohort of the LACE meta-analysis^[19]. For these reasons, it would be desirable to be able to accurately identify subgroups of NSCLC patients who would derive the greatest benefit from ACT.

Stage 1 disease

Hitherto all major adjuvant trials in NSCLC have used tumour stage as the criterion for selecting high-risk patients. Whilst adjuvant chemotherapy has become standard treatment for stages II and III NSCLC, it remains controversial for stage I tumours. The cohorts in the 2 meta-analyses of adjuvant UFT trials^[20,24] are almost exclusively made up of stage I lung adenocarcinomas within the Japanese population. Given their positive findings, they vindicate treatment with UFT in this population, however there are no studies confirming this approach to be effective outside Japan.

Stage 1A: Only a small number of stage I a patients have been entered into trials of adjuvant chemotherapy. In the LACE meta-analysis^[19] stage I a patients comprised 7% (347/4584) of the cohort; the HR for overall survival in this subgroup was 1.4 (95%CI: 0.95-2.06). The second

Collaborative Group meta-analysis^[20] collectively analysed 2058 cases with stage I a disease within their total cohort of 8447 patients; the HR for survival in this subgroup was 1.19 (95%CI: 0.84-1.68).

Stage 1B: Subset analyses of the IALT^[14], JBR.10^[16] and ANITA^[18] trials failed to show a benefit from chemotherapy for Stage 1b NSCLC. As discussed above, this is further reinforced by finding a trend towards an interaction between chemotherapy effect and disease stage in the updated JBR.10^[17] and ANITA trials. The LACE meta-analysis^[19] failed to show a benefit for stage I b tumours (HR, 0.93; 95%CI: 0.78-1.10), although the second Collaborative Group meta-analysis^[20] found survival HRs to be similar across stages I b-III NSCLC.

The Cancer and Leukemia Group B (CALGB) 9633 trial^[34] is the only adjuvant study of a pure population of stage I b NSCLC. It is also unique for its use of carboplatin instead of cisplatin. Three hundred and eighty-four patients were randomised to receive carboplatin plus paclitaxel, or observation. The preliminary results^[35] after a median follow-up of 34 mo were promising and showed an improvement in overall survival (HR, 0.62; $P = 0.028$) with chemotherapy. However the mature analysis after a median follow-up of 74 mo no longer showed a statistically significant survival benefit (HR, 0.83; 90%CI: 0.64-1.08³ $P = 0.12$) or disease-free survival benefit (HR, 0.80; 90%CI: 0.62-1.02, $P = 0.065$). Exploratory subgroup analysis of the CALGB 9633 results demonstrated a survival advantage from adjuvant chemotherapy for patients with tumours ≥ 4 cm in diameter (HR, 0.69; $P = 0.043$). Similar conclusions were found in the JBR.10 study where stage I b tumours ≥ 4 cm derived benefit from chemotherapy. In 2011 the IASLC re-classified stage I b tumours which are ≥ 5 cm to be stage II^[36]. Given that at least half of the stage I b patients in both the JBR.10 and CALGB 9633 cohorts had tumours ≥ 4 cm, a significant proportion of these cases will now thus be considered to have stage II disease, casting further doubt on the benefit of adjuvant chemotherapy for currently diagnosed stage I b tumours.

Age

As the world population continues to age, the elderly will comprise an increasing proportion of patients with NSCLC. Despite this they are poorly represented in clinical trials; in the LACE meta-analysis^[19] only 9% of patients were 70 years and older, yet this is close to the median age of diagnosis for NSCLC. This meta-analysis did not show evidence of an interaction between age and chemotherapy benefit.

A retrospective study evaluated the effect of age on adjuvant chemotherapy delivery, toxicity and survival in the JBR.10 study cohort^[37]. Patients were dichotomised using a cut-off age of 65 to define the elderly. The survival HR for adjuvant chemotherapy in the older age group was 0.61 ($P = 0.04$) which was similar to the treatment effect in the overall study population (HR, 0.69). There was no evidence of an interaction by age group.

This benefit was observed despite the authors finding that the older patients received less and lower doses of chemotherapy. It was also reassuring that there was no evidence that the older cohort had increased toxicities from undergoing chemotherapy.

A population-based study in Ontario compared survival for resected NSCLC cases diagnosed between 2001 and 2006; in 2004 adjuvant chemotherapy was adopted across Canada's universal health insurance program^[38]. Cases were identified using the Ontario Cancer Registry. This study found that only 16.2% of patients 70 years and older received adjuvant chemotherapy, compared to 42.7% of patients younger than 70. Despite this a small increase in 4-year survival from 47.1% to 49.9% could still be observed over this time period for patients 70 years and over (HR, 0.87; $P = 0.0123$). The adoption of chemotherapy was considered likely to have contributed to this improvement. Hence current evidence favours treating fit elderly patients with adjuvant chemotherapy.

Risk assessment models

An interactive online tool that uses clinicopathological variables to calculate an individual patient's relapse risk for NSCLC is available at www.adjuvantonline.com. It also calculates the estimated benefit of adjuvant chemotherapy and communicates the benefit of adjuvant chemotherapy in a format that is easy for patients and clinicians to comprehend. However, it should be noted that the ADJUVANT! model has only undergone external validation for its ability to predict recurrence for breast cancer in North American cohorts^[39].

Histology

A differential response to chemotherapy based on histologic subtype has been observed in advanced NSCLC. In this setting a large randomised study^[40] compared cisplatin and gemcitabine with cisplatin and pemetrexed and did not find a difference in overall survival between the treatment arms. However a pre-specified analysis showed that patients with adenocarcinoma and large cell carcinoma histology in the pemetrexed arm had improved survival. Pooled together into a "nonsquamous" subgroup by histology, their survival HR was 0.81 ($P = 0.005$). The treatment-by-histology interaction analysis ($P = 0.0011$) also showed that overall survival for patients with nonsquamous histology was significantly improved in the cisplatin/pemetrexed arm compared with the overall survival for patients treated with cisplatin/gemcitabine, or patients with squamous histology. This differential response to pemetrexed by histology was confirmed by re-analysing an older randomised study comparing pemetrexed and docetaxel in previously treated advanced NSCLC^[41], plus another study comparing maintenance pemetrexed to placebo^[42].

Hitherto no randomised adjuvant study on NSCLC has directly tested the effect of optimising chemotherapy by tumour histology in a similar manner. However, in the ongoing TASTE trial^[43] that restricts entry to non-

squamous tumours, all patients allocated to chemotherapy will receive cisplatin and pemetrexed. This trial is discussed further under "Ongoing studies".

Biomarkers

Tissue biomarkers can provide additional prognostic information to the existing clinico-pathological tumour staging information, and thus help with patient selection for adjuvant therapy. For example it may identify a subgroup of high-risk stage I patients who could benefit from adjuvant chemotherapy. In this section it is useful to note the distinction between prognostic and predictive biomarkers: a prognostic biomarker only provides information about cancer outcomes, regardless of therapy; on the other hand a predictive biomarker only gives information about the effect of a therapeutic intervention, independent of relapse risk^[44].

Excision repair cross-complementation group 1: The International Adjuvant Lung Cancer Trial Biology (IALT Bio) study^[45] examined whether immunohistochemistry (IHC) of lung cancer tissue of patients in the IALT trial (discussed above) could be used to determine which patients would obtain a benefit from cisplatin-based chemotherapy. The excision repair cross-complementation group 1 ERCC1 enzyme is critical for repairing cisplatin-mediated DNA damage, and overexpression has been linked to platinum resistance in tumour cell lines that include NSCLC. Using IHC, ERCC1 expression was evaluated retrospectively in a cohort of 783 patients of the 1045 enrolled in the original clinical trial. It found that patients whose tumours were ERCC1 negative had better overall survival with chemotherapy compared to the control group, with five-year survival being 47% *vs* 39% respectively (HR, 0.65; $P = 0.002$). Disease-free survival was also better with chemotherapy in this group compared to controls (HR, 0.65; $P = 0.001$). With ERCC1 positive tumours however, no significant difference was seen in overall survival between the chemotherapy and observation groups.

A systematic review and meta-analysis was conducted in 2011 to look at the prognostic and predictive utility of ERCC1 in lung cancer^[46]. This found considerable methodological weaknesses in published studies with variations in ERCC1 cutoff, lack of proven correlation between quantitative reverse-transcriptase quantitative polymerase chain reaction (RT-qPCR) assays with IHC, non-standardised protocols and inadequate study sample sizes. It did not find ERCC1 expression to be prognostic in metastatic NSCLC, however there was tentative evidence that high levels of ERCC1 expression predicted resistance to platinum-based chemotherapy. Consequently such patients had shorter survival and a reduced likelihood of tumour response compared to those with low levels of ERCC1 expression. The authors concluded that ERCC1 should only be considered a predictive NSCLC biomarker but not prognostic. They also recommended that ERCC1 should not be used

routinely in clinical decision making until adequately powered prospective trials are conducted.

The ERCC1 Targeted trial was a prospective adjuvant study that used ERCC1 to optimise chemotherapy. It was prematurely terminated as the antibody used did not appear prognostic/predictive based on interim results^[47].

Gene signatures: Gene expression profiling aims to identify unique “signatures” within the tumour’s genome that can help predict relapse risk, response to treatment, or both.

A 15-gene signature was identified in the cohort entered into the JBR.10 trial (discussed above) that was both prognostic and predictive^[48]. Microarray profiling was performed on 133 frozen tumour specimens collected from 482 patients enrolled in this study, to separate patients into a high and low risk group. Subsequently RT-qPCR was used in the same study to verify the microarray signature in this cohort, plus 30 additional cases from the study that were not profiled by microarray.

The prognostic value of this signature was tested using the cohort of patients randomised to observation, by dichotomising patients into high-risk and low-risk subgroups. Overall survival was significantly different between these subgroups, with a HR of 15.02 ($P < 0.001$) for patients whose tumours presented the signature. This finding was validated using 4 separate microarray datasets, and also subsequently using PCR on additional patients from the JBR.10 observation cohort.

This signature also had predictive value; high-risk patients derived a survival benefit from adjuvant chemotherapy (HR, 0.33; 95%CI: 0.17-0.63, $P = 0.005$) that was not seen with low-risk patients (HR, 3.67; 95%CI: 1.22-11.06, $P = 0.0133$). Additionally, although subgroup analysis in the original (clinical) trial found no benefit from chemotherapy in stage I B patients, this gene signature identified patients from this subgroup that had a survival benefit with adjuvant cisplatin and vinorelbine (HR, 0.44; 95%CI: 0.18-1.09, $P = 0.07$). Recently the signature has been validated in another independent cohort of 181 stage I and II patients^[49]. Furthermore, this study found that it was prognostic for survival in both adenocarcinoma and squamous cell carcinoma subtypes, as well as a subgroup of 48 stage I a patients where the survival HR was 5.61 (95%CI: 1.19-26.45, $P = 0.014$).

Another signature incorporating 14 genes has been developed by a United States-Chinese group using formalin-fixed paraffin-embedded (FFPE) specimens in a cohort of 361 patients from the University of California San Francisco with resected non-squamous NSCLC^[50]. This signature separated patients into low, intermediate and high-risk groups in terms of 5-year mortality. It was validated using 2 separate cohorts. The first was from Kaiser Permanente Northern California ($N = 433$), where multivariate analysis confirmed a survival HR of 2.04 ($P = 0.0016$) and 1.66 ($P = 0.0436$) for the high- and intermediate-risk groups, respectively. Using a China Clinical Trials Consortium dataset ($N = 1006$),

corresponding survival HRs were 2.37 ($P < 0.0001$) and 1.87 ($P = 0.0354$). The strengths of this method is that it uses FFPE tissue and qPCR which are easily available in the clinical setting, while the large validation cohorts from diverse geographical and ethnic backgrounds which enables better generalisability of the results. A prospective study is planned to compare adjuvant chemotherapy *vs* observation in stage I patients identified as high risk, using this signature.

A 61-gene signature has been identified that is predictive of a benefit from the MAGE-A3 vaccine that is currently being studied in metastatic melanoma and early NSCLC^[51]. This signature, determined by RT-qPCR, was developed using tumour samples from the melanoma cohort, where it was found to correlate with improved survival. The genes in this signature correlate with immune pathways involved in tissue-specific destruction such as interferon stimulated genes, CCR5 ligand, specific chemokine genes and immune effector function genes. The MAGE-A3 vaccine is concurrently being studied in the adjuvant setting for NSCLC and this is discussed further under “Ongoing studies”. Hence this molecular study also tested the gene signature for its utility as a predictive marker for NSCLC, using tumour samples from the adjuvant studies. Its presence correlated with an improved disease-free interval with vaccine treatment with a HR of 0.42 (95%CI: 0.17-1.03, $P = 0.06$).

At the time of writing, no biomarker has been prospectively validated for the adjuvant management of NSCLC^[52]. We predict that it is highly likely that EGFR (discussed in this article under “Targeted therapy” and “Ongoing studies”), currently used routinely in clinical practice as a predictive biomarker for advanced NSCLC, will also become a standard predictive biomarker for adjuvant therapy in the near future.

Individual preferences

The Preferences for Adjuvant ChemoTherapy (PACT) study surveyed 122 patients^[53] following resection for early NSCLC, and also their 82 respective cancer clinicians^[54] (medical oncologists and thoracic surgeons) to gauge the minimum survival benefit deemed necessary for them to be willing to undergo adjuvant chemotherapy. It found that the median values for the benefit to justify having chemotherapy were an increase in survival of 9 mo, alternatively a 5% increase in 3- or 5-year survival. These median values were similar between patients and clinicians, however the ranges varied widely between respondents, and even more so within the patient cohort. Compared to similar surveys for breast and colon cancer by the same authors, comparatively larger benefits were deemed necessary to justify having chemotherapy in this NSCLC cohort.

INTEGRATING ADJUVANT RADIATION

Post-operative radiotherapy (PORT) for NSCLC has been explored in multiple clinical trials which have yielded

conflicting results. A meta-analysis that included 2128 patients enrolled in nine randomised trials evaluating PORT *vs* surgery alone in resected NSCLC was published in 1998 and showed a significant detrimental effect of PORT on survival (HR, 1.21) with a 7% absolute reduction in overall survival at two years from 55% to 48% ($P = 0.001$)^[55]. On sub-group analysis, this adverse effect was greatest for patients with stage I - II disease, whereas for those with stage III disease there was no clear evidence of an adverse effect. This overview was updated in 2005 and still showed PORT to be detrimental with an 18% relative increase in the risk of death^[56].

The results of this meta-analysis are subject to a number of important limitations. The study included patients enrolled from 1966-1997, many of whom were treated with older radiotherapy techniques (including Cobalt machines) no longer consistent with current standards. The staging evaluation was variable and the analysis included a large number of early stage patients (approximately 25% had N0 tumours) not expected to benefit from PORT. Up to 30% of patients came from a single study^[57] where large dose per fraction (2.5Gy) and high total doses (up to 60Gy) were allowed which may have contributed to excess toxicity and decreased survival. A retrospective analysis of 7465 patients with stage II or III NSCLC from the Surveillance, Epidemiology and End Results (SEER) database between 1988-2002 confirms the findings of the meta-analysis^[58]. It found that PORT significantly decreased the 5-year survival rate in patients with N0 or N1 disease. However, patients with N2 disease had significantly higher 5-year survival with PORT (27% *vs* 20%, $P = 0.0077$).

Subsequent to the meta-analysis, adjuvant chemotherapy has become standard treatment for high-risk NSCLC. Additionally, there have been significant technical improvements in radiotherapy planning and delivery in the modern era including CT-based conformal planning which have made it possible to deliver radiation more safely and with greater precision. Four D-CT planning and respiratory gating now make it possible to control for respiratory motion, potentially reducing pulmonary toxicity. It is difficult to know if these advances in radiation techniques will lead to better outcomes as there are no recent randomised studies published on this, however a recent meta-analysis of "modern" PORT for stage III NSCLC reported an estimated absolute improvement in overall survival by 13% at 5 years and reduction in local recurrence as first relapse to 10%^[59].

Hence the salient question to current practice is whether there is a role for adjuvant radiation using contemporaneous techniques, in conjunction with adjuvant chemotherapy. To answer this question, the investigators of the positive ANITA trial of adjuvant vinorelbine plus cisplatin (discussed above) have published a subsequent retrospective analysis on the effect of PORT from this study^[60]. PORT was permitted in this trial in accordance with local institutional policy. An improvement in survival was seen for patients with N2 disease who received radiotherapy

with a median survival 47 mo *vs* 24 mo in patients given adjuvant chemotherapy, and 23 mo *vs* 16 mo respectively for the observation cohort. Conversely, patients with N0 or N1 disease had a significant detriment in survival through the addition of PORT. Whilst these findings concur with the meta-analysis and SEER findings, the unexpectedly large improvements in survival found in this study should be interpreted with some caution, particularly taking into account the retrospective nature of the analysis, and that radiation was allocated in this study by institutional policy and not randomisation.

The Lung Adjuvant Radiotherapy (LungART) trial^[61] is an ongoing international phase III study comparing PORT with observation following surgery and chemotherapy and will directly answer the important question on whether there is a benefit from radiotherapy after resection for stage III NSCLC.

Whilst survival is a key outcome when considering PORT, loco-regional control remains an important endpoint. The PORT meta-analysis provided data regarding local recurrence rates (LRR) for all included trials. There were fewer local recurrences but more deaths for PORT compared with surgery alone (N = 195 for PORT local recurrences *vs* 276 for surgery alone). However when the data were adjusted for the reduced survival, radiation was in fact found to be detrimental for local recurrence, with a HR of 1.16 (95%CI: 1.05-1.29, $P = 0.005$) favouring surgery alone. One study found no difference in LRR for 728 patients with completely resected NSCLC randomised to receive PORT (HR, 0.85; 95%CI: 0.64-1.14) or observation^[57]. Another study reported a significant overall reduction in LRR at the bronchial stump and/or mediastinum in the group randomised to PORT^[62]. A number of other studies have also reported a reduction in LRR favouring PORT^[59,63,64]. PORT should therefore be considered in the setting of close or involved surgical margins where the rate of local recurrence is high^[65].

The optimal sequence for integrating adjuvant chemotherapy and radiotherapy has not been established. A sequential approach delivering chemotherapy followed by radiotherapy has generally been favoured, although this is not supported by any randomised data. Adjuvant concurrent chemoradiation has been investigated in a number of phase two trials in patients with stage II and III disease and although the approach appears safe, a clear survival benefit has not been demonstrated^[11,66,67]. Some clinicians are also concerned this approach might compromise the ability to deliver the recommended doses and cycles of chemotherapy. Adjuvant concurrent chemoradiation after complete surgery is therefore not considered a standard treatment, although it is currently recommended as an option after surgical resection in patients with N2 disease and positive margins in the current National Comprehensive Cancer Network (NCCN) guidelines^[68].

Until further data becomes available, PORT should only be considered for patients with completely resected stage IIIA-N2 disease, or those at high risk of local recurrence due to close/involved surgical margins.

It should not be offered to patients with completely resected N0 or N1 disease outside a clinical trial.

ONGOING STUDIES

The presence of an activating EGFR mutation has been found to be a strong predictor of a response to EGFR inhibitors^[31]. In the setting of advanced NSCLC, several randomised trials have now consistently shown that patients with EGFR-mutant tumours have high response rates to front-line EGFR inhibition compared to chemotherapy^[33,69,70]. Hence, despite the negative result for adjuvant gefitinib in unselected NSCLC patients in the BR19 study^[30] there is enthusiasm to re-evaluate adjuvant EGFR inhibition in a patient population selected for sensitivity to this treatment. In this context the RADIANT trial compares adjuvant erlotinib with placebo in patients with EGFR-expressing tumours, and has now completed accrual^[71]. Two large ongoing trials are comparing adjuvant gefitinib with chemotherapy in China^[72] and Japan.

Bevacizumab, the monoclonal antibody against vascular endothelial growth factor (VEGF), has been shown to have activity in advanced NSCLC when added to chemotherapy^[73,74]. ECOG has recently completed accrual into a randomised trial that examines the benefit of adding bevacizumab to cisplatin-based chemotherapy in the adjuvant setting^[57].

The Tailored Post-Surgical Therapy in Early Stage NSCLC (TASTE) trial^[43] examines whether customising adjuvant treatment using biomarkers will improve outcomes. Patients in the experimental arm are firstly tested for the presence of an activating EGFR mutation; patients with these mutations will receive erlotinib for 12 mo. Patients without the mutation will be further tested for ERCC1 overexpression; if this is detected they will not be given any adjuvant treatment. Remaining patients in this arm will receive chemotherapy with 4 cycles of cisplatin and pemetrexed, similarly to all patients randomised to the control arm.

Another pharmacogenomics-driven study is the International Tailored Chemotherapy Adjuvant (ITACA) trial^[75]. Patients in the experimental arm are treated according to tumour ERCC1 and thymidylate synthase (TS) expression; increased expression of the latter enzyme correlates with resistance to antifolate drugs such as pemetrexed^[76,77]. Chemotherapy in this arm is with cisplatin/pemetrexed (low ERCC1, low TS), cisplatin/gemcitabine (low ERCC1, high TS), pemetrexed (high ERCC1, low TS), or paclitaxel (high ERCC1, high TS). In the control group, patient/oncologist preference is used to determine which one of 3 possible cisplatin combinations will be administered.

The MAGE-A3 protein has been recently identified as a relatively “pure” tumour antigen, being otherwise expressed primarily during embryogenesis. In adult humans, only the testis and placenta express this antigen. A randomised phase II trial of a vaccine to this antigen

recruited NSCLC patients whose tumours expressed the MAGE-A3 gene^[78]. There was a non-statistically significant improvement in DFS; consequently a confirmatory phase III trial^[79] has now completed accrual.

A small Japanese adjuvant study of 103 patients examined the addition of autologous activated killer T cells and dendritic cells to chemotherapy and found a statistically significant improvement in two-year survival (93.4% *vs* 66%) as well as five-year survival (81.4% *vs* 48.3%) with the addition of immunotherapy^[80]. This very encouraging initial result using a novel approach will no doubt spur interest for similar studies in the future.

CONCLUSION

The survival benefit from adjuvant chemotherapy has been seen to slowly but steadily improve over the last few decades. It is now evident that cisplatin-based chemotherapy offers an absolute overall survival benefit in the order of 5% to 10%. Given that the 2 trials that have shown the highest survival benefit used 4 cycles of high-dose cisplatin in conjunction with vinorelbine, this would currently be considered the optimal treatment regimen. Whilst there is clear evidence of benefit from chemotherapy for patients with stages II and III disease; the benefit for stage I tumours remains controversial. The development of a number of gene expression profile signatures to further stratify patients into low or high risk categories following conventional clinicopathological staging, may allow clinicians to determine which patients will gain a likely benefit from adjuvant therapy in the future. However this strategy requires prospective validation in randomised clinical trials. Given that the presence of activating mutations of EGFR have been found to be strongly predictive of a response to EGFR inhibitors in the setting of advanced NSCLC, similar results are eagerly awaited in the adjuvant setting. Progress in improving the survival of patients with NSCLC has been slow, but the recent improved understanding of the different molecular subtypes of this malignancy as well as the availability of new biological agents to target pathogenic pathways will hopefully translate into ongoing meaningful increments in outcome.

Abstract

First-generation epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKIs), including gefitinib and erlotinib, have proven to be highly effective agents for advanced non-small cell lung cancer (NSCLC) in patients harboring an activating EGFR mutation such as the exon 19 deletion mutation and L858R. Although those reversible small molecular targeted agents provide a significant response and survival benefit, all responders eventually acquire resistance. Second-generation EGFR-targeting agents, such as irreversible EGFR/HER2 tyrosine kinase inhibitors and pan-HER TKIs, may improve survival further and be useful for patients who acquired resistance to first-generation EGFR-TKIs. This review discusses novel therapeutic strategies for EGFR-mutated advanced NSCLC using first- and second-generation EGFR-TKIs.

INTRODUCTION

Epidermal growth factor receptor (EGFR) is the founding member of the ErbB family of 4 structurally related receptor tyrosine kinases, including EGFR (ErbB1), ErbB2, ErbB3 and ErbB4. The receptors of the ErbB family are activated after binding to peptide growth factors of the EGF family. Upon ligand binding, the ErbB receptors form either homo- or heterodimers and, after dimerization, auto- and transphosphorylation on tyrosine residues of the ErbB receptors occurs^[1]. Non-small cell lung cancer (NSCLC) tumors harboring specific EGFR mutations are dependent on EGFR signaling for uncontrolled proliferation and resistance to apoptosis^[2-4] (Figure 1). The 2 most frequent activating EGFR mutations, responsible for approximately 90% of this anomaly in the cell cycle, are the L858R point mutation and the exon

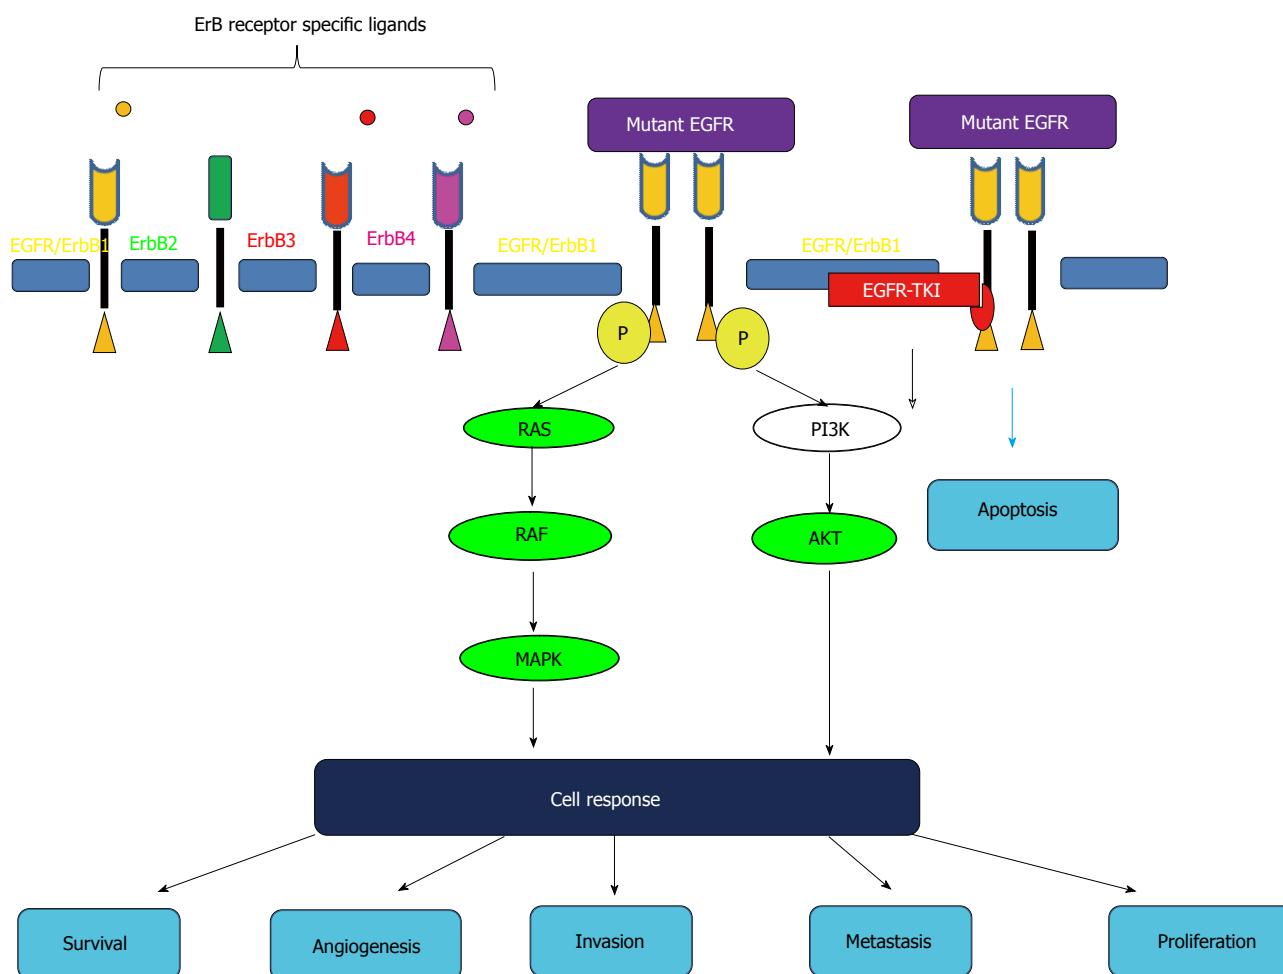

Figure 1 Cell-proliferative signaling pathways in lung cancer cell. The epidermal growth factor receptor (EGFR) family consists of 4 members: EGFR/ErbB1, ErbB2, ErbB3 and ErbB4. Specific ligands (e.g., EGF, TGF- α) binding to EGFR results in a conformational change of the receptor, exposing the dimerization domain and allowing for homodimerization with a second EGFR, or heterodimerization with another member of the EGFR family. Activation of the EGFR results in autophosphorylation of key tyrosine residues. These tyrosine phosphorylated sites leads to the activation of major downstream signaling cascades, including the Ras/Raf/MAPK pathway and PI3K/AKT pathway. These pathways act in a coordinated manner to promote cell survival. While wild type EGFR is activated in a ligand-dependent manner, mutant EGFR is constitutively activated. First- or second-generation EGFR-TKIs bind reversibly or irreversibly to the kinase domain and effectively inhibit EGFR tyrosine kinase by binding to the adenosine triphosphate-binding site of the enzyme and inhibit downstream signaling, leading to apoptosis of cancer cells.

19 deletion mutation^[5]. In the last decade, therapeutic agents targeting the EGFR signaling pathway, including 2 reversible EGFR tyrosine kinase inhibitors (TKIs) such as gefitinib and erlotinib, have been clinically effective in treating lung cancer patients harboring activating EGFR mutations^[6-12].

Despite the great efficacy of first-generation EGFR-TKIs in patients with EGFR-mutated NSCLC, all responders eventually develop resistance to these agents. The treatment strategies for NSCLC patients who developed resistance to first-generation EGFR-TKIs are actively studied. Recently, second-generation EGFR-TKIs, including afatinib (BIBW 2992) and dacomitinib (PF-00299804), became available; these drugs are intended to further prolong survival in patients harboring activating EGFR mutation and may overcome the resistance to first-generation EGFR-TKIs. This article focuses on the EGFR-TKI-based strategy for patients with advanced NSCLC expressing activated mutant EGFR.

STANDARD PLATINUM-BASED CHEMOTHERAPY VS FIRST-GENERATION EGFR-TKIS AS A FIRST-LINE TREATMENT OF EGFR-MUTATED NSCLC

Efficacy and toxicity

Four previous randomized phase III trials assessing first-line treatment demonstrated a significantly higher response rate (RR) and longer progression-free survival (PFS) in patients treated with first-generation EGFR-TKIs, including gefitinib and erlotinib, than in patients treated with standard platinum-based combination chemotherapy (Table 1). Although these trials met their primary endpoint with statistically significant longer PFS, no significant difference was observed in terms of overall survival (OS). No restrictions were imposed on treatment after the end of protocol therapy in these 4 trials and the majority of patients in the control arm received EGFR-

TKI therapy at least once.

In these 4 randomized phase III trials, severe adverse events or treatment-related toxicity leading to discontinuation of the therapy were significantly less prevalent in patients treated with first-generation EGFR-TKIs compared to standard chemotherapy. The most common adverse events in patients treated with first-generation EGFR-TKIs were cutaneous toxicity, including skin rash and dry skin, diarrhea and elevated transaminase level. Compared to chemotherapy, hematological toxicity, fatigue, alopecia and nausea were less prevalent in the experimental arm of first-generation EGFR-TKIs^[9-12].

Quality of life

Three randomized phase III trials comparing first-generation EGFR-TKIs to standard chemotherapy have shown EGFR-TKI to be superior to chemotherapy in quality of life (QoL) effects. Two randomized phase III trials of first-generation EGFR-TKIs, including the IPASS study^[7] and OPTIMAL study^[13], assessed QoL as a secondary endpoint using Functional Assessment of Cancer Therapy-Lung (FACT-L), Trial Outcome Index (TOI), or Lung Cancer-Specific Subscale (LCS; Table 2). Patients receiving first-line EGFR-TKIs experienced clinically relevant improvements in QoL compared to patients treated with standard platinum doublet chemotherapy in these studies. Among patients harboring activating EGFR mutations in the IPASS study, significant improvement of QoL was found in patients treated with gefitinib compared to patients treated with chemotherapy. Furthermore, rapid improvement of QoL both in terms of FACT-L and LCS was observed in patients with mutated EGFR. In the OPTIMAL study, patients with an improvement in QoL showed improved PFS compared with patients with stable or worsened QoL. Further significant correlations were observed between improved QoL and tumor re-

sponse with FACT-L, TOI and LCS.

In the NEJ 002 study, QoL was assessed by analyzing time to deterioration from baseline in the physical, mental and life well-being QoL scales. Time to defined deterioration in physical and life well-being significantly favored gefitinib over standard chemotherapy [hazard ratio (HR) of time to deterioration, 0.34; 95% confidence interval (CI), 0.23-0.50; $P < 0.0001$ and HR, 0.43; 95%CI: 0.28-0.65, $P < 0.0001$ respectively]^[14].

FIRST-GENERATION EGFR-TKIS FOR ELDERLY PATIENTS AND/OR PATIENTS WITH POOR PS (3-4)

In the WJOG 3405 study and the NEJ 002 study, patients of older age (≥ 75) and poor performance status (PS 2-4) were excluded. An earlier phase II trial demonstrated efficacy of gefitinib as a first-line treatment in elderly patients with activated mutant EGFR and/or patients with poor PS (3-4; Table 3)^[15-17]. Although each trial had a small sample size and was a single-arm phase II trial, high RRs (59%-74%) and long PFSs were observed. Inoue *et al.*^[15] reported utility of first-line gefitinib for extremely poor PS patients and approximately 80% of the patients enrolled this trial improved PS after initiation of gefitinib. Among them, some patients with PS = 4 experienced a dramatic improvement in systemic advanced disease shortly after initiation of gefitinib. No prospective clinical trials of gefitinib except for this study in advanced NSCLC patients with poor PS (3-4) have been conducted and there have been no randomized trials comparing EGFR-TKIs to chemotherapy as a first-line treatment of EGFR-mutated advanced NSCLC.

Although no randomized controlled trials of erlotinib in elderly patients harboring an activating EGFR

mutation have been conducted yet, 18 years old or older patients were enrolled in the OPTIMAL study and the EUROTAC study. No negative effects of erlotinib, such as severe toxicity, lower response and shorter survival, were documented in elderly patients in these studies. Another phase II trial showed that erlotinib is effective and relatively well tolerated in chemotherapy-naïve elderly patients (≥ 70) with advanced NSCLC^[18]. EGFR mutations were detected in 9 of 43 patients tested and all patients harboring an EGFR mutation achieved either a partial response (PR) or stable disease (SD).

Reck *et al*^[19] examined a subpopulation of elderly patients (≥ 70) receiving first-line erlotinib ($n = 485$) in the TRUST study ($n = 6580$), an open-label phase IV trial of erlotinib in advanced non-selected NSCLC patients who had previously failed, or were considered unsuitable to receive, standard chemotherapy or radiotherapy^[20]. In this subpopulation, disease control rate (complete response plus PR plus SD), median PFS and OS were 79% (*vs* 69% for the overall TRUST population; $P < 0.0001$), 4.57 mo (*vs* 3.25 mo), and 7.29 mo (*vs* 7.9 mo) respectively. Nev-

ertheless, elderly patients with poor PS (2-3) had worse survival outcomes than those with good PS (0-1). Median PFS of PS 0-1, 2 and 3 were 5.58 mo, 3.15 mo and 1.81 mo respectively. Median OS of PS 0-1 and 3 was 10.38 mo and 2.07 mo respectively. Eighteen percent of elderly patients had an erlotinib-related adverse event (AE) and 20 patients (4%) developed severe toxicity [grade ≥ 3 ; *vs* 173 patients (3%) in the overall TRUST population]. Twenty-seven percent of elderly patients needed a dose reduction of erlotinib (*vs* 17% in the overall TRUST population). No molecular information, including EGFR mutation status, was examined in this study. Considering the results of these studies, investigators concluded that first-line erlotinib may be well tolerated and be considered for elderly patients with advanced NSCLC the same as non-elderly patients.

WHICH LINE OF TREATMENT IS BETTER FOR FIRST-GENERATION EGFR-TKIS IN PATIENTS WITH MUTANT EGFR?

Several investigators have assessed first-generation EGFR-TKIs as a second/third-line treatment in patients with NSCLC carrying activated mutant EGFR based on their small prospective or retrospective studies and subset analysis of phase III trials (Table 4)^[21-25]. As for response rate and time to progression, these results were similar to the results of a previous large phase III trial of first-generation EGFR-TKIs as a first-line treatment. Rosell *et al*^[8] reported that no significant difference was observed between chemotherapy-naïve and chemorefractory patients in terms of RR (73.5% *vs* 67.4%), PFS (14 mo *vs* 13 mo) and OS (28 mo *vs* 27 mo) with erlotinib in patients with activated mutant EGFR.

In contrast, lower RR with gefitinib was documented

in the NEJ 002 study in patients who failed first-line chemotherapy compared to patients treated with gefitinib as a first-line treatment (56% *vs* 74%). Several studies documented that heterogeneity in EGFR gene expression and mutations was observed in patients with NSCLC^[26-28]. Bai *et al*^[29] reported that chemotherapy may reduce EGFR mutation frequency in patients with NSCLC. In their study, samples were derived from 3 cohorts and 409 patients were reviewed. The decrease in EGFR mutation rate was statistically significant and patients whose EGFR mutations switched from positive to negative after chemotherapy had a better RR than patients with a reverse change among the patients who received first-line chemotherapy with matched pre- and post-chemotherapy blood samples. A similar decrease in EGFR mutation rate was observed in tissues after neoadjuvant chemotherapy in the second cohort (34.9% *vs* 19.0%, $P = 0.013$). In the third cohort, 38.0% of the tumors showed intratumor heterogeneity of EGFR mutations, whereas 62.0% were homogeneous, either with an EGFR mutation or no mutation. The authors concluded that chemotherapy may reduce EGFR mutation frequency in patients with NSCLC.

Lee *et al*^[30] reviewed 23 randomized controlled trials comparing EGFR-TKIs or EGFR-TKIs plus chemotherapy to chemotherapy or placebo, including 13 studies as a first-line treatment, 7 as a second-line treatment, and 3 as maintenance therapy ($n = 14570$). Data on PFS were available from 21 trials of EGFR-TKIs, including gefitinib (10 trials), erlotinib (10 trials) and afatinib (1 trial), compared to control treatment. EGFR-TKIs prolonged PFS in patients with mutated EGFR and an EGFR mutation was predictive of PFS in all settings. In EGFR mutation-positive patients, EGFR-TKI treatment was associated with a lower risk of disease progression in first-line settings (HR, 0.43; 95%CI: 0.38 to 0.49, $P < 0.001$) and in second-line or later settings (HR, 0.34; 95%CI: 0.20 to 0.60, $P < 0.001$). This study demonstrates that the magnitude of effect on PFS in patients with mutated EGFR is similar to that in patients receiving EGFR-TKIs as either a first- or second-line treatment (HR, 0.43 and 0.34 respectively). EGFR-TKI treatment, however, had no impact on OS in patients with mutated EGFR.

A recent systematic review of chemotherapy trials for NSCLC indicated that PFS advantage is unlikely to be associated with an OS advantage due to the increasing impact of survival post-progression on OS^[31]. Salvage therapy after disease progression may have a great influence on the prolongation of survival. In randomized phase III trials, including the IPASS study, the WJTOG 3405 study and the OPTIMAL study, a considerable percentage of enrolled patients was not treated with EGFR-TKIs as a salvage therapy because of a patient's refusal and deterioration of the general condition: IPASS (36%), WJTOG3405 (41%) and OPTIMAL (30%). Although a considerable number of patients did not receive EGFR-TKI therapy after failure of standard chemotherapy, no statistically significant difference was noted in terms of overall survival in each trial.

GEFITINIB OR ERLOTINIB AS A FIRST-LINE TREATMENT OF NSCLC POSITIVE FOR AN ACTIVATING EGFR MUTATION

No trials comparing erlotinib directly with gefitinib as a first-line treatment in patients with activated mutant EGFR have been conducted. A retrospective study showed that PFS showed no difference with either agent in patients harboring an EGFR mutation^[32]. Among 224 patients, including 124 treated with gefitinib and 100 treated with erlotinib who were reviewed, 75 patients received EGFR-TKIs as first-line therapy and 146 patients tested positive for an activating EGFR mutation. In patients harboring an EGFR mutation, median RR and PFS with gefitinib and erlotinib was 51%, 10.5 mo ($n = 94$) and 58%, 10.4 mo ($n = 52$) respectively. No statistically significant difference was observed in terms of RR and PFS between patients treated with gefitinib and those treated with erlotinib. HRs for PFSs were 0.32-0.54 in previous randomized phase III trials of gefitinib as a first-line treatment compared to standard chemotherapy, including the IPASS study, First-Signal study^[33], WJTOG 3405 study and the NEJ 002 study.

On the other hand, HRs for PFSs were 0.16-0.37 in a phase III trial of first-line erlotinib, including the OPTIMAL study and EUROTAC study. Schwander *et al*^[34] reported at the International Society For Pharmacoeconomics and Outcomes Research (ISPOR) 2011 Annual International Meeting that erlotinib shows better efficacy as a molecular targeted agent in first-line settings compared to gefitinib in patients with EGFR-mutated advanced NSCLC. Investigators compared PFS HRs of erlotinib *vs.* gefitinib using indirect treatment comparison (ITC) assessment based on the OPTIMAL study and the IPASS study. A significant PFS difference (ITC HR, 0.33; 95%CI: 0.19-0.58, $P = 0.0001$) was observed. Furthermore, this statistically significant PFS difference was also observed when comparing OPTIMAL with WJTOG 3405 (ITC HR, 0.48; 95%CI: 0.24-0.97, $P = 0.0395$) or with NEJ 002 (ITC HR, 0.53; 95%CI: 0.30-0.90, $P = 0.0307$).

Paz-Ares *et al*^[35] identified congress reports and papers reporting PFS for EGFR-mutated NSCLC treated with chemotherapy, erlotinib or gefitinib (phase II / III trials/retrospective analyses) in a literature search and checked for duplication and reported the results at the 2012 Annual Meeting of the European Society of Medical Oncology (ESMO). Data were included from 20 chemotherapy studies ($n = 984$), 27 erlotinib studies ($n = 735$) and 56 gefitinib studies ($n = 1843$). Longer PFS was seen with both EGFR-TKIs compared with chemotherapy across treatment lines. Pooled median PFS of all lines of therapy for erlotinib and gefitinib was 12.4 mo (95%CI: 11.6-13.4 mo; $n = 735$) and 9.3 mo (95%CI: 8.9-9.8 mo; $n = 1843$) respectively. Furthermore, in the studies where 90% or more of patients received EGFR-TKIs in first-line settings (predominantly first-line), pooled median PFS for erlotinib and gefitinib was 12.0 mo (95%CI:

Table 5 First-generation epidermal growth factor receptor tyrosine kinase inhibitor plus chemotherapy for unselected patients with non-small cell lung cancer

^aDose of gefitinib is 250 mg; ^bDose of gefitinib is 500 mg. EGFR-TKIs: Epidermal growth factor receptor tyrosine kinase inhibitors; NSCLC: Non-small cell lung cancer; PFS: Progression-free survival; OS: Overall survival; CDDP: Cisplatin; GEM: Gemcitabine; PTX: Paclitaxel.

10.8-13.3 mo; $n = 354$) and 9.7 mo (95%CI: 9.0-10.5 mo; $n = 716$) respectively. In contrast, pooled PFS of all lines of therapy and predominantly first-line for chemotherapy was 5.6 mo (95%CI: 5.3-6.0 mo; $n = 984$) and 5.8 mo (95%CI: 5.5-6.2 mo; $n = 868$) respectively. The investigators concluded that patients with activated mutant EGFR derived a greater benefit from EGFR-TKIs than from conventional chemotherapy, especially when administered as a first-line treatment.

Retrospective analysis of AEs comparing gefitinib with erlotinib showed that erlotinib appeared to have higher toxicity than gefitinib at each approved dose^[36]. Among 142 patients with NSCLC, including 107 treated with gefitinib and 35 treated with erlotinib who were retrospectively reviewed, 70 patients had an activating EGFR mutation. In the study, a significantly higher rate of AEs, including rash, stomatitis, constipation and anorexia, was observed in the erlotinib group. This group also had a tendency to require a dose reduction due to AEs. Further comparison of the frequency of grade 2 AEs showed that rash was the main reason for a dose reduction in a significantly higher percentage of patients in the erlotinib group.

CHEMOTHERAPY PLUS FIRST-GENERATION EGFR-TKIS IN PATIENTS WITH MUTATED EGFR

An earlier large randomized phase III trial of chemotherapy plus first-generation EGFR-TKI in unselected chemotherapy-naïve patients with advanced NSCLC, including the INTACT-1 study (chemotherapy plus gefitinib)^[37], the INTACT-2 study (chemotherapy plus gefitinib)^[38], the TRIBUTE study (chemotherapy plus erlotinib)^[39] and the TALENT study (chemotherapy plus erlotinib)^[40], failed to show superiority to standard platinum doublet chemotherapy in terms of RR, PFS and OS (Table 5).

In the CALGB 30406 study, a randomized phase II trial comparing erlotinib plus chemotherapy (carboplatin plus paclitaxel) to erlotinib monotherapy in chemotherapy- and EGFR-TKI-naïve patients with advanced

NSCLC, activating EGFR mutations were detected in 40% (66 of 164) of the enrolled patients^[41,42]. The response rate, PFS and OS of erlotinib plus chemotherapy were: 70%, 14.1 mo and 31.3 mo; and 73%, 17.2 mo and 38.1 mo, respectively. Although statistical comparison between erlotinib monotherapy and erlotinib plus chemotherapy was not carried out in patients with mutated EGFR in this study, longer survival, including PFS and OS, was found in patients with mutated EGFR treated with erlotinib plus chemotherapy. The FASTACT-2 study, a randomized double-blind trial comparing chemotherapy to intercalated combination of chemotherapy (gemcitabine plus cisplatin or carboplatin) and erlotinib in untreated patients with advanced NSCLC, met its primary endpoint of PFS (median PFS 7.6 mo *vs* 6.0 mo, HR, 0.57; $P < 0.0001$)^[43]. Among patients with mutated EGFR, median PFS and median OS were significantly longer in patients treated with chemotherapy plus erlotinib (PFS: 16.8 mo *vs* 6.9 mo, HR, 0.25; 95%CI: 0.16-0.39, $P < 0.0001$; OS: 31.4 mo *vs* 20.6 mo, HR, 0.48; 95%CI: 0.27-0.84, $P = 0.0092$). In contrast, no significant difference in PFS and OS between patients treated with chemotherapy plus erlotinib and patients treated with chemotherapy plus placebo was noted in patients with wild-type EGFR. Serious AEs were observed in 34% of patients in the chemotherapy plus placebo group and 31% of patients in the chemotherapy plus erlotinib group. The number of adverse events that led to discontinuation of the therapy was not significantly different between the 2 groups.

No prospective studies of EGFR-TKI plus chemotherapy as a first-line treatment in patients with EGFR-mutated advanced NSCLC have been conducted. Indirect comparison of data available from the INTACT 1 and 2 studies, the TRIBUTE study and the TALENT study indicates that EGFR-TKIs plus chemotherapy were effective in reducing the risk of disease progression in patients harboring an activating EGFR mutation compared to chemotherapy alone (HR, 0.54; 95%CI: 0.30-0.95, $P = 0.049$)^[30]. In contrast, EGFR-TKIs plus chemotherapy were not more effective than EGFR-TKIs in reducing the risk of disease progression (HR, 1.42; 95%CI:

Table 6 Clinical trials of second-generation epidermal growth factor receptor tyrosine kinase inhibitors (afatinib, dacomitinib) against non-small cell lung cancer expressing activated mutant epidermal growth factor receptor

0.80-2.53, $P = 0.23$) in patients with mutated EGFR.

SECOND-GENERATION EGFR-TKIS

The second-generation EGFR-TKIs, including afatinib^[45] and dacomitinib^[45], are intended to improve efficacy of treatment in patients with activated mutant EGFR and to improve the outcome in patients who acquired resistance to first-generation EGFR-TKIs. Table 6 shows previous studies of second-generation EGFR-TKIs, including afatinib and dacomitinib, for patients with advanced NSCLC carrying activated mutant EGFR.

Afatinib is an irreversible pan-HER-TKI and binds to EGFR receptors carrying the T790M substitution, which is the mutation conferring resistance to first-generation EGFR-TKIs. The LUX-Lung 2 study was a multicenter phase II trial evaluating the efficacy of afatinib 40-50 mg daily as a first- or second-line treatment in patients with EGFR-mutated advanced NSCLC^[46]. Among 129 patients enrolled in the study, 23 patients tested positive for uncommon EGFR mutations and the other cases were positive for activating EGFR mutations, including the exon 19 deletion mutation and L858R. The response rate, median PFS and median OS in patients harboring an activating EGFR mutation were 66%, 15.0 mo and 32.0 mo respectively. The most severe AEs (grade 3-4) were diarrhea and skin-related events and approximately a quarter of patients who developed these AEs received 50 mg of afatinib as an initial dose. Nearly 70% (of the 99 patients who had an initial dose of 50 mg) had to have their dose reduced to 40 mg and more than a half of these patients needed a further dose reduction to 30 mg. In 30 patients with a starting dose of 40 mg, a dose reduction to 30 mg was needed in 11 (37%) patients.

The LUX-Lung 3 study was a randomized phase III trial comparing afatinib to standard platinum doublet chemotherapy as a first-line treatment in patients with advanced EGFR-mutated lung adenocarcinoma^[47]. In total, 345 patients harboring EGFR mutations were randomly assigned to treatment groups (230 to afatinib and 115 to chemotherapy) and an activating EGFR mutation such as the exon 19 deletion mutation and L858R was detected in 308 patients (204 in the afatinib group and 104 in the chemotherapy group). Median PFSs were 11.1 mo for

afatinib and 6.9 mo for chemotherapy (HR, 0.58; 95%CI: 0.43-0.78, $P < 0.001$) in the enrolled patients and 13.6 mo for afatinib and 6.9 mo for chemotherapy (HR, 0.47; 95%CI: 0.34-0.65, $P < 0.001$) in patients harboring an activating EGFR mutation. Compared to chemotherapy, afatinib significantly delayed deterioration of cancer-related symptoms, including cough and dyspnea (cough, HR, 0.60; $P = 0.007$; dyspnea, HR, 0.68; $P = 0.015$). The prevalence of AEs leading to discontinuation of the therapy was similar in both groups. The most frequent AEs were diarrhea (95%), rash or acne (89%), stomatitis or mucositis (72%), paronychia (57%) and dry skin (29%) in patients treated with afatinib. Afatinib controlled cough and dyspnea better than chemotherapy, whereas diarrhea, dysphagia and sore mouth were worse with afatinib. Global health status/QoL was also improved over time with afatinib compared to chemotherapy.

At the 2013 Annual Meeting of the American Society of Clinical Oncology (ASCO), Wu *et al*^[48] reported the results of LUX-Lung 6, a randomized phase III trial comparing afatinib to standard platinum doublet chemotherapy as a first-line treatment in Asian patients with advanced EGFR-mutated lung adenocarcinoma. There were 364 chemotherapy-naïve patients (242 treated with afatinib, 122 treated with cisplatin plus gemcitabine). Afatinib was administered daily at 40 mg. This study met its primary endpoint with significant longer median PFS compared to chemotherapy (13.7 mo *vs* 5.6 mo, HR, 0.26; $P < 0.0001$). The response rate was significantly higher in patients treated with afatinib (66.9% *vs* 23.0%, $P < 0.0001$). Severe AEs (grade 3-5) were noted in 36% of patients treated with afatinib. The most common AEs were rash/acne (14.6%), diarrhea (5.4%) and stomatitis/mucositis (5.4%) in patients treated with afatinib. AEs leading to discontinuation of treatment were reported in 5.9% of patients treated with afatinib and 39.8% of patients treated with chemotherapy. Patient-reported outcomes showed significantly better control of cancer-related dyspnea, cough and pain with afatinib.

Dacomitinib is an irreversible pan-HER inhibitor and binds irreversibly to the adenosine triphosphate domain of 3 kinase-active members of the HER family, including EGFR, HER2 and HER4. In preclinical studies, dacomitinib showed greater antitumor activity in first-

Figure 2 Major mechanisms of epidermal growth factor receptor resistance to epidermal growth factor receptor-tyrosine kinase inhibitors in lung cancer cell. Secondary epidermal growth factor receptor (EGFR) T790M mutation prevents binding of first-generation EGFR-tyrosine kinase inhibitors (TKIs), including gefitinib and erlotinib to EGFR, resulting in cancer cell survival (A). Afatinib inhibits the ATP-binding site of the tyrosine kinase associated with EGFR T790M, leading to apoptosis of cancer cell. MET amplification has been shown to confer resistance to EGFR-TKIs by activating phosphorylation of ErbB3 with activating of the PI3K/AKT pathway, resulting in cancer cell survival (B).

generation EGFR-TKI-resistant cell lines (including gefitinib and erlotinib) and in xenograft NSCLC models^[45,49]. In a randomized open-label trial comparing dacomitinib to erlotinib in previously treated patients with advanced NSCLC, 188 patients were randomly assigned to the 2 treatment groups^[50]. Although median PFS was significantly longer in patients treated with dacomitinib (2.9 mo *vs* 1.9 mo, HR, 0.66; 95%CI: 0.47-0.91, $P = 0.012$), no significant difference was noted in terms of median OS (9.5 mo *vs* 7.4 mo, HR, 0.80; 95%CI: 0.56-1.13, $P = 0.205$). Among all patients enrolled in the study, an activating EGFR mutation was detected in 30 patients (19 in the dacomitinib group, 11 in the erlotinib group). In patients with mutated EGFR, median PFS was 7.4 mo with either dacomitinib or erlotinib (HR, 0.46; 95%CI: 0.18-1.18, $P = 0.098$). AEs leading to treatment withdrawal were uncommon in both treatment arms. Common treatment-related adverse events were dermatological and gastrointestinal, predominantly grade 1 to 2, and more frequent with dacomitinib.

At the 2012 Annual Meeting of ASCO, Kris *et al.*^[51] reported the results of dacomitinib in chemotherapy-naïve patients with EGFR-mutated NSCLC. A total of 92 patients were enrolled in the study and 46 cases were positive for activating EGFR mutations. Among patients with mutated EGFR, RR was 74% (34 of 46 patients) and PFS at 4 mo after initiation of dacomitinib and PFS

were 95.5% (95%CI: 83.2-98.9%) and 18.2 mo (95%CI: 12.8-23.8 mo) respectively. For all 92 patients, common side effects (grade 3-4) were skin related toxicity (17%) and diarrhea (14%). Three patients (6.5%) with activated mutant EGFR discontinued the therapy because of drug-related toxicity.

TREATMENT AFTER A FAILURE OF FIRST-GENERATION EGFR-TKIS AGAINST EGFR-MUTATED NSCLC

Despite a good response and PFS benefits with first-generation EGFR-TKIs, the majority of responders ultimately develop resistance to the therapy after 9-14 mo^[7,9,11-12]. The most frequent secondary resistance to first-generation EGFR-TKIs is the EGFR T790M mutation (50%-60%) and the other mechanisms of resistance are amplification of the MET and HER2 genes, mutations in PIK3CA and BRAF, and conversion to small cell lung cancer^[52-54] (Figure 2). Approximately 30% of patients who acquired EGFR-TKI resistance have an unknown mechanism of resistance.

In the LUX-Lung 1 study, a randomized phase II b/III trial comparing afatinib to placebo in patients who failed first-generation EGFR-TKIs, 585 patients were randomly allocated to treatment groups (390 to afatinib

and 195 to placebo). Median overall survival was 10.8 mo (95%CI: 10.0-12.0 mo) in patients treated with afatinib and 12.0 mo (95%CI: 10.2-14.3 mo) in the placebo group (HR, 1.08; 95%CI: 0.86-1.35, $P = 0.74$). Median PFS was longer in the afatinib group than in the placebo group (3.3 mo *vs* 1.1 mo; $P < 0.0001$). The response rate was 7% (29 of 390 patients) in the afatinib group and 0.5% (1 of 195 patients) in the placebo group^[55].

Cetuximab is a chimeric human-murine monoclonal antibody that binds competitively and with high affinity to the EGFR receptor^[56]. In a study of cetuximab in NSCLC patients previously treated with EGFR-TKIs, the response rate, median PFS and median OS were 0%, 1.8 mo (95%CI: 1.6-5.4 mo), 7.5 mo (95%CI: 2.2-19 mo) respectively. Among 3 patients who harbored an activating EGFR mutation, 1 maintained its stable disease effect for approximately 6 mo^[57].

Janjigian *et al*^[58] reported safety and efficacy results of a cohort study of the combination of afatinib and cetuximab in patients with NSCLC who had acquired resistance to erlotinib or gefitinib. One hundred patients were enrolled in the study and received the therapy. An activating EGFR mutation was detected in 94% (94/100) and the EGFR T790M mutation was detected in 53% (53/100) of the patients. Ninety-six patients were evaluated for efficacy of the therapy. Twenty-nine patients (30%) had PR to the therapy. Seventeen (32%) of 53 patients harboring the secondary-resistance EGFR T790M mutation had PR. Treatment-related toxicity leading to discontinuation of the therapy was observed in 19% of the patients. The most common AEs associated with the therapy were skin rash (97%) and diarrhea (71%).

LUX-Lung 4 was a phase II trial of afatinib in Asian patients who failed gefitinib or erlotinib or both^[59]. Of the 62 patients enrolled in the study, 45 patients had activating EGFR mutations. The response rate, median PFS and median OS were 8.2% (95%CI: 2.7-18.1%), 4.4 mo (95%CI: 2.8-4.6 mo), and 19.0 mo (95%CI: 14.9 mo to not achieved) respectively. Among 2 patients harboring an EGFR mutation who acquired the T790M mutation, 1 patient had stable disease for 9 mo and another for 1 mo. The most common treatment-related AEs were diarrhea (100%) and rash/acne (92%). Twenty-nine percent of the patients enrolled in the study discontinued the therapy due to afatinib-related AEs.

Several investigators have suggested that erlotinib may have a stronger biological activity than gefitinib based on their own findings. Gefitinib (250 mg per day) is typically administered at 1/3 of its maximum tolerated dose, whereas erlotinib (150 mg per day) is administered at its maximum tolerated dose. *In vitro* data showed that the mean concentration of gefitinib in blood plasma is 0.24 µg/mL at the 300 mg daily dose and 1.1 µg/mL at 1000 mg/d. In contrast, median concentration of erlotinib at 150 mg/d was 1.26 µg/mL. Previous findings suggest that erlotinib (150 mg/d) has a higher biological dose of EGFR inhibition than gefitinib (250 mg/d)^[60]. In the results of previous retrospective studies of second-line

erlotinib after a failure of gefitinib in patients harboring activating EGFR mutations, RR and PFS were 3%-10% and 2-3 mo respectively^[61-63]. The investigators suggested that subsequent erlotinib may elicit a response and a survival benefit in patients with mutated EGFR, with good performance status, good response and shorter duration of gefitinib administration (less than 12 mo).

DISCUSSION

Our recommended first- and second-line therapeutic regimens, mainly based on the results of phase III studies, are shown in Figure 3. First- and second-generation EGFR-TKIs, including gefitinib, erlotinib and afatinib, and cytotoxic chemotherapy are optimal first-line therapies in patients harboring activating EGFR mutations. Chemotherapy is recommended as a second-line treatment after failure of first-line EGFR-TKIs, including gefitinib, erlotinib and afatinib, and second-line therapy using these EGFR-TKIs is recommended in patients who failed chemotherapy. Subsequent erlotinib therapy may be a reasonable treatment in specific patients who failed first-line gefitinib therapy.

Although the data from several trials are insufficient to definitively determine the optimal treatment for EGFR-TKIs in patients with EGFR mutations, EGFR-TKIs play a key role in the treatment of patients harboring EGFR mutations and non-administration of these agents could adversely affect survival. Therefore, EGFR-TKIs should be administered early in the course of treatment, as a first- or second-line therapy, so that a chance to administer these agents is not missed due to clinical deterioration or severe toxicity after cytotoxic chemotherapy. Physicians should select either chemotherapy or an EGFR-TKI according to the patient's clinical condition, including PS, age, organ function and complications in non-elderly patients harboring an activating EGFR mutation. For elderly patients (75 years or older) who should not receive chemotherapy and/or patients with poor performance status (PS 3-4), first-line treatment with gefitinib may be considered.

No QoL assessment is currently available comparing second-line EGFR-TKIs after failure of chemotherapy to second-line chemotherapy after failure of EGFR-TKIs in patients harboring an activating EGFR mutation, which is problematic. Furthermore, it is unclear which EGFR-TKI(s) are most desirable as an initial therapy and whether second-generation EGFR-TKIs can overcome acquired secondary resistance to first-generation EGFR-TKIs in NSCLC. Additionally, the appropriate timing for discontinuation of EGFR-TKIs after confirmation of tumor progression is not clear. Some retrospective studies suggest that continuation of EGFR-TKIs beyond disease progression may prolong overall survival of patients with mutated EGFR, with a good therapeutic response^[64,65]. Investigators concluded that EGFR-TKI responders should continue the therapy until the clinical condition and/or imaging findings are reversed to the condition at therapy initiation. Treatment assessment based on

Figure 3 First- and second-line treatment strategies for activating epidermal growth factor receptor-mutated advanced non-small cell lung cancer. First- or second-generation EGFR-tyrosine kinase inhibitors (TKIs), including gefitinib, erlotinib and afatinib, are recommended as initial EGFR-TKI therapy (A and B). First-line gefitinib is recommended in patients with poorer performance status who cannot be treated with systemic chemotherapy. First- (C) or second-line (A and B) cytotoxic chemotherapy is recommended in chemotherapy naïve patients. Subsequent erlotinib may be useful in specific patients who failed gefitinib (A).

response evaluation criteria in solid tumors (RECIST) may be unsuitable for EGFR-TKIs and a new treatment assessment that may impact survival is needed^[66]. Table 7 shows the ongoing trials for patients harboring activating EGFR mutations. The results of these studies will provide considerable information for EGFR-TKI selection for EGFR-mutated NSCLC. In the future, investigators need to assess the QoL of patients treated with EGFR-TKIs and to compare first- and second-line administration in the same study population.

CONCLUSION

In summary, the data reported suggest that activating EGFR mutations may play a key role in the efficacy of EGFR-TKIs. Administration of first- and second-generation EGFR-TKIs as first- or second-line therapy is an optimal strategy in patients with EGFR-mutated

advanced NSCLC. Second-generation EGFR-TKIs may be superior to first-generation EGFR-TKIs because of their stronger biological activity. Ongoing trials of EGFR-TKIs may identify an EGFR-TKI that is most applicable as an initial EGFR-TKI treatment. Furthermore, the results of these trials may establish new treatment guidelines for activating EGFR-mutated NSCLC and for NSCLC with acquired secondary resistance.

Abstract

The association between chronic obstructive pulmonary disease (COPD) and lung cancer has long been a subject of intense debate. The high prevalence of COPD in elderly smokers inevitably strengthens their coincidence. In addition to this contingent coincidence, recent studies have revealed a close association between the two diseases that is independent of the smoking history; that is, the existence of COPD is an independent risk factor for the development of lung cancer. Molecular-based evidence has been accumulating as a result of the efforts to explain the underlying mechanisms of this association. These mechanisms may include the following: the retention of airborne carcinogens followed by the activation of oncogenes and the suppression of tumor suppressor genes; the complex molecular mechanism associated with chronic inflammation in the distal airways of patients with COPD; the possible in-

volvement of putative distal airway stem cells; and genetic factors that are common to both COPD and lung cancer. The existence of COPD in patients with lung cancer may potentially affect the process of diagnosis, surgical resection, radiotherapy, chemotherapy, and end-of-life care. The comprehensive management of COPD is extremely important for the appropriate treatment of lung cancer. Surgical resections with the aid of early interventions for COPD are often possible, even for patients with mild-to-moderate COPD. New challenges, such as lung cancer CT screening for individuals at high risk, are now in the process of being implemented. Evaluating the risk of lung cancer in patients with COPD may be warranted in community-based lung cancer screening.

and chronic obstructive pulmonary disease (COPD). These diseases usually affect relatively elderly individuals. Because of the rapidly aging populations of many developed countries, the number of patients with lung cancer and/or COPD is growing. Lung cancer is one of the leading causes of death in many countries and accounted for approximately 1.37 million deaths worldwide in 2008^[1]. As was extensively discussed in the Global Initiative of Chronic Obstructive Lung Disease (GOLD)^[2], accurate estimations of the prevalence and mortality of COPD are difficult. The prevalence of COPD in a specific region varies because of differences in the survey methods, diagnostic criteria and analytic approaches^[3,4], ranging from 7.8% to 19.7% of the total population^[2]. COPD is often a primary cause of death. However, COPD can also contribute to death from other diseases, such as pneumonia, ischemic heart diseases and heart failure, making it difficult to estimate the COPD-associated mortality rate. Meanwhile, the Global Burden of Disease Study has projected that COPD will become the third leading cause of death worldwide by 2020^[5].

Because of the high prevalence of both conditions and strong common risk factors associated with smoking, the coexistence of lung cancer and COPD is inevitably high. In addition, recent studies have uncovered a non-confounding association between COPD and lung cancer development, together with its molecular mechanisms^[6,7]. Investigating and resolving the problems of the coexistence of these two diseases is important in view of their clinical relevance; their interaction leads to worse outcomes. This article reviews the current perspectives on the epidemiological, clinical, and etiological problems associated with the coexistence of lung cancer and COPD.

COEXISTENCE OF LUNG CANCER AND COPD ASSESSED ACCORDING TO PULMONARY FUNCTION

Because of the high mortality associated with lung cancer, the proportion of deaths from lung cancer among patients with COPD can reasonably be considered to

represent the coexistence of lung cancer among patients with COPD. As shown in Table 1, the causes of death reported in patients with COPD vary significantly among studies, and the proportion of deaths from lung cancer ranges from 4% to 33%^[8-16], presumably because of different patient characteristics and analytical methods. Among their investigation, a prospective study identified 731 deaths that occurred over 14.5 years out of 5887 asymptomatic non-smoking individuals who had mild or moderate airflow limitations, with an average FEV₁/FVC of 65.0% ± 6.1% and an average age of 48.4 ± 6.8 years. The primary cause of death was lung cancer, representing 33% of the total deaths^[16]. Three other prospective studies disclosed a high incidence of lung cancer development or mortality among patients with COPD or individuals with airflow limitations^[17-19]. Skillrud *et al*^[17] prospectively observed 113 individuals who had a %FEV₁ of 70% or less by comparing them with 113 age-matched, sex-matched, occupation-matched, and smoking history-matched individuals with a %FEV₁ of 85% or more. The 10-year cumulative rates of lung cancer development were 8.8% and 2.0% in the former and latter groups, respectively, resulting in a statistically significant difference ($P = 0.024$)^[17]. Kuller *et al*^[18] reported an increase in lung cancer mortality according to a reduction in the FEV₁. The lung cancer mortality per 1000 person-years was 3.02 and 0.43 in the lowest and highest quintiles of the FEV₁, respectively, and this association was not weakened by adjustments for smoking factors^[18]. The relative risk of COPD or airflow limitations associated with lung cancer was therefore calculated to be 4.4 and 7.0 in the studies by Skillrud *et al*^[17] and Kuller *et al*^[18], respectively. In a large-scale prospective study involving 448600 lifelong nonsmokers who were cancer-free at baseline and who had a 20-year follow-up period, Turner *et al*^[19] again found a significant association between lung cancer mortality and pulmonary emphysema, with a hazard ratio of 1.66 (95%CI: 1.06-2.59)^[19]. Wasswa-Kintu *et al*^[20] conducted a population-based meta-analysis to reveal that even a relatively small decrease in the FEV₁ (approximately 90% of predicted) increased the risk of lung cancer by 1.3-fold in men (95%CI: 1.05-1.62) and 2.6-fold in women (95%CI:

Table 2 Odds ratios for coincidental lung cancer based on factors indicative of chronic obstructive pulmonary disease or interstitial lung diseases, according to smoking status¹

	Never smoker (n = 284)	Ex-smoker (n = 101)	Current smoker (n = 179)	Total (n = 564)
FEV ₁ /FVC < 70%	10.42 (2.82-38.55) ³	5.89 (2.02-17.22)	7.456 (3.48-15.95)	7.17 (4.03-12.74)
%VC < 80%	2.02 (0.42-9.86)	No data ⁴	2.25 (0.62-8.11)	4.73 (2.00-11.17)
LAA score ≥ 1 ²	0.98 (0.21-4.43)	3.43 (1.50-7.85)	5.07 (2.51-10.28)	3.63 (2.24-5.89)
Fibrosis score ≥ 1	6.39 (2.13-19.18)	3.94 (1.20-12.88)	5.45 (2.39-12.44)	5.10 (2.82-9.24)
GGA score ≥ 1	2.32 (0.80-6.71)	3.59 (1.09-11.80)	2.48 (1.06-5.77)	2.71 (1.52-4.81)

¹See the reference by Mizuno *et al.*^[24] for details; ²Low attenuation area (LAA) was assessed using Goddard's scoring system; fibrosis and ground glass attenuation (GGA) were assessed using Kazzeroni's scoring system; ³Numbers in parentheses indicate 95%CI; ⁴No data calculated because of insufficient number.

1.30-5.31), concluding that even a modest reduction in the %FEV₁ is a significant predictor of lung cancer, especially among women^[20].

COEXISTENCE OF LUNG CANCER AND COPD ASSESSED BY CT IMAGES

The National Lung Cancer Screening Trial (NLST) for annual low-dose CT screening reported a 20% decrease in lung cancer mortality among heavy smokers between the ages of 55 and 74 years^[21]. This great achievement has resulted in several established guidelines recommending low-dose CT lung cancer screening for individuals with defined conditions, and the time when screening will be implemented as a part of community health care is drawing closer^[22]. The more common use of chest CT examinations in asymptomatic individuals would increase the chance of detecting pulmonary diseases, including lung cancer and pulmonary emphysema. Because a definitive diagnoses of COPD and pulmonary emphysema are based on functional and pathological criteria, respectively, they cannot, by definition, be diagnosed using CT^[2]. Nevertheless, the presence of a substantially distributed low attenuation area (LAA) in the pulmonary fields strongly suggests pulmonary emphysema and COPD. In fact, Goddard *et al.*^[23] proposed a scoring system, which is used worldwide, to evaluate pulmonary emphysema using CT.

Six studies, consisting of 2 cohort and 4 case-control studies, evaluating the relationship between CT-based emphysema and the risk of lung cancer have been published^[24-29], and Zurawska *et al.*^[30] concisely reviewed these studies. The relative risk (RR) for lung cancer, according to CT-based emphysema assessed using semi-quantitative visual methods, ranged from 1.9 to 4.7, with a pooled RR of 2.34 (95%CI: 1.46-3.76). Using multivariate analyses adjusted for covariates including age, sex, and smoking status, the adjusted odds ratio for lung cancer, according to the CT-based detections of emphysema, ranged from 1.73 to 3.14. Mizuno *et al.*^[26] analyzed CT images from 947 healthy individuals who underwent a low-dose CT screening and 256 patients with lung cancer. After adjusting for sex and age, 423 matched healthy individuals and 141 patients with lung cancer were extracted for inclusion in multivariate analyses, with stratification according

to their smoking status. The results disclosed that many functional and CT image factors indicative of COPD (relative risks for lung cancer; 7.17 with FEV₁/FVC < 70% and 3.63 with LAA score ≥ 1) or interstitial lung diseases (relative risks for lung cancer; 4.73 with %VC < 80%, 5.10 with a fibrosis score ≥ 1 and 2.71 with a GGA score ≥ 1) were also risk factors for coincident lung cancer in a manner that was independent of the smoking status (Table 2). These observations suggesting a close association between COPD and lung cancer seem to imply at least three possibilities: first, airflow limitation itself is a risk factor for the development of lung cancer; second, some putative inter-individual variations in the sensitivity to harmful substances, such as active smoking, passive smoking, air pollutants, and cooking oil fumes, may link COPD and lung cancer; and third, some specific genotypes may predispose individuals to both COPD and lung cancer.

POSSIBLE MECHANISMS UNDERLYING THE COEXISTENCE OF LUNG CANCER AND COPD

A growing volume of evidence suggests that some molecular mechanisms may link COPD and lung cancer. A genome-wide association study has uncovered some putative common loci responsible for both COPD and lung cancer^[31]. Taking advantage of such modern technologies, we are soon likely to benefit from abundant information regarding the molecular mechanisms involving the pathogenesis of COPD and lung cancer. The current major possible explanations are outlined below.

Retention of airborne carcinogens because of airflow limitations may enhance carcinogenesis in the airways

In this speculative scenario, the airflow limitations that result from COPD suppress the clearance of carcinogens from the airway, leading to cancer in the airway. This classical scenario is now decorated with modern technical terms including DNA repair errors, oncogene activations, impaired tumor suppressor genes, oncogenic microRNA, the involvement of epithelial-mesenchymal transition, and a wide variety of epigenetic alterations.

Chronic inflammatory processes arising from COPD may enhance carcinogenesis in the airways

An association between persistent chronic inflammation and cancer has long been recognized. Examples include the relationships between cirrhosis and hepatocellular carcinoma, inflammatory bowel disease and colorectal cancer, burns and squamous cell carcinoma of the skin, and dental prostheses and lingual cancer. Recently, the relationship between chronic inflammation and cancer has been explained by a series of processes in which unscheduled necrotic cell death as a result of inflammation causes subsequent epithelial proliferation resulting in the suppression of immunity^[32]. Meanwhile, a volume of evidence has proven that complex inflammatory processes involving many types of immune cells, cytokines, matrix metalloproteinases, reactive oxygen species, and growth factors cause tissue damage and remodeling. This phenomenon ultimately results in the development of COPD^[2]. These factors also contribute to the enhancement of carcinogenesis^[33,34]. Parimon *et al.*^[35] observed a reduced lung cancer risk in patients using inhaled corticosteroids in a dose-dependent manner. This observation strongly supports the idea that the pathophysiology of COPD may enhance the development of lung cancer.

Putative lung stem cells activated by chronic inflammation in patients with COPD may transform to lung cancer stem cells

There is no evidence supporting the existence of lung stem cells in humans or cancer stem cells in human lung cancer^[36]. However, Kim *et al.*^[37,38] has reportedly identified bronchioalveolar stem cells in mice. If distal lung stem cells exist in humans, chronic inflammatory stimuli as a result of COPD might activate and transform these lung stem cells into lung cancer stem cells^[7].

Genetic backgrounds common to both COPD and the development of lung cancer may exist

A deficiency or decrease in alpha-1 antitrypsin is known to increase the risk of lung emphysema development. This condition, acting directly or indirectly through tissue damage to the lung, also increases the risk of lung cancer development^[39-42], although some controversy regarding this point still exists^[43]. Smoking is the strongest definitive risk factor for lung cancer development. Tobacco-derived pro-carcinogens are activated to become carcinogenic by a cluster of phase I enzymes. These activated carcinogens are then degraded and excreted by a cluster of phase II enzymes. Although not fully understood, some polymorphisms of these enzymes are known to lead to increased or decreased enzymatic activities, most likely causing inter-individual variations in the sensitivity to smoking^[44-49]. A better understanding of these mechanisms may identify individuals who are susceptible to lung cancer development when exposed to active or passive smoking. More recently, a decreased serum level of Crab (Clara) cell secretory protein (CC-16) has been found to increase the risk of both COPD^[50] and lung cancer^[51].

PROGNOSIS

As discussed above and illustrated in Table 1, a substantial proportion of patients with COPD die from lung cancer. The coexistence of lung cancer clearly worsens the prognosis of patients with COPD, but a discussion of how COPD worsens the outcome of patients with lung cancer and how this might be overcome is important.

The deterioration of pulmonary function together with the risk of acute exacerbation of COPD would, in theory, make invasive diagnostic procedures, surgery, radiotherapy and chemotherapy difficult in patients with lung cancer. A retrospective study by Sekine *et al.* reported an increased rate of postoperative complications, including pneumonia and the need for a tracheostomy, increased cancer recurrence, and a decreased 5-year survival rate in patients with completely resected stage IA non-small cell lung cancer (NSCLC) and coexisting COPD; the 5-year survival rates of patients with COPD ($n = 80$) and of those without COPD ($n = 362$) were 77.0% and 91.6%, respectively ($P = 0.0001$)^[52]. A recent retrospective study involving 902 patients with stage IA to IIB NSCLC treated with surgical resection also disclosed that 63.4% (572/902) of the patient population had self-reported, physician-diagnosed COPD, and the patients with COPD had a poorer 5-year progression-free survival rate (50.1% *vs* 60.6%, $P = 0.007$) and a poorer 5-year overall survival rate (54.4% *vs* 69.0%, $P = 0.0002$) than the patients without COPD^[53].

TREATMENT

Treatment algorithms can be complex when different diseases coexist in the same patient. It seems reasonable to prioritize the treatment of diseases with a more serious impact on the prognosis: for example, the treatment for stage III small cell lung cancer would be given preference over the treatment for a coincidental low-grade prostatic cancer in the same patient. The situation, however, is totally different in patients with coexisting COPD and lung cancer. It is very important to diagnose, evaluate, and manage both the COPD and lung cancer in a comprehensive manner for the following reasons.

To avoid the deterioration of quality of life because of COPD

COPD symptoms significantly overlap with those of lung cancer. Cough, sputum, shortness of breath, body-weight loss, appetite loss, and even depression may arise from COPD rather than from lung cancer, in some cases. The appropriate treatment for COPD may relieve these symptoms, leading to an improved quality of life (QOL).

To avoid the acute exacerbation of COPD during treatment for lung cancer

The acute exacerbation of COPD can be precipitated by upper respiratory tract viral infections, bacterial infec-

tions of the tracheobronchial trees, and other factors. Once acute exacerbation has occurred, the mortality rate is high. In patients with COPD and lung cancer, stress or immunosuppression as a result of surgery, radiotherapy, chemotherapy, or a terminally ill status can act as predisposing factors for an acute exacerbation. It is particularly important to understand that COPD exacerbations can often be prevented with the appropriate management of the disease^[2].

To decrease the complications associated with lung cancer treatment

Acute lung injury is a serious complication associated with lung cancer treatment, especially when patients suffer from symptomatic or asymptomatic idiopathic pulmonary fibrosis (IPF). Acute lung injury can occur in patients undergoing surgery, thoracic radiotherapy, or cytotoxic or molecular-targeted therapy^[54,55]. Although this complication seems to be more frequent in Japanese patients than in patients from other countries, the precise epidemiology and underlying mechanisms are not well known. In contrast to IPF, the presence of COPD is not recognized as a significant risk factor for acute lung injury associated with lung cancer treatment.

To ameliorate the outcome of the surgical resection of lung cancer

As a result of improvements in anesthesiology, surgical technique, and postoperative managements including rehabilitation, the curative-intent surgical resection of lung cancer in patients with COPD has become safer than previously expected^[56]. When a lung cancer is located within a severely damaged emphysematous region, its resection does not necessarily impair pulmonary functions to the extent that a lung volume reduction surgery for severe emphysema would restore the impaired pulmonary function. In a study with a limited number of patients, Kobayashi *et al.*^[57] demonstrated better postoperative pulmonary functions than expected, with improved pre-operative symptoms and pulmonary function, in patients with treatment-naïve COPD and lung cancer who were treated with inhaled tiotropium, a long-acting anticholinergic bronchodilator, starting 2 wk prior to surgery. As limited resections of lung cancer often result in poor outcomes, a curative-intent standard resection is recommended even for patients with mild to moderate COPD, with the aid of early interventions including drug therapy and rehabilitation for COPD^[56].

FUTURE DIRECTIONS

Low-dose CT screening effectively detects 10-fold more lung cancers at earlier stages compared with screenings using conventional chest X-rays^[58]. As mentioned earlier, the NLST, a randomized trial involving subjects with a high risk of lung cancer, confirmed a 20% reduction in the lung cancer mortality among subjects allocated to a low-dose CT screening group compared with an X-ray

screening group^[21]. This screening strategy targeting individuals at high risk was based on their smoking history and age. Sekine *et al.*^[59] emphasized the importance of the early detection of COPD for the purpose of lung cancer screening and proposed CT screening for individuals with suspected COPD as a strategy to target individuals at high risk. Based on a quick questionnaire that collected information about age, smoking history, and chronic respiratory symptoms, they identified 878 individuals fulfilling the defined criteria out of 89100 participants (1.0%). A total of 567 of the 878 participants (64.6%) underwent further evaluation consisting of CT and spirometry, resulting in the detection of COPD in 161 participants, with 38.5% of them requiring COPD treatment^[60]. Although the data regarding lung cancer detection are not yet available because the trial is still ongoing, this strategy for identifying a high-risk population based on suspected COPD could be an alternative to identification strategies based on age and smoking history. We envision that this new approach could enable us to evaluate and manage COPD and lung cancer comprehensively at early stages and from screening through specialized treatment.

Key words: Acetylcholine receptor; Pathway; CHRNA; Nicotine; Pulmonary carcinoma

Core tip: Genome-wide association studies revealed that allelic variation in the $\alpha 5\text{-}\alpha 3\text{-}\beta 4$ nicotine acetylcholine receptor (nAChR) cluster on chromosome 15q24-15q25.1 was associated with a higher risk for development of lung cancer. nAChRs are membrane ligand-gated cation channels whose activation is triggered by the binding of the endogenous neurotransmitter acetylcholine (ACh) or other biologic compounds including nicotine. nAChRs have been found on lung cancer cells, underscoring the idea that the non-neuronal nAChR signaling pathway has considerable implications for lung cancer. Several studies involving the design of nAChR antagonists with improved selectivity might identify novel strategies for the treatment of lung cancer.

Abstract

Genome-wide association studies revealed that allelic variation in the $\alpha 5\text{-}\alpha 3\text{-}\beta 4$ nicotine acetylcholine receptor (nAChR) cluster on chromosome 15q24-15q25.1 was associated with lung cancer risk. nAChRs are membrane ligand-gated cation channels whose activation is triggered by the binding of the endogenous neurotransmitter acetylcholine (ACh) or other biologic compounds including nicotine. nAChRs have been found on lung cancer cells, underscoring the idea that the non-neuronal nAChR pathway has important implications for lung cancer. Several studies focusing on the treatment with nAChR antagonists with improved selectivity might trigger novel strategies for the intervention and prevention of lung cancer. Here we review the genetic risk factors for lung cancer in the nAChR gene cluster, the roles of nicotine receptors, and the molecular mechanisms of acetylcholine receptor pathways to lead to more opportunities for intervention and prevention of lung cancer.

INTRODUCTION

Lung cancer is a multifactorial disease, resulting from a combination of genetic, environmental, and psychological factors. The evidence that genetic factors influence lung cancer risk has been demonstrated by many studies, tracing back to the landmark study in 1963^[1]. This study demonstrated a 2.5-fold higher risk in smoking relatives of lung cancer cases compared with smoking relatives of controls^[1], fully suggesting the importance of genetic factors in lung cancer risk.

More recently, some large genome-wide association (GWA) studies identified an association between single-

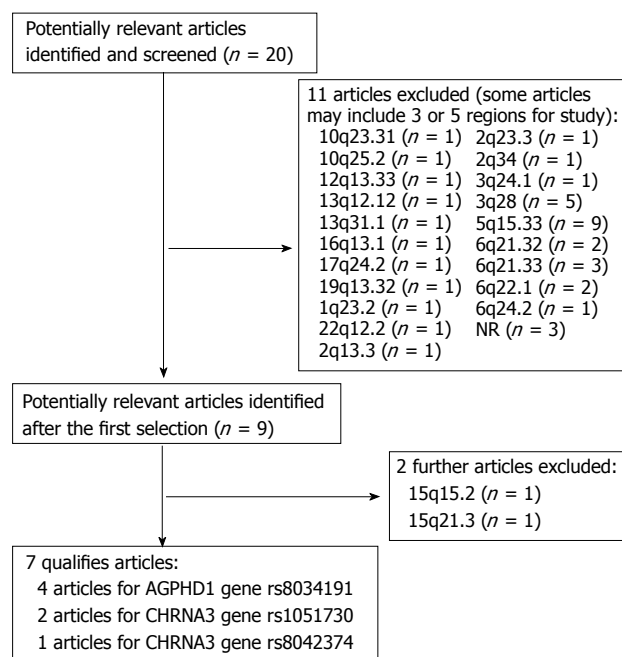

Figure 1 Flow diagram of search strategy and study selection^[67].

nucleotide polymorphism (SNP) variation at 15q24-15q25.1 and susceptibility to lung cancer^[2-11]. Genes mapping to this region of association include the $\alpha 5\text{-}\alpha 3\text{-}\beta 4$ nicotinic acetylcholine receptor (nAChR) cluster. nAChRs, encoded by the nicotinic acetylcholine receptor encoding (CHRN) genes^[2-4,12], are members of the Cys-loop superfamily of ligand-gated ion channels^[13], which are activated by endogenous agonist acetylcholine (ACh) and the exogenous compound nicotine^[14] and nitrosamines, potential lung carcinogens in cigarette smoke and foods.

CHRN genes are expressed in both neuronal and non-neuronal tissues, suggesting that nAChRs may play an important role in processes other than synaptic transmission. Indeed, apart from the classic role at neuromuscular junctions, nAChRs have also been implicated in the regulation of cellular processes such as proliferation^[15], cell-cell interaction, and cell death^[16-18]. A decreased survival correlation with lung cancer may be explained by effects of the nAChRs pathway through CHRNA proteins on tumor cell proliferation^[15], apoptosis, epithelial-mesenchymal transition, and proinvasive and angiogenic phenotypes^[19]. This review will provide an overview for better understanding the genetic risk factors for lung cancer in the nAChR gene cluster, the roles of nicotine receptors, and the molecular mechanisms of the cholinergic pathways to lead to more opportunities for intervention and prevention of lung cancer.

GENETIC RISK FACTORS IN THE NACHR GENE CLUSTER FOR LUNG CANCER

GWA studies for lung cancer

Lung cancer is a heterogeneous and challenging disease to treat. With the arrival of genotyping and genomic profil-

ing, management of non-small-cell lung cancer (NSCLC) has made several advances with the understanding of activating mutations in epidermal growth factor receptor (EGFR), fusion genes involving anaplastic lymphoma kinase (ALK), rearrangements in ROS-1. The next era of personalized treatment will involve a comprehensive genomic characterization of lung cancer. One important task in personalized medicine is to predict disease risk based on a person's genome, *e.g.*, on a large number of SNPs. GWA studies make SNP and phenotype data available to researchers.

Notably, the 15q24-15q25.1 region (CHRNA5/CHRNA3/CHRNA4) has been identified as a lung cancer risk spot by several GWA studies^[2-11]. Of one GWA study in the International Agency for Research on Cancer (IARC), there is 14% increased lung cancer susceptibility associated with nAChR cluster variation irrespective of smoking status^[3]. The same GWA result was identified by the other studies from the MD Anderson Cancer Center, United States^[2], and deCODE Genetics, Iceland^[4], respectively. Importantly, a non-synonymous variant rs16969968 of CHRNA5, inducing an amino acid substitution (D398N) in the second intracellular loop of the protein, can increase lung cancer risk by 30%^[3]. The SNP rs8023462 in CHRNA3/CHRNA4 intergenic region, interfering CHRNA3/CHRNA4 gene expression by interacting with GATA transcription factors, was the first functional evidence for association with lung cancer risk^[20].

To better understand the GWA studies for the nAChR gene cluster and lung cancer risk, we further investigate a catalog of all existing published GWA study data updated to December 20, 2013 from National Human Genome Research Institute (NHGRI) (<http://www.genome.gov/>), using the subject terms (CHRNA OR nAChR OR 15q25) AND (lung cancer OR lung adenocarcinoma OR lung adenocarcinoma (clinical stage) OR lung cancer (DNA repair capacity) OR lung cancer-asbestos exposure interaction). Twenty potentially relevant articles^[2,3,6,8-11,21-33] were produced according to the first primary screening strategy, of which 7 GWA studies met the subject terms for further evaluating the relationship of the nAChR cluster with lung cancer susceptibility^[2,3,6,8-11]. A flow diagram summarized the process of selecting and excluding articles with detailed reasons (Figure 1). All GWA studies for lung cancer at the 15q25.1 region are summarized in Table 1.

Considering that the statistical power of individual GWA study has been limited by the modest effect sizes of genetic variants and the financial constraints on the numbers of variants, it is stringent to perform meta-analyses of existing genetic data on the nAChR gene cluster to better understand disease loci harboring common variants associated with lung cancer risk. A total of 12 qualified articles between 2008 and 2011 screened from 40 potentially relevant articles were selected, including 16 studies with 9 in Caucasians, 4 in East Asians, 2 in African-Americans, and 1 in mixed (Caucasian, African-American and Hispanic) populations^[34]. CHRNA3 gene

rs1051730-A allele, compared with G allele, is associated with a 36% higher risk for lung cancer (95%CI, 1.27-1.46; $P < 0.0005$)^[34]. Surprisingly subgroup analyses suggested that rs1051730-A allele might be the factor for lung cancer susceptibility in Caucasians (OR = 1.32; 95%CI, 1.25-1.44; $P < 0.0005$), but not in East-Asians (OR = 1.51; 95%CI, 0.76-3.00; $P = 0.237$)^[34]. Allele frequency of rs1051730 in Asians was lower than that in Caucasians. For rs1051730, the minor allele frequency (MAF) was reported to be 0.39, 0.15, and 0.04 in Whites, African Americans, and Chinese, respectively, based on the HapMap data (<http://hapmap.ncbi.nlm.nih.gov/>), which was reported in our previous study^[35]. The Japanese finding^[36] consistent with our reported Chinese study^[35] also suggests that, like EGFR story, different genetic backgrounds may cause the discrepancy in lung cancer risk in different populations.

Owing to SNPs with weaker effects in influencing lung cancer risk could be missed given the stringent requirements for adjustment for multiple comparisons, nAChR pathway analysis has been proposed as a complementary approach to single SNP analyses in GWA studies. Using two lung cancer GWA studies data sets based on four studies: one a combined data set from Central Europe and Toronto (CETO)^[3]; the other a combined data set from Germany (HGF study)^[11,37] and MD Anderson Cancer Center (GRMD)^[2], comparison of pathway analysis approaches demonstrated that the nAChR pathway was identified as associated with lung cancer in CETO and GRMD^[38].

DNA methylation in the nAChR cluster with lung cancer risk

Although CHRNA5, CHRNA3 and CHRNB4 are clus-

tered together at the same locus, they exhibit differential susceptibility to aberrant methylation. Treatment of cancer cells exhibiting CHRNA3 hypermethylation with DNA methylation inhibitors caused demethylation of the CHRNA3 promoter and gene reactivation, inducing apoptotic cell death^[39]. Small hairpin RNA-mediated depletion of CHRNA3 in CHRNA3-expressing lung cancer cells led to resistance to apoptosis-inducing agents, underscoring the importance of epigenetic silencing of the CHRNA3 gene in human cancer^[39]. Silencing of the CHRNA3-encoding gene may result in over-representation of other nAChR subunits, notably CHRNA7 and CHRNA5^[39], which may stimulate cell survival and provide a proliferation advantage to tumor cells^[40,41]. In contrast to CHRNA3 hypermethylation, elevated CHRNB4 methylation, insufficient to induce significant silencing of the gene, failed to inhibit gene expression. Conclusively, the 15q25.1 locus may be under epigenetic regulation and that its deregulation may lead to lung cancer.

Interplay of smoking behaviors, nAChR cluster and lung cancer risk

Evidence that the nAChR cluster on 15q25 locus is associated with smoking status, nicotine dependence and the risk of lung cancer is inconsistent in different populations. The region of the nAChR cluster has been confirmed to be associated with a number of smoking-related traits, including nicotine dependence, cigarettes smoked per day, and heavy smoking, in some lung cancer GWA studies^[4,42], and in some genome-wide meta-analyses in Caucasian populations^[42-44]. For example, the Caucasian population with variant rs1051730 SNP in the nAChR cluster was related with lung cancer risk and

nicotine dependence, approximately smoking one and two more cigarette per day than those without variant rs1051730 SNP^[4]. Another study demonstrates further that association signals in the nAChR cluster affecting early smoking behaviors may have disparity with those contributing the mature nicotine dependence^[45].

Surprisingly, a Japanese case-control study^[36] reported associations between the selected SNPs in the nAChR cluster and risk of lung cancer and found that associations among never and ever smokers were similar. The association was consistent among non-smokers and smokers in our study^[35]. These studies might argue for a role of the nAChR cluster in lung cancer that is independent of smoking behavior in Asians.

These findings in different populations suggest a role for racial differences in the association between smoking behaviors, nAChR cluster, and risk of lung cancer. Reasons underlying the racial difference in the genotype with smoking associations are unclear. This discrepancy may be due to differences in genetic and environmental backgrounds. Alternatively, other factors that have not been taken into account, such as food intake and passive smoking, differentiate the mode of contribution of the nAChR cluster in non-smokers.

STRUCTURE AND FUNCTION OF NACHRS

The regulation of acetylcholine receptor pathways has been established from the primitive organisms, irrespective of neurons. There exist two types of AchRs, nAChRs and Muscarinic Ach receptors (mAChRs) of cholinergic signaling. nAChRs comprise five subunits, including ten α subunits ($\alpha 1$ - $\alpha 10$), four β subunits ($\beta 1$ - $\beta 4$), one δ , and one ϵ or γ subunit, which form hetero- or homo-pentamers enclosing a central ion channel. The nAChR subunit composition in turn further regulates the function and pharmacology of nAChRs^[16,17].

An autocrine or a paracrine acetylcholine receptor pathway for nAChRs

Acetylcholine receptor signaling in non-neuronal cells is comparable to acetylcholine receptor neurotransmission^[46]. Both nAChR families are expressed in cancer cells^[46], and both NSCLC and small-cell-lung cancer (SCLC) cell lines can synthesize and release Ach^[47]. The widespread synthesis of Ach beyond the nervous system has changed the paradigm of Ach acting merely as a neurotransmitter, and it may also act as an autocrine or a paracrine messenger able to interact with nAChRs. For example, non-neuronal Ach is released from the living NSCLC or SCLC cells and binds to nAChRs of its source and neighbouring cells to mediate autocrine and paracrine regulatory loops, prolonging cell survival with subsequent cell proliferation through mitogen-activated protein kinase (MAPK) pathway^[48-50] or with increase of vascular endothelial growth factor (VEGF) stimulating neoangiogenesis^[19]. All these effects can be blocked at

the level of the nAChRs^[48,51,52]. This novel paradigm necessitates the opportunity of marker-guided lung cancer intervention and prevention strategies, making balance between nAChR-mediated stimulation and inhibition^[16,53].

Metabolism of Ach

Ordinarily Ach is regarded as a classical neurotransmitter. Ach is synthesized intracellularly by the enzyme choline acetyltransferase (ChAT) from choline and acetyl-coenzyme A (AcCoA) before being released into the extracellular space to act on synaptic-adjacent cells. In contrast, the enzyme acetylcholinesterase (AChE) can rapidly clear the extracellular Ach pool into its inactive metabolites choline and acetate. This signaling system is targeted by various biological modulators which can inhibit Ach release or AChE activity^[54]. ChAT is strongly up-regulated, whereas AChE is down-regulated in squamous cell carcinoma (SqCC)^[54], which increases levels of Ach, providing endogenous proliferative stimuli to nAChRs.

Classical ionic channel activity of nAChRs

All nAChRs allow the influx of different cations (Na^+ , K^+ , Ca^{2+}), and the $\alpha 7$ nAChR is selective for Ca^{2+} . Binding of nicotine to $\alpha 7$ nAChR can cause Ca^{2+} influx into lung cancer cells and the subsequent membrane depolarization activates voltage-gated Ca^{2+} channels, which activates the MAPK pathway^[48]. Subsequently, MAPK activates complexes of the transcription factor NF- κ B that induce entry into S phase to promote cancer cell proliferation^[48]. Moreover, tobacco-specific nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) has been found to promote Ca^{2+} influx thought binding to nAChRs, activating both protein kinase C (PKC) and the MAPK pathway to stimulate the proliferation of SCLC cells^[49].

Cell proliferation mediated by nAChRs

The role of nAChRs in the growth regulation of cancer was first identified in 1989^[15], and reinforced further by the ability of generalized nAChR antagonists (*e.g.*, hexamethonium and mecamylamine) to reverse the proliferative effects of nicotine. Nowadays, the mechanism of nicotine-induced tumor cell proliferation and associated angiogenesis is an active area of research. In particular, $\alpha 7$ nAChR has been implicated in mediating the proliferative effects of nicotine, and $\alpha 7$ nAChR antagonist a bungarotoxin (α -BTx) or methyllycaconitine can attenuate the proliferative effects of nicotine in NSCLC and SCLC cells^[48,52]. These findings have been confirmed by the transfection of small interfering RNA targeting $\alpha 7$ nAChR in lung cells^[52]. This point implies that $\alpha 7$ nAChR is being considered a target for cancer therapy^[48], marking a new chapter in lung cancer research and the feasibility of using nAChRs as a viable molecular target for cancer therapy.

Cross-talk of nAChRs with the other signaling pathways

Beyond the above channel activity, nAChRs can be involved in other intracellular events involving various

Figure 2 nAChRs pathway in lung cancer. (1) ACh is synthesized intracellularly by the enzyme choline acetyltransferase (ChAT) from choline and acetyl-coenzyme A (AcCoA) before being released into the extracellular space. This signaling system is targeted by various biological modulators which can inhibit ACh release or ChAT activity. ChAT is strongly up-regulated in squamous cell carcinoma (SqCC), which increases levels of ACh, providing endogenous proliferative stimuli to nAChRs; (2) All nAChRs allow the influx of different cations (Na^+ , K^+ , Ca^{2+}), and the $\alpha 7$ nAChR is selective for Ca^{2+} . Binding of nicotine to $\alpha 7$ nAChR can cause Ca^{2+} influx into lung cancer cells and the subsequent membrane depolarization activates voltage-gated Ca^{2+} channels, which activates the MAPK pathway to promote cancer cell proliferation; (3) Hypermethylation of 15q25.1 locus and epigenetic silencing of the CHRNA3 gene may result in under-representation of $\alpha 3$ containing nAChR-subtypes, which in turn leads to over-representation of $\alpha 7$ and $\alpha 5$ containing nAChRs on the cell surface, further increasing Ca^{2+} influx mediated activation of the MAPK signaling cascade. As a result, cells with the complete or partial absence of the CHRNA3 subunit containing nAChRs may display defective cell death response; (4) $\alpha 7$ nAChR antagonist abungarotoxin (α -BTx) can attenuate the proliferative effects of nicotine in NSCLC and SCLC cells; and (5) The other findings suggest a strong connection between growth factor mediated VEGF pathway and the cholinergic angiogenic pathway. The endothelial cell (EC) migration induced by basic fibroblast growth factor (bFGF) and VEGF can be inhibited by blocking the nAChRs with α -BTx.

downstream nAChR-mediated signaling pathways, including Ca^{2+} /calmodulin, $\text{PKC}^{[49]}$, $\text{MAPK}^{[48-50]}$, and $\text{VEGF}^{[19]}$. It has been reported that EGFR was found to be on the list of high $\alpha 6\beta 3$ tumors, and nAChR may trigger the MAPK pathway in which EGFR was involved, leading to promotion of cell growth and proliferation. Thus, cross-talk between signaling downstream of EGFR and nAChR activation *via* the MAPK pathway may together promote

carcinogenesis^[50]. The other findings suggest a strong connection between growth factor mediated angiogenic pathway and the cholinergic angiogenic pathway^[19,55]. For instance, the endothelial cell (EC) migration induced by basic fibroblast growth factor (bFGF) and VEGF can be inhibited by blocking the nAChRs with α -BTx^[19]. Figure 2 simply summarizes the above mentioned nAChRs pathway in lung cancer.

NACHRS RESEARCH IN SOME SPECIAL LUNG CANCERS

Lung cancer in non-smokers

The carcinogenic nitrosamine N-nitrosodiethylamine (DeN) was identified recently to have the similar structure with ACh, acting as a high-affinity ligand for homo- and hetero-meric nAChRs in lung cancer cells^[56]. Considering the fact that DeN is contained in numerous foods and drinks^[57], such agents may lead to non-tobacco-related modulations of nAChRs. In addition, different nAChR subunit gene expression patterns were found between NSCLCs in smokers and non-smokers, and higher nAChR $\alpha 6\beta 3$ expression was associated with NSCLC tumors from non-smokers, as compared with those from smokers^[5].

Lung cancer in female patients

Neurotransmitter γ -aminobutyric acid (GABA) is recognized as the most important inhibitory neurotransmitter in the brain, but it also acts as a tumor suppressor for pulmonary adenocarcinoma (PAC)^[58] and carcinomas of the pancreas^[59], breast^[60] and colon^[61]. As $\alpha 4\beta 2$ nAChR regulates the release of GABA, desensitization of this receptor may therefore lead to GABA deficiency^[62]. Moreover, it has been shown that mRNA levels of the $\alpha 4$ nAChRs were significantly lower in PAC tissues than in normal lung tissue or other types of NSCLCs^[5]. Considering that oestrogen and phyto-oestrogens were reported to desensitize $\alpha 4\beta 2$ nAChR^[63], the predominance of PAC in women may therefore at least in part be the result of impaired $\alpha 4\beta 2$ nAChR function. Recent reports of clinical trials of the nAChR $\alpha 4\beta 2$ antagonist, which targets $\alpha 4\beta 2$ receptors in the brain, have shown its clinical efficacy in smoking cessation^[64]. It is possible that similar nAChR antagonists could block the effect on lung tumors, including lung cancer in women.

Lung cancer in pulmonary neuroendocrine cells

Pulmonary neuroendocrine cells (PNeCs) and SCLC can express high levels of $\alpha 7$ nAChR^[51]. $\alpha 7$ nAChR is the central regulator of proliferation, apoptosis and migration in SCLC cells through stimulating the release of some autocrine growth factors, including serotonin and neuropeptides^[51]. $\alpha 7$ nAChR antagonist α -BTx can attenuate the proliferative effects of nicotine in SCLC cells^[48,52].

SURVIVAL STUDIES FOR NACHRS

nAChRs are associated with resistance to gemcitabine, cisplatin and paclitaxel in NSCLC cell lines. Our research is the first study to investigate whether or not a genetic variant in the 15q25 region has a prognostic effect on the survival outcome of patients with lung cancer^[35]. The patients with CHRNA3 gene rs3743073G > T allele showed a higher risk of lung cancer and worst survival in Chinese Han patients with advanced stage NSCLC^[35]. A Caucasian study showed that CHRNA3 (rs1051730)

genotyping can improve customized chemotherapy based on tumor assessment of excision repair cross-complementing 1 (ERCC1) mRNA in stage IV NSCLC patients with a performance status of 0 (clinicaltrials.gov. identifier: NCT00174629)^[65]. A further Korean survival study demonstrated that a functional SNP, rs6495309C > T, in the promoter of the CHRNA3 gene, was the prognostic factor for resected early stage NSCLC^[66]. Compared with rs6495309 CC genotype, the patients in the studied Korean cohort with rs6495309 CT/TT genotype had a better 5-yr OS by 5% and better 5-yr DFS by 7%^[66].

NACHRS AS BIOMARKERS FOR LUNG CANCER - THE FUTURE PERSPECTIVE?

The use of nAChR antagonists that block the receptors still has some issues, because these receptors regulate many vital cell and organ functions, and deficiency or impairment of nAChR signaling will lead to overproduction of cytokines in some tissues and enhance tissue damage. Carefully designed animal studies are essential to investigate the potential side effects of nAChR antagonists on the brain, central nervous system, immune cells and muscle cells, which express high levels of nicotinic receptors.

In summary, strategies for marker-guided lung cancer intervention that targets nAChRs seem promising. nAChR antagonists could be potentially used in combination with established chemotherapeutic drugs to enhance the therapeutic response to chemotherapy. Future studies involving the design of nAChR antagonists with improved selectivity might trigger novel strategies for the intervention and prevention of lung cancer.

Abstract

Cohesive scientific evidence from molecular, animal, and human investigations supports the hypothesis that constitutive overexpression of cyclooxygenase-2 (COX-2) is a ubiquitous driver of mammary carcinogenesis, and reciprocally, that COX-2 blockade has strong potential for breast cancer prevention and therapy. Key findings include the following: (1) COX-2 is constitutively expressed throughout breast cancer development and expression intensifies with stage at detection, cancer progression and metastasis; (2) essential features of mammary carcinogenesis (mutagenesis, mitogenesis, angiogenesis, reduced apoptosis, metastasis and immunosuppression) are linked to COX-2-driven prostaglandin E₂ (PGE-2) biosynthesis; (3) upregulation of COX-2 and PGE-2 expression induces transcription of CYP-19 and aromatase-catalyzed estrogen biosynthesis which stimulates unbridled mitogenesis; (4) extrahe-

patic CYP-1B1 in mammary adipose tissue converts paracrine estrogen to carcinogenic quinones with mutagenic impact; and (5) agents that inhibit COX-2 reduce the risk of breast cancer in women without disease and reduce recurrence risk and mortality in women with breast cancer. Recent sharp increases in global breast cancer incidence and mortality are likely driven by chronic inflammation of mammary adipose and upregulation of COX-2 associated with the obesity pandemic. The totality of evidence clearly supports the supposition that mammary carcinogenesis often evolves as a progressive series of highly specific cellular and molecular changes in response to induction of constitutive overexpression of COX-2 and the prostaglandin cascade in the "inflammogenesis of breast cancer".

INTRODUCTION

More than a century ago, Virchow *et al*^[1,2] suggested that

chronic inflammation leads to cancer development by increasing cellular proliferation^[3]. Various models of carcinogenesis have been proposed involving inflammatory stimuli and mediators of wound healing^[4-6]. The recent discovery of the inducible cyclooxygenase-2 (COX-2) gene has rekindled interest in the causal link between inflammation and cancer, and various models of carcinogenesis have been proposed involving inflammatory stimuli and COX-2 expression^[7-10].

The current review synthesizes and interprets the accumulating body of evidence supporting COX-2 driven inflammogenesis as a general model of breast cancer development and the use of anti-inflammatory compounds that block COX-2 for breast cancer prevention and therapy. Evidence from molecular studies and meta-analyses of COX-2-inhibiting agents and breast cancer are discussed and based upon results, a general model of inflammogenesis of breast cancer is proposed involving induction of constitutive COX-2 over-expression and up-regulation of the prostaglandin cascade.

COX, PROSTAGLANDINS AND INFLAMMATION

Vane *et al.*^[11] discovered that the anti-inflammatory effects of aspirin [and all other nonsteroidal anti-inflammatory drugs (NSAIDs)] are primarily due to their inhibition of cyclooxygenase, the rate-limiting enzyme of the prostaglandin cascade. Metabolism of the essential fatty acid, arachidonic acid, *via* the cyclooxygenase pathway produces various prostaglandins that have a diverse array of physiologic activities throughout the human system. Indeed, these short lived molecules appear to control not only the inflammatory response, but they also help regulate constriction of blood vessels, contraction of smooth muscle, aggregation of platelets, sensitization of neurons to pain, flux of intracellular calcium, cell division, apoptosis, and many other molecular events that are critical for homeostatic physiology.

Two primary genes encode cyclooxygenase, a constitutive gene (*COX-1*) and its inducible isoform (*COX-2*)^[12-14]. The inducible *COX-2* gene is the master switch that activates the inflammatory response. Induction of COX-2 by any inflammatory stimulus (*e.g.*, tobacco, alcohol, ischemia, trauma, pressure, foreign bodies, toxins, bacteria, viruses, lipopolysaccharides, *etc.*) quickly results in the biosynthesis of prostaglandins of the E-series, particularly prostaglandin E₂ (PGE-2), and these prostaglandins in turn orchestrate the inflammatory response.

The cyclooxygenase pathway produces various prostaglandins, prostacyclins and thromboxanes from arachidonic acid and other fatty acids. In the initial step, COX catalyzes the oxidation of arachidonic acid to prostaglandin H-2 (PGH-2) which is rapidly converted to biologically active prostaglandins by specific enzymes. For example, PGH-2 is converted to the chief inflammatory prostaglandin, PGE-2, by PGE-2 synthetase.

Prostaglandin structure and function depend upon

the cell of origin and the level and type of catalytic COX enzyme. COX-1 is constitutively expressed at basal levels in many cells throughout the body, *e.g.*, gastrointestinal epithelium, renal tubules, vascular smooth muscle and blood platelets. Ordinarily, COX-1 expression is constitutive and sustains low levels of prostaglandins that are cytoprotective and maintain homeostasis. Conversely, the *COX-2* gene is silent (not transcribed) unless induced by inflammatory stimuli. Induced COX-2 transcription and expression markedly amplify the biosynthesis of PGE-2 which is the chief effector molecule of inflammation^[15].

Under normal conditions, acute inflammation is a tightly controlled self-limiting response to the offending stimulus. The process involves the integration of multiple cell types of the vascular and immune systems for the purpose of targeting, capturing, degrading, and removing the offending agent from the tissue under attack. Concurrent with acute inflammation, COX-2 expression and PGE-2 production by endothelial cells, epithelial cells, stromal cells, monocytes and lymphocytes increases up to 100 fold of basal levels. Amplification of the COX-2 inflammatory cascade is triggered by recognition of pro-inflammatory stimuli by toll-like receptors on the cell membranes of exposed cells and activation of nuclear factor kappa β (NF- $\kappa\beta$) which is often touted as a universal transcription factor^[16]. In addition, a variety of cytokines are secreted by infiltrating macrophages and other cells of the innate immune system. In particular, tissue necrosis factor α , γ -interferon and interleukins 1 and 6 (IL-1 and IL-6), stimulate the production of acute phase proteins such as C-Reactive protein, Amyloid A and complement, which assist in the inflammatory response^[17].

With abatement of the inflammatory stimulus, specific cytokines, particularly IL-1 and IL-6, exert feedback inhibition causing COX-2 expression and PGE-2 production to cease and the inflammatory process to subside. However, with sustained exposure to pro-inflammatory stimuli, continued overexpression of the COX-2 inflammatory cascade promotes the transition from acute to chronic inflammation. Molecular studies suggest that specific cytokines such as IL-6 and IL-1 β are responsible for recruiting monocytes to chronically inflamed tissues which may in turn disrupt the inhibitory feedback loop by secreting a variety of other pro-inflammatory cytokines^[18,19].

Constitutive expression of the *COX-2* gene and sustained biosynthesis of PGE-2 appear to be irrevocably linked to the initiation and promotion of mammary carcinogenesis. This review builds upon the evidence from molecular studies of COX-2, the rate-limiting enzyme of the prostaglandin cascade, reflecting its virtually ubiquitous role in mammary carcinogenesis, and reciprocally, epidemiologic studies documenting the beneficial impact of COX-2 blockade in breast cancer prevention and therapy.

Molecular studies are reviewed and updated data compiled to elucidate the role of COX-2 in the progression of breast cancer^[10]. Epidemiologic studies are reviewed and composite estimates derived by meta-analysis to

Figure 1 Cyclooxygenase-2 expression in the progression of breast cancer. COX-2: Cyclooxygenase-2.

quantify the impact of selective and non-selective agents that reduce breast cancer risk by inhibition of COX-2^[20]. Convincing evidence is presented showing that mammary carcinogenesis often evolves as a progressive series of highly specific cellular and molecular changes in response to induction of constitutive over-expression of COX-2 and the prostaglandin cascade in the “inflammogenesis of breast cancer”.

MOLECULAR EVIDENCE: COX-2 IN MALIGNANT AND PREMALIGNANT MAMMARY NEOPLASMS

Molecular studies using immunohistochemistry and reverse transcriptase polymerase chain reactions (RT-PCR) reveal that over-expression of COX-2 is a prominent feature of all stages of breast cancer. Furthermore, COX-2 is commonly found in premalignant lesions (dysplasia and atypia), carcinoma *in situ*, invasive cancer, and in particular, metastatic disease. In stark contrast to mammary cell populations that are in various stages of carcinogenesis, COX-2 is ordinarily not detectable in normal (non-inflamed) mammary tissues^[21,22].

The first investigation of COX-2 in human breast cancer specimens was conducted using immunohistochemistry and a human COX-2 primer^[23]. The study revealed the presence of COX-2 protein in 13 of 13 invasive human breast tumors, but not in samples of normal breast tissue. There was a statistically significant linear association between COX-2 and high (> 50%) tumor cell density ($P < 0.01$) with COX-2 protein localized to tumor cells.

Subsequently, molecular biologists from multiple independent laboratories have consistently observed COX-2 over-expression in all stages of breast cancer^[23-42]. Figure 1 shows the mean frequency of specimens over-expressing COX-2 in the progression of mammary carcinogenesis. Among studies of invasive breast cancer, 87% of specimens were positive for COX-2 and 57% had high levels of COX-2 expression. Significantly elevated frequencies of specimens with high COX-2 expression were also observed in premalignant lesions such as atypical hyperplasia (44%) and ductal carcinoma *in situ* (65%). Furthermore, several of the studies suggest that COX-2 expression is

correlated with the metastatic spread of breast cancer and has strong potential as a prognostic indicator of disease severity and progression^[30,31,35,37-39]. By comparison, all studies have found negligible or very weak focal COX-2 expression in normal tissues. It is indeed remarkable that high levels of COX-2 expression are evident throughout mammary carcinogenesis.

In an important prospective study conducted by Hartmann *et al.*^[43] at the Mayo Clinic, COX-2 expression was measured by immunohistochemistry in biopsy specimens from 235 women with atypical hyperplasia of the breast. Forty-one (17%) of the 235 women subsequently developed breast cancer during a median follow-up of 15 years. Notably, COX-2 expression at baseline was a significant predictor of risk. Compared to women without atypia, the cumulative incidence of breast cancer increased with increasing COX-2 expression, relative risk (RR) = 2.6 for weak or negligible expression, RR = 3.6 for moderate expression and RR = 5.7 for strong expression. The authors concluded that “COX-2 appears to be a biomarker that further stratifies breast cancer risk among women with atypia and may be a relevant target for chemoprevention strategies”^[43,44].

The molecular evidence clearly demonstrates that COX-2 over-expression is not only an early event in the genesis of breast cancer, but is present throughout the entire evolutionary process of breast cancer development and progression. Thus, COX-2 may be a useful biomarker of impending cancer and a prime target for molecular intervention in breast cancer prevention and therapy^[45].

COX-2 BLOCKADE IN BREAST CANCER PREVENTION AND THERAPY

The molecular evidence suggests that induction and constitutive upregulation of COX-2 and the prostaglandin cascade play a significant role in mammary carcinogenesis. But if inflammogenesis of breast cancer is to be upheld as a viable model, then the reciprocal relationship must also be true, *vis a vis.*, blockade of COX-2 should have significant inhibitory impact against mammary carcinogenesis. Critical evidence from animal and human investigations is discussed next.

Animal studies of breast cancer and COX-2 blockade

In the past quarter century, several independent investigations employing animal models of mammary carcinogenesis have generated compelling evidence that NSAIDs have significant and consistent chemopreventive effects against breast cancer development.

Karmali *et al.*^[46,47] first observed chemopreventive effects of NSAIDs against breast cancer and also elucidated differential effects of essential dietary fatty acids in prostaglandin (PG) biosynthesis and tumor promotion. Their studies showed that dietary supplementation with the n-6 fatty acid, linoleic acid, promoted tumor growth and development *via* enhanced arachidonic acid metabolism and elevated levels of PG activity, whereas the n-3

Figure 2 Effects of selective cyclooxygenase-2 blockade on DMBA-induced breast cancer in Sprague-Dawley rats^[51].

essential fatty acid, linolenic acid, had the opposite effect.

In several subsequent preclinical investigations of chemically induced breast cancer, supplemental administration of general NSAIDs such as aspirin, ibuprofen, piroxicam, sulindac, and others, in the diet or drinking water consistently reduced the growth and progression of breast tumors^[48-50]. The molecular basis for the antineoplastic effects of these general NSAIDs is linked to their inhibition of cyclooxygenase gene expression and enzyme activity. However, general NSAIDs have nonselective activity against both COX-1 and COX-2.

It is therefore important to note that recent preclinical studies have demonstrated even stronger antineoplastic effects of selective COX-2 inhibitors such as celecoxib, rofecoxib, valdecoxib, and nimesulide against breast cancer. Harris and colleagues initially reported that celecoxib markedly reduced the incidence of DMBA-induced breast cancer in Sprague-Dawley female rats^[51]. In their study, celecoxib reduced the incidence of breast cancer by 70% compared to controls. In the same trial, ibuprofen reduced the incidence of breast cancer by 40% (Figure 2). Further evidence for the primary role of COX-2 in mammary carcinogenesis comes from transgenic mouse models in which the overexpression of COX-2 is sufficient to induce malignant transformation of normal epithelial cells of the mammary gland^[52].

In summary, animal models of carcinogenesis provide compelling evidence that NSAIDs inhibit growth and development of breast tumors. While preclinical investigations provide consistent evidence that both selective and nonselective NSAIDs inhibit chemically induced carcinogenesis of mammary epithelial tumors, the strongest antineoplastic effects are clearly the result of intervention by administration of COX-2 blocking agents.

Human studies of non-selective COX-2 inhibitors and breast cancer

Meta-analysis of NSAIDs and breast cancer: Independent estimates from 37 studies were used in an updated meta-analysis of over-the-counter NSAIDs (primarily

aspirin or ibuprofen) and breast cancer^[53-91]. These reports were ascertained by a search of MEDLINE in the period 1970-2013 using combinations of key words: breast cancer with NSAIDs, aspirin and ibuprofen. Methods developed by Schlesselman and Greenland were adapted for combined analysis of the data from these studies^[92,93]. Estimates of RR and 95% confidence intervals were converted to $\ln(RR)$ with corresponding variance estimates (v). The combined estimate of risk in logarithmic form, $\ln(RR^*) = \sum \ln(RR)w / \sum w$, was obtained by weighting individual estimates by $w = 1/v$. A χ^2 test of heterogeneity was utilized to test for differences among studies.

RR with 95% CIs from these reports are shown in Figure 3. Among the 37 estimates, 25 were significantly less than 1.0 and only one was significantly greater than 1.0. The test for heterogeneity was not significant and the composite estimate shows a 25% reduction in the relative risk of breast cancer with regular use of aspirin or other OTC NSAIDs (Combined RR = 0.75, 95%CI: 0.67-0.84, $P < 0.001$).

Our review and meta-analysis of data from the epidemiologic literature therefore provides compelling evidence that regular intake of NSAIDs that nonselectively block COX-2 protects against the development of breast cancer. When data are combined by meta-analysis, it is estimated that regular NSAID intake is associated with a 25% reduction in overall breast cancer risk. This estimate is similar to the results of earlier meta-analysis by González-Pérez *et al.*^[94] who reported a 23% reduction in breast cancer risk with NSAID use^[93]. The available data suggest that significant reductions in breast cancer risk occur with 5 or more years of using low dosages of aspirin or other NSAIDs on a regular basis and long term studies suggest that the risk declines to maximal levels with regular intake for 10-20 years^[94]. It is also notable that some studies have found that NSAIDs may have a greater effect against estrogen receptor positive breast cancer^[72,77,80,86], and in one such study, a genetic polymorphism of the COX-2 gene was associated with a significant reduction in the risk of estrogen positive breast cancer^[80].

Study of selective COX-2 inhibitors and breast cancer

Based on the epidemiologic evidence that nonselective NSAIDs reduce human breast cancer risk, we initiated a case control study of selective COX-2 inhibitors to assess their effects on the relative risk of breast cancer. The study was conducted for women diagnosed with breast cancer during the window of time (1998-2004) in which two selective COX-2 inhibitors, celecoxib and rofecoxib, were available by prescription in the United States. In the study, 323 cases with pathologically confirmed invasive breast cancer were compared to 649 controls without cancer who were frequency-matched at a 2:1 rate to the cases by age and county of residence^[79].

Results of the investigation are shown in Table 1. Coxib use reduced the risk of breast cancer development by 71% (OR = 0.29, $P < 0.01$). Significant reductions in

Figure 3 Meta-analysis of breast cancer and nonsteroidal anti-inflammatory drugs. Estimates of relative risk (RR) and 95%CI are shown for individual studies. The horizontal dotted line reflects the combined estimate of RR = 0.75, 95%CI: 0.67-0.84, $P < 0.001$.

Table 1 Breast cancer and cyclooxygenase-2 blocking agents: Results of a case control study^[79]

Agent	OR (95%CI)
COX-2 inhibitor	0.29 (0.14-0.59)
Ibuprofen	0.37 (0.18-0.72)
Regular aspirin (325 mg)	0.51 (0.27-0.98)
Low dose aspirin (81 mg)	0.77 (0.41-1.41)
Acetaminophen	1.02 (0.39-2.20)
Selective COX-2 inhibitors: Celecoxib or Rofecoxib	

COX-2: Cyclooxygenase-2.

breast cancer risk were also noted for ibuprofen (63%) and regular 325 mg aspirin (49%) but not for low dose (81 mg) aspirin (23%). There was no effect of acetaminophen, an analgesic without COX-2 inhibiting properties (OR = 1.02). The inverse pattern of risk for acetaminophen, low dose aspirin, regular aspirin, ibuprofen and coxibs was significant by a linear trend test ($P < 0.05$) suggesting that chemopreventive effects become progressively stronger with greater selective COX-2 inhibition.

Comparative studies of breast cancer and other neoplasms

During the time period 1987-2008, we conducted a series of epidemiologic studies of NSAIDs and cancers of the breast, prostate, colon and lung^[57,59,61,69,79,95-99]. Five of these studies focused on cancer of the breast. In each investigation, information was obtained about the entire profile of NSAID use for each participant including both over-the-counter and prescription drugs. All studies were designed to specifically evaluate and compare the two major over-the-counter compounds, aspirin and ibuprofen. Following their FDA approval, selective COX-2

Figure 4 Comparison of selective and non-selective cyclooxygenase-2 inhibitors in cancer prevention. Bars represent 95%CI of each estimate^[100].

inhibiting agents were also evaluated. Effects of specific agents were quantified by estimating relative risks (or odds ratios) adjusted for cancer risk factors with standard errors and 95%CI. In each study, estimates for specific compounds were derived by comparison with a reference group that did not report using any type of NSAID. Furthermore, acetaminophen, a commonly used analgesic with little or no activity against either COX-1 or COX-2 was always evaluated as a comparator drug. Meta-analysis as described above was applied to examine effects of individual compounds for each individual cancer and across all malignancies^[100,101].

Figure 4 presents the individual and composite risk estimates for the four cancer sites with exposure to regular aspirin, ibuprofen or selective COX-2 inhibitors (celecoxib or rofecoxib). Daily intake of a selective COX-2 inhibitor (either celecoxib or rofecoxib) produced a significant reduction in the risk for each type of cancer (71% for breast cancer, 55% for prostate cancer, 70% for

colon cancer, and 79% for lung cancer). The observed chemopreventive effects of coxibs were associated with recommended daily doses of celecoxib (median dose = 200 mg) or rofecoxib (median dose = 25 mg). Significant risk reductions of slightly lesser magnitude were observed for over-the-counter NSAIDs with nonselective COX-2 activity, such as regular (325 mg) aspirin and (200 mg) ibuprofen. Daily intake of baby (81 mg) aspirin produced marginally significant risk reductions for colon cancer and lung cancer, but did not significantly reduce the risk of breast cancer or prostate cancer whereas daily acetaminophen, an analgesic without COX-2 activity, did not produce a significant change in the risk of any of the cancers studied. Composite risk reductions of 64%, 53% and 46% were observed for the selective COX-2 inhibitors (either celecoxib or rofecoxib), ibuprofen and aspirin, respectively; a significant dose response pattern that is consistent with the degree of selective COX-2 blockade (celecoxib > ibuprofen > aspirin).

Notably, selective COX-2 inhibitors (celecoxib and rofecoxib) were only recently approved for use in 1999. In 2004, rofecoxib (Vioxx) was withdrawn from the marketplace due to concerns about cardiovascular risk. Nevertheless, even in the short window of exposure to these compounds, the selective COX-2 inhibitors produced significant reductions in the risk of the four major human cancers (breast, prostate, colon, and lung). It is also important to note that ibuprofen produced effects similar in magnitude to the coxibs which is consistent with its high activity against COX-2. These results tend to substantiate the important role of COX-2 in carcinogenesis, and reciprocally, the strong potential for selective COX-2 blockade in cancer chemoprevention.

Therapeutic studies of NSAIDs in human breast cancer

Randomized clinical trials of nonselective COX-2 inhibitors such as aspirin and ibuprofen for human cancer therapy are lacking. Nevertheless, since these drugs are frequently regularly taken for pain relief in randomized clinical trials of cancer, some investigators have examined their therapeutic impact among patients.

Remarkably, the treatment-adjusted hazard ratios for NSAID users show significant reductions of recurrence risk or death in three cohorts of breast cancer patients. It is emphasized that effects of ibuprofen and aspirin estimated from these studies are adjusted for stage at cancer detection, surgical treatment, chemotherapy, radiation therapy and other prognostic indicators such as age, race and gender.

Kwan *et al.*^[102] examined the association between NSAID use and breast cancer recurrence among 2292 women diagnosed with breast cancer in the Life After Cancer Epidemiology Study. They observed that regular ibuprofen users experienced 44% less recurrence than non-users after five years of follow-up.

Blair *et al.*^[103] examined effects of NSAID intake on survival after invasive breast cancer diagnosis among 591 postmenopausal women ascertained through the Iowa Women's Health Study. Compared to nonusers, women

who regularly took an NSAID experienced a 36% reduction in breast cancer mortality and a 43% reduction in all-cause mortality after approximately 10 years of followup.

Holmes *et al.*^[104] examined effects of taking aspirin or non-aspirin NSAIDs such as ibuprofen among 4164 women presenting with invasive breast cancers in the Nurses Health Study. They found that aspirin intake after breast cancer diagnosis was associated with a decreased risk of breast cancer recurrence, death from breast cancer and death from any cause. Significant decreases in breast cancer mortality of 71% and 64% were noted for aspirin intake 2-5 times per week and 6-7 times per week, respectively. More limited results from the study suggested that daily intake of non-aspirin NSAIDs also reduced breast cancer mortality whereas acetaminophen use showed no evidence of survival benefit.

MODEL OF INFLAMMOGENESIS OF BREAST CANCER

Interaction of mammary epithelium and adipose tissue

White adipocytes are intimately and inseparably connected to the parenchyma of the human female breast throughout life^[105]. These cells provide the nutrients essential for the morphogenesis, maturation and function of the mammary epithelium. Homeostasis of the breast epithelium therefore depends vitally upon the integrity of the adipocyte population of the mammary gland. Far from being an inert fat storage depot and energy resource for parenchymal cells (*e.g.*, the mammary epithelium), white adipose tissue is an active endocrine organ that secretes a variety of bioactive proteins collectively called adipokines^[106].

Obesity, inflammation and breast cancer

Recent data from the World Health Organization and the International Agency for Research on Cancer reflects a 20% increase in the global incidence of breast cancer and a 14% increase in breast cancer mortality during the past five years^[107]. These increases are most likely largely attributable to the global pandemic of obesity that influences breast cancer development and progression.

In molecular studies of tissues from humans and animals, obesity leads to inflammation and infiltration of mammary and visceral adipose tissue by macrophages with activation of NF- κ B, overexpression of COX-2 and hypersecretion of PGE-2 and pro-inflammatory mediators and adipokines such as leptin, resistin, IL-6, IL-1 β and tumor necrosis factors (TNF)- α ^[108-111]. Furthermore, COX-2 driven PGE-2 biosynthesis induces transcription of CYP-19 and aromatase-catalyzed production of estrogen in a paracrine mechanism. Local estrogen biosynthesis in the breast parenchyma has been hypothesized to be a key feature of breast cancer development, particularly in postmenopausal women^[112,113].

Inflammogenesis of breast cancer by COX-2: Molecular mechanisms

Various molecular mechanisms may be responsible for

Figure 5 Model of COX-2-driven inflammogenesis of breast cancer. Key steps in the transition of normal mammary ductal epithelium to invasive cancer are as follows: (1) Healthy mammary adipose maintains homeostasis of the mammary epithelium; (2) Pro-inflammatory stimuli (e.g., adipokines, cytokines and n-6 PUFA) induce macrophage infiltration and chronic inflammation of the mammary stroma; (3) COX-2 is upregulated and constitutively expressed by adipocytes, immune cells and epithelial cells; (4) COX-2-catalyzed PGE-2 induces transcription of the *CYP-19* gene and aromatase-catalyzed estrogen biosynthesis by adipocytes; (5) Estrogen stimulates estrogen receptors of epithelial cells to promote cell proliferation; (6) PGE-2 induces CYP-1B1 in epithelial cells resulting in hydroxylation of estrogen that is converted to estrogen quinone that has mutagenic impact; and (7) PGE-2 induces a profile of genes in epithelial cells that promote angiogenesis, loss of apoptosis, immunosuppression and metastasis (see text for discussion). COX-2: Cyclooxygenase-2; PGE-2: Prostaglandin E2; n-6 PUFA: n-6 polyunsaturated fatty acids.

the initiation and promotion of mammary carcinogenesis by COX-2. It is indeed remarkable that the induction of constitutive COX-2 expression and PGE2 biosynthesis are sufficient to stimulate all of the key features of mammary carcinogenesis including mutagenesis, mitogenesis, angiogenesis, metastasis, inhibition of apoptosis and immunosuppression with reduced antineoplastic activity of T and B lymphocytes. These mechanisms are thoroughly reviewed and discussed elsewhere, e.g., Shiff *et al.*^[114] and Subbaramaiah *et al.*^[115].

As depicted in Figure 5, continuous over-expression of COX-2 can initiate and promote carcinogenesis by (1) increasing production of PGE-2 and other prostaglandins that strongly promote cell proliferation, e.g., correlative up-regulation of the gene for aromatase (CYP19) and estrogen biosynthesis in stromal cells, or activation of epidermal growth factor receptor (EGFR) that stimulate an intracellular cascade of mitogenic signaling (mitogenesis); (2) increasing production of estrogen quinones and other reactive oxygen species, e.g., malondialdehyde, that are carcinogenic (mutagenesis); (3) stimulation of vascular endothelial growth factor (VEGF) and platelet derived growth factor by PGE-2 resulting in de novo formation of blood vessels (angiogenesis); (4) increasing production of matrix metalloproteinases (MMP) *via* co-expression of COX-2 and the *Her-2/Neu* gene, thus enhancing invasive potential (metastasis); (5) stimulating telomerase expression, decreasing bioavailable arachidonic acid pools necessary for conversion of sphingomyelin to ceramide, and stimulation of the *Bcl-2* gene and inhibition of the *BAX* gene thereby reducing cell differentiation and apoptosis (anti-apoptosis); and (6) inhibiting proliferation of B and T lymphocytes, particularly natural killer T cells, thus lim-

iting antineoplastic activity (immunosuppression). All of these processes are discussed in some detail below.

Induction of COX-2

A key event in the carcinogenic process is induction of constitutive expression of the *COX-2* gene. Molecular studies from multiple laboratories reveal that adenocarcinoma of the breast is characterized by aberrant over-expression of COX-2 by breast cancer epithelial cells^[24,33-38]. As shown by Karmali *et al.*^[116] Rose *et al.*^[117], and others^[33-38], arachidonic acid production, COX-2 expression, and prostaglandin biosynthesis are increased *in vivo* by dietary n-6 polyunsaturated fatty acids (n-6-PUFAs) such as unconjugated linoleic acid, and decreased by n-3-PUFAs such as linolenic acid. High dietary intake of n-6-PUFAs may therefore be an important factor in the induction of constitutive COX-2 expression. This mechanism is compatible with the high rates of cancers of the breast, colon and prostate (neoplasms that characteristically over-express COX-2) in populations where n-6-PUFAs, particularly unconjugated linoleic acid, are abundant in the diet. The COX-2 enzyme efficiently catalyzes the conversion of essential dietary fats (principally arachidonic acid and unconjugated linoleic acid) into prostaglandins^[100,113,118].

Obesity has reached epidemic proportions in most industrialized nations in association with increased rates of a variety of chronic conditions such as type 2 diabetes, coronary heart disease and certain malignant neoplasms including breast cancer. The obese phenotype is characterized by the presence of fat-laden adipocytes that secrete pro-inflammatory adipokines (e.g., leptin and resistin) and stimulate infiltration of the mammary fat by

macrophages which secrete pro-inflammatory cytokines (*e.g.*, IL-6 and TNF- α). Since the COX-2 gene contains multiple promoter binding sites, these effector molecules may also participate in signal transduction cascades to induce constitutive overexpression of COX-2 and PGE-2 biosynthesis^[45,108-111,114,115]. Furthermore, *in vitro* studies of breast cancer tissues suggest that mutations or methylation of CpG islands at binding sites for these transcription factors in the promoter region of the COX-2 gene regulate the induction of COX-2 transcription^[119]. Thus, induction of constitutive COX-2 genetic expression may involve synergistic interactions between a number of micro-environmental epigenetic and genetic cofactors.

Mitogenesis

The COX-2 enzyme efficiently catalyzes the conversion of essential dietary fats (principally arachidonic acid and unconjugated linoleic acid) into prostaglandins. Induction of constitutive over-expression of COX-2 in a cell predominantly increases the biosynthesis of PGE-2, which is the chief prostaglandin of the inflammatory cascade. This short-lived intercellular hormone is capable of inducing the transcription of specific genes in the nucleus of nearby cells. In particular, PGE-2 has been found to stimulate the transcription of genes that have powerful mitogenic effects.

Importantly, it has recently been discovered that there is a strong link between prostaglandins and a paracrine mechanism of estrogen biosynthesis. This occurs when the chief prostaglandin, PGE-2, activates the promoter II region of the aromatase gene (*CYP-19*), which is responsible for local estrogen biosynthesis catalyzed by aromatase^[112]. Furthermore, several molecular studies have revealed a significant correlation between up-regulation of cyclooxygenase expression and CYP-19 transcription and aromatase-catalyzed estrogen biosynthesis in breast cancer tissues^[108,109,120-122]. Notably, this mechanism has been demonstrated in other malignant neoplasms including cancers of the lung, colon, and prostate and may in fact be a ubiquitous feature in cancer promotion and development^[123-130]. Clearly, the established molecular link between heightened levels of n-6 polyunsaturated fatty acids, COX-2, PGE-2, aromatase and estrogens, provides a basis for mammary carcinogenesis through unbridled mitogenesis.

An additional mitogenic mechanism is PGE-2 activation of EGFR that in turn triggers cell division through the mitogen-activated protein kinase (MAPK) cascade^[131-133]. Polakis *et al.*^[134] discovered that PGE-2 rapidly phosphorylates EGFR and triggers the extracellular kinase, ERK-2, thereby activating the mitogenic signaling cascade in normal gastric epithelium and colon cancer. Their studies indicate that PGE-2-induced EGFR trans-activation involves signal transduction *via* TGF- α and activated MMP. Other investigators have confirmed that co-expression of COX-2, PGE-2, and EGFR results in mitogenic activation in precancerous and cancerous tissues of multiple anatomic sites^[135-139]. In a recent molecular study of COX-2 and EGFR in human breast cancer

tissues from 55 patients, COX-2 expression was detected in cancer cells of more than 95% of specimens and EGFR expression was found to be dependent on COX-2 upregulation^[140].

Other COX-2 driven mechanisms may also be involved in delimiting cell proliferation of the ductal epithelium of mammary tissues. For example, PGE-2 expression is associated with disruption of contact inhibition in malignant cells from specimens of cancerous tissues from multiple anatomic sites.

Molecular examination of colon cancer specimens first revealed accumulation of the cell adhesion molecule, beta-catenin, in the nucleus of malignant cells^[133-136]. Cell adhesion is under the control of the gene for adenomatous polyposis coli (APC) and involves maintenance of the integrity of a molecular cell adhesion complex comprised of beta-catenin, APC protein, T-cell factor and actin. Familial adenomatous polyposis is caused by a mutation of the APC gene that causes dissociation of these cell adhesion complexes and the migration of beta catenin to the cell nucleus where it activates one of the peroxisome proliferator activated receptors (PPAR gamma) on the nuclear membrane. Castellone *et al.*^[137] conducted a series of experiments demonstrating that inhibition of PGE-2 biosynthesis by NSAIDs effectively reduces the accumulation of beta-catenin and the progression of colon cancer. Based on their results, over-expression of COX-2 with increased PGE-2 biosynthesis and binding to its receptor in turn activates a cytoplasmic G-protein receptor that binds axin thereby reducing phosphorylation of beta-catenin. This chain of molecular events leads to dissociation of the adhesion complex, accumulation of unphosphorylated beta-catenin in the cell nucleus, activation of the nuclear receptor, PPAR-gamma, and stimulation of cell proliferation through transcription of cell cyclin genes. Recent molecular studies suggest that this mechanism is not limited to the colon; that is, induction of cyclooxygenase and increased PGE-2 can result in cellular beta-catenin accumulation, nuclear PPAR-gamma activation, and subsequent cell proliferation and carcinogenesis in a variety of tissues including the mammary epithelium^[138,139].

Mutagenesis

Accumulated mutagenic damage to DNA is believed to contribute substantially to the etiology of breast cancer. Notably, there is strong experimental evidence to support the role of estrogen metabolites as carcinogenic agents. Specifically, the metabolism of estrogens by certain enzymes of the cytochrome P450 system produces catechol estrogens that can be further oxidized to form quinones that react directly with DNA or undergo redox cycling to generate reactive oxygen species that cause oxidative damage to DNA. This mechanism is of major significance in chronically inflamed breast tissue (*e.g.*, in obese women) wherein PGE-2 activates aromatase-catalyzed estrogen biosynthesis.

The quinone metabolites of estrogen are formed by the action of the same cytochrome P450 enzymes

responsible for the metabolism of polycyclic aromatic hydrocarbons (cytochrome P450 isoforms CYP-1A1, CYP-1B1, and CYP-3A). While most P450 enzymes are produced in the liver, CYP-1B1 is constitutively expressed in the mammary gland and other extrahepatic tissues. In the mammary gland, CYP-1B1 preferentially metabolizes estrogen to 4-hydroxyestrogen which is oxidized to form carcinogenic 3,4 estrogen quinone which in turn forms unstable adducts with adenine and guanine in DNA, leading to depurination and mutation *in vitro* and *in vivo*. Reduction of estrogen quinones to hydroquinones and catechols can also form reactive oxygen species by redox recycling^[140-147].

Another established mechanism of mutagenesis involves constitutive COX-2 expression and intermediate compounds formed by activation of the prostaglandin cascade. It is well known that lipid peroxidation in the human system generates reactive electrophilic compounds that have mutagenic potential. COX catalyze the two-step oxidation and peroxidation of arachidonic acid to form the intermediate prostaglandin endoperoxides, PGG-2 and PGH-2^[13,14,45,114,115,148]. Spontaneous breakdown of PGH-2 yields the mutagen, malondialdehyde (MDA) plus hydroxyheptadecatreonic acid, and specific enzymes of the cytochrome P450 system as well as thromboxane synthetase can also catalyze the breakdown of PGH-2 to MDA^[149]. Malondialdehyde reacts with DNA under physiological conditions to form DNA adducts, predominantly pyrimidopurine adducts of deoxyguanosine^[150]. Sharma *et al.*^[151] demonstrated that induction of COX-2 in human non-malignant colon epithelial cells produced increases in PGE-2, MDA, and characteristic DNA adducts that were similar to the levels observed in malignant colon epithelial cells. These findings underscore the potential for carcinogenesis due to oxidative damage and mutagenesis attributable to constitutive over-expression of COX-2.

Angiogenesis

VEGF is a potent stimulant of de novo blood vessel formation (angiogenesis) in a variety of tissues. Once believed present only in the endothelial lining of blood vessels, VEGF has now been discovered in virtually all types of cancers^[152,153]. Molecular investigations of breast cancer tissues provide strong evidence that COX-2-derived PGE-2 stimulates the synthesis and release of VEGF resulting in angiogenesis and ingrowth of new blood vessels that are immature and highly permeable thereby facilitating metastatic spread of tumor cells^[7,28,154]. Tumor secretion of VEGF (and other growth factors) may further amplify COX-2 expression in a positive feedback loop to produce lymphangiogenesis^[155,156]. Notably, inhibition of this vicious cycle by COX-2 inhibiting agents such as celecoxib has been found to limit angiogenesis and halt the progression and metastatic spread of tumors in animals^[157].

Suppression of apoptosis

Apoptosis or controlled cell death is an important regula-

tory mechanism for the maintenance of homeostasis in cell populations. Dysfunctional apoptosis results in immortalization of cells, a key feature of cancer cells. Inflammation, COX-2 over-expression, and increased PGE-2 are clearly anti-apoptotic, whereas, anti-inflammatory compounds that inhibit COX-2 are pro-apoptotic^[21,22,114,115,158].

Apoptosis is regulated by an intrinsic pathway that originates inside the cell and an extrinsic pathway that originates outside the cell and in molecular studies of breast cancer tissues, both pathways are inhibited by COX-2 over-expression^[159-161]. The intrinsic pathway involves mitochondrial release of cytochrome c and activation of caspase 9 and other enzymes that destroy the cell. Intrinsic apoptosis is triggered when the expression of two nuclear genes, Bcl-2 and BAX, favors BAX. Notably, COX-2 over-expression and prostaglandin biosynthesis promotes Bcl-2 and inhibits BAX, thereby blocking intrinsic apoptosis^[159,160].

The extrinsic pathway involves activation of death receptors on the cell membrane by TNF- α , - β and other epigenetic factors. This results in activation of caspase 8 and other enzymes that destroy the cell. Over-expression of COX-2 attenuates activation of this mechanism thereby blocking extrinsic apoptosis^[161].

Compounds that inhibit COX-2 and PGE-2 appear to enhance both intrinsic and extrinsic apoptosis and as a consequence, COX-2 inhibitors used in combination with radiation show beneficial synergism in the elimination of cancer cells in inoperable solid tumors^[162,163]. Nonsteroidal anti-inflammatory drugs have also been found to increase apoptosis by other mechanisms, *e.g.*, by increasing bio-available arachidonic acid pools necessary for conversion of sphingomyelin to ceramide since ceramide accumulation in the cell triggers apoptosis^[164]. In an interesting study of a breast cell line immortalized by introduction of the human telomerase gene, a selective COX-2 inhibitor, celecoxib, induced apoptosis and inhibited growth in association with upregulation of insulin-like growth factor^[165].

Metastasis

The Her-2/Neu oncogene is a member of the EGFR family. It is an important mediator of cancer cell growth and metastasis. Koki *et al.*^[7] and Subbaramaiah *et al.*^[166] demonstrated that COX-2 and Her-2/Neu are co-expressed in breast cancer tissues. Co-expression of COX-2 and Her-2/Neu stimulate the MAPK/AP-1 signaling cascade. When the Her-2/Neu receptor protein is activated, multiple other factors are activated that promote tumor development and metastatic spread of cancer cells^[7]. Overexpression of Her-2/Neu is now widely used by clinicians as a biomarker of poor prognosis and metastasis for patients with invasive breast cancer^[167].

Molecular studies of breast cancer tissues have demonstrated that high levels of COX-2 and PGE-2 are correlated with amplified Her-2/Neu expression and increased activity of MMP^[168,169]. The MMP are proteolytic enzymes that degrade basement membranes and are thus associated with tumor invasiveness, metastasis, and poor survival. Reciprocally, in animal models of breast cancer,

agents that inhibit COX-2 or block membrane receptors of PGE-2 have been found to reduce Her-2/Neu and MMP levels thereby decreasing the metastatic potential of cancer cells^[170,171].

Immunosuppression

Immunosuppression is a characteristic feature of cancer patients that correlates with disease promotion and progression. It is an interesting paradox that COX-2 over-expression and prostaglandin biosynthesis empowers cancer cell proliferation, immortalization, and metastasis on the one hand, while suppressing the function of important cells of the immune system on the other, thereby creating an immunosuppressed host with little ability to mount an immune defense against a developing tumor. Indeed, the induction of T cell anergy is an early event in the course of tumor progression^[172].

Prostaglandins, particularly PGE-2, are important modulators of immunosuppression. Pockaj *et al.*^[173] found that increased levels of PGE-2 suppress the immunocompetence of helper T-cells and dendritic cells in newly diagnosed breast cancer patients. Specifically, elevated levels of PGE-2 were associated with reduced secretion of antitumor factors by T-cells (interferon-gamma, TNF-alpha, and interleukins IL-2 and IL-12) and loss of immunocompetence in dendritic cells (reduced secretion of stimulatory molecules, loss of antigen-sensitizing function, reduced phagocytic activity, and lack of maturation potential). Defective T-cell and dendritic cell function due to COX-2 driven PGE-2 biosynthesis is therefore an important mechanism by which tumors evade immunosurveillance.

Web of causation of mammary carcinogenesis

It should be emphasized that the proposed “inflammogenesis model of breast cancer” is not mutually exclusive and may in fact be synergistic with other mechanisms of mammary carcinogenesis. For example, polycyclic aromatic hydrocarbons and other carcinogens present in tobacco smoke are mutagenic in mammary tissues^[174] and acetaldehyde, the primary metabolite of alcohol metabolism has powerful mutagenic impact in all tissues studied^[175]. The web of breast cancer causation may thus be particularly strong in obese women who are chronically addicted to both tobacco and alcohol and regularly consume diets with a high content of n-6 PUFA.

CONCLUSION

Cohesive scientific evidence from molecular, animal, and human investigations supports the hypothesis that induction of constitutive COX-2 over-expression and upregulation of the prostaglandin cascade play a significant role in mammary carcinogenesis, and reciprocally, blockade of the process has strong potential for breast cancer prevention and therapy. A summary of the evidence supporting the “inflammogenesis of breast cancer” is given below: (1) Epidemiologic investigations have consistently demonstrated that nonselective COX-2 inhibitors, such

as aspirin and ibuprofen, used on a regular basis, significantly reduce the risk of human breast cancer; (2) Selective COX-2 inhibitors, such as celecoxib, used on a regular basis have been shown to reduce the risk of human breast cancer; (3) Follow-up studies of women with breast cancer have consistently demonstrated that nonselective COX-2 inhibitors significantly reduce recurrence risk and breast cancer mortality; (4) Molecular investigations show that COX-2 expression is a characteristic feature of premalignant mammary neoplasms and ductal carcinoma *in situ*; (5) Molecular investigations show that COX-2 expression is a characteristic feature of invasive breast cancer and expression tends to intensify with stage at detection and cancer progression and metastasis; (6) All essential features of carcinogenesis (mitogenesis, mutagenesis, angiogenesis, reduced apoptosis, metastasis, and immunosuppression) are linked to COX-2-driven PGE-2 biosynthesis; and (7) Most notably, upregulation of COX-2 and PGE-2 expression induces transcription of CYP-19 and aromatase-catalyzed estrogen biosynthesis by the mammary adipose tissue which stimulates unbridled mitogenesis of ductal epithelium, and the extrahepatic mammary enzyme, CYP-1B1, converts paracrine estrogen to carcinogenic quinones that have potent mutagenic impact.

This review documents compelling evidence that mammary carcinogenesis often evolves as a progressive series of highly specific cellular and molecular changes in response to induction of constitutive over-expression of COX-2 and the prostaglandin cascade in the “inflammogenesis of cancer”. Based upon results, a general model of inflammogenesis of cancer is proposed involving induction of constitutive COX-2 expression and upregulation of the prostaglandin cascade.

It is emphasized that encouraging results regarding the chemopreventive and therapeutic effects of both selective and non-selective COX-2 inhibiting agents against cancer of the breast as well as other malignant neoplasms have been tempered by concerns about cardiovascular risk associated with taking compounds that inhibit COX-2^[10]. For example, data from randomized trials suggests that high dosages of some NSAIDs or combinations of such drugs may increase the risk of cardiovascular disease^[176]. Before recommendations can be made, more studies are needed to determine if certain COX-2 inhibiting drugs can be taken at dosages that prevent cancer without increasing the risk of heart conditions.

Abstract

The breast cancer care continuum entails detection, diagnosis, treatment, and survivorship. During this time, focus on the whole woman and medical concerns beyond the breast cancer diagnosis itself is essential. In this comprehensive review, we critically review and evaluate recent evidence regarding several topics pertinent to and specific for the woman living with a prior history of breast cancer. More specifically, we discuss the most recent recommendations for contraceptive options including long-acting reversible contraception and emergency contraception, fertility and pregnancy considerations during and after breast cancer treatment, management of menopausal vasomotor symptoms

and vulvovaginal atrophy which often occurs even in young women during treatment for breast cancer. The need to directly query the patient about these concerns is emphasized. Our focus is on non-systemic hormones and non-hormonal options. Our holistic approach to the care of the breast cancer survivor includes such preventive health issues as sexual and bone health, which are important in optimizing quality of life. We also discuss strategies for breast cancer recurrence surveillance in the setting of a prior breast cancer diagnosis. This review is intended for primary care practitioners as well as specialists caring for female breast cancer survivors and includes key points for evidence-based best practice recommendations.

Key words: Breast cancer; Contraception; Vasomotor symptoms; Vulvovaginal atrophy; Sexual health; Osteopenia; Osteoporosis; Breast cancer recurrence; Breast cancer surveillance

Core tip: Caring for women with breast cancer at the time of diagnosis, during, and after treatment goes well beyond addressing the breast cancer alone. Holistic care includes safe, effective and convenient contraceptive options; local progestin intrauterine contraception may present an option for some breast cancer survivors. Discussion regarding the effects of chemotherapy on future fertility and pregnancy is an important part of survivorship care for women in child-bearing years. Addressing the effects of breast cancer treatment including vasomotor symptoms, vulvovaginal atrophy and sexual well-being is vital for all breast cancer survivors, but especially important in the setting of adjuvant therapy with aromatase inhibitors.

Casey PM, Faubion SS, MacLaughlin KL, Long ME, Pruthi S. Caring for the breast cancer survivor's health and well-being. *World J Clin Oncol* 2014; 5(4): 693-704 Available from: URL:

INTRODUCTION

Breast cancer is the most common cancer diagnosis in women, and one in eight women will be diagnosed with breast cancer during her lifetime^[1]. Treatment, both surgical and chemotherapeutic, has evolved from the Halsted radical mastectomy to less invasive surgical techniques, combination treatment with focused radiation, and more effective adjuvant therapeutic options including tamoxifen and aromatase inhibitors (AIs)^[2]. These advances in early detection and effective therapies have led to a growing number of cancer survivors worldwide. As vital as these interventions are for a woman's ultimate survival, the overall quality of life of a woman with breast cancer encompasses additional issues to be addressed by the health care provider caring for her during and after the diagnosis and treatment. These issues are often only elicited with compassionate, yet direct inquiry. Adequately addressing these concerns may ultimately make a significant difference in the general health, adherence to recommended therapy, and overall well-being of the woman and her loved ones. In this review, we focus on issues of contraceptive options, fertility and pregnancy after breast cancer treatment, management of bothersome vasomotor symptoms (VMS), vulvovaginal atrophy (VVA) and other sexual health issues, prevention of bone loss, and evidence-supported surveillance for breast cancer recurrence. Ideally, coordination of care with specialists in oncology, reproductive endocrinology, women's health, breast health, gynecology, and primary care to address psychological and medical needs can provide a sense of a "medical home" extending beyond a woman's cancer diagnosis, and can contribute to her overall quality of life.

SURVEILLANCE AFTER BREAST CANCER

Breast cancer survival has been attributed to advances in screening mammography and adjuvant therapy. In the United States, this survival benefit has led to a growing population of women who are living with a history of breast cancer^[3]. With the new focus on patient centeredness, a multidisciplinary approach is the expectation for survivorship care in order to best address the woman's needs. A survey study demonstrated that breast cancer survivors reported a high rate of distress, neuropathy, chest wall, and arm pain. The majority of survivors stated that their medical needs were met, but only 49% reported that their psychological and spiritual needs were met following completion of cancer treatment^[4]. Surveillance to monitor for recurrence, management of treatment related adverse effects, and promotion of preventive and general health care are all integral components of improving quality of care of breast cancer survivors. The Institute of Medicine published a report in 2005, "From

Cancer Patient to Cancer Survivor: Lost in Transition," which was instrumental in promoting awareness of the importance of standardization of survivorship care, development of cancer treatment plans, and improvement in the quality of care of breast cancer survivors^[5].

The American Society of Clinical Oncology (ASCO) has outlined evidence-based recommendations for survivorship care^[6]. A study comparing intensive *vs* standard surveillance for early-stage breast cancer demonstrated no difference in the disease-free or overall survival^[7]. Recommendations for follow-up care after breast cancer include taking a history of symptoms and performing a physical examination every 3-6 mo for 3 years, then every 6-12 mo for 2 years, and then annually. Women are encouraged to perform monthly breast awareness and promptly report new findings to their health care provider. Breast imaging includes an annual mammogram for women with remaining breast tissue. Routine laboratory testing and radiologic studies are not recommended. Preventive health and screening guidelines for other cancers should follow average-risk recommendations. Women are advised to maintain a healthy lifestyle with regular exercise, avoidance of alcohol, and maintenance of a healthy weight^[8]. Those with a hereditary predisposition for breast cancer and those with a known breast cancer mutation are advised to have an annual breast MRI in conjunction with mammography^[9].

Adjuvant hormonal therapy has been shown to decrease breast cancer recurrence for hormone-dependent breast cancer^[10]. Both AIs and tamoxifen are typically prescribed for 5 years for estrogen receptor-positive breast cancer. There is further evidence that longer therapy is beneficial for estrogen receptor-positive disease. A recent large study, the Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) trial, comparing 5 years *vs* 10 years of tamoxifen demonstrated a further reduction in recurrence and mortality after 10 years of tamoxifen in women with early-stage estrogen receptor-positive breast cancer^[11].

However, common side effects of antiestrogen therapies such as exacerbation of VMS, vaginal dryness, vaginal bleeding or spotting, and arthralgias can negatively impact quality of life for many women. These adverse effects can result in early discontinuation and nonadherence to adjuvant hormonal therapy^[12]. Clinicians can be proactive in assessing and counseling patients experiencing medication-related side effects. Various management options are available to provide relief of bothersome symptoms and evaluation of worrisome findings, such as postmenopausal bleeding in the setting of tamoxifen therapy, and can improve therapy adherence and survival.

MANAGEMENT OF VASOMOTOR SYMPTOMS

Vasomotor symptoms are among the most common bothersome symptoms associated with the menopausal transition, occurring in up to 80% of women^[13]. Though the experience of VMS varies, recent evidence suggests

that VMS begin before the final menstrual period and may last for over a decade^[14]. Further, up to 10% of women in a Scandinavian study continued to experience VMS well into their 70s^[15]. Women undergoing treatment for breast cancer may also experience VMS as a consequence of therapy, specifically tamoxifen or AIs^[16].

Hormone therapy (HT) whether estrogen alone, estrogen plus progestin, or progestin alone effectively treats VMS^[17,18]. However, systemic hormone therapy has been associated with an increased recurrence risk in breast cancer survivors in some but not all studies^[19,20]. In a review of 15 studies between 1967 and 2001 by Batur *et al.*^[21], menopausal HT (estrogen plus progestin in 14 of the 15) was not associated with increased cancer recurrence, cancer-related mortality, or total mortality. Nonetheless, synthetic progestins demonstrate proliferative effects in the breast and may augment carcinogenesis by stimulating conversion of differentiated cancer cells to cancer stem cells^[22]. In addition, the 13-year follow-up of the Women's Health Initiative showed increased risk of breast cancer after approximately 5 years of therapy in the estrogen plus progestin group and not in the estrogen alone group, adding to the concern that certain progestins may increase breast cancer risk^[22,23]. There is no current data to support differential management of VMS for women with different receptor-positive tumor types (*i.e.*, ER, PR, and HER-2neu).

In short, women on HT diagnosed with breast cancer need to discontinue therapy. There is no evidence-based guidance as to whether a taper is preferable to abrupt discontinuation, though a slow taper may be preferable based on expert opinion^[24]. Approximately 50% of women who discontinue HT will experience recurrence of VMS^[25].

NONHORMONAL TREATMENT OPTIONS FOR VASOMOTOR SYMPTOMS

Given the safety concerns with HT use in breast cancer survivors, nonhormonal treatments are often considered^[26]. Lifestyle modifications for management of VMS are recommended as first-line interventions. They include avoidance of triggers (caffeine, alcohol, tobacco, warm beverages, spicy foods), dressing in layers, and the use of cooling or wicking clothing and bed linen. The results of studies regarding soy, exercise, and acupuncture have been mixed^[27-29], whereas paced respirations may be of some benefit for VMS management^[30,31]. Caution should be exercised with nonprescription products claiming efficacy for VMS, as robust scientific evidence is lacking. Further, these products are not regulated by the Food and Drug Administration (FDA) raising questions about safety.

A 2010 Cochrane review of 16 randomized controlled trials of nonhormonal interventions for VMS management in breast cancer survivors showed a mild-to-moderate effect with selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors

(SNRIs), gabapentin, clonidine, and relaxation therapy^[32]. Limitations of existing studies include significant placebo effect, differing measures of efficacy, and in many, short duration of treatment. Areas of uncertainty are potential long-term drug effects, optimal duration of therapy, and symptom recurrence upon discontinuation^[31].

Gabapentin has been shown to reduce VMS in breast cancer survivors^[33,34]. However, extended-release gabapentin did not meet FDA approval for this indication in 2013, due to concerns regarding marginal effectiveness and adverse effects such as dizziness.

Low-dose mesylate salt of paroxetine (Brisdelle 7.5 mg) modestly reduces VMS frequency in clinical trials and is the first FDA-approved nonhormonal option for VMS management^[35]. In a recent year-long randomized, double-blind, placebo-controlled trial, desvenlafaxine (Pristiq) was found to be associated with a statistically significant and clinically meaningful VMS reduction^[36]. However, desvenlafaxine did not receive FDA approval for this indication in 2011 due to concerns regarding the risk-benefit profile.

Sexual side effects of antidepressants, including difficulty with arousal and orgasm, are associated with many antidepressants with some exceptions (bupropion and mirtazapine)^[37]. In fact, bupropion has been used in the setting of sexual side effects associated with other antidepressants, though it has not been studied specifically in women with breast cancer^[38].

In breast cancer patients, an interaction between tamoxifen and SSRIs that strongly inhibit cytochrome P450 2D6 (CYP2D6) may exist, potentially reducing endoxifen, the bioactive form of tamoxifen. Newer evidence is concerning for a potential correlation between tamoxifen efficacy or risk of breast cancer recurrence with an inherited variant of the CYP2D6 allele or with the use of medications which may inhibit the CYP2D6 enzyme^[39]. Therefore, caution is currently advised when using strong inhibitors of CYP2D6 in breast cancer patients on tamoxifen.

Though some data suggest short-term improvement in VMS with stellate ganglion block in breast cancer survivors, results have been mixed and further investigation is needed^[40,41].

Providers may choose a VMS management option based on potential side effects, medical comorbidities, and patient preference. For example, if a patient suffers from migraine, gabapentin may be reasonable. If a mood disorder is present, an antidepressant may be most appropriate.

SEXUAL HEALTH CONCERNS IN THE BREAST CANCER SURVIVOR

While sexual health is increasingly identified as an important issue in cancer survivors, providers don't always query patients about sexual function, and patients are often reluctant to bring up concerns, fearing nothing can be done or dissuaded by provider discomfort^[42]. Most

patients are, however, interested in discussing sexual function and want their providers to broach the topic. Survivors of breast cancer face well-described sexual health challenges, including changes in body image, loss of fertility, impairment of relationships, lack of libido, VVA, and dyspareunia. Both the experience of cancer and its treatment can have a significant impact on sexual functioning. Chemotherapy-induced ovarian insufficiency (or risk-reducing oophorectomy) as well as medications used to treat or control disease may result in hormonal loss or blockade, potentially leading to changes in libido, VVA, dyspareunia, and decreased quality of life^[43].

MANAGEMENT OF VULVOVAGINAL ATROPHY IN THE BREAST CANCER SURVIVOR

In contrast with VMS, which tend to improve with time, symptoms associated with VVA progress over time. In women with VVA, meticulous vulvar care is important, and products with perfumes or dyes should be avoided (toilet tissue, soaps, fabric softeners, stimulating lubricants, vaginal hygiene products)^[44]. Vaginal moisturizers can be used on a regular basis to replace vaginal moisture, whereas lubricants are needed with sexual activity to reduce friction^[45]. First-line therapies for VVA include not only vaginal moisturizers and lubricants, but also regular sexual activity (with partner, device, or solo) to stimulate blood flow to the area. Though data is lacking, expert opinion favors proactively educating postmenopausal women about vulvovaginal health in order to preserve sexual function^[46]. This concept is perhaps even more pertinent for the breast cancer survivor. Pelvic floor physical therapy may be utilized to facilitate pelvic floor relaxation, and may include education, relaxation techniques of the pelvic floor muscles, deep breathing, biofeedback, and instruction on the use of lubricated vaginal dilators in graduated sizes to gently stretch vaginal tissues^[47]. Psychosocial interventions, including individual or couple counseling, cognitive behavioral therapy, and mindfulness-based interventions are utilized in breast cancer survivors to improve coping strategies. These also serve to address a number of concerns that impact sexuality including altered body image, anxiety, fear of recurrent disease, changes in relationships, and dyspareunia, though supportive evidence is sparse^[43].

In particular, breast cancer survivors on AI therapy experience profound estrogen deprivation, vaginal dryness, and dyspareunia^[48]. A few small studies have demonstrated significant increases in plasma estradiol concentrations in postmenopausal breast cancer patients on AIs treated with local vaginal estrogen therapy (LVET). However, no studies to date have revealed an increased risk of breast cancer recurrence with LVET use^[49]. It is becoming increasingly evident that severe VVA can have a negative impact on quality of life and may result in medication noncompliance. LVET for severe symptoms

is available in ring, cream, or tablet form, but the long-term safety and systemic absorption from these various preparations are still largely unknown. Newer evidence has demonstrated that serum pharmacokinetics can be used to determine the maximum annual dose delivered and serum estradiol levels of various LVETs. Vaginal estrogen tablets (10 µg) prescribed twice a week demonstrated the lowest annual delivered systemic dose as compared to other LVET^[44]. Providers should be aware of barriers to breast cancer treatment adherence and take into account individual patient's symptom severity, preference, and potential cancer recurrence risk when considering LVET.

A trial utilizing topical testosterone vaginal cream in 20 breast cancer patients on AIs revealed improvements in vaginal dryness, dyspareunia, and vaginal maturation index (VMI) without a change in estradiol levels. The significance of increased reported testosterone levels is unclear^[50]. Likewise, intravaginal dehydroepiandrosterone (DHEA) has been associated with improvements in bothersome vaginal symptoms, VMI, and vaginal pH without significant changes in serum estrogen or androgen levels^[51]. A trial of vaginal DHEA in 465 breast cancer survivors with VVA is underway, with results expected in 2014^[52].

Ospemifene is a selective estrogen receptor modulator (SERM) FDA-approved for treatment of moderate-to-severe dyspareunia. While it has demonstrated antiestrogenic effects in preclinical models of breast cancer, it has not been studied in breast cancer survivors and is not approved for use in this population or in those at high risk of breast cancer^[53].

FERTILITY AFTER BREAST CANCER

While many women are diagnosed with breast cancer after menopause, a 20-year-old woman in the United States has about a 0.5% chance of developing breast cancer in her reproductive years, bringing up the impact of cancer therapy on future fertility, and of pregnancy on cancer recurrence^[54]. In general, the impact of chemotherapy on fertility is related to age-related baseline fertility as well as the type and dose of chemotherapy used^[55,56]. In women who desire pregnancy after breast cancer, fertility preservation should be discussed at the time of diagnosis. While a full discussion is beyond the scope of this review, both embryo and oocyte cryopreservation are considered standard options. With cycle-day-independent ovarian stimulation protocols, the timing of cancer therapy initiation can be minimally affected. In order to reduce potential risks associated with increased estrogen levels at ovarian stimulation, many regimens now utilize letrozole. Gonadotropin-releasing hormone analogs should not be used for fertility preservation due to unproven efficacy^[57].

While women were previously counseled to wait two years prior to conceiving after breast cancer diagnosis, newer published data does not demonstrate an alteration in survival with breast cancer to pregnancy intervals

longer than 10 mo^[58]. Estrogen-receptor status does not impact breast cancer recurrence with pregnancy^[59]. Initial studies noting improved outcome in women who become pregnant after breast cancer were attributed to better baseline status in women who chose pregnancy, the so-called “healthy mother effect”^[60]. A meta-analysis designed to correct for the “healthy mother effect” included over 1000 women with pregnancy after breast cancer diagnosis and over 13000 health-matched controls. This study noted improved survival in women who became pregnant after breast cancer treatment as compared to those who did not, hazard ratio 0.51 [95% confidence interval (CI), 0.42-0.62] suggesting that pregnancy at least 10 mo post breast cancer treatment in women < 45 years does not adversely affect prognosis and may in fact significantly improve survival^[60].

About 50% of women can lactate after breast cancer therapy, but breast milk volume tends to be reduced^[61].

ASSOCIATION BETWEEN HORMONAL CONTRACEPTION AND BREAST CANCER

Though data is difficult to interpret given varying hormonal doses and lengths of follow-up, there is no clear evidence that hormonal contraceptive use (oral contraceptive have been most thoroughly studied), past or present, is associated with a significantly increased breast cancer risk^[62]. Importantly, older studies reporting a weak association contain data pertaining to older, higher dose contraceptive formulations not in use today^[63,64]. Therefore, patients can be reassured of the unlikely contribution of prior hormonal contraception to the breast cancer diagnosis.

CONTRACEPTION OPTIONS DURING BREAST CANCER TREATMENT AND BEYOND

Safe, effective, and convenient contraception should be discussed and made available to all women undergoing diagnosis, treatment, and surveillance for breast cancer. Women not wishing further fertility may consider male or female sterilization with inherent failure rates < 1%^[65,66]. A number of minimally invasive options for sterilization now exist including laparoscopic tubal ligation and hysteroscopic sterilization (Essure). It is important to note that the latter does not have immediate efficacy, and tubal occlusion must be confirmed by hysterosalpingogram 12 wk following the procedure^[67]. Therefore, as with male sterilization, another form of contraception should be used until efficacy can be assured^[65,67].

During the evaluation for breast cancer, a woman on hormonal contraception, including combined hormonal contraception, should continue using this method until she receives appropriate counseling regarding future reproductive goals, an assessment of medical needs beyond the breast cancer, and, most importantly, until a new

method is initiated. The United States Medical Eligibility Criteria for Contraceptive Use (US MEC) considers all hormonal contraception as “advantages generally outweigh theoretical or proven risks” in the setting of an undiagnosed breast mass^[68]. Nonhormonal methods including the copper T380 (CuIUD or ParaGard) and barrier methods have “no restriction in use” in this setting. However, even with perfect use, barrier method alone is unlikely to provide sufficient efficacy and convenience to most women, given its 15% failure rate^[69]. An unplanned pregnancy at a time when breast cancer treatment should be initiated can lead to needlessly difficult choices about pregnancy termination or treatment delay.

The Cu-IUD is the only hormone-free, long-acting reversible contraceptive (LARC) currently available in the United States and has “no restrictions for use” in the setting of current breast cancer^[68]. Pregnancy rates are < 1% per year with this method indicated for up to 10 years^[70]. In addition, a Cu-IUD can be placed at any time that pregnancy can be reasonably ruled out, as well as within 5 d of unprotected intercourse if emergency contraception is desired. Additional back-up contraception is not required after insertion. Further, due to its non-systemic mechanism of action, chemotherapy-associated nausea and vomiting does not alter efficacy.

While the Cu-IUD represents the first-line reversible contraception in women with breast cancer, concurrent medical issues such as endometrial proliferation on tamoxifen, anemia, menorrhagia, and dysmenorrhea may warrant consideration of local progestin therapy, especially in women with hormone receptor-negative tumor types. These considerations need to be balanced with US MEC rating of “unacceptable health risks, method not to be used” for all hormone-containing contraceptives. The newer 13.5 mg levonorgestrel releasing system (low dose LNG-IUS) (Skyla) has lower circulating levels than the 52 mg LNG-IUS (Mirena) used in prior studies of LNG-IUS and breast cancer^[71-74]. In addition to being an extremely effective reversible contraception that is effective for up to 3 years, low dose LNG-IUS may improve anemia, menorrhagia, and dysmenorrhea that can be associated with Cu-IUD, while exposing a woman to lower circulating levels of levonorgestrel than LNG-IUS (Mirena). However, there is currently no evidence regarding low dose LNG-IUS efficacy for menorrhagia treatment or its safety in the setting of breast cancer.

A small case-control study of women using LNG-IUS compared 79 women, who started or continued using LNG-IUS after diagnosis of breast cancer, and 120 controls. While there was no increased risk of recurrence overall, there was concern about the 3.39 adjusted hazard ratio of breast cancer recurrence (95%CI, 1.01-11.35) in a subgroup who developed breast cancer while using LNG-IUS and continued its use^[74]. This finding contrasts with population data that has not found an increased risk of breast cancer in LNG-IUS users as compared to Cu-IUD users in 5100 breast cancer patients and 20000 controls^[73].

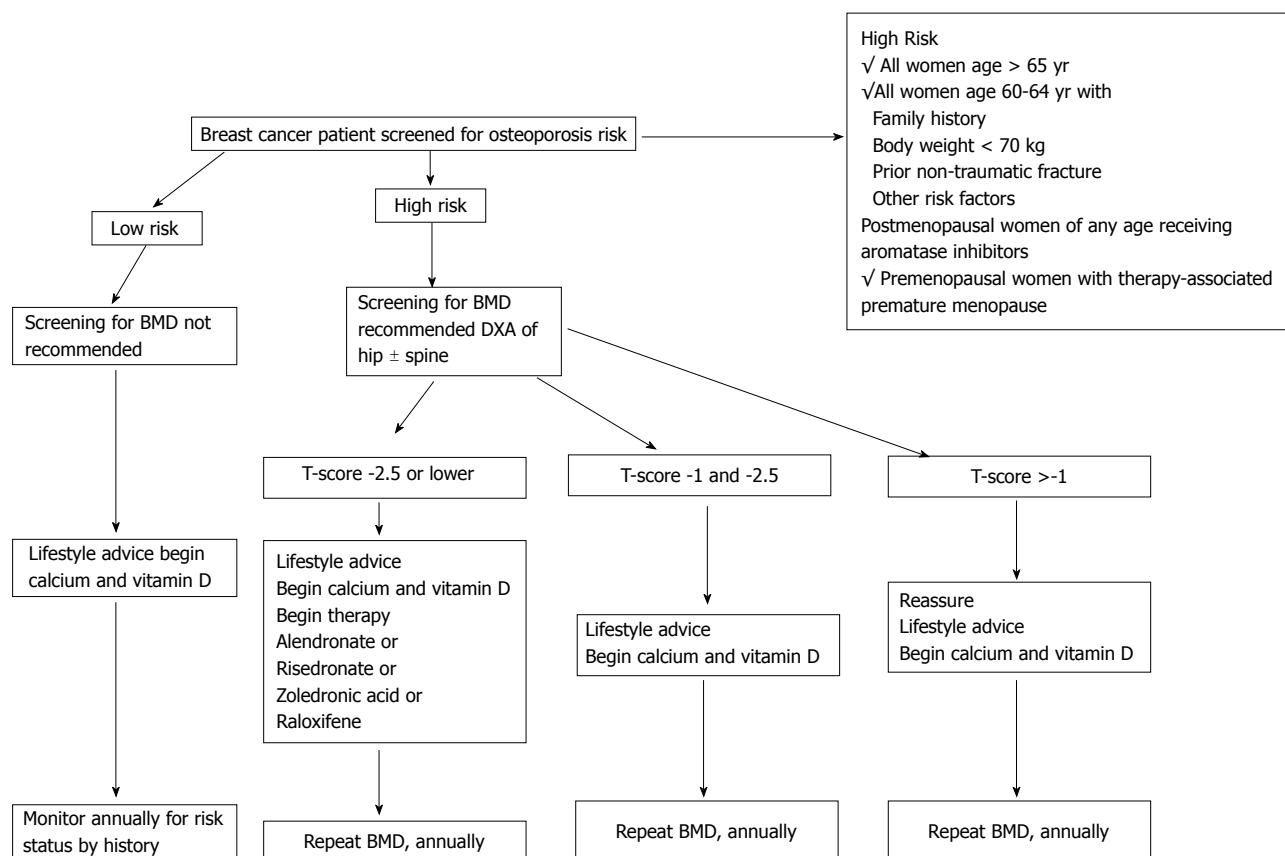

Figure 1 Recommended management strategy for patients with diagnosed nonmetastatic breast cancer^[97]. This management strategy is largely based on influence from results in non-breast cancer populations. BMD: Bone mass density; DXA: Dual energy X-ray absorptiometry bone scan. Reprinted with permission. © (2003) American Society of Clinical Oncology. All rights reserved.

LNG-IUS is indicated for the treatment of menorrhagia and can decrease menstrual blood loss by up to 90%^[75]. This is compared with a 40% reduction in menstrual blood loss with antifibrinolytics and about 25% with NSAIDs^[76,77]. Unfortunately, there is virtually no data on the contraceptive implant (Implanon, Nexplanon) in the setting of breast cancer^[78]. As with all other hormonal LARC methods, the US MEC rates the implant as “unacceptable health risk, method should not be used” with current breast cancer and as “theoretical or proven risks usually outweigh the advantages” after 5 years without breast cancer recurrence^[68].

When determining the need for contraception after breast cancer diagnosis, amenorrhea and elevated gonadotropins such as follicular stimulating hormone (FSH) are unreliable markers of infertility in women who have received chemotherapy^[55,79]. The incidence of chemotherapy-induced amenorrhea is reported to be 53%-89%, and is more likely to be reversible in women under 40 years than older women^[80].

EMERGENCY CONTRACEPTION

The World Health Organization (WHO) has determined that there is no medical condition wherein the risks of emergency contraception outweigh its benefits^[81]. There-

fore emergency contraception should be available to women diagnosed with and undergoing treatment for breast cancer.

The Cu-IUD can serve as 96% effective emergency contraception if inserted within 5 d post-unprotected intercourse, and can remain as primary hormone-free, yet reversible contraception for up to 10 years. In one study, over 80% of women who received Cu-IUD for emergency contraception continued using it for primary contraception thereafter^[82].

Additional emergency contraception methods include levonorgestrel (LNG or PlanB one step) and Ulipristal (UPA or Ella)^[83,84]. Plan B is now available in the United States without a prescription regardless of patient age, and is indicated for use within 72 h of unprotected intercourse^[84]. An efficacy rate of 85% has been reported. LNG alone is more effective than the combined Yuzpe regimen of oral contraceptives and is associated with fewer side-effects^[85]. UPA is indicated in a single dose for emergency contraception up to 5 d post-unprotected intercourse^[83]. Lower failure rates than LNG have been reported with UPA, (OR, 0.35, 0.58, 0.55 at 24, 72, and 120 h respectively)^[86]. Differences in efficacy of emergency contraception have been reported in women with normal vs elevated body mass index (BMI). As compared to women with a BMI < 25 kg/m², women with a BMI of

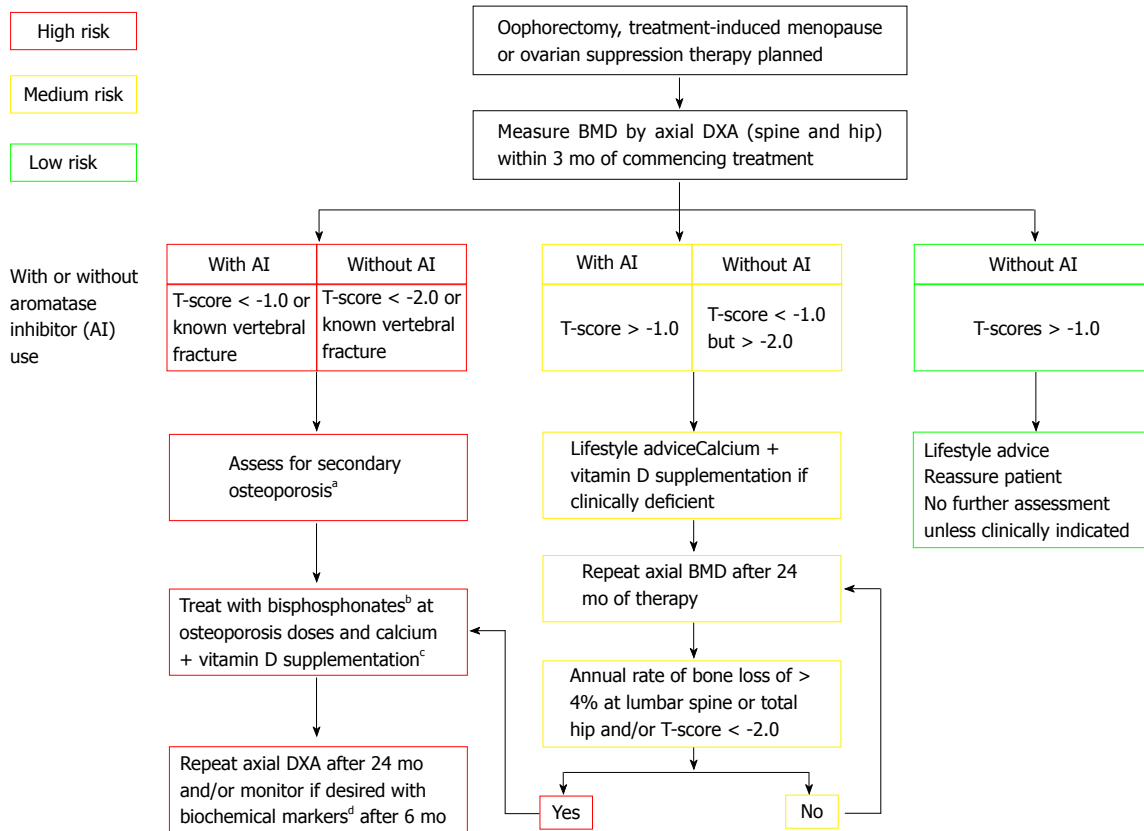

Figure 2 Adjuvant treatment associated with ovarian suppression/failure with or without concomitant aromatase inhibitor use in women who experience premature menopause^[92]. ^aErythrocyte sedimentation rate, full blood count, bone and liver function (calcium phosphate, alkaline phosphatase, albumin, AST/ALT), serum creatinine, endomysial antibodies, serum thyroid stimulating hormone; ^bAlendronate 70 mg per week, risedronate 35 mg per week, ibandronate (150 mg po monthly or 3 mg iv 3-monthly), zoledronic acid 4 mg iv 6-monthly; ^cTo be given as ≥ 1 g of calcium + ≥ 800 IU of vitamin D; ^dBiochemical markers such as serum C-terminal telopeptide of type I collagen or urinary N-telopeptide of type I collagen. 25–29 kg/m² had a 1.5-fold increased risk of pregnancy whereas those with a BMI > 30 kg/m² had a 3.6-fold increased risk with LNG EC *vs* UPA^[86]. Therefore, UPA or Cu-IUD, which do not have BMI-related efficacy differences, should be considered over LNG in women with elevated BMI.

BONE HEALTH

Bone health has been increasingly recognized as a significant issue for breast cancer survivors from the standpoint of osteoporosis prevention as well as its diagnosis and treatment^[87–89]. A recently published survey study found that women aged 65 and older with a breast cancer diagnosis had a higher prevalence of osteoporosis and falls. However, their risk was not more likely to have been identified by their health care provider, and bone health or fall prevention discussed^[90].

There are multiple mechanisms by which breast cancer treatment impacts bone health. Primary ovarian insufficiency or premature menopause often results from treatment with gonadotropin-releasing hormone agonists or chemotherapeutic agents in previously premenopausal women and increases risk of osteoporosis^[88]. The use of antiestrogen therapies can cause estrogen deficiency resulting in bone loss and reduced bone integ-

egrity^[91]. Tamoxifen has different effects on bone in pre-*vs* postmenopausal women. In premenopausal women, tamoxifen has been shown to cause a 1%–2% bone loss over 1–2 years, but experts note that this is not a clinically significant change, and that monitoring or treatment solely based on tamoxifen use is not indicated. In contrast, tamoxifen is associated with increased bone density in postmenopausal women^[92]. Of greater concern for a negative impact on bone health and fracture risk is the use of AIs. AIs are used in postmenopausal women with hormone receptor-positive breast cancer to reduce recurrence risk with a demonstrated survival benefit^[93,94]. However, AIs result in substantial reduction in estrogen production and estradiol levels, and are associated with decreased bone mineral density (BMD) and higher rate of fracture^[95].

Strategies for prevention of bone loss in all women, including those receiving antiestrogen therapies, include counseling on the importance of adequate calcium (1200 mg per day) and vitamin D (800–1000 IU per day) through diet or supplement, regular exercise including both weight-bearing and muscle strengthening, advice on fall prevention, smoking cessation, and avoidance of excess alcohol^[96].

In 2003 the ASCO published an algorithm (Figure 1) for screening and treatment specifically for breast cancer

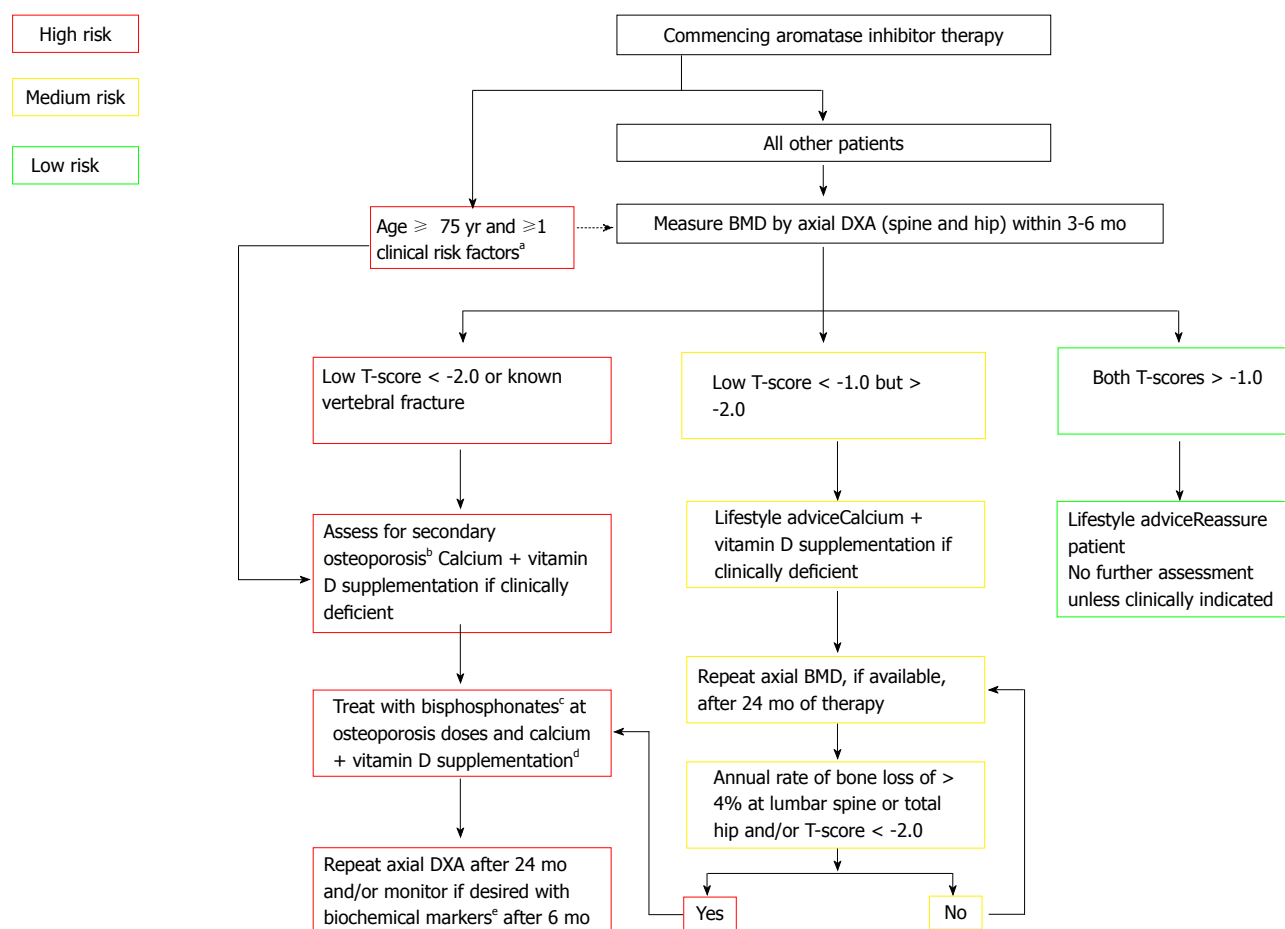

Figure 3 Postmenopausal adjuvant treatment with aromatase inhibitors^[92]. ^aPrevious low-trauma fracture after age 50, parental history of hip fracture, alcohol intake of ≥ 4 units/day, diseases associated with secondary osteoporosis, prior corticosteroids for > 6 mo, low BMI (< 22); ^bErythrocyte sedimentation rate, full blood count, bone and liver function (calcium phosphate, alkaline phosphatase, albumin, AST/ALT), serum creatinine, endomysial antibodies, serum thyroid stimulating hormone; ^cAlendronate 70 mg per week, risedronate 35 mg per week, ibandronate (150 mg po monthly or 3 mg iv 3-monthly), zoledronic acid 4 mg iv 6-monthly; ^dTo be given as ≥ 1 g of calcium + ≥ 800 IU of vitamin D; ^eBiochemical markers such as serum C-terminal telopeptide of type I collagen or urinary N-telopeptide of type I collagen. Reprinted with permission. © (2008) Elsevier.

patients that recommended BMD screening annually for all postmenopausal women on AIs and for premenopausal women with treatment-induced premature menopause, as well as for all breast cancer patients aged 65 years and older or those aged 60-64 years with risk factors. The treatment guideline at that time only called for bisphosphonate or raloxifene for women with a T-score of -2.5 or lower^[97]. A consensus statement from a UK Expert Group in 2008 divided that algorithm into specific guidelines for formerly premenopausal women with treatment-induced premature menopause (defined in the publication as < 45 years old) and for postmenopausal women treated with AIs (Figures 2 and 3). For women with continued menstruation or postmenopausal women older than 45 years old and either on tamoxifen or not on AIs, no specific recommendation is given for screening. Any woman with a T-score < -2.0 or with a history of vertebral fracture is advised to have evaluation for secondary causes of osteoporosis^[92].

For breast cancer patients with treatment-induced early menopause < 45 years old, a BMD measurement by spine and hip dual energy X-ray absorptiometry (DXA)

is recommended. If a woman not on an AI had a T-score < -2.0 , bisphosphonate treatment is recommended with a follow up DXA in 24 mo. With a score of -1.0 or higher, no further testing is indicated. If the T-score is between -1.0 and -2.5 , a repeat DXA in 24 mo is advised. For the woman on AI, the threshold for treatment drops to a T-score of < -1.0 with repeat DXA recommended at 24 mo post bisphosphonate initiation. For a woman on AI and in premature menopause at < 45 years old, a T-score > -1.0 results in a recommendation for DXA in 24 mo^[92].

For postmenopausal women starting AI therapy, DXA of the spine and hip is recommended. If the T-score is < -2.0 or if the woman is 75 years or older with any osteoporosis risk factors, a bisphosphonate is recommended with follow-up DXA in 24 mo. Similar to the algorithm for breast cancer patients with early menopause, a T-score of -1.0 or higher requires no further screening unless indicated by a change in the clinical situation. For a T-score between -1.0 and -2.5 , a follow-up DXA in 24 mo is recommended^[92].

All breast cancer patients with known vertebral fractures should be considered for treatment per the UK

Expert Group guidelines. Another indication for treatment is an annual bone loss rate of > 4% in both the premature menopause and postmenopausal AI-treated groups^[92].

CONCLUSION

In focusing on the woman undergoing treatment and surveillance for breast cancer, attention to a number of concurrent issues beyond the breast cancer itself will impact her satisfaction with treatment and overall care. Appropriate counseling and evidence-supported surveillance strategy along with age-appropriate testing will promote overall health and perhaps a sense of some control over her care. Careful attention to medication-related side effects including chemotherapy-induced VVA with resultant dyspareunia can certainly affect her well-being and relationship with her partner. The availability of nonhormonal treatment options for VVA and VMS can help her focus on her recovery. If future fertility is a concern, she should ideally be evaluated by a reproductive endocrinologist prior to initiation of chemotherapy and counseled regarding fertility preservation options. Pregnancy is generally not advised for at least 10 mo after breast cancer therapy, but advancing maternal age and other factors need to be considered in individual counseling. If contraception is desired, women should be counseled about both reversible and permanent hormone-free options, but they should not discontinue current contraception until the initiation of an alternate method. Chemotherapy-induced amenorrhea should not be considered permanent ovarian insufficiency, especially in women younger than 40 years. Likewise, elevated FSH in this setting is not an indicator of permanent ovarian insufficiency. Attention to bone health is important in breast cancer survivors, particularly in the context of chemotherapy-induced premature menopause or AI use. A multidisciplinary, comprehensive, and holistic approach to the woman with breast cancer can facilitate her transition from breast cancer patient to breast cancer survivor.
