In the last decade a multitude of attempts have been aimed at finding more efficacious and safer therapies for AHF[1]. While trials on pharmacologic agents such as endothelin receptor antagonists and adenosine receptor antagonists have mostly been disappointing, extracorporeal ultrafiltration has shown promising results that ranged from more efficient fluid and sodium removal to reduction in the rate of re-admission[2,3]. Indeed, ultrafiltration has been recognized as an emerging therapy for patients with AHF which can be used either as an alternative to conventional diuretic-based strategies or as an adjuvant therapy. However, it is noteworthy that patients with significant renal dysfunction have often been excluded from the ultrafiltration trials and as such their favorable results can hardly be extrapolated to common clinical scenarios in which the decline in renal function parallels deterioration in cardiac status[3,4].

In contrast to most previous AHF studies, the recently published Ultrafiltration in Decompensated Heart Failure with Cardiorenal Syndrome (CARRESS-HF) trial examined the role of ultrafiltration in management of patients with AHF who also presented with worsening renal function (WRF)[5]. In this randomized controlled trial that included 188 patients, ultrafiltration was compared to a diuretic-based pharmacologic therapy in patients who were admitted with a primary diagnosis of AHF and experienced acute CRS. Surprisingly, once the renal component was added to the clinical picture, the favorable findings of the previous trials were not observed anymore; ultrafiltration was found to be inferior to pharmacologic therapy with regards to its impact on both renal function and development of serious adverse events, and the recruitment of the patients had to be stopped. Although considered a trial of AHF, the unprecedented design of CARRESS-HF (*e.g.*, inclusion of patients with an increase in serum creatinine level as small as 0.3 mg/dL up to 3 mo prior to admission to the hospital) made it possible for the trial to also recruit and follow patients with cardiorenal physiology of less acuity.

CARDIO-RENAL PHYSIOLOGY AND ULTRAFILTRATION

Renal dysfunction is an established predictor of adverse outcomes in patients with HF. Until recently, the traditional model of therapy for HF mainly focused on low cardiac output (*i.e.*, low forward flow) being the trigger for a cascade of pathologic events ultimately leading to deterioration in renal function. Even though most patients admitted for AHF present with normal blood pressure, a significant subset still experience concomitant WRF and CRS. Therefore, the decrease in renal perfusion pressure secondary to reduced stroke volume, which was once considered the major mechanism, cannot fully explain renal dysfunction of all these patients. Indeed, more recent data suggested that WRF in the setting of AHF would correlate better with the degree of renal venous congestion rather than cardiac output (*i.e.*, high backward pressure)[6]. In this model, alteration in renal function is more related to right atrial and central venous pressure than cardiac index or left ventricular ejection fraction, hence proposing the hypothesis of backward rather than forward failure.

Does ultrafiltration therapy affect cardiac physiology and hemodynamic status? A number of studies including those using invasive methods have reported several beneficial effects on cardio-circulatory parameters such as cardiac index and systemic vascular resistance following ultrafiltration therapy. While the precise mechanisms remain to be determined, these positive results could still be explained to some extent by the aforementioned models of CRS. On the arterial side, efficient fluid removal by ultrafiltration therapy reduces left ventricular end-diastolic volume and pushes the heart towards the left side of the Frank-Starling curve.

Table 1 Proposed benefits of peritoneal dialysis therapy for heart failure

Continuous gentle ultrafiltration with minimal impact on hemodynamic status
Improvement in functional status and symptoms of volume overload
Reduction in number of days of heart failure-related hospitalizations
Restoration of diuretic responsiveness
Reduction in weight and improvement in volume status
Improvement in left ventricular ejection fraction
Sodium sieving effect and possibility of better control of natremia
Removal of pro-inflammatory mediators (medium-sized molecules)
Reduction in intra-abdominal pressure in patients with severe ascites
Improvement in quality of life
Improved atherogenic lipid serum profile
Lack of impact on neurohormonal activity (renin-angiotensin-aldosterone system and sympathetic nervous system)
Improved control of serum potassium level (hence providing the opportunity to use medications such as aldosterone receptor blockers)
Reduction in healthcare cost

Adapted from Courivaud *et al*[9], with permission.

This effect can hinder the intermediary pathways such as activation of renin-angiotensin-aldosterone and sympathetic nervous systems and their downstream adverse effects such as ventricular remodeling and perturbation in renal hemodynamics. On the right side, ultrafiltration extracts fluid directly and exclusively from the venous side of the circulation leading to immediate reduction in preload, ventricular wall stress, and capillary hydrostatic pressure. Decongestion of the venous side of the circulation has also been reported to improve renal vein engorgement without affecting counteracting intermediate pathways such as adenosine receptors and tubuloglomerular feedback that result in a decrease in glomerular filtration rate. We have previously reviewed the currently available data on the interactions between the cardiocirculatory system and the kidney in the setting of AHF, and the potential role of ultrafiltration in modifying these mechanisms[7].

RENAL IMPLICATIONS OF ULTRAFILTRATION TRIALS

The common theme in the above-mentioned models of CRS is the dependence of the renal component on the cardiac status (*i.e.*, a cardiocentric approach). They both assume that WRF is an adverse consequence of the decline in cardiac function rather than a separate and independent phenomenon. If this assumption were true, then ultrafiltration therapy would be expected to portend positive impact on renal hemodynamics and function as it is capable of improving cardio-circulatory physiology and reducing neurohormonal activation. However, available ultrafiltration trials, whether in AHF alone or in CRS, have so far failed to show any improvement in the associated WRF; they have either reported no impact or even observed adverse renal outcomes in this setting[3,5]. This important observation questions the accuracy of the above-mentioned cardiocentric models of WRF in AHF, and suggests that renal component of acute CRS is not merely a consequence of deterioration in cardio-circulatory status or the use of conventional therapies in a subset of patients; it can reflect an independent but related phenomenon that needs to be regarded and managed separately. In this model, a number of maladaptive mechanisms (*e.g.*, inflammation and endothelial cell dysfunction) are shared by the kidney and the heart resulting in a decline in the function of both organs and development of CRS. As such, any therapeutic option for this syndrome should not only target cardio-circulatory status, but it also needs to have the ability of addressing the adverse homeostatic consequences of the decline in renal function. In this respect, ultrafiltration might not be the optimal option for management of all cases of acute CRS, as supported by recent trials such as CARRESS-HF, simply due to the fact that it lacks any clearance property and cannot address the diverse metabolic and homeostatic derangements associated with concomitant renal dysfunction.

PERITONEAL DIALYSIS AND CHRONIC CRS

In the chronic setting, where patients present with various degrees of HF and slowly declining renal function, a therapy with the ability of simultaneously addressing both organs will be conceptually attractive and mechanistically relevant. Peritoneal dialysis (PD) can be such an option. PD has been shown to provide efficient intracorporeal ultrafiltration and sodium extraction in volume overloaded patients (especially through the use of icodextrin solution), while concurrently correcting the metabolic consequences of diminished renal function. It has also been reported to portend less well-characterized benefits such as removal of myocardial depressant factors and improvement in endothelial dysfunction (Table 1). It is noteworthy that not all proposed beneficial mechanisms are exclusive to PD; while many can be the direct consequences of using this specific therapeutic modality (*e.g.*, reduction in intra-abdominal pressure in patients with severe ascites), some can also be achieved through other methods of renal replacement therapy such as hemodialysis (*e.g.*, reduction in weight and improvement in volume status).

Several uncontrolled PD studies have so far reported favorable results for patients with chronic CRS despite the fact that they often used PD as "the last resort" for very sick patient populations who were refractory to alternative options and were not candidates for heart transplant[8-10]. For instance, in a study on 126 patients with refractory heart failure and various degrees of renal dysfunction, Courivaud *et al*[10] reported a 90% reduction in the number of days of hospitalization after initiation of PD (3.3 d/patient per month *vs* 0.3 d/patient per month; $P < 0.0001$).

Table 2 Selected studies on the role of peritoneal dialysis in heart failure

Ref.	Study design	No. of patients	Mean age (yr)	Male gender	NYHA class	EF	Renal function	Main findings	Comment
Koch *et al*[11]	Prospective	118	73.2	60.2%	Ⅲ (49.2%) Ⅳ (50.8%)	43.5%	Creatinine clearance 19.2 mL/min	Significant improvement in body Weight and NYHA class	Negligible incidence of peritonitis and catheter dysfunction
Núñez *et al*[8]	Prospective	25	75.1	72%	Ⅲ or Ⅳ (100%)	40%	eGFR 33 mL/min per 1.73 m^2	Significant improvement in patients' clinical status and NYHA class	Marked reduction in the number of days hospitalized for acute heart failure
Bertoli *et al*[12]	Multicenter retrospective	48	74	81%	Ⅱ (6%) Ⅲ (48%) Ⅳ (46%)	30%	eGFR 21 mL/min per 1.73 m^2	Significant improvement in NYHA class and reduction in the number of days hospitalized	Significant reduction in pulmonary artery pressure and improvement in EF
Courivaud *et al*[10]	Retrospective	126	72	69%	N/A	38%	eGFR 33.5 mL/min per 1.73 m^2	Significant reduction in the number of days hospitalized for acute heart failure	Improvement in cardiac function in patients with a an EF of 30% or less

NYHA: New York Heart Association.

The results of selected studies on the role of PD in HF are summarized in Table 2. Since HF is the single most common reason for hospitalization of patients over 65 and the majority of its cost is related to the in-hospital care, use of this home-based therapy for chronic CRS could potentially lead to significant savings in healthcare expenditure while providing a better quality of life for patients. The advantages, potential mechanisms, safety, and efficacy of this therapeutic modality for patients with HF has been discussed elsewhere[9]. In patients with significant residual renal function who do not require dialytic support, nocturnal automated PD or a single night time exchange with icodextrin solution could be sufficient to maintain euvolemia. Depending on the severity of HF, degree of volume overload, symptoms, and comorbidities, the PD therapy can be customized and some patients could use it only a few nights a week rather than every night. In patients with more severe renal dysfunction who require dialytic support for clearance, continuous ambulatory PD or automated PD with day time icodextrin exchange could have the greatest promise to generate the needed gentle continuous ultrafiltration while providing adequate clearance.

A major concern regarding the use of PD in this patient population has been that its morbidity might replace the morbidity from HF. This issue seems to be less compelling nowadays with reasonably low incidence of PD-related complications such as peritonitis, catheter dysfunction, and hernias as reported by most studies as well as the reports on the reduction in HF-related hospitalization after initiation of PD. Moreover, although the data are not consistent, it appears that PD does not alter the natural history of the disease and as such is unlikely to have a significant effect on survival of these patients. Finally, it should be noted that the current literature on the use of PD in the setting of HF still suffers from significant limitations which could hamper its more widespread use (*e.g.*, lack of an appropriately matched control group and relatively short follow-up periods). This could explain the fact that despite aforementioned advantages of this modality, PD is not yet considered by the professional cardiology societies as a therapeutic option for HF. Future prospective randomized studies with longer follow-up periods could address the knowledge gap and prove helpful in this regard.

In summary, based on the currently available data, PD represents one of the few options for patients with chronic CRS that not only is pathophysiologically and conceptually relevant, but is also reported to be safe and effective in several clinical trials. Recent technical advances such as possibility of initiating PD in the acute setting and placement of the PD catheter by interventional radiology could make this home-based therapeutic option even more accessible and intriguing[13].

Abstract

Atrial fibrillation (AF) is the most common type of sustained arrhythmia, which is now on course to reach

epidemic proportions in the elderly population. AF is a commonly encountered comorbidity in patients with cardiac and major non-cardiac diseases. Morbidity and mortality associated with AF makes it a major healthcare burden. The objective of our article is to determine the prognostic impact of AF on acute coronary syndromes, heart failure and chronic kidney disease. Multiple studies have been conducted to determine if AF has an independent role in the overall mortality of such patients. Our review suggests that AF has an independent adverse prognostic impact on the clinical outcomes of acute coronary syndromes, heart failure and chronic kidney disease.

INTRODUCTION

Atrial fibrillation (AF) is a commonly encountered arrhythmia in clinical practice[1] with an increased prevalence being reported with advanced age[2]. It is estimated that more than 8 million patients over the age of 80 will be affected by the year 2050[1,3]. Consequently, the associated healthcare expenses are also rising and have reached an all-time high of 16 to 26 billion dollars annually[4]. The major contributors to the burgeoning healthcare costs of AF include outpatient care and testing which accounted for nearly $1.5 billion of the total costs, prescription drugs that cost an approximate of $235 million, and also high costs associated with inpatient interventional procedures[4-6].

With a rising prevalence and economic burden, there is concern in the medical community regarding the temporal effect of cardiovascular conditions including atrial fibrillation on the clinical outcomes of associated comorbidities. In addition to its deleterious health consequences, cardiovascular disease is the number one cause of death in the United States and globally[7]. It is important to understand the role of other comorbidities in cardiovascular disease to prevent and reduce this mortality. In this article we focus on atrial fibrillation and commonly associated comorbidities. Atrial fibrillation is commonly encountered in the setting of acute coronary syndromes, heart failure and chronic kidney disease. The purpose of this article is to review the prognostic impact of atrial fibrillation on these comorbid conditions.

ACUTE CORONARY SYNDROMES

Acute coronary syndrome (ACS) is commonly associated with concomitant or incident AF. Most of the studies conducted have noted that the incidence of AF in ACS ranges from 2.3% to 23%[8]. Multiple factors explain this wide range of variation. The Cooperative Cardiovascular Project by Rathore *et al*[9] reported a higher incidence of AF in ACS patients, as the subjects were primarily elderly patients. Eldar *et al*[10] reported a lower incidence as they studied only paroxysmal AF. Some randomized controlled trials like TRACE and OPTIMAAL which studied the efficacy of angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) in acute myocardial infarction (AMI) have also reported lower incidences; the efficacy of these drugs in preventing atrial fibrillation had however been proven in earlier studies[11,12].

Broadly there has been a downward trend in the incidence of AF in AMI in studies done over time. This can be explained possibly by more widespread use of thrombolytic therapy and percutaneous coronary interventions (PCI) over the years. Advanced age, tachycardia at the time of admission, and advanced stage of heart failure were found to be the major clinical predictors of atrial fibrillation in patients with AMI[9,13,14].

Early studies done to assess the independent prognostic impact of atrial fibrillation on ACS outcomes were found to have contrasting results. A number of studies after multivariate analyses found atrial fibrillation to have no independent impact and concluded that it was more the coexisting comorbidities that contributed to the mortality[10,14-19]. However, a greater number of studies have reported that atrial fibrillation in the setting of AMI, results in a worse prognostic outcome[9,11-13,19-22].

However, two major meta-analyses done by Jabre *et al*[23] and Angeli *et al*[24] proved conclusively the independent impact atrial fibrillation had on AMI. In the analysis of 43 studies by Jabre *et al*[23] where 278854 patients were studied, it was observed that AF was associated with a 40% increase in risk mortality as compared to patients with normal sinus rhythm. While the impact of atrial fibrillation on both in hospital

mortality and long term mortality was noted, the timing of atrial fibrillation development, *i.e.*, new onset or pre-existing AF was not a contributor to the poor outcome as per this meta-analysis. Angeli *et al*[24], on the other hand, found that new onset atrial fibrillation had worse outcomes with an 87% higher risk compared to pre-existing atrial fibrillation. The study however only assessed in hospital mortality and not long-term outcomes.

Atrial fibrillation leads to a number of hemodynamic effects such as loss of atrial contraction, rapid ventricular rates, loss of atrio-ventricular synchrony and an irregular RR interval. All of these factors lead to a decreased cardiac output, which in turn explain the higher mortality rates[25,26].

Many mechanisms have been proposed to explain how AF is commonly encountered in the setting of ACS. Although many theories exist, the pathophysiological mechanism of the onset of AF after ACS is still not clearly understood. Conclusions drawn from experimental models and clinical investigations have shown different factors accounting for new-onset AF in ACS; it can be explained either by myocardial infarction causing atrial ischemia or atrial stretch[27]. Role of inflammation, autonomic nervous system activity, BNP and other hormone activation cannot be excluded as possible mechanisms for AF development in this patient subset[28,29]. Thus, proper understanding of the role of new onset AF complicating ACS can provide us with a new approach in formulating therapeutic guidelines.

Consensus has been reached on the independent role of AF on mortality in ACS. Treatment targeting the pathophysiological mechanism of AF development in ACS remains an area that needs to be explored. It therefore remains imperative to develop strategies to prevent AF onset and initiate aggressive treatment in case of a new onset AF in ACS.

HEART FAILURE

Heart failure (HF) and AF are closely linked cardiovascular diseases that often coexist and share a complex pathophysiological relationship. Both have continuously increasing prevalence, and the presence of AF in HF patients has been reported as being anywhere between 10% and 50%[30]. The difference in coexistence of this two-disease condition can be attributed to the different study settings, study design, severity of heart failure and other factors[30,31]. The prevalence of AF correlates directly with the severity of HF, as about 5% of patients with New York Heart Association (NYHA) class Ⅰ HF have AF and this prevalence increases to about 50% in NYHA class IV HF[32,33]. Regardless of the study design, a few factors like hypertension, prior history of ACS, diabetes, and obesity were commonly observed to be associated with an increasing prevalence of AF and HF.

Recent large heart failure trials have demonstrated the adverse prognostic influence of AF on HF[34]. A study conducted by Dries *et al*[35], in which data was obtained from SOLVD trial, showed AF was associated with an increased risk of all cause mortality in patients with symptomatic and asymptomatic left ventricular systolic dysfunction[35]. On the other hand, the COMET trial analysis by Swedberg *et al*[36] showed AF did increase mortality risk and HF hospitalizations but it was not identified as an independent risk factor for mortality when adjustment for other prognostic indicators was made[36].

AF also increases re-hospitalization rates, hospital stays, and has an overall adverse prognosis in HF patients that is very clearly evident in many studies. Mountantonakis *et al*[37] analyzed data obtained from 99810 patients enrolled in the Get with the guidelines - Heart failure Registry and concluded that AF independently was associated with adverse hospital outcomes and a longer length of in-hospital stay. Mentz *et al*[38] showed presence of AF on initial electrocardiogram in patients hospitalized with HF was associated with higher readmission, higher mortality and lower use of evidence-based therapies.

Corell *et al*[39] proved an adverse prognostic impact of AF in HF patients. Olsson *et al*[40] reviewed results from Candesartan in Heart failure-Assessment of Reduction in Mortality and morbidity (CHARM) program and showed that AF is associated with an increased risk of poor cardiovascular outcomes. In the meta-analysis by Mamas *et al*[41] which included 16 studies involving 53969 patients; the conclusion was that irrespective of left ventricular systolic function, AF has an overall adverse prognosis in HF patients.

Pathophysiological changes that explain the increased prevalence of AF in HF patients are not very well understood. It is difficult to ascertain in most cases if HF leads to AF or changes due to AF leads to worsening of the underlying HF. Studies have different conclusions on the cause - effect process but there is a general agreement about the vicious cycle of deterioration when both conditions co-exist. According to one thought process, HF results in specific electrophysiological changes in the atrium like prolonging the atrial refractory period or increasing heterogeneity of repolarization that leads to the development of AF[42]. On the other hand, HF also plays a part in concurrent worsening of AF through mechanical and hemodynamic changes. Atrial tissue stretching occurs as a result of the increased pressure and volume in HF patients, which in turn triggers AF by increasing automaticity and altering atrial repolarization[43]. Activation of the renin-angiotensin system secondary to HF and other neurohormonal changes also promotes the development of AF[43]. Further studies need to be conducted to understand the impact AF has on HF, especially in regards to the dynamic pathophysiological interplay and therapy should be aimed at correcting the predisposing factors.

Although beyond the scope of this article, the op-

timal management approach of AF in HF remains unclear. Pharmacological therapy remains the mainstay of choice in AF, and includes rate control and rhythm control. A recent meta-analysis involving 2486 patients suggested no significant difference in terms of mortality and thromboembolic events between both modes of pharmacological management. However, hospitalizations appear to be less frequent with rate control than with rhythm control[44]. Also there are data that suggest role of cardiac resynchronization therapy (CRT) in non-ischemic dilated cardiomyopathy and severe heart failure, which has favorable outcome on incidence of AF[45,46]. Further studies are warranted to determine the optimal management approach for AF in patients with HF.

CHRONIC KIDNEY DISEASE

It is a well-established fact that there is a high occurrence of cardiovascular disease in patients with chronic renal insufficiency. The overall prevalence of AF is higher among patients with end-stage renal disease (ESRD)[47]. Studies examining the prevalence of AF in cohorts pooled from the Dialysis Outcomes and Practice Patterns Study (DOPPS) and the United States Renal Data System (USRDS) estimated the occurrence of AF to range from 6% to 27% among patients with ESRD on dialysis[48-50]. This high rate of occurrence in ESRD patients is nearly two times higher than that reported in the general population[49]. Dissimilarity of the individual study pattern, study population, sample size, disease definition and diagnostic methods of AF can account for the difference between the prevalence of AF in this population.

Wetmore *et al*[50] and Wizemann *et al*[48] concluded that a significantly higher prevalence of AF exists in ESRD patients on dialysis. On the other hand, recent studies have found a higher incidence and prevalence of AF among patients with chronic kidney disease (CKD) who have not been started on dialysis, as is clearly evident in the ARIC study and CRIC study done by Alonso *et al*[51] and Soliman *et al*[52]. In the latter study by Soliman *et al*[52] where a multicenter cohort with a wide range of kidney function was studied, it was estimated that the prevalence of AF was at 18%.

Moreover, AF is an independent risk factor for ischemic stroke and death among patients with ESRD on dialysis[53]. A large cross sectional cohort study conducted by Winkelmayer *et al*[49], analyzed data from 1992 to 2006 for the prevalence of AF in hemodialysis patients from the United States Renal Data System (USRDS). According to this study, the prevalence of AF increased 3 fold from 3.5% in 1992 to 10.7% in 2006. A one-year mortality rate among patients with AF was twice that of those without AF and was as high as 72% after demographic variant adjustment was made.

Several mechanisms have been proposed to explain the increased risk of death in CKD patients with AF. Systemic inflammation could be responsible for the fibrotic changes seen in the kidney and myocardium and by could worsen cardiovascular outcomes such as heart failure, thromboembolic risk and stroke which in turn increases the risk of morbidity and mortality[35,54-57].

A large cohort study on adults with AF by Go *et al*[58] concluded that a lower level of GFR was associated with an increased risk of thromboembolism independent of the known AF risk factors. A higher rate of thromboembolic events was observed among individuals with a lower estimated GFR.

The cumulative effect of AF and CKD together has been shown to not only increase mortality but also the rate of cardiovascular events, as has been observed in two separate studies done by Nakagawa *et al*[59] in Japan and Genovesi *et al*[60] in Italy. From the findings of the study by Nakagawa *et al*[59], it was determined that a lower eGFR (< 60 mL/min per 1.73 m^2) with CHADS2 score > 2 was associated with a higher all-cause (12.9% *vs* 1.4% per year, $P < 0.001$) and cardiovascular (6.5% *vs* 0.2% per year, $P < 0.001$) mortalities compared to preserved eGFR (> 60 mL/min per 1.73 m^2) combined with CHADS2 score < 2. Also cardiovascular events, which include cardiac death, nonfatal myocardial infarction, or hospitalization for worsening of heart failure and ischemic stroke risk, were much higher in the same group (13.6% *vs* 1.5% per year, $P < 0.001$). The study concluded that a combined eGFR and CHADS2 score could be an independent powerful predictor of cardiovascular events and mortality in patients with nonvalvular AF[59].

Although there is a substantially increased risk of thromboembolism in patients with CKD and AF, there are no distinct guidelines to follow for thromboembolism prophylaxis in AF patients with CKD when compared to patients without CKD. Patients with severe renal impairment have been excluded from a vast majority of trials studying stroke prevention in AF, including trials that have formed the landmark for risk factor scoring schemes and guidelines. It therefore, poses a huge challenge to healthcare providers to treat this subset of patients. The available data suggests that the benefit from warfarin in terms of stroke reduction in CKD patients is not as clear as in the general population, and there is also an increased risk of bleeding complications[61].

One of the few studies that show a favorable outcome of anticoagulation for prevention of stroke in renal failure patients is the study by Hart *et al*[62]. Efficacy of adjusted-dose warfarin in prevention of stroke in atrial fibrillation patients with stage 3 CKD was demonstrated by this study. The study by Chan *et al*[63], a large retrospective cohort study of patients with AF on hemodialysis, suggests that warfarin use is associated with an increased risk for ischemic (HR = 1.81; 95%CI: 1.12-2.92) and hemorrhagic (HR = 2.22; 95%CI: 1.01-4.91) stroke. The data however is influenced by lack of appropriate monitoring and

difficulties in maintaining the international normalized ratio (INR) target[63].

Thus, it remains a dilemma to refer to the benefits of warfarin administration as has been determined by anticoagulation guidelines in the general population, to a group of people that have been actively excluded from clinical trials; the prediction rules for bleeding risk would be inaccurate and oversimplified and probably not suitable for clinical practice. In reality, there appears to be no large randomized controlled trials that evaluate the real risk *vs* benefit of full intensity anticoagulation including newer novel anticoagulants in patients with severe renal impairment. Information about management is limited and in the future there might be an opportunity to look into these patients and form risk stratification guidelines that can be followed.

LIMITATIONS

Although we have searched a wide range of appropriate literature from online data sources for our article, sometimes such studies are potentially susceptible to vary in conclusion due to different populations, settings, interventions, or outcome measures. All the studies we included have different limitations. Despite the limitations, the present article has important strengths, including a real-world large sample size from different studies and the absence of selection bias associated with clinical trials.

CONCLUSION

In conclusion, atrial fibrillation is a commonly encountered arrhythmia in clinical practice that has a rising prevalence and significant adverse prognostic implications on other comorbidities. In this article we concluded that AF, with its rising prevalence increases the economic burden on healthcare, and has an independent adverse prognostic impact on comorbidities like ACS, HF and CKD. A thorough understanding of AF prevalence and its pathophysiology, including the role of genetics, can serve as a potential biomarker for the prevention and treatment of AF[64,65]. Along with it, factors associated with AF and its increased association with other comorbidities, outcomes of these comorbidities in the setting of AF, prospective data and appropriate guidelines are needed to define more precisely how to treat these patients. Individual risk stratification may represent the best possible approach and provide opportunities for improvement in the future. Further studies need to be conducted to determine risk stratification for decision making and to develop an optimal management approach.

Abstract

The role of blood cholesterol levels in coronary heart disease (CHD) and the true effect of cholesterol-lowering statin drugs are debatable. In particular, whether statins actually decrease cardiac mortality and increase life expectancy is controversial. Concurrently, the Mediterranean diet model has been shown to prolong life and reduce the risk of diabetes, cancer, and CHD. We herein review current data related to both statins and the Mediterranean diet. We conclude that the expectation that CHD could be prevented or eliminated by simply reducing cholesterol appears unfounded. On the contrary, we should acknowledge the inconsistencies of the cholesterol theory and recognize the proven benefits of a healthy lifestyle incorporating a Mediterranean diet to prevent CHD.

Key words: Cholesterol; Statins; Coronary heart disease; Mediterranean diet; Cardiovascular disease; Mortality

Core tip: Traditional efforts to prevent cardiovascular disease have emphasized the benefits of cholesterol lowering and statin drugs. Often overlooked is the fact that numerous studies of cholesterol lowering have failed to demonstrate a mortality benefit and the benefits of statins may have been overstated. The Mediterranean diet has consistently lowered cardiovascular events and mortality in numerous studies and does not typically lower cholesterol levels. Alternative theories of atherosclerosis are independent of cholesterol metabolism and may provide the key to future preventive strategies.

INTRODUCTION

Nearly twenty years ago two landmark randomized clinical trials appeared in *The Lancet* which forever changed the course of medicine for patients with coronary heart disease (CHD). The 4S study employed a cholesterol-lowering statin drug and reported a 30% mortality reduction[1]. The Lyon Diet Heart Study utilized the Mediterranean diet and reported a 70% mortality reduction[2]. Subsequent studies of the Mediterranean diet have confirmed these findings and also shown a reduced risk of cancer, diabetes, and Alzheimer's disease[3-6]. Subsequent statin studies have led the United States Food and Drug Administration to issue warnings regarding the increased risk of diabetes and decreased cognition with statin drugs. Paradoxically, statins have gone on to become a multi-billion dollar industry and the foundation of many cardiovascular disease prevention guidelines while the Mediterranean diet has often been ignored. We believe this statin-centric cholesterol-lowering approach to preventing CHD may be misguided.

ASSOCIATION DOES NOT EQUAL CAUSATION

The cholesterol hypothesis links cholesterol intake and blood levels to cardiovascular disease. Because cholesterol is considered a risk factor for atherosclerosis many believe that lowering cholesterol in the blood is the best way to prevent CHD. Ideally, risk factors should help us distinguish those who will develop a disease from those who will not. However, if one examines the original Framingham Heart Study data (as an example) it is clear that the cholesterol levels of those who developed CHD and those who did not overlap except when the total cholesterol level exceeded 380 mg/dL or was less than 150 mg/dL (Figure 1). Moreover, cholesterol may be associated with CHD but that does not prove causation. Despite the fact that high triglycerides and low HDL have long been associated with CHD, studies designed to raise HDL or lower triglycerides have failed to reduce CHD mortality. Similarly, cholesterol should not automatically become a treatment target. It may be a leap of faith to assume that lowering cholesterol is the best way to prevent CHD.

LOWERING CHOLESTEROL MAY NOT LOWER CARDIOVASCULAR MORTALITY

The rare occurrence of CHD in isolated, rural societies such as Tukisenta, New Guinea has been attributed to low cholesterol levels[7]. However, it is equally plausible that the diets and lifestyles of these individuals may protect them from CHD. While we may never be certain if low cholesterol or a healthy lifestyle (or both) are responsible for preventing CHD in these societies, there is ample evidence that lowering cholesterol does not consistently lower CHD mortality. Reducing

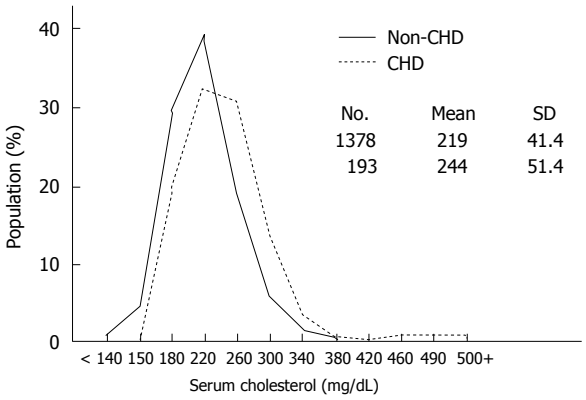

Figure 1 Serum cholesterol distribution among coronary heart disease and non-coronary heart disease patients in the Framingham Heart Study[43]. Reprinted with permission of the publisher. CHD: Coronary heart disease.

cholesterol blood levels by reducing dietary saturated fats is commonly recommended, but an exhaustive review and meta-analysis of 72 dietary studies concluded that reduced consumption of saturated fat does not reduce cardiovascular mortality[8]. Many drugs such as niacin, fibrates, and bile acid sequestrants can lower cholesterol levels, but the recent AHA/ACC guidelines on cholesterol concluded that these drugs do not lower CHD mortality rates[9]. Moreover, the results of cholesterol-lowering statin trials, as will be discussed and analyzed later, do not consistently lower mortality rates[10]. Consider also the dramatic mortality benefit of the Mediterranean diet in the Lyon Diet Heart Study which was achieved without a reduction in cholesterol levels[2-4]. Thus, the hypothesis that lowering cholesterol lowers mortality from CHD is not supported by many clinical research studies.

EARLY STATIN TRIALS MAY HAVE BEEN FLAWED

Early statin trials reported significant mortality benefits, yet serious concerns have been raised in some studies regarding biased results, premature trial terminations, under reporting of adverse events, high numbers of patients lost to follow-up and oversight by the pharmaceutical company sponsor[10]. Heightened awareness within the scientific community regarding problems in clinical trial conduct and analysis - exemplified by the unreported risk of heart attacks in patients taking the pain killers Vioxx and Celebrex - led to new regulatory rules for clinical trials in 2005[11]. Curiously, statin trials conducted after 2005 have failed to demonstrate a consistent mortality benefit[10].

MORTALITY RESULTS ARE MORE IMPORTANT THAN COMBINED CLINICAL ENDPOINTS

Cholesterol-lowering statin trials are often viewed as supporting the cholesterol hypothesis by reporting

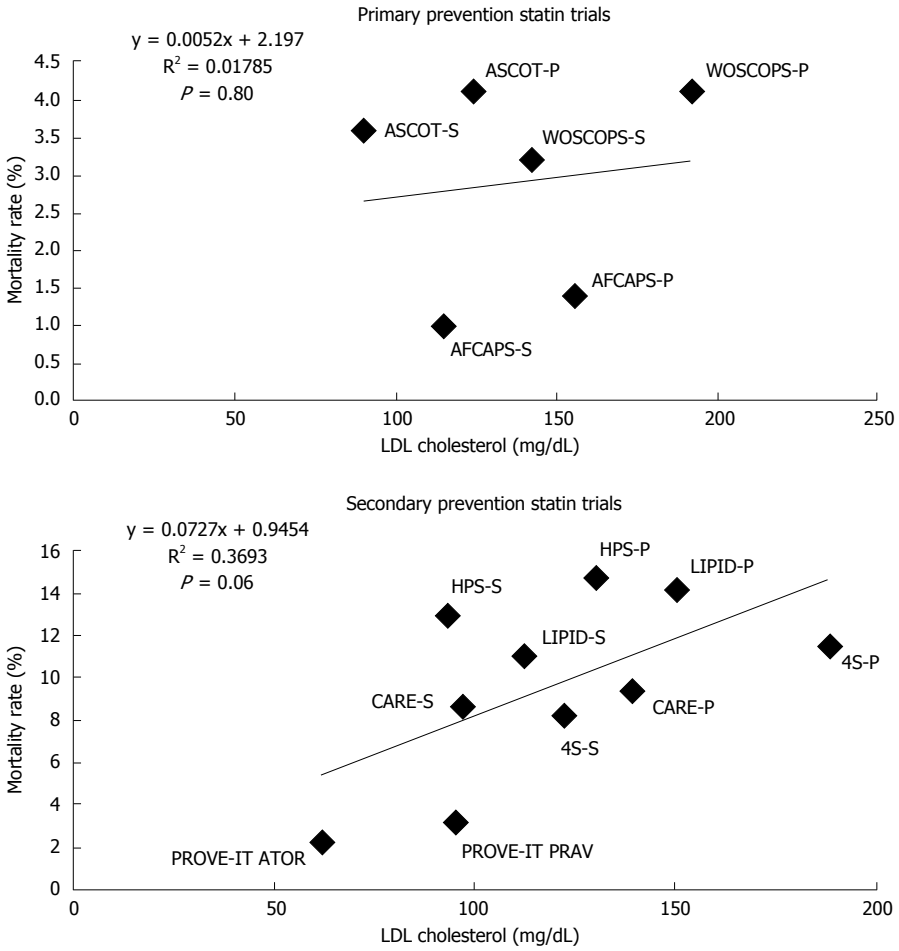

Figure 2 Comparison of mortality rates to low-density lipoprotein cholesterol levels using the randomized clinical trials cited in reference 14 (taken as an example).

significant reductions in combined clinical endpoints. Clinical endpoints are valuable and should not be ignored, but the ultimate measure of efficacy is total mortality that reflects both the treatment effect and potentially fatal side effects. Utilizing combined endpoints may lead to an exaggeration of perceived benefit by assigning equal importance to disparate clinical events such as a hospital admission for angina and death from a heart attack[12,13]. Some have argued that there is a linear relation between low-density lipoprotein (LDL) levels and CHD events[14]. This analysis may be inaccurate because it combines different types of CHD events from diverse studies into one endpoint even though each study defines CHD events differently. A more meaningful analysis compares total mortality rates to LDL cholesterol levels. When we performed such an analysis on these same statin trials - those analyzed in reference 14 - we found no statistically significant relationship (Figure 2).

MORTALITY BENEFITS OF STATINS ARE INCONSISTENT

Although a number of statin trials have reported a mortality benefit, quite a few have not. A corollary to the cholesterol hypothesis posits that patients at highest risk should derive the greatest benefit from cholesterol lowering. However, statin trials in the elderly (PROSPER), in patients with heart failure (CORONA, GISSI-HF), and in patients with renal failure (4D, AURORA, SHARP) have all failed to demonstrate a mortality benefit[10,15]. A Cochrane meta-analysis of 18 cholesterol-lowering trials (some with statins) in patients with peripheral arterial disease also failed to demonstrate a mortality benefit[16]. A separate meta-analysis of 11 statin trials for high-risk primary prevention similarly failed to demonstrate a mortality benefit[17]. Another Cochrane meta-analysis of statin usage after acute coronary syndromes concluded there was no mortality benefit[18]. The Cholesterol Treatment Trialists (CTT) performed a meta-analysis of 27 statin trials and concluded that statins were clearly beneficial in reducing cardiovascular events[19]. However, when the same 27 trials were assessed for mortality outcomes, no benefit was seen[20]. The coronary calcium score is considered to be one of the best predictors of cardiovascular risk, yet the St. Francis Heart Study showed no clinical benefit in asymptomatic patients with coronary calcium scores > 80th percentile randomized to statin therapy[21]. Finally,

diabetes mellitus is considered a CHD risk equivalent, but the three randomized controlled trials specifically designed and powered to assess the effect of statins in diabetes all failed to demonstrate a mortality benefit (CARDS, 4D, ASPEN)[22-24].

ALTERNATIVE THEORIES OF ATHEROSCLEROSIS AND CHD COMPLICATIONS ARE CHOLESTEROL INDEPENDENT

The dramatic benefits of the Mediterranean diet are likely due to multiple mechanisms which do not directly involve cholesterol. Independent of cholesterol metabolism are the true fatal complications of coronary atherosclerosis - thrombotic coronary occlusion, acute myocardial ischemia, left ventricular dysfunction, and malignant arrhythmias. The hemostatic system appears to be a principal modulator of atherosclerotic plaque formation and progression and the Mediterranean diet can favorably alter elements of the coagulation cascade[25,26]. Plaque rupture and intra-plaque hemorrhage leads to progressive atherosclerosis, thrombosis causes acute coronary syndromes, and sudden cardiac death is the main cause of cardiac mortality. At the genetic level large scale, genome-wide association studies have identified 46 loci directly linked to CHD, yet a majority of these loci have no apparent relation to cholesterol or traditional risk factors[27]. Although we can't change our genes, epigenetic studies have shown that the Mediterranean diet can favorably alter the expression of atherogenic genes[28], whereas a recent cholesterol-lowering statin trial failed to demonstrate a similar effect[29]. At the cellular level we now know that atherosclerosis is an inflammatory disease where macrophages and T lymphocytes likely play a dominant role. Whether or not specific anti-inflammatory therapies will be successful remains to be determined, but prior experience with Vioxx and Celebrex, which unexpectedly increased cardiovascular deaths, emphasizes the importance of proceeding cautiously. Recent studies have demonstrated that the Mediterranean diet can reduce markers of inflammation[26]. Accumulating evidence also implicates sugar in the pathogenesis of atherosclerosis. Diabetes is considered a coronary artery disease equivalent yet diabetics typically have average cholesterol levels. Other studies indicate that those who drink sugar-sweetened beverages are at much higher risk for CHD[30]. How elevated levels of blood glucose lead to atherosclerosis and why cholesterol lowering statins increase the risk of diabetes remains enigmatic, yet the totality of evidence suggests molecular mechanisms of atherosclerosis that are independent of cholesterol metabolism. The Mediterranean diet has been shown to reduce the risk of developing diabetes and the metabolic syndrome[31,32]. Elegant research into the gut microbiota is also providing an alternative theory of atherosclerosis[33]. Consider that L-carnitine, a component of red meat, is metabolized by the gut microbiota into trimethylamine oxide (TMAO). TMAO, in turn, promotes atherosclerosis and has been associated with a higher risk of cardiovascular events independent of traditional risk factors such as cholesterol. The gut microbiota can also adapt to changes in diet, which may explain why some vegans do not produce any TMAO after an L-carnitine challenge and how the Mediterranean diet may exert its anti-inflammatory and anti-atherosclerotic effects[34].

STATIN DRUGS HAVE UNINTENDED CONSEQUENCES

If statins have failed to consistently reduce mortality one must ask if statins improve the quality of life. Serious or fatal statin adverse events are rare, but side effects are not. The incidence of muscular aches and weakness in statin trials is highly variable, and real world experiences may differ from clinical trial reports. Consider that the adherence rates for statins in the elderly are poor with nearly 75% of primary prevention patients stopping the drug within the first two years[35]. More recently a cohort study of statin users reported a 53% discontinuation rate although a very high percentage were able to continue statin therapy after being rechallenged[36]. In the largest statin survey ever conducted, the National Lipid Association observed that roughly 30% of statin patients reported experiencing muscle pain and weakness and 57% of surveyed patients reported stopping the drug due to side effects[37]. One may debate the relationship of statins to diabetes and dementia, but the fact remains that the FDA now requires disclosure of these warnings. Most distressing is the recent report of gluttonous behavior among statin users who mistakenly believe they are "protected" by taking statins and can eat whatever they want[38].

CONCLUSION

The debate over the cholesterol hypothesis and statins has raged for decades. Some may point to the recent decline in cardiovascular deaths in the United States as proof of statin effectiveness, but this view fails to incorporate the impact of smoking cessation, lifestyle changes, and dramatic improvements in heart attack survival rates due to timely reperfusion and the availability of external and implantable defibrillators. Others may argue that statins are started too late in life to be effective (the horse may already be out of the barn) and reference Mendelian randomization studies which show that rare individuals with genetically low cholesterol levels have a much lower incidence of CHD[39].

However, this concept should not be extrapolated to the 99.99% of us who lack these genes and also fails to explain how the Mediterranean diet reduces mortality within months of initiation[2-4]. In 1996 Nobel laureates Brown and Goldstein anticipated the eradication of coronary disease in their *Science* editorial, "Exploitation of recent breakthroughs - proof of the cholesterol hypothesis, discovery of effective drugs, and better definition of genetic susceptibility factors - may well end coronary disease as a major public health problem early in the next century"[40]. History has proven otherwise, and the global prevalence of CHD, despite worldwide statin usage and cholesterol lowering campaigns, has reached pandemic proportions. Coronary heart disease is an extremely complex malady and the expectation that it could be prevented or eliminated by simply reducing cholesterol appears unfounded. After twenty years we should concede the anomalies of the cholesterol hypothesis and refocus our efforts on the proven benefits of a healthy lifestyle incorporating a Mediterranean diet to prevent CHD[2-4,41,42].

Abstract

Duchenne and Becker muscular dystrophy (DMD/BMD) are X-linked muscular diseases responsible for over 80% of all muscular dystrophies. Cardiac disease is a common manifestation, not necessarily related to the degree of skeletal myopathy; it may be the predominant manifestation with or without any other evidence of muscular disease. Death is usually due to ventricular dysfunction, heart block or malignant arrhythmias. Not only DMD/BMD patients, but also female carriers may present cardiac involvement. Clinically overt heart failure in dystrophinopathies may be delayed or absent, due to relative physical inactivity. The commonest electrocardiographic findings include conduction defects, arrhythmias (supraventricular or ventricular), hypertrophy and evidence of myocardial necrosis. Echocardiography can assess a marked variability of left ventricular dysfunction, independently of age of onset or mutation groups. Cardiovascular magnetic resonance (CMR) has documented a pattern of epicardial fibrosis in both dystrophinopathies' patients and carriers that can be observed even if overt muscular disease is absent. Recently, new CMR techniques, such as postcontrast myocardial T1 mapping, have been used in Duchenne muscular dystrophy to detect diffuse myocardial fibrosis. A combined approach using clinical assessment and CMR evaluation may motivate early cardioprotective treatment in both patients and asymptomatic carriers and delay the development of serious cardiac complications.

Key words: Muscular dystrophies; Electrocardiography; Heart failure; Echocardiography; Cardiovascular magnetic resonance imaging

Core tip: Duchenne and Becker muscular dystrophy are the commonest X-linked muscular diseases. Death is usually due to cardiac disease including ventricular dysfunction, heart block or malignant arrhythmias. Female carriers may also present cardiac involvement. Overt heart failure may be delayed or absent. Electrocardiography findings include conduction defects, arrhythmias and myocardial necrosis. Echocardiography assesses a marked

variability of left ventricular dysfunction. Epicardial fibrosis in both patients and carriers has been documented by Cardiovascular Magnetic Resonance (CMR), even if overt muscular disease is absent. A combined approach using clinical and CMR assessment may motivate early cardioprotective treatment and delay serious cardiac complications.

INTRODUCTION

Duchenne and Becker muscular dystrophy (DMD/BMD) includes a group of X-linked muscular diseases responsible for over 80% of all cases of muscular dystrophy[1]. The incidence of DMD is 1 in 3500 male newborns with a prevalence of 6 in 100000 males[1] and is characterized by weakness of leg, pelvic and shoulder girdle muscles starting in early childhood. BMD is a milder variant of dystro-phinopathy with a better prognosis. The incidence of BMD is 1 in 18450 males and prevalence 2.4 per 100000 in the general population[2,3]. First symptoms appear between ages of 3-21 years with a mean age of onset at 11 years. Age at death is at 21-89 years with an average age of about 45 years[4-7].

In DMD, boys are diagnosed as toddlers and most are wheelchair bound by age 15. Death usually occurs at the age of 20 years, due to respiratory complications or cardiomyopathy. Currently more patients survive until the age of 30 years, due to home ventilation and corticosteroids, which can prolong ambulation by 2-3 years, reduce risk of scoliosis and postpone pulmonary and heart failure after the age of 20 years[1]. Despite this documented efficacy, more than 25% of DMD boys are not treated with corticosteroids, either due to side-effects or lack of response[1]. In BMD, the disease is milder and more heterogenous, compared to DMD. Muscle weakness often is first noticed in adolescence or young adulthood. Cardiac involvement in BMD may precede the skeletal muscle decline, with death due to cardiomyopathy often occurring before the age 60 years[1].

Mutations leading in the absence of a functional dystrophin protein cause DMD, whereas mutations leading in a reduced amount or shortened dystrophin protein cause BMD[8,9]. Dystrophin is a large (427 kDa) subsarcolemmal protein that represents a physical link between the intracellular actin cytoskeleton and the extracellular matrix[10]. Loss or abnormal dystrophin destabilizes the sarcolemma, making the muscle fibers susceptible to contraction injury[11]. The repeated episodes of necrosis followed by regeneration finally lead to replacement of muscles by fat and connective tissue that is clinically manifested as progressive muscle weakness[10]. Dystrophin is also a scaffold protein that localizes other proteins to the sarcolemma and forms a highly organized multimeric dystrophin-associated glycoprotein complex (DGC)[10]. Dystrophin deficiency disrupts the DGC, resulting in downregulation and/or mislocalization of the dystrophin-associated proteins.

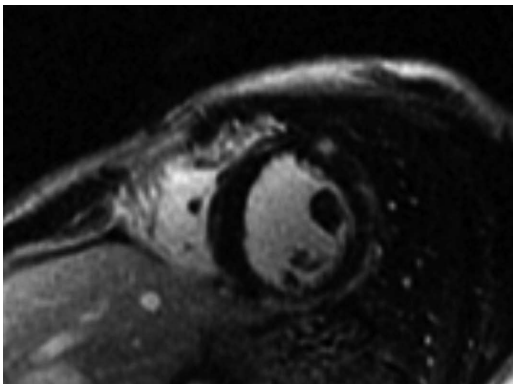

Figure 1 Fibrosis of the left ventricle in ecker muscular dystrophy patient, presented as late gadolinium enhancement in the inferolateral wall of left ventricular.

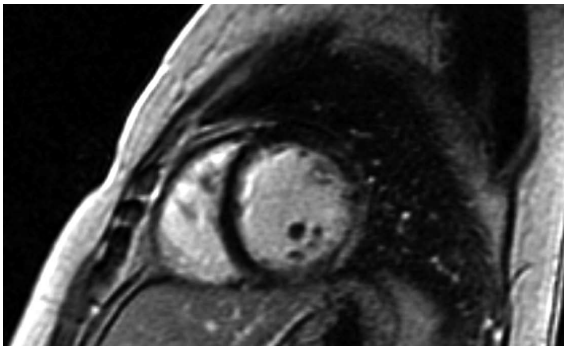

Figure 2 Fibrosis of the left ventricle in a mother Duchenne muscular dystrophy carrier, presented as late gadolinium enhancement in the lateral wall of left ventricular.

CARDIAC DISEASE IN DMD/BMD

Cardiac disease in DMD is progressive and finally leads to ventricular dysfunction, usually accompanied by ventricular dilation[12]. Pathology examination during the late stages of the disease shows cardiomyocytes' hypertrophy, atrophy and fibrosis[13-15]. Fibrosis of the left ventricle in DMD, BMD and DMD/BMD carriers has been observed at autopsy[13-15] and after evaluation with cardiovascular magnetic resonance (CMR) using late gadolinium enhancement (LGE)[16-19] (Figures 1 and 2).

The majority of DMD after the third decade of their age have established cardiomyopathy[20]. Although clinically overt heart failure may be delayed or absent, due to relative physical inactivity, cardiomyopathy is

the leading cause of death in DMD and myocardial damage precedes decline in left ventricular systolic function. Neither the age of onset nor the severity of cardiomyopathy was correlated with the type of mutation[21]. It was recently documented that in DMD with pre-served ejection fraction, the addition of eplerenone to background ACE inhibitors or ARB attenuates the progressive decline in left ventricular systolic function[22].

Cardiomyopathy is the main clinical complication in patients affected by subclinical or mild BMD. The clinical presentation is usually characterized by early right ventricular dysfunction and is later associated with left ventricular impairment. In mild BMD, myocardial damage may develop because the patients, who are unaware of a possible cardiac disease, can still perform strenuous muscle exercise and, through pressure or volume overload, may induce mechanical stress, which is harmful for dystrophin-deficient myocardial cells[23].

Cardiac disease in female carriers of dystrophinopathies may present with hypertrophy, arrhythmias or dilated cardiomyopathy[24]. The percentage of clinically overt cardiac involvement increases significantly with age, from 15% in carriers < 16 years to 45% in carriers > 16 years. By contrast, significant cardiac disease is unlikely in female carriers < 16 years[25]. In a cross-sectional study of 85 DMD and 44 BMD carriers aged 18-58 years, left ventricular dilatation and dilated cardiomyopathy were assessed in 18% and 8%, respectively[26]. Electrocardiography (ECG) abnormalities were found only in 47% of this population[27]. Another series of 56 adult, female carriers did not present any ECG abnormalities, but ventricular dilatation or hypertrophy was documented in 14% and dilated cardiomyopathy in 7% of them[28]. Nevertheless, severe heart failure may develop in some women necessitating heart transplantation to survive[29,30]. Exercise may unmask left ventricular (LV) systolic dysfunction in female carriers[31]. In a study by our group, CMR documented myocardial fibrosis in the majority of DMD and BMD mother-carriers, although the clinical presentation and the usual noninvasive assessment were mildly abnormal[19]. Therefore, detailed cardiac evaluation, at least once after the teenage years, should be recommended in all female carriers in order to start early cardiac treatment[32].

DMD is associated with increased R/S ratio in the right precordial leads, deep Q waves in the lateral leads, conduction abnormalities and arrhythmias (mainly supraventricular but also ventricular). In a study of 131 DMD, ECG was abnormal in 78.6%. All were in sinus rhythm and the following percentages were found for the main variables studied: short PR interval = 18.3%; abnormal R waves in V1 = 29.7%; abnormal Q waves in V6 = 21.3%; abnormal ventricular repolarization = 54.9%; abnormal QS waves in inferior and/or upper lateral wall = 37.4%; conduction disturbances in right bundle branch = 55.7%; prolonged QTc = 35.8% and wide QRS = 23.6%[33]. According to the study by Petri *et al*[34], ECG abnormalities were non-progressive in BMD and asymptomatic SVT and NSVT were present in 21% and 14%, respectively. Both ECG and Holter monitoring are necessary for DMD/BMD assessment. Serial clinical evaluation, including routine monitoring of electrocardiograms may detect early cardiomyopathy in DMD/BMD, even if left ventricular function is still preserved[35].

Echocardiography has already documented marked differences in LV function of DMD patients, independently of age of onset or mutation groups[21]. It has also proved a high prevalence of LV dysfunction in DMD, with frequent evidence of systolic ventricular asynchrony, particularly in patients with EF < 35%[36]. New echocardiographic techniques, using transmural strain profile (TMSP), can detect subclinical LV dysfunction in patients with DMD without wall motion abnormalities by conventional echocardiography[37]. The application of myocardial strain imaging in DMD patients was characterized by decreased peak systolic strain of the posterior wall, despite normal standard echocardiographic findings[38]. However, these studies were not universally accepted for the routine assessment of DMD/BMD.

Cardiovascular magnetic resonance (CMR) a non-invasive, non-radiating technique has been proved the most robust tool for detection of early myocardial fibrosis in DMD, BMD and female carriers, using late gadolinium enhancement (LGE). The pathology of cardiomyopathy in dystrophinopathies includes the presence of subepicardial fibrosis in the inferolateral wall[39], similar to that observed in viral myocarditis. The application of CMR in DMD/BMD and female carriers, in addition to the standard monitoring is of great value because: (1) Early start of heart failure treatment may delay the progression of LV dysfunction[22,40]; (2) Myocardial fibrosis, assessed by LGE, may be observed, even if the echocardiographic evaluation remains normal[16-18,40] and can potentially be used as an early sensitive index to start cardioprotective treatment; (3) It can be also applied as a screening tool to detect patients at high risk for ventricular arrhythmias, more advanced disease, adverse LV remodelling and death[41]. An impaired LV systolic function (LV-EF $\leqslant$ 45%) and a "transmural" pattern of myocardial fibrosis independently predict the occurrence of adverse cardiac events in DMD/BMD patients. Even in DMD/BMD patients with relatively preserved LV-EF (> 45%), the simple and visually assessable parameter "transmural LGE" is of additive prognostic value[42]; (4) in mutation carriers, CMR revealed a pattern of fibrosis similar to that observed in DMD[36], but without any correlation with genotype-phenotype[43], even in the absence of overt muscular disease; and (5) new CMR techniques, such as postcontrast myocardial T1 mapping, have been used in DMD to detect diffuse myocardial fibrosis. It was documented that post-contrast T1 obtained from the Look-Locker sequences (T1LL) ratio is abnormally shortened in DMD compared

with controls, even in DMD patients with otherwise normal CMR study. It is assumed that the application of more aggressive therapy for DMD with shorter T1LL may improve morbidity and mortality in DMD cardiomyopathy[44].

CONCLUSION

To conclude, heart involvement is common in both DMD/BMD and female carriers. Serial cardiac evaluation, including clinical examination, ECG, Holter monitoring, echocardiographic and CMR study, is the "sine qua non" for this population. Early detection of heart involvement should motivate early cardiac treatment with ACE inhibitors and b-blockers to delay serious cardiac complications.

Abstract

AIM: To investigate if magnetic resonance (MR)-guided biopsy can improve the performance and safety of such procedures.

METHODS: A novel MR-compatible bioptome was evaluated in a series of *in-vitro* experiments in a 1.5T magnetic resonance imaging (MRI) system. The bioptome was inserted into explanted porcine and bovine hearts under real-time MR-guidance employing a steady state free precession sequence. The artifact produced by the metal element at the tip and the signal voids caused by the bioptome were visually tracked for navigation and allowed its constant and precise localization.

RESULTS: Cardiac structural elements and the target regions for the biopsy were clearly visible. Our method allowed a significantly better spatial visualization of the bioptoms tip compared to conventional X-ray guidance. The specific device design of the bioptome avoided inducible currents and therefore subsequent heating. The novel MR-compatible bioptome provided a superior cardiovascular magnetic resonance (imaging) soft-tissue visualization for MR-guided myocardial

biopsies. Not at least the use of MRI guidance for endomyocardial biopsies completely avoided radiation exposure for both patients and interventionalists.

CONCLUSION: MRI-guided endomyocardial biopsies provide a better than conventional X-ray guided navigation and could therefore improve the specificity and reproducibility of cardiac biopsies in future studies.

Key words: Endomyocardial biopsy; Cardiovascular magnetic resonance (imaging); Magnetic resonance imaging-guided interventions; Real-time imaging

Core tip: Myocardial biopsy is the method of choice for assessing tissue pathologies. Cardiac magnetic resonance imaging (MRI) provides a 3D visualization and discrimination of soft-tissue and could therefore enable a targeted specimen sampling. We developed a novel MR-compatible bioptome which was evaluated by *in-vitro* experiments in a 1.5T MRI system under real-time MR-guidance. MRI-guided endomyocardial biopsies provide a superior soft-tissue visualization, a better than conventional X-ray guided navigation and could therefore improve the specificity and reproducibility of cardiac biopsies in future studies. Not at least the use of MRI guidance for endomyocardial biopsies completely avoided radiation exposure for both patients and interventionalists.

INTRODUCTION

Endomyocardial biopsy (EMB) is the "gold" standard diagnostic tool in the detection and classification of myocardial pathologies. It is recommended in the management and diagnosis of cardiomyopathies and inflammatory myocardial diseases[1-4].

Despite the benefits, EMB indications and their procedural management are controversially discussed. Reasons include EMB's low sensitivity when conducted under fluoroscopic guidance[5,6] as well as its potential complications. Thus, EMB may cause pericardial tamponade, severe arrhythmias or structural damages of the tricuspid valve[1]. Since sensitivity of EMB is low, clinicians are forced to increase the amount of samples (> 6, according to the AHA/ACCF/ESC scientific statement[1]) while focal pathologies like fibrosis in different forms of myocarditis may remain undetected.

In the clinical routine, fluoroscopy is used to guide the EMB procedure, offering a high frame rate (⩽ 30 fps) and high spatial resolution (2-3 line pairs/mm). However, this technique provides only two-dimensional projection images containing overlays of all anatomic structures in the X-ray beam in combination with a low soft-tissue contrast. Furthermore, it exposes both patient and interventionalist to a substantial radiation burden[7].

Cardiac magnetic resonance imaging (CMR) is a non-invasive modality which offers superior soft-tissue contrast, enables tissue characterization and allows the capture of specific slices with any required spatial orientations. Furthermore, contrast-enhanced CMR itself is able to visualize distinct pathologies like myocardial fibrosis, necrosis or inflammation and additionally provides macroscopic information, which may be complementary to that acquired by EMB[8]. Consequently, targeted myocardial biopsies under CMR guidance could reduce the number of required samples, increase specificity and sensitivity of the retrieved tissue samples and obviate radiation exposure. However, due to the very high static magnetic and radiofrequency (RF) electromagnetic fields, conventional metal bioptomes cannot be used in the MRI environment. First, the RF signals induce significant heating, mainly at the tip of metal wires leading to the necrosis of tissue[9,10], and secondly, metal devices lead to massive CMR image disturbance that could impair visualization of target areas. However, such problems can be overcome by MRI-compatible needles, which are already in use for real-time MR-guided tissue biopsies in static organs like breast, brain, liver, kidney or the prostate[11-14].

The localization and navigation of an invasive interventional instrument in the MRI system can be achieved with either active or passive tracking. While active tracking is more precise and faster since the bioptome's position is always known, it requires substantial modifications and cost-intensive miniaturized electrical extensions within the instrument. Conversely, passive tracking requires only minor modifications of the device to assure an appropriate visualization because it is implemented solely on the MRI system or additional computer systems and uses only the acquired real-time images to determine the instrument's position. This can be carried out manually by the operator, possibly supported by a software solution, but it requires a significant amount of operator training.

Therefore, we sought to develop and assess the feasibility of a novel MR-compatible bioptome for passive tracking in an *in-vitro* model to address these technical issues. Subsequently, we applied this method and performed endomyocardial biopsies in explanted animal heart models.

Table 1 Magnetic resonance imaging imaging sequences used during the real-time guidance procedures

Name	Type	SAR (W/kg)	Frame rate (fps)	Flip angle (degrees)	TR/TE (ms)	Resolution (mm)
Interactive	Balanced SSFP	0.765	8	45	3.10/1.55	1.79 × 1.79 × 6

SSFP: Steady state free precession.

MATERIALS AND METHODS

MRI system

All experiments were carried out in a cylindrical 1.5T MRI system (Achieva 1.5T, Philips Medical Systems, Best, The Netherlands) using the built-in birdcage coils for excitation and a cardiac 32-channel receive coil. The images were obtained with standard real-time sequences which provides continuous scanning and tracking of the bioptome's position in every possible angulation of three imaging planes within space (Table 1).

Bioptome

The major safety concern when using conventional metallic instruments that have dimensions in the range of the RF field's wave length is the possibility of tissue heating. The B_0-field of a 1.5T system correlates with a RF frequency of 64 MHz that corresponds then to a wavelength λ_{Air} of approx. 0.78 m in saline (0.9% NaCl), which is comparable to human body conditions. Therefore, characteristic RF wave lengths like $\lambda/2$ and $\lambda/4$ are well in the range of an outstretched bioptome, which could then lead to significant heating at the forceps of conventional endomyocardial bioptomes.

The shaft and the tip of the distal end of bioptome were constructed by using non ferromagnetic metals, synthetics and ceramic. The mechanical properties of the sample extraction mechanism at the tip of the MR bioptome were identical to a conventional device. It consisted of two spoon-shaped parts with sharp edges that could be pressed together and opened with a handle at the grip part. The spoons were coated with an MRI-visible marker to help determining the opening state. The device was engineered in close collaboration with H. + H. Maslanka GmbH, Tuttlingen, Germany.

The MR bioptome in the tested version did not have the capability of deflecting the tip for navigation purposes, which was compensated with a separate deflectable sheath (see below).

Deflectable sheath

The sheath prototype we used was a guiding catheter developed for electrophysiology applications and provided by Imricor (Burnsville, MN). It had the ability to deflect and steer the MR bioptome during the procedure and was fully MR-compatible causing neither heating nor disturbing imaging artifacts[15]. It was open at the distal end and a port prevented the outflow of blood at the proximal side. Its inner lumen provided a tight fit of the MR bioptome, effectively preventing a reverse flow of blood. The level of deflection (up to 150 degrees) at the tip could be adjusted and maintained in two directions with a mechanism at the grip. The diameter was approximately 3.7 mm.

Tracking and visualization of the instrument

In this study, we focused on a passive tracking approach with MRI visible markers at the spoons and the distal end of the device but without the need of an additional coil at the bioptome's tip and electronics inside the bioptome to evaluate the possibility of an affordable, easily available biopsy system as established in conventional EMB while benefiting from the imaging capabilities of MRI.

The necessary procedural adjustments of the corresponding image plane were conducted by the technician at the console while an MRI in-room monitor allowed the interventionalist to instruct the technician and navigate the bioptome. The MRI-control software provided an interface for real-time image visualization and parameter manipulation to allow a real time tracking of the bioptome within the phantom or heart.

Heart model

All procedures involving animals were reviewed and approved by the Institutional Animal Care and Use Committee of the Regierungspräsidium Karlsruhe Case Number 35-9185.81/G-79/12.

The most beneficial aspect of the MR-guided myocardial biopsy was the targeted and specific retrieval of tissue samples. To reproduce the complex anatomical structures present in a human heart, explanted porcine and bovine hearts were employed. With their anatomical properties being comparable to human hearts, they provided an appropriate test environment to evaluate the navigation features and the new MR biopsy system.

When a catheter is pushed forward in a living heart, crossing the valve plane can normally be achieved in ventricular diastole (right ventricular biopsy) or systole (left ventricular biopsy). In an explanted, *ex-vivo* heart, the valves are static and might permanently obstruct the anatomic path of the instrument. Since their presence was not of primary concern for the actual experiment, the valve cups were removed during the preparation of the models.

A transparent plastic tube was attached at the orifice of the superior vena cava (SVC) into the right atrium (ostium venae cavae superioris) to mimic the venous vasculature normally guiding the instrument *in-vivo* into the right atrium and ventricle (Figure 1). The blood flow was not simulated.

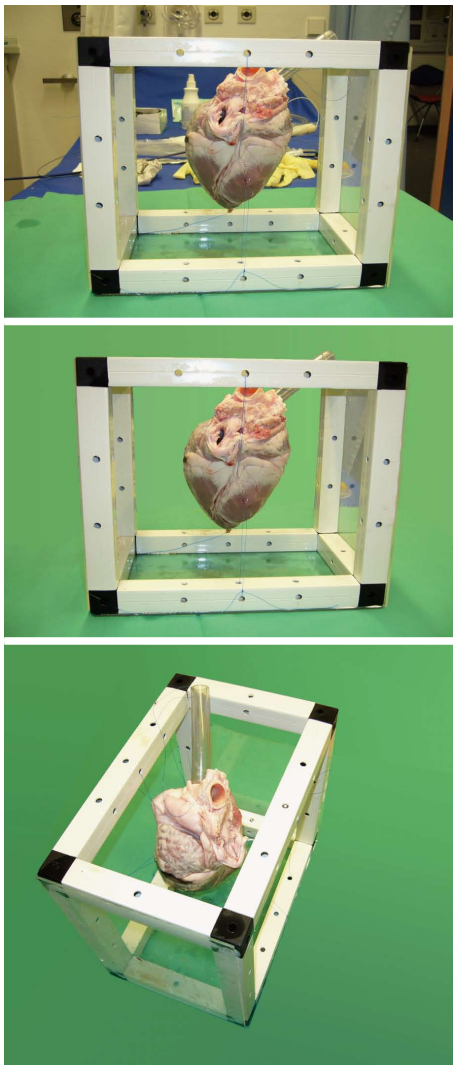

Figure 1 Model of swine heart with plastic tube attached to the trunk of the vena cava. The heart is fixated in a plastic frame to maintain form and position when submerged into the saline filled phantom.

To be able to evaluate the success of the biopsy later, several target areas of the endocardium were marked with an injection of a mixture of india ink and gadolinium. The first served as a visual marker in the specimen, the latter mimicked the elevated levels of gadolinium deposition in scar or fibrotic tissue areas eligible for an EMB. In the employed interactive sequences, a gadolinium marked area would appear as slightly brighter spot compared to the surrounding tissue.

Monitoring of heating

Due to the design and material composition of the MR bioptome, a heating problem was not expected. Nevertheless, the temperature was constantly monitored with a fiber optic-based thermometer (Fotemp, Optocon, Dresden, Germany) during the first experiment. One sensor was placed in the vicinity of the tip of the MR bioptome[16,17], the second recorded the overall temperature of the phantom filling.

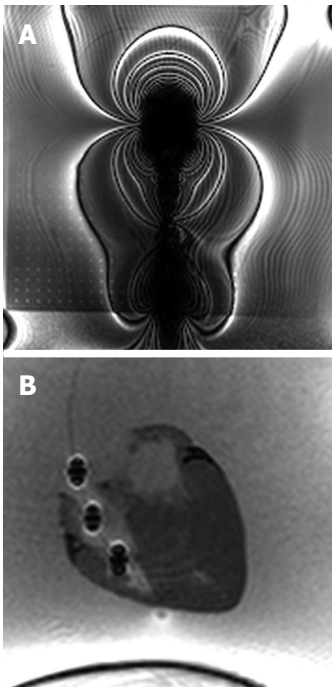

Figure 2 Cardiac magnetic resonance imaging-Images of conventional bioptome for endomyocardial applications (A), novel bioptome with three metal markers at the distal end inserted into a swine heart model (B).

RESULTS

Safety aspects/heating

During the course of the *in-vitro* experiments, the metal parts of the MR bioptome induced no heating. Only a general heating (< 1 ℃) of the phantom due to the constant exposure to the RF field and the heat dissipated by the MRI system during operation was detected.

Imaging and tracking

The new design of the MR bioptome effectively prevented the device from a negative interaction with the RF fields present during the MRI examination in terms of excessive artifacts. Only the coating of the sample cutting mechanism caused a small artifact at the tip (size approx. 2 mm × 2 mm, Figure 2), but this did not overlay the target structures in the heart (Figure 3). The shaft of the MR bioptome and the sheath caused a signal void compared to the surrounding tissue. At the same time signal voids supported the visual tracking of the tip of the MR bioptome when being pushed forward inside the sheath. The size of the artifact slightly increased when the tip left the isolating sheath and was exposed directly to the saline (Figure 3).

The opening and closing states of the sample cutter were slightly visible on the MRI images (Figures 4 and 5) when the bioptome was not moving. All maneuvers were carried out (1) in a saline (0.9% NaCl) filled but otherwise empty plastic container; and (2) in a porcine

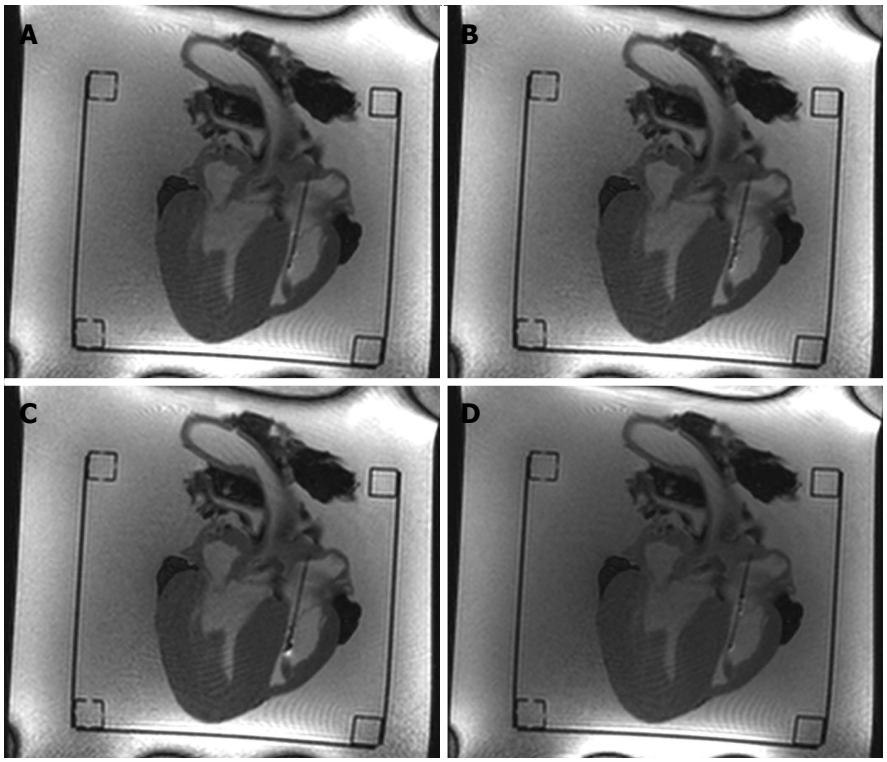

Figure 3 Real-time magnetic resonance image frames showing bioptome inside bovine heart. The bioptome is pushed forward through a plastic tube (A, B), is bare in the heart model (C) and then pulled back (D).

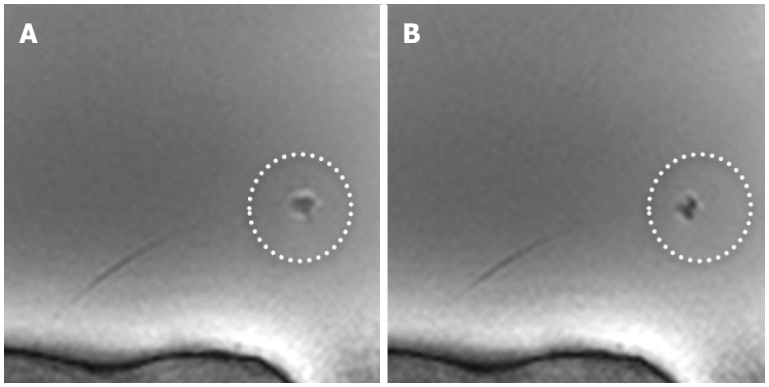

Figure 4 Real-time magnetic resonance imaging image frames with closed (A) and opened (B) cutter.

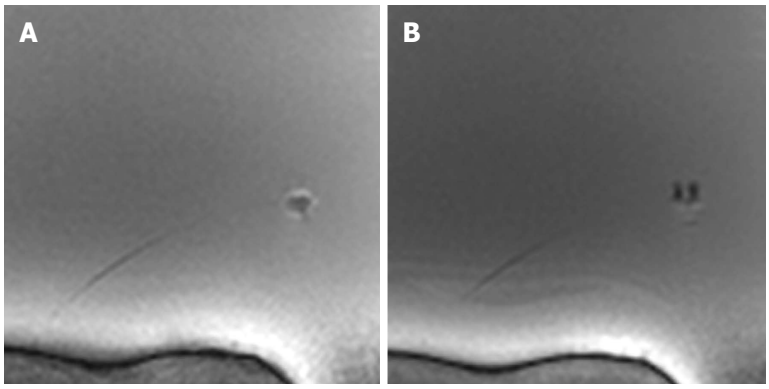

Figure 5 Real-time magnetic resonance imaging image frames with opened (A) and moving (B) tip.

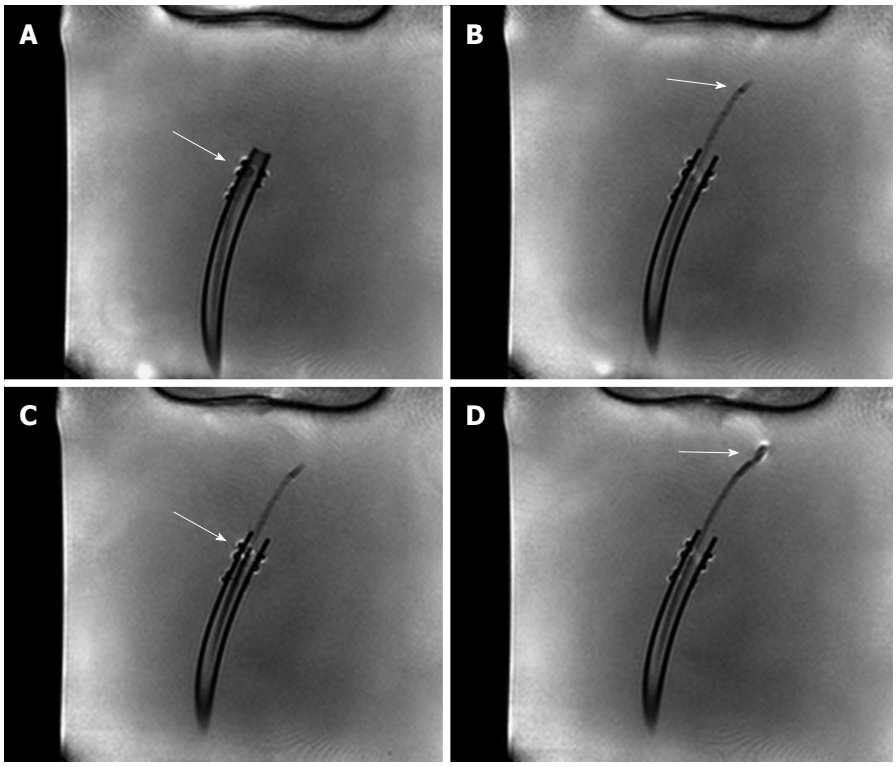

Figure 6 Real-time magnetic resonance imaging image frames showing bioptome and sheath inside saline filled phantom. The empty sheath is pushed forward in a plastic tube (A, B), later the bioptome is guided inside the sheath (C) until the tip is bare in the phantom (D).

heart (Figure 6) submerged in the saline.

The passive, visual tracking of the MR bioptome/sheath system and especially the tip was easily feasible due to the static design of the experiment. As shown in Figure 5, a moving tip caused turbulences in its vicinity which resulted in an artifact similar to the opened sample cutting mechanism. As a consequence, only for a non-moving tip, the opening/closing state could be reliably determined.

The control interface of the scanner supported a quick re-adjustment of the current imaging plane into parallel and orthogonal planes to follow the bioptome's movement. The achieved frame rate was approx. 4 fps for one slice when using an automatic continuous imaging mode. The visualization of orthogonal slices was only manually possible with manual plane re-adjustment causing the frame rate to decrease to approx. 0.3 fps to 0.25 fps.

Handling

In case of a jugular venous insertion, the interventionalist's access to the MR bioptome would be realized from the rear end of the scanner bore. Even the limited inner bore diameter of the MRI system (60 cm) left enough space to maneuver the bioptome. The handling was acceptable, but required a leaned-forward position of the interventionalist that was less comfortable than when carrying out a fluoroscopy.

When an access into the femoral venous system was simulated, the interventionalist stood in front of the CMR system. Here, the handling was better because it allowed a more upright position during the procedure.

Biopsy

The new MR bioptome retrieved tissue samples of appropriate size and quality (Figure 7). As with a conventional X-ray bioptome, the samples were derived from the endocardium and a visual inspection of the lesion area showed no irregular defects of the tissue. The samples were all taken at the targeted areas (Figure 8) and no rupture or substantial damage to the free lateral wall of the right ventricle was induced. Histological examinations of the specimen were abandoned because of the expected tissue degradation due to the time delay of about 12 h between the slaughter of the animals and the actual experiments.

DISCUSSION

To our knowledge, this is the first *in-vitro* study using MR-guided endomyocardial biopsy. The main findings of this study are as follows: (1) The visualization of the anatomical soft-tissue structures inside the heart is superior compared to fluoroscopy and allowed a good localization of the MR bioptome; (2) The biopsies could be performed successfully without any unintended damages to the endomyocardial tissue; and (3) No dangerous heating of the introduced instruments and surrounding environment was observed.

In the study presented here, we could show the feasibility of MRI-guided myocardial biopsies. During

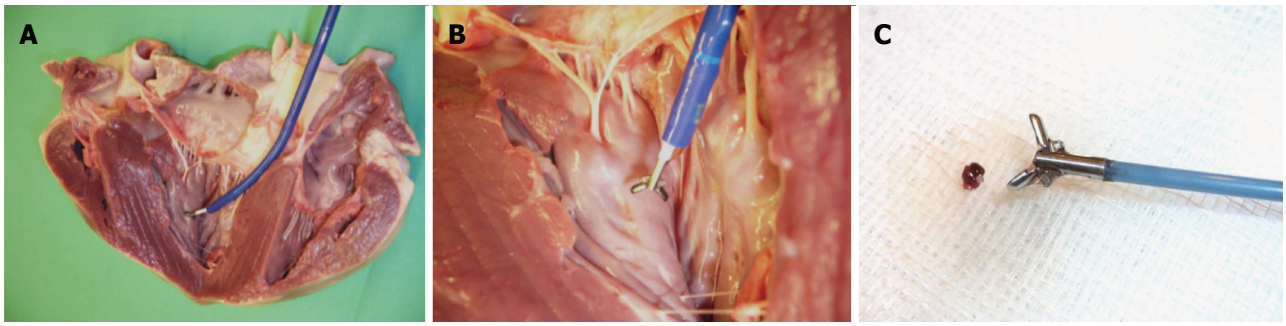

Figure 7 Close-up images of experimental *in-vitro* setup as shown in Figure 1: Opened porcine heart model with magnetic resonance bioptome (white) advanced through sheath (blue) (A), opened magnetic resonance bioptome forceps (B), magnetic resonance bioptome with tissue sample retrieved from endocardium (C).

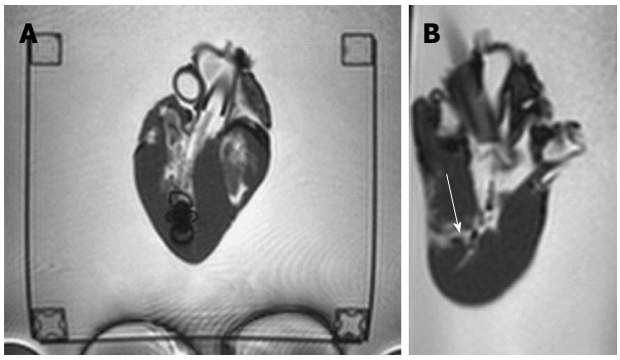

Figure 8 Side by side comparison of initial (A) and improved (B) version of magnetic resonance imaging compatible bioptome. Note the huge artifact in (A). The tip is highlighted in the circle. The targeted region is marked by previous Gadolinium injection (arrow).

the development of the novel device, we were able to reduce the size and the amount of artifacts to a level where no relevant areas in the vicinity of the instrument where obstructed. The visualization by MRI imaging allowed a clear and reliable distinction of the myocardial structures and therefore a safe and precise navigation to the targeted location previously marked with gadolinium injections. This targeted approach can potentially provide a higher sensitivity and specificity of each individual biopsy tissue sample and therefore reduce the number of required biopsy samples as well as the likelihood of complications.

The decision to use a separate bioptome and sheath system, as opposed to an all-in-one design provided substantial advantages. It allowed the maintenance of the position of the sheath while retrieving the individual samples from the myocardium. This could reduce the risk of valvular damage caused by repeated passages for sample acquisitions.

In conclusion, the complete absence of ionizing radiation is an important benefit of MRI based procedures, especially in younger patients with the need of repeated biopsies or multiple interventional procedures, *i.e.*, in cardiac transplant recipients.

Despite the significant advantages of MR-guided compared to fluoroscopically guided endomyocardial biopsies, MRI guidance also provides a number of challenges: (1) An overestimation of the image quality might be caused by the absence of motion artifacts of the static *ex-vivo* heart models. Further *in-vivo* experiments are required to evaluate the imaging capabilities when the heart as well as the instrument are constantly shifting and twisting during a cardiac cycle. Additionally, blood flow artifacts around the instrument could further impair the tracking performance; and (2) Since only one spatial slice is scanned, the operator can lose the tip's location of a passively tracked object when the instrument leaves the actual slice, whereas fluoroscopy with its projected image will always display the instrument as long as it is in the X-ray beam. This issue was successfully compensated by adding multiple passive markers at the distal end of the device. It could be further compensated with an active tracking system.

COMMENTS

Background

The aim of this study was to demonstrate the feasibility of magnetic resonance imaging (MRI)-guided endomyocardial biopsy in an *in-vitro* study. The motivation to use MRI was its superior soft tissue visualization and three-dimensional imaging capabilities when compared to the traditionally used fluoroscopy providing only two-dimensional projection images. Furthermore, the complete absence of ionizing radiation.

Research frontiers

As conventional bioptoms comprise multiple metallic components that prevent their use in an MRI environment. Furthermore, the navigation is more complex in MRI as this modality can only visualize objects in the imaging plane, whereas fluoroscopy creates projection images containing all objects in the X-ray beam.

Innovations and breakthroughs

In this study, a novel and fully MRI compatible instrument was developed. It could be successfully evaluated in a cylindrical 1.5T MRI system using bovine heart models. The bioptome was well visible and allowed precise discrimination from the surrounding tissue.

Applications

The new instrument allowed us to show the feasibility of MRI-guided interventional procedures, enabling radiation free procedures while benefitting from the widely accepted soft-tissue visualization and characterization capabilities of cardiac MRI.

Peer-review

The article under review represents the authors to present an *in-vitro* study to explore the feasibility of real-time MRI-guided endomyocardial biopsies. They found that MRI-guided endomyocardial biopsies provide a better than conventional X-ray guided navigation and could therefore improve the specificity and reproducibility of cardiac biopsies in future studies. The issue is interesting.

Author contributions: All the authors contributed to this manuscript.

Institutional review board statement: The institutional ethics review committee approved the retrospective anonymous analysis of the patients, in accordance with European guidelines for good clinical practice.

Informed consent statement: All patient's relatives signed informed consents for the clinical procedures performed during admission. No special tests were done for the realization of this study, nor there was any follow-up. Therefore, no specific informed consent was obtained for this the retrospective anonymous observational study.

Conflict-of-interest statement: The authors declare no conflicts of interest.

Data sharing statement: Technical appendix, statistical code, and dataset available from the corresponding author at estebanlopezdesa@secardiologia.es. Consent was not obtained but the presented data are anonymized and risk of identification is very low or absent.

Abstract

AIM: To assess the safety of therapeutic hypothermia (TH) concerning arrhythmias we analyzed serial electrocardiograms (ECG) during TH.

METHODS: All patients recovered from a cardiac arrest with Glasgow < 9 at admission were treated with induced mild TH to 32-34 ℃. TH was obtained with cool fluid infusion or a specific intravascular device. Twelve-lead ECG before, during, and after TH, as well as ECG telemetry data was recorded in all patients. From a total of 54 patients admitted with cardiac arrest during the study period, 47 patients had the 3 ECG and telemetry data available. ECG analysis was blinded and performed with manual caliper by two independent cardiologists from blinded copies of original ECG, recorded at 25 mm/s and 10 mm/mV. Coronary care unit staff analyzed ECG telemetry for rhythm disturbances. Variables measured in ECG were rhythm, RR, PR, QT and corrected QT (QTc by Bazett formula, measured in lead v2) intervals, QRS duration, presence of Osborn's J wave and U wave, as

well as ST segment displacement and T wave amplitude in leads Ⅱ, v2 and v5.

RESULTS: Heart rate went down an average of 19 bpm during hypothermia and increased again 16 bpm with rewarming (P < 0.0005, both). There was a non-significant prolongation of the PR interval during TH and a significant decrease with rewarming (P = 0.041). QRS duration significantly prolonged (P = 0.041) with TH and shortened back (P < 0.005) with rewarming. QTc interval presented a mean prolongation of 58 ms (P < 0.005) during TH and a significant shortening with rewarming of 22.2 ms (P = 0.017). Osborn or J wave was found in 21.3% of the patients. New arrhythmias occurred in 38.3% of the patients. Most frequent arrhythmia was non-sustained ventricular tachycardia (19.1%), followed by severe bradycardia or paced rhythm (10.6%), accelerated nodal rhythm (8.5%) and atrial fibrillation (6.4%). No life threatening arrhythmias (sustained ventricular tachycardia, polymorphic ventricular tachycardia or ventricular fibrillation) occurred during TH.

CONCLUSION: A 38.3% of patients had cardiac arrhythmias during TH but without life-threatening arrhythmias. A concern may rise when inducing TH to patients with long QT syndrome.

Key words: Cardiac arrest; Therapeutic hypothermia; Post-cardiac arrest síndrome; Cardiac arrythmias; QT interval

Core tip: Induced, therapeutic hypothermia is a treatment for post-cardiac arrest syndrome with a potential survival benefit; however it is not widely used. We aimed to assess the safety of this therapy regarding cardiac arrhythmias through a systematical evaluation of electrocardiograms (ECG) changes during hypothermia and telemetry data. Our conclusions are that therapeutic hypothermia according to current practice is safe with arrhythmias in one third of the patients (38.3%) but no life-threatening arrhythmias. Bradycardia and reversible prolongation of ECG intervals are common findings. A concern may rise when inducing hypothermia to patients with arrhythmias related to long QT syndrome.

Electrocardiographic changes during induced therapeutic hypothermia in comatose survivors after cardiac arrest. *World J Cardiol* 2015; 7(7): 423-430 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i7/423.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i7.423

INTRODUCTION

In 2002, two randomized clinical trials demonstrated that inducing mild therapeutic hypothermia (TH) between 32 ℃ and 34 ℃ Celsius during 12 to 24 h improve survival and neurologic outcome in comatose adults recovered from ventricular fibrillation (VF) cardiac arrest (CA)[1,2]. Thenceforth, the recommendation to induce TH has been extended to non-VF cardiac arrest, and in-hospital CA[3-6]. Today, TH is the only in-hospital treatment that improves survival in comatose patients recovered from a CA[7]. Despite the evidence, TH is still underused nowadays. Some causes have been proposed: technical difficulties, lack of experience with cooling methods, safety concerns and the many gaps on various issues such as optimal target temperature, duration of TH or rewarming rate[8,9].

While there are reports about complications and side effects of hypothermia from more than 50 years ago[10-12], the vast majority of the information on cardiovascular and side effects comes from case reports, accidental deep hypothermia or induced deep hypothermia in cardiac surgery. Known side effects of TH are shivering[13], increased risk of infection[2,14], increased diuresis, electrolyte abnormalities such as hypokalemia, hypophosphatemia and hypomagnesaemia[15], hyperglycemia, coagulopathy with increased risk of bleeding, bradycardia and complex effects in hemodynamics, with small reduction in cardiac output that balances with the decrease of metabolic rate[16]. The randomized clinical trials of TH did not show any differences in arrhythmias between patients assigned to TH or normothermia, but there is paucity of data regarding electrocardiographic abnormalities in humans recovered from a cardiac arrest under controlled mild hypothermia.

In this prospective, observational study we performed a systematic analysis on serial electrocardiograms (ECG) and arrhythmias during TH, in order to describe changes and assess the safety of TH concerning ECG alterations and rhythm disturbances.

MATERIALS AND METHODS

We prospectively collected data about every CA admission in the Coronary Care Unit of a Spanish tertiary hospital during a period of 3 years. TH was performed according to current guidelines to those patients recovered from CA with any initial rhythm and Glasgow ⩽ 8 at admission. Sedation was obtained with midazolam, fentanyl and muscular relaxation with cisatracurium. All drugs adjusted to body weight and administered by intravenous infusion through a central venous line. Patients where cooled to a target temperature of 32 ℃ to 34 ℃, as soon as possible, with cold fluid infusion. TH was maintained with physical measures (ice packs, isolating blankets) during 24 h in the first 20 patients. The rewarming process was passive, withdrawing cooling measures, during 12 to 24 h. In the last 34 patients an intravascular cooling device (Coolgard 3000®, Zoll medical Corp, Chelmsford, MA) was used to induce, maintain (33 ℃ for 24 h) and withdraw TH, set to fastest cooling speed at induction

Table 1 Baseline characteristics of study population

Patients	47
Age (median, range)	65.9 (19-85)
Male	40 (85.1%)
Cardiogenic shock at admission	15 (31.9%)
Urgent coronary angiography	28 (59.6%)
Left ventricular ejection fraction	43.2 (15.3%)
Initial Rhythm, *n* (%)	
Ventricular Fibrillation	30 (63.8)
Asystole	14 (29.8)
Pulseless Electrical Activity	3 (6.4)
Rhythm at admission, *n* (%)	
Sinus rhythm	31 (66)
Atrial fibrillation	8 (17)
AV block/nodal rhythm/paced rhythm	8 (17)
TH protocol	
Temperature at admission	35.7 (0.7)
Induction time (from admission to TH, h)	4.8 (2.6)
Time in TH (median, range, h)	20.8 (5-28.5)
Temperature during TH	32.8 (0.5)
Rewarming time (from TH to 36 ℃, h)	11.3 (7.4)
Cause of CA, *n* (%)	
Acute coronary syndrome	21 (44.7)
Chronic coronary disease[1]	8 (17.0)
Chronic heart failure	4 (8.5)
Others/unknown[2]	14 (29.8)

[1]This group represents those patients with known preexisting coronary disease but without an acute coronary syndrome diagnosis at admission. Presumed cause were ventricular arrhythmias secondary to chronic coronary disease; [2]No final diagnosis of the cardiac arrest could be made for this group, all of these patients died during admission. TH: Therapeutic hypothermia. Data are number (percentage) or mean (standard deviation).

and slow rewarming at a rate of 0.08-0.17 ℃/h, to slowly rewarm the patient in 12-24 h. Core temperature was measured with a Swan-Ganz catheter or urinary catheter.

During TH, all patients were under mechanical ventilation, muscular relaxation and sedation. Inotropics or vasodilators were used if necessary to maintain a target mean arterial pressure of 80-90 mmHg. Patients underwent urgent coronary angiogram (and percutaneous coronary intervention if necessary) if ST elevation acute coronary syndrome (ACS) or clinical indication. Echocardiogram was performed at admission. Complete 12 lead ECG were recorded at admission (ECG A), during peak hypothermia or minimum stable temperature (ECG B) and after rewarming (but before sedation was withdrawn, ECG C). Continuous ECG telemetry was recorded during TH. The ethical board of the hospital approved TH protocol.

For the present study we selected all consecutive patients (n = 54) that underwent TH. Baseline characteristics of the patients, cooling rates and temperatures of TH protocol, clinical outcome data, ECG telemetry data and original ECG were recorded. ECG analysis was blinded and performed with manual caliper by two independent cardiologists from blinded copies of original ECG, recorded at 25 mm/s and 10 mm/mV. Coronary care unit staff analyzed ECG telemetry for rhythm disturbances. Variables measured in ECG were rhythm, RR, PR, QT and corrected QT (QTc by Bazett formula, measured in lead v2) intervals, QRS duration, presence of Osborn's J wave and U wave, as well as ST segment displacement and T wave amplitude in leads II, v2 and v5. Quantitative data was obtained through arithmetical mean of 2 measured values. If there was any discordance in rhythm analysis or categorical variables, a final joint decision was reached with a third cardiologist.

Statistical analysis of measured intervals was performed with paired t-tests for related samples. Statistical significance was considered at $P < 0.05$ (two sided). Continuous variables are represented as means and standard deviation in brackets and categorical variables as percentages. Statistical analysis was performed with SPSS 15 (SPSS Inc, Chicago, IL).

The statistical methods of this study were reviewed by Pablo Salinas, MD, PhD, and bachelor degree in biostatistics.

RESULTS

A total 54 post-CA patients were included in the TH protocol. Of this 54 patients, 7 had one ECG missing (4 of them died before rewarming, 3 had unsatisfactory quality or were missing), therefore a total of 47 patients make the study population. PR interval changes were only considered when the 3 ECG were in sinus rhythm, 29 patients (61.7%).

Baseline characteristics of study population are shown in Table 1. Twenty one percent of the patients were under intraaortic balloon counterpulsation and 10% had a temporary transvenous pacemaker implanted, all of them during coronary angiogram. Two patients (4%) received continuous veno-venous hemofiltration therapy. Three patients (6.4%), already at TH target temperature, required premature protocol termination because of clinical indication, two because of hemodynamical instability and one because of emergent surgery of intraperitoneal hemorrhage, spleen and hepatic lacerations due to traumatic resuscitation. Median hospital stay was 11.5 d, ranging from 2 to 71 d. Mechanical ventilation was maintained for a median of 5.1 d. In-hospital survival rate was 53.2%. Implantable defibrillator was implanted in 23% of survivors.

Comparison of heart rate, QRS duration and RR, PR, and QTc intervals among ECG at admission (ECG A), during hypothermia (ECG B) and in normothermia after rewarming (ECG C) are shown in Table 2 and Figure 1. Changes form ECG A to ECG B were a statistically significant increase in RR interval (decrease of heart rate of 19.5 bpm, $P < 0.0005$); a non-significative prolongation in PR interval; a minor significant prolongation of QRS duration of 9.9 ms, $P = 0.041$; and a significant increase in QTc interval of 57.5 ms ($P < 0.0005$). Changes from ECG B to ECG C were a statistically significant decrease in RR interval (increase of heart rate of 15.9 bpm, $P < 0.0005$); a small

Table 2 Changes in electrocardiograms intervals, represented as means, standard deviation (in brackets) and *P* for difference

	Admission (ECG A)	During MTH (ECG B)	After MTH (ECG C)	*P* for difference (A to B)	*P* for difference (B to C)	*P* for difference (A to C)
RR interval (ms)	653.8 (174.6)	818.1 (222.6)	656.9 (114.4)	< 0.0005[a]	< 0.0005[a]	0.9
Heart rate (bpm)	97.9 (24.9)	78.3 (19.8)	94.2 (17.4)	< 0.0005[a]	< 0.0005[a]	0.3
PR interval (ms)	169.2 (42.7)	179.3 (37.5)	161.2 (37.0)	0.090	0.003[a]	0.2
QRS duration (ms)	108.8 (23.2)	118.7 (37.9)	102.0 (22.9)	0.041[a]	< 0.0005[a]	0.029[a]
QT interval (ms)	353.8 (58.1)	448.1 (106.1)	374.9 (72.0)	< 0.0005[a]	< 0.0005[a]	0.042[a]
QTc interval (ms)	441.7 (50.7)	499.2 (95.5)	463.9 (76.4)	< 0.0005[a]	0.017[a]	0.046[a]

Indicates statistical significance ([a]*P* < 0.05); ms: Milliseconds; ECG: Electrocardiograms.

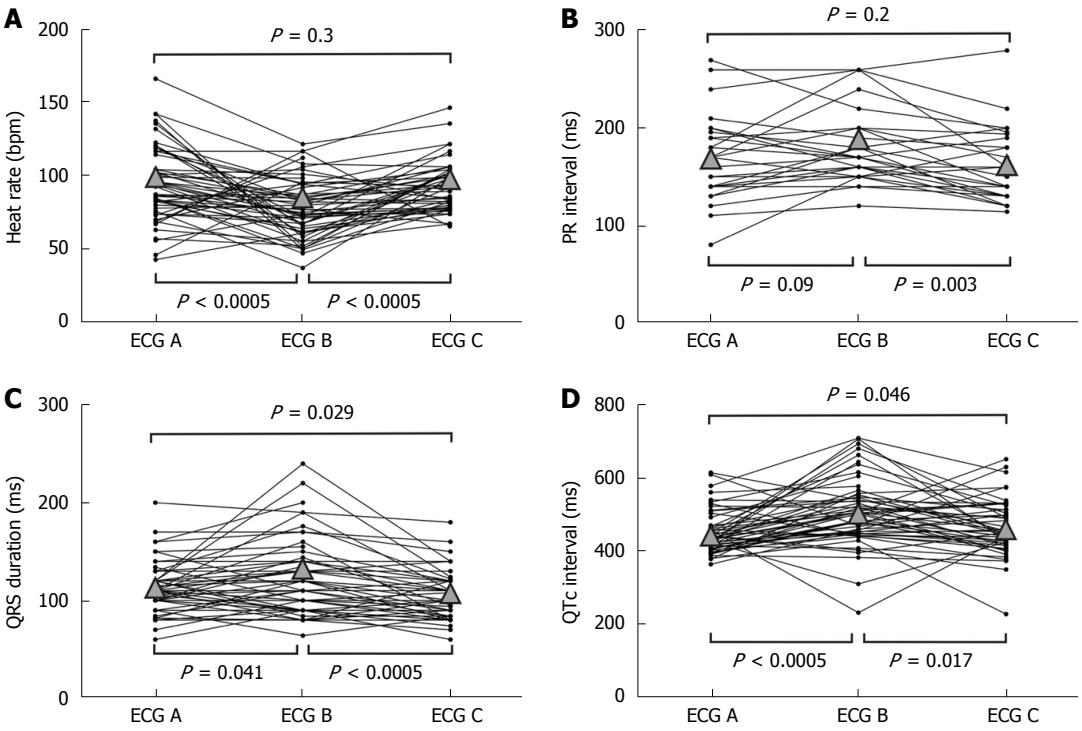

Figure 1 Graphics and statistical significance for paired *t*-test analyses for related samples. A: Heart rate (bpm); B: PR interval (ms); C: QRS duration (ms); D: QTc interval (ms). The dark dots are individual values of each single patient. Triangles represent mean values, shown in Table 2. Electrocardiograms (ECG) A represents ECG at admission; ECG B was performed at peak hypothermia and ECG C was recorded after rewarming.

significant decrease in PR interval of 18.1 ms (*P* = 0.003); a significant but small shortening of QRS duration of 16.7 ms, *P* < 0.0005; and a significant shortening of QTc interval of 35.3 ms (*P* = 0.017). Comparing basal ECG (A) with post-TH ECG (C), there were no significant difference in heart rate or PR interval; but we found a slight significant shortening in QRS duration of 6.8 (*P* = 0.029) and a significant increase in QTc of 22.2 ms (*P* = 0.046), with a final mean QTc interval above the upper limit of normal QTc interval (463.9 ms).

Comparison of T wave amplitude and ST segment deviation are shown in Table 3. On the whole there were no significant changes, except for a progressive decrease in amplitude of T wave in lead v5 through the TH process, a minor descent in ST from ECG B to ECG C in lead v5, and a slight decrease in amplitude of T wave in lead II. Osborn or J wave was observed in 21.3% of the patients in ECG B (Figure 2, arrow) with average amplitude of 0.2 millivolts. All of them appeared with cooling and reverted when patient was rewarmed. No U wave was detected in any ECG.

Arrhythmia analysis is shown in Table 4. Any new arrhythmia occurred in 38.3% of the patients during TH. The most frequent arrhythmia (50% of the patients with arrhythmias) was non-sustained monomorphic ventricular tachycardia (VT), 55% of them in patients with ACS. A 10.6% had severe bradycardia (< 50 bpm) or paced rhythms. An 8.5% had rapid nodal rhythms and 6.4% atrial fibrillation. Neither polymorphic VT, nor sustained VT, nor VF (considered as life-threatening arrhythmias) happened during TH. Twelve percent of the population changed to sinus rhythm after TH induction: half of them were in atrial fibrillation and the other half in accelerated nodal rhythm. Two patients (4.2%) had a reversible change of rhythm with TH: one in sinus rhythm developed an atrial fibrillation during TH and then relapsed to sinus rhythm and the other with an atrial fibrillation at admission had an accelerated nodal

Figure 2 Electrocardiograms in lead Ⅱ from the same patient. Reversible prolongation of all electrocardiograms (ECG) intervals may be observed. A: ECG at admission, core temperature was 35.9 ℃; B: ECG at peak hypothermia, 33 ℃. Osborn or J wave is marked with a black arrow; C: ECG after rewarming, core temperature was 36.4 ℃.

Table 3 Changes in ST segment and T wave, represented as means, standard deviation (in brackets) and *P* for difference

	Admission (ECG A)	During MTH (ECG B)	After MTH (ECG C)	*P* for difference (A to B)	*P* for difference (B to C)	*P* for difference (A to C)
ST deviation lead II	+ 0.05 (1.4)	- 0.20 (1.4)	- 0.12 (0.7)	0.2	0.3	0.4
ST deviation lead v2	+ 0.39 (3.2)	+ 0.08 (0.6)	+ 0.32 (1.0)	0.4	0.06	0.9
ST deviation lead v5	- 0.25 (1.9)	- 0.38 (0.8)	- 0.16 (0.8)	0.6	0.036[a]	0.7
T wave lead II	+ 1.0 (1.8)	+ 0.63 (1.1)	+ 0.38 (1.2)	0.2	0.1	0.036[a]
T wave lead v2	+ 2.0 (3.6)	+ 2.10 (3.2)	+ 1.62 (2.4)	0.8	0.3	0.5
T wave lead v5	+ 1.60 (2.9)	+ 0.84 (2.3)	+ 0.04 (2.4)	0.1	0.013[a]	< 0.0005[a]

Indicates statistical significance ([a]$P < 0.05$). Units are millivolts. +: ST segment elevation or T-wave positive deflection; -: Descent in ST segment or T-wave negative deflection.

Table 4 Incidence of arrhythmias or rhythm changes during hypothermia

New arrhythmias during TH	38.3%
Non sustained monomorphic VT	19.1%
Bradycardia < 50 bpm/paced rhythm	10.6%
Accelerated nodal rhythm	8.5%
Atrial fibrillation	6.4%
Sustained VT	0%
Polymorphic VT or VF	0%
Change to sinus rhythm with TH	12.8%
Atrial fibrillation to sinus rhythm	6.4%
Accelerated nodal rhythm to sinus rhythm	6.4%

TH: Therapeutic hypothermia; VT: Ventricular tachycardia; VF: Ventricular fibrillation.

rhythm in TH and then reverted to atrial fibrillation with rewarming. No patient needed pacemaker implantation or chronotropic drugs as a result of bradycardia during TH. Supraventricular tachycardias were treated following current guidelines if considered necessary. No treatment was given to non-sustained VT.

DISCUSSION

In the 1950's there was a growing interest in hypothermia as a protective measure in the beginnings of open-heart surgery. Some reports from intraoperative ECG obtained during circulatory occlusion and profound hypothermia (reaching 21-23 ℃), described a decrease in heart rate and a prolongation in PR, QRS and QT intervals. Arrhythmias were common and were related to core temperature. During mild hypothermia most frequent arrhythmias were ectopic atrial rhythms and nodal rhythms. A remarkable incidence of atrial fibrillation occurred below 30-32 ℃[10,11]. VF appeared associated with circulatory occlusion. Other studies in dogs suggested temperature thresholds for VF below 26 ℃ and asystole below 18 ℃[10,11,17]. Changes in ECG and arrhythmias in these reports are subject to multiple confounding factors: very low temperatures, myocardial ischemia, circulatory occlusion, cardioplegic solutions and the open-heart surgery itself. Because of those factors, previously described changes can hardly be applicable to current mild controlled TH.

Since the beginning of our decade, and after a gap in the literature of 40 years, hypothermia has regained interest, partly because the mechanism involved in its therapeutic effect were progressively clarified. Most information about complications and side effects come from old reports, animal experimentation and case reports. In the present study we provide a systematized analysis of cardiac arrhythmias and

temperature-dependent, sequential ECG changes during TH performed to an unselected post-CA population.

According to our findings, during TH to a target temperature of 32-34 ℃ in post-CA patients, some ECG changes may be expected: a considerable decrease in heart rate, a minimum prolongation of PR interval, a slight prolongation of QRS duration and a significant prolongation in QTc interval. All of these changes were reversible, except the prolongation of QTc interval (at least in the first 24 h after rewarming). Temperature-related changes in ST segment and T wave were not conclusive, but there was a trend towards flattening of T waves through TH process. ST segment and T wave changes may be interfered by previous cardiac disease and cause of CA, as almost half of the patients had an ACS.

The Osborn wave, or J wave, first observed in 1938 and fully described in 1953[18], is a frequent ECG feature in deep hypothermia. It can be seen as a notch or hump-like deflection in the terminal forces of QRS or between QRS and ST segment, more visible in precordial leads[19]. The amplitude and duration correlates with temperature, and although literature rarely describes it in mild hypothermia, we found a J wave in 21.3% of the patients (Figure 2, arrow). It is caused by a temperature dependent, transmural voltage gradient of a transient potassium current, more intense in epicardium than endocardium.

On the whole, ECG changes found in our study are concordant with those described previously in deep hypothermia[20-23]. Medical staff as well as nurses working with patients treated with induced TH should be aware of the possible arrhythmias and ECG changes that may occur. An example of ECG changes is shown in Figure 2. These changes are secondary to low body temperature and should not be considered pathological. Prolongation of action potential and decrease of myocardial conduction velocity has been proposed as physiopathological explanations for these phenomena[16]. These changes were reversible with rewarming and did not deteriorate hemodynamic status or clinical situation.

Bradycardia is one of the most disturbing effects of hypothermia because CA-recovered patients are often in cardiogenic shock and cardiac output decreases along with heart rate. In our series, patients with low initial heart rates did not decrease further, but maintained or increased their heart rates (Figure 1A). Besides, some studies suggest that the relation between heart rate and cardiac output inverses with hypothermia and that allowing mild TH to reduce heart rate could actually improve myocardial contractility. This is explained because hypothermia worsens diastolic function in the myocardium, and this is partially balanced by bradycardia[24,25]. External pacing or administration of chronotropic drugs is not recommended during TH to increase cardiac output[16].

The use of TH in post CA patients was safe with no life-threatening arrhythmias that worsened hemodynamic stability or required withdrawing the TH protocol. Non life-threatening arrhythmias were found in less than a half of the patients (38.3%).

The behavior of QTc interval in our TH series was remarkable (Figure 1D). We found a mean baseline QTc interval in the upper normal limits (mean 441 ms), it increased with TH (mean 499 ms), and partially reverted with rewarming, but final QTc interval was still lengthened when compared to initial QTc interval (463 ms) and was above upper normal limits. In spite of that, we had no arrhythmias related to prolongation of QT interval, like polymorphic ventricular tachycardia. We presumably (some patients died before a cause of the CA could be elucidated) did not have any patient with arrhythmic CA caused by long QT, but as QT and QTc intervals lengthen with TH, and remain lengthened afterwards, a concern may raise about safety of hypothermia in patients with long QT CA. Further investigation about this issue is warranted.

There is a concern about whether TH may increase the risk for arrhythmias and that the hypothermic myocardium can be somewhat resistant to antiarrhythmic drugs during hypothermia. It is well known that deep hypothermia under 30° increments the risk for atrial fibrillation and progressively with cooling under 28° the risk for life-threatening arrhythmias as VT and VF is increased[26]. Conversely, controlled mild TH is associated with higher rates of ROSC in animal CA models and is successfully used as a treatment for junctional ectopic tachycardia in infants[27-29]. Our study supports all previous reports that controlled, mild TH, is a safe technique with no increased risk for malignant arrhythmias and a relatively small number of minor arrhythmias that on the other hand can not only be attributed to TH but also to post-CA situation and previous cardiac disease.

Our study has some limitations. Accuracy of manual calipers is limited but represents day-by-day clinical practice. Arrhythmias and ECG changes could be interfered by several confounding factors like electrolyte disturbances. We had no control group, so this point cannot be ruled out in our study. However, our findings are congruent with those previously described in hypothermia and the fact that the changes were reversible with rewarming supports that TH was the cause of these changes. Recent trials show conflicting evidence regarding optimal target temperature, one of them suggests a benefit from deeper hypothermia (32 ℃ *vs* 34 ℃), while other found no benefit of 33 ℃ over normothermia (36 ℃)[30,31]. It would be relevant to know the "arrythmical" safety of different temperature levels, however our study did not analyzed different target temperatures.

In summary, therapeutic hypothermia according to current practice is safe with a 38.3% of patients having cardiac arrhythmias during TH but without life-threatening arrhythmias. Main ECG changes were bradycardia and prolongation of PR, QRS and QT

intervals. A concern may rise when inducing TH to patients with long QT syndrome.

COMMENTS

Background

Induced therapeutic hypothermia is currently recommended by most cardiac arrest guidelines, to improve the prognosis of the so-called post-cardiac arrest syndrome. However it is not widely used and has some controversies. Some of the main concerns that prevent intensive care physicians from inducing therapeutic hypothermia are the potential pro-arrhythmic effects of hypothermia. A study regarding cardiac arrhythmias is relevant to reassure patient's safety, especially for patients with heart disease.

Research frontiers

The influence of hypothermia over cardiac rhythm and cardiac conduction system is unknown and main data comes from case reports of accidental deep hypothermia.

Innovations and breakthroughs

This study allows a more comprehensive understanding of the influence of mild hypothermia in cardiac conduction. It shows a reversible prolongation of all cardiac intervals measured by electrocardiograms, suggesting that mild hypothermia slows cardiac conduction speed. The absence of life-threatening arrhythmias is reassuring for using this therapy in cardiac patients.

Applications

This study must be interpreted with caution due to the relatively small sample and its observational nature. However, it supports the "electrical" safety of therapeutic hypothermia for cardiac patients. Future lines of research suggested by the study are the potential influence of QT prolongation by hypothermia in long-QT syndromes, and the need for experimental (most probably in animal models) studies on the influence of hypothermia and cardiac conduction speed.

Terminology

Hypothermia: any temperature below 35.5-36 ℃. It may be accidental (cold exposure in winter) or induced (cold fluid or specific devices); Target temperature: The desired temperature in induced hypothermia. Usually 32-34 ℃. Some groups are investigating 32 ℃ *vs* 34 ℃, while others advocate for only preventing hyperthermia (≤ 36 ℃).

Peer-review

It is an important topic and well written and well presented.

Abstract

Left ventricular aneurysms are a frequent complication of acute extensive myocardial infarction and are most commonly located at the ventricular apex. A timely diagnosis is vital due to the serious complications that can occur, including heart failure, thromboembolism, or tachyarrhythmias. We report the case of a 78-year-old male with history of previous anterior myocardial infarction and currently under evaluation by chronic heart failure. Transthoracic echocardiogram revealed a huge thrombosed and calcified anteroapical left ventricular aneurysm. Coronary angiography demonstrated that the left anterior descending artery was chronically occluded, and revealed a big and spherical mass with calcified borders in the left hemithorax. Left ventriculogram confirmed that this spherical mass was a giant calcified left ventricular aneurysm, causing very severe left ventricular systolic dysfunction. The patient underwent cardioverter-defibrillator implantation for primary prevention.

Key words: Myocardial infarction; Echocardiography; Coronary artery disease; Left ventricular aneurysm; Coronary angiography

Core tip: Early diagnosis of ventricular aneurysms following acute transmural myocardial infarction is vital due to the serious complications that can occur. We report the case of a 78-year-old male with history of previous anterior myocardial infarction and currently under evaluation by chronic decompensated heart failure. Subsequent investigation revealed a huge thrombosed and calcified anteroapical left ventricular aneurysm. The peculiar findings of echocardiography, fluoroscopy and left ventriculography are shown with demonstrative images.

INTRODUCTION

True left ventricular aneurysms are a frequent complication following acute extensive myocardial infarction. Early diagnosis is crucial due to the serious complications that can potentially occur, including heart failure, thromboembolism, or tachyarrhythmias.

CASE REPORT

A 78-year-old male with history of previous anterior myocardial infarction and currently under evaluation by chronic decompensated heart failure (NYHA functional class Ⅲ), underwent transthoracic echocardiogram revealing the presence of a huge and peripherally calcified anteroapical left ventricular aneurysm with a giant mural thrombus (Figures 1-3). Elective coronary angiography was performed which demonstrated that the left anterior descending artery was chronically occluded (Figure 4) and nonsignificant lesions in the other coronary arteries. Fluoroscopic imaging revealed a complete oval calcified image enclosed within an abnormal cardiac silhouette (Figure 5). Left ventriculogram confirmed that this image corresponded of a giant calcified and thrombosed left ventricular aneurysm, causing severe left ventricular systolic dysfunction (Figure 6). The calculated left ventricular ejection fraction was only 7%. The patient underwent cardioverter-defibrillator implantation for primary prevention.

DISCUSSION

Left ventricular aneurysms are a frequent complication of acute extensive myocardial infarction and are most commonly located at the ventricular apex[1,2]. A timely diagnosis is vital due to the serious complications that can occur, including heart failure, thromboembolism, or tachyarrhythmias. The benefits of surgical repair of left ventricular aneurysm have long been debated. Although a large amount of studies have showed that aneurysmectomy might improve the outcome[3], the results from the STICH trial have questioned the benefit of this treatment[4]. Therefore, indication for aneurysmectomy depends on the decision of individual surgeons, and should be based on the assessment of the left ventricular dimensions, mitral valve regurgitation severity, extent of myocardial scar tissue and viability of the other regions of the left ventricle, and surgery should be performed in centers with a high surgical experience.

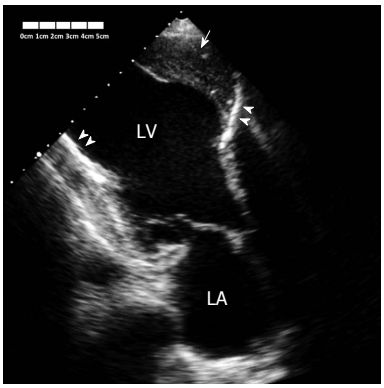

Figure 1 Transthoracic echocardiogram using apical three chamber view showing the big anterior left ventricular aneurysm (arrow). The wall of the aneurysm was calcified (arrowheads), and the aneurysm was covered with thrombus (arrow). LA: Left atrium; LV: Left ventricle.

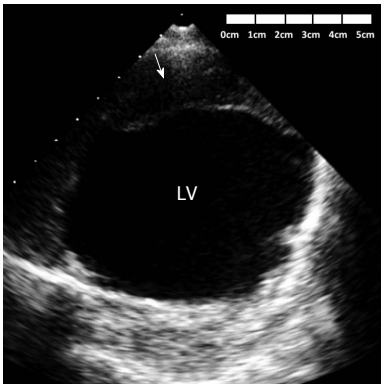

Figure 2 Transthoracic echocardiogram using parasternal short axis view at the midventricular level showing the thrombus (arrow) covering the anterior wall aneurysm. LV: Left ventricle.

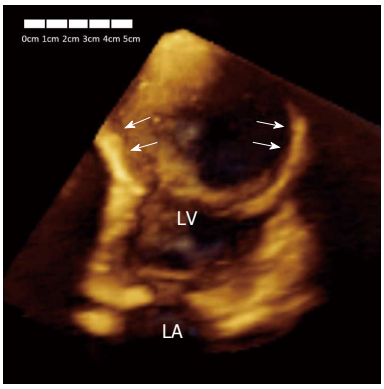

Figure 3 Three-dimensional echocardiography in apical four chamber view showing the big size of the aneurysm (arrows). LA: Left atrium; LV: Left ventricle.

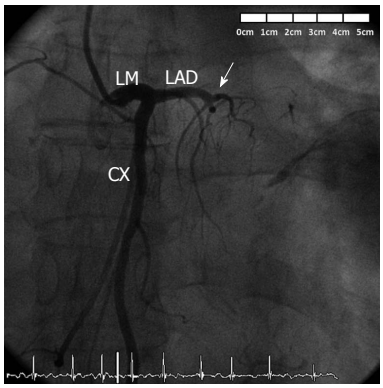

Figure 4 Left coronary angiography demonstrating a proximal occlusion of the left anterior descending artery (arrow). CX: Circumflex coronary artery; LAD: Left anterior descending coronary; LM: Left main coronary artery.

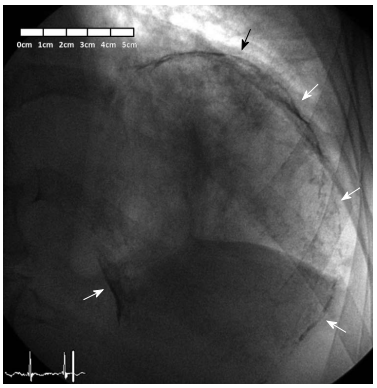

Figure 5 Fluoroscopic imaging in right anterior oblique projection showing a complete oval calcified mass (arrows), corresponding with the left ventricular aneurysm.

COMMENTS

Case characteristics

A 78-year-old male with history of previous anterior myocardial infarction and currently under evaluation by chronic decompensated heart failure.

Clinical diagnosis

Giant thrombosed left ventricular aneurysm.

Differential diagnosis

Intrathoracic mass.

Imaging diagnosis

Echocardiography and coronary angiography were used for the diagnosis of left ventricular aneurysm.

Treatment

The patient received an implantable cardioverter-defibrillator for primary prevention and was referred for consideration of cardiac transplantation.

Related reports

True left ventricular aneurysms are widely recognized as a common and serious complication following acute transmural myocardial infarction. However, this case is particular because of the huge size of the aneurysm.

Experiences and lessons

The recognition of ventricular aneurysms is of great importance due to the numerous complications that can potentially occur. Echocardiography and catheterism are fundamental tests for diagnosis.

Peer-review

It is a interesting case and well described.

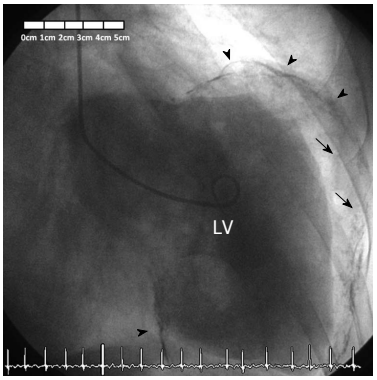

Figure 6 Left ventriculogram confirming diagnosis of a giant calcified and partially thrombosed left ventricular aneurysm, with severe left ventricular systolic dysfunction. The wall of the aneurysm is calcified (arrowheads), and the aneurysm is covered with thrombus (arrows). LV: Left ventricle.

Abstract

Intravascular thrombosis, a critical pathophysiological feature of many cardiovascular disorders, leads to the formation of life-threatening obstructive blood clots within the vessels. Rapid recanalization of occluded vessels is essential for the patients' outcome, but the currently available systemic fibrinolytic therapy is associated with low efficacy and tremendous side effects. Additionally, many patients are ineligible for systemic thrombolytic therapy, either due to delayed admission to the hospital after symptom onset, or because of recent surgery, or bleeding. In order to improve the treatment efficacy and to limit the risk of hemorrhagic complications, both precise imaging of the affected vascular regions, and the localized application of fibrinolytic agents, are required. Recent years have brought about considerable advances in nanomedical approaches to thrombosis. Although these thrombus-targeting imaging agents and nanotherapies are not yet implemented in humans, substantial amount of successful *in vivo* applications have been reported, including animal models of stroke, acute arterial thrombosis, and pulmonary embolism. It is evident that the future progress in diagnosis and treatment of thrombosis will be closely bound with the development of novel nanotechnology-based strategies. This Editorial focuses on the recently reported approaches, which hold a great promise for personalized, disease-targeted treatment and reduced side effects in the patients suffering from this life-threatening condition.

Key words: Thrombosis; Thrombus imaging; Nanomedicine; Targeted nanoparticles; Thrombolytic drug-delivery systems

Core tip: The prevalence of thrombosis, the formation of life-threatening clots obstructing vital blood vessels, continues to rise. Accurate diagnosis and rapid recanalization of an occluded artery is essential to improve outcomes and reduce the mortality in acute myocardial infarction or stroke. The current thrombolytic therapy often fails to diminish the occlusion and is associated with a high rate of hemorrhagic complications. Develop-

ment of directed nanosystems for local thrombolysis, characterized by a strong fibrinolytic effect and low bleeding risk, is therefore one of the most urgent tasks in the prevention and the therapy of acute thrombotic events.

Cicha I. Thrombosis: Novel nanomedical concepts of diagnosis and treatment. *World J Cardiol* 2015; 7(8): 434-441 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i8/434.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i8.434

INTRODUCTION

Intravascular thrombosis, the formation of life-threatening obstructive blood clots within the vessels, underlies a number of cardiovascular disorders such as heart attack, ischemic stroke, pulmonary embolism, and deep vein thrombosis[1,2]. Among these, atherothrombotic diseases (ischemic heart disease and stroke) are collectively responsible for 25% of all deaths worldwide[3]. In contrast, the burden of venous thromboembolism (VTE) is not well documented. According to the recent analyses[4], its incidence ranges between 1-2 per 1000 individuals in most of the studies, resembling the frequency of myocardial infarction[5], and the deaths due to VTE are estimated at 300000 per year in the United States[6]. Globally, the prevalence of thrombotic disorders continues to increase, particularly in the developing countries. However, despite significant advances in understanding of the disease mechanisms, which led to the development of more effective anti-thrombotic and thrombolytic drugs[7], the effect of these therapies on the patients' outcomes remains disappointing: According to the published data, less than 25% of high cardiovascular risk patients receiving antiplatelet therapy avoided a fatal thrombotic event[8]. The inherent problem with the conventional antithrombotic approaches is the increased risk of bleeding, as the existing therapeutics destabilize hemostatic processes. Among the most urgent challenges in this field are thus (1) identification of patients at increased risk for thrombosis and precise estimation of individual disease burden, as well as (2) development of safe and effective strategies to prevent thrombotic events and/or rapidly diminish vascular occlusion. These challenges have been intensively addressed by the researchers across the globe, resulting in a number of innovative approaches to diagnosis and treatment of thrombosis, as outlined below.

DIAGNOSIS OF THROMBOTIC DISEASE

Individual burden of thrombosis

In order to improve the diagnosis, risk stratification, and management of thrombotic syndromes, reliable methods of *in vivo* assessment of the thrombotic risk in patients with cardiovascular diseases are needed. Although thrombin is the most important serine protease within the coagulation cascade[9], thus far the diagnostic tests are lacking that are able to rapidly and reliably assess its activity in clinical settings. To address this need, a novel urinary nanomarker assay based on thrombin-sensitive iron oxide nanoparticles was recently developed that allows detection of thrombin activity and thus quantitative estimation of thrombosis burden *in vivo*[10]. The nanomarkers were produced by coupling iron oxide nanoworms with thrombin-cleavable peptides linked to a synthetic reporter system, composed of the protease-resistant peptide, glutamate-fibrinopeptide B, which was modified at the termini with ligands detectable by an immunoassay (fluorescein, or Alexa488, and biotin). In a mouse model of pulmonary embolism induced by thromboplastin[11], the circulating nanomarkers sucessfully accessed the local sites of thrombosis and released the reporters upon cleavage by thrombin. The urinary clearance of these reporters was detectable by ELISA with high sensitivity and significantly correlated with the thrombosis burden estimated by the histochemically analyzed amount of fibrin deposited in the lungs[10]. Given the need of rapid and reliable *in vivo* assessment of the thrombotic burden in cardiovascular patients, this urine analysis-based assay represents a very promising platform for use in clinical practice.

Imaging of thrombosis in vivo

During the thrombotic event, initially smaller clots form larger obstructive thrombi, which require a long time for recanalization, and a high dose of thrombolytic agents, or a high rate of mechanical clot disruption[12]. Both the burden and the localization[13,14] of thrombi are known to affect clinical outcomes and mortality[12,15]. By providing essential information about the size and localization of the thrombi, direct thrombus imaging would have an immense impact on clinical practice: Without a tool for *in vivo* imaging in the clinical settings, individualisation of the thrombolytic therapy is impossible. The recommended fixed dose of intravenous tissue plasminogen activator (tPA; 0.9 mg/kg) is thus insufficient in some patients, resulting in resistance to thrombolysis, or excessive in others, leading to increased risk of hemorrhagic complications.

Intravascular thrombus formation therefore represents a target for novel nanoparticle-based diagnostics. As early as in 2001, thrombus detection *in vivo* by magnetic resonance imaging (MRI) was accomplished in dogs using anti-fibrin monoclonal antibodies conjugated to lipid-encapsulated perfluorocarbon nanoparticles containing gadolinium-chelate[16]. More recently, *ex vivo* optical imaging of atherothrombosis in ApoE-deficient mice fed a high-fat diet was reported with lipopeptide nanoparticles carrying a fluorescently-labeled pentapeptide Cys-Arg-Glu-Lys-Ala (CREKA), which binds to clotted plasma proteins in the blood vessels[17]. Intravascular fibrin detection by MRI in this mouse model was also described by Makowski *et al*[18]

using a commercially available gadolinium-based fibrin-binding peptide EP-2104R. Another fibrin-targeting peptide (GPR, Gly-Pro-Arg) has been utilised in studies by Obermeyer *et al*[19] and McCarthy *et al*[20]. The former group applied bacteriophage MS2 capsids functionalized with GPR peptide on the exterior of each protein shell for fibrin imaging. The GPR-modified capsids were evaluated *in vitro* with regard to the fibrin imaging. Near-infrared fluorophores on the interior surface of the capsids enabled optical detection of their binding to fibrin clots with improved signal-to-background ratio as compared with non-targeted nanoagents[19]. Furthermore, in a mouse model of ferric chloride injury to jugular vein, McCarthy *et al*[20] utilised fluorescently labeled cross-linked iron oxide nanoparticles functionalized with GPR or FXIIIa-targeting peptides to obtain multimodal nanoagents exhibiting either covalent or noncovalent binding to thrombi. These nanosystems allowed *in vivo* detection of thrombus by both MRI and optical imaging modalities.

Apart from fibrin, activated platelets represent an important target for detection of intraluminal thrombi and endothelial activation, a marker of ongoing atherothrombotic disease. Therefore, the development of contrast agents for imaging of P-selectin, expressed by activated platelets, has been the aim of numerous efforts. In particular, the research group of Bachelet *et al*[21] and Manzo-Silberman *et al*[22] developed several nanosystems for *in vivo* P-selectin detection based on polysaccharide fucoidan (a mimic of sialyl Lewis X, the natural ligand of P-selectin) derived from brown seaweed. Radiolabeled fucoidan was demonstrated a suitable P-selectin targeting agent for *in vivo* single-photon emission computed tomography imaging of platelet-rich thrombi in rat models of infective endocarditis and elastase-induced aortic aneurysms, as well as endothelial activation in a model of myocardial ischemia-reperfusion[23]. Very recently, this group tested ultrasmall superparamagnetic iron oxide nanoparticles (USPIO) coated with fucoidan for molecular MRI of intraluminal thrombus: In a rat model of elastase-induced aortic aneurysms, all thrombi detected in MRI by USPIO-fucoidan particles were correlated with P-selectin immunostaining and USPIO detection by electron microscopy, whereas no intraluminal thrombi were detectable upon control USPIO[24]. In a study by Ta *et al*[25], iron oxide nanoparticles were coupled with a single-chain antibody that specifically binds to ligand-induced binding sites (LIBS) on glycoprotein IIb/IIIa (CD41/CD61), the most highly expressed molecules on the surface of activated platelets. LIBS-targeting nanocontructs showed a strong and specific binding to activated platelets *in vitro*, as well as *in vivo* by intravital microscopy and MRI of mouse carotid arteries[25].

Iron oxide nanoparticles allow *in vivo* visualization of thrombi with MRI. However, MRI is rarely the test of choice for the management of patients with acute thrombotic events, due to the time restrictions of clinical management, or contraindications for MRI in some patients. For most clinical decision making involving the administration of tPA, computed tomography (CT) is the current standard[26] due to its speed and convenience. However, non-contrast CT often does not allow a precise assessment of extent and distribution of thromboemboli, because the density of the thrombus is often not much different from that of the surrounding blood. Therefore, efficient and safe contrast agents are needed to achieve the enhancement of thrombus imaging with the clinical CT. Addressing this issue, thrombus detection using microCT has been recently tested in a mouse model of ferric chloride-induced carotid thrombosis utilising glycol chitosan (GC)-gold nanoparticles as contrast agents[27]. The study showed that these nanoparticles became trapped in the blood clots proportionally to thrombotic insult, and allowed the quantitative characterization and serial monitoring of thrombus evolution, embolization, and *in situ* recurrent thrombosis, as well as the assessment of therapeutic efficacy of tPA-induced thrombolysis. Due to a long circulating half-life, GC-gold nanoparticles remained available for entrapment into fibrin matrix for up to 3 wk, allowing repetition or ongoing monitoring of thrombogenesis and thrombolysis with microCT[27].

Collectively, the above-discussed studies demonstrate that nanosystems which target fibrin or activated platelets can enhance the detection and the diagnosis of intravascular thrombi by means of existing imaging modalities. Thus far however, little is known about their safety and efficacy in humans. Provided low toxicity and a good therapeutic index, these nanosystems should improve risk stratification when translated into the clinical practice, and allow personalized therapeutic regimen in thrombosis-related diseases.

PREVENTION AND TREATMENT OF THROMBOSIS

Current therapies

Platelet activation and aggregation are the key processes involved in thrombosis and thromboembolic disorders. The best preventive measures for the thrombotic events in the risk patients are thus antiplatelet or anticoagulation therapy. Although aspirin still plays an essential role in the primary and secondary prevention of atherothrombosis, new generation antithrombotic therapies are rapidly evolving. In combination with aspirin, ADP $P2Y_{12}$ receptor antagonists are used in the management of acute coronary syndromes and percutaneous coronary interventions in order to prevent adverse cardiac events and stent thrombosis[28]. Oral anticoagulation used for the treatment of VTE and for the prevention of emboli in patients with atrial fibrillation has advanced with the use of direct thrombin and factor Xa inhibitors that do not require therapeutic monitoring[29]. Although antiplatelet and anticoagulant therapy is essential for the primary and secondary prevention of atherothrombosis, systemic pre-treatment

with antithrombotic agents is associated with increased risk of hemorrhagic complications after intravenous thrombolysis in patients with acute ischemic stroke[30].

Acute management of stroke focuses on stabilizing the patient and ensuring the maximal reperfusion of the ischemic brain tissue. Hence, intravenous thrombolysis remains the mainstay treatment for acute ischemic stroke: A statistically and clinically significant improvement in outcomes is observed for carefully selected patients treated with tPA within 4.5 h of stroke onset[31]. While no other medication has demonstrated comparable efficacy, tPA remains the only drug for acute ischemic stroke approved by Food and Drug Administration since 1996[32]. However, its use is very limited both by the narrow eligibility and administration window, and by the risk of hemorrhagic complications[33], so called thrombolysis-related symptomatic intracerebral haemorrhage, which occurs in about 6% of patients and is associated with nearly 50% mortality[34,35]. Additionally, in some patients eligible for tPA treatment, the outcome is poor, when occlusion occurs in large arteries (internal carotid artery, middle cerebral artery or basilar artery). For these subgroups of stroke patients, an endovascular (intraarterial) administration route has been developed, but its clinical benefit remains unproven. Randomized controlled clinical trials did not show any added benefit of endovascular treatment over intravenous tPA alone in intravenous tPA-eligible patients, even in patients with persistent large-artery occlusion, nor have these trials provided evidence of clinical benefit in patients who were ineligible for intravenous tPA because of being > 4.5 h from symptom onset[36].

Alternative means of reperfusion, ideally based on individual thrombus burden estimation are therefore needed. For this purpose, thrombus-targeted nanosystems could serve as carriers for direct delivery of therapeutic agents to the occlusive thrombi in order to increase the effective local concentrations of antithrombotic drugs.

Antiplatelet and anticoagulant medications for prevention of thrombosis

Current antiplatelet drugs are only partially effective in preventing thrombus formation and thromboembolic events. Consequently, much interest is drawn both to the discovery of novel antiplatelet medications and to the optimization of the existing ones. The group of Chen *et al*[37] reported the synthesis of novel, self-assembly anti-platelet aggregation peptides containing L-arginine and L-aspartic acid, that were complexed with Cu(Ⅱ) to form stable nanoparticles. In a rat model of thrombus formation, these peptides at 5 μmol/kg achieved anti-thrombotic activity comparable to 110 μmol/kg aspirin, whereas the peptide-Cu(Ⅱ)-nanocomplexes were equally effective in reducing the thrombus weight already at 100-fold lower concentrations (0.05 μmol/kg). More recently, the same group reported a successful approach to overcome the low response to aspirin observed in some patients, which severely decreases its efficacy at the tolerated doses[38]. In that study, aspirin was conjugated to the Arg-Gly-Asp-Val (RGDV) tetrapeptide, resulting in a nano-assembly targeting glycoprotein Ⅱb/Ⅲa, the receptor for RGD peptide on the surface of the activated platelets. *In vitro*, aspirin-RGDV particles inhibited platelet aggregation induced by thrombin or arachidonic acid more effectively than free aspirin. A very strong antithrombotic effect of aspirin-RGDV was also observed in a rat model of thrombosis - whereas aspirin exhibited no antithrombotic activity at 16.7 μmol/kg, aspirin-RGDV significantly and dose-dependently inhibited thrombus formation in the treated rats already at doses of 0.1 and 1 nmol/kg[38]. Targeted delivery of aspirin to thrombus and its local release to activated platelets thus resulted in an extraordinarily potent inhibition of thrombus formation, overcoming the apparent non-response to aspirin. Formation of thrombi was also effectively prevented by novel heparin-conjugated carbon nanocapsules in a mouse model of acute hindlimb thromboembolism[39]. Compared to the injection of heparin alone, those heparin-functionalized carbon nanocapsules displayed superior antithrombotic activity *in vitro* and *in vivo*, representing a promising nanocarrier system for anticoagulant delivery.

Some of the most common cardiovascular interventions, including stent implantation or prosthetic heart valve replacement, are associated with increased risk of thrombosis, necessitating prolonged or even lifelong antiplatelet therapy. Particularly after cessation or premature discontinuation of the therapy, the incidence of thrombosis is high. Gene therapy is considered a safe strategy to increase the local expression of thrombolytic agents over an extended period of time, in parallel reducing the systemic risk of hemorrhagic complications. Ji *et al*[40] used a chitosan nano-*tPA* gene plasmid to locally transfect dog cardiomyocytes at the time of mechanical heart valve replacement. The transfected gene significantly increased the survival of animals and prevented thrombus formation on mechanical valves, without affecting systemic hemostasis. In a further study by the same group[41], the *tPA* gene plasmid was packaged in albumin nanoparticles crosslinked to ultrasonic microbubbles. Following intravenous administration, a local therapeutic ultrasound treatment of the heart after valve replacement had been performed, which resulted in increased myocardial expression of *tPA* and prevented thrombosis for 8 wk after operation.

Thrombolytic therapies

Rapid recanalization of thrombus-occluded arteries is essential to improve outcomes and reduce the mortality in acute myocardial infarction or stroke. Development of delivery systems for local thrombolysis is therefore one of the most urgent tasks in the prevention and the therapy of acute thrombotic events. Within the coagulation cascade, thrombin represents the most important target of direct anticoagulants. As an

example, hirulog, an analogue of the natural thrombin inhibitor hirudin was locally delivered to the thrombus using lipid nanoparticles containing a fibrin-binding peptide. Upon administration of the fibrin-targeting hirulog-carrying particles, significantly higher levels of antithrombin activity were achieved in the aortic tree of ApoE-deficient mice as compared with non-targeted particles[17].

The effects of another potent thrombin inhibitor, d-phenylalanyl-l-prolyl-l-arginyl-chloromethyl ketone (PPACK) were investigated the group of Myerson *et al*[42] and Palekar *et al*[43] in a mouse model of acute arterial thrombosis due to photochemical injury of the carotid artery. Perfluorocarbon nanoparticle-bound PPACK outperformed both heparin and uncomplexed PPACK in inhibiting thrombosis, and formed a local clotting barrier that remained effective even as systemic effects rapidly diminished[42]. Similarly, PPACK-liposomes administered prior to the arterial injury significantly delayed the time to arterial occlusion as compared to free PPACK. Whereas systemic anticoagulant profiles returned to control levels within 50 min, the inhibition of thrombus formation was maintained at the injury site beyond 2 h[43]. The establishment of a potent and long-acting anticoagulant surface over a newly forming clot with the use of thrombin targeted nanoparticles offers an alternative site-targeted approach to the management of acute thrombosis.

As described in detail above, intravenous infusion of tPA is characterized by several drawbacks, including low efficacy combined with a high risk of bleeding complications[35]. Therefore, several innovative strategies aiming at targeted and/or local applications of plasminogen activators have been designed. The possibility of magnetic-targeting of tPA for local thrombolysis was investigated by Ma *et al*[44] in a rat embolic model. Magnetite nanoparticles bound to tPA (tPA equivalent of 0.2 mg/kg) were administered intraarterially under guidance of an external magnet moving along the iliac artery. Magnetic tPA-nanoparticles accumulated in the thrombus-affected region and achieved an effective target thrombolysis with < 20% of a regular dose of free tPA. Another tPA delivery nanosystem comprising basic gelatin and zinc acetate was tested by Kawata *et al*[45] in a swine acute myocardial infarction model. Within this nanosystem, tPA activity was reduced *in vitro* to approximately 50% of free tPA and was fully recoverable by transthoracic ultrasound application. In comparison to treatment with free tPA (0.447 mg/kg), which recanalized the occluded coronary artery in only 1 of 10 swine, nanoparticles containing the same dose of tPA with ultrasound activation achieved recanalization in 9 of 10 swine within 30 min, suggesting that this nanosystem bears promising potential for improved intravenous thrombolysis.

In attempt to create a theranostic construct with fibrinolytic activity, McCarthy *et al*[46] synthesized a multimodal nanoagent using magnetofluorescent crosslinked dextran-coated iron oxide nanoparticles conjugated to tPA. Thrombus-targeting was achieved by nanoparticle functionalization with an activated FXIIIa-sensitive peptide. In murine models of arterial and venous thrombosis, the FXIIIa-targeted fibrinolytic nanoagent efficiently bound the margin of intravascular thrombi as detected by intravital fluorescence microscopy. The fibrinolytic activity of the nanoagent compared to free tPA was subsequently evaluated in a murine model of pulmonary embolism, showing that the FXIIIa-targeted agent lysed pulmonary emboli with similar efficacy as free tPA[46].

Targeted tPA delivery to stenotic arteries by employing universal hemodynamic phenomena was described by Korin *et al*[47]. Since occlusions in blood vessels result in local increases in shear stress, the authors designed micro-aggregates of poly-lactic-glycolic acid nanoparticles coated with tPA. Under physiologic flow conditions with shear stress values up to 70 dyn/cm^2, these micro-aggregates remained stable, but the exposure to abnormally high shear stress in the regions of vascular occlusion/stenosis resulted in their rapid break up followed by local drug release. As compared with free drug, the shear-activated tPA-coated nanoparticles rapidly dissolved the ferric chloride-induced arterial thrombi in mouse mesenteric arteries, with complete clearance of occluding thrombi within 5 min after application[47]. Moreover, upon infusion of lethally large fibrin clots, the immediate application of the shear-activated tPA-coated nanoparticles increased survival by 80%. The doses of shear-activated tPA-nanoparticles required for clot dissolution were about 100-times lower than the doses required for achieving comparable effects with free drug[47]. This strategy, utilizing a universal hemodynamic phenomenon of increased shear stress upon reduction in vessel diameter should result in a broad applicability for all occlusive vascular conditions, including *e.g.,* treatment of stenotic atherosclerotic plaques, pulmonary emboli, and ischemic stroke.

Venous thromboembolism, including deep vein thrombosis and pulmonary embolism, remains a common and potentially life-threatening disease[48]. Standard treatments aim to minimize acute morbidity and mortality by preventing the potentially fatal embolization of the initial thrombus and to reduce the long-term complications of post-thrombotic syndrome. For patients with VTE, catheter-based revascularization therapy [catheter-directed thrombolysis (CDT)] has emerged as favoured means of administration replacing systemic thrombolysis. Urokinase-type plasminogen activator (uPA) is commonly used for CDT in the clinical settings of VTE. However, similar to arterial thrombosis treatment, strict eligibility criteria are necessary to reduce the risk of bleeding complications, which limit the applicability of this therapy. To minimize the adverse effects and increase therapeutic benefits, Jin *et al*[49] produced uPA-coated, self-assembled chitosan and tripolyphosphate nanoparticles. In a

rabbit model of thrombosis, a significant improvement in the thrombolytic effect compared with free uPA was observed upon administration of uPA-carrying nanoparticles. Additionally, the study confirmed the superiority of CDT for improving clot lysis and minimizing adverse effects over drug-induced systemic thrombolysis.

CONCLUSION

The potential clinical impact of nanotechnology in terms of thrombosis prevention and management is enormous. But in spite of the promising results obtained in the vast number of bench investigations that have been published in the recent years, the thrombus-targeting imaging nanoagents and fibrinolytic nanotherapies are not yet implemented in humans. To ensure clinical safety and feasibility, the intravascular diagnostic and drug-delivery systems must be subject to a close toxicologic and pharmacologic scrutiny prior to their application in patients. Thus, substantial amount of *in vivo* studies will be necessary before the successful basic research can be translated into clinical trials. Despite multiple safety and regulatory constraints, the future progress in diagnosis and treatment of thrombosis is expected to benefit strongly from the development of novel nanotechnology-based strategies.

Abstract

Over the last decades, the concern for the radiation injury hazard to the patients and the professional staff has increased in the medical community. Since there is no magnitude of radiation exposure that is known to be completely safe, the use of ionizing radiation during medical diagnostic or interventional procedures should be as low as reasonably achievable (ALARA principle). Nevertheless, in cardiovascular medicine, radiation exposure for coronary percutaneous interventions or catheter ablation of cardiac arrhythmias may be high: for ablation of a complex arrhythmia, such as atrial fibrillation, the mean dose can be > 15 mSv and in some cases > 50 mSv. In interventional electrophysiology, although fluoroscopy has been widely used since the beginning to navigate catheters in the heart and the vessels and to monitor their position, the procedure is not based on fluoroscopic imaging. Therefore, non-fluoroscopic three-dimensional systems can be used to navigate electrophysiology catheters in the heart with no or minimal use of fluoroscopy. Although zero-fluoroscopy procedures are feasible in limited series, there may be difficulties in using no fluoroscopy on a routine basis. Currently, a significant reduction in radiation exposure towards near zero-fluoroscopy procedures seems a simpler task to achieve, especially in ablation of complex arrhythmias, such as atrial fibrillation. The data reported in the literature suggest the following three considerations. First, the use of the non-fluoroscopic systems is associated with a consistent reduction in radiation exposure in multiple centers: the more sophisticated and reliable this technology is, the higher the reduction in radiation exposure. Second, the use of these systems does not automatically lead to reduction of radiation exposure, but an optimized workflow should be developed and adopted for a safe non-fluoroscopic navigation of catheters. Third, at any level of expertise, there is a specific learning curve for the operators in the non-fluoroscopic manipulation of catheters; however, the learning curve is shorter for more experienced operators compared to less experienced operators.

Key words: Catheter ablation; Atrial fibrillation; Radiation exposure; Fluoroscopy time; Dose area product; Electro-anatomic mapping

Core tip: After 25 years from the formulation of the ALARA principle, the awareness of the potential hazard related to radiation exposure has greatly increased in medicine. Non-fluoroscopic three-dimensional systems, introduced in interventional electrophysiology to support complex procedures, have the potential to significantly decrease the use of fluoroscopy. In interventional electrophysiology, the clinical perspective is to perform procedures with minimal use of fluoroscopy without endangering the safety and efficacy. However, to achieve this task the use of the non-fluoroscopic system has to be optimized and a learning curve is necessary even for operators experienced in fluoroscopy-based electrophysiology.

NEED FOR REDUCTION OF RADIATION EXPOSURE IN ELECTROPHYSIOLOGY PROCEDURES

Over the last years, the awareness of the risk related to the use of ionizing radiation in medicine has progressively increased. Cardiac imaging procedures lead to substantial radiation exposure in many patients: in a population-based analysis[1], the median cumulative effective dose over 3 years was 15.6 mSv and, among patients receiving a high annual dose (> 20-50 mSv), repeat cardiac catheterization procedures are the largest contributors to the radiation dose. The potential risks related to this radiation exposure are expected to be vastly outweighed by the benefits, especially if the procedure is appropriately justified and carefully optimized[2]. Although it is difficult to assess the consequences of the deterministic (dose-dependent) and stochastic (non dose-dependent) effects for the exposure to low-dose ionizing radiations used in cardiovascular imaging, the estimate of lifetime additional risk of cancer spans between 1/2000 and 1/1000 per single cardiovascular procedure[3]. It should be also taken into account that several patients undergo repeat procedures and that a younger patient population is more sensitive to the induction of cancer than an older patient population[4]. Similarly, the risk related to radiation exposure is not negligible for the medical staff. Noteworthy, according to a survey undertaken in Tuscany, Italy[5], interventional cardiologists and electrophysiologists represent more than 60% of the medical staff receiving the highest annual radiation exposure (> 6 mSv), with no statistically significant difference between physicians and nurses/technicians. This radiation exposure is by far greater than the one of the urologists, radiologists, and personnel of nuclear medicine. Moreover, according to the same source[5], the median lifetime professional exposure is 54 mSv, leading to an estimate lifetime attributable risk of cancer of 1 out of 200.

A decade ago, a document[6] endorsed by the main American scientific societies in cardiovascular medicine was published. This document states the clinical competence required for physicians performing fluoroscopically-guided invasive cardiovascular procedures to optimize patient safety and image quality. Importantly, it also highlights the ALARA principle, previously proposed by the United States National Council on Radiation Protection and Measurements[7]: due to both the stochastic and deterministic effect of radiation, there is no magnitude of radiation exposure that is known to be completely safe and, therefore, the use of ionizing radiations should be As Low As Reasonably Achievable. This principle confers to physicians the responsibility for reducing as much as possible the dose of radiation during cardiovascular procedures, in order to minimize the radiation injury hazard to the patients, to the professional staff and to themselves. The dose delivered to the patient depends on the following three factors: (1) type and setting of the X-ray equipment; (2) patient size; and (3) physician conduct. Consequently, all these three factors should be considered and optimized to comply with the ALARA principle. Importantly, opposite to what is commonly thought, fluoroscopy time poorly expresses the dose delivered to the patient. In fact, this value only reflects the operator's attitude to use radiation during a given procedure. Moreover, the same value of fluoroscopy time may correspond to a very different radiation exposure, depending on the predominant use of low-dose fluoroscopy or high-dose cine loop acquisition. Therefore, a reliable surrogate measurement for the total amount of X-ray energy delivered to the patient is the dose-area product (DAP), expressed usually in Gy·cm^2 and automatically measured by X-ray systems[6].

In the real world, after the dissemination of the ALARA principle, the process of optimization is still ongoing. Optimization depends on several factors, some of which are difficult to identify and control. Considering again the data by Chen *et al*[1], based on a population enrolled between 2005 and 2007, after the ALARA principle was diffused, percutaneous coronary interventions or electrophysiologic procedures were the main determinants of radiation exposure in the population receiving the highest radiation dose (> 20 mSv). As mentioned above, one of the determinants of the dose to the patient is the physician's conduct, which may be very much dependent on the physician's experience in a given procedure. In fact, in the very early phase of a physician's learning curve, the workflow can be far from being optimized and this can result in an excessive use of fluoroscopy. In this context, newer methodologies of teaching and learning can be effectively used. One small study performed in our

center[8] shows that the training implemented by a high-fidelity hybrid simulator reduces from 10 to 5 min, on average ($P < 0.0001$), the fluoroscopy time per patient spent by fellows novice in electrophysiology to position catheters in the conventional sites at the beginning of the procedure. In the future, if this or similar training modalities are not considered, we may face a new paradox: while the more experienced operators minimize radiation exposure in complex procedures using established techniques and technologies, the less experienced physicians use a higher dose for a standard and relatively simple procedure.

Recently, the European Society of Cardiology published two position papers on the appropriate and justified use of medical radiation in cardiovascular imaging[9] and on the practical ways to reduce radiation dose for patients and staff during electrophysiology procedures[10]. Focusing on the field of interventional electrophysiology, these papers report the radiation dose to the patients for electrophysiology procedures. This dose may vary from 3.2 mSv for a simple diagnostic electrophysiology study to a higher value for complex procedures, such as atrial fibrillation ablation, for which the median dose is 16.6 mSv, ranging from 6.6 to 59.6 mSv[10]. Another review of 17 studies, 12 of them published after the year 2000, reports an effective dose even higher (20.3 mSv) for catheter ablation of cardiac arrhythmias, in general, including ablation of less complex arrhythmias[11]. As suggested by the consensus document[10], this situation still requires further improvement, once optimization of X-ray equipment and shielding of the laboratory personnel are obtained. In fact, non-fluoroscopic three-dimensional systems, namely the Ensite-NavX (St.Jude Medical, United States) and the CARTO (Biosense Webster, United States), widely used since the late nineties for ablation of complex arrhythmias, can be used effectively to reduce radiation exposure during electrophysiology procedures. In a randomized study[12], the use of these systems for catheter ablation of cardiac arrhythmias reduced X-ray exposure with a similar efficacy and safety compared to the conventional approach. However, it should be highlighted that the use of these systems does not *per se* reduce radiation exposure, but the operators should develop procedural workflows to rely on non-fluoroscopic guidance as much as possible without compromising safety[10]. Especially for complex left atrial procedure during which the operator may face different anatomic variants, integration in these systems of pre-acquired three-dimensional imaging from computed tomography or magnetic resonance scan has the potential to drastically reduce the radiation exposure during the procedure[9].

The following sections will focus on reducing radiation exposure in catheter ablation of atrial fibrillation. This is an increasingly used procedure especially in patients with paroxysmal forms and, moreover, the use of fluoroscopy in such a complex and demanding procedure can be high. Therefore, reduction of radiation exposure in this procedure is expected to increase the net benefit of the procedure, minimizing the risks, which can be also related to the radiation exposure especially in case of repeat procedures.

ZERO OR NEAR-ZERO FLUOROSCOPY FOR ATRIAL FIBRILLATION ABLATION?

Unlike percutaneous coronary interventions, electrophysiologic procedures are based on recording and interpretation of intracavitary electrograms. Therefore, although fluoroscopy is very useful to maneuver and check the position of catheters, imaging based on ionizing radiations is not an integral part of the electrophysiologic procedure. In fact, ablation of various types of supraventricular and ventricular tachycardia with no use of fluoroscopy is feasible both in children[13-18] and adults[19-22] using non-fluoroscopic three-dimensional systems. Also a complex procedure, such as pulmonary vein isolation to treat atrial fibrillation, is feasible with no use of fluoroscopy[23,24]. Although these studies certainly demonstrate the feasibility of zero-fluoroscopy procedures, this issue deserves several considerations, especially in the case of complex procedures such as atrial fibrillation ablation. First, the majority of the reported series and in particular those on catheter ablation of atrial fibrillation are small and from very experienced centers. Even for senior electrophysiologists there may be a learning curve in the transition from fluoroscopically based procedures to zero-fluoroscopy procedures[17]. Second, even in the best scenario of published data on procedure planned to be with no fluoroscopy, very limited radiations are used in some cases[23] to assist a part of the procedure. Extrapolating these data to a wider population, it is unlikely that in the near future electrophysiologists will be able to work in laboratories not equipped with X-ray systems. Therefore, the zero-fluoroscopy strategy does not seem to bring any benefit in term of laboratory costs. Third, in ablation of atrial fibrillation with no fluoroscopy, some technologies, which require specific expertise and add costs in centers in which they are not routinely used, become necessary. In fact, to safely navigate catheters in the heart with no fluoroscopy, intracardiac ultrasounds is mandatory and imaging integration with pre-acquired computed tomography or magnetic resonance imaging very useful to obtain a high resolution anatomy of the left atrium and pulmonary veins[23,24]. The use of the recently introduced contact force sensing technology should be also considered mandatory to avoid excessive tissue/catheter contact when catheters are maneuvered with no fluoroscopy[22]. Fourth, the workflow of a zero-fluoroscopy procedure requires accurate cardiac chamber reconstruction before non-fluoroscopic catheter navigation. This can be done correctly only by experienced operators and, in any case, may significantly prolong the procedure duration, especially at the beginning of the specific learning curve in zero-

Table 1 Techniques and technologies for catheter ablation of atrial fibrillation in the four patient cohorts considered in our center

	1st cohort	2nd cohort	3rd cohort	4th cohort
No. of patients	30	30	30	30
Procedure technique	Double TSP-C Circular mapping catheter Imaging integration (CT scan)	Unchanged	Unchanged	Unchanged
NF technology	2nd generation NF 3-DS (CARTO XP)	3rd generation NF 3-DS (CARTO3)	Unchanged	CARTO3 + contact force sensing
Technology feature for NF use	NF visualization of the mapping/ablation catheter	NF visualization of all inserted catheter	Unchanged	Monitoring of the electrode/tissue contact added
NF 3-DS optimization	Yes	No	Yes (Table 2)	Yes (Table 2)
Timing	Last 30 cases with CARTO XP	First 30 cases with CARTO3	After 12 mo	After 12 mo

3-DS: Three dimensional system; CT: Computed tomography; NF: Non-fluoroscopic; TSP-C: Transseptal catheterization.

fluoroscopy procedures.

After these considerations, it can be concluded that zero-fluoroscopy procedures are a very interesting perspective for the future, but they are not common practice at present. Certainly, children and pregnant women are ideal candidates for zero-fluoroscopy catheter ablation, when other treatments fail or are not feasible. On the other hand, currently, every effort should be made by every operator to decrease as much as possible the use of radiation without endangering the procedure safety and efficacy until near-zero fluoroscopy procedures become routine.

LESSON LEARNED IN THE REDUCTION OF RADIATION EXPOSURE FOR ATRIAL FIBRILLATION ABLATION

Even in very experienced hands, catheter ablation of atrial fibrillation without a non-fluoroscopic three-dimensional system is associated with a fluoroscopy time of approximately 60 min[25] and, consequently, with a relatively high radiation exposure. However, as already mentioned[10], a non-fluoroscopic system without a workflow aimed at optimizing its use does not necessarily reduce the radiation exposure. In fact, in catheter ablation of atrial fibrillation, the sporadic use of non-fluoroscopic systems may paradoxically double the fluoroscopy time and radiation exposure when the system is used, due to the complexity of the procedure[26]. In a retrospective analysis[27] spanning 6 years (2004-2009) and including four cohorts of patients who showed comparable clinical characteristics and underwent catheter ablation of atrial fibrillation by using in a non-randomized way fluoroscopy or one of the non-fluoroscopic systems (Ensite NavX, CARTO XP, CARTO3), a third generation non-fluoroscopic system (CARTO 3) was associated with the shortest fluoroscopy time with no difference with the other 3 groups in term of procedural data and clinical outcomes. Although the reduction was statistically significant, the average fluoroscopy time using CARTO 3 in this study was still close to one hour (52 ± 21 min). This underlines the complexity of the variables that may determine the reduction of radiation exposure, which is not merely due to the use of a specific non-fluoroscopic system. Another study[28] further supports this concept. In this study, over six months, 120 patients were randomly assigned to use fluoroscopy only, a second generation (CARTO XP), or a third generation (CARTO3) non-fluoroscopic system to support catheter ablation of atrial fibrillation. The procedure was performed by operators with a specific experience in reduction of radiation exposure. While there was no difference in the clinical and anatomic variables among the three groups, the fluoroscopy time was shorter and less than 3 min for the whole procedure when the third generation non-fluoroscopic system was used with an optimized procedural workflow.

We evaluated the process of reduction of radiation exposure in catheter ablation of atrial fibrillation using a non-fluoroscopic three-dimensional electroanatomic system both in a single- and multicenter experience[29,30]. In our center, the procedural data of four cohorts of patients, sampled sequentially, were considered[29]. Each cohort included atrial fibrillation patients undergoing the first procedure of pulmonary vein isolation. The technologies and techniques used in each cohort are reported in Table 1. Among the four cohorts there was no significant difference in the clinical characteristics of the patients, in term of age, sex, body mass index, type and duration of atrial fibrillation, which reflects the homogeneous criteria used to select candidates for atrial fibrillation ablation in the considered time interval. The procedure was standardized as described elsewhere[31] and it was alternatively performed by two operators with a similar experience in atrial fibrillation ablation (> 400 procedures each), although the background in interventional electrophysiology was different (23 years *vs* 10 years, respectively). Importantly, the radiation exposure for the pre-procedure computed tomography scan was very low (< 1 mSv) due to an optimized acquisition protocol[31]. In the 3rd and 4th cohort, the use of a third generation non-fluoroscopic three-dimensional system was optimized by adopting the features listed in Table 2, including in the 4th cohort the recently introduced

Table 2 Features of the third generation non-fluoroscopic system CARTO 3 useful to minimize fluoroscopy during an electrophysiology procedure

Feature	Function
Imaging integration with pre-acquired CT or MRI image	Allows high resolution visualization of the LA and PVs; once registered in the system, the mapping/ablation catheter can be navigated with minimal use of fluoroscopy
Display in stable mode of the icon of the mapping/ablation catheter	Allows stable visualization of the mapping/ablation catheter on the system, similar to the one visualized on fluoroscopy
Colors on the distal part of the mapping/ablation catheter	Indicate the direction of the deflection of the distal part of the catheter
Catheter projection	Estimates the distance from the catheter tip to the surface of the electroanatomic map or to the surface of the CT/MRI image
Contact force sensing	Measures in grams the contact between the catheter tip and the tissue; used to avoid excessive contact during catheter manipulation and to optimize contact during ablation
Real time display of the circular mapping catheter	Allows real time visualization of the circular mapping catheter during positioning into the PVs
Highlight of the circular mapping catheter electrodes	Identify the position of the electrodes of the circular mapping catheter; used to identify the site of a conducting gap during circumferential PV ablation
Catheter snapshot	Shows a memorized position of a catheter (*e.g.*, circular mapping catheter); used to precisely re-navigated a previous catheter positioning

CT: Computed tomography; LA: Left atrium; MRI: Magnetic resonance imaging; PV: Pulmonary vein.

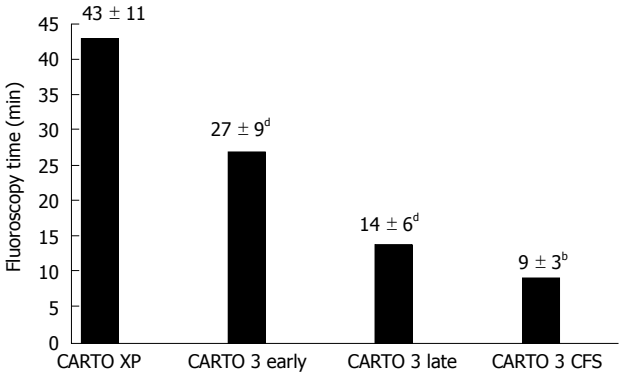

Figure 1 Histogram of fluoroscopy time (in minutes) for the whole procedure of pulmonary vein isolation in four cohorts of patients with atrial fibrillation, using the non-fluoroscopic CARTO system with progressively new technologies and protocols. There is a progressive and significant reduction in fluoroscopy time, but the greatest percent reduction (-48%) is observed between the second and third cohort, CARTO 3 early *vs* CARTO 3 late. In these two cohorts the technology was the same, but in the second one the system was used with an optimized protocol to reduce fluoroscopy. $^{b}P < 0.001$ *vs* the previous cohort; $^{d}P < 0.0001$ *vs* the previous cohort. CFS: Contact force sensing.

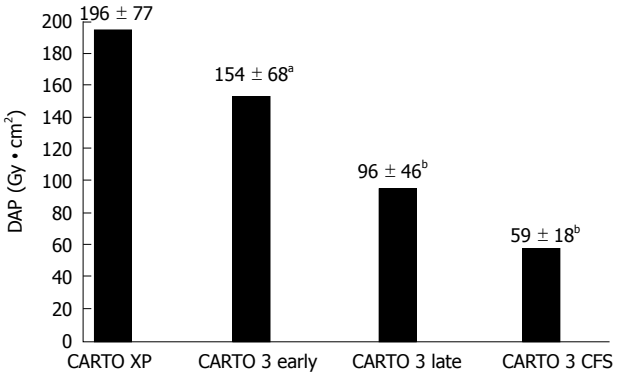

Figure 2 Histogram of dose area product values (in Gy•cm^2) for the whole procedure of pulmonary vein isolation in the same cohorts shown in Figure 1. As in Figure 1, there is a progressive and significant reduction in radiation exposure, expressed by the dose area product value. $^{a}P < 0.05$ *vs* the previous cohort; $^{b}P < 0.0001$ *vs* the previous cohort. DAP: Dose area product; CFS: Contact force sensing.

contact force sensing technology[32]. This was mainly used to avoid excessive contact force between the tip of the mapping/ablation catheter and the endocardium when the catheter was advanced non-fluoroscopically. Importantly, during non-fluoroscopic navigation of the catheter, its position was continuously monitored on the CARTO, to avoid events at risk for complications, such as entrapment of the circular mapping catheter in the mitral valve apparatus. While the procedural data, in term of procedure duration, number of pulmonary vein isolated, radiofrequency energy time, acute success and complication, was not significantly different among the four cohorts, there was a progressive decrease in fluoroscopy time and DAP values, as shown in Figures 1 and 2, respectively. Sub-analyzing data per operator, there are interesting findings when the 1st cohort is compared to the 2nd and the 2nd to the 3rd. In the first comparison, the more experienced operator obtained a 46% reduction (from 41 ± 9 to 22 ± 6 min, on average; $P < 0.0001$) in fluoroscopy time compared to only a 22% reduction (from 43 ± 13 to 33 ± 9 min, on average; $P = 0.0012$) obtained by the less experienced operator. Interestingly, an opposite phenomenon was observed in the second comparison: the more experienced operator, who had already obtained a greater reduction in the use of fluoroscopy, had a 36% reduction in fluoroscopy time (from 22 ± 6 min to 14 ± 5 min, on average; $P < 0.001$), definitely smaller than the 54% reduction obtained by the second operator (from 33 ± 9 min to 15 ± 7 min, on average, $P < 0.001$).

These data deserve two considerations, on the technology and the learning curve, respectively. First, the ability to reduce significantly radiation exposure towards a near zero-fluoroscopy procedure depends on the type and quality of the non-fluoroscopic system. A third generation non-fluoroscopic system, able to reliably visualize all the catheters inserted in the heart,

allows catheter manipulation with minimal or no use of fluoroscopy leading to an immediate improvement in radiation exposure compared to the older system. This was confirmed in the multicentric study in 240 consecutive patients undergoing catheter ablation of atrial fibrillation[30]. In this study, the average fluoroscopy time decreased from 26 ± 15 min to 16 ± 12 min ($P < 0.001$) and the positive effect of adopting the third generation system was significant in all the participating centers. The importance of the technology is further confirmed by the observation in our center of a still significant reduction in radiation exposure when the newer contact force sensing technology was introduced. The second consideration is on the need for a specific learning curve. Although in the multicenter study[30] the reduction in the use of fluoroscopy is observed in all centers, the percent reduction spans from 25% to 56% among centers. This is likely to be related to a specific learning curve in reduction of radiation exposure. In fact, considering again the data from our center, a more experienced electrophysiologist may exhibit a shorter learning curve in the reduction of radiation exposure, while a less experienced one eventually reaches the same level of ability in non-fluoroscopic maneuvering of catheters after a longer learning curve.

CONCLUSION

Over the last years, the awareness of the radiation injury hazard to the patients and the professional staff has greatly increased. Reduction in the radiation exposure in a complex electrophysiology procedure, such as atrial fibrillation ablation, should be considered. This is an increasingly used procedure with usually longer fluoroscopy times. Therefore, the decrease in radiation exposure is expected to improve the net benefit of the procedure for the patient and to minimize the radiation injury hazard for the professional staff. The lesson learned so far tells us that sophisticated technologies have to combine with a specific know-how to achieve this task. In fact, non-fluoroscopic three-dimensional systems with their constant updating in the technology content have a key role, but minimization in the use of radiations is obtained if these technologies are used with an optimized protocol and after a specific operators' learning curve. This may last several months and be longer for less experience operators.

Abstract

Atherosclerosis is a major complication of diabetes, increasing the risk of cardiovascular related morbidities and mortalities. The hallmark of diabetes is hyperglycemia which duration is best predicted by elevated glycated haemoglobin A_{1c} (HbA_{1c}) levels. Diabetic complications are usually attributed to oxidative stress associated with glycation of major structural and functional proteins. This non-enzymatic glycation of long lived proteins such as collagen, albumin, fibrinogen, liver enzymes and globulins result in the formation of early and advanced glycation end products (AGEs) associated with the production of myriads of free radicles and oxidants that have detrimental effects leading to diabetic complications. AGEs have been extensively discussed in the literature as etiological factors in the advancement of atherogenic events. Mechanisms described include the effects of glycation on protein structure and function that lead to defective receptor binding, impairment of immune system and enzyme function and alteration of basement membrane structural integrity. Hemoglobin (Hb) is a major circulating protein susceptible to glycation. Glycated Hb, namely HbA_{1c} is used as a useful tool in the diagnosis of diabetes progression. Many studies have shown strong positive associations between elevated HbA_{1c} levels and existing cardiovascular disease and major risk factors. Also, several studies presented HbA_{1c} as an independent predictor of cardiovascular risk. In spite of extensive reports on positive associations, limited evidence is available considering the role of glycated Hb in the etiology of atherosclerosis. This editorial highlights potential mechanisms by which glycated hemoglobin may contribute, as a causative factor, to the progression of atherosclerosis in diabetics.

Key words: Glycated hemoglobin; Glycoxidative stress; Advanced glycation end products; Atherosclerosis; Diabetes mellitus

Core tip: Glycated hemoglobin is a useful marker for the diagnosis of diabetes progression. Many studies present glycated haemoglobin (HbA_{1c}) as an independent predictor of cardiovascular risk in diabetics. Although haemoglobin (Hb) is a major circulating protein, limited

information is available about the role of glycated Hb as such in the etiology of atherosclerosis. This editorial highlights potential mechanisms by which glycated hemoglobin may contribute, as a causative factor, to the progression of atherosclerosis in diabetics.

Saleh J. Glycated hemoglobin and its spinoffs: Cardiovascular disease markers or risk factors? *World J Cardiol* 2015; 7(8): 449-453 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i8/449.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i8.449

EDITORIAL

Abundant evidence exists that patients with diabetes mellitus have an increased risk of atherosclerosis and are more vulnerable to its progression into cardiovascular disease[1]. Several mechanisms were proposed to describe the pathogenesis of atherosclerosis in diabetic patients. Vascular endothelial cell damage, as a result of blood flow shear stress, increased blood viscosity and oxidative stress were described in several studies[1-4]. The chronic hyperglycemic state in diabetes creates an environment of oxidative stress manifested as a glycoxidative state[5]. This state is characterized by the accumulation of glycated proteins that are further modified into advanced glycation end products (AGEs). The discovery of AGEs dates back to 1912 when Louis-Camille Maillard originally observed a chemical reaction between amino acids and reducing sugars that gave browned foods their desirable flavor[6]. Human proteins normally undergo spontaneous non-enzymatic glycation reaction forming low levels of glycated products[7]. However, chronic exposure to abnormally high glucose levels leads to further modifications. The aldehyde group of the glucose molecule combines with the amino group of a lysine molecule in a protein to form a Schiff base which is a double bond between the carbon atom of the glucose and the nitrogen atom of lysine. The Schiff bases form Amadori products that undergo further molecular rearrangements producing advanced glycated end products AGEs. The formation of AGEs is accompanied by the release of myriads of oxidants and free radicals that cause oxidative damage in the cells and extracellular matrix. Subsequent degradation of AGEs produces more reactive oxidant species and protein reactive aldehydes that contribute to further macromolecular alterations[1,8,9]. In diabetes, long-lived proteins such as collagen, elastin and many enzymes are affected by advanced glycation which disrupts their structure and function[10]. Accumulation of AGE products contribute to a variety of vascular complications through the formation of cross-links between molecules leading to hardening of the vascular extracellular matrix (ECM) and increasing vascular permeability[9-11]. Modification of the extracellular matrix by AGEs traps cholesterol rich lipoproteins promoting their oxidation and stimulates an inflammatory response that accelerates plaque formation and advancement of the atherogenic process. Evidence of the formation of AGEs and their detrimental role in the pathogenesis and development of cardiovascular disease is extensively reported in the literature[10-13].

GLYCATED HEMOGLOBIN AS A DIAGNOSTIC MARKER AND ADVANCED GLYCATION PRODUCT

The extent and duration of hyperglycemia is best predicted by increased levels of glycated hemoglobin (glycated Hb) of which HbA_{1c} is considered a reliable marker[14,15]. HbA_{1c} in the medical literature is commonly described as a useful measure to reflect the duration of increased blood glucose levels up to several months[14]. Numerous studies have shown positive associations between elevated HbA_{1c} levels and cardiovascular disease including acute coronary syndrome, acute myocardial infarction and heart failure[15,16]. Large prospective cohort studies showed that HbA_{1c} is not only a diagnostic marker of diabetes progression, but also an independent cardiovascular risk predictor[17]. As mentioned earlier, prolonged sugar exposure produces early and AGEs affecting different proteins. A major example of early glycated proteins is HbA_{1c} which is further modified, through a series of reactions, into Hb-AGE[18]. Under normal conditions Hb-AGE constitutes 0.42% of circulating Hb levels which increases to 0.75% in diabetic subjects[19]. In spite of extensive reports showing positive associations between increased HbA_{1c} levels and cardiovascular risk in diabetics, the role of HbA_{1c} and Hb-AGE as potential etiological culprits in diabetic disease progression has been rarely discussed. This editorial highlights mechanisms by which glycated Hb may contribute, as a causative factor, to the initiation and development of atherosclerosis in diabetics.

HB GLYCATION ACCENTUATES INTRACELLULAR OXIDATIVE STRESS AND INCREASES ERYTHROCYTE FRAGILITY

Besides albumin, hemoglobin comprises a major fraction of circulating proteins that are susceptible to early and advanced glycation events. Glycation is accelerated in diabetics[11] where glucose uptake by erythrocytes is insulin independent and highly uncontrolled. Furthermore, glycated Hb is more readily oxidized and degraded by erythrocyte proteolytic enzymes than unglycated Hb[20,21] enhancing oxidative stress by increasing the release of heme and free iron in association with free radicles[22-25]. The released ferrous iron (II) reacts with hydrogen peroxide *via* the

Fenton reaction forming ferric iron (II) and hydroxyl radicals[26]. These reactive species contribute to further oxidative stress damaging lipids and proteins that alter cell membrane properties and lead to increased erythrocyte fragility[27,28]. High exposure to oxygen during gas transport render erythrocytes even more vulnerable to oxidative damage. However, damage is normally prevented by anti-oxidant factors that maintain a balanced intracellular oxidation status. This balanced environment maintains an intact Hb structure which itself exerts a stabilizing effect on erythrocyte membrane structure. When Hb structure is altered due to persistent glyco-oxidative stress, Hb becomes more susceptible to degradation decreasing the life span of erythrocytes. Studies have shown a decreased life span of 6.9 d for 1% increase in glycated Hb levels[29].

HB GLYCATION AFFECTS BLOOD VISCOSITY AND CONTRIBUTES TO ENDOTHELIAL INFLAMMATION AND VASCULAR DYSFUNCTION

Intracellular glyco-oxidative stress may contribute to vascular endothelial damage through several mechanisms: (1) accumulation of intracellular free radicals alters erythrocyte membrane properties leading to erythrocyte aggregation, increased blood viscosity and impaired blood flow. Shear stress, due to thicker abrasive blood consistency, affecting the vascular endothelium and triggering an inflammatory response that contribute to subsequent atherogenic events[3,4,27,28,30]; (2) buildup of free radicles promotes the oxidation of ferrous Hb (Hb-Fe^{2+}) into ferric Hb (Hb-Fe^{3+}) (methemoglobin), which is further modified, through several oxidation steps, into ferryl hemoglobin (Hb-Fe^{3+}/Fe^{4+}). The ferryl iron (Fe^{4+}) is unstable and regains the Fe^{3+} state by reacting with specific amino acids in hemoglobin forming covalently cross-linked Hb multimers[31]. The altered Hb structure promotes cellular damage and releases ferryl Hb into the subendothelial matrix. Silva *et al*[32] demonstrated that ferryl Hb, rather than Hb, or methemoglobin, increased endothelial permeability and production of pro-inflammatory monocyte adhesion proteins that promote macrophage accumulation and a local inflammatory reaction preceding plaque formation; (3) Free Hb penetrates the vascular smooth muscle layer[33] and inactivates endothelium-dependent relaxation induced by acetylcholine[34] possibly through binding to nitric oxide (NO) which is a potent vasodilator which initiates vaso-relaxation in response to stimuli. Nitric oxide also inhibits formation of oxidized LDL[35] which detrimental to endothelial integrity. Inactivation of NO is a major marker of endothelial dysfunction manifested in impaired vasoactive responses[35]. Rodríguez-Mañas *et al*[36] demonstrated that highly glycosylated Hb inhibited nitric oxide mediated relaxation to a larger extent than low glycated and unglycated Hb. The authors suggested that Hb-AGEs may exacerbate this effect as abundant *in vitro* and *in vivo* evidence demonstrates that AGEs inhibit nitric oxide production and function[36]; and (4) Furthermore, accelerated degradation of erythrocytes releases heme which sensitizes endothelial cells to oxidative damage and promotes oxidation of endothelial proteins and low density lipoproteins (LDLs)[31].

Altogether, these adverse modifications trigger a proliferative inflammatory response in the subendothelial space which involves recruitment of a myriad of inflammatory and immune factors including monocytes, platelets, lymphocytes and increased production of various growth factors and cytokines such as IL-1 and TNF-α and adhesion molecules[37]. Oxidized LDL particles are subsequently scavenged by macrophages forming lipid rich foam cells that contribute to the formation of fatty streaks and subsequent build-up of plaque. As atherosclerotic plaque builds up, further insult to the endothelium activates a vicious cycle of inflammatory/oxidation events and further progression of atherosclerosis[38]. The list of endothelial mediators that contribute to this inflammatory/atherogenic process continues to grow. Interleukin-17 (IL-17), produced by T-helper cells, induces chemokines such as IL-6, IFN-γ and TNF-α to recruit monocytes and neutrophils to the site of inflammation. Recent evidence points to additional allergic/hypergic responses, induced by IL-17, which involve cytokines such as IL-8 and eotaxin believed to play a role in atherogenesis. IL-17 induces eotaxin secretion from smooth muscles, macrophages and fat tissue in the atheromatous plaque[39]. The recruitment of eosinophils by eotaxin during the inflammatory process was recently linked to vascular inflammation and cardiovascular disease[40]. Exploring the relation between these inflammatory mediators and oxidative modification of glycated Hb may provide new avenues for understanding the progression of atherogenic events.

In summary, accumulating evidence suggests that glycation of Hb and formation of Hb-AGE in diabetics exacerbate cellular oxidative stress releasing potent oxidants which contribute to endothelial oxidative damage and trigger a vicious cycle of oxidative/inflammatory responses. Recruitment of inflammatory mediators contributes to the progression of atherogenesis and the development of diabetic vascular complications. Designing preventive and therapeutic measures that target hemoglobin glyco-oxidative pathways may be useful tools for the management and control of atherosclerosis progression and cardiovascular disease in diabetics.

Abstract

Adipose tissue-derived stem cells (ADSCs) are adult stem cells that can be easily harvested from subcutaneous adipose tissue. Many studies have demonstrated that ADSCs differentiate into vascular endothelial cells (VECs), vascular smooth muscle cells (VSMCs), and cardiomyocytes *in vitro* and *in vivo*. However, ADSCs may fuse with tissue-resident cells and obtain the corresponding characteristics of those cells. If fusion occurs, ADSCs may express markers of VECs, VSMCs, and cardiomyocytes without direct differentiation into these cell types. ADSCs also produce a variety of paracrine factors such as vascular endothelial growth factor, hepatocyte growth factor, and insulin-like growth factor-1 that have proangiogenic and/or antiapoptotic activities. Thus, ADSCs have the potential to regenerate the cardiovascular system *via* direct differentiation into VECs, VSMCs, and cardiomyocytes, fusion with tissue-resident cells, and the production of paracrine factors. Numerous animal studies have demonstrated the efficacy of ADSC implantation in the treatment of acute myocardial infarction (AMI), ischemic cardiomyopathy (ICM), dilated cardiomyopathy, hindlimb ischemia, and stroke. Clinical studies regarding the use of autologous ADSCs for treating patients with AMI and ICM have recently been initiated. ADSC implantation has been reported as safe and effective so far. Therefore, ADSCs appear to be useful for the treatment of cardiovascular disease. However, the tumorigenic potential of ADSCs requires careful evaluation before their safe clinical application.

Key words: Adipose tissue-derived stem cells; Cardiovascular disease; Acute myocardial infarction; Ischemic cardiomyopathy; Hindlimb ischemia; Stroke

Core tip: Adipose tissue-derived stem cells (ADSCs) have been used for the treatment of cardiovascular disease with the efficacy of ADSC implantation demonstrated in animal models. However, the mechanisms under-

lying the capacity of ADSCs for regenerating the cardiovascular system remain controversial. ADSCs may differentiate into blood vessels and cardiomyocytes, fuse with other cell types, obtaining the characteristics of those cells, and secrete paracrine factors that have proangiogenic and/or antiapoptotic activities. This review also discusses recently initiated clinical trials using autologous ADSCs.

INTRODUCTION

Cardiovascular disease (CVD) is a leading cause of morbidity and mortality worldwide. Despite advances in the treatment of acute myocardial infarction (AMI) using percutaneous coronary intervention, the treatment of heart failure (HF), which occurs as a result of the death of myocardial tissues and subsequent tissue remodeling, is still a challenging problem. As cardiomyocytes are terminally differentiated cells with minimal regenerative capacity, heart transplantation is currently the only treatment option for end-stage ischemic heart disease. The development of new therapies for AMI and HF is required to meet this substantial clinical requirement. Thus, stem cell therapy for CVD has recently gained substantial attention.

Stem cells are defined as cells capable of self-renewal and differentiation into a variety of phenotypes[1]. Stem cells comprise embryonic stem cells (ESCs) and adult stem cells (ASCs). ESCs were originally isolated from the inner cell mass of blastocysts[2], and are pluripotent stem cells capable of giving rise to all three germ layers. However, several issues, including ethical concerns and teratoma formation, limit the clinical use of ESCs. Induced pluripotent stem (iPS) cells are also pluripotent stem cells that have very similar characteristics to ESCs[3,4]. As ethical problems can be avoided, iPS cells represent a potentially promising option for stem cell therapy. However, cancer formation is a major issue that needs to be overcome before widespread acceptance of the use of iPS cells in clinical settings. ASCs are multipotent stem cells that reside in various adult tissues. Among ASCs, bone marrow-derived mesenchymal stem cells (BMMSCs) and adipose tissue-derived stem cells (ADSCs) are the most extensively studied. BMMSCs are reported to have the potential to differentiate into various cell types including bone, cartilage, cardiac muscle, skeletal muscle, vascular endothelial cells (VECs), and vascular smooth muscle cells (VSMCs)[5,6]. BMMSCs have been used to treat CVD in clinical settings, with promising results reported in a number of studies[7-14], although other studies failed to demonstrate positive outcomes[15,16]. ADSCs have gained substantial attention recently as subcutaneous adipose tissues are abundant and can be easily harvested using liposuction, a procedure that is less invasive than bone marrow aspiration, with minimal donor discomfort. Adipose tissue contains a significantly greater proportion of stem cells than the bone marrow (5% *vs* 0.01%) and is therefore a convenient source of stem cells[17]. Furthermore, ADSCs reportedly do not express class II major histocompatibility complexes[18,19], suggesting that ADSCs may be suitable for allogenic transplantation in addition to autologous transplantation. In this review, we discuss the characteristics of ADSCs and their potential use in the treatment of CVD.

CLASSIFICATION OF ADSCS

ADSCs can be obtained from subcutaneous adipose tissues with the use of collagenase digestion. Freshly isolated ADSCs (fADSCs) are known to be heterogeneous and contain hematopoietic cells ($CD45^+$ and/or $CD34^+$) and VECs ($CD34^+/CD31^+$) in addition to stem cells ($CD44^+$ and $CD105^+$)[20]. fADSCs can be cultured on plastic dishes in the presence of fetal bovine serum (FBS). Non-adherent cells, those that do not attach to plastic dishes, can be removed to obtain cultured ADSCs (cADSCs), a relatively homogeneous population that expresses stem cell markers, such as CD44 and CD105, but not hematopoietic lineage markers, including CD11b, CD45, and CD34 or the VEC marker CD31[21,22]. Artificially-modified ADSCs (mADSCs) are a type of ADSCs produced through the introduction of specific genes[23,24] or pre-treatment with drugs[25] before administration. The purpose of artificial modification is to improve the function of ADSCs, such as proangiogenic and antiapoptotic activities. cADSCs have been the most widely used type, particularly in animal studies. However, fADSCs may be more suitable for clinical applications for several reasons. First, fADSCs can be rapidly prepared compared with cADSCs as cell culture is not required while preparing fADSCs. The rapid preparation and administration of stem cells may be required to achieve sufficient recovery from tissue ischemia when treating AMI or critical hindlimb ischemia. Second, the preparation of fADSCs is technically less challenging compared with that of cADSCs as it does not require the use of foreign materials such as FBS. ADSCs used in clinical settings must not contain any foreign materials derived from animals or humans other than the individual patient receiving the stem cell therapy. Therefore, it is desirable to avoid culturing in the preparation of ADSCs for clinical applications.

DIFFERENTIATION POTENTIAL OF ADSCS *IN VITRO*

ADSCs have the potential to differentiate into cartilage,

bone, tendon, and fat when cultured under lineage-specific conditions[26-29]. Furthermore, ADSCs have the potential to differentiate into VECs, VSMCs, and cardiomyocytes *in vitro* (Table 1), the main components of the cardiovascular system. Miranville *et al*[30] isolated and examined the characteristics of human fADSCs. Human fADSCs were found to express CD34 (27.6%-63.4%) with CD34 positive cells shown to be composed of two populations: $CD34^+/CD31^+$ cells (probably VECs) and $CD34^+/CD31^-$ cells. The authors demonstrated $CD34^+/CD31^-$ cells expressed CD31 and von Willebrand factor (vWF) when cultured in a medium containing vascular endothelial growth factor (VEGF) and insulin-like growth factor (IGF). Planat-Benard *et al*[31] used relatively fresh human cADSCs cultured on plastic dishes for 3 d without passaging. Approximately 90% of these cells were found to express CD34, and they expressed VEC markers, including CD31 and vWF, when cultured in a semisolid medium. Rodríguez *et al*[32] studied human cADSCs cultured in MCDB 131 medium supplemented with 1% FBS. The authors found these cells expressed VSMC markers, including α-smooth muscle actin (SMA), calponin, caldesmon, myosin heavy chain, and smooth muscle protein 22-α (SM22α). Furthermore, differentiated cells contracted in response to carbachol demonstrated contractile capacity. Jeon *et al*[33] demonstrated the use of sphingosylphosphorylcholine (SPC) to induce the differentiation of human cADSCs into VSMCs, as determined by SMA, calponin, and SM22α expression. They also found that SPC-induced differentiation of ADSCs into VSMCs depended on transforming growth factor-β (TGF-β), shown to be secreted by ADSCs in an autocrine manner. Rangappa *et al*[34] incubated rabbit cADSCs with 5-azacytidine. The authors demonstrated that these cells differentiated into spontaneously beating cardiomyocytes with expression of myosin heavy chain, sarcomeric α-actinin, and troponin I. Gaustad *et al*[35] incubated human cADSCs with rat cardiomyocyte extracts and demonstrated ADSC expression of cardiomyocyte markers, including sarcomeric α-actinin, desmin, and cardiac troponin I. Differentiated cells were also shown to beat autonomously. Planat-Bénard *et al*[36] cultured murine fADSCs in a semisolid methylcellulose medium without 5-azacytidine and found that ADSCs expressed cardiac-specific markers, such as transcription factors, GATA-4, and Nkx2.5. These cells demonstrated spontaneous beating with acceleration in response to isoproterenol, a β-agonist, and deceleration in response to carbamylcholine, an acetylcholine agonist.

DIFFERENTIATION POTENTIAL OF ADSCS *IN VIVO*

It has also been suggested that ADSCs express VEC, VSMC, and cardiomyocyte markers *in vivo* (Table 2). For example, cADSCs administered in a hindlimb ischemia model[31] and AMI model[37] were reportedly incorporated into tissues and were found to express VEC markers, such as CD31 and vWF. ADSC implantation has been shown to improve blood flow in a murine hindlimb ischemia model[31]. Jack *et al*[38] injected human cADSCs into the bladder and urethra and demonstrated the expression of SMA, a marker for VSMCs, by engrafted cells. Valina *et al*[37] injected porcine cADSCs into the coronary artery following the induction of AMI and found that a proportion of engrafted cells expressed SMA. The authors also found that left ventricular function recovered following administration of ADSCs. Strem *et al*[39] prepared fADSCs from Rosa 26 mice ubiquitously expressing β-galactosidase and injected these cells into the intraventricular chamber following myocardial cryoinjury. The authors demonstrated co-expression of β-galactosidase with myosin heavy chain, Nkx2.5, and troponin I. Yamada *et al*[40] transplanted the CD29 positive fraction of murine cADSCs into the infarct border zone of an AMI model and demonstrated

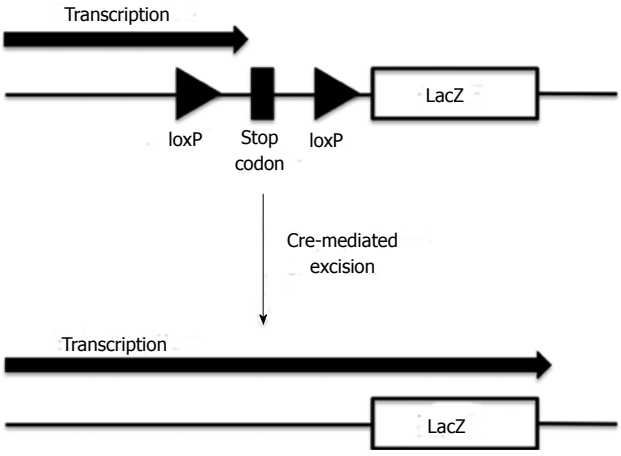

Figure 1 Schematic representation of LacZ expression following the excision of a floxed stop codon by Cre recombinase.

the expression of cardiomyocyte markers, such as sarcomeric actin and GATA-4. Furthermore, improved left ventricular function was observed in this study.

However, cell fusion should be considered carefully before concluding that ADSCs have the potential to differentiate into VECs, VSMCs, or cardiomyocytes *in vivo*. The *in vivo* fusion of administered ADSCs with tissue-resident VECs, VSMCs, and/or cardiomyocytes may lead to ADSCs acquiring the phenotypes of the corresponding fused cell types, making it appear as if ADSCs are directly differentiating into these cell types. In fact, cell fusion has been shown to occur with the *in vivo* administration of BMMSCs. Alvarez-Dolado *et al*[41] used R26R mice that contain a *lacZ* reporter gene downstream of a stop codon flanked by loxP sites (floxed). The *lacZ* reporter gene was therefore only expressed when the loxP-flanked stop codon was excised by Cre recombinase (Figure 1). The authors lethally irradiated these mice and transplanted BMMSCs from mice that ubiquitously express Cre recombinase and green fluorescent protein (GFP). If cells from the donor and recipient fused, the Cre enzyme would excise the Lox P-flanked stop codon, thereby allowing the expression of the *lacZ* gene. The results of this study revealed β-gal$^+$ (fused) and GFP$^+$ cells in the brain, heart, and liver of recipients, at 2 and 4 mo post-transplantation. Thus, BMMSCs potentially fuse with other cell types *in vivo*. There have been no reports so far clearly demonstrating the fusion of ADSCs with other cell types *in vivo*. Bai *et al*[42] injected both human fADSCs and cADSCs into murine hearts and examined the occurrence of cell fusion using fluorescence *in situ* hybridization to detect human X chromosomes and murine Y chromosomes. The authors did not detect co-localization of human X chromosomes with murine Y chromosomes in individual cells, excluding the possibility of cell fusion events. However, similar techniques used to detect cell fusion by BMMSCs (*e.g.*, the transplantation of ADSCs derived from transgenic mice expressing Cre recombinase into recipients expressing a *lacZ* reporter gene downstream of a floxed stop codon) should be used to conclusively determine whether ADSCs fuse with other tissue-resident cell types. Interestingly, Metzele *et al*[43] artificially fused human cADSCs with neonatal rat cardiomyocytes using hemagglutinating virus of Japan. The authors demonstrated spontaneous beating of fused ADSCs and the expression of human troponin I, suggesting fused ADSCs produced cardiomyogenic proteins. Furthermore, fused ADSCs were positive for the cell proliferation marker Ki67, suggesting proliferating capacity in marked contrast to terminally differentiated cardiomyocytes that are unable to proliferate. Therefore, ADSCs may stimulate the regeneration of heart muscles through *in vivo* fusion with cardiomyocytes.

PRODUCTION OF PARACRINE FACTORS BY ADSCS

ADSCs have been shown to produce a variety of proangiogenic and antiapoptotic factors. Rehman *et al*[44] examined the production of paracrine factors by human cADSCs. The authors showed that ADSCs produced VEGF, hepatocyte growth factor (HGF), and TGF-β. VEGF production increased five-fold when ADSCs were cultured under hypoxic conditions. Condi-

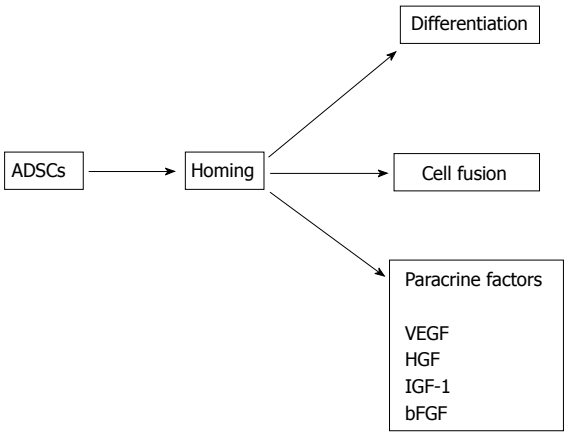

Figure 2 Possible mechanisms underlying the effect of adipose tissue-derived stem cells on regeneration of the cardiovascular system. ADSCs: Adipose tissue-derived stem cells; VEGF: Vascular endothelial growth factor; HGF: Hepatocyte growth factor; IGF-1: Insulin-like growth factor-1; bFGF: Basic fibroblast growth factor.

tioned medium (CM) obtained from hypoxic ADSCs significantly increased the proliferation and survival of VECs. Furthermore, the administration of these ADSCs significantly improved perfusion in a hindlimb ischemia model. Nakagami *et al*[45] reported murine cADSCs produce VEGF and HGF. The authors also administered ADSCs in a mouse hindlimb ischemia model and found transplanted ADSCs improved blood flow. However, transplanted ADSCs did not express VEC or VSMC markers, suggesting that ADSCs did not differentiate into vascular components in this study. Sadat *et al*[46] demonstrated human cADSCs produce VEGF and IGF-I and that these cytokines contribute to the antiapoptotic effects of ADSCs on cardiomyocytes. The authors implicated the secretion of VEGF by ADSCs in the ADSC-induced stimulation of tube formation by VECs. Yeghiazarians *et al*[47] administered BMMSCs and their lysates into the heart in a murine AMI model. The authors revealed that both BMMSCs and their lysates improved cardiac function and histology to similar extents, suggesting cytokines produced by BMMSCs, but not cells *per se*, are required for the recovery of cardiac function. Bhang *et al*[48] used a three-dimensional spheroid culture of human ADSCs to prepared CM. The authors injected CM into ischemic regions in a murine hindlimb ischemia model. They detected restoration of blood perfusion in this model. Albersen *et al*[49] injected rat cADSCs and their lysates into the penis in a rat model of cavernous nerve injury. The authors found that both ADSCs and their lysates restored erectile function to similar extents. These results suggest substances secreted by ADSCs, rather than cells *per se*, are critical for their regenerative function. Collectively, these results suggest that paracrine factors produced by ADSCs play a major, if not all, role in the regeneration of the cardiovascular system, although the differentiation and cell fusion of ADSCs may also be involved. The possible mechanisms underlying the regenerative effects of ADSCs on the cardiovascular system are summarized in Figure 2.

SURVIVAL OF ADSCS *IN VIVO*

The survival and engraftment of ADSCs *in vivo* have been examined within 30 d of ADSC implantation in the majority of studies[37,50-53]. Yin *et al*[54] injected swine cADSCs into the coronary artery following induction of AMI and examined the fate of ADSCs 8 wk after injection. The authors found that many ADSCs expressed troponin T and α-sarcomeric actin, indicating the ability of ADSCs to survive for 8 wk. Bai *et al*[42] introduced a luciferase reporter gene into human cADSCs and transplanted these cells into the murine heart muscle using an AMI model. The authors detected luciferase-positive ADSCs by bioluminescence imaging. Bioluminescence was observed 16 wk after ADSC transplantation, indicating that some ADSCs survived for 16 wk. However, murine cADSCs transplanted in a hindlimb ischemia model were found to barely remain in ischemic tissues 28 d after transplantation[45]. Therefore, the survival and engraftment of ADSCs in recipient tissues appear to vary according to the animal species and experimental models used.

APPLICATION OF ADSCS TO TREAT CVD

AMI and ischemic cardiomyopathy

Many studies have demonstrated the efficacy of ADSC administration in recovering cardiac function in AMI models. cADSCs have been predominantly used in animal models[37,39,40,51-57], although fADSCs[58] and mADSCs[23-25,59] have also been used. ADSCs have been transplanted *via* the coronary artery[37,53,54,57] and directly into cardiac muscles[23-25,39,40,51,55,56,58,59] in previous studies. Although ADSC implantation into the heart showed efficacy in recovering cardiac function in most studies, the underlying mechanisms remain controversial. Transplanted ADSCs expressed VEC, VSMC, or cardiomyocyte markers in numerous studies[37,39,40,52-55,57,59]; however, the "differentiation" of ADSCs was either not detected or examined in other studies[23-25,51,56,58]. Bai *et al*[42] transplanted both fADSCs and cADSCs in a murine AMI model and found both cell types recovered cardiac function to a similar extent. A proportion of transplanted fADSCs and cADSCs were found to express cardiomyocyte markers, including troponin I and connexin 43. These results are encouraging as fADSCs may be more suitable for clinical applications than cADSCs for reasons outlined above. ADSCs differentiated into specific cell types have been used to treat chronic MI. Okura *et al*[60] induced the differentiation of human cADSCs into cardiomyoblast-like cells (CLCs) *in vitro* and transplanted these cells into the swine coronary arteries 4 wk following the induction of MI. Cardiac function was

recovered by CLC implantation. Furthermore, implanted CLCs expressed human α-cardiac actin, Nkx2.5, and GATA-4. Several studies have used a monolayer sheet to transplant ADSCs into chronic MI models. Miyahara *et al*[61] cultured rat ADSCs on a temperature-responsive polymer to prepare a monolayer of ADSCs. The authors transplanted these cells onto scarred myocardium at 4 wk following coronary ligation. Transplanted cells grew *in situ* to form a thick stratum containing newly-formed blood vessels. The transplantation of monolayered cells prevented ventricular wall scarring and improved cardiac function. Okura *et al*[62] induced the differentiation of human cADSCs into CLCs *in vitro* and prepared monolayer sheets of human CLCs and ADSCs using a temperature-responsive polymer. The authors then transplanted these cells onto the infarcted areas of rats 4 wk following the induction of MI. The authors demonstrated that the implantation of CLCs, but not ADSCs, resulted in a long-term recovery of cardiac function and improved survival. Furthermore, CLCs, but not ADSCs, were found to express human troponin I.

Clinical trials of ADSCs in the treatment of AMI have recently been initiated. The AdiPOse-derived stem ceLLs in the treatment of patients with ST-elevation myOcardial infarction (APOLLO) trial is a double-blind, placebo-controlled, phase Ⅰ/Ⅱa trial[63]. Autologous fADSCs were transplanted into the coronary artery of AMI patients with ST-segment elevation following successful revascularization. During the 6-mo follow-up period, improvements in the left ventricular ejection fraction and myocardial perfusion and reductions in the infarct size were demonstrated. The subsequent phase Ⅱ/Ⅲ trial, called ADVANCE, is currently ongoing. In this trial, AMI patients with ST elevation are treated with intracoronary implantation of autologous fADSCs. The primary endpoint is reduction in the infarct size as measured by magnetic resonance imaging. The adiPose-deRived stEm Cells In the treatment of patients with non revaScularizable ischEmic myocardium (PRECISE) trial enrolled patients who had chronic ischemic cardiomyopathy (ICM) not amenable to any revascularization procedures[64]. Autologous fADSCs were transplanted into cardiac muscles from endocardial sites. Maximal oxygen consumption and total left ventricular mass were significantly improved by ADSCs implantation. The ATHENA trial is an ongoing clinical trial intending to treat patients who have chronic ICM with HF symptoms using autologous fADSCs. The endpoints of this trial include peak oxygen consumption, perfusion defects, HF symptoms, left ventricle end-systolic and diastolic volume, and ejection fraction.

Dilated cardiomyopathy

Several studies have demonstrated the efficacy of ADSC implantation in the recovery of cardiac function using dilated cardiomyopathy (DCM) models. Lin *et al*[65] used a rat DCM model induced by the injection of porcine myosin and implanted cADSCs into cardiac muscle. The effect of combination therapy with ADSCs and sildenafil, a phosphodiesterase type-5 inhibitor, was also evaluated. This study found that either ADSCs implantation alone or sildenafil treatment alone was effective for the recovery of cardiac function, with combination therapy being the most effective. Hamdi *et al*[66] transplanted a monolayer sheet of murine cADSCs onto the heart surface in a murine DCM model, in which a floxed serum response factor gene is conditionally deleted using the expression of Cre recombinase. The authors found many blood vessels in transplanted sheets and some transplanted ADSCs in the cardiac muscle, a proportion of which expressed CD31. The authors further demonstrated the recovery of cardiac function and significant reduction of cardiac fibrosis following ADSC transplantation. Pınarlı *et al*[67] transplanted cADSCs into a doxorubicin-induced HF model. They further examined combination therapy of ADSC transplantation with resveratrol, a polyphenolic compound found in red grapes with an antioxidant activity. This study found either ADSC implantation alone, or resveratrol administration alone, was effective in recovering cardiac function, although combination therapy was found to be most effective.

Hindlimb ischemia

A number of studies have demonstrated that ADSC implantation improves blood flow in animal hindlimb ischemia models. fADSCs[30,68], cADSCs[31,45,48,69-76], and mADSCs[77] have all been used in these studies. Although the efficacy of ADSC administration in the recovery of blood flow appears conclusive, the mechanisms underlying the ability of ADSCs to recover blood flow remain controversial. ADSCs have been shown to engraft and express VEC and/or VSMC markers in some studies[30,31,69,70,72,75,77]. However, other studies have shown that engraftment was either not observed or examined[68,76] or paracrine factors secreted by ADSCs appeared to predominantly mediate the recovery of blood flow[45,48,70,71,73,74,77]. Lee *et al*[76] performed the transplantation of autologous cADSCs in 15 patients with critical limb ischemia. Although this was a pilot study, ADSC implantation caused no complications during the follow-up period and clinical improvement was observed in 66.7% patients. Larger-scale clinical studies are required to conclusively evaluate the efficacy and safety of ADSC transplantation in the treatment of limb ischemia.

Stroke

Several studies have demonstrated ADSC implantation induces functional recovery following brain ischemia in animal models of cerebral infarction (CI)[78-81]. Kang *et al*[78] occluded the middle cerebral artery (MCA) to induce CI and transplanted human cADSCs into the lateral ventricle. Transplanted ADSCs migrated to the border zone of the injured area and intact brain tissue and into injured areas. A proportion of ADSCs were found to express microtubule-associated protein 2 (MAP2), a neuron marker, and glial fibrillary acid

protein (GFAP), an astrocyte marker. Furthermore, ADSC implantation improved motor and somatosensory behavior following CI, although no reduction in the area of CI was observed following ADSC implantation. Gutiérrez-Fernández *et al*[79] injected cADSCs intravenously following MCA occlusion in rats and found a significant recovery of motor function, although no reduction in the infarct size or ADSC engraftment into damaged tissues was observed. Furthermore, the expression of VEGF, synaptophysin, a neuron marker, and neurofilament was significantly increased following ADSC injection, although it was not examined whether ADSCs *per se* produced these molecules. Liu *et al*[80] transplanted human cADSCs into the right corpus striatum and cerebral cortex of rats following MCA occlusion. Neurological deficits were significantly attenuated by ADSC administration. Significantly increased expression of brain-derived neurotrophic factor (BDNF), nerve growth factor, and basic fibroblast growth factor mRNA and increased protein levels of BDNF and Bcl-2 were observed following ADSC transplantation, although it was not examined whether ADSCs produced these molecules.

Coronary artery restenosis

Balloon injury of the carotid artery and wire injury of the femoral artery have been widely used as models of coronary artery restenosis. We implanted rat cADSCs around the femoral artery from the adventitial side following wire injury of the femoral artery and found that ADSC implantation significantly inhibited neointimal formation and stimulated re-endothelialization[82]. We also demonstrated that ADSCs produced angiopoietin-1 (Ang-1) and that the effect of ADSC administration diminished when expression of Ang-1 was suppressed using small interfering RNA (siRNA) against Ang-1[83] (Figure 3), indicating that Ang-1 produced by ADSCs plays a critical role in the inhibition of neointimal formation. Although drug-eluting stents (DES) are widely used and they potently inhibit restenosis, the use of DES does not always improve patient outcomes, most likely due to increased risk of late thrombosis[84,85]. Because DES inhibit the proliferation of VECs as well as VSMCs by secreting antiproliferative drugs, DES may delay re-endothelialization, resulting in thrombus formation. Therefore, agents that stimulate re-endothelialization, such as Ang-1, may be more suitable for the suppression of neointimal formation than currently used inhibitors of cell proliferation. Systematic analysis of ADSC cytokine production is required to identify molecules that inhibit neointimal formation and stimulate re-endothelialization.

FUTURE DIRECTIONS

Careful examination of the following points is required before the safe and effective clinical application of ADSCs.

Tumorigenesis

Although ADSCs may be less prone to forming tumors than ESCs, it has been reported that BMMSCs form tumors *in vivo*[86]. Furthermore, several reports have suggested ADSCs promote the proliferation of cancer cells both *in vitro* and *in vivo*[87-89]. Therefore, ADSCs may stimulate the growth of pre-existing tumors even if ADSCs *per se* do not form tumors.

Effects of age and comorbid diseases on the function of ADSCs

Patients suffering from CVD are often older and have comorbid diseases, such as hypertension and diabetes. When considering the autologous transplantation of ADSCs in these patients, it is necessary to examine whether age and comorbid diseases affect the function of ADSCs. Several studies have demonstrated that ADSCs collected from aged patients have less capacity for proliferation and differentiation compared to those collected from young donors[90-92]. Furthermore, several reports have shown that ADSCs collected from diabetic mice, hemodialysis patients, and HF patients have less capacity for proliferation, differentiation, or proangiogenic cytokine production[93-95]. Therefore, patients requiring ADSC transplantation for the treatment of CVD may not have access to high-quality autologous ADSCs. Allogenic transplantation of ADSCs may be required in these patients.

Improved ADSC survival and function

The use of mADSCs may improve the survival and/or function of ADSCs. The incubation of ADSCs with chemical compounds, culture in hypoxic conditions, or the introduction of ectopic genes are all potential methods for the pre-implantation modification of ADSCs. It is noteworthy that ADSCs cultured under hypoxic conditions have demonstrated increased capacity for proliferation, proangiogenic cytokine production, and maintenance of stemness[96-98]. The incubation of fADSCs under hypoxic conditions prior to implantation into patients may be a feasible strategy for improving the results of ADSC implantation.

Identification of paracrine factors

ADSCs produce a variety of paracrine factors, as aforementioned, and these factors appear to play a major role in the regeneration of the cardiovascular system. Elucidation of cytokine combinations with the greatest efficacy in the regeneration of the cardiovascular system may remove the need for ADSC implantation in the future.

CONCLUSION

Evidence accumulated from animal studies has indicated that ADSCs show efficacy in the treatment of CVD including AMI, ICM, and critical limb ischemia. Clinical trials have reported the safety and efficacy of ADSC

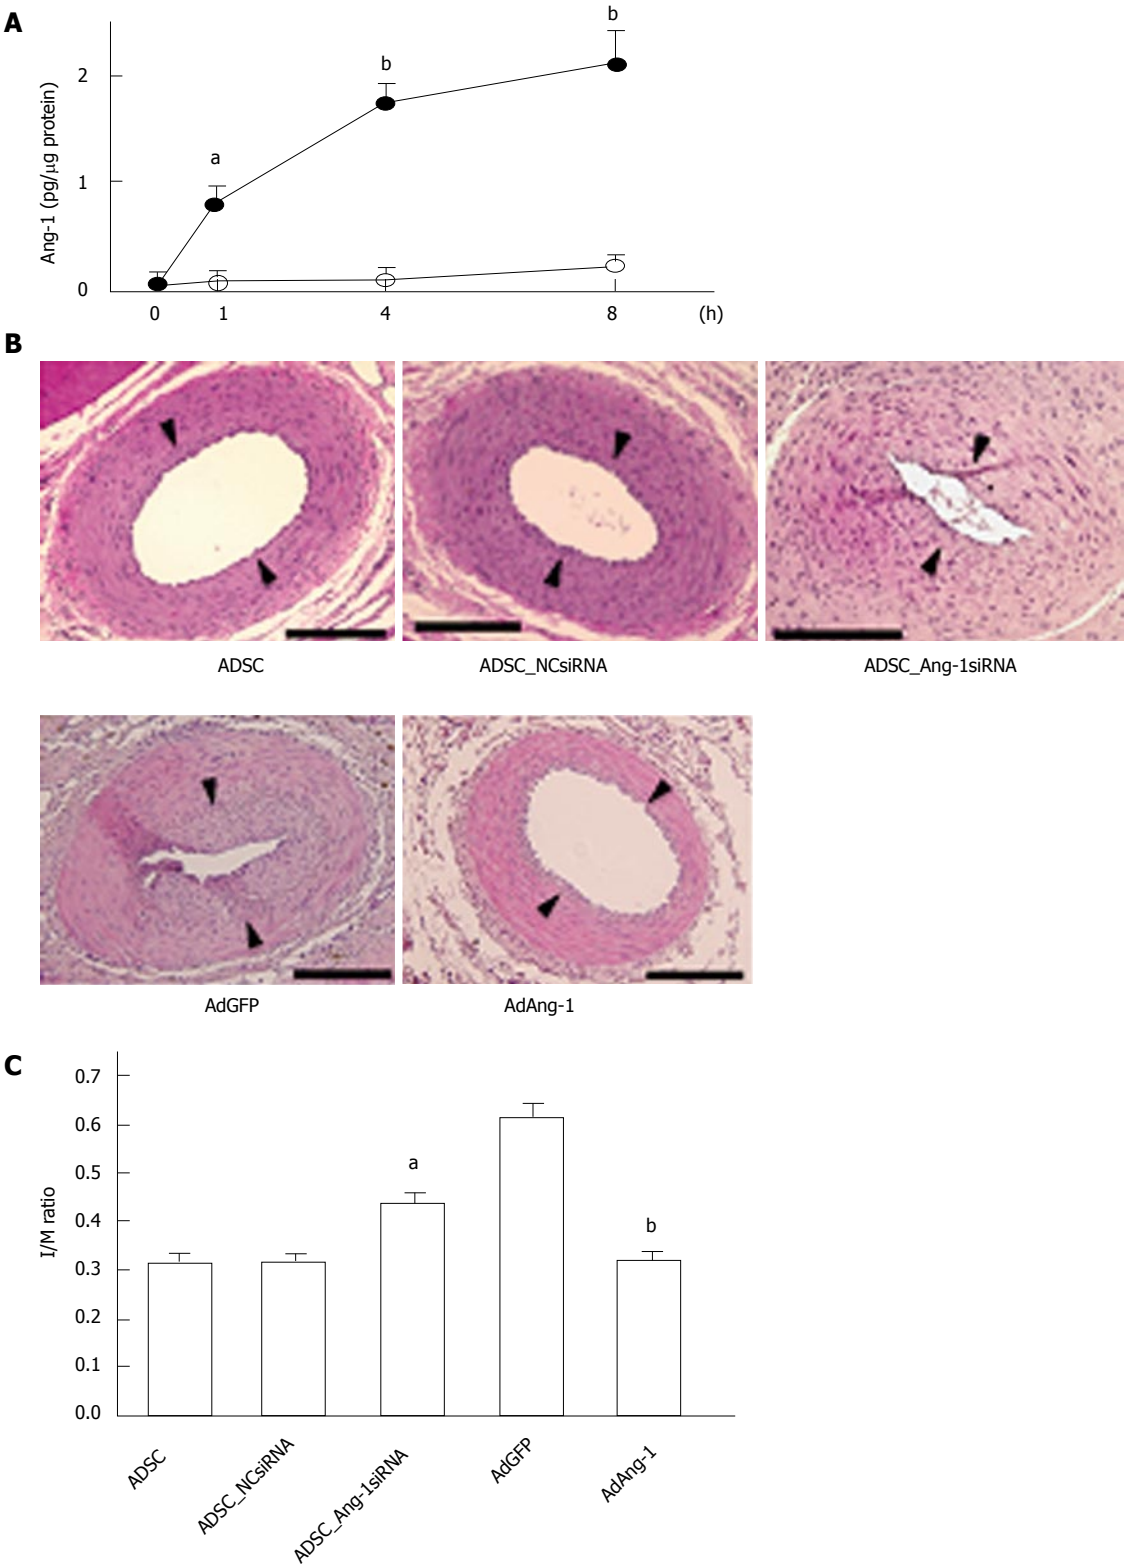

Figure 3 Ang-1 is implicated in Adipose tissue-derived stem cell-induced suppression of neointimal formation. A: ADSCs produce Ang-1, particularly when cultured in medium containing growth factors for VECs. Rat ADSCs were plated in 24-well plates and cultured in control medium (open circles) or medium containing growth factors for VECs (EGM: closed circles) for 1 wk. After washing with PBS, the medium was replaced with serum-free Dulbecco's modified Eagle medium and incubated for the indicated periods. Ang-1 accumulation was measured with an enzyme-linked immunosorbent assay kit. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* 0 h ($n = 6$ per group); B: Effect of knockdown of endogenous Ang-1 in ADSCs and forced expression of Ang-1 on neointimal formation. ADSCs were infected with lentivirus expressing negative control siRNA (NCsiRNA), which does not suppress the expression of mammalian mRNA, or lentivirus expressing Ang-1 siRNA (Ang-1siRNA). ADSCs not infected with lentivirus were used as positive controls (ADSC). ADSCs were cultured in EGM for 1 wk. ADSCs (10^6 cells) were seeded from the adventitial side immediately after wire injury of the rat femoral artery. Adenoviruses expressing green fluorescent protein (AdGFP) or Ang-1 (AdAng-1) were also injected into the femoral artery from the adventitial side following wire injury. Femoral arteries were harvested 14 d after injury for histological analyses. Arrowheads indicate the position of internal elastic lamina. Bars represent 100 μm; C: I/M ratios were compared among the groups ($n = 8$ per group). $^{a}P < 0.05$ *vs* NCsiRNA infection and $^{b}P < 0.01$ *vs* AdGFP infection. PBS: Phosphate-buffered saline; ADSCs: Adipose tissue-derived stem cells; VECs: Vascular endothelial cells.

implantation in the treatment of CVD. ADSCs may regenerate tissues through a number of mechanisms including direct differentiation into VECs, VSMCs, and cardiomyocytes, fusion with tissue-resident cells, and secretion of proangiogenic and antiapoptotic cytokines. The malignant potential of ADSCs should be carefully examined in the future.

Abstract

Early repolarization syndrome (ERS), demonstrated as J-point elevation on an electrocardiograph, was formerly thought to be a benign entity, but the recent studies have demonstrated that it can be linked to a considerable risk of life - threatening arrhythmias and sudden cardiac death (SCD). Early repolarization characteristics associated with SCD include high - amplitude J-point elevation, horizontal and/or down-slopping ST segments, and inferior and/or lateral leads location. The prevalence of ERS varies between 3% and 24%, depending on age, sex and J-point elevation (0.05 mV *vs* 0.1 mV) being the main determinants. ERS patients are sporadic and they are at a higher risk of having recurrent cardiac events. Implantable cardioverter-defibrillator implantation and isoproterenol are the suggested therapies in this set of patients. On the other hand, asymptomatic patients with ERS are common and have a better prognosis. The risk stratification in asymptomatic patients with ERS still remains a grey area. This review provides an outline of the up-to-date evidence associated with ERS and the risk of life - threatening arrhythmias. Further prospective studies are required to elucidate the mechanisms of ventricular arrhythmogenesis in patients with ERS.

INTRODUCTION

Sudden cardiac death (SCD) is defined as natural death due to cardiac causes in a person who may or may not have previously recognized heart disease but in whom the time and mode of death are unexpected[1]. In the context of time, "sudden" is defined for most clinical and epidemiologic purposes as 1 h or less between a change in clinical status heralding the onset of the terminal clinical event and the cardiac arrest itself[1]. The overwhelming majority of SCD cases are related to cardiac arrhythmias[2]. The commonest electrophysiologic mechanisms leading to SCD are ventricular arrhythmias. About 10% of the cases of SCD are related to primary electrophysiological disorders with known (*e.g.*, Brugada syndrome) or unknown (*e.g.*, idiopathic VF) ion-channel abnormalities[1,3-8].

Early repolarization (ER), also recognized as "J-waves" or "J-point elevation"' is an electrocardiographic abnormality consistent with elevation of the junction between the end of the QRS complex and the beginning of the ST segment in 2 contiguous leads[9,10]. Grant *et al*[11] are considered to be the first who used the term ER to describe ST-segment deviations and related T wave inversion and premature repolarization was thought to be the underlying aetiology.

The so - called "early repolarization syndrome (ERS)" was unanimously and indisputably regarded as "normal," a "normal variant", or a "benign early repolarization" until 2000[12]. However, numerous more recent reports have suggested a relationship between ER and an increased risk of death from cardiac arrhythmias[8,13-19].

ERS is an electrocardiographic (ECG) entity characterized by J-point elevation manifested either as either QRS slurring (at the transition from the QRS segment to the ST-segment) or notching (a positive deflection inscribed on terminal S wave), ST segment elevation with upper concavity and prominent T-waves in at least two contiguous leads[20] (Figure 1).

PREVALENCE

The ERS is commonly seen in athletes, cocaine users, hypertrophic obstructive cardiomyopathy and defects and/or hypertrophy of interventricular septal defects[21-24]. Prevalence of ERS varies between 3% and 24% in the general population, depending on the population studied and methods used for ECG interpretation. Young individuals, especially those predisposed to vagotonia, males, African Americans, and athletes are subpopulations known to have a higher prevalence of ERS[19,20]. Tikkanen *et al*[13] demonstrated that the location (inferior *vs* lateral leads) as well as J-point elevation of > 0.2 mV are linked to a significant risk of death from cardiac arrhythmias (adjusted relative risk, 2.98; 95%CI: 1.85-4.92; $P < 0.001$).

HISTORICAL PERSPECTIVE

The J-deflection presenting as either QRS slurring or notching was first described in 1936 by Shilpey *et al*[25] and was considered a normal ECG variant. In 1938, Tomaszewski[26] presented the case of an accidently frozen man whose ECG demonstrated a very slowly inscribed deflection between the QRS complex and the earliest part of the ST segment, representing a J wave. In 1953, Osborn[27] described a "current of injury" later named "the Osborn wave" in acidotic and hypothermic dogs at rectal temperatures < 25 ℃.

In 1961, Wasserburger *et al*[28] further defined ER as a 1-4 mm takeoff of the ST-segment at the end of the QRS complex with a distinct notch or slur on the downslope of the R wave in the mid to left precordial leads.

In 1999, Gussak *et al*[29] suggested that ER may be malignant in some cases, based on observations that an ER pattern in arterial perfused wedge preparations can easily convert to one which gives rise to polymorphic ventricular tachycardia.

In 2000, evidence supporting above hypothesis was provided by Kalla *et al*[30] and Takagi *et al*[31]; they reported VF in patients with prominent J-wave and ST segment elevation in inferior leads without structural heart diseases and postulated that idiopathic VF with an ER pattern in inferior leads may represent a variant of the Brugada syndrome. In 2008, Haïssaguerre *et al*[8] and Nam *et al*[32] described a strong relationship between J-waves and many different forms of ventricular arrhythmias in the absence of known heart disease.

CELLULAR, MOLECULAR AND GENETIC CONSIDERATIONS

The pathophysiologic basis of the ER is currently not fully understood. The most discussed hypothesis incriminates that this may be related to either an increased susceptibility or vulnerability to cardiac arrest in critical ischemic conditions such as acute coronary syndromes[33], or to subtle changes in the cardiac action potential[34]. ER in its simplest form occurs in early phase of the cardiac action potential and is caused by the cardiac transient outward potassium current (I_{to}). If a situation arises where there is a reduced density of the I_{to} channels in the endocardium compared with

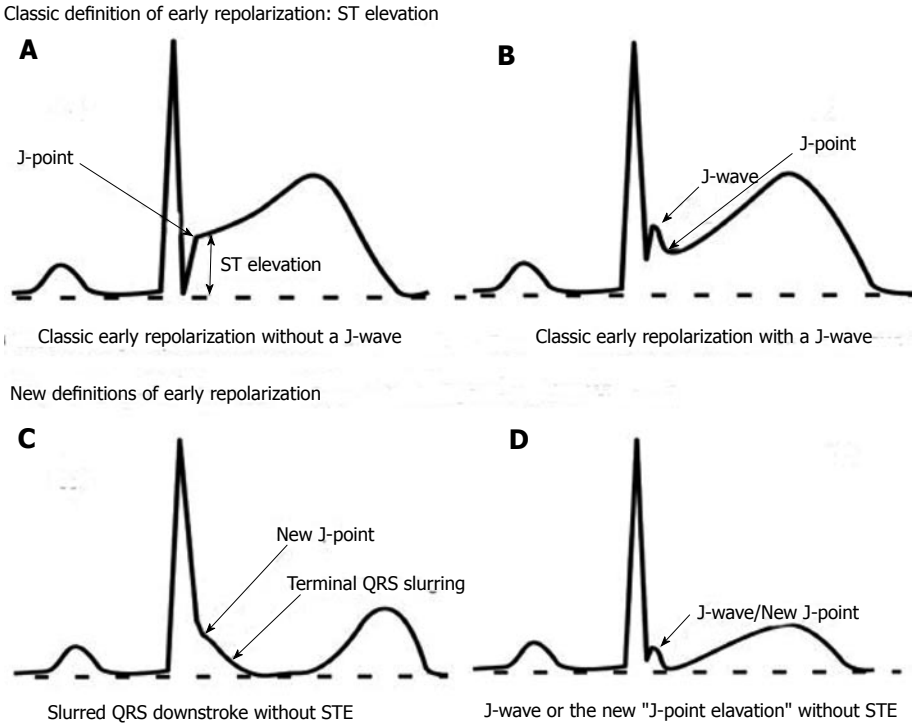

Figure 1 Examples of the classic and new definitions of early repolarization. Examples of the original (classic) and emerging (new) definitions of early repolarization (ER). A and B show the classic form of STE-type ER, which is the form identified by ECG software algorithms. Notice the presence of a J wave in (B), followed by an ascending/upsloping ST segment. Both forms are considered benign; C and D show the malignant form of ER demonstrated as slurring at the end of QRS complex (C) or a discrete notch/J wave (D) followed by a horizontal/downslopping ST segment (no ST elevation). Reproduced from ref.[49], with permission from the publisher. STE: ST elevation type ER; ECG: Electrocardiographic.

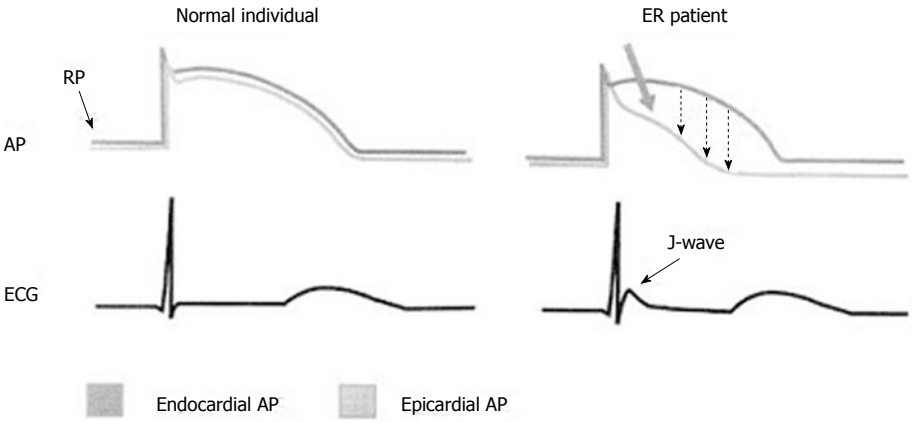

Figure 2 Schematic representation of the possible mechanisms underlying J-wave occurrence. Action potentials from epicardium and endocardium from normal individuals (left) and early repolarization (ER) patients (right) as well as the respective electrocardiograms are shown. A prominent phase I-notch and the loss of epicardial dome in phase - 2 (thick arrow) results in transmural dispersion of repolarization (dashed arrows) and appearance of the J-wave and ST-segment elevation on the surface ECG. AP: Action potential; ECG: Electrocardiogram; ER: Early repolarization; RP: Resting potention. Reproduced with permission, from ref.[67].

epicardium or mid-myocardium[35], a large Ito current can occur that results in electrocardiographic ER and large voltage gradients that may generate J wave elevation (Figure 2) and have the propensity to initiate life threatening arrhythmias[34,35].

Another hypothesis regarding the mechanism causing ER suggests an association of localized depolarization abnormalities with repolarization anomalies, as it happens in type 1 Brugada syndrome[36-39].

The genetic basis of ER syndrome continues to be elucidated, with the evidence restricted to either case reports or preliminary studies that fall short of clearly identifying the genetic basis of ER[40,41]. The reported implicated gene mutations involve the *KCNJ8* gene (responsible for the ATP sensitive potassium channel Kir6.1 - I_{KATP} current), *CACNA1C*, *CACNB2*, *CACNA2D1* genes (responsible for the cardiac L-type calcium channel - $I_{Ca.L}$ current), and the *SCN5A* gene (responsible for the sodium channel - I_{Na} current)[40-44]. All of these might enhance the underlying inward – outward current imbalance responsible for accelerated epicardial repolarization.

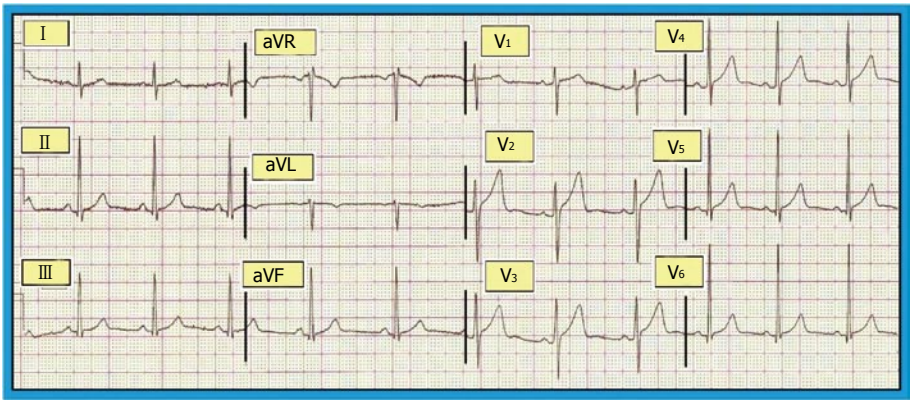

Figure 3 Benign early repolarization: Electrocardiogram showing ST segment elevation by at least 0.1 mV from the baseline. Reproduced with permission, from ref.[68].

CLINICAL MANIFESTATIONS OF ERS

The clinical presentation of patients with ERS can be subdivided into two main groups. The first includes those that manifest recognized symptoms of ERS, *i.e.*, high risk patients with syncope and survivors of cardiac arrest[45]. A study by Abe *et al*[46] demonstrated that the ER was noticed in 18.5% in patients with syncope compared to 2% in healthy controls, this equates to almost 10 - fold increase risk of syncope in patients with ERS. Although very rare, this group is highly likely to have recurrent cardiac events. In his study, Haissaguerre demonstrated 41% risk of arrhythmia recurrences in this cohort, when he followed up 64 ERS patients for a median of 51 mo[8].

The second and the most common group are asymptomatic patients who are incidentally noted to have an ER pattern on their ECG[8]. Overall, this group is less likely to have adverse cardiac events, and the challenge here lies in distinguishing those with risk of sudden cardiac death from those that are likely to run a benign course of the condition[47,48].

ECG DIAGNOSIS OF ERS

The electrocardiographic hallmark of ERS is elevation (> 1 mm above baseline) of the QRS - ST junction manifested as either QRS slurring or notching, ST-segment elevation with upper concavity, and prominent T-waves in two or more contiguous inferior and/or lateral leads in a patient resuscitated from otherwise unexplained ventricular arrhythmia[20]. Recent studies omitted ST segment elevation from the definition of ERS, and state that the J point changes described above is sufficient to diagnose ERS[49]. The inclusion or exclusion of right precordial leads is also an area for debate. Haïssaguerre *et al*[8] argue that in order to differentiate ERS from Brugada Syndrome, right precordial leads should be excluded, while others state that, the distinction is less straightforward. The latter group are backed by recent data pointing out the similarities in mechanism, overlapping genetic predisposition and the clinical findings of both conditions. Indeed, the term "J-Wave Syndrome" has been suggested to describe ERS and Brugada Syndrome as a spectrum of a clinical condition[36].

Antzelevitch *et al*[36] described three subtypes of ERS, and highlighted a pattern of risk profile: (1) type 1: It shows ER in the lateral precordial leads that is seen in healthy male athletes and has the lowest risk of malignant arrhythmias (Figure 3); (2) type 2: It shows ER in the inferior and inferolateral leads and is associated with a greater risk of malignant arrhythmias; and (3) type 3: It shows ER pattern in all ECG leads (Figure 4) and has the highest risk of malignant arrhythmias and electrical storms.

The Heart Rhythm Society/European Heart Rhythm Association/Asia Pacific Heart Rhythm Society (HRS/EHRA/APHRS) consensus statement on the diagnosis and management of primary inherited arrhythmia syndromes recommended criteria for the diagnosis of ER is shown in Table 1[50].

DIFFERENTIAL DIAGNOSIS

Early Repolarisation syndrome have a wide differential including Brugada Syndrome, short and long QT syndromes as well as other conditions causing ST segment elevation (ST segment elevation MI, acute pericarditis and idiopathic VF). Brugada sydnrome (BS), perhaps the closest clinical entity to ERS, is a primary repolarisation disorder characterized by a prominent J-wave causing a pattern of incomplete right bundle branch block and ST-segment elevation in the right precordial leads (V1-V3) (Figure 5) and significant risk of sudden cardiac death in individuals with no known structural heart disease[51]. BS, an autosomal dominant condition, is more common in males and has a variable penetrance[52,53]. Symptoms of BS include syncope with or without any warning signs, seizures and nocturnal agonal respiration; however, ECG remains the cornerstone of diagnosis of BS[54]. However, the Brugada ECG feature of provocation by sodium channel blocker is not observed in ER[55]. In fact, sodium channel blockers in most patients with ER

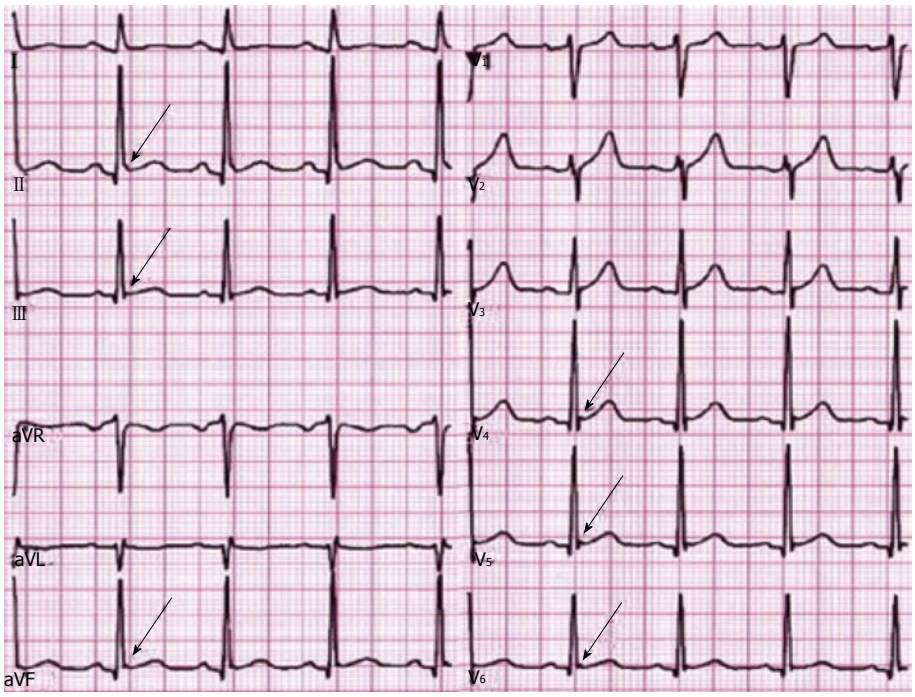

Figure 4 Malignant early repolarization: J-wave elevation (arrows) as slurring (lead II) and notching in the inferior and lateral leads and ascending ST segment in most leads. Reproduced with permission, from ref.[69].

Table 1 Heart Rhythm Society/European Heart Rhythm Association/Asia Pacific Heart Rhythm Society consensus statement on the diagnosis and management of primary inherited arrhythmia syndromes recommended criteria for the diagnosis of early repolarization

ER expert consensus recommendations on early repolarization diagnosis
ER syndrome is diagnosed in the presence of J-point elevation ≥ 1 mm in ≥ 2 contiguous inferior and/or lateral leads of a standard 12-lead ECG in a patient resuscitated from otherwise unexplained VF/polymorphic VT
ER syndrome can be diagnosed in an SCD victim with a negative autopsy and medical chart review with a previous ECG demonstrating J-point elevation ≥ 1 mm in ≥ 2 contiguous inferior and/or lateral leads of a standard 12-lead ECG
ER pattern can be diagnosed in the presence of J-point elevation ≥ 1 mm in ≥ 2 contiguous inferior and/or lateral leads of a standard 12-lead ECG

ER: Early repolarization; ECG: Electrocardiogram; SCD: Sudden cardiac death. Reproduced from ref.[50], with permission from the publisher.

attenuate the J-point, whereas the J-point is augmented by sodium-channel blockers in the right precordial leads in patients with a Brugada ECG.

In acute pericarditis, there is J-point elevation with resultant ST segment elevation, as seen in ER. Symptom presentation is distinctly different in the two conditions. Unlike ER, most patients with acute pericarditis have ST elevations diffusely in most or all limb and precordial leads. Additionally, patients with acute pericarditis often have deviation of the PR segment, which is not present in ER.

While patients with acute myocardial injury due to ST elevation myocardial infarction (STEMI) can initially have J-point elevation with concave ST segment elevation, the ST segment elevation typically becomes more pronounced and convex (rounded upward) as the infarction persists. However, the primary distinguishing factor between ER and acute myocardial injury is the presence of clinical symptoms such as chest pain or dyspnoea. ER and notching of the terminal QRS need to be considered in risk stratification for arrhythmias in patients with coronary artery disease and after coronary artery bypass grafting.

Table 2 gives a list of conditions with J-wave on the ECG.

BENIGN OR MALIGNANT

The identification of high-risk patients with ERS remains challenging. Currently, surface ECG is the only available tool in order to differentiate between the benign and the malignant forms of ERS. A horizontal or descending ST-segment elevation has been associated with adverse outcomes (compared with a rapidly ascending ST-segment elevation) following J-point elevation[56,57]. The extent of the J-point elevation may also have prognostic implication: a slurred or notched J-point elevation ≥ 2 mm (0.2 mV) appears to be associated with a higher risk[13,57]. Other abnormalities, such as localization of the ER pattern in inferior or inferolateral (compared with lateral) leads[3] or extension of ER into a BrS pattern, may also represent a worse prognosis[19,58,59].

The benign type of ERS is commonly associated with young age group, left ventricular hypertrophy on ECG,

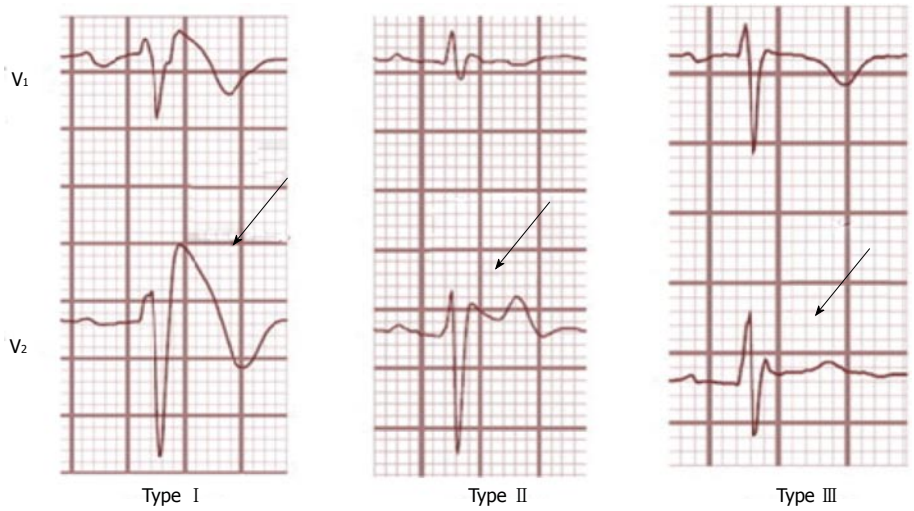

Figure 5 Brugada electrocardiogram-types. Type-1 is characterized by a complete or incomplete right bundle-branch block pattern with a coved morphology ST-segment elevation of ≥ 2 mm in the right precordial leads (V1-V3) followed by a negative T-wave. In type-2, ST-segment elevation has a saddleback appearance with a high takeoff ST-segment elevation of > 2 mm, a trough displaying > 1-mm ST-elevation followed by a positive or biphasic T-wave. Type-3 has an ST-segment morphology that is either saddleback or coved with an ST-segment elevation of < 1 mm. Reproduced with permission, from ref.[69].

lower blood pressure and lower heart rate, which are all features of healthy, physically active individuals. On the other hand, the malignant form of ERS, characterized by horizontal or descending ST-segment variation (Figure 6), is associated with older individuals and ECGs suggestive of ischaemic heart disease[60].

It appears that the morphology of the ST-segment could help in distinguishing "benign" from "malignant ER"[57]; nonetheless, there is no way to know who would be at considerable risk when presenting with slurring or notching of the QRS unless they have had a cardiac arrest[34].

TREATMENT

The ER pattern is a benign incidental finding, without any specific signs or symptoms attributed to it. There is no current risk stratification strategy for asymptomatic patients with ER pattern in general population and within families with ER pattern that would allow for identification of higher risk individuals with the ER pattern who might be candidates for treatment. The current consensus is that these patients do not require specific investigations or therapeutic interventions[28].

Among the survivors of SCD due to idiopathic VF, the reported rate of recurrent VF ranges between 22% and 37% at two to four years[6]. Because these patients have no structural heart disease, they have an excellent prognosis for long-term survival if VF is treated. As a result, such patients are best treated with an implantable cardioverter-defibrillator (ICD)[6,60-63]. HRS/EHRA/APHRS consensus statement on the diagnosis and management of primary inherited arrhythmia syndromes recommendations for therapeutic interventions in ERS are shown in Table 3[50].

It has been demonstrated that patients with VF and ER have a higher prevalence of recurrence of VF than VF patients without ER (43% *vs* 23%, $P < 0.001$) during a five years follow-up[8]. In a multicenter observational cohort study of 122 patients (90 males, mean age 37 ± 12 years) with ER in the inferolateral leads and more than three episodes of idiopathic VF (including those with electrical storm), isoproterenol was effective for the acute suppression of VF, immediately suppressing electrical storms in seven of seven patients[64]. In terms of long term therapy, VF recurrences have been demonstrated to be effectively suppressed by quinidine therapy[64]. Encouraging results recently emerged from a study by Gurabi *et al*[65], who demonstrated that in addition to quinidine, cilostazol, and milrinone suppress the hypothermia - induced VT/VF in a canine left ventricular model.

However, there exists a "gray area" in between the two ends of the spectrum, where no clear guidelines exist. Examples include patients with syncope who may have a "malignant" ER pattern and/or a significant family history of sudden cardiac death. The current guidelines suggest that ICD implantation may be

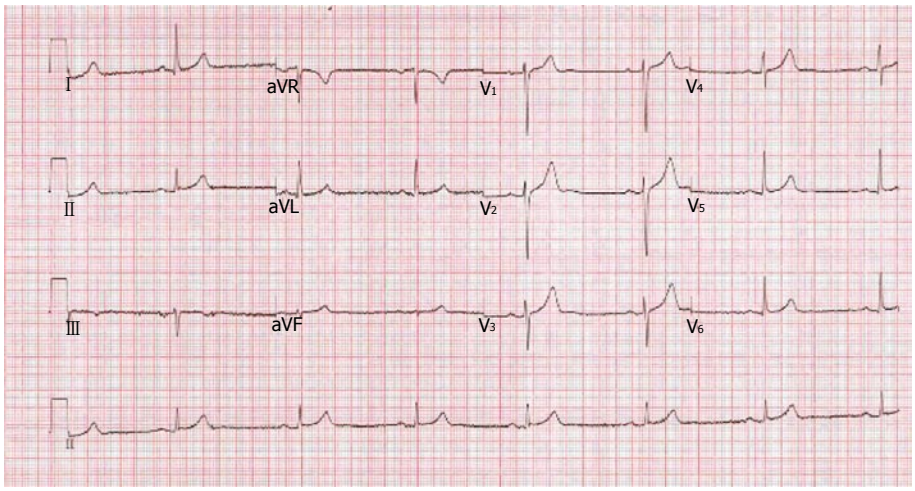

Figure 6 Malignant early repolarization: Horizontal ST-segment after early repolarization.

Table 3 Heart Rhythm Society/European Heart Rhythm Association/Asia Pacific Heart Rhythm Society consensus statement on the diagnosis and management of primary inherited arrhythmia syndromes recommendations for therapeutic interventions in early repolarization syndrome

Expert consensus recommendations on early repolarization therapeutic interventions		
Class Ⅰ	1	ICD implantation is recommended in patients with a diagnosis of ER syndrome who have survived a cardiac arrest
Class Ⅱa	2	Isoproterenol infusion can be useful in suppressing electrical storms in patients with a diagnosis of ER syndrome
	3	Quinidine in addition to an ICD can be useful for secondary prevention of VF in patients with a diagnosis of ER syndrome
Class Ⅱb	4	ICD implantation may be considered in symptomatic family members of ER syndrome patients with a history of syncope in the presence of ST-segment elevation > 1 mm in 2 or more inferior or lateral leads
	5	ICD implantation may be considered in asymptomatic individuals who demonstrate a high-risk ER ECG pattern (high J-wave amplitude, horizontal/descending ST segment) in the presence of a strong family history of juvenile unexplained sudden death with or without a pathogenic mutation
Class Ⅲ	6	ICD implantation is not recommended in asymptomatic patients with an isolated ER ECG pattern

ER: Early repolarization; ECG: Electrocardiogram; ICD: Implantable cardioverter-defibrillator.

considered in high-risk individuals with unexplained syncope[50].

SCREENING FAMILY MEMBERS

There are no current recommendations can be given to do ECG screening of the families of individuals with asymptomatic ER pattern or individuals with strong family history of ER or ER with VF. There are no recognized provocative tests that would help in diagnosing concealed ER in family members of patients with ERS, although preliminary observation advocate that concealed ER cases may be recognized by Valsalva maneurve[50,66].

CONCLUSION

In the recent years, ER syndrome has been associated with a significant risk of life - threatening arrhythmias and cardiac death. It is currently not possible to identify asymptomatic individual patients with ER who are at a higher risk of having cardiac arrhythmias with any clinically useful degree of accuracy. It is also not possible to identify asymptomatic individuals with a primary arrhythmogenic disorder attributable to ER. All patients with ER should continue to have modifiable cardiac risk factors addressed.

Until we have a better knowledge, physicians are left with the observation that in patients with ER in the inferolateral leads, life-threatening ventricular arrhythmias may occur and may lead to sudden cardiac death. Since there are a large number of patients who fit such a criteria but do not appear to have excess risk of arrhythmias, further data is needed to reveal how to identify the group of patients who would be at a significant risk and what measures can be taken to prevent it.

Abstract

Left ventricular twist is an essential part of left ventricular function. Nevertheless, knowledge is limited in "the cardiology community" as it comes to twist mechanics. Fortunately the development of speckle tracking echocardiography, allowing accurate, reproducible and rapid bedside assessment of left ventricular twist, has boosted the interest in this important mechanical aspect of left ventricular deformation. Although the fundamental physiological role of left ventricular twist is undisputable, the clinical relevance of assessment of left ventricular twist in cardiomyopathies still needs to be established. The fact remains; analysis of left ventricular twist mechanics has already provided substantial pathophysiological understanding on a comprehensive variety of cardiomyopathies. It has become clear that increased left ventricular twist in for example hypertrophic cardiomyopathy may be an early sign of subendocardial (microvascular) dysfunction. Furthermore, decreased left ventricular twist may be caused by left ventricular dilatation or an extensive myocardial scar. Finally, the detection of left ventricular rigid body rotation in noncompaction cardiomyopathy may provide an indispensible method to objectively confirm this difficult diagnosis. All this endorses the value of left ventricular twist in the field of cardiomyopathies and may further encourage the implementation of left ventricular twist parameters in the "diagnostic toolbox" for cardiomyopathies.

Key words: Left ventricular mechanics; Left ventricular twist; Cardiomyopathy

Core tip: Left ventricular twist is an essential part of left ventricular function. Nevertheless, knowledge is limited in "the cardiology community" as it comes to twist mechanics. It has become clear that increased left ventricular twist in for example hypertrophic cardiomyopathy may be an early sign of subendocardial (microvascular) dysfunction. Furthermore, decreased left ventricular twist may be caused by left ventricular

dilatation or an extensive myocardial scar. Finally, the detection of left ventricular rigid body rotation in noncompaction cardiomyopathy may provide an indispensible method to objectively confirm this difficult diagnosis. All this endorses the value of left ventricular twist in the field of cardiomyopathies and may further encourage the implementation of left ventricular twist parameters in the "diagnostic toolbox" for cardiomyopathies.

INTRODUCTION

As early as the 16th century Leonardo da Vinci[1,2] wrote about the twisting deformation of the heart and Richard Lower compared the myocardial contraction with "the wringing of a linen cloth to squeeze out the water" in his observations of myocardial contraction in 1669[3,4]. A complex spiral architecture is the mechanical basis for this wringing motion[5,6]. The left ventricle comprises of obliquely orientated multiple layers of cardiomyocytes, transforming from a subendocardially located (smaller-radius) right-handed helix to a subepicardial (larger-radius) left-handed helix.

This helix generates a torsional motion pattern caused by rotation in a clockwise direction (as seen from the apex) at the level of the mitral valve (basal level) and counter clockwise rotation of the apex (apical level). This twisting deformation performs a fundamental part in the mechanical efficiency of the heart resulting in a 60% ejection fraction with only 15% fibre shortening[7]. Furthermore, left ventricular untwisting is essential in actively aiding diastolic filling[8]. The physiology of left ventricular twist and changes of left ventricular twist in different cardiomyopathies are reviewed in this paper.

ASSESSMENT OF LEFT VENTRICULAR TWIST

By his first description of left ventricular twist, Leonardo da Vinci[1,2] has been a constant inspiration for scientists in their pursuit to comprehend the functioning of the human heart. Nevertheless, reliable quantitative measurement of left ventricular twist in a non-invasive manner has not been possible until recently.

Speckle tracking echocardiography is based on automated tracking of a specific portion of myocardial tissue being visualized by a pattern of gray values, a speckle pattern, on an ultrasound image. These gray values are the result of the analysis of the reflection of ultrasound interfering with the myocardial tissue. Therefore, movement of speckle patterns represent motion of myocardial tissue[9].

In case a of suitably high frame rate, the pattern of speckles is conserved from frame to frame[10]. By following a specific pattern of speckles, the motion of the corresponding myocardial segment can be tracked, thus allowing to quantify deformation of the myocardium and, as a function of time, deformation rate (Figure 1). Several validation studies[11,12] showed good correlation between left ventricular twist assessment by commercially available speckle tracking software and magnetic resonance imaging. Also, speckle tracking derived left ventricular twist has been shown to be feasible and reproducible, and may thereby be used as a method to follow-up patients[13].

PHYSIOLOGY OF LEFT VENTRICULAR TWIST

After the first description of left ventricular twist by Da Vinci, it lasted until the late 1960s before a more detailed description of twist was provided by Streeter *et al*[5] in a study of post-mortem canine hearts. Generally, myofibre position changes gradually from +60 degrees (circumferential axis as a reference) subendocardially to -60 degrees at the subepicardium. The counter coiled helix of subepi - and subendocardial fibres generates twist. The direction of basal and apical rotation is dominated by the larger - radius fibres at the subepicardium, caused by their longer arm of movement[14]. The significance of the direction of fibres has been demonstrated in patient studies as well[15]. Left ventricular twist showed a linear relation with sphericity index (as a measure of change in left ventricle fibre orientation, because in more spherically shaped hearts fibres are supposed to be oriented more horizontally) in patients with a dilated cardiomyopathy, supporting the hypothesis on twist mechanics and the influence of the direction of fibres on the twisting left ventricular deformation[14].

The influence of aging on twist was studied by several groups[16-19]. In all these studies, aging appeared to be related to an increase of left ventricular twist. As the function of the fibres at the subendocardium deteriorates when getting older, even in normal hearts[20,21], the reduction of the opposing rotational forces of the subendocardium will result in an increase of apical rotation by the already dominant subepicardial fibres and consequently in an increase of left ventricular twist. This increase of left ventricular twist appears to be a part of "physiological cardiac aging". One may hypothesize that this increase of twist contributes to the conservation of left ventricular stroke volume with ageing.

Untwisting begins after left ventricular twist reaches its peak, usually shortly before end-systole. Systolic twisting leads to storage of potential energy in the compressed coil of twisted fibres of the left

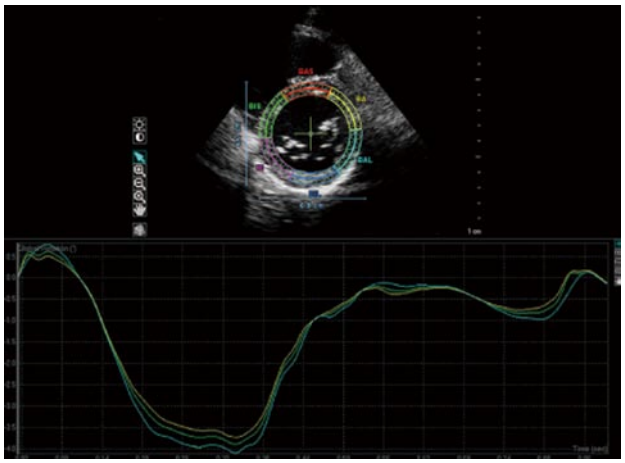

Figure 1 Example of QLAB workstation speckle-tracking analysis. Upper panel: 2D echo image of the basal left ventricular short axis. The software fully automatically draws the epicardial and endocardial contour of the myocardium. Lower panel: The software calculates the change in angle between the left ventricular (LV) wall and the virtual LV center during the cardiac cycle (green line). The blue and yellow line represent the angulation of the epicardial en endocardial angulation, respectively.

ventricular wall[19]. During isovolemic relaxation this coil springs open and releases this energy. Fibres at the subepicardium that are still depolarized and are at that time - in contrast to systole - not overruled by active contraction of the fibres located at the subepicardium, might dynamically reinforce this role of untwisting in diastole[19,22]. It was shown by magnetic resonance imaging that there is an important dissociation of time of untwist and filling, approximately 40% of the untwist takes place during isovolumic relaxation[23]. Furthermore, the extent of the diastolic intraventricular pressure gradient is strongly related to untwisting. Even more so, untwist precedes the development of this pressure gradient, thereby potentially being an important indicator of suction during early diastole[24,25].

TWIST MECHANICS IN CARDIOMYOPATHIES

Hypertrophic cardiomyopathy

Left ventricular twist in patients with hypertrophic cardiomyopathy is moderately increased, in particular the left ventricular basal rotation[26-29]. This augmented rotation at mitral valve level is probably caused by reduced counteraction of the subendocardial fibres, due to subendocardial ischemia caused by endocardial microvascular insufficiency and increased oxygen demand[30,31]. This is supported by the phenomenon of increased rotation being most pronounced in the hypertrophic segments[26]. A larger difference in radius between the subepicardium and subendocardium will increase the arm of effect on the already dominant fibres of the subepicardium and consequently will increase rotation at mitral valve level (basal rotation)[26].

There is a significant relation between the pattern of hypertrophy on apical rotation and twist. If the septum has a sigmoid curvature, rotation of the apex is more pronounced than in reverse septal curvature hearts. Outflow tract obstruction is more common in patients in whom the septum has a sigmoid curvature. The resulting intraventricular forces from these outflow tract gradients can lead to microvascular insufficiency and thereby to more (sub)endocardial ischemia. Subsequently, this lack of oxygen might cause impairment of the countereffect of contraction of the subendocardially located myocardial fibres on left ventricular twist.

The necessity to objectively demonstrate diastolic dysfunction in hypertrophic cardiomyopathy has caused an ongoing pursuit for a non invasive and load independent technique for quantifying the severity of diastolic dysfunction. For instance Takeuchi *et al*[32] examined the effect of left ventricular hypertrophy in hypertensive patients on untwisting of the left ventricle. In moderate to severe hypertrophy, untwisting was reduced and delayed as compared to healthy individuals, supposedly resulting in decreased function of left ventricular diastole. In hypertrophic cardiomyopathy[33] and also in aortic stenosis[34] the untwisting rate, being the mean untwisting velocity during the isovolumic relaxation phase, is decreased and as a result untwisting is delayed[27]. In hypertrophic cardiomyopathy this was most obvious in the affected segments[27,29]. Also, compromised elastic characteristics lead to suboptimal transformation of the potential kinetic energy stored in the twisted heart. Peak diastolic untwisting velocity is reduced in hypertrophic cardiomyopathy whereas it is augmented in aortic stenosis. In aortic stenosis twist is increased more severe. Release of the relatively high amount of potential energy results in increased untwisting, possibly compensating for otherwise diastolic dysfunction[27,35]. In hypertrophic cardiomyopathy twist is just discreetly increased, weakening this effect[27,33].

Dilated cardiomyopathy

Twist in non-ischaemic dilated left ventricles is known to be reduced. The abnormal shape of the left ventricle in dilated cardiomyopathy may cause a change in fibre orientation. This fibre orientation is of importance in left ventricular twist as described earlier. This influence was found as an independent linear relation between left ventricular sphericity index and peak systolic twist. The more dilated the left ventricle, the more decreased the left ventricular twist. Actually, also in patients with dilated cardiomyopathy and comparable left ventricular ejection fraction, sphericity index was still significantly related to left ventricular twist[15]. Nonetheless, derangement of myocardial fibre architecture is not the only cause for decreased left ventricular twist in patients with non-ischaemic dilated cardiomyopathy as fibrosis appeared to play a role in decreased left ventricular twist.

The extent of myocardial fibrosis in dilated cardiomyopathy has been evaluated by cardiac magnetic

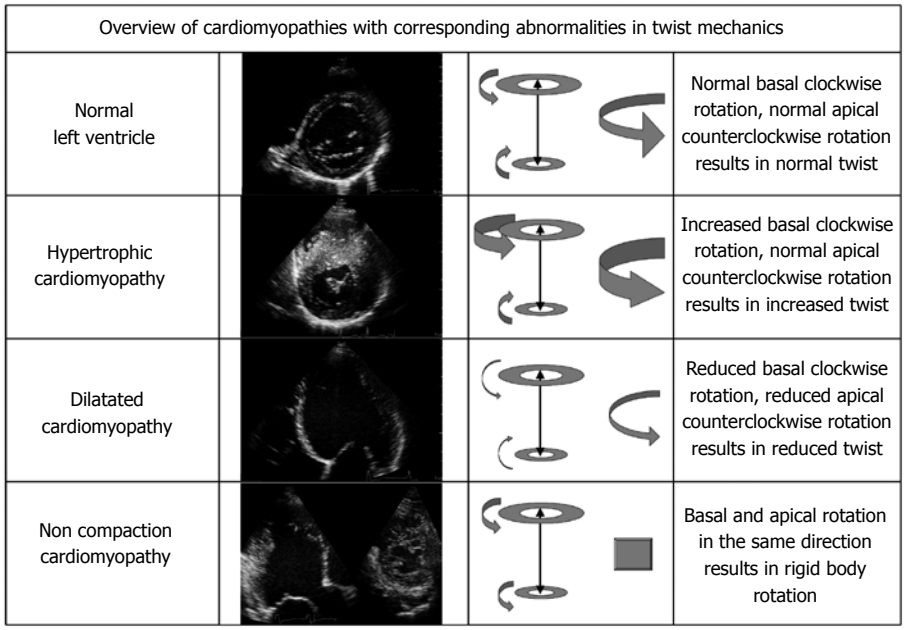

Figure 2 Overview of cardiomyopathies with corresponding abnormalities in left ventricular twist mechanics.

resonance imaging with late gadolinium enhancement. Fibrosis proved to be related to twist[36]. Reduction of twist indicated more extensive cardiac fibrosis.

As explained earlier, very rapid left ventricular untwisting is known to play a prominent part in fast filling in early diastole. However, in dilated hearts untwisting is delayed, leading to an apex-to-base-rotation delay. This will interfere with early diastolic suction and might harm filling of the left ventricle in dilated cardiomyopathy[27,37,38].

Noncompaction cardiomyopathy

Noncompaction cardiomyopathy is still subject to debate because of the shortcoming on consensus on its pathogenesis, diagnosis and treatment[39-41].

In the final embryonic development of the heart the myocardial tissue is transformed in a compact myocardium together with the formation of epicardial and endocardial fibre as oppositely wound helices[6,42]. As noncompaction cardiomyopathy is supposed to be caused by intrauterine arrest of cardiac embryogenesis during this transformation[43], distorted left ventricular twist features may be expected, even more than in the situation of reduced systolic function and a normally compacted myocardium. This was recognised in clinical studies[44-48] where noncompaction cardiomyopathy patients displayed a twist pattern with basal and apical rotation in the same direction, resulting in almost full absence of left ventricular twist. This rotation pattern is known as left ventricular rigid body rotation[44,49]. Rigid body rotation demonstrated, in a relative large study, to have a good predictive value for the diagnosis of noncompaction cardiomyopathy[47]. Even more interesting, all familial noncompaction cardiomyopathy patients showed rigid body rotation. The fact that noncompaction cardiomyopathy diagnosis is most definite in these patients underscores the good sensitivity of rigid body rotation in diagnosing noncompaction cardiomyopathy.

The clinical importance of left ventricular rigid body rotation was shown in more recent studies, where rigid body rotation was found in a majority of noncompaction cardiomyopathy patients as well[50,51], but the patients with rigid body rotation and noncompaction cardiomyopathy proved to have a lower NYHA functional status as compared to the patients without rigid body rotation[48].

Ischemic cardiomyopathy

An optical device attached to the apex was used in a canine model to study the early effects of myocardial ischemia[52]. Ischemia was inflicted by occluding the anterior descending coronary artery. Early after induction of ischemia, there was a paradoxical increase of apical rotation. This finding was ascribed to secluded ischemia of the subendocardium, resulting in a declined counteractive effect of the fibres located at the subendocardium[27,52].

Also, Moen *et al*[53] used speckle-tracking echocardiography on eight anesthetized pigs to define regional myocardial function in anterior wall ischemia. They discovered left ventricular twist remained normal until there was extensive impairment of perfusion of the left anterior descending artery.

Sun *et al*[54] induced a myocardial infarction in 7 pigs, leading to decreased twist, specifically in the area perfused by the occluded coronary artery[27,54]. Hence, it was suggested that twist might be used to assess wall motion abnormalities in order to localize cardiac ischemia. Conversely, in a clinical study using dobutamine stress echo in 125 patients with myocardial infarction or ischemia, the influence of myocardial infarction on left ventricular twist proved to be related

to size rather than localisation of infarction. In addition, stress-induced myocardial ischemia did not influence left ventricular twist[55]. Other studies on anterior myocardial infarction patients showed a decreased apical rotation in the infarcted left ventricle however with a preserved left ventricular basal rotation[56,57].

When left ventricular myocardial infarction was complicated by left ventricular aneurysm formation, rotation of the apex was lost or even reversed, consequently losing left ventricular twist. Restorative surgery as a treatment of this problem is rather complex: the aim is to reconstruct a near normal ventricular chamber after aneurysm formation and thus reducing left ventricular volume and improving ejection fraction[58]. Setser *et al*[59] did not see a significant improvement in their patients left ventricular twist after traditional left ventricular reconstruction. Much more interesting however; when an improved restoration technique was used, where residual myocardium around the defect was re-approached endeavouring to redirect fibre orientation displaced by infarct scar toward a more physiological gross disposition, left ventricular twist did improve in all patients[60]. This encouraging concept of fibre orientation based surgical reparative surgery, could expand the potential of repairing the failing heart.

CONCLUSION

Left ventricular twist is an essential part of left ventricular function. Nevertheless, knowledge is limited in "the cardiology community" as it comes to twist mechanics.

Fortunately, evolution of echocardiography, permitting speckle tracking to precisely assess left ventricular twist, has boosted the awareness of this fundamental feature of cardiac mechanics. The vital role of twist in the physiology of the heart is undisputable. Nevertheless, the significance of twist assessment in daily clinical practice in patients with a cardiomyopathy still has to be established[27]. On the other hand, twist analysis has contributed substantially to the understanding of pathophysiology in a diversity of cardiomyopathies (Figure 2). Increased twist in for example hypertrophic cardiomyopathy may be an early sign of subendocardial (microvascular) dysfunction. Furthermore, decreased twist might be initiated by left ventricular dilatation or an extensive myocardial scar. Finally, the detection of rigid body rotation in noncompaction cardiomyopathy could serve as an indispensible method to accurately diagnose this challenging entity. All this highlights the importance of left ventricular twist in the field of cardiomyopathies and may further encourage the implementation of left ventricular twist parameters in the "diagnostic toolbox" for cardiomyopathies[27].

Abstract

Lactate, as a metabolite of easy and quick assessment, has been studied over time in critically ill patients in order to evaluate its prognostic ability. The present review is focused on the prognostic role of lactate levels in acute cardiac patients (that is with acute coronary syndrome, cardiogenic shock, cardiac arrest, non including post cardiac surgery patients). In patients with ST-elevation myocardial infarction treated with mechanical revascularization, hyperlactatemia identified a subset of patients at higher risk for early death and in-hospital complications, being strictly related mainly to hemodynamic derangement. The prognostic impact of hyperlactatemia on mortality has been documented in patients with cardiogenic shock and in those with cardiac arrest even if there is no cut-off value of lactate to be associated with worse outcome or to guide resuscitation or hemodynamic management. Therapeutic hypothermia seems to affect *per se* lactate values which have been shown to progressively decrease during hypothermia. The mechanism(s) accounting for lactate levels during hypothemia seem to be multiple ranging from the metabolic effects of reduced temperatures to the hemodynamic effects of hypothermia (*i.e.*, reduced need of vasopressor agents). Serial lactate measurements over time, or lactate clearance, have been reported to be clinically more reliable than lactate absolute value also in acute cardiac patients. Despite differences in study design, timing of lactate measurements and type of acute cardiac conditions (*i.e.*, cardiogenic shock, cardiac arrest, refractory cardiac arrest), available evidence strongly suggests that higher lactate levels can be observed on admission in non-survivors and that higher lactate clearance is associated with better outcome.

INTRODUCTION

Hyperlactatemia is known to be associated with adverse outcome in critical illness[1-3]. However, the source, patho-physiology and metabolic function of lactate remain unclear probably because lactate is widely produced and it is cardinal to many energy-related pathways[4].

In recent years, available evidence strongly suggests that stress hyperlactatemia is due to increased aerobic lactate production with or without lactate clearance and that it is probably due to adrenergic stimulation. In other words, increased lactate levels are indicative of a stress response and lactate is a source of energy and not a waste product.

Lactate, since it is easy and quick to measure even at the bedside, has been widely investigated in critically ill patients to assess its prognostic role[5].

The present review is focused on the prognostic role of lactate levels in acute cardiac patients (acute coronary syndrome, cardiogenic shock, cardiac arrest). Post cardiac surgery patients are not included.

LACTATE IN THE HEART

In a normal heart, at rest, β-oxidation of fatty acids provides about 60%-90% of Adenosine triphosphate (ATP) while pyruvate produces 10%-40% of ATP[6]. However, fatty acids show lower production efficiency and increased intracellular free fatty acids activate uncoupling proteins, so that protones leak into the mitocondria without generating ATP[7]. That is why inhibition of β-oxidation is associated to an increased in mechanical efficiency of the left ventricle.

Lactate is an important fuel for the stressed heart[8]. During exercise the uptake of lactate by the myocardium and its use increase as well as during β-adrenergic stimulation and shock[4,9].

In presence of increased lactate concentrations, lactate might represent up to 60% of cardiac oxidative substrate. During shock, lactate is the most important fuel for the heart. Indeed, in laboratory animals, lactate depletion is associated with shock and mortality[10,11] while lactate infusion increased cardiac performance in cardiogenic and septic shock[12].

Hyperlactatemia can be viewed as part of the stress response including increased metabolic rate, sympathetic nervous system activation, accelerated glycolysis and a modified bioenergetic supply. In animals with cardiogenic shock[13] and in patients with cardiogenic shock, a marked increment in glycolysis and gluconeogenesis associated with hyperlactatemia was described[14]. In healthy subjects and in cardiogenic shock[12], it was observed, using an infusion of labelled lactate, that 50% of this lactate was oxidized and 20% used for glucose synthesis, without differences between the two subgroups. All these data strongly suggest that lactate is a source of energy in stress conditions.

PROGNOSTIC SIGNIFICANCE OF LACTATE

Acute coronary syndrome

Few investigations assessed whether lactate values are a diagnostic tool in patients with chest pain. In 129 patients with chest pain[15], lactate values measured on arrival identified those chest pain patients with critical cardiac illness (*i.e.*, severe congestive heart failure) while lactate concentrations within the normal range had a high negative predictive value for diagnosis of acute myocardial infarction (AMI). In patients arriving at the emergency department for suspected AMI[16], lactate values on arrival were highly sensitive for the diagnosis of AMI, mainly in those patients with more than 2 h of chest pain. In 229 patients admitted to coronary care unit[17] admission lactate showed the greatest predictive power for shock development.

To date, the prognostic significance of lactate in acute coronary syndrome (ACS), that is unstable angina, no ST elevation myocardial infarction and ST elevation myocardial infarction (STEMI), has been investigated in observational, mainly single-center, studies[18,19].

In 1176 STEMI patients[20], hyperlactatemia measured at arrival in the catheterization laboratory was associated with worse outcome measures [increased 30-d mortality, larger enzymatic infarct size and increased use of intra-aortic balloon pump (IABP)]. Among non survivors with admission lactates $\geqslant$ 1.8 mmol/L, the fifty percent died within a day after percutaneous coronary intervention (PCI). Hypotension, higher heart rate, poor Thrombolysis in myocardial infarction-flow, diabetes and non-smoking were independently associated with hyperlactatemia. In 253 STEMI non-diabetic patients with STEMI[21], lactate, measured after PCI, was an independent predictor of mortality together with C-peptide and homeostatic model assessment, an index of acute insulin resistance.

In 807 STEMI patients treated with PCI[22], our group observed that lactate values were independently associated with early mortality only in the subgroup of patients in advanced Killip classes. Lactate concentrations (measured in the early phase of STEMI) were influenced by the degree of hemodynamic impairment (as indicated by Killip class), of myocardial ischemia (as inferred by Tn I), and by glucose values.

Moreover, lactate represented an independent marker for complications (acute pulmonary edema and arrhythmia) observed during intensive cardiac care unit (ICCU) stay in 445 STEMI patients[19] and in 481 ACS patients with cardiogenic shock treated with IABP, lactate was an independent predictor of IABP-related complications (hemorrhagic, ischemic events) together with use of inotropes and nadir platelet count[22].

Overall, according to the available evidence hyperlactatemia in STEMI patients submitted to primary PCI identified a subset of patients at higher risk for early death and in-hospital complications, being strictly related mainly to hemodynamic derangement. Similarly in 754 consecutive patients with acute decompensated heart failure (ADHF) (ACS in the 52%)[23] admission lactate values > 3.2 mmol/L were associated with increased in-hospital mortality in ADHF patients either with or without ACS.

Cardiogenic shock

In 2006, in 38 patients with cardiogenic shock (CS) following acute myocardial infarction and retrospectively analyzed, interleukin-6 concentrations were independently associated with increased 30-d mortality while lactate values were not[24]. In the following years, increasing evidence supported the notion of lactate as a prognostic factor in circulatory shock[14,25]. In 45 CS patients complicating STEMI[26], increased lactate values (that is > 6.5 mmol/L) were independently associated with in-hospital death. Similar results were reported in other investigations[27,28].

The strict relationship relation between lactate and hemodynamic impairment was documented in 25 CS patients in whom a short-term increase in mean arterial pressure with norepinephrine was associated with a significant reduction in lactate levels, better cardiac performance and improved microcirculatory variables[29].

So far there is no cut-off value of lactate associated with worse outcome[30]. Lactate values higher than 2.0 mmol per liter was one of the diagnostic criteria for impaired end-organ perfusion (together with altered mental status; cold, clammy skin and extremities; oliguria with urine output of less than 30 mL/h) in a randomized multicenter trial, including 600 CS patients complicating AMI randomized to intraaortic balloon counterpulsation (301 patients) or no intraaortic balloon counterpulsation (299 patients). Intra-aortic balloon pump did not affect serum lactate concentration as well as the length of ICU stay, catecholamine therapy (dose and duration), and renal function and its use was not associated with a reduced 30-d mortality.

Cardiac arrest

The prognostic significance of lactate levels in cardiac arrest was investigated mainly in observational studies, not homogeneous for study design, inclusion criteria (cardiac arrest of cardiac/not cardiac origin) and time and number of lactate determination. The influence on lactate value of treatments such as mild hypothermia and support therapy like extracorporeal membrane oxygenation (ECMO) are so far not completely elucidated. Thus, there is no cut-off of lactate values in post-cardiac arrest patients to be associated with increased mortality and/or neurological impairment or to be use to guide resuscitation or post-resuscitation hemodynamic management.

Hyperlactatemia observed in the early phase in cardiac arrest patients may be related to both the ischaemia that occurs during arrest and to the inflammation resulting from ischemia-reperfusion injury[31-34].

Hyperlactatemia in post cardiac patients has been reported in several investigations[31-34]. In 128 out-of-hospital cardiac arrest patients[33] it was reported a progressive increased mortality associated with hyperlactatemia (39% lactate < 5 mmol/L, 67% lactate 5 mmol/L to 10 mmol/L, and 92% lactate ⩾ 10 mmol/L; $P < 0.001$). In out-of-hospital cardiac arrest (OHCA) patients[35] blood ammonia and lactate on arrival were independent prognostic factors and, when combining both biomarkers, the positive predictive value was nearly 100%.

An association between lactate levels and neurological outcome has been documented in recent investigations[36]. In 930 cardiac arrest patients who underwent therapeutic hypothermia (TH) collected from the Korean Hypothermia Network[37] high levels of lactate measured 1 h after return of spontaneous circulation were related to early mortality and poor neurological outcome. In 184 OHCA patients[38], lactate levels < 5 mmol/L and lower epinephrine doses (< 1.5 mg) were predictors of a normal Glasgow Coma Scale. Lactate concentrations measured at 6, 12, 24 and 48 h were significantly lower in the good neurological outcome group than in the poor neurological outcome group, while admission lactate values were comparable between the two subgroups. Moreover, in 76 OHCA patients submitted to TH, lactate clearance (6-h and 12-h) was related to good neurological outcome also when adjusted for confounding factors[39].

However, data on the effect of therapeutic hypothermia on lactate values are so far not uniform. In a prospective trial comparing moderate induced hypothermia with normothermia in OHCA survivors[40], during hypothermia it was reported an increment in lactate values, together with reduced pH values, reduced MAP and increased glucose levels. On the other hand, when comparing therapeutic hypothermia and normothermia[41], no significant difference in peak lactate values, arterial pressure, and need of vasopressors was reported in comatose survivors of ventricular fibrillation with STEMI. On the other hand,

in 20 CS patients after successful resuscitation[42], the initially increased lactate levels were lower in the hypothermic than the control group.

When measured serially during hypothermia in cardiac arrest patients[43], the lactate levels decreased from induction (6.68 ± 3.64; 0.5-1.7 mmol/L) to the maintenance phase (3.29 ± 2.44) and normalized in the rewarming phase.

Recently[44], in 33 cardiac arrest patients treated with TH, we observed that lactate values showed a progressive reduction during hypothermia, reduction which was independent of blood pressure variations, since mean arterial pressure showed no significant changes throughout hypothermia and of volemia (central venous pressure remained unvaried). It can be hypothesized that in patients submitted to TH lactate values are influenced by more complex mechanism(s) beyond perfusion (as indicated by mean arterial pressure) and/or volemia (as inferred by central venous pressure). We can suppose that the metabolic effect(s) of temperature may have contributed to lactate reduction, since hypothermia induces a reduction in metabolic rate (8% per degree centigrade drop in core temperature)[45] and in oxygen consumption (as previously observed when applying therapeutic hypothermia to critically ill febrile patients)[46]. In addition, pharmacological agents may have affected lactate values, since vasoactive pharmacological drugs influences the rate of glycolysis, where the rate of pyruvate utilization does not meet the rate of glycolysis, leading to lactate production[47]. As a matter of fact, in cardiac arrest patients[44] a decrease in vasopressor dose was observed during hypothermia.

In our series, lactate levels when measured during hypotermia were associated with in-ICCU death and, similarly, in 199 post cardiac arrest patients submitted to hypothermia[48], lactate (at 12 and 24 h, respectively) were significantly associated with adverse outcomes.

In the last years, a few reports analyzed the relation between hyperlactatemia and mortality in patients with refractory cardiac arrest treated with venous-arterial ECMO support. In 57 patients with refractory cardiac arrest who received ECMO during cardiopulmonary resuscitation, recruited over a six-year period[49], lactate values (measured on the first, third and seventh days, respectively) showed a significant correlation with weaning and survival. In 66 CA patients treated with ECMO, lactate concentration ⩾ 21 mmol/L (measured before cannulation) was associated with worse outcome together with fibrinogen ⩽ 0.8 g/L, and prothrombin index ⩽ 11%[50]. More recently, in 15 consecutive OHCA patients due to acute coronary syndrome submitted ECMO support, combination of base excess (less than -10 mmol/L) and lactate (> 12 mmol/L), measured 3 h after starting ECMO, can be used to predict multiorgan failure occurrence and mortality in the following 21 h[51].

LACTATE CLEARANCE

Lactate clearance have been reported to be more reliable on clinical grounds than absolute value of lactate for risk stratification in different critically ill conditions, ranging from sepsis to trauma[52-59].

Lactate clearance in acute cardiac patients has been investigated to date in few reports, all including observational single-center investigations performed in different populations of acute cardiac patients. Despite differences in study design, timing of lactate measurements and type of acute cardiac conditions (*i.e.*, cardiogenic shock, cardiac arrest, refractory cardiac arrest), available evidence strongly suggests that higher lactate levels can be observed on admission in non-survivors and that higher lactate clearance is related to more favourable outcome.

In 394 survivors from cardiac arrest[60], serum lactate levels, measured on admission and at 48 h, was retrospectively analyzed. Lactate values were lower in survivors at 6-mo after cardiac arrest than in non-survivors.

In 51 CS patients complicating STEMI[61], we observed that a 12-h lactate clearance < 10% was independently associated with early death and with poor survival rate at follow up. Since a more compromised renal failure (as indicated by a lower estimated glomerular filtration rate) was observed in patients with a low lactate clearance, associated with a lack of differences in haemodynamics (left-ventricular ejection fraction and mean arterial pressure) and transaminase values (as indexes of liver function), we supposed that a more compromised renal function may have a role in the development of persistent hyperlactataemia in these patients. Since no differences were observed in mean arterial pressure, left ventricular ejection fraction, and incidence of PCI failure between patients with 12 lactate clearance < 10% and those with 12 lactate clearance ⩾ 10%, it cannot be ruled out that microvascular alterations (despite global hemodynamic restoration) may be responsible for persistent increased lactate values in patients who exhibited a 12 lactate clearance < 10%.

Similarly, in 96 CS patients following AMI treated with percutaneous cardiopulmonary support, lactate clearance calculated at 48 h < 70% was one of the independent predictors for in-hospital mortality[62] (together with older age ⩾ 67 years and unsuccessful revascularization).

Data on the lactate clearance in patients with cardiac arrest supported by ECMO are quite scarce and not uniform.

In a heterogeneous series of 43 patients supported by ECMO for cardiogenic shock or cardiac arrest, hyperlactatemia at 6 h after ECMO implantation were observed in patients who died within 30 d[63].

In 51 patients who hadwitnessed out-of-hospital refractory cardiac arrest and were supported by ECMO upon arrival in the hospital[64], lactate clearance (values were measured before and 1-2 h after ECMO implantation) was greater in patients who survived. Conversely, in 24 patients with refractory cardiac supported by ECMO[65] lactate values, measured on

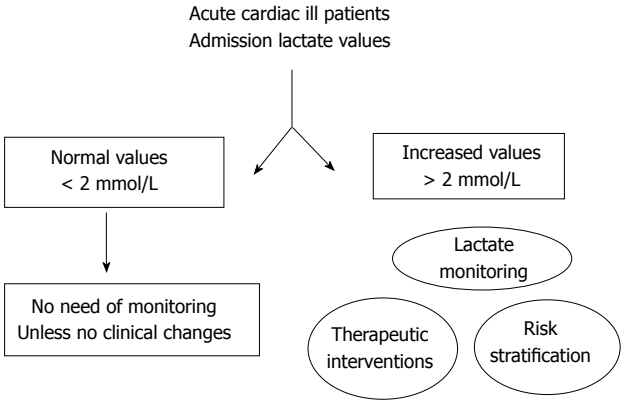

Figure 1 Admission lactate values.

admission, at 12 h and at 24 h, significantly decreased over time, with no differences between non-survivors and survivors and with no influence on outcome. A strict relation was documented between lactate and mean arterial (that is system perfusion) which increased both in survivors and in non-survivors. This relation probably explains why no difference was detectable in the dynamic behavior of lactate values during the first 24 h since admission between survivors and non survivors. Moreover, since lactate values can be related to mean arterial pressure (and not to renal function or gluycemia) it can be supposed that they may be considered a marker of perfusion, that is ECMO support efficacy in these patients.

CONCLUSION

In patients with acute coronary syndrome, cardiogenic shock and/or cardiac arrest, data on the prognostic impact of hyperlactatemia mainly stem from observational investigations. However, hyperlactatemia in these patients is associated with worse outcome, even if a cut-off value of lactate is so far not available.

Serial lactate measurements or lactate clearance have been reported to be more reliable for risk stratification in acute cardiac patients and, on a clinical ground, repeated measurement of lactate is highly advisable especially in those patients who showed increased values on admission (Figure 1). Further investigations are needed to identify the cut-off value of lactate to guide hemodynamic management.

Abstract

AIM: To evaluate the safety and efficacy of the permanent high interventricular septal pacing in a long term follow up, as alternative to right ventricular apical pacing.

METHODS: We retrospectively evaluated: (1) 244 patients (74 ± 8 years; 169 men, 75 women) implanted with a single (132 pts) or dual chamber (112 pts) pacemaker (PM) with ventricular screw-in lead placed at the right ventricular high septal parahisian site (SEPTAL pacing); (2) 22 patients with permanent pacemaker and low percentage of pacing (< 20%) (NO pacing); (3) 33 patients with high percentage (> 80%) right ventricular apical pacing (RVA). All patients had a narrow spontaneous QRS (101 ± 14 ms). We evaluated New York Heart Association (NYHA) class, quality of life (QoL), 6 min walking test (6MWT) and left ventricular function (end-diastolic volume, LV-EDV; end-systolic volume, LV-ESV; ejection fraction, LV-EF) with 2D-echocardiography.

RESULTS: Pacing parameters were stable during

follow up (21 mo/patient). In SEPTAL pacing group we observed an improvement in NYHA class, QoL score and 6MWT. While LV-EDV didn't significantly increase (104 ± 40 mL *vs* 100 ± 37 mL; P = 0.35), LV-ESV slightly increased (55 ± 31 mL *vs* 49 ± 27 mL; P = 0.05) and LV-EF slightly decreased (49% ± 11% *vs* 53% ± 11%; P = 0.001) but never falling < 45%. In the RVA pacing control group we observed a worsening of NYHA class and an important reduction of LV-EF (from 56% ± 6% to 43% ± 9%, P < 0.0001).

CONCLUSION: Right ventricular permanent high septal pacing is safe and effective in a long term follow up evaluation; it could be a good alternative to the conventional RVA pacing in order to avoid its deleterious effects.

Key words: Right ventricular septal pacing; Parahisian pacing; Resynchronization therapy; Left ventricular cardiac function; Permanent cardiac pacing

Core tip: We evaluated the safety and efficacy of the permanent high interventricular septal pacing in a long term follow up, as alternative to right ventricular apical pacing. We retrospective evaluated 244 patients with a narrow QRS implanted with a single/dual chamber pacemaker with ventricular screw-in lead placed at the right ventricular high septal (parahisian) site. Contemporary we checked the clinical evolution of two control groups of patients: without ventricular stimulation and with conventional right ventricular apical stimulation. In a long term follow up we observed stability of pacing parameters and ejection fraction, and improvement in New York Heart Association class, quality of life and exercise tolerance.

Right ventricular septal pacing: Safety and efficacy in a long term follow up. *World J Cardiol* 2015; 7(8): 490-498 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i8/490.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i8.490

INTRODUCTION

The treatment of atrioventricular block or sinus node disease is represented by artificial pacemaker implant; usually the ventricular catheter is placed in right ventricular apical (RVA) position. This therapy proved efficacious in long term follow up, granting improvement in life expectancy and quality of life (QoL). However, similarly to the negative hemodynamic and clinical effects of spontaneous left bundle branch block, new data have emerged showing negative effects of the left bundle branch block-like activation determined by RVA pacing[1-5].

Several published studies[6-10] demonstrated that more than 40% of the heart beats are paced from the right ventricular apex, an increase in the incidence of atrial fibrillation, heart failure, hospitalizations and even death is observed. When ventricular pacing is necessary permanently or for long periods of time, sites for a more physiologic pacing should be identified to avoid he occurrence of ventricular desynchronization[11-13].

A better way to pace the heart in case of intraventricular conduction delay (especially left bundle branch block) is biventricular pacing: comparing to RVA pacing, it can improve left ventricular ejection fraction and volumes and reduce mitral regurgitation and sympathetic nervous system activity[14-17]. His bundle pacing may be considered as a reliable and effective method to prevent mechanical desynchronization when intraventricular conduction is preserved and QRS is narrow[18,19]. However, it requires adjuntive skills and may be more challenging and time-consuming; it is not always applicable and higher pacing thresholds have to be accepted[20]. The right ventricular septal pacing in the parahisian area, early penetrating the His-Purkinje conduction system, produces a more physiological ventricular activation, very similar to the one that is achieved with direct His bundle pacing[21].

We aimed to evaluate feasibility, safety and long-term clinical efficacy of permanent right ventricular septal pacing in the parahisian area, performed to obtain a shorter QRS duration than that resulting from conventional right ventricular apical pacing.

MATERIALS AND METHODS

Population

From January 2001 to December 2011, we evaluated 244 patients implanted with a single or dual-chamber pacemaker with the ventricular lead positioned in the high interventricular septum (parahisian site): "SEPTAL pacing" group.

The patients were implanted at the Cardiology Clinic of Azienda Ospedaliero-Universitaria (AOU) Maggiore della Carità in Novara (School of Medicine, Study University of Piemonte Orientale, Italy) (181 patients), at the Division of Cardiology of the Ospedale Civile in Ivrea, Italy (50 patients), and at the Division of Cardiology of the Ospedale SS. Annunziata in Cosenza, Italy (22 patients).

The mean age of patients was 74 ± 8 years; 169 patients were men (69%) and 75 patients were women (31%). Inclusion criteria were: (1) permanent VVIR pacing after AV node ablation for permanent atrial fibrillation with uncontrolled (high) ventricular rate, despite negative dromothropic therapy comprising digoxin, beta-blockers and diltiazem as monotherapy or associated (51 patients; 21%); (2) permanent VVIR pacing in permanent atrial fibrillation with impaired AV conduction and low ventricular frequency (81 patients; 33%); (3) permanent DDD(R) pacemaker in patients

Table 1 Comparison of pre-implantation clinical features in the patient control groups (NO pacing and right ventricular apical pacing) and parahisian pacing group

	NO pacing	RVA pacing	PH pacing
Total patients	22 patients	33 patients	244 patients
Age (yr)	75 ± 7	77 ± 9	74 ± 8
Sex	13 M/9 F	21 M/12 F	169 M/ 75 F
NYHA class	1.09 ± 0.29	1.15 ± 0.36	2.13 ± 0.46
LV ejection fraction (%)	57 ± 5	55 ± 8	53 ± 11
LV end-dyastolic volume (cc)	89 ± 25	98 ± 22	100 ± 37
LV end-systolic volume (cc)	38 ± 13	47 ± 17	49 ± 27
Associated heart diseases	Ischemic heart disease: 6/22 (27%) Valvular heart disease: 2/22 (9%) Hypertensive heart disease: 2/22 (9%) No significant heart disease: 12/22 (55%)	Ischemic heart disease: 12/33 (37%) Valvular heart disease: 4/33 (12%) Hypertensive heart disease: 3/33 (9%) No significant heart disease: 14/33 (42%)	Ischemic heart disease: 80/244 (33%) Valvular heart disease: 29/244 (12%) Hypertensive heart disease: 90/244 (37%) No significant heart disease: 45/244 (18%)
Atrial fibrillation	1 (5%)	4 (12%)	132 (54%)
Sinus rhythm	21 (95%)	29 (88%)	112 (46%)

Comparison of pre-implantation clinical features in the patient control groups [NO pacing and right ventricular apical (RVA) pacing] and parahisian (PH) pacing group. NYHA: New York Heart Association; LV: Left ventricular.

with sinus rhythm and first and second degree AV block, symptomatic for syncope/dizziness (82 patients; 34%); and (4) permanent DDD(R) pacemaker in patients with sinus rhythm and complete AV block (30 patients; 12%).

All patients had a narrow spontaneous QRS complex (mean 101 ± 14 ms; always < 120 ms), detected at standard ECG; in patients with AV node ablation a narrow QRS was detected during junctional escape rhythm after radiofrequency (RF) AV ablation; in patients with atrial fibrillation not undergoing AV ablation, a narrow QRS was documented during 24-h Holter recording.

At the same time, we retrospectively evaluated two other "control groups" of patients (all implanted at the Cardiology Clinic of AOU Maggiore della Carità in Novara, School of Medicine, Study University of Piemonte Orientale, Italy): (1) 22 consecutive patients with ventricular apical pacing (single or dual chamber pacemakers) but percentage of permanent pacing < 20%, retrospectively detected by pacemaker telemetry, owing to the presence of spontaneous AV conduction and preserved intraventricular conduction (QRS < 120 ms): "NO pacing" control group; (2) 33 consecutive patients with a ventricular or dual-chamber pacemaker providing a high percentage of ventricular pacing (> 80%) in the apex of the right ventricle, always retrospectively detected by pacemaker memories: "RVA pacing" group.

Before the implantation procedure, all patients were planned to undergo a complete evaluation.

Following assessments were performed: (1) New York Heart Association (NYHA) functional class; (2) quality of life (QoL), evaluated with "Minnesota Living with Heart Failure" questionnaire[22]; (3) twenty-four hour Holter monitoring; (4) six-minute walking test; (5) standard 2D-echocardiogram with measurement of left ventricular end-diastolic (LV-EDV) and end-systolic (LV-ESV) volumes computed according to a biplane Simpson's method, and left ventricular ejection fraction (LV-EF).

Clinical characteristics of the population are presented in Table 1: enrolled patients presented LV-EF values close to the lower limit of the normal range, narrow QRS with normal electrical axis and moderate compromission of functional class.

Implant procedure

In patients with permanent atrial fibrillation and AV node ablation, pacing leads were placed after RF ablation procedure. A quadripolar RF catheter was used to map the His bundle and an active fixation bipolar lead was placed as near as possible to the hisian dipole of the catheter. A second conventional bipolar lead was placed at the right ventricular apex. The septal and the apical leads were then connected to the "atrial" and "ventricular" pacemaker channels, respectively. The pacemaker was programmed in "DDDR" mode with "short" atrio-ventricular delay (*i.e.*, 90 ms). Thus, if the parahisian stimulation was effective through the "atrial" channel, the following RVA pulse pacing was inhibited or delivered during the refractory period through the "ventricular" channel. While, in case of ineffective parahisian stimulation, the RVA pulse pacing ensured ventricular capture.

In patients with permanent atrial fibrillation and bradyarrhythmia (without indication to AV node ablation), a single chamber VVIR pacemaker was used and connected to the lead positioned in the parahisian area, without RVA back up lead.

In patients with sinus rhythm and advanced spontaneous AV block (first, second or third degree) a conventional atrial lead was placed in addition to the parahisian lead; both leads were connected to a DDD/

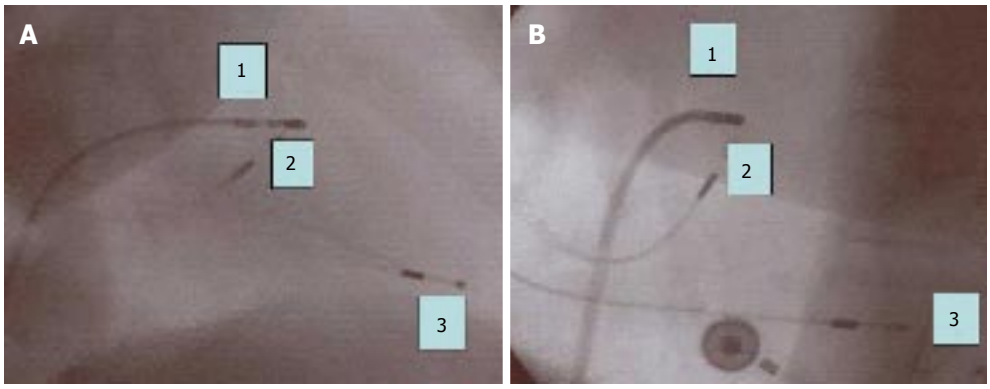

Figure 1 Antero-posterior (A) and left anterior oblique (B) fluoroscopic projections showing leads position after the "ablate and pace" procedure and parahisian pacing. 1 = quadripolar radiofrequency catheter mapping the Hisian site; 2 = screw-in bipolar lead positioned near the His-bundle; 3 = bipolar lead positioned in right ventricular apex.

DDDR pacemaker.

Following criteria were applied to obtain parahisian pacing[20]: (1) positioning of the tip of the screw-in lead as close as possible to the mapping dipole of the electrophysiological catheter (distance < 1 cm in left and right oblique projections) (Figure 1); (2) even if larger than the spontaneous QRS, the duration of the paced QRS had to be < 130 ms; (3) full concordance between electrical axis of the paced QRS and that of the spontaneous QRS; and (4) the pacing threshold had to be < 1 V (pacing of the muscular portion of the interventricular septum).

Control groups patients were implanted with a conventional apical right ventricular lead (and conventional atrial lead in dual chamber pacing).

Statistical analysis

Continuous variables with normal or Gaussian distribution of each group of patients were expressed in terms of average ± SD. Pre-implantation and follow-up data in the parahisian pacing group were analyzed and compared by means of the parametric Student *t* test for paired data. Similar parameters observed in the three groups were compared by means of the Student *t* test for numerically different samples with the same variance. A value of $P \leqslant 0.05$ was considered statistically significant.

The study was reviewed by our expert Biostatistic Gabriele Dell'Era, MD.

RESULTS

Implant data

To obtain the parahisian high septal pacing we used: (1) a bipolar catheter with 1.5 mm retractable screw lead (CapsureFix 4068/5068/5076; Medtronic Inc., Minneapolis, Minnesota) in 172 patients; (2) a bipolar catheter with 1.5 mm retractable screw lead (Cristalline ICQ09B, Vitatron BV, The Netherlands) in 10 patients; (3) a bipolar catheter with 1.5 mm retractable screw lead (Tendril 1488T/1888T; St.Jude Medical, Inc. St. Paul, Minnesota) in 12 patients; (4) a bipolar catheter with 3 mm retractable screw lead (10627 Medtronic Inc., Minneapolis, Minnesota) in 5 patients (controlled clinical evaluation); and (5) a bipolar, fixed screw, steroid eluting lead (Select Secure 3830, Medtronic Inc., Minneapolis, Minnesota) in 45 patients.

The total radiological exposure time was 15 ± 9 min (range from 3 to 68 min for the first implant with Select Secure system). Electrical parameters at the parahisian site were measured in bipolar configuration.

We excluded from the analysis 14 patients (6%), in which the criteria for parahisian pacing were not met, specifically the paced QRS was > 130 ms.

For patients in analysis, the average duration of the basal QRS was 101 ± 14 ms, and 122 ± 9 ms during parahisian pacing.

We obtained an average parahisian pacing threshold of 0.6 ± 0.3 V (at 0.5 ms pulse duration), pacing impedance 736 ± 238 Ω, endocavitary potential 10.1 ± 5.3 mV; we never recorded high-amplitude "far-field" type atrial potentials from the parahisian lead.

Parahisian pacing follow up

The average follow up of the 230 patients in analysis was 21 mo/patient, with a maximum of 70 mo for the first enrolled patient and a minimum of 12 mo for the last one.

In one patient a 3 cm dislodgment of the parahisian lead was reported. However, the paced QRS appeared superimposable to that recorded at the end of the implantation.

During long-term follow-up, the duration of the QRS during parahisian pacing remained comparable to that recorded at the implantation. Electrical measurements from the parahisian position remained stable and acceptable during time: pacing threshold was 0.6 ± 0.3 V at implantation and 0.8 ± 0.5 V at follow-up, mean endocardial potential was 10.1 ± 5.3 mV at implantation and 9.1 ± 4.4 mV at follow up, pacing impedance was 736 ± 238 ohms at implantationand 540 ± 116 ohms at follow up.

The clinical results at long-term follow-up were (Table 2): (1) In 167/230 patients (73%) we compared

Table 2 Long term follow up results of parahisian pacing

	Basal	Parahisian pacing	*P* value
NYHA class (167 pts)	2.15 ± 0.51	1.59 ± 0.55	< 0.001
6-min walk (m) (70 pts)	354 ± 90	400 ± 88	0.03
QoL (score) (70 pts)	29 ± 18	19 ± 7	0.02
LV-EDV (mL) (121 pts)	100 ± 37	104 ± 40	0.35
LV-ESV (mL) (121 pts)	49 ± 27	55 ± 31	0.05
LV-EF (%) (121 pts)	53 ± 11	49 ± 11	0.01

NYHA: New York Heart Association; QoL: Quality of life; LV-EDV: Left ventricular end diastolic volume; LV-ESV: Left ventricular end systolic volume; LV-EF: Left ventricular ejection fraction.

Table 3 New York Heart Association functional class before implantation and at follow-up, in patients with a low percentage of stimulation (NO pacing), with apical pacing (right ventricular apical pacing) and with parahisian pacing groups

	NO pacing (22 pts)	RVA pacing (33 pts)	PH pacing (167 pts)
Baseline	1.09 ± 0.29	1.15 ± 0.36	2.15 ± 0.51
Follow-up	1.22 ± 0.52	1.88 ± 0.99	1.59 ± 0.55
Significance	0.32 (ns)	*P* < 0.05	*P* < 0.001
	Unchanged	Worsening	Improvement

RVA: Right ventricular apical; PH: Para hisian.

NYHA functional class measured before implantation and at a mean follow-up of 18 ± 16 mo: the prolonged parahisian pacing led to a significant improvement from 2.15 ± 0.51 to 1.59 ± 0.55; $P < 0.001$ (Figure 2); (2) The quality of life score and exercise performances (6 min walk), performed in a sub-group of 70/230 patients (30%), significantly changed after a mean follow up of 14 ± 2 mo (QoL score from 29 ± 18 to 19 ± 17, $P = 0.02$; 6 min walk distance from 354 ± 90 m to 400 ± 88 m, $P = 0.03$) (Figure 2); (3) In 121/230 patients (53%) we compared echocardiographic volumes and ejection fraction before and after parahisian pacing (Figure 3): LV-EDV went from 100 ± 37 to 104 ± 40 mL, $P = 0.35$; LV-ESV from 49 ± 27 to 55 ± 31 mL, $P = 0.05$; LV-EF from 53% ± 11% to 49% ± 11%, $P = 0.01$. Medium-long term evaluation of the LV-EF showed values superimposable to enrollment values, confirming that parahisian pacing can prevent deterioration of the left ventricular function.

Control groups comparation

In RVA-paced patients QRS duration increased significantly (average 165 ± 10 ms, with values always > 130 ms).

In the "NO pacing" control group, the NYHA functional class was good both at the baseline and during follow-up; the conduction system disease did not significantly affect the functional class, which did not change during follow-up in the absence of ventricular pacing. By contrast, in "RVA pacing" patients there was a trend toward worsening NYHA functional class, though the upper classes of overt heart failure were not reached. Thus, during follow-up the NYHA functional class was better in patients without stimulation and those on PH stimulation (no significant difference between these two groups) and worse in patients stimulated at the apex ($P < 0.05$ *vs* unstimulated patients and *vs* PH-stimulated patients) (Table 3). QoL scores did not significantly differ among the three groups: 21 ± 19 score in NO pacing patients; 29 ± 13

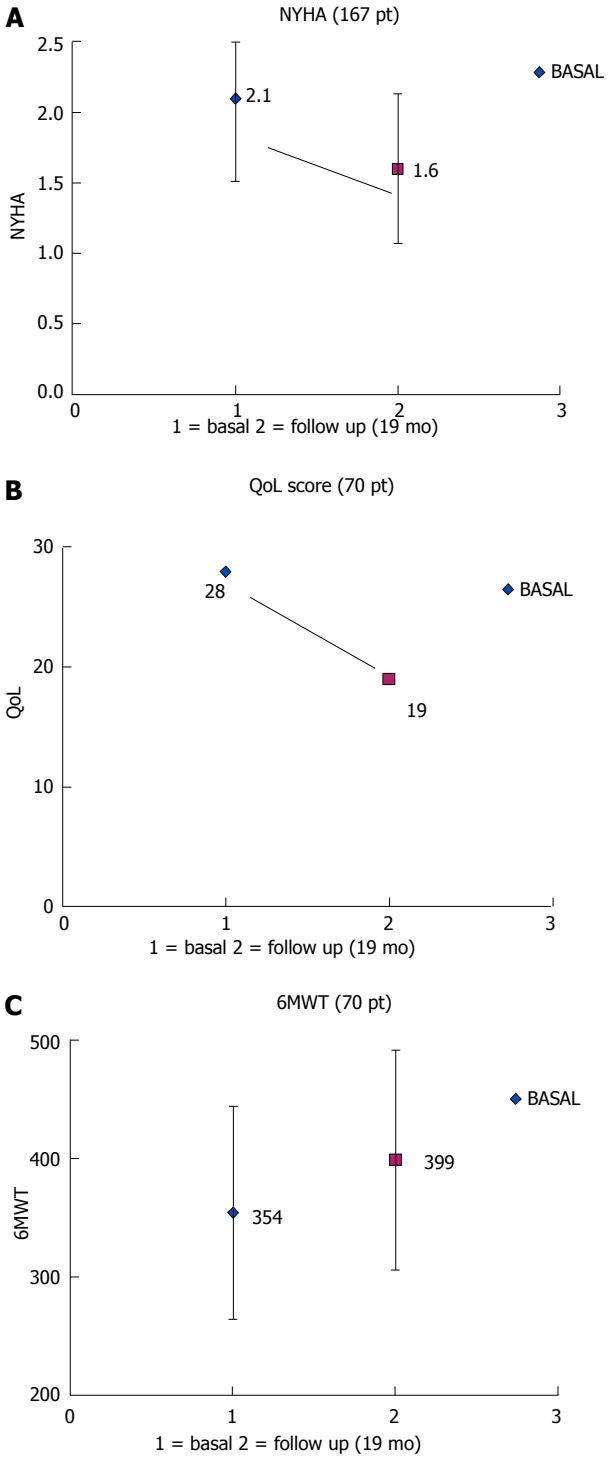

Figure 2 Clinical data before pacemaker implant (basal) and after septal pacing follow up. A: New York Heart Association functional class (NYHA); B: Quality of life (QoL) minnesota score; C: Six-minute walking test (6mwt) (meters).

Table 4 Evolution of echocardiographic parameters: end-diastolic volume, end-systolic volume and ejection fraction in the NO pacing group (22/22 patients), in the right ventricular apical pacing group (33/33 patients) and in the parahisian group (121/230 patients)

		Basal	Follow-up	*P*
Contr	EDV (mL)	88 ± 25	99 ± 46	0.23 (ns)
(22 pts)	ESV (mL)	38 ± 13	46 ± 29	0.11 (ns)
	EF (%)	57 ± 5	56 ± 5	0.1 (ns)
RVA	EDV (mL)	98 ± 23	139 ± 31	< 0.0001
(33 pts)	ESV (mL)	44 ± 14	79 ± 22	< 0.0001
	EF (%)	56 ± 6	43 ± 9	< 0.0001
PH	EDV (mL)	100 ± 37	104 ± 40	0.35 (ns)
(121 pts)	ESV (mL)	49 ± 27	55 ± 31	0.05
	EF (%)	53 ± 11	49 ± 11	0.01

in RVA pacing patients; 19 ± 17 in PH pacing patients (P < 0.06 RVA group *vs* NO pacing; P < 0.07 PH group *vs* NO pacing). Exercise tolerance, expressed in meters walked in 6 min, was better in patients without persistent pacing (448 ± 110 m) than in PH-stimulated patients (400 ± 88 m), but the difference was not significant; on the contrary it was worse in RVA-stimulated patients (338 ± 158 m) (P < 0.05 *vs* both "NO pacing" and PH-stimulated patients).

Left ventricular volumes and ejection fraction (EF) values in the controls and parahisian pacing groups of patients are shown in Table 4. In patients without significant ventricular pacing (NO pacing group), left ventricular function was almost unchanged during follow-up; indeed, no significant changes in volumes and EF were recorded (P = ns). All patients on ventricular pacing, however, presented some differences. The average end-diastolic and end-systolic volumes increased markedly in the RVA group, while in the PH group these volume increments were so modest as to be almost comparable to those observed in control patients. In RVA-paced patients, the increased left ventricular volumes led to a significant reduction in the mean EF to below normal values (post-pacing average of 43% ± 9% *vs* 56% ± 6% at the baseline; mean decrease of 13.2 percentage points, P < 0.0001); in PH patients, left ventricular function was fairly well preserved (post-pacing EF 49% ± 11%, *vs* 53% ± 11% baseline; mean change of 4 percentage points) (Figure 4).

DISCUSSION

Cardiac pacing aims at providing an adequate cardiac rhythm, restoring a physiological excito-conduction of the heart. Two elements are traditionally considered as cornerstone for "physiologic pacing": the maineinance of a correct atrioventricular sequence and the presence of chronotropic response (*via* rate-responsive sensors) during exercise or stress; till recent times, dual-chamber rate-response pacemakers were considered "physiological".

However, we know that conventional RVA pacing has the potential to induce electro-mechanichal desynchronization, causing potential harm (negative remodeling and worsening heart failure) in less than normal heart[23,24].

Therefore, a real physiological pacing must: (1) increase the cardiac frequency according to the metabolic needs; (2) keep correct atrioventricular sequence of activation; and (3) keep inter and intraventricular synchrony.

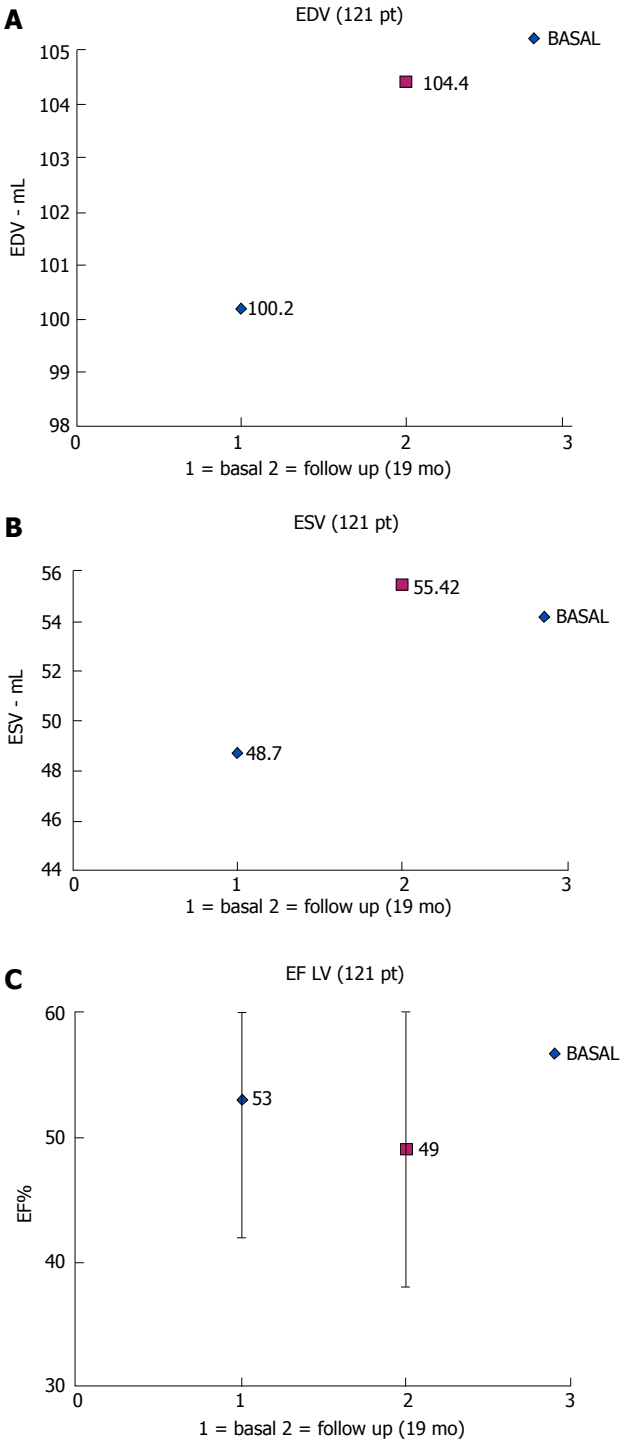

Figure 3 Echocardiographic data before pacemaker implant (basal) and after septal pacing follow up. A: End diastolic left ventricular volumes (EDV); B: End systolic left ventricular volumes (EDV); C: Left ventricular ejection fraction (EF LV).

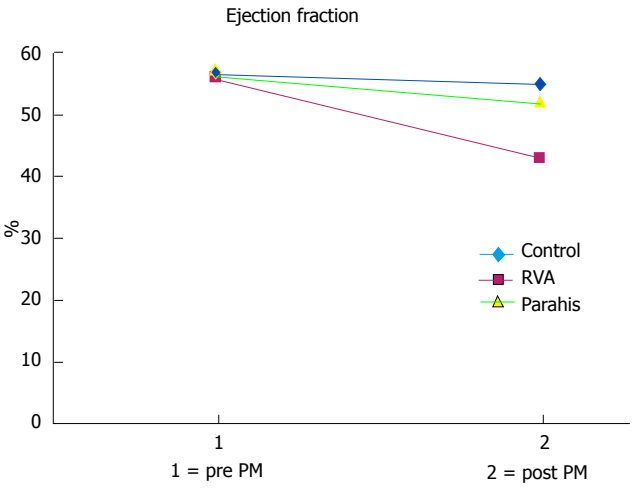

Figure 4 Average values of left ventricular ejection fraction at the baseline (1) and after two years of follow-up (2) in patients without significant stimulation (blue: control NO pacing), right ventricular apex paced patients (red: right ventricular apical) and parahisian paced patients (green: parahis). In control patients and PH patients, the ejection fraction remained essentially normal (values above 50%), while in RVA patients it declined significantly to average values of around 40. RVA: Right ventricular; PH: Parahisian.

Biventricular pacing proved effective in improving quality of life and cardiac function in patients with left bundle branch block (spontaneous electromechanical desynchronization)[14,17]. However, when intraventricular conduction is preserved and an atrioventricular block occurs, pacing must be as physiological as possible[25]. His bundle pacing has already established itself as an effective alternative to biventricular pacing for these patients. Indeed, it uses the His-Purkinje system without inducing intraventricular conduction delays[18,19]. Unfortunately, direct His bundle pacing may be challenging, needs high pacing electrical output and may pose the risk of traumatic (post-screwing of the pacing lead) His bundle block[20].

In our experience, a simpler and reliable method to achieve physiological intraventricular conduction is the so-called parahisian pacing: placing the tip of the catheter in the upper muscular part of the interventricular septum, activation is granted through the myocardium, but the His-Purkinje conduction system is activated at the same time[21]. With this technique, a fairly narrow (120-130 ms) QRS with an electrical axis concordant to the non-paced QRS can be obtained[26].

We already presented data about the improvement of hemodynamic and functional parameters obtained with parahisian pacing compared to conventional right apical pacing at a short follow up in patients undergoing AV node ablation for permanent atrial fibrillation with unsatisfactory rate control despite optimal therapy[27,28].

Long-term follow-up confirms these results, showing that parahisian pacing confers a durable improvement of quality of life, functional class and exercise tolerance. The improvement is sustained over time, modifying the expected natural progression of the underlying cardiopathy by means of a preserved atrioventricular and interventricular synchrony and by rate regularization; ejection fraction was positively affected, too, avoiding deterioration usually observed in paced patients.

Therefore, parahisian pacing should be considered easy to apply, reliable and effective in preventing the detrimental remodeling caused by non-physiological right ventricular apical pacing[29]. This kind of physiological pacing may be proposed as first line in patients needing high ventricular pacing percentage, presenting with preserved intraventricular conduction and mild systolic left ventricular dysfunction[30-32].

Limits of the study

The aim of the study was to evaluate the long term safety of septal parahisian permanent cardiac pacing and this has been definitively confirmed.

As for the long term efficacy of this pacing site, the main limitation of the study was the heterogeneity of our population: 54% of patients had atrial fibrillation (21% with concomitant AV node ablation) and VVIR pacing, 46% were in sinus rhythm with various AV block degrees and DDD(R) pacing.

This can surely affect the general prognosis, but all patients had an high percentage of ventricular pacing and a more "physiological" site of stimulation, respect to RVA pacing, could make the difference. In effect, basal NYHA functional class, higher in parahisian group than in control groups of patients, improved during the follow up; on the contrary, patients with high percentage RVA pacing had a NYHA class worsening (Table 3). Unfortunately, we could not collect definite informations about hospital readmission for heart failure and long-term mortality of our patients: this is another limitation to better establish the long term efficacy of parahisian septal permanent pacing.

The second main limit of the the study was the retrospective evaluation of patients; however, in every group (NO pacing, RVA pacing and SEPTAL pacing) the patients evaluated were consecutively enrolled and this could reproduce a real world situation.

Surely, the superiority of parahisian septal *vs* RVA permanent pacing should be evaluated and confirmed with a prospective multicenter study.

COMMENTS

Background

The usual way to treat symptomatic severe bradycardia is to implant an artificial pacemaker, with a stimulating lead in the apex of the right ventricle of the heart, providing electrical stimuli that generate the pulse. Unfortunately, that kind of stimulation can be detrimental in the long term, causing progressive heart failure in a number of patients. Alternative strategies were attempted: one of the most promising seems the placement of the stimulating lead in the upper region of the interventricular septum (parahisian site, near the division between right and left bundle branches), a position that can partly reproduce the physiological electrical activation of a normal heart. This kind of cardiac stimulation is called "septal parahisian pacing".

Research frontiers

The authors' group pioneered septal parahisian stimulation; the authors think

that this kind of cardiac pacing must have a wide diffusion (as an alternative to the usual way) and they provide support to their hypothesis with this paper, reporting safety and efficacy in a long term follow up.

Innovations and breakthroughs

In the past, some concerns arose about long-term safety and efficacy of septal pacing. In addition, some authors described it as difficult to perform for the traditionally trained interventional cardiologists. This paper shows that septal parahisian pacing can be easily obtained (some "tips and tricks" are provided to attempt the procedure) and that long term safety is guaranteed; in addition, better outcomes in term of exercise capacity, quality of life and cardiac function are obtained.

Applications

Patients with symptomatic severe bradycardia will benefit from a physiologic heart stimulation, if treated with septal parahisian pacing, avoiding unfavorable long term effect of the conventional electrical therapy.

Terminology

Septal parahisian (PH) pacing is a kind of cardiac stimulation that uses a transvenous lead placed in the upper region of the inter-ventricular septum, near the division between right and left bundle branches, to determine "physiological" ventricular electrical depolarization. The ejection fraction of the left ventricle is the measure commonly used to quantify cardiac function, and is negatively affected by conventional cardiac artificial pacemakers in a number of patients.

Peer-review

Very good work has been performed by Eraldo Occhetta *et al* comparing the safety, efficacy and benefits of right ventricular septal pacing *vs* right ventricular apical pacing. Congratulation to the authors for adding valuable data for the long-term superiority of septal pacing above apical stimulation.

Abstract

A 69-year-old man was admitted to our center to undergo catheter ablation of paroxysmal atrial fibrillation refractory to antiarrhythmic drug therapy. This procedure required access to the left atrium through the interatrial septum. During hospitalization, the patient performed routinely pre-procedure transthoracic echocardiography and gadolinium-enhanced cardiac magnetic resonance showing a normal anatomy of both the fossa ovalis and the interatrial septum. Access to the left atrium proved difficult and several unsuccessful attempts to perform the trans-septal puncture were made under both fluoroscopy and intracardiac echocardiography guidance, even with radiofrequency energy delivery. Finally, trans-septal puncture was successfully carried out using a novel nitinol J-shaped "SafeSept" trans-septal guidewire, designed to cross the interatrial septum through the trans-septal needle thanks to a special sharp tip. Moreover, thanks to its rounded J shape that reduces the risk of atrial perforation, the "SafeSept" guidewire, when advanced into the left atrium, becomes atraumatic.

Key words: Trans-septal puncture; "SafeSept" guidewire; Atrial fibrillation; Interatrial septum; Intracardiac echocardiography

Core tip: In recent years, the number of percutaneous therapeutic techniques requiring trans-septal catheterization has increased. We present the case of a 69-year-old man with a ten-year history of paroxysmal atrial fibrillation. Access to the left atrium proved difficult and several unsuccessful attempts to perform the trans-septal puncture were made under both fluoroscopy and intracardiac echocardiography guidance, even with radiofrequency energy delivery. Finally, trans-

septal puncture was successfully performed using a novel nitinol "SafeSept" trans-septal guidewire. If the interatrial septum is thickened, scarred, fibrous, too mobile and/or aneurismal, the use of the "SafeSept" guidewire may be a safe and effective option.

Difficult case of a trans-septal puncture: Use of a "SafeSept" guidewire. *World J Cardiol* 2015; 7(8): 499-503 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i8/499.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i8.499

INTRODUCTION

Atrial fibrillation (AF) catheter ablation is a common therapeutic approach. The access to the left atrium, required to perform the procedure, is usually achieved through the interatrial septum. Trans-septal catheterization during catheter ablation results in high success rates with low complication incidence. Failure of the trans-septal approach is often related to unfavorable anatomical features of both the interatrial septum and the fossa ovalis[1,2]. In particular cases, trans-septal puncture can prove difficult even with the support of transesophageal or intracardiac echocardiographic imaging[3,4], or using radiofrequency energy to facilitate trans-septal puncturing[5,6]. In these cases, the use of the "SafeSept" trans-septal guidewire can be a valid alternative for achieving catheterization across the interatrial septum[7].

CASE REPORT

We present the case of a 69-year-old man with a ten-year history of paroxysmal AF. One year earlier, he had undergone catheter cryoablation of a common typical atrial flutter. After the procedure, several recurrences of paroxysmal AF refractory to antiarrhythmic drug therapy were recorded. The patient was then referred to our hospital for pulmonary vein disconnection by radiofrequency ablation. The patient had never undergone a previous procedure requiring trans-septal approach or heart surgery and did not have congenital heart defects.

During hospitalization, the patient underwent a baseline electrocardiogram that showed normal sinus rhythm and an echocardiogram that demonstrated a large left atrium (Ø 54 mm). The membrane of fossa ovalis was confirmed to be intact by gadolinium-enhanced cardiac magnetic resonance imaging, performed before ablation to assess left atrium and pulmonary vein anatomy and merge morphological and electroanatomic information during AF ablation.

At first a percutaneous trans-septal puncture was attempted. A decapolar catheter was inserted *via* femoral venous approach guided by fluoroscopy into the coronary sinus. A trans-septal needle (BRK, St Jude Medical Inc.) was advanced through a long sheath (SLO, 8 F, St. Jude Medical Inc., St. Paul, MN, United States) against the septum. By a percutaneous contralateral femoral venous approach, an ultrasound catheter (AcuNav, Siemens Healthcare, Mountain View, CA, United States) was advanced for intracardiac echocardiography monitoring. This technique was used to guide the needle to the correct position against the fossa ovalis. Normal interatrial septum anatomy was observed during the positioning.

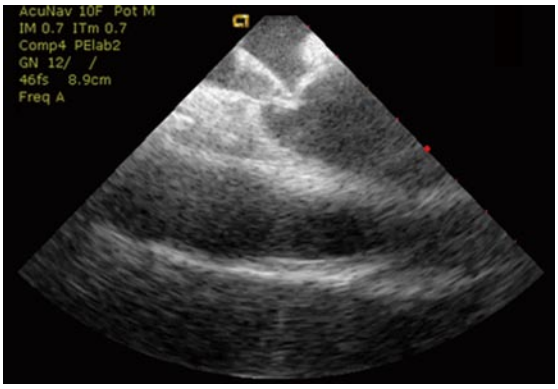

Figure 1 Intracardiac echo imaging. Correct localization of the puncture site with tenting of the fossa ovalis without crossing the interatrial septum.

Several unsuccessful attempts to obtain a trans-septal puncture were performed by two expert electrophysiologists despite changing site of puncture, needle orientation, needle types and different curved sheaths. During needle puncture, a strong resistance against the septum was encountered; both fluoroscopy and intracardiac echocardiography showed tenting of the fossa ovalis, but puncturing was not achieved despite the correct location of the needle (Figure 1).

An electrosurgical cautery generator was used to facilitate trans-septal catheterization. A standard cautery pen was placed upon the proximal portion of the trans-septal needle, then a radiofrequency pulse was delivered for few seconds at 45 W. Two unsuccessful attempts with this technique were performed.

The previous techniques were unsuccessful because of the anatomical features of the interatrial septum (*i.e.*, unusual thickness of the fossa ovalis).

In order to get a successful fossa ovalis puncture, a special trans-septal guidewire ("SafeSept" Pressure Products, Inc., United States) was considered as an option (Figure 2).

The "SafeSept" is a nitinol trans-septal guidewire designed to easily cross the interatrial septum through the trans-septal needle thanks to a special sharp tip that allows it to penetrate the fossa ovalis without the use of a particular hard contact. Moreover, the "SafeSept" is non-traumatic when advanced into the left atrium thanks to its rounded J shape, thus reducing the perforation risk of the atrial wall. The trans-septal guidewire's distal end can be easily visualized thanks to a radiopaque coil.

Figure 2 "SafeSept" trans-septal guide wire. Details of the radiopaque coil and the rounded J shape of the tip.

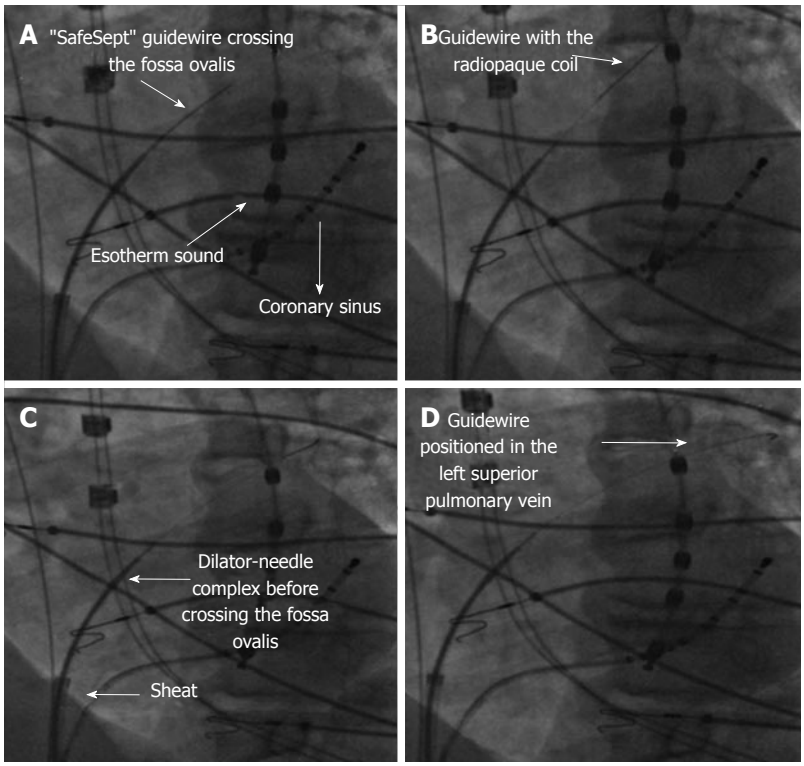

Figure 3 Sequence of fluoroscopy imaging of trans-septal puncture in the same projection (left anterior oblique view). A: The esotherm sound for the esophageal temperature control and coronary sinus catheter are in place. The "SafeSept" guidewire penetrates the fossa ovalis; B: The "SafeSept" guidewire is visible in the left atrium thanks to radiopaque coil; C: The trans-septal assembly (needle, dilator and sheath) is placed in the right atrium before crossing the fossa ovalis; D: The distal part of trans-septal guidewire is positioned in the left superior pulmonary vein.

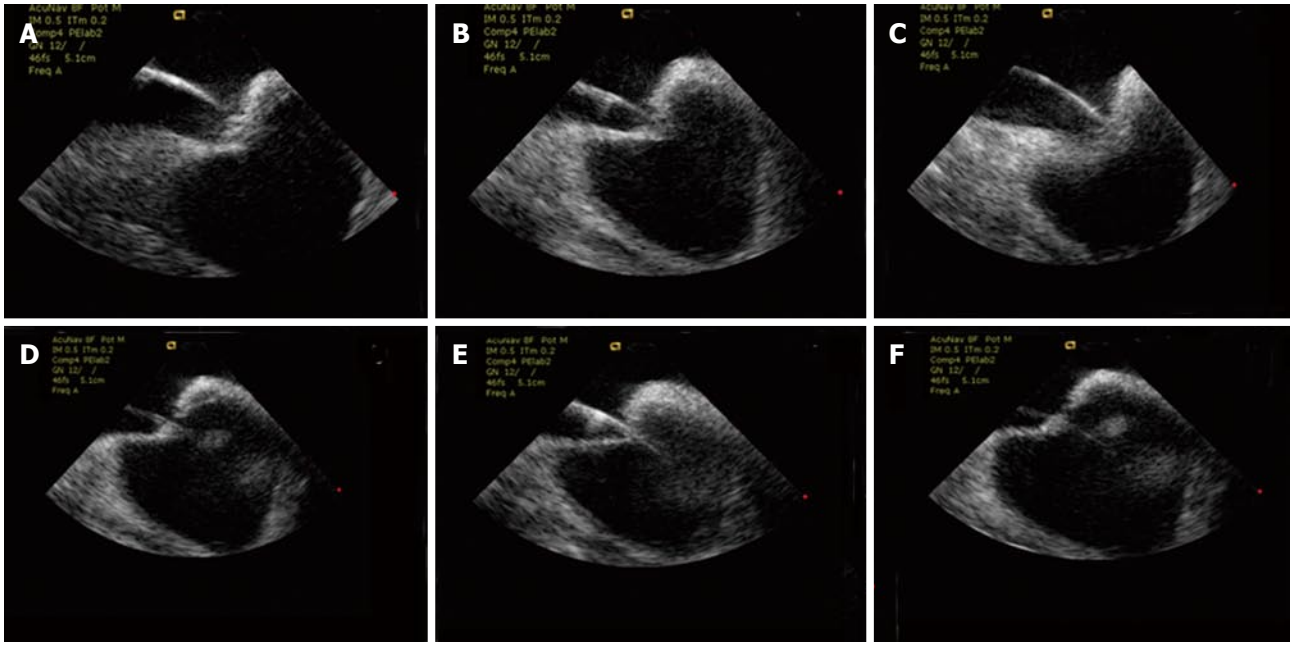

Figure 4 Sequence of intracardiac echo imaging of trans-septal puncture. The "SafeSept" guidewire is advanced through the trans-septal needle; while tenting constant force on the septum (A-C), the "SafeSept" easily crosses the fossa ovalis (D-F).

The trans-septal assembly (needle, dilator and sheath) was advanced over the guidewire. In particular, under fluoroscopic and intracardiac echo guidance, the "SafeSept" was advanced through the trans-septal needle; while tenting and maintaining constant force on the septum, the guidewire was advanced and easily crossed the interatrial septum (Figures 3 and 4). The wire (clearly visible thanks to its radiopaque coil) was further positioned in the left superior pulmonary vein.

The trans-septal needle was then advanced through the dilator and long sheath over the "SafeSept" across the fossa ovalis into the left atrium. Then the long sheath was placed in the left atrium and both trans-septal guidewire and dilator were pulled out.

Afterwards, unfractionated heparin was administered (100 U/kg) and pulmonary vein disconnection was successfully performed by radiofrequency ablation supported by the EnSite NavX electroanatomic mapping system.

DISCUSSION

In recent years the number of percutaneous therapeutic techniques requiring trans-septal catheterization has significantly increased[1,2]. The risks of complications related to perforation of the posterior atrial wall or aortic bulb remain limitations of this technique in the presence of anatomical alterations (distorted and/or thickened atrial septal tissue)[8].

Usually the trans-septal puncture is performed through fossa ovalis because it is the region offering the least resistance. This site can be located fluoroscopically and through the use of standard electrode catheters as anatomical landmarks (His region or, bulb of the aorta with a "pig-tail" catheter).

Intracardiac echocardiography was helpful to visualize the fossa ovalis in order to guide trans-septal puncture thus avoiding perforation of structures adjacent to the atrial septum or pericardial tamponade[3,4]. In the presence of unfavorable anatomy (*i.e.*, a thickened atrial septum, extremely elastic or aneurysmal fossa ovalis, presence of fibrosis due to a previous catheterization), trans-septal puncture may be challenging even with the use of these methods.

A brief application of radiofrequency to the septum, either through a dedicated radiofrequency catheter system or the use of an electrosurgical cautery pen, could be helpful in facilitating both fluoroscopy and imaging guidance[5,6].

In extremely difficult puncturing, "SafeSept" could be a valid option to cross the interatrial septum[7,9,10]. After crossing the septum, the guidewire immediately bends into a J shape, so as to be atraumatic when advanced into the left atrium. Furthermore, a radiopaque coil is positioned on the distal end of the wire to provide a fluoroscopic visualization during every step of the procedure.

In conclusion, trans-septal catheterization may be challenging if the interatrial septum is thickened, scarred, fibrous, too mobile and/or aneurysmal. The use of fluoroscopy, intracardiac ultrasound and RF energy are helpful, but may sometimes not be enough to achieve trans-septal catheterization. In these cases, the use of the "SafeSept" trans-septal guidewire may be a safe and effective option.

COMMENTS

Case characteristics

A 69-year-old man affected by palpitations with diagnosis of paroxysmal atrial fibrillation.

Clinical diagnosis

The patient had several recurrences of paroxysmal atrial fibrillation after the cryoablation of a common typical atrial flutter.

Differential diagnosis

Difficult trans-septal puncture using fluoroscopy and intracardiac echocardiography, radiofrequency energy delivery and "SafeSept" trans-septal guidewire.

Laboratory diagnosis

The patient had no alterations of hematological values.

Imaging diagnosis

Transthoracic echocardiography and gadolinium-enhanced cardiac magnetic resonance imaging showed a normal anatomy of the fossa ovalis and interatrial septum.

Pathological diagnosis

Access to the left atrium proved difficult and several unsuccessful attempts to perform the trans-septal puncture were made under both fluoroscopy and intracardiac echocardiography guidance, even with radiofrequency energy delivery.

Treatment

Trans-septal puncture was successfully carried out using a nitinol J-shaped "SafeSept" trans-septal guidewire.

Related reports

Very few cases of unsuccessful trans-septal puncture that require the use of nitinol J-shaped "SafeSept" trans-septal guidewire have been reported in the literature.

Term explanation

The novel nitinol J-shaped "SafeSept" trans-septal guidewire is designed to cross the interatrial septum through the trans-septal needle thanks to a special sharp tip but simultaneously is a non-traumatic device due to its rounded J-shape that reduces the risk of atrial wall perforation.

Experiences and lessons

Trans-septal catheterization may be challenging if the interatrial septum is thickened, scarred, fibrous, too mobile and/or aneurysmal. The use of fluoroscopy, intracardiac ultrasound and radiofrequency energy are helpful, but may sometimes not be enough to achieve trans-septal catheterization. In these cases, the use of the "SafeSept" trans-septal guidewire may be a safe and effective aid.

Peer-review

This manuscript showed a case of paroxysmal atrial fibrillation in whom SafeSept was effective for trans-septal puncture. The case is peculiar and interesting.

Abstract

Heart failure (HF) is a syndrome recognized as a health problem worldwide. Despite advances in treatment, patients with HF still have increased morbidity and mortality. Testosterone is one of the most researched hormones in the course of HF. Growing interest regarding the effect of testosterone, on a variety of body systems, has increased the knowledge about its mechanisms of action. The terms central and peripheral effects are used to distinguish the effects of testosterone on cardiac and extracardiac structures. Central effects include influences on cardiomyocytes and electrophysiology. Peripheral effects include influences on blood vessels, baroreceptor reactivity, skeletal muscles and erythropoesis. Current knowledge about peripheral effects of testosterone may explain much about beneficiary effects in the pathophysiology of HF syndrome. However, central, *i.e.*, cardiac effects of testosterone are to be further explored.

Key words: Cardiomyocytes; Exercise; Electrophysiology; Heart failure; Vasodilation; Testosterone

Core tip: Patients with heart failure often have a lower endogenous testosterone level. Testosterone has a number of effects on cardiac and extracardiac structures *via* genomic and non-genomic mechanisms. We summarize current knowledge about the involvement of testosterone in heart failure syndrome.

Bušić Ž, Čulić V. Central and peripheral testosterone effects in men with heart failure: An approach for cardiovascular research. *World J Cardiol* 2015; 7(9): 504-510 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i9/504.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i9.504

INTRODUCTION

Despite many advances in medicine, heart failure (HF) remains one of the leading causes of increased morbidity and mortality among adult population. In recent years, there has been growing interest in

Table 1 Effects of nonphysiological testosterone levels

	Supraphysiological	Subphysiological
Cardiomyocytes	Hypertrophy	Hypotrophy
QT interval	Shortening	Prolongation
Vasculature	Vasodilation	Not known
Skeletal muscles	Hypertrophy	Hypotrophy
Exercise capacity	Increased	Decreased
Baroreceptor sensitivity	Increased	Attenuated

hormonal disturbances that accompany HF. A body of evidence suggests that several hormones and a variety of metabolic signals may be altered in a way that instigates progression of the disease[1]. Within this framework, testosterone receives vivid research interest.

Many epidemiological studies have found a high incidence of comparably lower testosterone level in men with coronary heart disease, regardless of patient's age[2]. Moreover, population studies have found an association of increased all-cause and cardiovascular mortality with low testosterone levels in general population as well as within a subpopulation of men with coronary heart disease[3-7].

Testosterone deficiency has been implicated in the pathophysiology of HF, contributing to some characteristics of this syndrome such as reduced skeletal muscle mass, oxygen consumption, reduced exercise capacity and cachexia[8]. The association of serum testosterone levels with clinical severity of HF seems to be present only in non-obese HF patients[9]. In obese patients with HF, lower testosterone levels and a lack of correlation with the disease severity may suggest altered hormonal and hemodynamic mechanisms which could contribute to a better prognosis and the obesity paradox[9].

To distinguish and classify various cardiovascular, hormonal, muscular and other mechanisms the terms central, *i.e.*, cardiac and peripheral, *i.e.*, extracardiac effects are used to describe the effects of testosterone on cardiac and extracardiac structures (Figure 1). Those effects are particularly important under the circumstances of nonphysiological testosterone levels (Table 1).

CENTRAL EFFECTS OF TESTOSTERONE

Cardiomyocytes

Testosterone is responsible for protein synthesis and hypertrophy of the cardiac muscle of several investigated species, including humans, through a receptor-specific interaction which results in an increased amino acid incorporation into proteins[10]. In a post-infarction model of HF, testosterone supplementation led to a particular type of myocardial hypertrophy with a significant increase in left ventricular mass, but without increase in hypertrophy markers or collagen accumulation[11]. It appears that testosterone stimulates the expression of α-myosin heavy chain as opposed to β-myosin heavy chain which is usually seen in pathological cardiac hypertrophy, thus indicating a "physiological" type of cardiac hypertrophy with potentially long term improvement in cardiac function[10]. An animal study of ischemia-reperfusion injury showed that testosterone reduced cardiomyocyte injury by upregulating cardiac α1 adrenoceptor and possibly by activating cardiac mitochondrial ATP-sensitive potassium (K^+) channels[12].

It has been also suggested that testosterone has an influence on myocardial contractility. Gonadectomy in male rats changed the transcriptional and translational control of genes encoding the L-type calcium (Ca^{2+}) channel, the Na^+/Ca^{2+} exchanger, β1 adrenoceptors, and myosin heavy chain subunits which reduced cardiomyocyte contractile capacity[13,14].

Ventricular function

Among other clinical parameters, several studies have assessed the left ventricular ejection fraction in HF patients who received testosterone supplementation[15-19]. While some animal studies showed that androgens are important for cardiac contractility, such findings were not reported in humans. Despite improvement in exercise capacity and ventilatory efficiency in patients receiving testosterone supplementation, there was no improvement in left ventricular ejection fraction[15-19].

Higher serum levels of testosterone, most frequently found in athletes using prohibited anabolic androgen steroids, have been shown to cause myocardial hypertrophy[20,21]. However, in a study by Malkin *et al*[4], patients with HF that received testosterone supplementation had no increase in myocardial mass nor in wall thickness, thus suggesting that testosterone supplementation is safe if kept in physiologic doses.

Cardiac electrophysiology

Both endogenous and exogenous sex hormones have been shown to affect cardiac electrophysiology[22,23]. Changes in QT interval are associated with an increased risk of atrial and ventricular tachyarrhythmias, and of sudden cardiac death[24,25]. Several studies have been performed in order to explore the influence of testosterone on QT interval duration. It has been reported that ventricular repolarization was prolonged in castrated men compared with noncastrated men[26]. In addition, women with hyperandrogenism had shorter QT-interval duration than did their respective control[26]. Furthermore a negative linear correlation was found between the duration of QT interval and serum testosterone levels in hypogonadic men after receiving a single intramuscular administration of testosterone[27].

Low testosterone levels have been also associated with the incidence of atrial fibrillation, particularly in men over 80 years of age[28]. Hence, testosterone supplementation could possibly be beneficial for primary prevention of atrial fibrillation. However, an animal study from 2014, showed that testosterone supplementation in aging rabbits increased arrhythmogenesis by

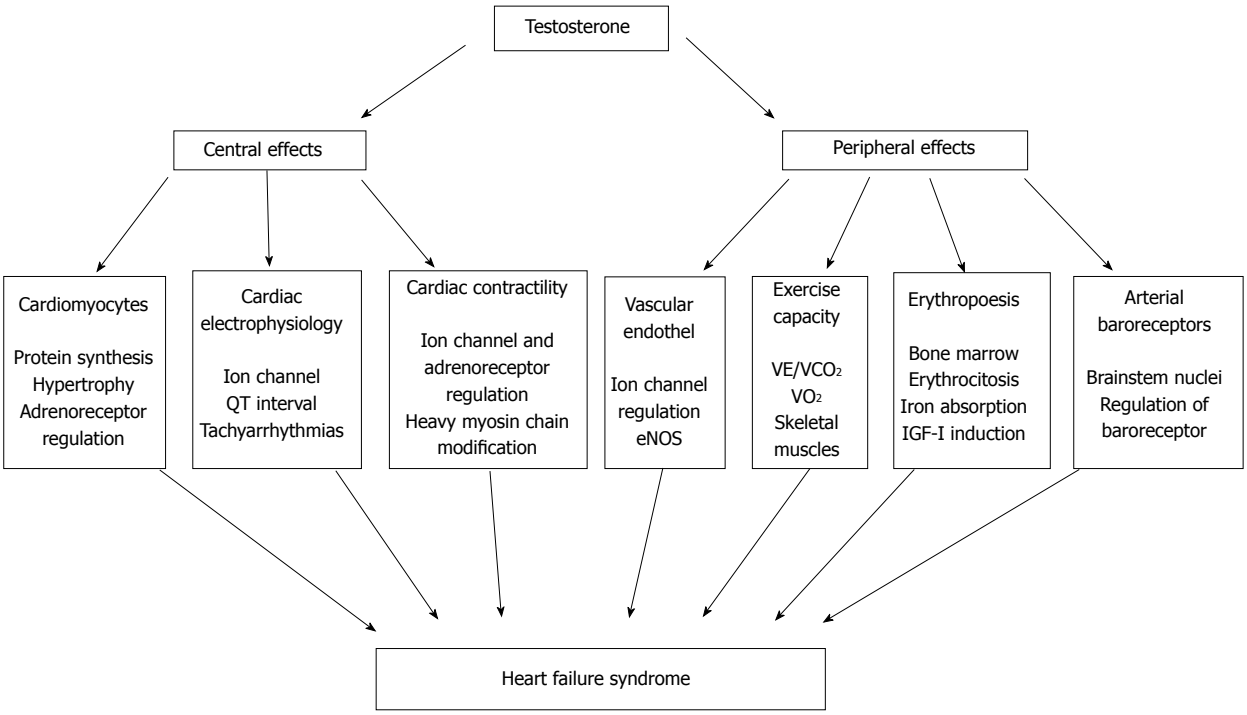

Figure 1 Testosterone effects that may be implicated in the pathogenesis of heart failure syndrome. eNOS: Endothelial nitric oxide synthase; VE/VCO_2: Ventilation to carbon dioxide production ratio; VO_2: Oxygen consumption; IGF-I: Insulin growth factor-I.

enhancing adrenergic activity which brought the previous hypothesis in question[29].

Several mechanisms, through which testosterone acts on cardiac electrophysiology, have been proposed. An animal study from 2005 found that testosterone induced a dose dependent shortening of action potential duration through non-genomic enhancement of slowly activating delayed rectifier K^+ current and suppressing the L-type Ca^{2+} current[30]. In another animal study, dihydrotestosterone, a metabolite of testosterone, induced QT interval shortening through an increased current density of inward repolarizing rectifier K^+ current and by rapidly activating delayed rectifier K^+ current[31]. Finally, in another animal study, repolarization of canine ventricular myocardium was significantly modified by testosterone, most likely due to increased expression of ion channel proteins[32]. However, those mechanisms are still being explored and at the moment there is not enough information about the effects of testosterone on cardiac electrophysiology.

PERIPHERAL EFFECTS OF TESTOSTERONE

Vascular effects

Basic cellular and molecular mechanisms through which testosterone regulates vascular responsiveness are not entirely understood. Animal studies suggest that testosterone affects vascular reactivity by both influencing endothelium-dependent and independent actions in a variety of vascular beds[33]. In HF, peripheral vasodilation produces a reduced cardiac afterload and increased cardiac output[34]. Coronary vasodilation improves myocardial oxygenation thereby achieving a beneficiary effect in HF patients[8,34].

Endothelium-dependent effects of testosterone include long term genomic and rapid non-genomic effects. Nitric oxide (NO) is a powerful vasodilator synthesized by the endothelial NO synthase (eNOS) and released, among other tissues, by the vascular endothelium[35]. Testosterone modulates NO release which in addition way is affecting vasoreactivity[36]. It is not fully understood whether this testosterone effect is genomic or non-genomic. There are several proposed mechanisms through which testosterone may act on NO synthesis and release. A study from 2012 showed that testosterone, *via* non-genomic activation of intracellular signaling pathways and Ca^{2+} influx, increases endothelial NO synthesis and additionally inhibits platelet aggregation[37]. Furthermore, in another study where vascular aging was explored, testosterone increased expression of genes that govern replicative life span which subsequently inhibited endothelial senescence *via* upregulation of eNOS activity[38].

In addition to well explored endothelium-dependent mechanisms, several studies investigated endothelium-independent effects of testosterone. The crucial endothelium-independent mechanism, which may underlie the vasodilatory effect of testosterone, involve ion channel function of the smooth muscle cells influencing K^+ channel opening and/or Ca^{2+} channel inactivation[39]. In an electrophysiological patch-clamp study, testosterone inactivated L-type voltage-operated

Ca^{2+} channels and consequently restricted Ca^{2+} influx and thereby inducing vasodilation[40]. Testosterone also shares the same molecular binding site as nifedipine on the subunit of L-type Ca^{2+} channels which causes channel blockade and may induce vasodilation[41]. Moreover testosterone blocks Ca^{2+} influx *via* store-operated Ca^{2+} channels by blocking their response to prostaglandin F2a[42]. As another option, a study from 2008 showed that testosterone activates voltage-operated K^+ channels and/or large-conductance Ca^{2+} activated K^+ channels, thereby increasing intracellular K^+ efflux and inducing vasodilation[43].

Baroreceptor sensitivity

It has been established that arterial baroreceptor sensitivity is attenuated in HF which is an important adverse prognostic indicator[44]. In light of this, Caminiti *et al*[18], sought out to investigate the effect of testosterone supplementation on baroreceptor sensitivity in patients with HF. Their results showed an increase in baroreceptor sensitivity in the testosterone treated group. Although they weren't able to identify the mechanisms through which testosterone enhances baroreceptor sensitivity, several animal studies have shown that testosterone administration improves arterial baroreceptor control of heart rate through an enhancement of cardiac efferent vagal activity[45-47]. It is possible that this effect takes place at central nervous system sites, because androgen receptors have been identified in brainstem nuclei that are involved in the baroreflex cardiac regulation[48].

Exercise

Patients with HF have poor exercise capacity test results. This is a consequence of poor left ventricular function, a poor ventilatory efficiency and muscle wasting which is enhanced in HF syndrome leading to early fatigue and limited exercise tolerance. Although peak oxygen consumption (VO_2) and ventilation to carbon dioxide production ratio (VE/VCO_2 slope) express different pathophysiologic segments of the cardiorespiratory response to exercise in HF, they both are facets of that response. Ventilatory efficiency, commonly assessed by the minute VE/VCO_2 and VO_2, is a powerful prognostic marker in the HF patients[49].

Another important segment in exercise capacity are skeletal muscles. Several morphological and functional irregularities, relatively independent of reduced blood flow, present in the skeletal muscle of HF patients contribute to early lactic acidosis and fatigue during exercise[50]. These changes are involved in the pathophysiology of HF and have been gathered under the term "the muscle hypothesis"[51]. According to this hypothesis, exaggerated ergoreflex activation occurs in exercising muscles of HF patient which leads, *via* activation of sympathetic system, to fatigue and an excessive ventilatory response in a form of dyspnea.

Recent studies have shown that testosterone supplementation improves exercise capacity, peak VO_2 and VE/VCO_2 slope[16-18]. The mechanism through which testosterone affects cardiorespiratory parameters in HF patients can be in part explained by the association of muscle ergoreflex overactivity with VE/VCO_2 slope[52]. Animal studies have indicated that anabolic androgens attenuate muscle fatigue in response to exercise, though the precise mechanism of this effect has not been identified[53,54]. Combination of exercise training and testosterone supplementation may beneficiary change muscle structure and function[50,55]. This may attenuate muscle ergoreflex activity and ventilatory response to exercise in HF patients and consequently improve exercise test results[50,55].

Erythropoesis

Further mechanism of testosterone that could explain improvement in exercise capacity and ventilatory response is the increase in hemoglobin level and oxygen delivery. A body of evidence suggests an association of lower hemoglobin levels with increased risk of hospitalization, poorer clinical status and death due to HF[56,57].

Testosterone has a strong stimulatory effect on erythropoiesis[58-60]. Suggested mechanisms of this effect are stimulation of intestinal iron absorption, erythrocyte iron incorporation and hemoglobin synthesis[60]. Although testosterone was found not to affect erythropoietin or soluble transferrin receptor levels, it is possible that testosterone has a direct effect on the bone marrow hematopoietic stem cells through the induction of insulin growth factor-I *via* androgen receptor-mediated mechanisms[61-63].

CLINICAL IMPLICATIONS

Testosterone deficiency is an independent risk factor of worse outcome in patients with HF of both sexes[64]. Testosterone supplementation results in positive physiological and biochemical changes in patients with HF and testosterone administration acutely increases cardiac output and reduces peripheral vascular resistance[15,65]. In addition, transdermal testosterone administration induces coronary vasodilation and increases coronary blood flow and improves angina threshold in patients with coronary artery disease[66,67].

An interesting question is whether testosterone may be helpful in women as it prove useful in men? As opposed to men, it seems that testosterone is not a significant factor of sudden cardiac arrest in women[68]. The only testosterone supplementation study that included female patients with HF showed no difference in effect on functional capacity and muscle strength therefore indicating no differences in possible mechanisms of action between male and female HF patients[69].

Another interesting issue is a possibility of the interplay among testosterone therapy and other endogenous anabolic hormones. Growth hormone and insulin growth factor-I levels are important for

preserving both cardiac morphology and performance in adult life[1]. Individuals with low insulin growth factor-I levels undergo cardiovascular alterations that are reminiscent of those observed in HF patients and are corrected by replacement therapy[70,71]. An interaction also exists between testosterone and insulin growth factor-1 through androgen receptor-mediated mechanisms[61-63]. Whether testosterone acts directly on insulin growth factor-I or indirectly by influencing the growth hormone is to be investigated.

FUTURE RESEARCH

Testosterone is currently one of the most investigated hormones in the course and prognosis of HF syndrome. Over the past decade, growing interest has widen research targets that could contribute to symptoms and pathophysiology of HF on all body systems. Studies have been performed in order to establish whether testosterone can be included in the standard therapy for HF patients with a low testosterone level.

Several unanswered questions should be addressed in future studies: (1) are the effects of exogenous testosterone on tissues, organs and body systems the same as the effects of endogenous testosterone? (2) is there a difference between the routs of testosterone administration which could be important for testosterone supplementation? (3) what is the role of testosterone on cardiac fibrosis and remodeling[34,71]? and (4) has testosterone adverse effects in the elderly, particularly in those with an advanced ischemic or other heart disease[34]?

In conclusion, current knowledge about peripheral effects of testosterone may explain much about beneficiary effects in the pathophysiology of HF syndrome. However, many fields of testosterone's central, *i.e.*, cardiac effects are to be further explored.

Abstract

Leptin is an adipokine that has been linked with the cardiovascular complications resulting from obesity such as hypertension and heart disease. Obese patients have high levels of circulating leptin due to increased fat mass. Clinical and population studies have correlated high levels of circulating leptin with the development of cardiac hypertrophy in obesity. Leptin has also been demonstrated to increase the growth of cultured cardiomyocytes. However, several animal studies of obese leptin deficient mice have not supported a role for leptin in promoting cardiac hypertrophy so the role of leptin in this pathological process remains unclear. Leptin is also an important hormone in the regulation of cardiac metabolism where it supports oxidation of glucose and fatty acids. In addition, leptin plays a critical role in protecting the heart from excess lipid accumulation and the formation of toxic lipids in obesity a condition known as cardiac lipotoxicity. This paper focuses on the data supporting and refuting leptin's role in promoting cardiac hypertrophy as well as its important role in the regulation of cardiac metabolism and protection against cardiac lipotoxicity.

Key words: Leptin; Leptin receptor; Lipotoxicity; Cardiotoxicity; Obesity; Diabetes

Core tip: Leptin is a hormone derived from adipocytes which regulates food intake and body weight. It is present at high levels in obese individuals where it can impact organs such as the heart. Leptin has been shown to both promote and protect the heart against

obesity induced heart disease. This review examines the controversial role of leptin in the development of cardiac hypertrophy as well as its important role in regulating cardiac metabolism and protecting the heart against obesity induced lipotoxicity.

INTRODUCTION

Leptin is a hormone most abundantly produced by white adipocytes which then acts in the hypothalamus of the brain to decrease appetite and increase energy expenditure. Leptin was discovered in the early 1990's after genetic mapping of a mutation in the gene found in a specific strain of obese mice, the *ob/ob* mouse, which was originally described in the 1950's[1,2]. These mice are characterized by having no leptin which results in marked hyperphagia, decreased energy expenditure and obesity. Another strain of obese mice called *db/db* mouse was subsequently found to have a mutation in the *ObR* gene encoding the leptin receptor[3]. This strain of mice is characterized by having very high levels of circulating leptin due to lack of functional leptin receptors, marked hyperphagia, decreased energy expenditure and obesity. There are also several rat strains with defective leptin receptor such as the Zucker fatty (*fa/fa*) rat and the Koletsky fatty rat[4,5]. Recently, a zinc-finger approach was utilized to create a rat model of leptin receptor deficiency on a salt-sensitive hypertension background[6]. All of these models as well as development of cell type/tissue-specific knockouts of the *ObR* gene have greatly increased our knowledge about the physiological role of leptin[7].

While leptin is mainly expressed in adipose tissue, it is also expressed in peripheral organs such as the heart[8]. Leptin receptors are also highly expressed in the heart of several species including humans[9,10]. In the rat heart, the long form of the leptin receptor is expressed in addition to other shorter isoforms[11]. Reverse-transcriptase polymerase chain reaction of the mouse heart readily reveals expression of all isoforms of the leptin receptor similar to the expression pattern found in the brain[12] (Figure 1). The long form of the leptin receptor, ObRb, activates signaling through the Janus kinases (JAK)/ signal transducers and activators of transcription (STAT) pathway and other Src Homology 2 domain containing proteins such as suppressor of cytokine signalling and SHP-2 (Src-like homology 2 domain containing protein tyrosine phosphatase) and STAT[13]. Short leptin receptor isoforms (ObRa, ObRc, ObRd) contain a box 1 motif which is able to bind JAK and activate other signal transduction cascades[13]. The ObRe which is also referred to as the soluble leptin receptor can regulate serum leptin concentration and also serves as a carrier protein delivering the hormone to its membrane receptors[14]. Not only are leptin receptors expressed in the heart but they are also regulated by various stimuli. Cardiac ischemia has been reported to have varying effects on expression of leptin receptors, with studies demonstrating that a 30 min ischemic period was associated with a decrease in leptin receptor expression and another study reporting that a 40 min ischemic period increased leptin receptor expression[11,15]. The specific role of leptin in cardiac ischemia was addressed in an elegant study utilizing cardiac-specific deletion of leptin receptors. Cardiac-specific deletion of leptin receptors resulted in a decrease in contractile function and metabolism of glucose and in an increase in mortality and morbidity following cardiac ischemia[16]. These results highlight the important cardio-protective function of leptin in cardiac ischemia due in part to its role in the regulation of cardiac metabolism which will be discussed in greater detail below. Leptin receptors in the heart are also regulated by pressure and stretch. It has been reported that pressure-overload induced cardiac hypertrophy resulted in a significant increase in the long form of the leptin receptor (ObR-B) but not the short form (ObR-A) in the heart[17]. The controversial role of leptin in cardiac hypertrophy will be addressed in the following section below.

THE ROLE OF LEPTIN IN CARDIAC HYPERTROPHY

Leptin has several functions in the heart including stimulation of fatty acid and glucose metabolism, prevention of steatosis, and protection against apoptosis (Figure 2). It also can raise blood pressure and heart rate through central mechanisms and promotes cardiac inflammation (Figure 2). Although obesity is associated with hyperleptinemia, increased cardiac mass and left ventricular (LV) wall thickness, it is unclear if leptin can directly cause cardiac hypertrophy (Figure 2). Epidemiologic studies have demonstrated positive correlations between plasma leptin levels and LV hypertrophy[18]. However, most of these observations are confounded by the fact that increased body mass and plasma leptin levels are highly correlated[19]. Obesity is also usually accompanied by hypertension which is the most common cause of cardiac hypertrophy[20]. In addition to increased blood pressure, obesity may cause cardiac hypertrophy by several other mechanisms including neurohormonal (renin-angiotensin-aldosterone system) and sympathetic nervous system activation, insulin resistance and hyperglycemia, and increased blood volume[21,22]. The exact roles of leptin in regulating cardiac structural changes in obesity such as hypertrophy are not well understood. In fact, differential hypertrophic and antihypertrophic effects of leptin have

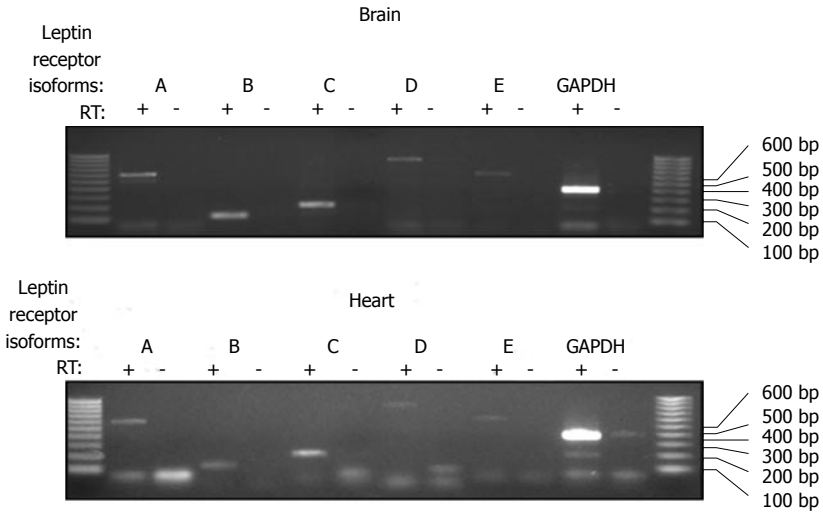

Figure 1 Comparison of leptin receptor isoforms in the mouse brain and heart. RNA was isolated from the brain and heart and reverse transcribed into cDNA. Polymerase chain reaction was then performed using primers specific for each mouse isoform of the leptin receptor as previously described[12]. All 5 of the leptin receptor isoforms were detected in the mouse heart as well as the brain.

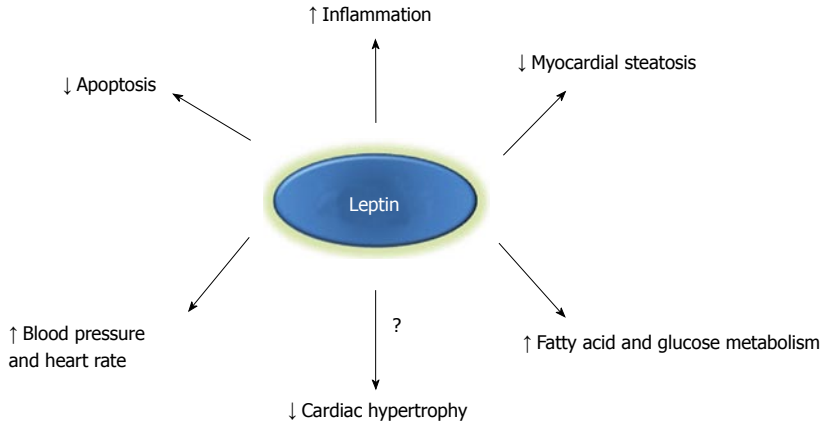

Figure 2 Potential mechanisms by which leptin may mediate cardiac function. Leptin may exert cardioprotective or maladaptive effects through hemodynamic factors such as increased heart rate and blood pressure, metabolic changes including augmented fatty acid or glucose utilization, reduced cardiac apoptosis, or structural cardiac changes such reduced cardiac lipid accumulation and possibly attenuated myocardial hypertrophy. Increased inflammation may be beneficial in some cardiac conditions (*i.e.*, post-myocardial infarction) depending on the timing and extent of the inflammatory response.

been reported and may be related to temporal effects or synergistic interactions with other obesity-associated factors.

Does leptin directly cause cardiac hypertrophy?

One of the earliest studies demonstrating a pro-hypertrophic effect of leptin comes from an experiment by Rajapurohitam *et al*[23] in which cultured neonatal rat ventricular myocytes were treated with varying concentrations of leptin. The authors observed a 42% increase in cell surface area 24 h after administration of 3.1 nmol/L leptin. Exposure to leptin also significantly increased cell size in cultured human and neonatal rat cardiomyocytes[24,25]. Leptin treatment increased matrix metalloproteinase-2 activity and collagen Ⅲ and Ⅳ mRNA expression but resulted in no change in total collagen synthesis. Tajmir *et al*[26] demonstrated hyperplasia of both murine and human cardiomyocytes in response to leptin treatment which appeared to be mediated by activation of extracellular signal-regulated kinase (ERK) 1/2 and phosphatidylinositol-3 kinase. However, studies by Piñieiro *et al*[27] did not observe any effect of Leptn to increase cell size of murine HL-1 cardiomyocytes while these *in vitro* results suggest leptin contributes to adverse cardiac remodeling and hypertrophy, the results from whole animal and human studies are not that clear regarding the direct role of leptin to cause cardiac hypertrophy.

Human patient studies have reported associations of plasma leptin levels with cardiac hypertrophy. In hypertensive insulin-resistant men, fasting plasma leptin levels were positively correlated with myocardial wall thickness, but not with LV mass. This relationship was significant even after controlling for BMI, waist-to-hip ratio and blood pressure suggesting an independent effect of leptin on cardiac structure[28]. In another study, LV mass was found to be positively correlated with leptin levels after controlling for body mass index (BMI)[29]. After gastric bypass surgery and profound weight loss, there were significant reductions in BMI, insulin resistance and leptin levels, but only leptin levels were significantly correlated with the decrease in LV mass on multivariable analyses. These clinical findings suggest that leptin may contribute to the LV hypertrophic process. In a study of 36 hypertensive men, plasma leptin was significantly predictive of echocardiographic wall thickness independent of 24 h ambulatory blood pressure. However, other significant predictors in this model included insulin sensitivity and night-time diastolic blood pressure[18].

The mechanisms by which leptin may contribute to myocardial hypertrophy are poorly understood. In addition to its powerful effects to regulate appetite and body weight, leptin also has a powerful effect to activate

the sympathetic nervous system *via* central nervous system pathways. Chronic leptin infusion increased arterial blood pressure which increases cardiac afterload and which would lead to increased cardiac hypertrophy over the long-term[30]. Leptin is also associated with increased heart rate which would also tend to increase myocardial workload and promote hypertrophy[31]. In addition to these effects, leptin may also contribute to endothelial dysfunction and vascular stiffness which could also contribute to cardiac hypertrophy[32]. It is important to note, however, that many of the reported effects of leptin are based on either short-term animal studies, *in vitro* experiments or epidemiologic data which makes it difficult to determine the direct role of leptin in regulating cardiac hypertrophy.

While it is clear that obesity is associated with cardiac hypertrophy, the role of leptin as a mediator or cause is still under investigation. Evidence strongly supporting an antihypertrophic role of leptin comes from an elegant experiment by Barouch *et al*[33] in which they evaluated LV structure and function, including LV wall thickness and mass, in *ob/ob* and *db/db* mice. To differentiate the direct effects of leptin on cardiac hypertrophy from the effects of obesity, the investigators subjected *ob/ob* mice to intravenous leptin infusion or caloric restriction. Administration of leptin significantly reduced wall thickness and reduced myocyte size by approximately 25%. While both the leptin-treated *ob/ob* mice and the calorie-restricted mice lost a similar amount of body weight, the pair fed group had no significant reduction in LV mass or wall thickness suggesting a leptin dependent effect in the reversal of myocardial hypertrophy. Additionally, the hypertrophic LV changes in the *ob/ob* mouse are not related to changes in blood pressure since these mice are normotensive[34]. Another important observation of this study was that the increase in myocardial wall thickness was not related to fatty infiltration of the heart muscle, as cardiac myocyte size was found to be increased in *ob/ob* mice[33].

Additional evidence for an antihypertrophic effect of leptin comes from experiments performed in our lab[35]. We evaluated the direct effect of leptin on myocardial lipid accumulation and LV hypertrophy in *db/db* mice and transgenic *db/db* "rescue" mice in which the normal rat leptin receptor was overexpressed or "rescued" in a cardiomyocyte-specific manner. After 30 wk of study including serial metabolic parameters and echocardiographic assessments, both the *db/db* and "rescue" mice were morbidly obese, hyperglycemic, and had high plasma triglycerides compared to lean control mice. The *db/db* mice developed significant cardiac hypertrophy and increased LV wall thickness. The "rescue" mice, in which cardiac leptin signaling was restored, had lower heart weights and LV wall thickness compared to *db/db* mice suggesting an antihypertrophic effect of leptin. If leptin had a direct hypertrophic effect, our *db/db* cardiac leptin receptor rescue mice would be primed for an increase in myocardial mass in this setting. *db/db* mice have very elevated circulating leptin levels, and our transgenic "rescue" mice had evidence of increased leptin signaling in the heart as indicated by elevated levels of phosphorylated STAT3. If increased leptin signaling directly leads to cardiac hypertrophy our transgenic "rescue" model would have developed an increase in myocardial mass and wall thickness due to high circulating leptin and augmented leptin receptor responsiveness. One limitation of this study was that we did not specifically evaluate myocyte sizes but instead measured wall thickness and heart weight[35].

In summary, the available data on the effects of leptin on cardiac growth and hypertrophy are conflicting and are summarized in Table 1. Hyperleptinemia is associated with cardiac hypertrophy but the presence of many confounding factors makes it difficult to establish a causal relationship. Furthermore, acute and chronic effects of leptin differentially regulate myocyte growth. Obesity and subsequent leptin resistance may play an important role in this relationship. Animal studies suggest that hyperleptinemia does not directly cause cardiac hypertrophy but may rather play an integral role in cardiac structural alterations that occur in response to obesity and the associated hemodynamic and metabolic changes. Additional, well controlled studies are warranted to better delineate the mechanisms by which leptin may regulate cardiac structural remodeling.

Leptin and cardiac function

In addition to its role in regulating cardiac structural changes, leptin may also be an important factor in regulating cardiac function. Leptin has been associated with pathophysiologic cardiovascular conditions including coronary artery disease and congestive heart failure[36,37]. Leptin has important effects on systemic hemodynamics and myocardial metabolism (as discussed in detail below) which may also have profound effects to regulate cardiac function. Similar to its potential implication in cardiac hypertrophy, the effects of hyperleptinemia on cardiac function have been difficult to assess given the number of confounding factors associated with obesity that all have detrimental effects on the heart. As obesity and its co-morbid conditions such as hypertension and diabetes are increasingly prevalent, understanding the relationships and mechanisms by which each of these conditions impacts the development and progression of congestive heart failure has important clinical implications for its prevention and treatment.

Elevated leptin levels have been observed in patients with dilated cardiomyopathy and have been suggested to be a marker of heart failure progression[38]. In a prospective study of 4080 older men followed for 9 years, increased BMI and circulating leptin levels were independent predictors of incident heart failure. After adjustment for BMI and other potential mediators, increased leptin levels remained significantly associated with an increased risk for heart failure in men without pre-existing coronary artery disease[39]. Leptin levels were also associated with incident congestive heart failure and cardiovascular disease in an elderly cohort

Table 1 Effects of leptin on cardiac mass and left ventricular hypertrophy

	Ref.	Findings	Effect of leptin on LVH
In vitro experiments	Rajapurohitam *et al*[23]	Exposure of cultured neonatal rat ventricular myocytes to leptin (0.31 to 31.4 nmol/L) increased cell area by 42%	Pro-hypertrophic
	Xu *et al*[25]	Exposure of cultured neonatal rat cardiomyocytes to leptin (1-1000 ng) for 4 h increased cell surface area	Pro-hypertrophic
	Piñieiro *et al*[27]	Exposure of murine HL-1 cells to leptin did not increase cell size of cardiomyocytes	Neutral
	Madani *et al*[24]	Treatment of human pediatric cardiomyocytes with 6 nmol/L leptin increased cell size by 60%	Pro-hypertrophic
	Tajmir *et al*[26]	Treatment of HL-1 cells with 60 nmol/L leptin increased cell numbers 2.3-fold	Pro-hypertrophic
In vivo experiments	Barouch *et al*[33]	6-mo-old leptin deficient *ob/ob* mice had increased myocyte diameters compared with wild-type mice. Leptin (*iv*) treatment in *ob/ob* mice completely reversed LVH and normalized wall thickness as well as reduced cellular hypertrophy by approximately 25%. Pair-feeding did not significantly reduce LV mass despite similar weight loss	Anti-hypertrophic
	Hall *et al*[35]	*db/db* mice developed LVH (increased wall thickness and heart weights). Transgenic *db/db* mice with cardiomyocyte-specific leptin receptor rescue did not cause LVH; in fact the heart weights were reduced	Anti-hypertrophic
Epidemiologic studies	Paolisso *et al*[28]	Plasma leptin level was correlated (n = 55 males) with interventricular wall (r = 0.34) and posterior wall (r = 0.38) thicknesses after adjusting for BMI and waist/hip ratio	Pro-hypertrophic
	Paolisso *et al*[18]	Study of 36 hypertensive patients demonstrating increased LV wall thickness (but not LV mass) measured by echo was associated with plasma leptin independent of BMI or waist/hip ratio (P = 0.001)	Pro-hypertrophic
	Perego *et al*[29]	Study of 31 obese subjects undergoing gastric bypass surgery demonstrated leptin was independently associated with LV mass (β = 10.66, P = 0.001). One year after surgery, decrease in LV mass only correlated with the decrease in leptin levels (P = 0.01)	Pro-hypertrophic
	Lieb *et al*[40]	Cross-sectional analysis of 432 aged (> 70 yr) participants in the Framingham Heart Study demonstrated leptin concentrations were inversely correlated with LV mass (β = -0.134, P = 0.02), left atrial size (β = -0.131, P = 0.04) and LV wall thickness (β = -0.134, P = 0.02) measured by echo	Anti-hypertrophic
	Martin *et al*[41]	In 1464 MESA Study participants who underwent cardiac magnetic resonance imaging, a 1-SD increment in leptin was associated with smaller LV mass (β = -4.66%, P < 0.01), LV volume (β = -5.87, P < 0.01), and reduced odds ratio for presence of LVH (OR = 0.65, P < 0.01) after adjustment for age, gender, race, height, and weight	Anti-hypertrophic

LVH: Left ventricular hypertrophy; BMI: Body mass index.

from the Framingham Heart Study. However, after adjustment for BMI the association with congestive heart failure was negated[40]. More recently, investigators from the Multi-Ethnic Study of Atherosclerosis demonstrated that leptin levels were not associated with incident cardiovascular events after adjustment for cardiovascular risk factors and BMI[41]. Based on these epidemiologic data, it remains unclear whether leptin is associated with development of heart failure, and if so, whether it plays a causal or compensatory role?

Leptin exerts physiologic effects that may be detrimental in states of cardiac dysfunction or heart failure. Leptin's hemodynamic effects generally increase myocardial workload *via* activation of the sympathetic nervous system. These effects include increasing resting heart rate and blood pressure[30]. Leptin may therefore act synergistically with other factors associated with obesity such as hyperglycemia, inflammation, and oxidative stress to accelerate the development of cardiovascular disease. However, it is possible that the chronic effects of leptin may have adverse consequences on myocardial function and the acute effects may provide a compensatory response to cardiac insults such as ischemia or heart failure.

Evidence for an acute beneficial effect of leptin comes from studies in experimentally-induced myocardial infarction and heart failure. McGaffin *et al*[16] induced anterior myocardial infarctions in control mice and in mice with cardiac-specific deletion of the leptin receptor. Mice lacking the leptin receptor specifically in the heart developed more LV dysfunction and had higher mortality after induction of myocardial infarction. The disruption of leptin signaling was associated with more LV dilation, hypertrophy, inflammation and adverse cardiac remodeling post-myocardial infarction. These investigators also demonstrated that many of the beneficial effects of leptin in this setting may be mediated *via* the AMP-activated protein kinase (AMPK) pathway.

We have studied the acute protective effects of leptin in a model of heart failure induced by Cre-recombinase activation[42]. Activation of Cre-recombinase is a widespread molecular tool used to conditionally delete or express genes in a tissue-specific and temporal manner. This technique has been somewhat limited due to observations by our lab and others that induction of Cre-recombinase activity in the heart can lead to transient LV dysfunction and a dramatic drop in ejection fraction[43,44]. Specifically, we reported that conditional deletion of the cardiac leptin receptor resulted in severe cardiogenic shock and death of the animals which was most likely related to impaired myocardial energy metabolism[42].

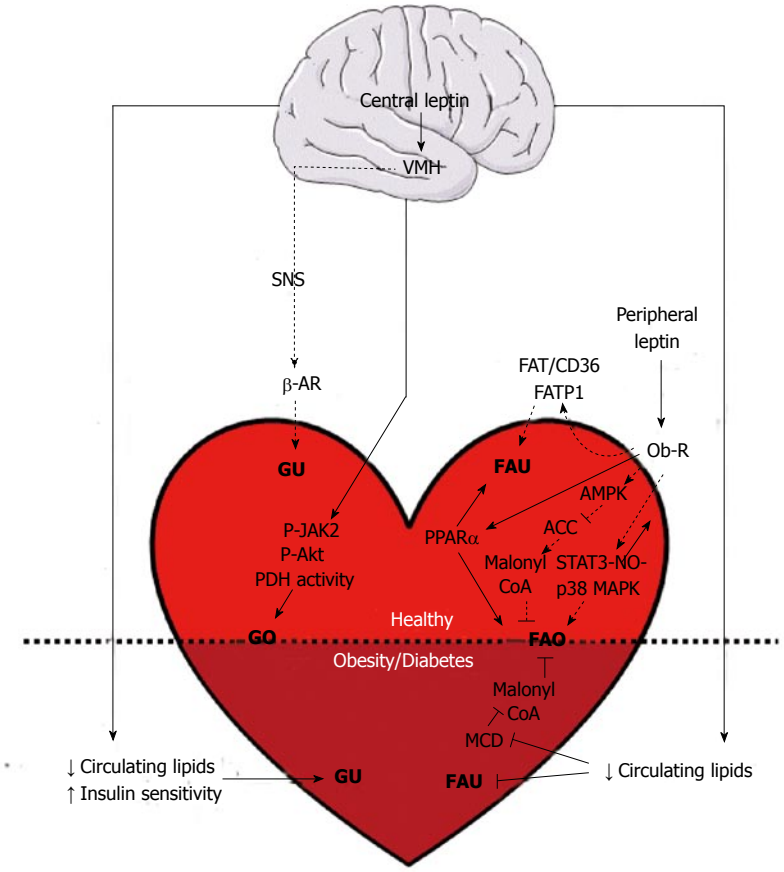

Figure 3 Cardiometabolic effects of leptin in health and obesity. Triangular and flat arrowheads represent stimulatory and inhibitory effects on the designed targets, respectively. Dotted lines indicate acute leptin effects (appearing between less than an hour and several hours of treatment), while plain lines represent chronic leptin effects (reported after several days or weeks of treatment). ACC: Acetyl-CoA carboxylase; AMPK: AMP-activated protein kinase; β-AR: Beta-adrenergic receptor; FAO: Fatty acid oxidation; FAT/CD36: Fatty acid translocase/cluster of differentiation 36; FATP1: Fatty acid transport protein 1; FAU: Fatty acid uptake; GO: Glucose oxidation; GU: Glucose uptake; MAPK: Mitogen-activated protein kinase; MCD: Malonyl-CoA decarboxylase; NO: Nitric oxide; Ob-R: Leptin receptor; P-Akt: Phosphorylated Akt kinase; PDH: Pyruvate dehydrogenase; P-JAK2: Phosphorylated Janus kinase 2; PPARα: Peroxisome proliferator-activated receptor alpha; SNS: Sympathetic nervous system; STAT3: Signal transducer and activator of transcription 3; VMH: Ventromedial hypothalamus. Horizontal black line demarcates differences between the healthy heart and the heart in obesity/diabetes.

These results emphasize the important role that leptin plays in cardiac metabolism which will be discussed in further detail in the next section.

Further evidence for a beneficial effect of leptin on cardiac function comes from experiments showing aged *ob/ob* and *db/db* mice have increased cardiac myocyte apoptosis and decreased survival compared with wild-type controls[45]. Leptin treatment significantly reduced apoptosis in *ob/ob* mice as well as in isolated myocytes. Although *ob/ob* and *db/db* mice generally have normal LV systolic function, they appear to have LV diastolic functional abnormalities[35,46]. These studies suggest that intact cardiac leptin signaling is important for normal cardiac function and may be protective against cardiac insults such as ischemia.

ROLE OF LEPTIN IN THE REGULATION OF CARDIAC METABOLISM

The role of leptin in the control of whole body energy homeostasis in humans is well established[47]. The effects of leptin on myocardial metabolism, and the consequences for cardiac adaptation in disease states, are far less well understood. Our knowledge in that area comes from studies performed on live rodents and isolated heart preparations. These studies have focused on the metabolism of glucose and free fatty acids, the main substrates for energy provision of the heart. Altogether, the investigations have revealed a dichotomy between central and peripheral actions of leptin (Figure 3). However, variations in the age or strain of animals, and in the experimental conditions employed, have made it difficult to identify with certainty the molecular regulatory pathways involved. It should also be noted that most studies used male animals only. Consequently, it is unknown whether the metabolic actions of leptin on the heart are characterized by a sexual dimorphism. This part of the review will focus first on the cardiometabolic effects mediated by leptin signaling in the brain. The metabolic consequence of leptin signaling activation in cardiac muscle will then be reviewed. Lastly, the effects of leptin on cardiac metabolism in disease states, and their impact on contractile function, will be discussed.

Centrally mediated effects of leptin on cardiac metabolism

Pioneering work performed with the leptin-deficient *ob/ob* mice demonstrated that chronic intraperitoneal leptin injection at a sub-active dose for the reduction of body weight gain or hyperinsulinemia was sufficient to normalize blood glucose levels[48]. It was later demonstrated in the same animal model that acute intravenous infusion of leptin increased glucose turnover and stimulated the uptake of glucose in peripheral organs, including the heart. The 6-fold increase in myocardial glucose uptake did not significantly impact heart rate[49]. Both intravenous and intracerebroventricular (*icv*) infusions of leptin were found to similarly increase glucose turnover in C57BL/6J wild-type mice[50]. A single bolus injection of leptin in the ventromedial

hypothalamus of young Sprague Dawley rats also resulted in a 4-fold increase in myocardial glucose uptake[51]. This increase in glucose uptake was shown to be additive to the one induced by an intravenous administration of insulin[42]. Based on these observations it was concluded that this rapid increase in peripheral glucose utilization is governed by a central mechanism, independent from insulin, and involving the activation of sympathetic nerves and the local activation of β-adrenergic receptors on target tissues[52]. A week of daily *icv* leptin administration in C57BL mice on a low-fat diet also resulted in an increase in myocardial glucose oxidation that was associated with increased phosphorylation of JAK2 and Akt kinases, and with increased pyruvate dehydrogenase activity (Figure 3). Rates of palmitate oxidation were not significantly altered, and here again, the switch toward higher glucose utilization did not modify mechanical function of the heart[53]. Thus, in rodents with normal leptin sensitivity, both acute and chronic activation of central leptin signaling favor myocardial glucose utilization through mechanisms stimulating the uptake and the oxidation of this substrate. Although the involvement of other hormonal signals cannot be ruled out, the effect seems to be independent from insulin secretion or from a change in insulin sensitivity.

Peripheral effects of leptin on cardiac metabolism

Unlike the reports on its central actions, there is little evidence to support a stimulatory effect of peripheral leptin on myocardial glucose metabolism: While a small but significant increase in glucose uptake was reported when hearts of Wistar rats were perfused in the Langendorff mode with a low dose of leptin (1 ng/mL), the effect may have been caused by the absence of fatty acids in the perfusate[54]. Indeed, in hearts of male Sprague Dawley rats perfused in the working mode with both glucose and palmitate, rates of glucose oxidation were unaffected by the presence of a pharmacological dose of leptin (60 ng/mL). Conversely, the total oxidation of fatty acids, from both exogenous (palmitate) and endogenous (triacylglycerol stores) origin, increased by 82%[55]. Using similar experimental conditions, Sharma and colleagues confirmed the existence of a leptin-mediated increase in exogenous palmitate oxidation that occurred in absence of changes for the rates of glucose oxidation[56]. Experiments performed with HL-1 cardiomyocytes partly corroborate these results: while a 1 h incubation with leptin failed to modify basal or insulin-stimulated glucose uptake and oxidation, it resulted in increased palmitate uptake and oxidation[57]. The increase in palmitate uptake was linked to the upregulation of the fatty acid transporters FATP1 and CD36. It is noteworthy that the incubation of neonatal rat ventricular myocytes with leptin for 72 h induced the expression of peroxisome proliferator-activated receptor alpha (PPARα), a key activator of fatty acid metabolism in the heart[58]. However, while increased fatty acid oxidation in HL-1 cells was traced to an increase in AMP-activated protein kinase activity and to the subsequent inhibition of malonyl-CoA production (a potent endogenous inhibitor of mitochondrial fatty acid uptake), this mechanism was not induced in the isolated rat heart[55]. Instead, in the intact heart, leptin was found to stimulate fatty acid oxidation by a STAT-3-nitric oxide-p38 MAPK-dependent mechanism (Figure 3)[56]. In conclusion, based on experimental settings where both glucose and fatty acids were present, the activation of myocardial leptin signaling rapidly stimulates fatty acid uptake and oxidation without affecting glucose oxidation. In the long term, leptin may also promote fatty acid oxidation through the upregulation of PPARα.

Metabolic effects of leptin in disease states

Obesity and diabetes are characterized by an increased reliance of the heart on fatty acid oxidation for energy provision. Sustained high rates of fatty acid uptake and oxidation inhibit both basal rates of glucose oxidation and insulin-stimulated glucose utilization, leading to a dramatic reduction in cardiac mechanical efficiency (work performed per unit of oxygen consumed)[59,60]. This metabolic remodeling has been observed in *ob/ob* mice, and persists even when the isolated hearts are perfused under low fatty acid condition[61]. However, this metabolic remodeling is reversible, and glucose intolerant patients undergoing a modest weight loss present with reduced myocardial fatty acid uptake and with improved cardiac mechanical function[62]. Sloan and colleagues elegantly demonstrated the importance of hypothalamic leptin signaling in the regulation of the balance of myocardial substrate selection during weight loss. By combining calorie restriction with leptin treatments in *ob/ob* mice, they showed that the hormone is necessary to normalize basal myocardial palmitate oxidation and to restore the insulin-mediated switch to glucose utilization[63]. The authors attributed their results to the leptin-mediated inhibition of the rise in circulating free fatty acids caused by calorie restriction, thereby leading to the normalization of myocardial fatty acid oxidation gene expression and to the improvement of myocardial insulin sensitivity. In accordance with these results, Keung *et al*[53] observed that chronic central leptin treatment (*via* intracerebroventricular infusion) of C57BL mice inhibited the increase in myocardial fatty acid oxidation caused by high-fat feeding. The effect was also linked to an improvement in insulin sensitivity and to a decrease in circulating lipid levels, with a subsequent reduction in the expression of cardiac malonyl-CoA decarboxylase, the enzyme that degrades malonyl-CoA (Figure 3). Although the absolute rates of myocardial glucose oxidation were unaffected, this resulted in an increased contribution of glucose metabolism to Krebs cycle activity[53]. Lastly, in a rat model of insulin-dependent diabetes, increased glucose uptake in cardiac muscle as well as in several other organs, together with the suppression of hepatic glucose output, is part of the mechanism by which the activation of central leptin signaling normalizes gly-

cemia[64].

Heart failure also elicits disturbances in the balance between fatty acid and glucose oxidation. Severe heart failure has generally been associated with increased glucose oxidation and decreased fatty acid oxidation, a switch in substrate meant to improve mechanical efficiency of the stressed heart[65]. The expression of leptin and of its receptor increases more than 4-fold in the failing human heart, suggesting increased activity of this signaling pathway as the condition progresses[66]. In a murine model with heart failure from ischemic origin, cardiomyocyte-specific deletion of the leptin receptor exacerbated the deterioration of myocardial structure and function. While myocardial metabolism was normal in the unstressed heart, cardiac specific loss of leptin receptors completely inhibited the switch toward increased glycolysis and glucose oxidation post myocardial infarction and enhanced the development of heart failure[16,67]. These results indicate that both central and cardiac leptin signaling play an important role in metabolic adaptation of the heart in heart failure. The beneficial effects of leptin are achieved either by favoring the return to a normal energy balance in dysregulated metabolic states, or by facilitating the transition toward a state of improved mechanical efficiency.

What is lipotoxicity?

Excess fatty acids as occurs in individuals who consume too many calories or expend too few calories are normally stored as triglycerides in white adipose tissue. However, when there is a defect in the amount of adipose tissue as seen in lipodystrophy or an excessive amount of fatty acids are consumed which exceed the ability of white adipose tissue to expand as seen in obesity, fatty acids can start to accumulate in organs such as the heart. With obesity, the substrate preference and utilization of the heart becomes altered such that substrate utilization is shifted towards fatty acids. This switch towards fatty acid metabolism is promoted by the increased expression of proteins involved in fatty acid oxidation such as carnitine palmitoyltransferase-1 (CPT1). These alterations in normal fatty acid oxidation can promote the formation of toxic lipids like ceramide and contribute to cardiac dysfunction observed in obesity[68-71]. Several studies have demonstrated that increases in ceramide production which arises by condensation of unoxidized palmitoyl-CoA and serine causes cells including cardiac myocytes to undergo apoptosis and die[72,73]. Diacylglycerol (DAG) is another lipid that can mediate fatty acid-induced toxicity. DAG acyl transferase (DGAT) is the enzyme responsible for the addition of the final fatty acid onto DAG to convert it to triglyceride. Transgenic mice which overexpress DGAT in the heart have increased lipid accumulation in the form of increased triglyceride levels but they are protected from lipotoxic induced cardiac dysfunction[74]. Thus, the specific role of increased triglyceride accumulation in the development of cardiac lipotoxicity remains controversial.

Role of lipotoxicity in heart disease

Descriptions of fat storage in the heart date all the way back to the 1800's and were thoroughly described by Smith *et al*[75] in the 1930's. Over 10 years ago Sharma and colleagues described intramyocardial lipid accumulation in human heart failure that was identical to that found in the zucker diabetic fatty (ZDF) rat[76]. These studies clearly demonstrated that increased myocardial lipid accumulation was associated with an upregulation of PPARα responsive genes and an increase in the inflammatory marker tumor necrosis factor-α (TNF-α) both of which are thought to contribute to the cardiac contractile dysfunction observed in both ZDF rats and human patients[76]. Recent advances in cardiac imaging techniques has resulted in the measurement of cardiac triglyceride levels in various patient populations with mixed results regarding the significance of increased cardiac triglyceride accumulation on cardiac function. Several studies in overweight and insulin resistant patients have positively correlated increased myocardial triglyceride levels with alterations in cardiac structure and function[77,78]. Myocardial triglyceride accumulation has also been found to contribute to the pathology of severe aortic stenosis[79]. While these studies have implicated cardiac triglyceride accumulation to alterations in cardiac function several studies have not reported such a correlation. McGavock *et al*[80] reported increased myocardial triglyceride accumulation in the absence of any changes in cardiac function in patients with type Ⅱ diabetes. Likewise studies by Nyman correlated increased epicardial and pericardial fats but not intramyocardial triglyceride accumulation with alterations of cardiac function in male patients with metabolic syndrome[81]. Lastly, studies by Liu *et al*[82] reported that although myocardial triglyceride levels correlated with increases in BMI, they failed to correlate with alterations in cardiac function in healthy African-American males. Although increases in cardiac triglyceride levels have been documented in several pathological conditions as well as in the metabolic syndrome and type Ⅱ diabetes, their specific role in altering cardiac function in these conditions is still unresolved.

There are several experimental models of cardiac lipotoxicity in rats and mice. The most studied are the models of leptin signaling deficiency such as the ZDF rat and the *ob/ob* and *db/db* mouse models[83]. Several other models of cardiac lipotoxicity have been developed in which myocardial fatty acid uptake is increased above normal by overexpression of fatty acid transport protein 1 (FATP1) or cardiac specific expression of long chain acyl CoA synthase 1 (ACS1)[84,85]. Models of cardiac lipotoxicity have also been created by overexpression of enzymes CPT1 and the transcription factor PPAR-α stimulating the β-oxidation of fatty acids. Interestingly, both cardiac specific deletion and overexpression of PPAR-α result in cardiac lipid accumulation with the deletion of PPAR-α decreasing expression of critical enzymes involved in β-oxidation

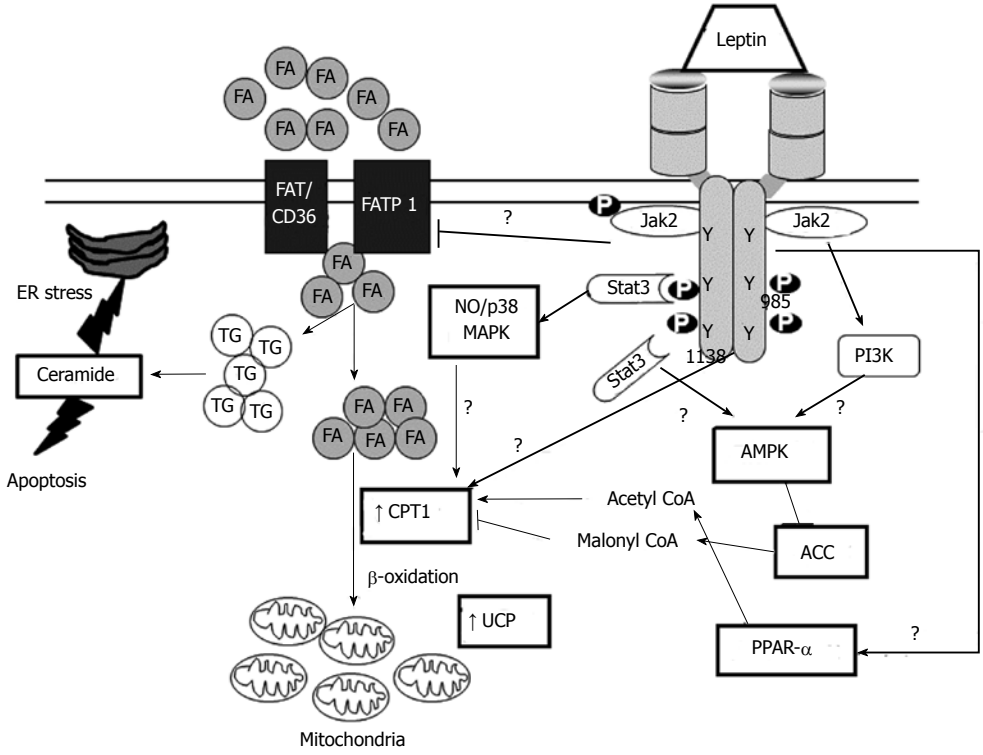

Figure 4 Leptin and cardiac lipotoxicity. Triangular and flat arrowheads represent stimulatory and inhibitory effects on the designed targets, respectively. Heavier lines represent proposed actions of leptin. ACC: Acetyl-CoA carboxylase; AMPK: AMP-activated protein kinase; CPT-1: Carnitine palmityl transferase-1; ER: Endoplasmatic reticulum; FA: Fatty acids; FAT/CD36: Fatty acid translocase/cluster of differentiation 36; FATP1: Fatty acid transport protein 1; NO: Nitric oxide; P-JAK2: Phosphorylated Janus kinase 2; PPARα: Peroxisome proliferator-activated receptor alpha; STAT3: Signal transducer and activator of transcription 3; TG: Triglycerides; UCP: Uncoupling protein.

of fatty acids and overexpression of PPAR-α resulting in increased transport of fatty acids into the heart[86,87].

While the mechanism of cardiac lipid accumulation in these various models may differ, the end result by which lipids cause cardiac dysfunction is similar in these various models. The accumulation of lipids such as ceramide and DAG to toxic levels promotes cardiomyocyte apoptosis *via* increases in reactive oxygen species production which induces non-coding RNAs such as growth arrested DNA-damage inducible gene (*GADD*)[88,89]. Accumulation of these toxic lipids also promotes endoplasmic reticulum stress which induces eukaryotic elongation factor and leads to cell death[90]. Excess lipid accumulation in the heart also interferes with insulin signaling resulting in cardiac insulin resistance and down-regulation of the IRS1/PI3K/Akt pathway which is a protective pathway in the heart[91].

Role of leptin in protection against cardiac lipotoxicity

Plasma leptin levels are elevated in individuals with obesity due to expansion of white adipose tissue mass. In obesity, it is hypothesized that there is central resistance to the effects of leptin on appetite and energy expenditure which results in increased adiposity and an increase in plasma leptin levels[7]. The increase in plasma leptin levels is also believed by some investigators to be an underlying cause for cardiovascular pathology in obesity[92,93]. However, an alternative hypothesis put forth by Unger proposes that increased plasma leptin levels are a protective mechanism preventing steatosis of organs such as the liver, pancreas, and heart in obesity[94].

Much of what is known about the role of leptin in protecting against lipotoxicity is derived from strains of leptin and leptin receptor deficient rodents. For example, leptin receptor deficient rats and mice are characterized by marked steatosis of peripherial organs such as the heart. Previous studies by Sharma *et al*[76] have reported that intracardial lipid accumulation and subsequent alterations in cardiac function and gene expression seen in the ZDF rat are remarkably similar to that observed in human patients with heart failure. Likewise studies in leptin receptor deficient *db/db* mice have also reported increased cardiac triglyceride accumulation that is associated with the development of cardiomyopathy and alteration of cardiac metabolism[95-97]. The leptin deficient *ob/ob* mouse also displays severely increased cardiac triglyceride levels associated with diastolic dysfunction[46]. Interestingly, the alterations in cardiac metabolism and cardiac lipid accumulation characterizing the *ob/ob* mouse appear to be totally dependent on leptin insufficiency as calorie restriction used to normalize body weight does not improve the increase in plasma fatty acid levels, the enhanced uptake of fatty acids by the heart or the increase in cardiac lipid accumulation[63]. Both central and peripheral administration of leptin restored myocardial insulin sensitivity and decreased myocardial fatty acid transport and lipid accumulation

independently of calorie restriction[63].

The important role of leptin to protect against lipotoxicity was first demonstrated in the liver and pancreas where adenoviral restoration of leptin receptor in these tissues in ZDF rats decreased triglyceride accumulation and protected against lipotoxic injury[98,99]. In the heart, increases in plasma leptin levels achieved by adenoviral overexpression of leptin in the liver were able to normalize cardiac triglyceride levels and restore normal cardiac function and histology in cardiac specific acyl CoA synthase transgenic mice which are a model of severe cardiac steatosis[100]. We recently reported that cardiac specific overexpression of leptin receptors normalized cardiac triglyceride levels and diastolic function in *db/db* "rescue" mice despite these mice being severely obese, hyperglycemic, and hyperlipidemic[35]. This effect was associated with enhanced STAT3 phosphorylation in the hearts suggesting that activation of this pathway is involved in the protection against lipid accumulation in the heart[35].

At the molecular level, leptin can protect against cardiac lipotoxicity through several pathways. One mechanism by which leptin protects against cardiac lipotoxicity is through induction of fatty acid oxidation. Fatty acid oxidation is highly regulated by the AMPK pathway. AMPK can phosphorylate acetyl-CoA carboxylase (ACC) and malonyl CoA decarboxylase (MCD). Phosphorylation of these proteins has opposite effects on their activity which results in decreased levels of malonyl CoA which is the first committed step in lipogenesis and a powerful inhibitor of carnitine palmityl transferase-1 (CPT-1)-mediated fatty acid oxidation (Figure 4). Previous studies in skeletal muscle have demonstrated that leptin can increase AMPK phosphorylation to promote fatty acid oxidation[101]. However, acute leptin treatment (60 min) in the isolated working rat heart stimulated fatty acid oxidation without any changes in AMPK phosphorylation state, ACC activity, or malonyl-CoA levels[55]. These results suggest that leptin may stimulate cardiac fatty acid oxidation through a mechanism that does not include AMPK activation; however, the effects of chronic leptin exposure *in vivo* have not been determined. Leptin may also promote fatty acid oxidation in the heart by decreasing the sensitivity of CPT-1 to malonyl CoA *via* an Akt related signaling pathway[102]. Uncoupling proteins are another potential pathway by which leptin may increase fatty acid oxidation. Leptin can act centrally to increase uncoupling protein levels *via* β-adrenergic mediated mechanism,and the hormone may also directly regulate uncoupling protein levels in skeletal muscle and the heart[103]. Leptin can also increase cardiac fatty acid oxidation through a STAT-3–nitric oxide–p38 MAPK-dependent mechanism (Figure 4)[56]. Leptin may also protect against cardiac lipotoxicity by its actions on fatty acid transport into cardiac myocytes. Leptin has been demonstrated to decrease the levels of both the fatty acid transport protein, fatty acid translocase (FAT/CD36), and plasma membrane-associated fatty acid-binding protein (FABPpm) in skeletal muscle; whereas, it has been reported to increase both FAT/CD36 as well as FATP1 in cultured mouse cardiomyocytes[57]. These results from cultured cells are in opposition to studies in leptin deficient *ob/ob* mice in which the levels of expression of genes that stimulate fatty acid uptake were increased in the heart[46]. Although the exact mechanism(s) need to be worked out, it is more than likely that the stimulation of fatty acid oxidation by leptin in the heart reduces the amount of lipid intermediates such as ceramide and DAG below toxic levels[104]. This in turn decreases lipid mediated apoptosis and protects cardiac function in obesity (Figure 4).

CONCLUSION

Leptin is a hormone derived from adipose tissue which undoubtedly plays an essential role in the regulation of body weight and appetite. However, emerging studies have demonstrated that leptin is also a critical hormone for the cardiovascular system which can regulate metabolism and function of the heart. It is clear that leptin exerts diverse functions in the heart (Figure 2). While some of leptin's effects can be deleterious to cardiac function primarily through its central actions on blood pressure and heart rate, its potential growth effects on the heart to promote cardiac hypertrophy are not clear. Leptin does have beneficial actions on myocardial fatty acid and glucose metabolism and the loss of cardiac leptin signaling can adversely affect the heart's response to stresses such as transient ischemia. Leptin may also directly protect the heart against excessive lipid accumulation in obesity. The development of leptin receptor antagonists has resulted in some investigators suggesting that blockade of leptin signaling in the heart may be beneficial in obesity to attenuate cardiac hypertrophy and improve cardiac function[105-107]. However, given leptin's beneficial actions on cardiac metabolism and lipid accumulation, any intervention on leptin's action in the heart must be considered very carefully. Clearly, more animal studies are needed to unravel the biological roles and mechanistic actions of leptin before any interventional studies specifically targeting leptin in the heart are undertaken.

Abstract

Physicians cannot rely solely on the angiographic appearance of epicardial coronary artery stenosis when evaluating patients with myocardial ischemia. Instead, sound knowledge of coronary vascular physiology and of the methods currently available for its characterization can improve the diagnostic and prognostic accuracy of invasive assessment of the coronary circulation, and help improve clinical decision-making. In this article we summarize the current methods available for a thorough assessment of coronary physiology.

Key words: Coronary heart disease; Coronary physiology; Endothelial dysfunction; Microvascular dysfunction; Fractional flow reserve; Coronary flow reserve; Index of microcirculatory resistance

Core tip: Assessment of the coronary circulation in the cathlab cannot be limited to angiography nowadays. The interventional cardiologist needs to be aware of current knowledge on coronary physiology and of the methods and measurements available for its characterization in clinical practice and research. In this article we review the main methods to assess the functional severity of coronary stenosis, myocardial blood flow, microvascular circulation, and endothelial function.

INTRODUCTION

Physicians rely on angiography to assess the coronary vasculature of patients with symptoms of myocardial ischemia. However, angiography has a low interobserver agreement[1], and acknowledged limitations for the assessment of myocardial ischemia in a variety of settings, such as intermediate, eccentric or diffuse coronary stenosis[2]. Notably, intermediate lesions are the most frequently found in coronary angiography[3]. The importance of determining which lesions truly produce ischemia and thus require intervention is underscored by clinical trials showing that revascularization of non-ischemia inducing stable lesions does not improve patient outcomes, and may in fact be deleterious[4-6]. Also, a considerable percentage of patients referred to the catheterization laboratory for angina, or even myocardial infarction, have angiographically normal, or only mildly diseased, coronary arteries[7], which highlights the importance of factors beyond epicardial fixed stenosis in the development of myocardial ischemia. Among these factors, coronary microvascular disease and coronary tone dysregulation due to endothelial dysfunction are frequent causes of myocardial ischemia[8-10]. Furthermore, a normal coronary angiogram does not accurately predict prognosis in all patients, since patients with microvascular or endothelial dysfunction have an increased risk of major adverse cardiac events[11].

This article reviews the most important methods currently available to the invasive cardiologist for a comprehensive physiological assessment of the coronary circulation. After a brief reminder of the coronary structure and the physiology of flow regulation, we will discuss the contemporary methods used to assess coronary flow, flow reserve, epicardial stenosis, microvascular function, and, finally, endothelial function.

CORONARY STRUCTURE AND PHYSIOLOGY

From a physiological perspective, the coronary circulation is structured in three main compartments. The first compartment (R1) is formed by the large epicardial coronary arteries, with a size over 500 μm. These are the conduction vessels, which offer minimal resistance to flow under normal conditions, accounting for less than 10% of the overall resistance of the coronary circulation. Accordingly, blood pressure remains unaltered along these vessels. The second compartment (R2) is formed by extramyocardial prearterioles, 100-500 μm in diameter. The third coronary compartment is formed by arterioles (< 100 μm) and capillary vessels. The second and third compartments, generically known as "microcirculation", are accountable for over 90% of the total coronary resistance, and therefore are the main regulators of flow[3,12].

The microvascular compartments are responsible for coronary autoregulation of flow. Because myocardial extraction of oxygen is very high at rest, an increase in oxygen demands must be met with an increase in coronary blood flow. Intramyocardial arterioles respond to metabolic signals, directly diffused from the myocardium, with vasodilation or vasoconstriction. When arterioles relax to reduce resistance and increase myocardial flow, proximal prearterioles and large epicardial arteries respond with flow-mediated dilation, which happens mainly through the release of nitric oxide by the endothelium[12].

In pathological conditions, when a severe epicardial stenosis develops, epicardial resistance increases causing a pressure drop in the distal circulation. This is registered by the prearterioles, which respond with vasodilation to maintain a normal flow and pressure in the arteriolar compartment. It is through this autoregulation that the coronary circulation manages to maintain myocardial blood flow within a normal range in the face of moderate or even severe coronary atherosclerosis. It is also because of this mechanism that the functional significance of a coronary stenosis may be obscured to the interventional cardiologist at rest, and become evident only under conditions of maximal hyperemia.

CORONARY BLOOD FLOW MEASUREMENT

There are currently two methods available for measuring coronary blood flow in clinical practice: Doppler velocity and thermodilution. Both methods require engaging the coronary artery with a guide catheter, and introducing an intracoronary diagnostic 0.014 wire in the vessel. Heparin must be administered before the procedure, at the same doses as used during percutaneous coronary intervention.

Doppler-velocity coronary flow measurement

Coronary blood flow can be assessed by blood velocity measurement using an intracoronary Doppler wire (Flowire, Volcano Corp, San Diego, CA, United States)[13]. After engaging the coronary artery with a guiding catheter and administering heparin, the Doppler wire is positioned into the artery, usually at a proximal segment. Doppler-derived blood flow velocity is recorded in a dedicated console, and the average peak velocity (APV) is calculated with the use of integrated automatic software. Coronary flow is then estimated from the APV and the crossectional vessel area, 5 mm distal to the tip of the wire. The vessel area can be calculated from the angiographic vessel diameter, or directly measured by intravascular ultrasound or optical coherence tomography. Thus, the formula to calculate the coronary blood flow by Doppler is:

$$CBF = 0.5 \times APV \times (D^2 \pi)/4$$

where CBF is coronary blood flow (cm^3/s); APV is

Table 1 Substances used in the catheterization laboratory for coronary vascular function assessment

Substance	Doses	Site of action	Endothelium response	Effect
Adenosine	Iv: 140 μg/kg per minute Ic: 20-150 μg bolus	Microvascular	Independent	Direct vasodilation
Acetylcholine	Ic: 10^{-6} M/10^{-5} M/ 10^{-4} M	Micro and macrovascular	Dependent	Vasodilation if normal endothelial function; vasoconstriction if endothelial dysfunction
Nitroglycerin	Ic: 200 μg bolus	Macrovascular	Independent	Vasodilation
Nitroprusside	Ic 0.3-0.9 μg/kg bolus	Micro and macrovascular	Independent	Vasodilation
Papaverine	Ic: 8-20 mg bolus	Micro and macrovascular	Independent	Enzyme Phosphodiesterase inhibition Vasodilation
Regadenoson	Iv: 400 μg bolus	Microvascular	Independent	Adenosine receptor agonist vasodilation

average peak velocity (cm/s); and D is coronary diameter (cm).

Thermodilution coronary blood flow measurement

Coronary blood flow can be estimated by the indicator dilution method, using an intracoronary thermodilution wire (PressureWire, St Jude Medical Inc.; St. Paul, MN, United States)[14]. This wire has two temperature sensors, located at its proximal and distal parts. The wire is introduced into the coronary artery, until the more distal sensor is at least 50 mm away from the catheter tip. A bolus of 3 mL of saline injected through the guiding catheter produces a change in temperature that is recorded by both sensors, and a thermodilution curve is recorded. This is repeated 3 times and the results are averaged. Flow is derived from the thermodilution formula:

$$CBF = V/Tmn$$

were *CBF* is coronary blood flow (cm^3/s); *V* is vessel volume (cm^3) between the injection site and measuring site; and *Tmn* is mean transit time (s), which is calculated by the system console from the thermodilution curve.

As can be appreciated, both methods for measuring coronary blood flow require estimation of the vessel crossectional area or the vessel internal volume, which introduces a source of inaccuracy, and limits their actual use in clinical practice. Fortunately, however, both methods are well suited for a simple and reliable estimation of the most important flow-derived measurement: coronary flow reserve.

CORONARY FLOW RESERVE

Coronary flow reserve (CFR) is defined as the ratio between coronary blood flow at maximal hyperemia and at baseline condition[15]. It expresses the capacity of the coronary circulation to respond to a physiological increase in oxygen demands with a corresponding increase in blood flow. In animals and healthy subjects CFR is usually over 3, meaning their coronary circulation can triple the baseline flow when needed. In humans with chest pain and angiographically normal coronary arteries, however, the average CFR is lower, at 2.7 ± 0.6[16]. Therefore, a cutoff value of 2.0 has been widely accepted for CFR in the clinical practice[3]. Because it is a ratio of two flows, CFR is dimensionless.

Two different methods of assessing CFR invasively are available, based on the previously described systems for coronary flow measurement: Doppler and thermodilution. In both cases, flow determination is made at baseline, and then repeated under maximal hyperemia. Hyperemia can be achieved with several drugs, such as papaverine, nitroprusside or adenosine, but most often the latter is used. A complete description of the main substances used in the catheterization laboratory is shown in Table 1.

Adenosine produces a direct, endothelium-independent vasodilation of the coronary microcirculation, while having no appreciable effect on the epicardial vessel. It can be administered intravenously, at a dose of 140 μg/kg per minute[17], which usually achieves maximal stable hyperemia in 2-3 min. A central vein or a large brachial one must be used for the drug to reach sufficient concentration in the coronary circulation. Alternatively, hyperemia can be achieved by a single intracoronary bolus of adenosine administered through the guiding catheter. Doses for intracoronary injection range from 30-60 μg in the left coronary artery, and 20-30 μg in the right[3]. Higher doses, however, have been shown to be safe[18,19].

CFR can be assessed by coronary Doppler, using the method described above for flow measurement[13]. After engaging the artery with a guiding catheter, the wire is advanced and positioned at a segment where a stable Doppler signal is obtained, away from a coronary stenosis and branch ostia. The wire must not move between baseline and hyperemia measurements. Thus, since adenosine does not induce epicardial vasodilation, and the wire position does not change throughout the procedure, the crossectional area of the vessel can be assumed constant and removed from the flow equation, which leaves a simplified formula for CFR estimation:

$$CFR = APVh/APVb$$

where APVh is average peak velocity (cm/s) during maximal hyperemia, and APVb is average peak velocity

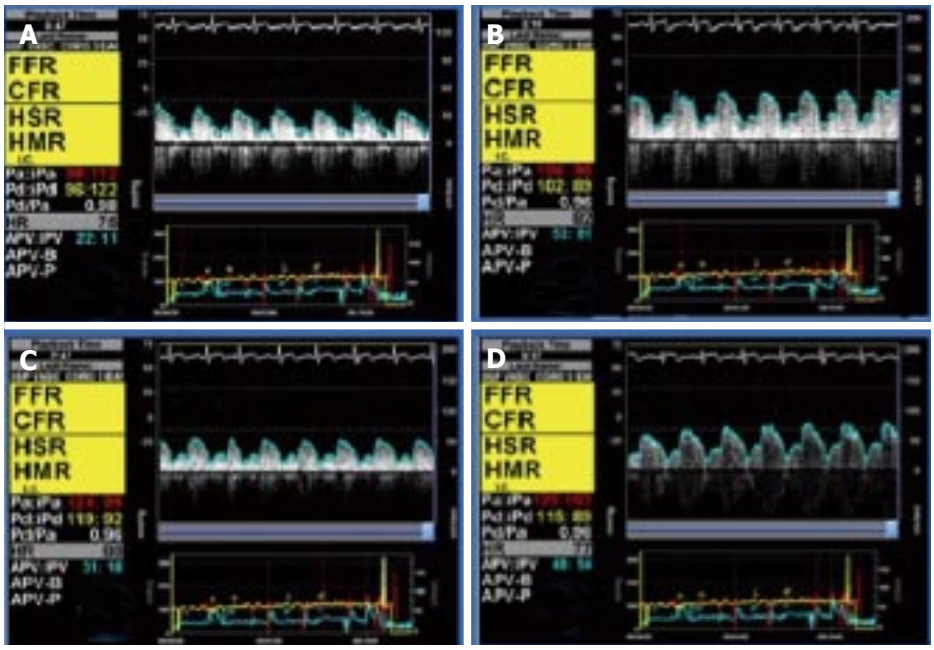

Figure 1 Microvascular function measured by intracoronary Doppler. A shows an intracoronary Doppler tracing at baseline condition, with an APV of 22 cm/s; B shows Doppler at the same position during maximal hyperemia, induced with an adenosine intracoronary bolus of 200 μg, with an APV of 53 cm/s. CFR is therefore 2.4, indicating a normal endothelium-independent microvascular function; in C and D, increasing doses of intracoronary acetylcholine have been administered; the APV is compared with the baseline tracing to determine the degree of microvascular vasodilation induced by acetylcholine, which in this case is normal, suggesting a normal endothelium-dependent microvascular function. CFR: Coronary flow reserve; APV: Average peak velocity.

(cm/s) at baseline condition. Figure 1 shows an example of CFR measurement with intracoronary Doppler.

Similarly, CFR can be calculated with the use of the thermodilution technique, by comparing mean transit time between hyperemia and baseline[17]. The pressure-temperature wire must be advanced distally into the artery, since mean transit time is more reproducible when the distal thermistor is at least 50 mm away from the catheter tip[14]. Care should be taken not to move the wire from the original position where baseline measurements are made. After three baseline thermodilution curves are obtained, hyperemia is achieved by intravenous infusion of adenosine.It is important to use intravenous administration, because the effects of an intracoronary bolus only last a few seconds, and will thus not suffice to obtain the thermodilution curves under stable maximal hyperemia. Finally, CFR is calculated with the equation:

$$CFR = Tmn.b/Tmn.h$$

where Tmn.b is mean transit time at baseline (s), and Tmn.h is mean transit time during hyperemia (s). Note that, because transit time is inversely related to flow, in this equation the hyperemia factor is in the denominator, and the baseline in the numerator, conversely to the Doppler method. An example of this technique can be found in Figure 2.

Pitfalls and contraindications

Since both thermodilution and Doppler techniques require the use of adenosine, the most common side effects associated are those described to this substance: bradycardia, hypotension, flushing, dyspnea and chest discomfort; however, the effects of adenosine disappear in seconds after the infusion is stopped or the bolus is administered, so concerning side effects are exceptional. Probably the only truly serious complication of adenosine administration is persistent bronchospasm, which is why it should be avoided in asthmatic patients[20]. If bronchospasm occurs, adenosine may be antagonized with theophylline[21].

The procedure is safe in experienced hands. However, physicians must be aware of the generic potential complications related to the insertion of guiding catheters and wires in the coronary arteries, such as coronary thrombosis, dissection, and spasm.

CFR has two main limitations. First, when an abnormal CFR value is obtained in a stenotic artery, it does not pinpoint the exact level at which flow is limited - that is, it does not help differentiate between epicardial and microvascular flow limitation. Second, given that CFR arises from the ratio of hyperemic to baseline flow, any disturbances in the baseline condition of the patient (tachycardia, stress, vasoactive drugs, abnormal loading conditions, *etc*.) will alter the ratio, thus possibly rendering a falsely abnormal CFR value.

Since CFR assesses the whole coronary vascular tree (*i.e.*, macrovascular and microvascular compartments), a normal CFR value reflects a basically healthy coronary circulation. The best CFR cutoff value for the detection of inducible ischemia is around 2.0, according to most studies[22-27]. The same cutoff value is useful to decide safe deferral of percutaneous coronary intervention when

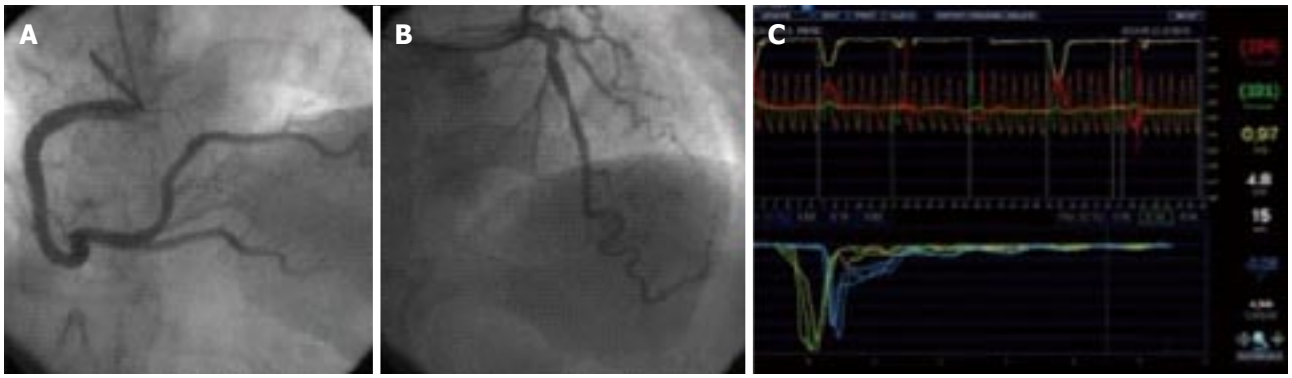

Figure 2 Coronary flow reserve measured by thermodilution. A 60-year-old woman with episodes of atypical chest pain was referred to the catheterization laboratory for coronary angiography. A and B: Show angiographically normal epicardial coronary arteries. A microcirculation study was performed, using a thermodilution PressureWire, and intravenous adenosine for hyperemia; C: Shows the thermodilution curves, with a mean transit time of 0.70 s at baseline and 0.15 s during hyperemia, and a resulting coronary flow reserve of 4.5. Index of Microvascular Resistance was 15, within normal range. We concluded that microvascular function was preserved.

assessing angiographically intermediate lesions[28,29]. A reduced coronary flow reserve, on the other hand, is an independent predictor of poor clinical outcomes in diverse settings, such as angina without severe coronary stenosis[30] and percutaneous coronary intervention[31].

Conclusion

In conclusion, CFR is a simple measurement of flow, which evaluates both the epicardial and microvascular compartments, and usually reflects normal physiology and good prognosis when it is found to be within normal limits. But other measures are needed in order to specifically investigate epicardial and microvascular disease. These measures are described and discussed below.

MEASURES OF EPICARDIAL CORONARY OBSTRUCTION

Fractional flow reserve

As we described earlier in this article, the small vessels of the heart, below 400 μm, are responsible for most of the coronary resistance, and therefore for the regulation of myocardial flow. These vessels autoregulate their resistance with the purpose of maintaining a constant myocardial blood flow independently of blood pressure, across a wide range of pressures. Similarly, when a coronary stenosis appears, the microvascular circulation regulates the resistance to flow to compensate for the stenosis.

In a state of steady maximal hyperemia, as can be achieved with adenosine, coronary autoregulation is abolished, and coronary blood flow is directly proportional to blood pressure. This principle has been used to substitute the measurements of flow by the more simple and reproducible measurements of pressure[32]. Because epicardial stenoses produce a pressure drop due to friction and separation of flow across the obstruction, different pressures can be obtained proximally and distally to a coronary stenosis, and, in a state of hyperemia, these pressures can be considered proportional to flow. Thus fractional flow reserve (FFR) arises from the ratio of the maximal flow achievable by the coronary artery with the epicardial stenosis, compared with the theoretical maximal flow of the same artery without the stenosis. Because in normal conditions the intracoronary pressure does not vary along the epicardial artery, the blood pressure at the tip of the guiding catheter is chosen to represent the theoretical pressure of the non-stenotic artery; this is compared to the pressure detected by a pressure wire distal to the stenosis. Although theoretically venous pressure should be taken into account, in clinical practice it is disregarded, and the simplified equation for FFR is used:

$$FFR = Pd/Pa$$

where Pd is the mean pressure distal to the stenosis (mmHg), recorded by the pressure wire, and Pa is the mean aortic pressure (mmHg), recorded by the tip of the guiding catheter.

To measure FFR, the coronary artery should be engaged with a guiding catheter, as with previous methods. Intracoronary nitroglycerin is administered to abolish epicardial reactivity, and a pressure wire (PressureWire, St Jude Medical Inc., St. Paul, MN, United States; or PrimeWire Prestige, Volcano Corp., San Diego, CA, United States) is advanced into the artery. Pressure is balanced against the fluid filled guiding catheter placing the wire transducer at the tip of the catheter, and then the lesion under investigation is crossed with the wire. Maximal hyperemia is induced, and the simultaneous pressure tracings of the wire and the catheter are recorded. FFR is automatically calculated with integrated software, using the mentioned equation.

Hyperemia is usually achieved with adenosine, either intravenous (140 μg/kg per minute)[33] or by intracoronary bolus. Adenosine bolus doses vary from 40 to 150 μg[33,34], although higher doses have been

proposed and deemed safe[18]. Alternatively, other drugs may be used, such as papaverine, at doses of 8-20 mg[33]; regadenoson, in a single intravenous bolus of 400 μg[35]; or nitroprusside, in intracoronary bolus of 0.3-0.9 μg/kg[36,37]. These three have the advantage of providing a longer hyperaemic plateau than intracoronary adenosine, but have been less extensively tested in the clinical setting.

The theoretical normal value of FFR in a coronary artery without stenosis is 1, since there should be no appreciable pressure drop along the vessel. A cutoff value of 0.75 (expressing a maximal-flow reduction of 25% attributable to the epicardial stenosis) accurately predicts inducible ischemia[38-40]. The most important clinical studies, however, set a cutoff of 0.8 for safe deferral of coronary intervention[41,42], and accordingly, the current European[43] and American[44] guidelines for revascularization recommend intervention in cases of coronary stenosis with FFR $\leqslant$ 0.8. As pointed out by Pijls *et al*[33], less than 10% of lesions fall into this grey area between 0.75 (almost certain ischemia) and 0.8 [safe deferral of percutaneous coronary intervention (PCI)]. In these cases, sound clinical judgement should be applied. It should also be noted that, while great emphasis has been made on cutoff points, the FFR values express a continuous rather than dichotomic function of risk[45], which highlights the importance of keeping a clinical perspective and evaluating the global risk/benefit profile all treatment options[46].

Pitfalls and contraindications

FFR is a feasible and reproducible technique, minimally modified by the baseline characteristics and hemodynamic status of the patient. Despite its reproducibility, some pitfalls and limitations have been reported.

Pharmacological side effects of adenosine are the same as those described in CFR. Accordingly, the patient must be in a stable hemodynamic condition, and adenosine should be avoided in patients with bronchospasm, severe hypotension, bradycardia or conduction disturbances.

In patients with sequential lesions or diffuse coronary disease, FFR does not provide precise information on which specific lesion is responsible for the ischemia. In such patients, the pressure pullback recording during stable hyperemia may allow identification of the culprit lesion. In order to perform this pullback recording, intravenous adenosine should be used, since an intracoronary bolus will not provide stable hyperemia.

Attention should always be paid to careful technique. The pressure wire signal must be carefully balanced at the tip of the catheter, and the balancing checked at the end of the procedure to rule out pressure drift. The tip of the catheter must be correctly positioned, to avoid damping of the pressure signal and obstruction of the coronary ostium. Submaximal hyperemia may occur, especially if a small peripheral vein is used. In this case, a central vein or an intracoronary bolus should be used to obtain maximal hyperemia.

Finally, FFR is not recommended to assess unstable thrombotic coronary lesions, *i.e.*, in acute myocardial infarction, or when thrombus or instability are evident, since pressure drop across the stenosis would provide an incomplete assessment of the risk associated with this kind of lesions.

Conclusion

In conclusion, FFR has become an indispensable tool in the catheterization laboratory to make decisions on revascularization of intermediate lesions. It can be performed in almost all elective clinical situations, providing functional information with relevant clinical implications and limited pitfalls. Figure 3 shows an example of an FFR procedure to decide revascularization in multivessel disease.

INSTANTANEOUS WAVE FREE RATIO

One of the few pitfalls of FFR is the necessity for maximal hyperemia. Without maximal microvascular vasodilation, the linear relation between pressure and flow that supports the use of FFR disappears. Coronary resistance, however, is not constant throughout the cardiac cycle; and we have already mentioned how, in some cases, stable maximal hyperemia is suboptimal or dubious, and in other rare cases adenosine may be contraindicated. To overcome these difficulties, a new physiologic measure of obstruction has been developed: instantaneous wave free ratio (iFR).

Using wave intensity analysis of simultaneous pressure-velocity recordings, Sen *et al*[47] identified a period of the cardiac cycle when there are no compression or expansion waves, and the coronary microvascular resistance at rest is minimal and stable, and very similar to the averaged resistance achieved with adenosine. The wave-free period is calculated beginning 25% of the way into diastole, and ending 5 ms before the end (covering around 75% of diastole).

A pressure wire (Verrata, Volcano Corp, San Diego, United States) is inserted in the coronary artery, following the same steps and precautions as with FFR, except that no hyperemia is induced. The wire is attached to a console with built-in proprietary software, which identifies the diastolic period of interest and automatically calculates iFR. The formula of iFR is identical to FFR, but instead of the averaged pressure of the whole cardiac cycle, it only uses the averaged pressure of the mentioned interval:

$$iFR = Pd/Pa$$

iFR is highly reproducible and has excellent correlation with FFR (r = 0.90; P < 0.001)[47]. A cutoff value of $\leqslant$ 0.90 has been set, which has an overall diagnostic accuracy of 80% to predict an FFR $\leqslant$ 0.80[48]. Because dichotomic agreement is logically lower around the cutoff values, a hybrid strategy has been proposed

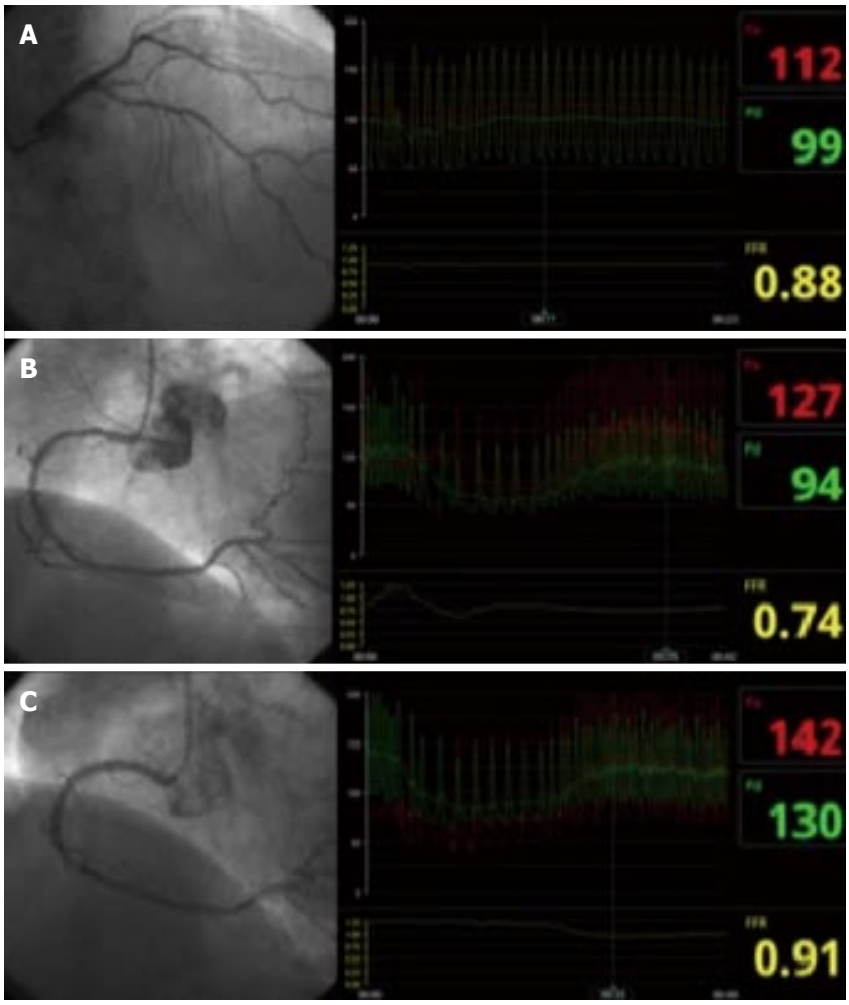

Figure 3 Functional assessment of epicardial stenosis. A 77-year-old woman with exertional angina was referred for coronary angiography. Two intermediate lesions were found in the proximal and distal segments of the left anterior descending artery (LAD) (A), and in the proximal and mid segments of the right coronary artery (RCA) (B). Fractional Flow Reserve was non-significant on the LAD (FFR 0.84) and significant on the RCA (FFR 0.74). Accordingly, percutaneous coronary intervention was performed with a drug-eluting stent on the RCA (C). A post-intervention FFR confirmed that the good angiographic result was also associated with functional improvement (FFR 0.91). Six months after the procedure the patient remains asymptomatic. FFR: Fractional flow reserve.

and tested[49,50], which would involve using an upper cutoff of 0.93, above which the coronary stenosis is considered non-significant, and a lower cutoff of 0.86, below which the stenosis is considered significant and PCI is indicated. When iFR falls between these two values (0.86-0.93, the "adenosine zone"), FFR is indicated, and the clinical decision is made according to the FFR value. This strategy may allow for two thirds of patients to be studied without hyperemia, maintaining a 95% agreement with an FFR-for-all strategy[50]. Benefits of this strategy would include reductions in cost and time, and assessment of patients who are unsuitable candidates for adenosine administration such as those with asthma, bradycardia and hypotension. Upcoming important clinical trials, such as the SYNTAX-II[51] should establish the clinical usefulness of this strategy.

HYPEREMIC STENOSIS RESISTANCE INDEX

Both CFR and FFR show good correlation with non-invasive testing for inducible ischemia. However, when both measurements are made, many patients exhibit a degree of discordance between CFR and FFR determination of ischemia[52,53]. In this context, an index of epicardial resistance that includes information from flow and pressure may have an additional value. The Hyperemic Stenosis Resistance index (HSR) is calculated from simultaneous pressure and Doppler intracoronary tracings, using a pressure-flow guidewire (Combowire, Volcano Corp, San Diego, United States). HSR is defined as the ratio of hyperemic stenosis pressure gradient (Pa-Pd) and hyperemic average peak velocity:

$$HSR = (Pa - Pd)/APV$$

where HSR represents hyperemic stenosis resistance (mmHg × s/cm); Pa represents mean aorta pressure (mmHg); Pd distal pressure (mmHg); and APV average peak velocity (cm/s). In normal epicardial arteries, no pressure gradient is expected, so the HSR should be 0. The best cutoff value has been identified at 0.8, and it

shows better diagnostic accuracy for ischemia than FFR and CFR[52]. The main limitation of HSR is that it requires the use of a Doppler-pressure wire, which increases the cost of the procedure. Also, it is less validated in clinical practice than FFR and CFR. An index of stenosis resistance derived from thermodilution flow calculations has not been validated to date.

MEASURES OF MICROVASCULAR RESISTANCE

As mentioned above, the main determinant of myocardial blood flow in physiological conditions is the microcirculation. FFR, iFR and HSR give specific information on the resistance to flow of epicardial stenoses; on the other hand, CFR provides an estimation of the overall resistance to flow in the coronary circulation. Thus, if a patient has a low CFR with normal FFR, this is usually attributed to microvascular dysfunction. This may not always be correct, however, as diffuse epicardial disease or altered resting conditions may have an impact of CFR independent of the microvascular circulation[53]. For this reason, resistance indices that provide specific information about the microcirculation have been developed.

HYPEREMIC MICROVASCULAR RESISTANCE

Using a Combowire for simultaneous determination of intracoronary pressure and Doppler velocity during adenosine-induced hyperemia, a resistance index called hyperemic microvascular resistance (HMR)[54], can be determined from this equation:

$$HMR = Pd/APV$$

where HMR is hyperemic microvascular resistance (mmHg×s/cm); Pd is the pressure in the distal part of the artery (mmHg); and APV is the average peak velocity at the same point (cm/s). Note that venous pressure is here disregarded to simplify the calculations. There are no clearly set cutoff values for HMR, but Meuwissen *et al*[54,55] have shown that the median HMR of patients with abnormal CFR is 2.4, compared with 1.9 of patients with normal CFR.

INDEX OF MICROCIRCULATORY RESISTANCE

Fearon *et al*[56] first described the index of microcirculatory resistance (IMR) in 2003, representing minimal microcirculatory resistance measured during conditions of hyperemia. IMR is calculated from the average pressure in the distal part of the coronary artery and the coronary blood flow measured by thermodilution, with the use of a specific pressure wire (PressureWire, Radi Medical Systems, St Jude Medical Inc.; St. Paul, Minn). Mean transit time correlates inversely with flow, so its inverse is used to substitute absolute flow. Theoretically, wedge coronary pressure and central venous pressure should be included in the equation to account for collateral flow and loading conditions. However, as this is usually impractical in the clinical setting, it is most common to disregard both measurements and use the simplified equation:

$$IMR = Pd \times Tmn$$

where IMR is index of microcirculatory resistance (mmHg×s); Pd is distal pressure (mmHg); and Tmn is mean transit time (s) - all measured during stable hyperemia. In practice, this simplified equation is usually correct, unless there is severe epicardial disease in the artery, in which case collateral flow may be a confounding factor. In such circumstances, the wedge coronary pressure can be measured during PCI, or alternatively an empirical corrected formula[57] may be used:

$$IMR = Pa \times Tmn \times [1.35 \times (Pa/Pd) - 0.32]$$

An IMR higher than 25 is considered abnormal[58], expressing a damaged coronary microcirculation.

Elevated IMR is related to adverse clinical outcomes in acute myocardial infarction[59], percutaneous intervention[60], and angina with apparently normal epicardial arteries[61].

In conclusion, when simultaneous measurement of pressure and flow indexes is performed, the calculation of a microvascular resistance index (either Doppler or thermodilution derived) adds specific information on the status of the microcirculation, and allows for a better diagnostic and prognostic assessment.

ENDOTHELIAL FUNCTION

The vascular endothelium is a monolayer of cells that covers the internal lumen of all the blood vessels, separating the blood from the vascular wall and organ tissues. The endothelium is a major determinant of coronary resistance and flow. In response to physiological triggers, the vascular endothelium regulates arterial smooth muscle tone through the release of vasodilators - mainly nitric oxide and prostacyclin - and vasoconstrictors, such as endothelin-1. When the vascular endothelium is damaged or dysfunctional, this function of coronary flow regulation is altered, which results in an insufficient vasodilation, or even paradoxical vasoconstriction, in response to a physiological increase in oxygen demands, such as exercise or stress. This flow dysregulation can be the cause of chronic angina or acute coronary syndromes, even in the absence of coronary epicardial stenosis.

The coronary vasomotion can be assessed directly and invasively by coronary angiography, using mainly

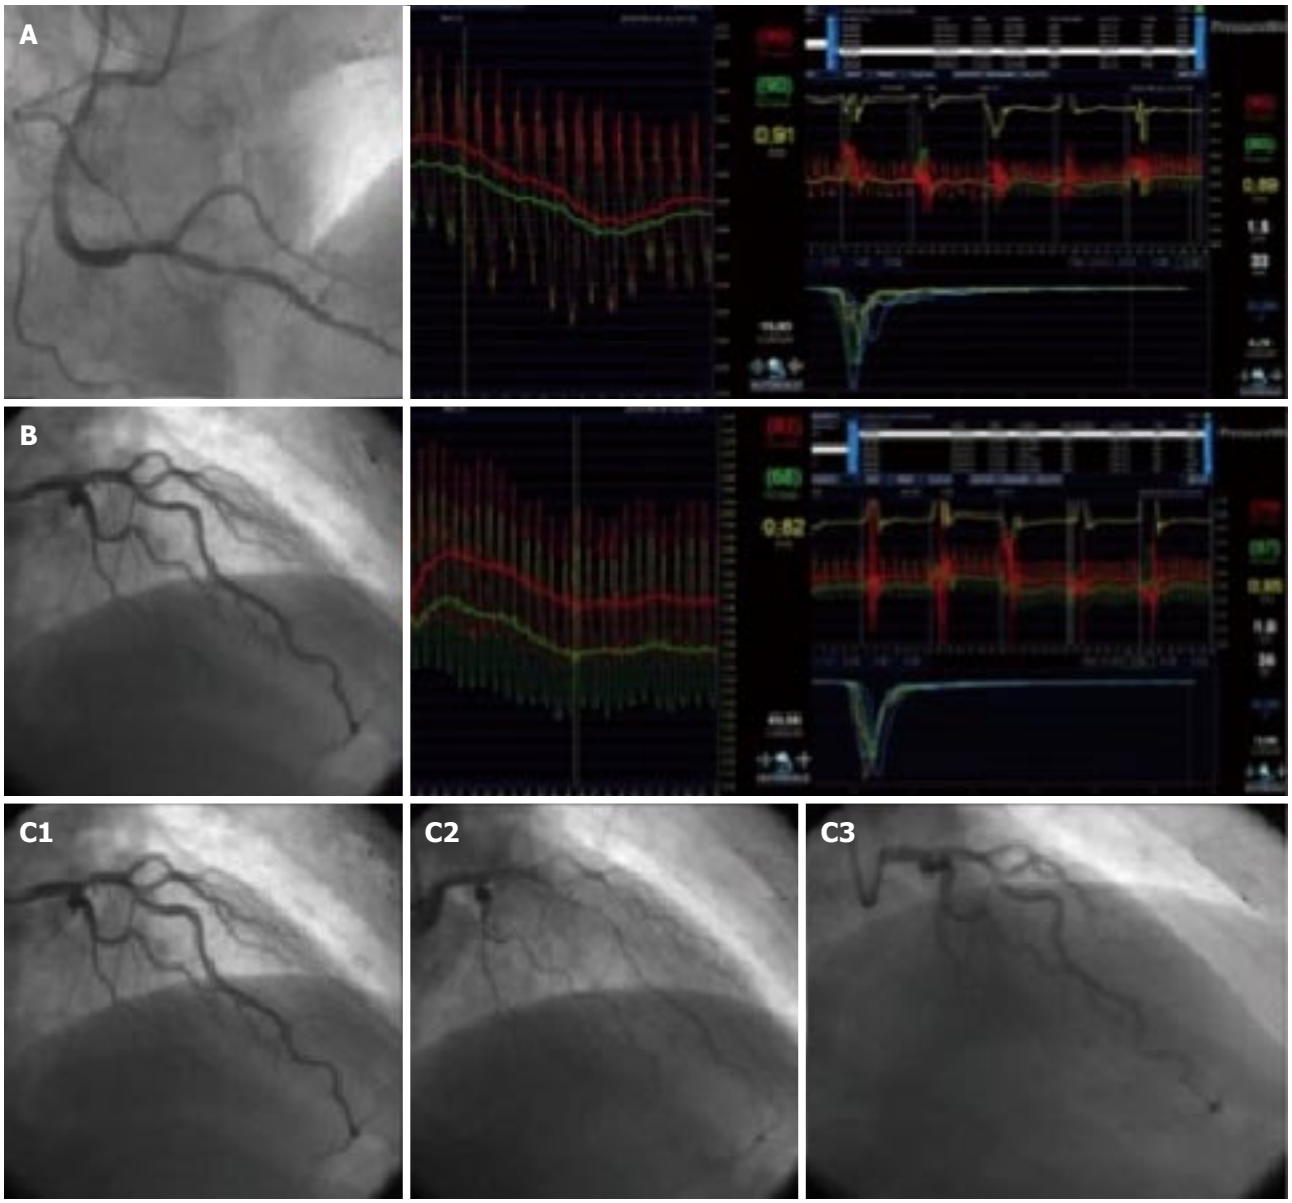

Figure 4 Thorough physiological assessment: Fractional flow reserve, microvascular and endothelial function. A 66-year-old man with typical angina, both resting and exertional, was referred for coronary catheterization. The coronary angiogram showed moderate lesions on the posterior descending artery of the RCA (50%) and on the middle LAD (40%). Panel A depicts the coronary stenosis of the RCA on the left box; FFR of this lesion on the centre box, with a value of 0.91; and microvascular study on the right box, with a CFR of 1.5 (low) and IMR of 33 (elevated); Similarly, Panel B shows the angiogram of the LAD (left), the FFR of 0.82 (centre), and the microvascular study (right), with a CFR 1 (low) and IMR 24 (borderline); Panel C shows the successive angiograms at baseline (C1), after 20 μg of acetylcholine (C2), and after 200 μg of nitroglycerin (C3). As can be appreciated, a severe diffuse spasm of the left coronary artery was induced by acetylcholine. We concluded that both coronary stenosis were non-significant, and decided on optimal medical therapy. The study also revealed microvascular endothelium-independent dysfunction, and macrovascular vasospasm due to endothelial dysfunction. CFR: Coronary flow reserve; FFR: Fractional flow reserve; IMR: Index of microcirculatory resistance; LAD: Left anterior descending artery; RCA: Right coronary artery.

acetylcholine as a trigger of endothelium-dependent vascular reactions[62-64]. In the presence of a healthy endothelium, acetylcholine at the doses used induces NO release, which results in coronary vasodilation, both epicardial and microvascular; conversely, if the endothelium is dysfunctional, NO release will be blunted and the predominant net effect will be vasoconstriction due to muscarinic stimulation of smooth muscle. Macrovascular vasodilation or vasoconstriction is evaluated by successive angiographies; the microvascular compartment, being the major determinant of flow velocity, is evaluated using intracoronary Doppler.

Before the endothelial function test, no nitroglycerin should be administered, to allow for epicardial reactivity. Ideally, the patient should be off vasoactive medication for 48 h, although in clinical practice this is not always feasible. The coronary artery - most often the left - is engaged with a guiding catheter, and a baseline angiography is performed to serve as a reference. A coronary microcatheter is advanced into the proximal part of a main vessel, usually the left anterior descending artery, and a Doppler wire (FloWire

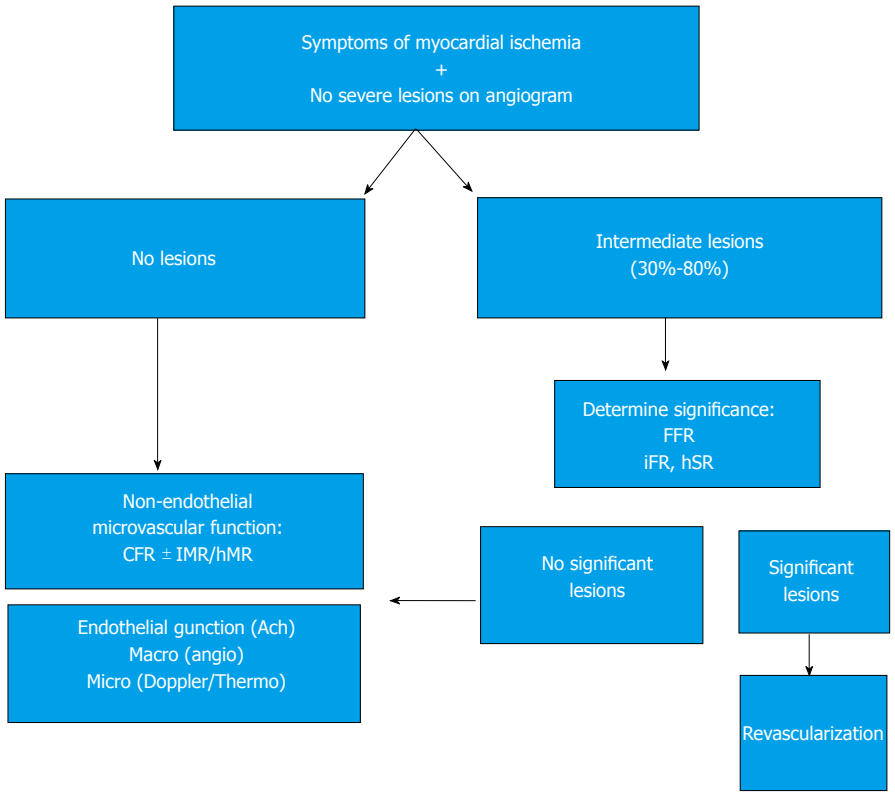

Figure 5 Summary of the proposed evaluation algorithm of patients with symptoms of ischemia without significant coronary lesions. CFR: Coronary flow reserve; IMR: Index of microcirculatory resistance; FFR: Fractional flow reserve; hMR: Hyperemic microvascular resistance; hSR: Hyperemic Stenosis Resistance index.

or ComboWire, Volcano Corp., San Diego, United States) is advanced through the microcatheter into the artery. After checking for signal quality, a baseline tracing of Doppler is recorded. Next, three consecutive infusions of acetylcholine are administered through the microcatheter, at concentrations of 10^{-6} mol/L, 10^{-5} mol/L and 10^{-4} mol/L, at a rate of 1 mL/min, 2-3 min per infusion. After each infusion, the Doppler APV and a coronary angiogram are recorded. Finally, 200 μg of nitroglycerine are administered intracoronary, to evaluate macrovascular endothelium-independent response.

The epicardial endothelial response is considered normal if vasodilation - or at least no vasoconstriction - is observed. The response is considered pathological if a reduction ⩾ 20% in coronary artery diameter occurs. A normal microvascular response to acetylcholine would be a 50% increase in APV. If a lower vasodilation, or even vasoconstriction occurs, the microvascular endothelial response is considered abnormal[64].

Most studies o endothelial function have followed this protocol approximately. It has the advantage of evaluating both the macrovascular and microvascular compartments, and the added safety of injecting the drug directly into the LAD. However, other protocols have been described and found safe. The study of the microvascular response by thermodilution, although seldom used, is feasible and has been validated[65]. Some groups[9,66] inject acetylcholine directly into the left main artery (at increasing doses ranging from 2 to 100 μg, for example 2-20-100 μg; each infusion over 3 min), and perform exclusively macrovascular angiographic assessment. This approach, although admittedly less complete than the first, still frequently offers valuable information.

Pitfalls and contraindications

Acetylcholine should be avoided in patients with severe intestinal and/or urologic obstructive disease, as it may enhance muscular contractions. Special attention should be paid to patients with bradycardia or hypotension. Generally, the coronary spasm related to macrovascular endothelial dysfunction is easily reverted with intracoronary nitroglycerin. In any case, vasospasm may cause serious complications, so the patient must be monitored and the procedure must be conducted with utmost care.

Conclusion

Endothelial dysfunction limits maximal coronary flow, and can be the cause of angina without epicardial stenosis[67,68]. It is an important risk factor for poor outcomes in this setting[11], as well as in stable coronary artery disease[69], acute myocardial infarction[70], heart failure[71], and heart transplant[72]. A more detailed account of the importance of endothelial function in coronary heart disease can be found in our recent review[73]. The finding of severe acetylcholine-induced spasm can also assist the physician in the optimization of the medical therapy.

Table 2 Main parameters available to assess coronary macrovascular and microvascular circulation

Technique	Cutoff value	Implications	Commentary
CFR	< 2	Unspecific macrovascular and microvascular inability to increase flow	Patients with CFR > 2 have favorable outcomes
FFR	≤ 0.8	Functionally significant epicardial stenosis	Extensive clinical validation Requires vasodilation
iFR	≤ 0.9	Functionally significant epicardial stenosis	Functionally significant epicardial stenosis Vasodilation-Independent
HSR	0.8 mmHg × s/cm	Functionally significant epicardial stenosis	Requires doppler-pressure wire Convenient in the presence FFR/CFR discordances
HMR	> 2 mmHg × s/cm	Microvascular dysfunction	Requires doppler-pressure wire
IMR	> 25 mmHg × s	Microvascular dysfunction	Thermodilution method

CFR: Coronary flow reserve; FFR: Fractional flow reserve; iFR: Instantaneous wave free ratio; HSR: Hyperemic stenosis resistance index; HMR: Hyperemic microvascular resistance index; IMR: Index of microcirculatory resistance.

DISCUSSION

Myocardial ischemia should not be considered to happen exclusively in the presence of critical coronary epicardial stenoses. The physiological significance of intermediate lesions cannot be properly assessed by angiography, and in this case a pressure wire should always be used to decide intervention or deferral. In the absence of significant coronary stenoses, a complete evaluation of the microcirculation and the endothelial function can help identify the fundamental problem, or at the very least reassure the patient and the physician.

When studying a patient with stable angina or acute coronary syndrome, the interventional cardiologist should not be content with an angiography showing non-significant epicardial disease. If there are intermediate lesions (30%-70%), FFR should be performed to rule out ischemic lesions; if the arteries are clearly non-stenotic, or if FFR is normal, we propose that microvascular endothelium-independent (CFR and microvascular resistance), and macro and microvascular endothelium-dependent function should be assessed. This thorough protocol can be performed in a matter of minutes, and with a very low risk[10]. Recent studies[9,10] show that, in most patients with angina who are extensively evaluated, an alteration can be found that explains the symptoms. Figure 4 shows an example from our centre following this protocol in a complex patient. Figure 5 summarizes this diagnostic algorithm.

In other clinical settings, such as stenting, myocardial infarction and heart transplant, vascular function affects clinical outcomes, and can serve as a prognostic marker. Also, coronary physiological parameters can be of interest as surrogate markers of safety and efficacy in clinical trials for new devices, such as drug eluting stents[66,74] and bioabsorbable scaffolds[75]. The interventional cardiologist should be acquainted with the methods used to perform these measurements and their interpretation. Table 2 summarizes the main parameters available to date.

CONCLUSION

Coronary physiology assessment in the catheterization laboratory is essential to help decision making in patients with coronary artery disease, providing functional and prognostic information. Physicians, especially interventional cardiologists should implement its use in daily clinical practise.

Abstract

Heart failure (HF), the number one cause of death in the western world, is caused by the insufficient performance of the heart leading to tissue underperfusion in response to an injury or insult. It comprises complex interactions between important neurohormonal mechanisms that try but ultimately fail to sustain cardiac output. The most prominent such mechanism is the sympathetic (adrenergic) nervous system (SNS), whose activity and outflow are greatly elevated in HF. SNS hyperactivity confers significant toxicity to the failing heart and markedly increases HF morbidity and mortality *via* excessive activation of adrenergic receptors, which are G protein-coupled receptors. Thus, ligand binding induces their coupling to heterotrimeric G proteins that transduce intracellular signals. G protein signaling is turned-off by the agonist-bound receptor phosphorylation courtesy of G protein-coupled receptor kinases (GRKs), followed by βarrestin binding, which prevents the GRK-phosphorylated receptor from further interaction with the G proteins and simultaneously leads it inside the cell (receptor sequestration). Recent evidence indicates that adrenal GRK2 and βarrestins can regulate adrenal catecholamine secretion, thereby modulating SNS activity in HF. The present review gives an account of all these studies on adrenal GRKs and βarrestins in HF and discusses the exciting new therapeutic possibilities for chronic HF offered by targeting these proteins pharmacologically.

Key words: G protein-coupled receptor; G protein-coupled receptor kinase; Heart failure; Sympathetic nervous system; Adrenergic receptor; Adrenal medulla

Core tip: The present manuscript is a mini-review describing the current knowledge in the field of adrenal GRKs and βarrestins, both of which are protein families that regulate adrenergic receptor function throughout the cardiovascular system. We specifically discuss the roles of these proteins in the adrenal medulla, as they pertain to regulation of catecholamine secretion and of

sympathetic activity in chronic heart failure (HF). We also outline the exciting new possibilities of targeting these molecules in the adrenal glands for HF therapy.

Adrenal G protein-coupled receptor kinase-2 in regulation of sympathetic nervous system activity in heart failure. *World J Cardiol* 2015; 7(9): 539-543 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i9/539.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i9.539

INTRODUCTION

The sympathetic (adrenergic) nervous system (SNS) induces in the heart positive chronotropy, inotropy, lusitropy, dromotropy, accompanied by a decrease in venous capacitance, and constriction of resistance and cutaneous vessels[1,2]. All of these effects aim to prepare the body for "fight or flight response" and are mediated by the two catecholamines (CAs) norepinephrine (NE) and epinephrine (Epi)[3,4]. These are synthesized and released *via* the following mechanisms: (1) cardiac sympathetic nerve terminals release NE directly into the heart; (2) the adrenal medulla releases Epi and NE into the circulation; and (3) peripheral, local adrenergic nervous systems[5-7].

The actions of NE and Epi are mediated by the ARs, which are all G protein-coupled receptors (GPCRs) and consist of three α_1AR subtypes, three α_2AR subtypes (α_{2A}, α_{2B}, α_{2C}), and three βAR subtypes[8]. The main role of βARs in the heart is positive inotropy and chronotropy in response to CAs[9]. Agonist activation of GPCRs compels the cognate heterotrimeric G protein to dissociate from guanosine triphosphate and instead bind guanosine diphosphate on its Gα subunit; this results in splitting of the heterotrimer into two active functional components, Gα and $G_{\beta\gamma}$ subunits, both of which mediate signaling[9,10]. With specific regards to the α_2ARs, the α_{2B}AR is expressed in vascular smooth muscle causing vasoconstriction, while centrally located α_2ARs lower sympathetic outflow and systemic blood pressure[11,12]. NE release is controlled by presynaptic α_2ARs[13], since genetic deletion of α_2ARs leads to cardiac hypertrophy and HF, thanks to increased cardiac NE release and adrenal CA secretion[14,15].

Most GPCRs are subject to agonist-promoted desensitization and/or downregulation[16-18]. This process occurs courtesy of the GPCR kinases (GRKs) and the βarrestins[19]. The βarrestins uncouple the receptor from the G proteins, subsequently internalizing it[20]. GRK2 and GRK5 are the prominent GRKs in the heart and in most other tissues, including the adrenals[20,21]. Receptor internalization *via* the βarrestins results in either its resensitization or its degradation (downregulation)[20,21]. The receptor-bound βarrestins can also tranduce their own, G protein-independent intracellular signals[20,21]. Herein, we review the current literature regarding the roles of adrenal GRK2 and βarrestins in regulation of SNS activity in HF, with a focus on the therapeutic targeting of adrenal GRK2 as a sympatholytic strategy in chronic heart failure (HF).

ADRENAL GRK2 AND SNS ACTIVITY IN HF

A salient pathophysiological feature of chronic HF is SNS hyperactivity, reflected by increased levels of circulating Epi and NE[3,4,22]. Although it normally serves as a mechanism to re-adjust the heart from underperforming, it ultimately becomes cardiotoxic, contributing to HF progression, morbidity and mortality[3,4,22]. Adrenal CA secretion is stimulated by nicotinic cholinergic receptors and is refined by presynaptic inhibitory α_2ARs[5,23,24]. α_2ARs, similarly to cardiac βARs, also undergo GRK-dependent desensitization[10]. Of note, increased GRK2 expression and activity occur in the adrenal medulla during HF, which critically influence CA secretion from this source[25]. In particular, as we and others have documented, adrenal GRK2 overexpression is responsible for severe adrenal α_2AR dysfunction in chronic HF, leading to a loss of the sympatho-inhibitory function of these receptors in the adrenal medulla (and possibly also in sympathetic neurons); thus, CA secretion is chronically elevated[25-29]. The importance of the role of adrenal GRK2 in HF is evidenced by that its inhibition leads to a significant reduction in CA circulating levels, restoring not only adrenal, but also cardiac function[25]. In fact, HF rats treated with adrenal-specific βARKct (a GRK2 inhibitory mini-gene[30]) gene delivery show improved cardiac function and cardiac βAR number and signaling[25]. Therefore, an important crosstalk at the level of entire organs seems to exist in chronic HF and adrenal GRK2 is a crucial regulator of the circulating CA levels that affect HF progression. Consequently, adrenal GRK2 targeting to restore α_2AR function and reduce CA secretion from the adrenal medulla may provide a novel sympatholytic strategy for chronic HF treatment[25-29].

Another study demonstrating the advantages of therapeutic targeting of adrenal GRK2 is a study performed in transgenic mice having GRK2 genetically deleted only in cells expressing the phenylethanolamine-N-methyl-transferase enzyme. These mice lack GRK2 in their adrenal medullae[26]. These mice exhibit significantly reduced SNS activity during progression to chronic HF secondary to myocardial infarction (MI), as reflected by their circulating CA levels measured at 4 wk post-MI. In addition, their cardiac contractility, structure/morphology (dilatation), and βAR signaling/function, all show marked improvement at the same time-point (4 wk) post-MI[26]. Thus, prevention of the sympathetic "rush" that attacks the myocardium shortly after an MI thanks to adrenal GRK2 inhibition can help the heart work close to normal and limit its tissue damage, which normally occurs in the period directly following a heart attack. Therefore, adrenal GRK2 inhibition applied as early as possible after an MI may provide significant

survival and quality of life benefits in human HF. Of note, this is exactly the same rationale behind start of β-blocker therapy immediately after the heart attack in MI patients.

Adrenal GRK2 regulates CA secretion also under normal conditions, as adrenal βARKct transduction resulted in lowering of circulating CA levels in normal, otherwise healthy rats, and adrenal GRK2 overexpression increased their CA levels[27]. In addition, exercise training, beneficial for the cardiovascular system as it reduces HF-related SNS overactivation, can also normalize adrenal GRK2 expression and α_2AR function in HF rats[28].

It is also very likely that, in chronic HF, GRK2-mediated α_2AR deregulation also occurs in the cardiac adrenergic terminals, thus contributing to excessive NE release. Thus, global GRK2 blockade will decrease systemic circulating CA's, and perhaps a small molecule GRK2 inhibitor is best-suited for that therapeutic purpose. In that vein, it is interesting to point out that the known antidepressant drug (selective serotonin reuptake inhibitor, SSRI) paroxetine was recently shown to inhibit myocardial GRK2, thereby improving experimental HF in post-MI mice[29]. However, the results of this study must be treated with extreme caution, given that paroxetine exerts a variety of pharmacological effects, which may have contributed to its amelioration of cardiac function post-MI. For instance, it can also inhibit the other major cardiac GRK isoform, GRK5 (albeit to a lesser extent than it inhibits GRK2)[30], and it also activates glycogen synthase kinase (GSK)3-beta[31], which is known to have beneficial actions in cardiac fibrosis, hypertrophy and adverse remodeling[32]. In fact, exactly because it activates pancreatic GSK3β, paroxetine can precipitate insulin resistance/diabetes mellitus[31], a significant adverse effect that can potentially limit the drug's usefulness in HF therapy. Nevertheless, paroxetine may aid in the development of more specific (and potent) pharmacological GRK2 inhibitors by serving as a lead drug compound[30].

In summary, GRK2 inhibition is a novel sympatholytic strategy in HF, curbing CA release from SNS nerve terminals and the adrenal glands. In addition, it can be safely combined with β-blockers, as this combination cuts SNS overactivity and blocks adrenal GRK2 in HF[33]. However, while β-blockers improve inotropy of the failing heart indirectly, by protecting it from the catecholaminergic overstimulation[34,35], adrenal GRK2 inhibition can block also the non-cardiac adverse effects of the SNS (activation of endothelin, renin-angiotensin-aldosterone axis, *etc.*). Additionally, β-blockers acutely lower cardiac contractility and thus, are contraindicated in the acute setting of HF[36]. Adrenal GRK2 blockade, by diminishing global SNS activity in a cardiac-independent manner, may thus be much safer than β-blockers, as a sympatholytic approach, for acute HF. Finally, adrenal GRK2 inhibition would allow for reduction of dose and propensity for adverse effects of β-blocker therapy.

ADRENAL βARRESTINS AND SNS ACTIVITY IN HF

Aldosterone is another elevated hormone in HF and produces various detrimental effects on the failing heart, including adverse cardiac remodeling and HF progression post-MI[37-40]. It can also stimulate sympathetic neurons in the central nervous system to enhance NE release[37-40]. Aldosterone is produced by the adrenocortical zona glomerulosa cells in response to AT_1 receptor activation by angiotensin Ⅱ (Ang Ⅱ)[41,42]. A crucial role for βarrestin1 in mediating AT_1 receptor-induced aldosterone synthesis and secretion in the adrenal cortex has been documented[43]. Specifically, βarrestin1 causes upregulation of steroidogenic acute regulatory protein (StAR), the most critical enzyme in its biosynthesis[43]. Moreover, βarrestin1 does so independently of G proteins[43]. *In vivo*, adrenal βarrestin1 appears to be a major regulator of normal circulating aldosterone levels, since its upregulation, specifically in the adrenal gland, can cause hyperaldosteronism in normal healthy animals[43]. Importantly, in chronic HF, which is also characterized by hyperaldosteronism, adrenal βarrestin1 overexpression/overactivity promotes aldosterone elevation, resulting in accelerated cardiac adverse remodeling and deterioration of heart function[44]. Moreover, the cardio-toxic effects of aldosterone in post-MI HF are prevented by adrenal βarrestin1 inhibition *in vivo*[44] and βarrestin1-knockout mice progressing to HF after experimental MI fail to show any elevation in their circulating aldosterone levels, remaining essentially normal even as late as 4 wk post-MI[45]. CA levels are also significantly reduced in post-MI βarrestin1-knockouts, contributing to the overall better survival and cardiac function of these animals in post-MI HF[45]. Thus, adrenal βarrestin1 is a major driving force behind the cardio-toxic hyperaldosteronism and SNS hyperactivity, both of which accompany and aggaravate chronic HF. Thus, adrenal βarrestin1 inhibition might also be of therapeutic value in post-MI HF therapy. In fact, considering that it also participates in the adrenal GRK2-dependent α_2AR desensitization/downregulation, which chronically elevates CA secretion in HF[25,45], it becomes apparent that adrenal βarrestin1 inhibition could be an attractive therapeutic strategy for countering neurohormonal cardiotoxicity in HF.

CONCLUSION

Preclinical studies on cardiac GRK2 inhibition have established it as a promising therapeutic modality for HF. However, recent studies have brought GRK2 targeting in another organ, the adrenal medulla, to the limelight of potential HF therapies. Adrenal GRK2 inhibition appears to directly lower the neurohormonal (*i.e.*, sympathetic) burden of the failing post-MI heart, without affecting the heart muscle *per se*. As better, safer, and more effective vectors for gene therapy and/

or small molecule inhibitors get developed, the potential for GRK2 inhibition, in both the heart and adrenals, to find its place in the HF therapeutic armamentarium will continue to rise exponentially in the years to come.

Abstract

Heart failure (HF) is the leading cause of hospitalization among older adults and the prevalence is growing with the aging populations in the Western countries. Epidemiologic reports suggest that approximately 50% of patients who have signs or symptoms of HF have preserved left ventricular ejection fraction. This HF type predominantly affects women and the elderly with other co-morbidities, such as diabetes, hypertension, and overt volume status. Most of the current treatment strategies are based on morbidity benefits such as quality of life and reduction of clinical HF symptoms. Treatment of patients with HF with preserved ejection fraction displayed disappointing results from several large randomized controlled trials. The heterogeneity of HF with preserved ejection fraction, understood as complex syndrome, seems to be one of the primary reasons. Here, we present an overview of the current management strategies with available evidence and new therapeutic approach from drugs currently in clinical trials, which target diastolic dysfunction, chronotropic incompetence, and risk factor management. We provide an outline and interpretation of recent clinical trials that failed to improve outcome and survival in patients with HF with preserved ejection fraction.

Key words: Diastolic dysfunction; Preserved ejection fraction; Co-morbidities; Clinical trials

Core tip: Heart failure (HF) has preserved left ventricular ejection fraction (HFpEF) accounts for approximately 50% of all patients diagnosed with HF, with similary poor outcomes. To date, only the prevention of HFpEF by treating the cardiovascular risk factors (coronary artery disease, atrial fibrillation, hypertension, diabetes, and obesity) has been shown to be efficient. This observation suggests that investigators in future trials should specify the indication of hospitalization for HF and may request to verify the details of patients' admissions. We provide an outline and interpretation

of recent clinical trials that failed to improve outcome and survival in patients with HF with preserved ejection fraction.

Becher PM, Fluschnik N, Blankenberg S, Westermann D. Challenging aspects of treatment strategies in heart failure with preserved ejection fraction: "Why did recent clinical trials fail?" *World J Cardiol* 2015; 7(9): 544-554 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i9/544.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i9.544

INTRODUCTION

Prevalence of heart failure (HF) has been rising in the recent past[1,2]. Epidemiologic reports suggest that approximately 50% of patients who have signs or symptoms of HF have preserved left ventricular ejection fraction (HFpEF)[3-5]. It has been observed that the morbidity and the mortality rates of HFpEF patients are significantly increased when compared to the reference population[3,6]. Moreover, it appears that the all-cause mortality of patients with HFpEF is comparable to patients with HF with reduced ejection fraction (HFrEF).

Patients with HFpEF are older, more likely women, and more often have hypertension[7,8]. Chronic hypertension is the most common cause in addition to age, with suggestion to 60% of patients suffering from HFpEF being hypertensive[7]. Diabetes and obesity also contribute independently to the development of diastolic and vascular dysfunction[9], both being important in the HFpEF pathophysiology. Most of the common treatment of HFpEF is based on morbidity benefits and reduction of clinical HF symptoms. Several co-morbidities are important drivers of the clinical outcome in the HFpEF population. Excluding patients with co-morbidities from clinical trials to enhance the specificity reduces clinical event rate and entails loss of statistical power to detect differences.

Current guidelines recommend the management of treating hypertension, heart rate reduction, volume status, and prevention of myocardial ischemia[10]. However, current intervention strategies available for HFrEF have not been supported by clinical trials for HFpEF[11,12].

Here, we present an overview of the current recommended therapeutic options with available evidence and new therapeutic approaches from drugs currently in clinical trials, which aim at impaired diastolic function, chronotropic incompetence, and risk factor management. We provide an outline and interpretation of previous clinical trials that failed to improve outcome and survival in the HFpEF population.

BETA-BLOCKERS

Study of effects of Nebivolol Intervention on outcomes and Rehospitalisation in Seniors with HF trial (SENIORS).

The mechanism behind β-blockers' therapeutic potential in enhancement diastolic function in patients with HFpEF is believed to be associated with negative chronotropic and inotropic properties in stabilizing heart rate and optimizing left ventricular (LV) relaxation[13].

The SENIORS trial (Study of effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with HF) enrolled 2128 patients aged greater than 75 years who had either an LVEF less than 35% or a hospitalization for HF in the previous year and randomly assigned them to placebo or nebivolol. In the SENIORS trial 752 patients displayed a preserved LVEF (mean 49.2%).

The SENIORS trial indicated that nebivolol significantly reduced the composite outcome of death and cardiovascular hospitalization. In detail, the SENIORS trial demonstrated a 15% reduction in the relative risk of the composite of all-cause mortality of cardiovascular admission in patients older than 70 years of age with history of congestive HF[14]. The investigators consumed two primary aims distinct from previous trials on β-blockers. First, was to demonstrate the safety and efficacy of nebivolol in elderly HF patients, a group that has been under-represented in previous clinical studies. Secondly, another goal, of this trial was to demonstrate nebivolol's safety and efficiency across a broad range of LVEF, including the HFpEF population.

Conversely, in the SENIORS trial there was no difference in the primary outcome when patients were stratified according to preserved or reduced LVEF using a cut-off of > 35% to define preserved EF[14]. Subsequent analyses suggested no strong interaction between the therapeutic benefit of nebivolol and LVEF above or below 35%, but this does not entirely allay concerns that there might be no benefit in those with an LVEF greater than 45%.

Besides, patients with atrial fibrillation, a common co-morbidity of both HFrEF and HFpEF, do not appear to benefit whether or not LVEF is reduced[15]. In addition, it has to be mentioned that more than half of the patients, included in the SENIORS trial, had LVEF values ranging between 35%-50% and therefore would not be considered to have HFpEF.

However, in a separate analysis of patients with an LVEF cut-off greater than 40%, there was no statistical interaction, suggesting that nebivolol was of comparable benefit in reduced LVEF and preserved LVEF patients. The definition of HFpEF used a low cut-off LVEF of greater than 35% therefore making it difficult to extrapolate these findings to most patients with HFpEF who have a higher LVEF.

Furthermore, the SENIORS echocardiography substudy randomized 112 patients in 29 european centres, of whom 104 were evaluable for the study; 43 with LVEF ⩽ 35% and 61 with an LVEF > 35%[16]. LV end-systolic volume (ESV), LVEF, mitral valve E/A ratio, and E-wave deceleration time were assessed at baseline and after 12 mo.

In the group with LVEF ⩽ 35%, nebivolol reduced

ESV and improved EF; no changes were observed in the E/A ratio or E-wave deceleration time. In LVEF > 35% group, no significant changes in either systolic or diastolic parameters were observed. This absence of detectable differences with standard echocardiography in patients with predominant diastolic dysfunction questions the mechanism of benefit on morbidity and/or mortality in this HF population. In the separate analysis of patients with an EF cut-off greater than 40%, there was no noted statistical interaction, suggesting that nebivolol was of comparable benefit in reduced EF and preserved EF patients.

Swedish HF registry

Lund *et al*[17] from the Karolinska Institute, Stockholm in Sweden, conducted a study to examine whether β-blocker therapy is associated with reduced mortality in patients with HFpEF.

The investigators used data from the Swedish HF Registry, which includes 67 hospitals with inpatient and outpatient units and 95 outpatient primary care clinics in Sweden. The analysis included 41976 patients, 19083 patients with HFpEF[17]. Of these, 8244 were matched 2:1 based on age and β-blocker use, yielding 5496 treated and 2748 untreated patients with HFpEF. Another analysis involved 22893 patients with HFrEF, of whom 6081 were matched, yielding 4054 treated with β-blockers and 2027 untreated patients.

In patients with HFpEF, use of β-blocker therapy was associated with lower all-cause mortality but not with lower combined all-cause mortality or HF hospitalization. In detail, in the matched HFrEF cohort, β-blockers were associated with reduced mortality (HR = 0.89; 95%CI: 0.82-0.97; *P* = 0.005) and also with reduced combined mortality or HF hospitalization (HR = 0.89; 95%CI: 0.84-0.95; *P* = 0.001).

This study provides a rationale for performing large-scale randomized trials with this inexpensive category of drugs.

However, because myocardial ischemia can drive the development of HFpEF, its presence should be detected and treated with anti-ischemic therapies, which still include β-blockers. Patients with evidence of myocardial ischemia could also be considered for revascularization with percutaneous coronary intervention or coronary artery bypass surgery.

However, current guidelines do not recommend the use of β-blockers solely for HFpEF, unless it is used to optimize treatment of comorbidity, such as controlling ventricular rate in atrial fibrillation or tachyarrhythmia, or hypertension.

Since cardiac output is the product of heart rate and stroke volume, patients with HFpEF are often dependent on augmentation of heart rate in order to increase cardiac output.

Negative chronotropic medications are recommended in HFpEF to increase the diastolic filling period, but slowing the heart rate in the absent of tachycardia tends to only prolong diastasis, where transmitral flow is minimal or absence[18]. More importantly, recent studies have repeatedly shown that chronotropic incompetence is highly prevalent and associated with exercise disability in HFpEF[19-21]. Indeed, in the setting of reduced systolic and diastolic reserve, chronotropic reserve may represent the only mechanism to augment cardiac output during exercise, although there is concern that inadequate ability to enhance relaxation with tachycardia may limit stroke volume responses. β-blockers, especially at high doses may aggravate rather than alleviate exercise intolerance.

However, slowing elevated heart rate can prolong LV filling time in abnormally stiff LV and also prolong coronary perfusion. As a result, we recommend the careful use of β-blockade to optimize chronotropic incompetence (induced by atrial fibrillation or tachyarrhythmia) by stabilizing heart rate and optimizing LV relaxation with regard to heart rate profile under basal and exercise conditions in patients with HFpEF. Moreover, additional benefical effects of β-blockers have to be reconsidered. In detail, nebivolol itself would possible confer additional effects due to the NO enhancing action of the drug. This action of nebivolol is exerted *via* a signaling pathway starting from the activation of β3-adrenergic receptors and leading to overexpression of inducible NO synthase. Cardiac NO production by nebivolol could participate in the cardiovascular effects of nebivolol treatment in patients affected by hypertension and HF.

Adequate prospective trial data regarding the effects of β-blockers in HFpEF are not currently available. In this regard it is interesting to know that Pieske *et al* (Charité - Berlin, Germany) are planning an additional large multicenter trial with about 2300 participants with preserved LVEF in order to investigate the effects of β-blockers treatment starting in 2015.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

Perindopril in elderly people with chronic HF trial

The theoretical benefits of Angiotensin-converting enzyme inhibitors (ACEi) in HFpEF rest on pathophysiological basis that angiotensin II contributes to myocardial hypertrophy and adverse cardiac fibrosis. To date, only one substantial trial of ACEi has been conducted in the HFpEF population, the perindopril in elderly people with chronic HF (PEP-CHF). The PEP-CHF Trial included 850 patients, older than 70 years of age with HFpEF (LVEF > 45%) with echocardiographic evidence of diastolic dysfunction[22]. The primary endpoint of the trial was a composite of all-cause mortality or unplanned HF related hospitalization. A significant reduction in HF hospitalization rate was observed in posthoc analysis of the results at 1 year, when cross over rates to open label ACEi were used. However, early beneficial effects of perindopril treatment

were lost by the end of the trial.

A major limitation of the trial was the high rate of discontinuation at 18 mo (62%), the majority of whom went on open-label ACEi (about 90%). In addition, the event rate in the trial was lower than expected, further reducing the power of the trial. Perindopril appeared favorable at 1-year follow-up when the large majority of patients were on study drug, although these data should not be considered definitive given the post-hoc nature of the analysis. Although the PEP-CHF trial also does not provide conclusive evidence that perindopril is of benefit in this population, the observed favourable trends on hospitalization and days in hospital for HF (early seen beneficial effects), combined with improvements in symptoms and functional capacity provide arguments for its use.

Effects of candesartan in patients with chronic HF and preserved left-ventricular ejection fraction: The CHARM-Preserved trial

In the effects of candesartan in patients with chronic HF and preserved left-ventricular ejection fraction: The CHARM-Preserved trial (CHARM-Preserved) trial, 3023 (mean age 67 years, 40% women) patients were randomly assigned to the angiotensin receptor blocker (ARB) candesartan or placebo and followed 37 mo[23]. Adequate patients were aged greater than 18 years, suffering from HF for more than 4 wk, were in NYHA class II-IV, had a history of hospital admission and had a greater LVEF than 40%. The primary outcome (cardiovascular death or HF admission) was neutral (P = 0.051), but only slightly short of the primary outcome. A possible explanation of this finding could be the rates of study-drug discontinuation due to adverse events or laboratory abnormalities, which were significantly higher in the candesartan group (17.8% *vs* 13.5%, P = 0.001). In detail, candesartan was discontinued in more patients due to hyperkalemia, worsening creatinine levels or hypotension. In an echocardiography substudy of CHARM-Preserved, only 44% had moderate or severe diastolic dysfunction, which conferred a 3-fold increased risk but it is not clear whether these patients obtained a greater benefit from candesartan. Overall, CHARM-Preserved results were related with reduced hospitalization with candesartan[23]. However, the LVEF cut-off value of 40% and a non-defined diastolic function identified the study population as not a true HFpEF population.

Irbesartan in patients with HF and preserved ejection fraction trial

The Irbesartan in patients with HF and preserved ejection fraction trial (I-Preserve), the largest trial in the HFpEF population so far, randomly assigned 4128 patients (mean age 72 years, 60% female) to irbesartan or placebo[24]. The observation period was about 49.5 mo (mean). All included patients were aged greater than 60 years, had symptoms of HF and had a greater LVEF than 40%. The primary outcome (death from any cause or hospitalization for cardiovascular cause) occurred 36% of patients in the irbesartan group and 37% in the placebo treated group[24]. There were no significant differences in the primary endpoints between the two groups. This trial also found no treatment benefit in any group and no significant difference in secondary endpoints such as CV death, HF death, exercise testing, NT-proBNP levels, and quality of life (Table 1).

However, it is essential to mention that in this study a high percentage of patients were already receiving ACEi and spironolactone. The investigators speculated that the treatment of a large proportion of patients with multiple inhibitors of the RAS might have left reduced opportunity for further benefit from the addition of an angiotensin-receptor blocker. Furthermore, it seems to be possible that HFpEF does not appear to involve neurohormonal activation as a critical pathophysiologic mechanism in the same way that HFrEF does.

The rationale for using ACEi and ARBs in patients with HFpEF is blocking the neurohumoral signaling leading to HF progression and poor clinical outcomes. First, the CHARM-Preserved trial showed a significant reduction in hospitalization rate caused by HF, but failed to display a significant reduction in cardiovascular mortality. Moreover, in an echocardiography substudy of CHARM preserved, only 44% had moderate or severe diastolic dysfunction. Second, the I-Preserved trial failed to show a reduction in risk of the composite outcome, cardiovascular hospitalization and all-cause mortality. However, the not insignificant co-medication in this trial could be one reason for the neutral endpoints. Third, the PEP-CHF trial also failed to demonstrate a reduction in composite all-cause mortality and hospitalization caused by HF.

Also because of the neutral results of these three main outcome trials the current guidelines do not recommend the use of ACEi and ARBs for HFpEF. Nevertheless, when hypertension and other co-morbidities like LV hypertrophy and atherosclerotic vascular disease are involved ACEi and ARBs are first-line therapy and should also be given to patients with HFpEF. A possible mechanism for potential benefit of ACEi and ARBs could be afterload reduction and reduced and reduced wall tension, leading to improved diastolic function.

MINERALOCORTICOID RECEPTOR ANTAGONISTS

Randomized controlled aldosterone receptor blockade in diastolic HF trial

Series of RCTs[25,26] have shown that treatment with mineralocorticoid-receptor antagonists (MRAs) improved some properties of cardiac performance in patients suffering from HFpEF. The randomized controlled aldosterone receptor blockade in diastolic HF (ALDO-HF) trial displayed an improvement in ejection fraction,

E/É relation, LV mass and LV end-diastolic volume[27]. However, these findings were not related with an enhancement in exercise capacity.

In the ALDO-HF trial, treatment with MRAs decreases renal function. Therefore, MRAs cannot be recommended based on the mentioned results. Physicians treating patients with MRAs should carefully monitor renal function and potassium levels. Whether the improved left ventricular function observed in the ALDO-HF trial is of clinical significance requires further investigation in larger HFpEF populations.

Treatment of preserved cardiac function HF with an aldosterone antagonist trial

The rationale to use MRAs for HFpEF therapy has been initially generated in experimental studies. These studies suggested that a blockade of the aldosterone-induced signaling may lead to anti-hypertrophic and anti-fibrotic effects[28]. Moreover, clinical trials EPHESUS and EMPHASIS-HF demonstrated significant reductions in risk of death from cardiovascular causes or first hospitalization for HF in patients after myocardial infarction and mild HF symptoms. However, in these trials solely patients with reduced LVEF were included.

MRAs such as spironolactone are highly effective in patients with HF accompanied with reduced LVEF[29-32].

In the treatment of preserved cardiac function HF with an aldosterone antagonist (TOPCAT) trial, patients with at least one symptom of HF were included if those patients had an ejection fraction greater than or equal to 45%[33].

Moreover, increased natriuretic peptide levels in the foregoing 60 d or a hospital admission in the previous year (with management of HF a major component of the care provided) were required, and these eligibility criteria were used for stratification of patients at randomization of this study[33]. Three thousand four hundred and forty-five patients undertook randomization in 6 different countries (United States, Argentina, Brazil, Canada, Russia and Georgia) to spironolactone or placebo.

Regarding a mean follow-up of 3.3 years (mean), the incidence rate of the primary composite outcome of death from cardiovascular causes, cardiac arrest, or hospitalization for HF was 5.9 events per 100 person-years in the spironolactone group and 6.6 events per 100 person-years in the placebo group.

Overall, the TOPCAT trial showed neutral results. There was a significant reduction in the secondary outcome of hospitalization for HF with spironolactone treatment.

Patients randomized to treatment with spironolactone had a fewer admission rate for HF, but an increased risk for renal dysfunction and hyperkalemia[34].

The majority of patients from Russia and Georgia were included in the hospitalization stratum (therefore no increased NT-proBNP was present) and thus were at lower cardiovascular risk, whereas patients from the United States were further balanced between the two mentioned strata. However, a post hoc analysis showed, that spironolactone treatment seemed to benefit patients in the United States but not those patients in Russia or Georgia. In detail, a total of 3445 subjects were recruited over a period of 4 years from 270 clinical centers in the United States (1151), Russia (1066), Georgia (612), Canada (326), Brazil (167) and Argentina (123), and were randomized on 1:1 basis

to either spironolactone (target dose of 30 mg daily) or placebo. Patients with uncontrolled hypertension, those with infiltrative or hypertrophic cardiomyopathy and patients with elevated baseline serum potassium levels (> 5.0 mmol/L) were excluded. The overall event rate was low, with 3-year mortality being 10.2%. This is in sharp contrast with the previously reported annual mortality rates of 22%-29% in large community-based studies[35]. This concern is further intensified by a primary event rate (in the placebo group) of 8.4% in Russia and the Republic of Georgia: A rate which not only is unheard of in HF studies, but also one that is remarkably less than that observed in the "American" arm of the same study (31.8%).

It is remarkable that geographic differences in outcome have been a significant relevance in previous trials involving patients with HF. Possible factors in such geographic variation include differences in the clinical characteristics of the patient population, standards of care and methodological knowledge of clinical trials[34].

To conclude, TOPCAT was a neutral study. Spironolactone failed to reduce the primary outcome compared to placebo in patients with HFpEF. However, it did reduce the rate of HF hospitalizations. A signal of benefit was also seen in patients with elevated natriuretic peptides and in a geographical subset of patients. Based upon these findings, a mixed response from the medical community is expected: Some clinicians will not prescribe spironolactone for HFpEF patients, while others will continue using it especially in patients with elevated natriuretic peptides and/or in those with objective evidence of diastolic dysfunction. Finally, we prescribe spironolactone for HFpEF patients during carefully monitoring of renal function and serum potassium levels given the overall positive data from the Americas in TOPCAT.

DIGITALIS THERAPY

Digitalis investigation group ancillary trial

It has been shown that treatment with digoxin has beneficial effects on hospitalization in patients with HFrEF. Treatment with digoxin reduced the total number of hospitalizations. In the digitalis investigation group ancillary trial 988 patients suffering from chronic HF and ejection fraction greater than 45% were randomized to treatment with digoxin or placebo[36].

After 37 mo (mean follow-up), patients treated with digoxin or placebo had similar rates of the primary composite of hospitalization of HF or cardiovascular death[36]. However, an early benefit in patients with digoxin treatment was lost by the end of follow-up of the trial.

In ambulatory patients with chronic mild to moderate diastolic HF and normal sinus rhythm receiving angiotensin-converting enzyme inhibitor and diuretics, digoxin had no effect on natural history end points such as mortality and all-cause or cardiovascular hospitalizations[36].

To conclude, there is fragile evidence of digoxin in patients with HFpEF. Similar to β-blockers, guidelines do not recommend the use of digoxin solely for HFpEF, unless for treatment of co-morbidities, such as atrial fibrillation or tachyarrhythmia. However, common use of digoxin in the elderly HFpEF population with increased renal dysfunction seems not to be advisable.

INHIBITION OF THE LATE CURRENT OF THE CARDIAC ACTION POTENTIAL (LATE INA)

RAnoLazIne for the treatment of diastolic HF in patients with preserved ejection fraction: the RALI-DHF proof-of-concept study

In a small, randomized (phase Ⅱ) trial 18 patients were included who received ranolazine infusion followed by 2 wk of oral application[37]. It was shown by the investigators that left ventricular end-diastolic pressure and pulmonary capillary wedge pressure were reduced in patient with ranolazine treatment whereas in patients with placebo treatment there were no significant effects seen (clinicaltrails.gov NCT01163734). However, at the end of the trial no significant differences were observed by echocardiography and exercise capacity. In addition, a planned multi-center trial has been abandoned due to low recruitment. Finally, results of two ongoing studies are earliest expected in 2016.

PHOSPHODIESTERASE-5 INHIBITION

Sildenafil, a phosphodiesterase-5 (PDE-5) inhibitor is currently approved for treatment of pulmonary arterial hypertension (PAH)[38-40]. A small clinical trial observed improvements in pulmonary pressure, right ventricular (RV) function and LV relaxation after treatment with sildenafil in patients suffering from HFpEF. In a phase Ⅲ ongoing trial the effect of sildenafil on patients suffering from HFpEF and PAH will be studied[41]. Moreover, sildenafil treatment led to an enhancement of systolic and diastolic LV function in a one-year randomized double-blind study placebo controlled study in patients suffering from stable HF and reduced ejection fraction[42].

PhosphdiesteRasE-5 inhibition to improve clinical status and exercise capacity in diastolic HF trial

Controversial findings have been oberserved from the PhosphdiesteRasE-5 inhibition to improve clinical status and EXercise Capacity in Diastolic Heart Failure (RELAX) trial[43] with HFpEF patients. Here, no significant improvement in diastolic function, exercise capacity and quality of life was observed.

In addition, in a multi-center study 216 patients with HFpEF and increased pulmonary artery pressures did not affect exercise capacity or clinical constitution over a time period of 24 wk[44]. Furthermore, longterm analyses of NT-proBNP and endothelin-1 displayed no significant changes between sildenafil and placebo

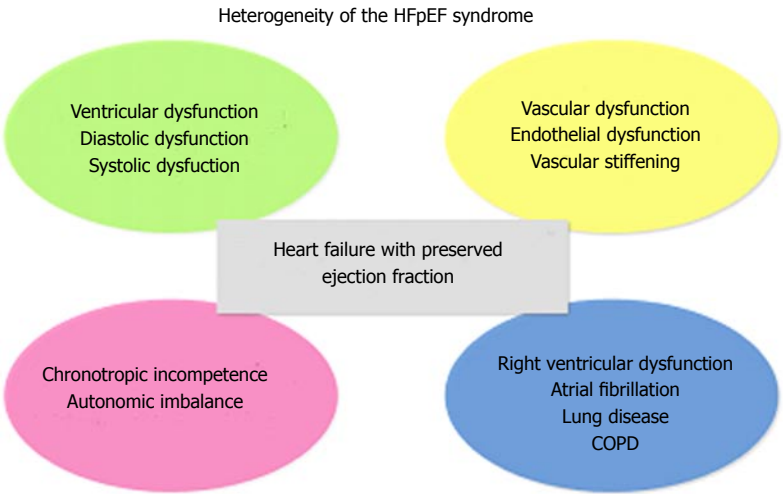

Figure 1 Overview of multiple effectors for the heterogeneity of the heart failure has preserved left ventricular ejection fraction syndrome. COPD: Chronic obstructive pulmonary disease; HFpEF: Heart failure has preserved left ventricular ejection fraction.

treated groups. However, in a one-year single center trial of sildenafil in patients with HFpEF described significant improvements in with sildenafil treated patients when compared to placebo treated patients[41].

The lack of benefit of sildenafil treatment could be because the inclusion and exclusion criteria. In this trial, the included patients did not have pulmonary hypertension and suggested by highly increased NT-proBNP levels had advanced HF; this could explain the less-responding to sildenafil-treatment.

Furthermore, in a small clinical trial including 44 patients suffering from HFpEF (LVEF > 50%) and PAH inhibition by PDE-5 displayed a significant improvement in diastolic dysfunction, pulmonary pressures and right ventricular performance over an oberservation period of 12 mo[41]. Given the results, PDE-5 inhibition for HFpEF without proven increased PAP should not be used.

DEVICE THERAPY

No substantial clinical trials of implantable cardiac defibrillators or cardiac resynchronization therapy exist in the HFpEF population.

A large trial of cardiac resynchronization therapy (CRT) in patients suffering from an LVEF between 36% to 50% has been stopped due to poor outcome[45].

CRT is currently limited to those patients with LVEF < 35%, sinus rhythm, QRS > 150 ms, and left bundle branch block (LBBB) pattern. A retrospective analysis of the predictors of response to CRT has shown that CRT may offer a valuable option for these patients[46,47]. However, this finding has to be proven in a prospective, randomized multicenter trial. To date, CRT should not be used as matter of routine in patients with HFpEF. Furthermore, a current small clinical trial used a cardiovascular simulation to provide insights into the potential effects of an inter-atrial shunt on rest and exercise hemodynamics in patients suffering from HFpEF[48]. The principal finding of this study is that the inter-atrial shunt lowers left atrial (LA) pressure and that this effect is particularly pronounced during the marked increase in LA pressure and increased left-to-right atrial pressure gradient during exercise in this patient population.

However, the marked reduction in LA pressure (and pulmonary capillary pressure) could allow patients to exercise longer, potentially resulting in higher heart rates and higher values of cardiac output.

There exist currently two different devices in clinical development to create a device to make a precisely sized interatrial septal defect that will maintain patency for this purpose. Whether the findings of this theoretical simulation provide insights into patient selection criteria and the expected magnitude of hemodynamic improvement has to be proven in further clinical trials.

Possible optimizations of clinical trials for HFpEF in the future

For future clinical trials in HFpEF better matching of treatments for the precise type of HFpEF seems to be necessary (Figure 1).

However, in retrospect it has been elucidated that the type of therapy tested in previous clinical trials may not be the correct match for the type of HF population included. This line of argument incorporates the ALDO-DHF trial, which included patients with early-stage HFpEF and not manifest volume overload.

Moreover, in the RELAX trial, which enrolled symptomatic HF patients with volume overload but not necessarily those with overt PAH and RV dysfunction. However, the inclusion and exclusion criteria should focus on patients with early HFpEF, in whom exercise intolerance is one of the main indicators and in whom there is objective evidence of exercise-induced increase in LV filling pressures. Excluding patients with co-morbidity to try to increase the specifity of HFpEF may purely make matters worse by excluding those patients at high risk. If co-morbidities drive the clinical course of the patient, then treatment directed only at cardiac function may be ineffective. In addition, diagnosis of HFpEF should not be based solely on clinical criteria and the absence of HFrEF (Figure 2).

Natiuretic peptides provide considerable confidence for improved clinical trial design. HFpEF is a

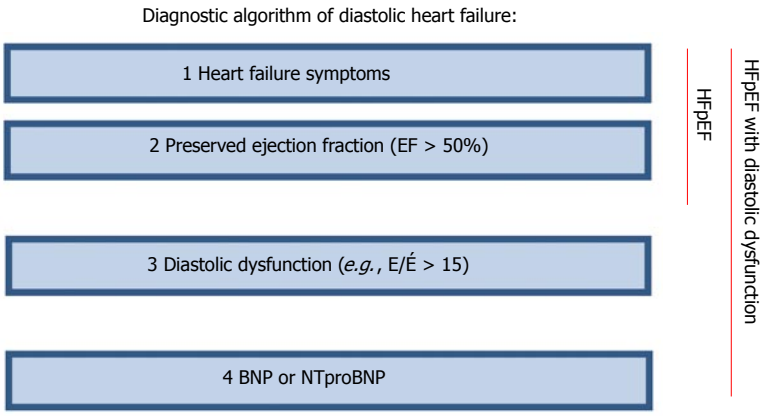

Figure 2 Diagnostic algorithm of diastolic heart failure. BNP: B-type natriuretic peptide; NT-proBNP: N-terminal of the B-type natriuretic peptide; E/É: Pulsed-wave Doppler E wave velocity divided by tissue Doppler E wave velocity; HFpEF: Heart failure has preserved left ventricular ejection fraction.

heterogeneous and a complex syndrome and only specific phenotypes may respond to a particular therapeutic intervention (Figure 1).

Sufficient diagnosis and phenotyping seems to be essential. The disappointment in the last clinical trials that have proven so effective in treating HFrEF supports an urgent need for novel drug approaches to HFpEF (Figure 3). Underpowered clinical trials should be avoided and study designs need a focus on more consistent patient populations to control the impact cardiovascular co-morbidities. To conclude, ethnicity, cultural differences, co-medication, cut-off values and local clinical practice might influence results of clinical trials. Additional endpoints that include for example, quality of life evaluation and correct timing for effective therapeutic intervention must be kept in mind when planning expensive multicenter RCTs.

PROMISING NEW THERAPY STRATEGIES

Soluble guanylate cyclase inhibitors

Solid evidence supports augmentation of (cGMP) signaling as a potential therapeutic strategy for HFpEF[49]. Direct soluble guanylate cyclase stimulators target reduced cGMP generation due to insufficient sGC stimulation and represent a promising method for cGMP enhancement.

In the SOCRATES-Preserved trial (soluble guanylate cyclase stimulator in HF patients with PRESERVED EF; clinicaltrial.org NCT01951638) stimulation of the soluble guanylate cyclase by the oral soluble guanylate cyclase stimulator BAY1021189 is currently being investigated over 12 wk in patients with worsening HFpEF.

I_f channel inhibition

The SHIFT trial demonstrated that significant heart rate reduction *via* ivabradine, inhibitor of the I_f channel of the sinoatrial node, led to a significant reduction in hospitalization caused by HF and cardiovascular mortality in the HFrEF population[50]. Interestingly, the effects of ivabradine in HFpEF have been studied in a small recent trial of 61 patients, randomized to placebo or ivabradine (5 mg twice a day). Treatment with ivabradine showed an enhancement in exercise capacity and an improvement in LV filling pressures. In addition, a larger multi-center study enrolling about 400 patients is going to evaluate the properties of ivabradine concerning diastolic function, NT-proBNP levels and exercice capacity (www.clinicaltrialsregister.eu-EUCTR2012-002742-20-DE).

Dual angiotensin receptor blocker-neutral endopeptidase inhibitors

Although studies conducted with ARBs or ACEi alone did not display enhancements in HFpEF patients, pathophysiological evidence support the rationale for targeting the renin angiotensin system (RAS) in this population of patients.

The Prospective comparison of ARNI with ARB on Management of HF with preserved ejectionN fraction (PARAMOUNT) study[51], a phase Ⅱ trial conducted in 308 patients in 13 countries, compared the effects of LCZ696 and the ARB valsartan on the concentrations of natriuretic peptides. The natriuretic peptide investigated in this study, NT-proBNP, is a marker of cardiac wall stress, and levels are increased in patients with HF[51].

The agent LCZ696 in the PARAMOUNT study is the first compound to show both reductions in NT-proBNP and left atrial size (LA) in HFpEF patients, powerful predictors of outcome in HF. The favorable effects of LCZ696 seen in patients with HFpEF in the PARAMOUNT trial are encouraging, and further testing of this agent in this patient population is warranted.

LCZ696 acts by inhibiting both the angiotensin receptor and the enzyme responsible for the breakdown of the natriuretic peptides (neprilysin). LCZ696's dual mechanism of action thus acts to restore the altered neurohormonal balance in HFpEF[52]. These dual effects may be important in the treatment of HFpEF. Moreover, the large outcome trial PARAGON-HF will test the efficacy and safety in HFpEF patients (clinicaltrials.gov NCT01920711).

CONCLUSION

HFpEF accounts for approximately 50% of all patients diagnosed with HF, with similary poor outcomes. To date, only the prevention of HFpEF by treating the cardiovascular risk factors (coronary artery disease, atrial fibrillation, hypertension, diabetes, and obesity) has been shown to be efficient. This observation suggests that investigators in future trials should specify the indication of hospitalization for HF and may request to verify the details of patients' admissions.

However, dual inhibition of the RAS and neprilysin by the agent LCZ696 represents a novel promising therapeutic target for treating patients with HF. LCZ696 in the PARAMOUNT trial is the first agent to show both reductions in NT-proBNP levels and LA size in HFpEF patients, each strong predictors of outcome in HF. The favorable effects of LCZ696 seen in patients with HFpEF in the PARAMOUNT trial are encouraging. Further testing of dual of RAS and neprilysin inhibition in the HFpEF population is warranted.

Abstract

Electrical storm (ES) is a clinical condition characterized by three or more ventricular arrhythmia episodes leading to appropriate implantable cardioverter-defibrillator (ICD) therapies in a 24 h period. Mostly, arrhythmias responsible of ES are multiple morphologies of monomorphic ventricular tachycardia (VT), but polymorphic VT and ventricular fibrillation can also result in ES. Clinical presentation is very dramatic in most cases, strictly related to the cardiac disease that may worsen electrical and hemodynamic decompensation. Therefore ES management is challenging in the majority of cases and a high mortality is the rule both in the acute and in the long-term phases. Different underlying cardiomyopathies provide significant clues into the mechanism of ES, which can arise in the setting of structural arrhythmogenic cardiomyopathies or rarely in patients with inherited arrhythmic syndrome, impacting on pharmacological treatment, on ICD programming, and on the opportunity to apply strategies of catheter ablation. This latter has become a pivotal form of treatment due to its high efficacy in modifying the arrhythmogenic substrate and in achieving rhythm stability, aiming at reducing recurrences of ventricular arrhythmia and at improving overall survival. In this review, the most relevant epidemiological and clinical aspects of ES, with regard to the acute and long-term follow-up implications, were evaluated, focusing on these novel therapeutic strategies of treatment.

Key words: Electrical storm; Ventricular tachycardia/fibrillation; Structural heart disease; Antiarrhythmic therapy; Implantable-cardioverter defibrillator; Shock; Catheter ablation

Core tip: Electrical storm is an increasingly common and life-threatening syndrome. The proper management of this arrhythmic emergency is related to a comprehensive assessment of each case. In this review we report all the essential aspects regarding the clinical and

diagnostic evaluation, pharmacological treatment and, with special emphasis, catheter ablation approaches.

Electrical storm: A clinical and electrophysiological overview. *World J Cardiol* 2015; 7(9): 555-561 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i9/555.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i9.555

INTRODUCTION

Electrical storm (ES), also referred as arrhythmic storm, refers to a clinical condition characterized by 3 or more arrhythmia episodes of ventricular tachycardia (VT) or ventricular fibrillation (VF) leading to implantable cardioverter-defibrillator (ICD) therapies (Antitachycardia Pacing, ATP, or Direct Current shock, DC-shock), occurring over a single 24 h period[1]. ES represents an arrhythmic emergency that often affects patients at high risk of sudden cardiac death who previously underwent ICD implantation. In this setting ICD correctly interrupts VT/VF episodes; however ventricular arrhythmias, in terms of arrhythmogenic substrate, represent the gradual evolution of the underlying structural heart disease. In this review, we assess the most relevant epidemiological and clinical aspects of ES, with regard to the acute and long-term follow-up implications, focusing on novel therapeutic strategies of treatment.

CLINICAL CHARACTERIZATION

The term ES was introduced in the 1990s to describe an instability condition, highly malignant, characterized by repetitive episodes of ventricular arrhythmias[2]. Nowadays, ES implies several appropriate ICD interventions aimed at terminating the arrhythmic episodes.

ES has been reported in 10%-40% of patients in secondary prevention whereas the incidence of ES is lower (3.5%-4%) in primary prevention[3-16]. However, the correct incidence of ES is uncertain due to several confounding factors such as population considered, type of cardiomyopathy, pharmacological therapy undertaken and other variables. In addition, most of the studies concerning ES incidence were retrospective thus including only the patients who survived the arrhythmic event.

ES mainly affects patients with advanced dilated cardiomyopathy, both ischemic and non-ischemic, representing the gradual evolution of the underlying arrhythmic substrate; however, ES may affect patients with different types of structural heart disease, such as valvular or congenital heart disease, as well as patients without structural heart disease (*i.e.*, Brugada syndrome)[17].

The most significant predictors of ES are severe reduction of left ventricle (LV) function, advanced age and previous VT/VF episodes[8,10,11,13,18,19]. Monomorphic ventricular tachycardia is the most common arrhythmia documented in ES patients. VT episodes, hemodynamically unstable and interrupted with ATP or DC-shock, are the rule, with evidence of multiple VT morphologies[20]. Anyway, clinical presentation of ES is variable[9].

Less commonly, ES has been recorded in patients in whom premature ventricular complexes are the trigger of VT/VF both in acute myocardial infarction and in absence of structural heart disease[16,21]. The latter are often patients with "primitive ventricular fibrillation", in whom the trigger of the arrhythmia has not been documented, presenting with multiple VF episodes after ICD implantation, mostly refractory to pharmacological therapy. Therefore, in this setting, the identification of ES triggers may be of interest in preventing VT/VF episodes, particularly in case of electrolyte disorder[9,14]. The role of adrenergic system in maintaining ES is of special interest as well; in terms of acute event treatment[7,16]. Adrenergic activation seems to play a key role in patients with arrhythmogenic right ventricular cardiomyopathy/dysplasia due to the well known arrhythmic sensitivity to adrenergic stimulation; although in the majority of these patients the trigger is unkown[22].

ACUTE PRESENTATION, PROGNOSTIC RELEVANCE

ES is an arrhythmic emergency related to recurrent consecutive episodes of ventricular arrhythmia, with low likelihood of spontaneous termination.

The clinical scenario of ES is the result of a combination of various factors: in patients with structural heart disease affected by chronic heart failure, ES causes worsening of heart failure with high risk of pulmonary edema/cardiogenic shock. These events are much more frequent and severe, less stable the arrhythmic condition and the functional status are. ICD therapies even if allow arrhythmic episodes termination and prevent sudden cardiac death, do not play any role in stabilizing the clinical scenario. Moreover, the continuous intervention of ICD, implies unfavorable hemodynamic effects[3], also resulting in psychological distress, adrenergic hyperactivity, and patient discomfort[22,23].

No reproducible data on acute mortality in ES are available. It should be reminded that acute mortality represents a common cause of death in patients with severe structural heart disease, in most of cases as cardiogenic shock or electromechanical dissociation in the setting of unmanageable arrhythmias[3]. Literature data show that patients with ES present an increased risk of sudden arrhythmic or cardiac death in the mid-term follow up[8-10,16,24]; furthermore, these findings were not confirmed just in few papers[7,13]. The MADIT Ⅱ trial showed that patients with VT episodes interrupted by ICD have a significantly higher risk of sudden and non-sudden cardiac death. Moreover, patients who have survived ventricular arrhythmias have an increased risk

of worsening heart failure and of mortality related to it[25]. Specifically, in the MADIT Ⅱ trial, Sesselberg *et al*[11] have shown that ES is the most important independent predictor of mid-term cardiac death (increased risk of 7-fold), resulting particularly significant in the first 3 mo after ES (increasing risk of 18-fold). The results of SCD-HeFT trial are comparable, in addition, Poole *et al*[26] observed that not only appropriate shocks - directly related with arrhythmic events - but also inappropriate shocks impact on an increased mortality. More specifically the authors reported a significant increase of death in patients with appropriate (HR = 5.68; $P < 0.001$) and inappropriate shocks (HR = 1.98; $P = 0.002$). In particular, multiple shocks were associated with a 8-fold risk of death (HR = 8.23; $P < 0.001$).

These findings support the hypothesis that the recurrence of frequent arrhythmic events (and even more ES) strongly impacts on the evolution of patients' clinical history, particularly by worsening the cardiac function. In this setting multiple shocks could have their own etiopathogenetic role related to repeated myocardial injury.

DIAGNOSIS AND CLINICAL MANAGEMENT

Patients with ES require a diagnostic evaluation of their structural heart disease, the type of arrhythmia and the presence of clinical triggers. The most common triggering factors are acute myocardial ischemia, electrolytic disorders and adverse drug effects. Identification of triggers is a key point: sometimes it allows the suppression of arrhythmias through simple therapeutic interventions, such as in case of hypokalaemia. Acute myocardial ischemia must be accurately identified and excluded through clinical and non-invasive diagnostic parameters. However, in most patients with coronary artery disease and previous history of myocardial infarction presenting with ES, myocardial ischemia is just a secondary effect of the arrhythmias. Myocardial ischemia should therefore be interpreted and consequently treated with the aid of pharmacological and/or interventional therapies in the presence of acute coronary syndrome. In the majority of cases, however, ES represents the evolution of an arrhythmogenic substrate in patients with previous VT/VF episodes.

Therapeutic interventions first depend on the arrhythmic pattern and on the hemodynamic stability of patients. ICD interrogation is the preliminary diagnostic step to evaluate the appropriateness of shock delivery and arrhythmic parameters (heart rate, electrogram analysis, trigger). ICD reprogramming is mandatory in order to both limit ICD shock delivery and attempt VT/VF interruption with antitachycardia pacing[27,28]. The accuracy of the diagnosis of ventricular arrhythmia may only occasionally show interpretative troubles in single-chamber ICD recipients in whom the comparison between basal and arrhythmic electrograms should be carried out carefully privileging reading from multiple recording channels.

ES patients require hospitalization. A continuous ECG and vital signs monitoring must be performed in the Coronary Intensive Care Unit or in a dedicated Emergency Arrhythmia Unit. During the evaluation phase, the possibility to document and characterize different morphologies of VT responsible for the clinical scenario is relevant, also with regard to a possible ablative treatment[20].

Hemodynamic and metabolic evaluations are needed in order to perform urgent interventions through intravenous therapies, such as inotropic agents or hydroelectrolytic infusion.

In the acute setting, prevention of arrhythmic recurrence should be as efficient as possible, by means of: (1) amiodarone is the first choice drug, unless contraindicated (presence of hyperthyroidism, long QT interval)[29]; (2) beta-blocker administration plays an important role because of its antiarrhythmic and antiadrenergic effect. Beta-blockers administration should be limited in patients with labile hemodynamic compensation or severe reduction of LV function; (3) lidocaina and azimilide are second choice drugs, useful in case of contraindications to previous medications[14,30]; (4) verapamile should be used as drug of choice in case of premature ventricular beats originating from His-Purkinje system; and (5) finally, atrial or sequential atrio-(bi)ventricular pacing are useful to avoid bradycardia[31,32].

Sedation is pivotal to stabilize patients with ES, but hemodynamic and/or respiratory instability can limit the use of sedation drugs, such as benzodiazepine. In these cases mechanical ventilation with oro-tracheal intubation are absolutely required in refractory forms of ES. In some cases mechanical ventilation allows safer drugs administration otherwise not tolerated.

ROLE OF CATHETER ABLATION

The role of catheter ablation (CA) in patients with VT is becoming more and more relevant, as a definite treatment of multiple forms of arrhythmias and a complementary intervention in cases of high electrical instability, thus improving prognosis and quality of life in patients with advanced forms of heart disease. This observation creates the rationale to investigate the possibility to apply CA in patients with frequently recurring ventricular arrhythmias and ES[33].

Preliminary reports regarding the role of CA in the treatment of ES are limited to patients with specific clinical characteristics and/or small case series. Silva *et al*[34] reported a success rate of 80% in an ES population with recurrent hemodynamic stable VT; Schreieck *et al*[35] reported acute success in most of cases of a selected population undergoing CA of hemodynamic unstable arrhythmias guided by substrate mapping. Also Bänsch *et al*[16] described CA in patients with acute

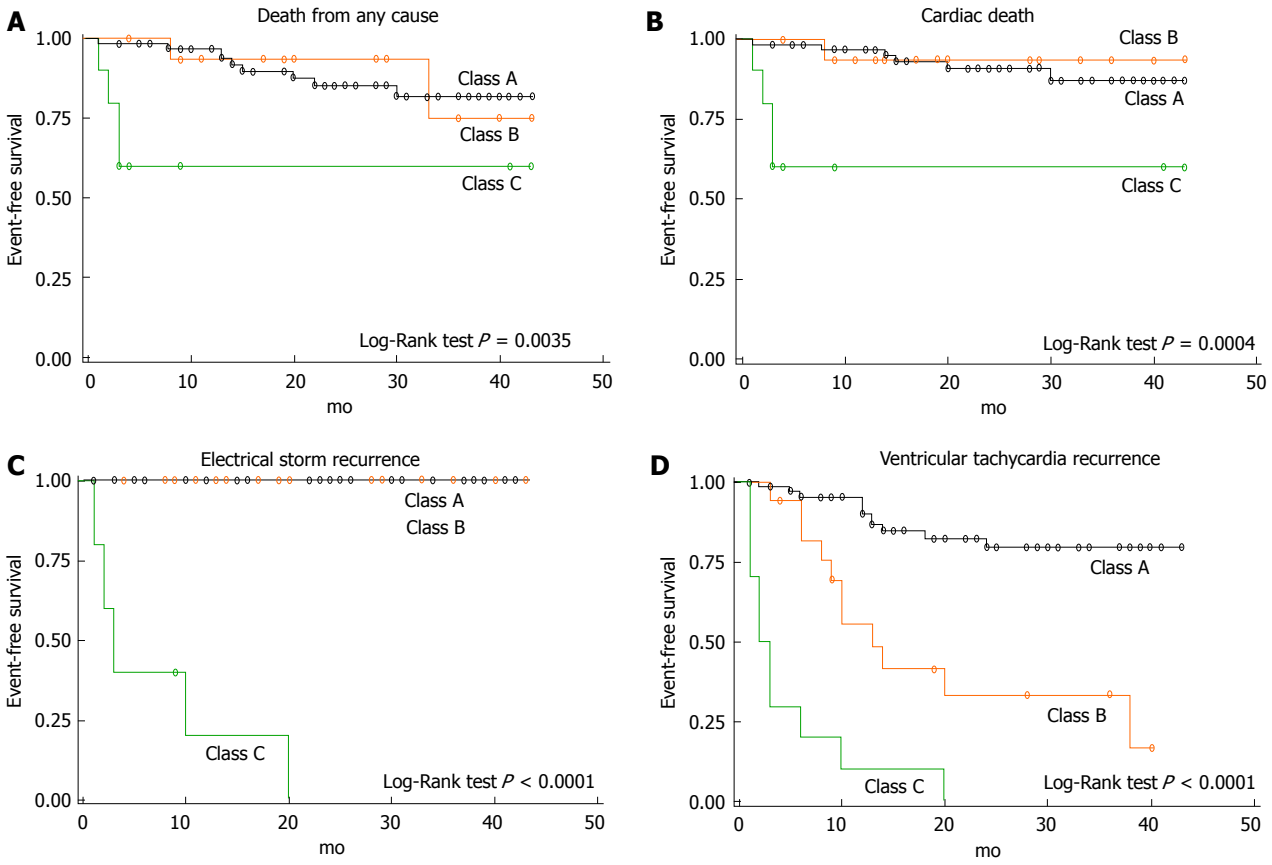

Figure 1 Kaplan-Meier survival analysis after catheter ablation of electrical storm. Class A indicates catheter ablation success, defined as suppression of each ventricular tachycardia (VT) morphology; Class B indicates partial success, defined as suppression of each clinical VT; Class C indicates failure, defined as persistence of one or more clinical VT (reprinted from Carbucicchio *et al*[20]).

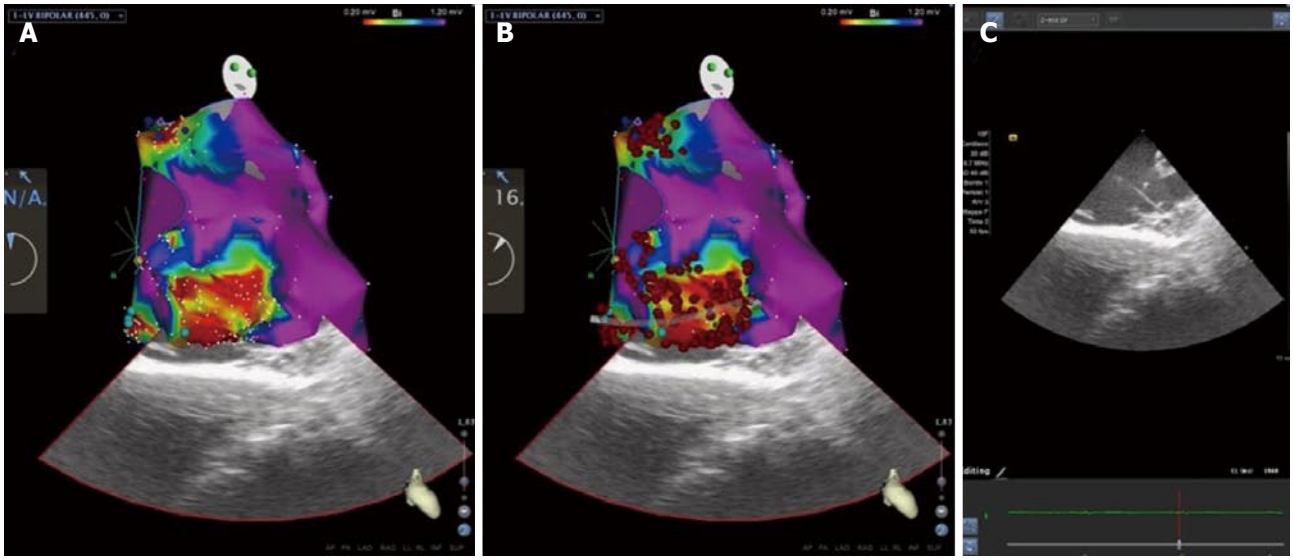

Figure 2 Modern approach of mapping and ablation for the treatment of electrical storm: High-density electroanatomical mapping of the left ventricle using CARTOSOUND contact-force technology (Biosense Webster, Diamond Bar, CA, United States). A: Two distinct peri-valvular scars, in the mitro-aortic continuity and below the mitral annulus, in the setting of idiopathic cardiomyopathy are visualized. Scars are characterized by dense scar (abnormal bipolar electrograms < 0.20 mV), surrounded by a border zone (0.20-1.20 mV) in which late potentials, are tagged (dark and light blue dots); B: Radiofrequency ablation lines are dragged for dechanneling and isolation of all proarhythmic sites; C: Intracardiac echocardiography imaging is aiming at substrate characterization and correct positioning of the catheter during mapping and ablation.

myocardial infarction and ES in whom VF was triggered by premature ventricular contractions, targeted by CA.

The ability to assess the feasibility and effectiveness of CA in a wider ES population arises from more

recent experiences, which better represent the profile of patients with complex, hemodynamically non-tolerated, drug-refractory ventricular arrhythmias, mostly in the setting of structural heart disease with severe impairment of left ventricular function. In this population, Carbucicchio *et al*[20] have described for the first time VT suppression in 90% of patient undergoing one or more CA procedures with or without the use of haemodynamic mechanical support. Moreover, the authors have shown that non-inducibility of VT at the end of the procedure was predictive of no recurrence of ES or VT at 2 years follow-up; accordingly, CA survival was improved in arrhythmia-free patients (Figure 1). This experience once again shows that ES represents a turning point in the natural history of patients with dilated cardiomyopathy and ventricular arrhythmias and that the treatment of arrhythmic burden plays a favourable effect on the clinical history of these patients both in terms of arrhythmic death and acute heart failure. More recent studies have confirmed that CA of ES is effective in reducing mortality in the middle-term follow up[18,36].

Regarding management of patients with ES or with recurrent VT following points must be taken in account: (1) clinical management in this setting is highly demanding. It requires an experienced Intensive Care Unit staff and a multidisciplinary approach that includes anesthesiological and psychological support; (2) advanced CA strategies in these patients are particularly complex (Figure 2). Obviously, the use of electroanatomical mapping (EAM) to guide CA is mandatory, and a substrate-guided approach is commonly more efficient, limiting activation mapping manoeuvres[37]. An epicardial approach should be preferred in all patients with non-ischemic cardiomyopathy to minimize recurrences. In patients with unstable VT or very depressed cardiac function, or in those presenting with cardiogenic shock, hemodynamic mechanical support allows patients stabilization and enhances efficacy and safety of CA, and can be used both during intraprocedurally as in the post-procedural period[38]; and (3) in selected patients, requiring concomitant surgical indications or in whom a percutaneous approach is not feasible, surgical ablation guided by EAM (endo- and/or epicardial) may be taken into account, in an experienced and multidisciplinary setting.

CONCLUSION

ES is an "extreme" ventricular arrhythmia affecting ICD patients with structural heart disease and is a major predictor of cardiac death in the short-term follow-up. Problems related to the treatment of ES patients are complex, depending on the type of patient as well as on the treatment of cardiac emergency, and require high standard facilities and specialized skills.

CA for the treatment of ES is particularly promising and should be considered the elective form of treatment to achieve long-term rhythm stabilization and to prevent heart failure. The possibility to modify the arrhythmic substrate by CA in an early phase, thus preventing critical situations deriving from repetitive ICD interventions, looks promising, but necessitates further corroborations.

Author contributions: Balzer J and Zeus T designed the concept of the study, prepared the manuscript and figures, performed the interventional procedures and drafted the manuscript; Hellhammer K and Veulemans V performed the clinical and echocardiographic data assessment before and during the intervention; Eschenhagen S and Kehmeier E made critical revisions related to the quality of the acquired data and participated in the creation of figures and images; Meyer C, Rassaf T and Kelm M participated in the performance of the interventional procedures, and in the design and review of the manuscript; all authors read and approved the final manuscript.

Supported by A Restricted Grant from the Federal State Government of North Rhine-Westphalia and the European Union (EFRE-Program "Med in.NRW"), No. 005-GW01-235A.

Institutional review board statement: No ethical approval by the local institutional review board was necessary for the additional application of this novel fusion imaging technology. The data analysis was conducted retrospectively without the necessity of providing an ethics committee approval.

Institutional animal care and use committee statement: Animal experiments were not performed for the conduction of this study.

Conflict-of-interest statement: Jan Balzer has received fees for serving as a speaker from Philips Healthcare. Other authors have none conflict of interest to declare.

Data sharing statement: Technical appendix, statistical code, and datasets are available from the corresponding author. Participants gave written informed consent for the performance of each interventional procedure. Written informed consent was not obtained for the additional application of the fusion imaging software. The presented data are anonymized and the risk of identification is low.

Abstract

AIM: To present our initial clinical experience using this innovative software solution for guidance of percutaneous structural heart disease interventions.

METHODS: Left atrial appendage, atrial septal defect and paravalvular leak closure, transaortic valve repair and MitraClip® procedures were performed in the catheter laboratory under fluoroscopic and echocardiographic guidance. The two-dimensional and three-dimensional images generated by the transesophageal echocardiography probe were interfaced with the fluoroscopic images in real-time using the EchoNavigator®-system.

RESULTS: The application of the novel image fusion technology was safe and led to a better appreciation of multimodality imaging guidance due to improved visualization of the complex relationship between catheter devices and anatomical structures.

CONCLUSION: The EchoNavigator®-system is a feasible and safe tool for guidance of interventional procedures in structural heart disease. This innovative technology may improve confidence of interventional cardiologists in targeting and positioning interventional devices in order to increase safety, accuracy, and efficacy of percutaneous interventions in the catheter laboratory.

Key words: Fusion imaging; Interventional guidance; Percutaneous interventions; Structural heart disease; Echocardiography

Core tip: Interventions in structural heart disease require adequate echocardiographic and fluoroscopic imaging for safe accomplishment of the procedure. Recently, a novel fusion imaging technology has been introduced, allowing for the first time to merge echocardiographic and fluoroscopic images in the catheter laboratory in real time. As one of the first centers worldwide, we used this innovative technology for guidance of interventions in structural heart disease, demonstrating its potential benefits for guiding complex interventions in structural heart disease.

Balzer J, Zeus T, Hellhammer K, Veulemans V, Eschenhagen S, Kehmeier E, Meyer C, Rassaf T, Kelm M. Initial clinical experience using the EchoNavigator®-system during structural heart disease interventions. *World J Cardiol* 2015; 7(9): 562-570 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i9/562.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i9.562

INTRODUCTION

Adequate peri-procedural image guidance is indispensable for safe accomplishment of cardiovascular interventions[1]. In contrast to coronary interventions where fluoroscopy remains the dominant imaging modality, the evaluation and treatment of structural heart disease requires continuous soft-tissue information that cannot be provided by fluoroscopy alone. Therefore, percutaneous interventions in the catheter laboratory are usually monitored additionally by two-dimensional (2D) and especially three-dimensional (3D) transesophageal echocardiography (TEE)[2]. Both techniques are presented side by side on different screens, necessitating the interventionalist to mentally reconstruct and fuse the presented information. Recently, the EchoNavigator®-system (Philips Healthcare, Best, The Netherlands) has been introduced as a novel software solution, allowing to merge echocardiographic and fluoroscopic images on the same display in real time[3,4]. In this study we aim to present our initial clinical experience with this innovative technology and describe its potential benefits during percutaneous interventions in structural heart disease.

MATERIALS AND METHODS

From January 2014 until July 2014 we used the EchoNavigator® software for guidance of 127 interventions in structural heart disease [3 paravalvular leaks, 11 atrial septal defects (ASDs), 31 transapical transcatheter aortic valve repair (TAVR) procedures, 35 left atrial appendage (LAA) occlusions, and 47 MitraClip® procedures]. Conscious sedation with continuous hemodynamic monitoring was applied in all cases, with the exception of the 31 transapical TAVR procedures, where general anesthesia was applied. After insertion of the procedure specific sheath, patients were sedated, and the TEE probe was inserted by an experienced echocardiographer before initiating the procedure by the interventionalist. For the additional application of this fusion imaging technology no ethical approval was necessary. All patients gave written informed consent for the performance of each interventional procedure.

EchoNavigator®

The technology of the EchoNavigator®-system relies on a real-time co-registration and visualization of 2D/3D TEE and fluoroscopy. The method consists of an image-based TEE probe localization and calibration algorithm. This algorithm automatically finds and tracks the position and the direction of the TEE probe within the fluoroscopic image[5]. After synchronization of TEE and fluoroscopy images, the system automatically tracks and follows the rotation of the C-Arm, based on the angulation of the gantry[6]. The results of this co-registration process are visualized to the interventional cardiologist on a large specific display that can be divided and arranged in up to 4 sections at discretion of the interventionalist. The 4 sections are assigned to different functions, depicting different views and are labeled as follows: (1) Echo: The Echo-view demonstrates online the images from the echo machine that can only be manipulated by the echocardiographer; (2) X-ray: The X-ray-view displays the actual fluoroscopic view depending on the angulation of the gantry. For a precise co-registration of the TEE probe, the probe has to be central in this view, the correctness of the co-registration being illustrated by a green edging of the probe. In case that the co-registration is not correct, *e.g.*, after movement of the TEE probe, the edging of the probe will turn into red; (3) C-Arm: The beam flow of the matrix array transducer is marked as a purple 3D sector in the X-ray-view, presenting the 3D Echo information of this sector in the C-Arm-view. Changes in angulation, rotation or position of the TEE probe are immediately registered

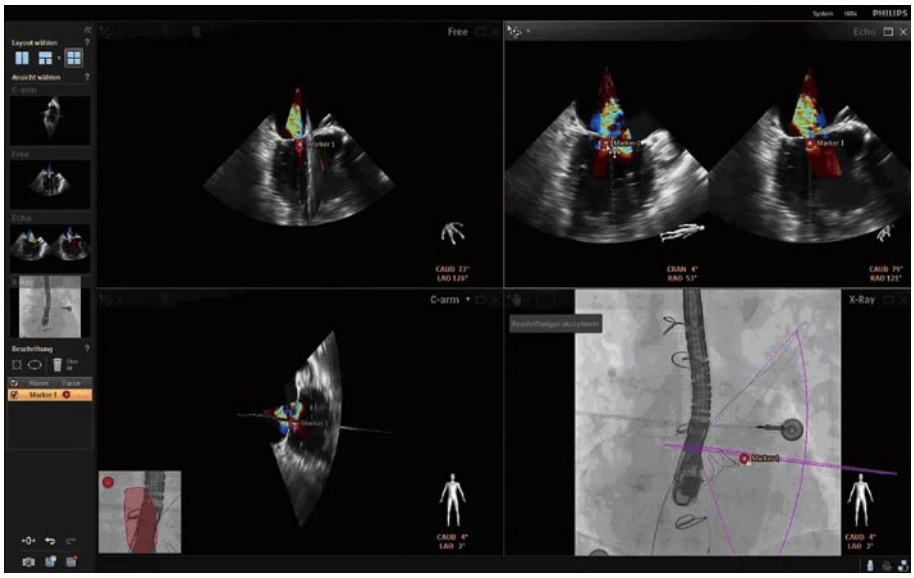

Figure 1 Specific points of interest can be marked in the ultrasound image by the interventionalist that will automatically appear on the fluoroscopic image. In this case of a MitraClip® procedure, the echocardiographer displays the mitral valve with Color Doppler in the X-plane mode in order to define the most regurgitant jet (right upper panel). The interventionalist can then steer particular markers using the table-side control mouse, and place them to define the region of interest for the MitraClip® procedure. After adjusting the marker, it will appear on the fluoroscopic image, representing the exact region of interest, where the MitraClip® should be implanted (right lower panel).

and updated on the fluoroscopic image; and (4) Free: The Free-view also displays 2D and 3D TEE information that can be manipulated by the interventionalist with a sterile covered mouse on the catheter table. The interventionalist can rotate and crop into 3D data sets in any direction.

Specific points of interest can be marked in the ultrasound image by the interventionalist that will automatically appear on the fluoroscopic image (Figure 1). There is also the opportunity to switch between different TEE modalities (2D, 3D, 2D and 3D Color Doppler), and different view settings (2D, X-Plane, 3D Zoom and 3D Full Volume).

RESULTS

Feasibility of the EchoNavigator® during interventions in structural heart disease

All 127 procedures were performed using the EchoNavigator®-system for peri-interventional guidance. The application led to safe accomplishment of all performed procedures without any complications related to the peri-procedural imaging guidance.

Percutaneous edge to edge repair of mitral regurgitation using the MitraClip® system: The unique visualization of the mitral valve apparatus using 3D TEE for planning and performing the procedure allows improved understanding of the morphological and functional changes induced by the MitraClip® system. In this context, a recent study demonstrated that the procedural effects of the MitraClip® system upon the mitral valve apparatus can best be detected using 3D TEE with various offline reconstruction techniques[7]. The peri-interventional evaluation of the mitral valve, including the leaflets, the annulus, and the subvalvular apparatus using 3D TEE is therefore of major importance. On the other hand, the orientation of the guiding system and the dedicated structures of the Clip with its grippers can be much better delineated using fluoroscopy. Therefore, a multimodality approach for guidance of MitraClip® implantations using 2D/3D TEE and fluoroscopy is of essential importance. Our results demonstrate that the translation of specific echocardiographic markers into the X-ray-view can improve the visualization of the complex relationship between catheter devices and anatomical structures during MitraClip® procedures (Figure 2). In this context, the EchoNavigator®-system was especially usefull for the transseptal puncture, that can be performed using fluoroscopy and 2D TEE imaging alone. In special situations, the 3D images improve the visualization of the transseptal puncture side for better definition of the correct height above the mitral valve, necessary for sufficient movement of the delivery guide and the device[8]. The fact, that the designated point of puncture can be marked in either the 2D or the 3D echocardiographic view, is very helpful for placement of the needle in the fluoroscopic image. Severe complications can arise when the Clip perforates the thin wall of the atrial septum, leading to cardiac tamponade[9]. The designation of three echocardiographic orientation points (interatrial septum at puncture site, crista terminalis between pulmonary vein and the LAA, and the center of the mitral valve) into the fuoroscopic image can prevent injury of the left atrium, even when the Clip movements are monitored with X-ray within this virtual triangle. When more than

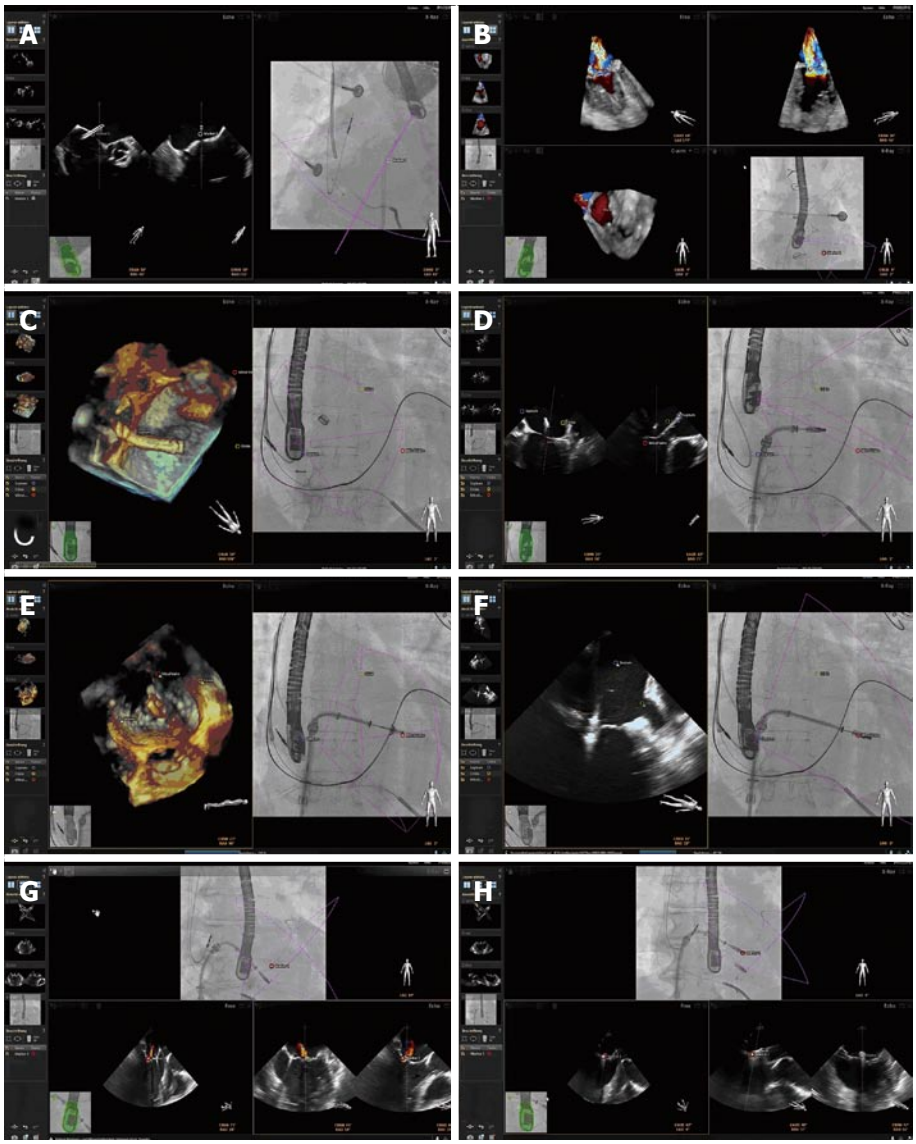

Figure 2 EchoNavigator® during MitraClip® procedures. A demonstrates the Echo-view on the left, depicting an X-plane-view of the interatrial septum. The interventionalist can set markers in this view for exact delineation of the optimal puncture site that will automatically appear in the X-ray-view on the right. A 3D full volume color doppler image is shown in the right upper panel of B. After cropping into this data set, the maximum regurgitant jet was depicted and marked within this image. On the left side of C, a 3D view of the septum with the delivery system and especially the three points of interest (Septum, Crista, and Mitral valve) is demonstrated. The connection between these three points creates a virtual triangle in the X-ray-view on the right side of C, outlining the area at risk outside this triangle in the X-ray-view in D, where contact of the MitraClip® device with its surrounding structures potentially can lead to complications, such as perforation with cardiac tamponade. E demonstrate the process of Clip orientation orthogonally towards the commissure in the 3D view, and the grasping of leaflets in the 2D intercommisural view in F. The X-ray-view in both figures on the right display demonstrates the correct position of the Clip right on top of the red marker, corresponding with the echo images. G demonstrates the residual regurgitant jet on the lateral side of the first Clip. This jet was marked in the echo image and was then used for orientating a second Clip in the X-Ray image, as demonstrated in H. 2D: Two-dimensional; 3D: Three-dimensional.

one Clip needs to be implanted, the exact relation of the Clips to each other can be misjudged due to blooming artefacts of the echocardiographic image[10]. In this situation, fluoroscopy is very helpful to illustrate the spatial relation of both Clips. The EchoNavigator®-system enables the translation of the residual jet from the echocardiographic image into the X-ray image for exact implantation of the second Clip.

LAA occlusion: In non-valvular atrial fibrillation the interventional closure of the LAA has shown to be a successful alternative to oral anticoagulation[11]. The main steps of the procedure are the transseptal crossing of the guiding catheter into the left atrium and the placement of the occluder into the LAA. Basically, the intervention can be performed using fluoroscopy alone, but the advantages of 3D TEE for peri-interventional guidance during the procedure could be clearly demonstrated in recent studies[12]. 2D TEE allows the interventionalist to measure the orifice of the appendage in different 2D cut planes, but 3D TEE additionally allows 3D measurement of the perimeter for exact definition of the landing zone and correct device selection[13]. The EchoNavigator®-system revealed to be very useful for the performance of the transseptal puncture (Figure 3). Furthermore, the exact delineation of the landing zone

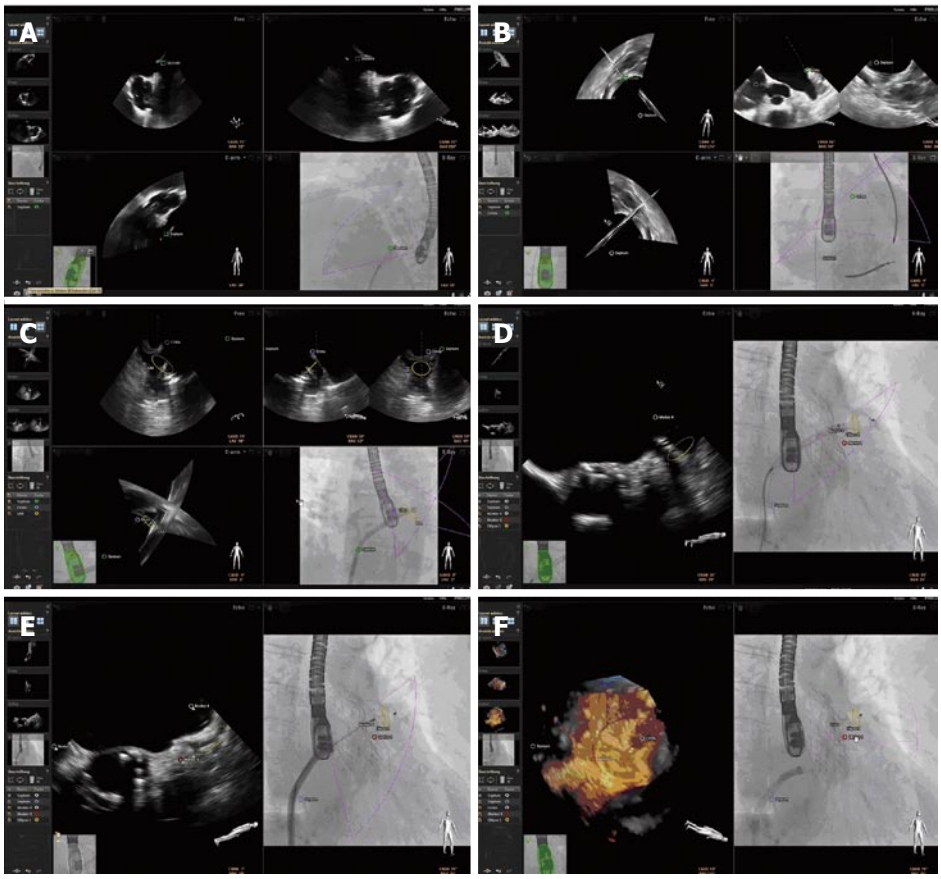

Figure 3 Echonavigator® during left atrial appendage occlusion. A demonstrates how the point of interest for potential transseptal crossing along the interatrial septum is marked in the Echo image. B demonstrates in the X-ray-view, that the wire is located cranial of the Crista terminalis, that initially was assigned in the Echo image. C depicts an ellipsoid ring, representing the landing zone for the occluder device marked yellow in the X-plane view of the 2D Echo image. D displays the deployment of the lobe of the left atrial appendage occluder, detecting that correct device size was chosen. E shows this ellipsoid marker right in between the lobe and the disc of the occluder after deployment of the disc. The red marker represents the location of the circumflex coronary artery. F shows the final result after disconnecting the guiding system from the occcluder. The left panel gives a nice 3D overview of the site of implantation, displaying the difference of the landing zone (yellow circle) and the orifice area of the left atrial appendage.

derived from the echocardiographic images allowed for secure implantation of the device, therewith preventing mismatch and dislocation of the occluder.

ASD occlusion: Interventional techniques for the closure of interatrial communications can be performed using echocardiography as the only imaging modality. In a recent study the feasibility of interventional closure of ASDs without fluoroscopy was demonstrated[14]. TEE provides an imaging technique to guide ASD closures, providing fast and complete information about the underlying pathomorphology, improving spatial orientation, and additionally monitoring online the appropriate position of the device without loss of image quality. Furthermore, the additional information supplied by the 3D images helps to better understand the anatomy and the pathomorphology of the defect during guidance of the intervention, leading to shorter procedure times and less radiation exposure to the patient[15]. Our initial experience with the EchoNavigator®-system in such procedures indicates safe implantation of devices in ASDs. After placement of the echocardiographic marker delineating the ASD into the X-ray-view, the guide wire passage orientated towards this point enormously facilitated the procedure (Figure 4).

TAVR: For safe and precise performance of TAVI procedures, knowledge about the exact anatomy of the aortic root an its surrounding structures obtained by different imaging modalities is indispensable[16]. The use of TEE for peri-interventional guidance is limited, as it often requires general anesthesia and the probe may also partially obstruct the optimal fluoroscopic view. Particularly in patients treated over the transapical approach where general anesthesia is needed anyway, TEE has its place during and after valve implantation. For secure valve implantation, the exact knowledge about the alignment of the hinge points of the three leaflets is crucial[17]. With fluoroscopic imaging alone it is difficult to place the gantry in a position, where the hinge points are in the exact same cut plane. 3D TEE has proven to be very useful for aortic annular sizing and exact delineation of the hinge points during valve sizing and implantation[18]. The EchoNavigator®-system allows transfer of specific 2D and 3D echocardiographic

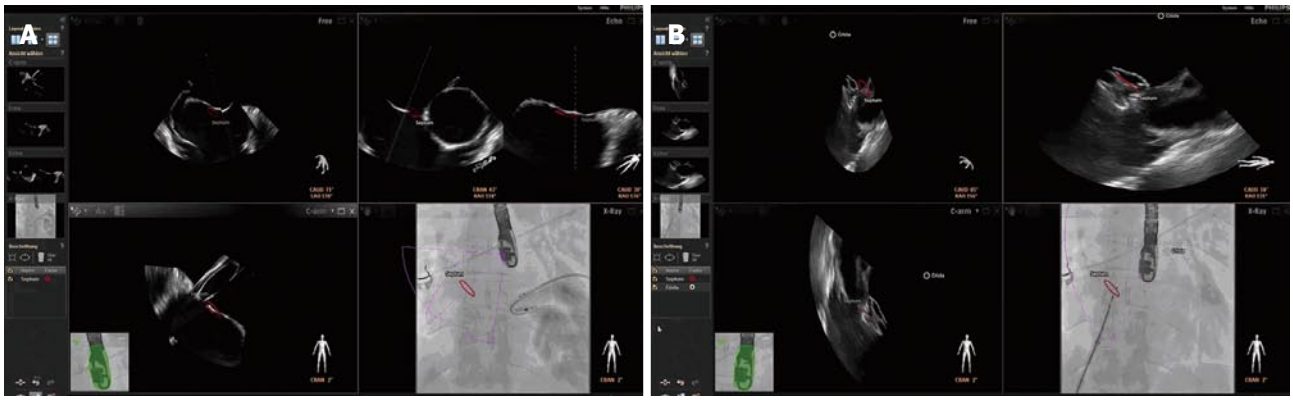

Figure 4 EchoNavigator® during atrial septal defect closure. A: Shows in the Echo-view in the right upper panel an X-plane view of the interatrial septum with a bicaval and a short axis view. The defect is clearly illustrated and marked with a red circle, appearing also in the X-ray-view as the target lesion; B: Demonstrates the occluder device after deployment of both the left and the right atrial disc. Note in the right upper panel that the two discs embrace the red target marker, where the defect was previously located.

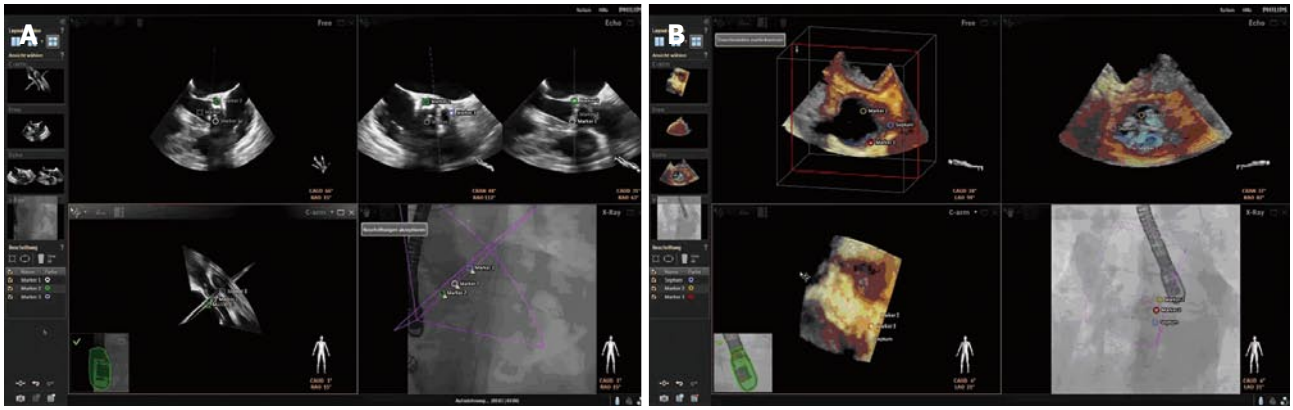

Figure 5 EchoNavigator® during transcatheter aortic valve repair. For precise delineation of the aortic annulus, the hinge points of the three leaflets of the aortic valve were marked in the Echo image, as illustrated in the right upper panel in A. These markers then appeared in the fluoroscopic X-ray-image in the right lower panel. Afterwards, the gantry was moved in order to transfer the three markers in one orthogonal image plane. This was also performed using 3D TEE for a better spatial orientation along the annulus plane of the aortic valve (B).

markers into the fluoroscopic image (Figure 5). This allows the interventionalist to correct the position of the gantry to the point where all three hinge point markers derived from echocardiography create one orthogonal plane.

Percutaneous closure of prosthetic paravalvular leaks: Different multimodality imaging techniques have been proposed for peri-interventional guidance of these procedures, including a combination of fluoroscopy and TEE[19]. The advantage of 3D TEE is the improved spatial resolution of the defect, especially during placement of the guide wire through the defect after transseptal puncture[20]. The interaction between the prosthetic leaflets and the occluder system leading to possible obstruction and malfunction of the prosthetic valve can better be illustrated by 3D TEE. The application of the EchoNavigator®-system is very helpful for percutaneous closure of paravalvular leaks (Figure 6). It allows the interventionalist to focus more upon the fluoroscopic image as it better delineates the catheter and the devices. Especially the precise steering of the guide wire through the defect is facilitated using this innovative technology.

DISCUSSION

The major findings of the present study are: (1) the application of the EchoNavigator®-system is feasible and safe during interventions in structural heart disease; (2) the EchoNavigator®-system allows merged display of echocardiographic (2D, 3D, Color-Doppler, X-Plane Imaging) and fluoroscopic images in real-time, allowing the interventionalist to interact with both imaging modalities simultaneously.

The benefits of fusion imaging technologies have already been described in the recent past, especially for the combination of CT-angiography and fluoroscopy images during transapical TAVR procedures for exact assignment of the correct site for the transapical access[21]. The integration of echocardiographic images into the X-ray image in real-time during percutaneous interventions were hampered so far by the complex nature of the echocardiographic data. The EchoNavigator®-system

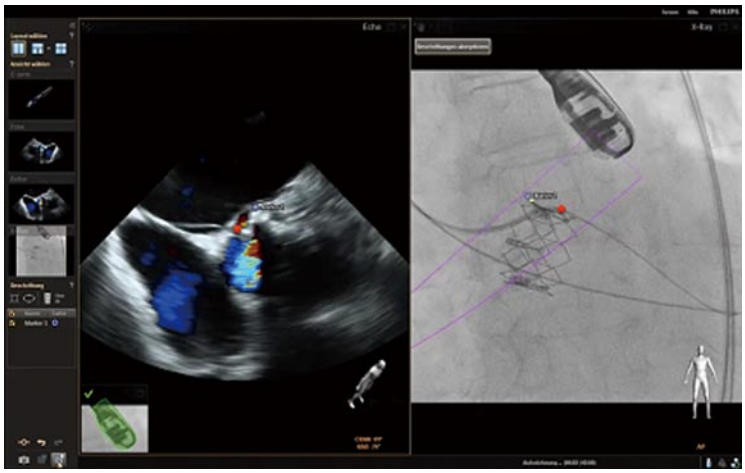

Figure 6 A case of a prosthetic paravalvular leak presenting aortic regurgitation after transcatheter aortic valve repair. The left panel demonstrates the Echo image in a short axis view, presenting the aortic annulus and depicting the regurgitant jet with Color Doppler. Here the marker was placed incorrectly, consequently transfering the marker next to the destination in the fluoroscopic image in the right panel. The red marker demonstrates where the region of interest should have been defined, reflecting the correct position in the fluoroscopic image.

is the first integrative solution to merge the two major important imaging modalities echocardiography and fluoroscopy in real time during interventions in structural heart disease. This technology facilitates the procedures, as echocardiographic soft tissue information is copied into the fluoroscopic image in real-time without time-consuming offline reconstruction. Traditionally, the interventional cardiologist is more familiar with the standard fluoroscopy projections compared with the classical TEE orientations. This new technology therewith fulfills the needs of the traditional interventionalist, who is not always used to the different 2D and 3D image orientation from TEE, by delineating the information from echocardiography into the more familiar fluoroscopic image. Only few studies have described the application of the EchoNavigator® during structural heart disease interventions so far. Sündermann *et al*[4] were the first to document an influence of radiation dose and procedure time under guidance of MitraClip procedures using the EchoNavigator®. They discovered a reduction in radiation and procedure time especially in complex procedures were more than one clip was implanted. This underlines the strength of this technology, simplifying the exact detection of the target point for the implantation of more than one clip next to the already implanted clip. The more complex the intervention becomes during the procedure, the more beneficial is the gain of the additional information given by the supporting software. Recently, González Gómez *et al*[22] described the advantage of the technique for transseptal punctures, according to our own results. Especially in MitraClip procedures the exact height of the puncture is essential for the success of the intervention. Using the EchoNavigator® the puncture site can even be defined before pullback of the needle from the superior caval vein into the right atrium. The precision of this fusion imaging technology is remarkable. Our own experience indicates that the applied markers depicting the target structures correlate very well with the definite location of the catheter devices. Moreover, in cases where the matching of echocardiographic and fluoroscopic data was unsatisfactory, we switched back to the conventional image guidance without the overlay. This approach always warrants an exit strategy in cases where the confidence into the fusion technology is somehow affected, anticipating possible misguidance by the EchoNavigator®-system. Next to the advantages of the EchoNavigator®, there also are some limitations. The technology described in this paper is based on a co-registration process of the TEE probe into the fluoroscopic image, simultaneously transferring the data into the virtual coordinate system of the X-ray display. The specific points of interest that can be marked with the software do not follow the acute movements of the echocardiographic speckles, making the combined image with the marked reference points quite static. The newest release of the EchoNavigator® allows a translation of the entire echocardiographic dataset into the X-ray-image, making the fusion of both modalities even more impressive, as recently published by our group[23].

Limitations

Our manuscript is supposed to give "tips and tricks" while working with the EchoNavigator® technology according to our initial experience in 127 patients. Our study lacks information about the benefit of the technology in the context of reducing the procedure length or the radiation dose. Data demonstrating these effects are currently only available for MitraClip procedures[4]. Prospective randomized multi-center studies with a larger sample size are necessary to demonstrate potential benefits of this promising technology for the patient. At this time, the main benefit of the EchoNavigator®-system is the facilitation of procedures by online fusion of two important imaging modalities, leading to better confidence of the interventionalist into the procedure and producing a better communication between the echocardiographer and the operator.

In conclusion, the EchoNavigator®-system is a feasible and safe tool for guidance of interventional procedures in structural heart disease. This innovative technology may accelerate the learning curve of interventional cardiologists in order to increase safety, accuracy, and efficacy of percutaneous interventions in the catheter laboratory. Further research is necessary

to evaluate the clinical value of this promising new tool, but it is likely that such a visualization technology might have a significant impact on the success and the safety of cardiovascular procedures in the catheter laboratory.

COMMENTS

Background

The number of percutaneous interventional procedures for the treatment of structural heart disease in patients that are ineligible for conventional open heart surgery is increasing permanently. Less invasive techniques allow for save accomplishment of these highly complex interventions in the catheter laboratory. Still, complications can arise during the procedure due to inadequate imaging of the target structures, often with fatal outcome for the patient.

Research frontiers

Side by side imaging of cardiac soft tissue anatomy and catheter devices using echocardiography and fluoroscopy is essential for safe performance of interventional procedures in structural heart disease, though assuming mental fusion and reconstruction of each imaging modality by the interventionalist. Online fusion imaging technologies can determine a faster and better understanding of the complex relationship between anatomical landmarks and catheter devices and have the potential to facilitate the procedure.

Innovations and breakthroughs

In the current study the authors demonstrate for the first time the application of a novel image fusion technology (EchoNavigator®) to guide different types of complex interventions in structural heart disease. To our knowledge, no similar studies presenting such a broad applicability of this hybrid imaging technique have been published so far.

Applications

The study results of the present study suggest that online fusion of echocardiographic soft tissue anatomy and fluoroscopic catheter devices is a breakthrough for precise monitoring of interventions in structural heart disease. The impressive images in this article implicate the value of this innovative technology for upcoming interventional procedures that afford even more an exact delineation of cardiac anatomy for safe performance of complex procedures. Furthermore, the technique does not exclude the standard operating procedure using solely echocardiography and fluoroscopy side-by-side. The generated overlay images rather must be considered accessory with in fact tremendous additional value.

Terminology

The name of the new software "EchoNavigator®" implicates the way it is used for monitoring of interventions in the catheter laboratory. 2D and 3D echo information can be translated into the fluoroscopic image for best navigation of the procedure using a combination of both imaging modalities.

Peer-review

This is an excellent manuscript about the clinical experience using the EchoNavigator®-system. The authors have suggested that the EchoNavigator®-system is a feasible and safe tool for guidance of interventional procedures, such as left atrial appendage, atrial septal defect and paravalvular leak closure, transaortic valve repair and MitraClip® in structural heart disease. This manuscript is nicely structured and very well written.

Abstract

AIM: To investigate the contribution of anti-platelet therapy and derangements of pre-operative classical coagulation and thromboelastometry parameters to major bleeding post-coronary artery bypass grafting (CABG).

METHODS: Two groups of CABG patients were studied: Group A, treated with aspirin alone (n = 50), and Group B treated with aspirin and clopidogrel (n = 50). Both had similar preoperative, clinical, biologic characteristics and operative management. Classic coagulation parameters and rotational thromboelastometry (ROTEM) profiles were determined preoperatively for both groups and the same heparin treatment was administered. ROTEM profiles (INTEM and EXTEM assays) were analyzed, both for traditional parameters, and thrombin generation potential, expressed by area-under-curve (AUC).

RESULTS: There was no significant difference between

rates of major bleeding between patients treated with aspirin alone, compared with those treated with aspirin and clopidogrel (12% *vs* 16%, $P = 0.77$). In the 14 cases of major bleeding, pre-operative classic coagulation and traditional ROTEM parameters were comparable. Conversely we observed that the AUC in the EXTEM test was significantly lower in bleeders (5030 ± 1115 Ohm*min) than non-bleeders (6568 ± 548 Ohm*min) ($P < 0.0001$).

CONCLUSION: We observed that patients with a low AUC value were at a significantly higher risk of bleeding compared to patients with higher AUC, regardless of antiplatelet treatment. This suggests that thrombin generation potential, irrespective of the degree of platelet inhibition, correlates with surgical bleeding.

Key words: Platelet inhibitors; Thromboelastometry; Bleeding; Acute coronary syndrome; Coronary artery bypass grafting

Core tip: To establish the timing of discontinuation of double antiplatelet therapy before coronary artery bypass grafting (CABG), it is crucial to identify predictors of bleeding. We analysed preoperatively classic parameters and thromboelastometry on 100 patients operated for CABG after presenting with acute coronary syndrome, to investigate the contribution of anti-platelet therapy and derangements of pre-operative coagulation status to major bleeding post-CABG. We observed that patients with a low area-under-curve (AUC) value in EXTEM were at a significantly higher risk of bleeding compared to patients with higher AUC, regardless of anti-platelet treatment. This suggests that thrombin generation potential, irrespective of the degree of platelet inhibition, correlates with surgical bleeding.

INTRODUCTION

Post-operative bleeding is a major complication following coronary artery bypass grafting (CABG), with excessive bleeding occurring in 10% of patients, causing increased requirements of blood products, re-intervention and mortality[1-3]. Guidelines recommend ceasing clopidogrel therapy 5 d prior to CABG in order to minimise the risk of post-operative haemorrhage[4,5]. However, patients presenting for urgent and emergent CABG are often treated with double antiplatelet therapy, as recommended in major guidelines for the emergency management of acute coronary syndrome (ACS), prior to performing the diagnostic angiogram[6]. Ceasing clopidogrel and waiting the recommended 5 d prior to performing CABG would put these patients at higher risk of adverse coronary events[7]. Furthermore, as newer more potent platelet inhibitors such as ticagrelor and prasugrel become more widely used, patients presenting for CABG will increasingly be treated with these drugs[8-10]. As a result, it would be important to be able to detect patients at risk of excessive bleeding post-CABG, especially among those treated with double anti-platelet therapy. We devised the following study to determine whether bleeding risk could be predicted from the presence of double antiplatelet therapy, classical coagulation parameters or by rotational thrombo-elastometry performed prior to surgery.

MATERIALS AND METHODS

Patient selection

Among 905 patients operated for CABG between January 2006 and December 2008, we selected those presenting with ACS, and prospectively enrolled 50 consecutive patients without pre-operative clopidogrel exposure (Group A = 50 pts) and 50 consecutive patients with preoperative clopidogrel exposure within two days prior to intervention (Group B = 50 pts), who fulfilled inclusion criteria. The decision to stop double-antiplatelet therapy was at the discretion of the treating cardiologist. All patients signed informed consent for this observational study on prospectively collected data.

All patients who, within 2 d of surgery, were either on a daily oral regimen of 75 mg of clopidogrel or received a 300 mg oral loading dose prior to percutaneous coronary intervention (PCI), made up the clopidogrel study group. They were compared with a control-group of patients who had no clopidogrel exposure. Both patient groups received aspirin (100 mg) and low-molecular-weight-heparin (nadroparin calcium) prior to surgery. Patients with a history of previous cardiac surgery, concomitant valvular surgery or preoperative exposure to either warfarin or platelet glycoprotein IIb/IIIa inhibitors were excluded.

Recognized risk factors for perioperative bleeding in cardiac surgery were assessed including advanced age, female gender, low weight and renal insufficiency (Table 1).

Clotting profiles

Baseline haematocrit, platelet counts, prothrombin time (PT) and activated partial thromboplastin time (aPTT) were assessed because of their influence on blood product transfusions.

Thromboelastometry was performed on fresh blood within 2 h of being drawn from patients prior to induction of anaesthesia, with a ROTEM® (Tem International GmbH, München, Germany) coagulation analyzer, according to the standard protocols supplied by the

manufacturer[11].

Prior to analysis, the samples were stored at room temperature. The sample tubes were gently inverted five times to re-suspend any sedimentation before pipetting the blood. Two standard ROTEM® assays named INTEM® and EXTEM® were performed. INTE® and EXTEM® (ellagic acid and tissue factor activation, respectively) represent assays in which the intrinsic and the extrinsic coagulation pathways are triggered, respectively. The ROTEM® method defines various parameters: Clotting time (CT, s) the time from the beginning of the coagulation analysis until an increase in amplitude of 2 mm, which reflects the initiation phase of the clotting process. Clot formation time (CFT, s) the time between an increase in amplitude of the thrombelastogram from 2 to 20 mm. Alpha-angle (°), the tangent to the clotting curve through the 2 mm point. The CFT and alpha-angle reflect measures of the propagation phase of WB clot formation. Maximum clot firmness (MCF, mm) is the maximum amplitude reached in thromboelastogram and correlates with the platelet count and function as well as the concentration of fibrinogen[12]. Area-under-curve (AUC), defined as the area under 1st derivative (*i.e.,* velocity) curve ending at a time point that corresponds to MCF, reflects thrombin generation potential[13].

Intraoperative management

All surgical procedures were performed through a median sternotomy and with cardiopulmonary-bypass (CPB), in a standard fashion. A comparable intraoperative heparin anticoagulation regimen was utilized in all patients; initial heparin dose was calculated using a minimum standard of 400 units/kg with additional dosing administered during the procedure, in order to maintain a target activated-clotting-time (ACT) value greater than 480 s.

Management of bleeding

Post-operative bleeding was carefully managed according to our institution's diagnostic - therapeutic algorithm[14]. PT, aPTT, platelet count, antithrombin III and ROTEM paramaters (INTEM, EXTEM and HEPTEM) are assessed and any abnormalities are corrected with relevant blood products (platelets, fresh frozen plasma, cryoprecipitate), protamine sulphate, fibrinogen or recombinant factor VIIa according to the underlying cause of bleeding.

Ongoing bleeding at a rate of 500 mL/h in the first hour, 400 mL/h in the first 2 h, 300 mL/h in the first 3 h, 200 mL/h in the first 4 h, despite optimisation of coagulation paramaters or the presence of cardiac tamponade are considered indications for re-intervention for bleeding. The amount of post-operative blood loss and the rate and amount of transfused blood products used both intra- and post-operatively were recorded.

Clinical outcomes

Major bleeding was considered to have occurred when $\geqslant$ 3 units of blood, fresh frozen plasma, platelets or surgical revision were required. Chest tube outputs assessed at 12 h were the primary measure of postoperative bleeding. Transfusion quantity was recorded for the three main blood product types (red blood cells, platelets and fresh frozen plasma) during operation and ICU stay. Clinical outcomes specific to CABG recovery included reoperation for bleeding, mortality, acute myocardial infarction, stroke and postoperative atrial fibrillation until discharge. General post-surgical outcomes evaluated were duration of intubation and postoperative length of ICU stay.

Statistical analysis

The prevalence of bleeding-related haematologic, laboratory and clinical risk factors in the two groups was compared by means of contingency tables of categorical variables and the two-sided Fisher exact test. Two sample *t* tests with equal or unequal variances were used to compare continuous variables with reasonably normal distribution of the original or transformed units, otherwise Kruskal-Wallis equality-of-populations rank test was used. Distributional differences were further analyzed with Graphic Box plot comparisons between groups. Multivariable stepwise forward and backward logistic regression of the bleeding event *vs* risk factors was made, with 0.05 significance limits to enter or retain. Confounding factors (age, weight and sex), bleeding related clinical risk factors (hypertension, renal failure, cerebrovascular events and treatment) and the variables enumerated above in the clotting profile paragraph were included. The event probability predicted from the logistic result was compared to the observed empiric probability, calculated on patients' deciles. A correlation analysis of laboratory ROTEM tests

was further performed to identify parameters closely related to the logistic result. All data were manipulated and analyzed using STATA (StataCorp LP, Texas, United States). The statistical review of the study was performed by a biomedical statistician.

RESULTS

Patient characteristics

The baseline characteristics of those with and without preoperative clopidogrel exposure were comparable in age, gender, weight and renal failure (Table 1). There was a significantly higher incidence of ventricular dysfunction (P = 0.02) in the clopidogrel group. The baseline classic coagulation parameters (hematocrit, platelet count, PT, aPTT) and ROTEM parameters (CT, CFT, MCF, alpha angle and AUC of INTEM and EXTEM) were also comparable between the groups (Table 2).

Surgical and clinical outcomes by anti-platelet therapy exposure

No statistically significant differences between the two groups in term of postoperative bleeding, blood product transfusions (Table 3) and clinical outcomes (Table 4) were observed.

Patients on double treatment showed a greater frequency of major bleeding (8 *vs* 6 episodes), greater mean chest tube output at 12 h (539 ± 239 mL *vs* 509 ± 234 mL), and mean number of blood products transfusions, although these differences were not statistically significant. One patient in the single treatment group required surgical re-intervention due to bleeding.

The length of stay in the ICU (days) and of mechanical ventilation (hours) were comparable between the groups. There was 1 death in group A and 0 in group B, 1 myocardial-infarction in group A and 0 in group B, 1 stroke in group A and 0 in group B. Therefore there was a greater number of major adverse events in the group treated with aspirin alone (3 events, 6%; OR = 0.75; P = 0.24) compared with the double treatment group (0 events, 0%).

Aspirin only	-1.18	0.31	0.02-4.58	0.39

Odds ratios are adjusted for concomitant variables. EF: Ejection fraction; AUC: Area-under-curve.

Preoperative predictors of bleeding risk

From the comparison of the risk-factors for perioperative bleeding (advanced age, female gender, low weight and renal insufficiency), and preoperative haemocoagulatory status between all patients who bled (n = 14) and those who did not, no significant difference was noted.

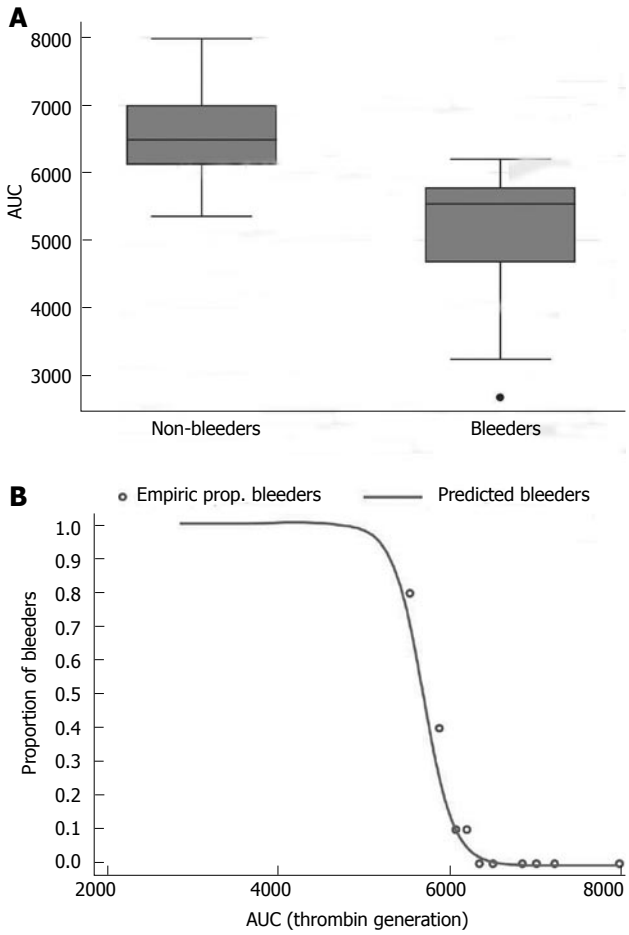

Figure 1 Predictors of bleeding risk. A: AUC-EXTEM in non-bleeders and in bleeders (patients with major bleeding) (P = 0.0001); B: Bleeding risk prediction and AUC-EXTEM: Each circle represents one decile of the patient population, showing the proportion of patients who bled compared with their mean AUC. The curve is a line of best fit, clearly showing a threshold at an AUC of 6000, below which the bleeding risk increases markedly. AUC: Area-under-curve.

After performing a logistic multivariate analysis (details in Table 5), the backward stepwise variable selection showed a significant independent relationship of bleeding risk only with AUC activity (coefficient –0.0099; OR = 0.99; 95%CI: 0.98-0.99; P < 0.001). In fact, patients who bled had lower AUC-value (Thrombin-generation-potential) in the EXTEM test (5030 ± 1115 Ohm*min) than those who did not bleed (6568 ± 548 Ohm*min) (P < 0.0001) (Figure 1A). We observed a good correlation (r = 0.96) between AUC and MCF, a clot quality indicator, that similarly was increased in patients who did not bleed (65.7 ± 5.6 mm) than those who did (51.9 ± 12.5 mm) (P < 0.0001), although these values were still within the normal range (50-72 mm). At this point we identified a threshold value for AUC and MCF which predicted bleeding in our patients, that is 6000 for AUC and 60 for MCF (Figure 1B). In fact, all patients with an AUC and MCF below these cut off values were at increased risk of major bleeding, and the lower these values the greater the risk. Furthermore patients with higher AUC and MCF values were at a lower risk of significant haemorrhagic events.

DISCUSSION

Post-CABG bleeding is a major issue in cardiac surgery and remains difficult to predict. Concerns about bleeding risk have resulted in the recommendation to cease double antiplatelet therapy prior to elective CABG[5]. There are still many patients who present for urgent CABG with double antiplatelet therapy, and increasingly patients will have been exposed to more potent antiplatelet agents such as prasugrel and ticagrelor[8-10]. Hence, we set out to determine if it was possible to predict post-operative bleeding with pre-operative clotting characteristics via analysis of classical coagulation assays (aPTT, PT) as well as a suite of ROTEM analyses. We also compared haemorrhagic and thrombotic complications between single and double treated patients.

Main findings

Our data showed a higher frequency of major bleeding in the double antiplatelet therapy group (16% *vs* 12%), but this was not statistically significant (P = 0.77). However, assuming that it represents a true difference, to attain a P value of 0.05 with a test power of 70% the sample size required is 978 patients on each arm. On the contrary the major adverse events (MACE: Death, stroke and myocardial infarct) were limited to group A (6%) (Table 4), but this difference was not statistically significant (P = 0.24).

Comparison of classic and ROTEM parameters between the 14 "bleeder" patients and the "non-bleeders", showed that differences were limited to AUC and MCF, in the EXTEM test. Patients with lower AUC and MCF values were at a higher risk of suffering major bleeding, regardless of whether they were treated with clopidogrel or not. MCF reveals the quality of the clot and is linked to thrombin generation and the change in AUC observed here is a reflection of the increase in MCF.

Clot generation is a composite process involving both primary and secondary haemostasis, as well as intrinsic and extrinsic pathways. Yet bleeding risk after CABG, the tendency has been to focus on the platelet, probably because of its major role in athero-thrombosis[15,16]. And the extensive experience with the use of antiplatelet agents in minimising further ischemic events. Nevertheless, despite receiving the same standard ACS medical treatment some patients bleed while others do not, and although this may be attributed to the recognized response variability (so called "resistance") observed with clopidogrel or aspirin[15], our results indicate that differences in patients' thrombin generation potential may be an important determinant of bleeding.

We believe that a broader perspective may be necessary: Platelets and platelet-inhibition play very important roles but their complicate interplay with other pieces of the haemostatic process should be taken into account. ROTEM is appropriate for providing such analyses, and unique in allowing evaluation of

every element of thrombosis and clot lysis[17], especially fibrinogen and factor XIII.

Indeed, we found that clot quality is a predictor of post-operative bleeding. We believe that association of MCF and AUC with haemorrhagic risk derives from the role of thrombin, which is fundamental as it affects every step of clot formation: It has a role in activation of fibrinogen to fibrin as the final common pathway from both intrinsic and extrinsic pathways, it activates factor XIII which promotes clot stability by cross linking fibrin polymers within the clot[18] and contributes to platelet activation, acting on at least three diverse platelet receptors[19]. We propose that in post surgical patients a high clot quality prior to surgery, as indicated by higher MCF and AUC values in the EXTEM test, can effectively clot despite the inhibition of platelet activation by aspirin and clopidogrel.

The mechanism by which patients with greater thrombin generation potential are able to form effective clots in the face of double antiplatelet therapy are probably twofold: (1) platelet activation is multifactorial, in addition to adenosine diphosphate (ADP) and thromboxane A2, thrombin also plays a critical role and is the most potent of the platelet activators[15], and patients who are better able to generate thrombin may thus sufficiently activate their platelets despite inhibition of the first two pathways by clopidogrel and aspirin respectively; and (2) patients with a higher MCF and hence higher thrombin generation may be able to affect greater thrombin deposition and stabilisation by factor XIII and hence form a stable clot despite decreased platelet activation and aggregation. In such circumstance the metaphor would be to a brick wall: Despite the presence of fewer effective bricks (platelets) in the presence of clopidogrel therapy, patients with a higher MCF can counterbalance by applying more higher-quality mortar (thrombin), thus producing a stable wall (clot).

Clinical implications

Besides characterizing MCF and AUC as factors influencing post-surgical bleeding, we identified a threshold at which the risk becomes significant: an AUC < 6000, corresponding to an MCF of < 60. This is important in two ways: (1) these values are within the normal range and yet the patients are at high risk of post-operative bleeding; and (2) identification of patients at risk may allow improved management in these patients.

While rotational thromboelastometry has been previously studied in relation to post CPB haemorrhage it has demonstrated mixed results. Published studies generally show that ROTEM parameters obtained intra-operatively or-post operative can predict post-operative excessive blood loss, but not those obtained prior to commencing bypass[20-23]. Our results differ from these as we have seen that ROTEM analysis performed prior to the institution of CPB can predict post-operative bleeding. This difference is difficult to explain, but may be related to the use of different ROTEM parameters, the high proportion of patients treated with clopidogrel in our cohort and differing definitions of major post-operative bleeding amongst these studies.

The capacity to recognize patients at high risk of post-operative bleeding may influence the decision to perform CABG in the first instance and further permit adjustment of surgical procedure and post-operative management to reduce the risk of haemorrhage in patients who are treated with CABG. As an example, patients at a high risk of bleeding may be treated with off pump CABG, avoiding CPB and hence lowering the risk of haemorrhagic events[24]. This is extremely important as CPB results in coagulopathy due to activation and consumption of platelets and coagulation factors, such as thrombin, which results in an increased risk of post-operative bleeding[25]. Other management options would include a more targeted use of blood product derived coagulation factor infusions, as well as the potential development of new pharmacological interventions involving replacement of individual clotting factors, such as recombinant activated factor VII, and factor XIII, prothrombin complexes and fibrinogen.

On the other hand, patients with higher thrombin generation potential may represent a subgroup more prone to develop ischemic rather than hemorrhagic complications (myocardial infarction, recurrent angina, stroke), thus deserving double antiplatelet therapy[26].

Study limitations

While these results are promising for the determination of risk of post-operative bleeding in CABG patients, the study does have several limitations. While AUC and MCF were seen to correlate well with bleeding risk in EXTEM analysis, INTEM analysis did not demonstrate such a relationship. This may result from the use of LWMH in all patients, a factor which affects the intrinsic pathway and hence INTEM analyses. Furthermore, ROTEM, while giving a good overall impression of a patient's haemostatic function, is not the ideal tool for the assessment of platelets, rather a platelet function analyzer would be the gold standard for such analyses[13], which would have allowed better determination of the contribution of antiplatelet response variability to bleeding risk in our cohort[27]. Additionally the sample size in this study was small and the patients were not randomised to the two treatment arms, thus limiting our ability to comment on the differential effect of single and double antiplatelet on postoperative haemorrhage risk. Further studies in groups not treated with LMWH, the use of platelet function analyser and greater sample size and randomization would allow greater understanding of the factors relating to bleeding risk identified in our study. Finally, we cannot generalize our results to newer antiplatelet agents such as prasugrel and ticagrelor.

In conclusion, we have seen that patients with a low AUC value (thrombin-generation-potential) are at a significantly higher risk of bleeding as compared to patients with higher AUC, regardless of whether they were treated with clopidogrel. Hence this study provides

a promising insight into the potential role of ROTEM analyses in the prediction of post-CABG bleeding risk; future research on this topic may contribute to a more effective intra- and post- operative management.

COMMENTS

Background

Post-operative bleeding is a major complication following coronary artery bypass grafting (CABG). Guidelines recommend ceasing clopidogrel therapy 5 d prior to CABG in order to minimise the risk of post-operative haemorrhage. However, patients presenting for urgent and emergent CABG are often treated with double antiplatelet therapy, as recommended in major guidelines for the emergency management of acute coronary syndrome, prior to performing the diagnostic angiogram. Ceasing clopidogrel and waiting the recommended 5 d prior to performing CABG would put these patients at higher risk of adverse coronary events.

Research frontiers

As yet there is no effective way to predict which patients will have significant bleeding after CABG. In fact, it would be important to be able to detect patients at risk of excessive bleeding, especially among those treated with double anti-platelet therapy.

Innovations and breakthroughs

While rotational thromboelastometry has been previously studied in relation to post cardiopulmonary-bypass haemorrhage it has demonstrated mixed results. Published studies generally show that rotational thromboelastometry (ROTEM) parameters obtained intra-operatively or-post operative can predict post-operative excessive blood loss, but not those obtained prior to commencing bypass. The authors devised the following study to determine whether bleeding risk could be predicted from the presence of double antiplatelet therapy, classical coagulation parameters or by rotational thrombo-elastometry performed prior to surgery. The authors found that there was no significant difference between rates of major bleeding between patients treated with aspirin alone, compared with those treated with aspirin and clopidogrel. In the cases of major bleeding, pre-operative classic coagulation and traditional ROTEM parameters were comparable. Conversely the authors observed that the area-under-curve in the EXTEM test was significantly lower in bleeders than non-bleeders, regardless of antiplatelet treatment. This suggests that thrombin generation potential, irrespective of the degree of platelet inhibition, correlates with surgical bleeding. Moreover, the authors were able to define a threshold at which bleeding risk becomes significant.

Applications

The ability to identify patients at high risk of post-operative bleeding is important as it may influence the decision to perform CABG in the first instance and further allow tailoring of surgical technique and post-operative management to reduce the risk of haemorrhage, and achieve a more targeted use of blood products. On the other hand, patients with higher thrombin generation potential may represent a subgroup more prone to develop ischemic rather than hemorrhagic complications, thus deserving double antiplatelet therapy.

Terminology

ROTEM consists in a viscoelastic method for hemostasis testing in whole blood, which can be used to detect clotting disorders and drug effects. Moreover, through appropriate assays, it can provide differential diagnostic information to support decisions in therapy.

Peer-review

This is an interesting manuscript about the predictive factors of bleeding after CABG in patients with previous acute coronary syndrome.

Abstract

Constrictive pericarditis (CP) is an inflammatory disease of pericardium. Pericardial calcification in X-ray provides a clue for the diagnosis of CP. An extensive "eggshell" type of calcification is rarely seen in CP. We hereby report a case of CP with eggshell calcification of pericardium, encircling whole of the heart. A need for multimodality imaging and hemodynamic assessment followed by surgical pericardiectomy is discussed.

Key words: Contrictive pericarditis; Calcification; Pericardiectomy; Right heart failure

Core tip: Idiopathic contrictive pericarditis (CP) with extensive pericardial calcification is rarely seen. We hereby report a case of CP with extensive "eggshell" calcification of heart, who presented with right heart failure. A need for multimodality imaging and hemodynamic assessment is discussed in the article.

INTRODUCTION

Constrictive pericarditis (CP) is an inflammatory disease of pericardium. Its etiology includes infection,

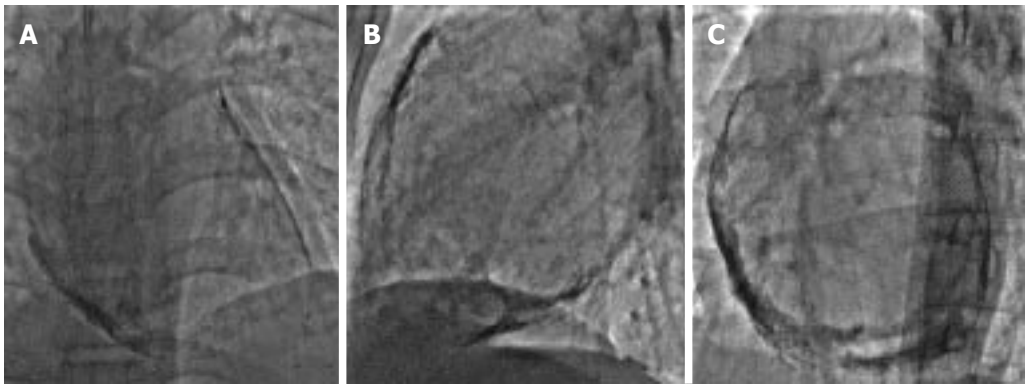

Figure 1 Fluoroscopy images in antero-posterior (A), lateral (B) and left anterior oblique 30º (C) views show circumferential pericardial calcification around the heart.

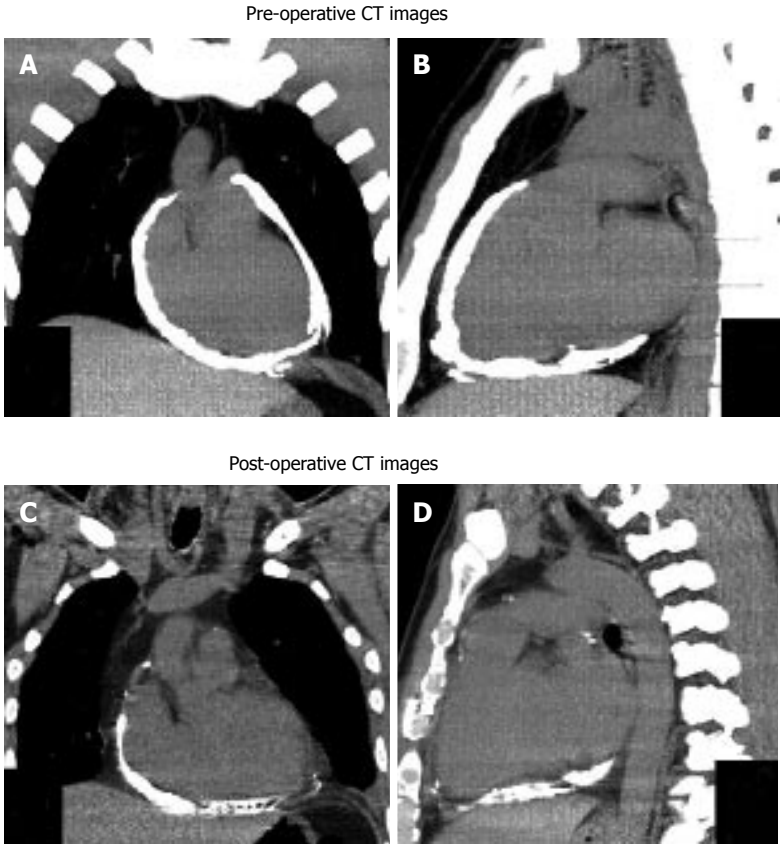

Figure 2 Computed tomography. Non-contrast computed tomography reconstructed images in coronal (A) and sagittal (B) planes show thick, calcified pericardium around the heart. A repeat CT following partial pericardiectomy in coronal (C) and sagittal (D) planes show residual calcified pericardium at right atrial and posterior surface of the heart. Calcified pericardium is absent along the antero-lateral surface of the heart. CT: Computed tomography.

connective tissue disorders, chest trauma, irradiation, post-cardiac surgery and idiopathic-type[1]. Extensive pericardial calcification is rarely seen in CP. We hereby report a case of CP presented with extensive "eggshell" like calcification of whole of pericardium.

CASE REPORT

A 43-year-old male presented with shortness of breath, NYHA class-Ⅲ of 6-mo duration. There was no history of fever, productive cough, joint pain, orthopnea and pedal edema. Clinical examination revealed a jugular venous pulse of 18 cm, prominent X and Y descents. Cardiac auscultation revealed a pericardial knock. Two-dimensional echocardiogram showed 10-mm thick, calcified pericardium; about 25%-variation in mitral diastolic flow velocities with respiration and a dilated inferior vena cava of 24-mm dimension. Fluoroscopy revealed dense circumferential calcification all around the heart (Figure 1). A computed tomography (CT) scan confirmed the circumferential thick pericardial calcification like an eggshell, encircling the heart (Figures 2 and 3). Angiography revealed normal epicardial coronaries without any external compression.

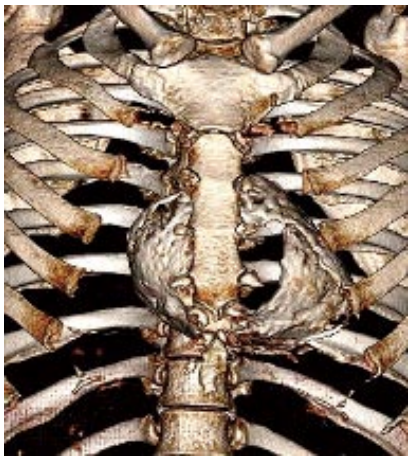

Figure 3 Pre-operative non-contrast computed tomography reconstructed volume rendered image shows pericardial "eggshell" calcification around the heart.

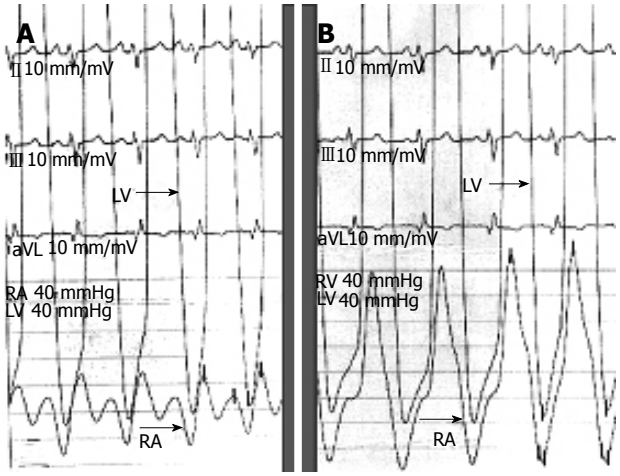

Figure 4 Hemodynamic tracing during catheterization. A: Right atrial (RA) pressure tracing shows prominent X and Y descent; B: Ventricular pressure tracing shows typical "dip-and-plateau configuration" during diastole. RV: Right ventricle; LV: Left ventricle.

Hemodynamic data revealed elevated mean right atrial (RA) pressure of 20 mmHg. Right ventricle (RV) and left ventricle (LV) end-diastolic pressure was 23 and 28 mmHg, respectively. Pulmonary artery systolic and mean pulmonary capillary wedge pressures were 44 and 24 mmHg, respectively. There was near equalization of elevated RA, RV and LV end-diastolic pressures. Right atrial pressure tracing showed prominent X and Y descent (Figure 4A), and ventricular pressure tracing showed typical "dip-and-plateau configuration" (Figure 4B) suggestive of CP. He had surgical pericardiectomy for densely calcified CP. Following median thoracotomy, thickened, calcified, firmly adherent pericardium was resected and excised from anterior and left lateral aspect of the heart (Figure 5). The densely adherent pericardium from surface of right atrium and posterior wall was not resected. Histopathology of pericardium revealed dystrophic calcification without any evidence of granulomatous or giant cell inflammation. Mycobacterial

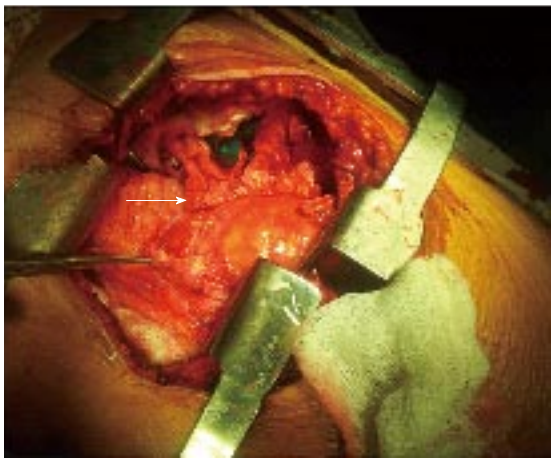

Figure 5 Surgical image shows resected thick and calcified pericardium (white arrow) from anterior surface of heart.

and fungal cultures of the excised pericardium were negative. He had uneventful recovery and was discharged on 7th post-operative day. A post–operative CT scan showed absence of calcified pericardium along antero-lateral surface of the heart (Figures 2C and D). He remained asymptomatic during 1-year follow-up.

DISCUSSION

Constrictive pericarditis is a sequale of chronic inflammation of pericardium. Among the various etiologies, idiopathic type is a common cause for CP[1,2], which was present in index case. The clinical presentation is mostly of right heart failure. Any patient presented with dyspnea, raised jugular venous pulse, hepatic and systemic venous congestion should be evaluated for CP. Pericardial calcification in chest X-ray can suggest CP, however it is present in only 5%-27% of cases[3]. Extensive "eggshell" like calcification is rarely seen in CP[4], as was present in index case. Echocardiography is an initial imaging test for diagnosis of CP[5]. In patients with equivocal echocardiography findings, CT or Cardiac Magnetic Resonance can confirm the diagnosis[5]. The extent of severe calcification and involvement of adjacent structures is clearly defined by CT, as demonstrated in index case. Cardiac catheterization is required for hemodynamic assessment and to rule out coronary compression by calcified thickened pericardium[6]. A multi-modality imaging and hemodynamic assessment is essential for proper evaluation of CP[5]. Surgical pericardiectomy is the definite treatment for CP. Those with calcified and firmly adherent pericardium, median thoracotomy is preferred over antero-lateral thoracotomy[7]. Calcified CP also has higher surgical risk, incomplete pericardial resection and poor hemodynamic outcomes following surgery[7]. However, index case had a successful outcome following partial antero-lateral pericardiectomy *via* median sternotomy approach. In conclusion, we present a case of idiopathic CP with extensive eggshell calcification of

the heart, who had successful surgical pericardiectomy, and had a favourable long term outcome.

COMMENTS

Case characteristics

A 43-years-old male presented with shortness of breath, New York Heart Association class-III of 6-mo duration.

Clinical diagnosis

Clinical examination revealed a raised jugular venous pulse with prominent X and Y descents.

Differential diagnosis

Cardiac auscultation revealed a pericardial knock. Two-dimensional echocardiogram showed 10-mm thick, calcified pericardium with significant trans-mitral diastolic flow velocities variation.

Imaging diagnosis

Fluoroscopy revealed dense circumferential calcification all around the heart. A computed tomography scan confirmed the circumferential thick pericardial calcification like an eggshell, encircling the heart. Cardiac catheterization revealed near equalization of elevated right atrial, right ventricle, and left ventricle end-diastolic pressures and ventricular pressure tracing showed typical "dip-and-plateau" pattern suggestive of constrictive pericarditis.

Pathological diagnosis

He had surgical pericardiectomy for densely calcified CP. Histopathology of pericardium revealed dystrophic calcification without any evidence of granulomatous or giant cell inflammation. An importance of multi-modality imaging with hemodynamic assessment is discussed in management of constrictive pericarditis.

Peer-review

This is an interesting article on calcified constrictive pericarditis. The paper is nicely documented.

Abstract

Inflammation plays an essential role in the development of atherosclerosis. The initiation and growth of atherosclerotic plaques is accompanied by recruitment of inflammatory and precursor cells from the bloodstream and their differentiation towards pro-inflammatory phenotypes. This process is orchestrated by the production of a number of pro-inflammatory cytokines and chemokines. Human arterial intima consists of structurally distinct leaflets, with a proteoglycan-rich layer lying immediately below the endothelial lining. Recent studies reveal the important role of stellate pericyte-like cells (intimal pericytes) populating the proteoglycan-rich layer in the development of atherosclerosis. During the pathologic process, intimal pericytes may participate in the recruitment of inflammatory cells by producing signalling molecules and play a role in the antigen presentation. Intimal pericytes are also involved in lipid accumulation and the formation of foam cells. This review focuses on the role of pericyte-like cells in the development of atherosclerotic lesions.

Key words: Atherosclerosis; Arteries; Intima; Immune-inflammatory processes; Pericyte-like cells

Core tip: Intimal stellate cells, expressing smooth muscle α-actin that co-express antigen 3G5 antigen (known to be specific for pericytes), reside in the intima of human large arteries. There cells have been defined as "pericytes-like satellite cells" or "intimal pericytes". Because of the peculiarities of the distribution of these cells and because of the current lack of our knowledge about the spectrum of the expression of other pericyte-associated markers in the arterial wall, it is reasonable to avoiding at this time to identify smooth muscle α-actin(+)/3G5 antigen(+) stellate-shaped cells as true pericytes. The review highlights the importance of intimal pericytes in atherosclerosis.

INTRODUCTION

Cardiovascular disorders (CVDs) are currently the main cause of mortality in developed countries, and atherosclerosis is the major contributor to the CVD risk[1]. The disease affects large arteries causing lipid deposition in the arterial wall, local inflammatory process and the formation of plaques. Atherosclerotic plaques progression leads to luminal narrowing of blood vessels, which by itself can result in the ischemia of corresponding organs. However, most dangerous is the acute thrombus formation on the surface of a ruptured atherosclerotic plaque. Thrombosis can lead to rapid and life-threatening events, such as acute coronary syndrome and stroke[2]. Early stages of atherosclerosis development are mostly clinically silent, and the first manifestations of the disease are often fatal. At the same time, subclinical atherosclerosis is a prevalent condition in the modern society, especially among the ageing population. It has been reported recently that up to 5% of women and 12% of men over the age of 80 suffer from asymptomatic atherosclerotic carotid artery stenosis[3]. Other studies demonstrated the high rate of asymptomatic atherosclerosis incidence in young and middle-aged people, with up to 100% of apparently healthy individuals having atherosclerotic lesions at various stages of progression[4,5]. Along with the well-known benefits of life style correction, the development of more specific therapies could help decreasing the risk of atherosclerosis progression and consequent CVD development. It is therefore important to improve our understanding of the pathological mechanisms that trigger atherosclerotic lesion development in the arterial wall.

The intimal barrier of human arterial wall consists of the endothelium and the subendothelial net-like tissue layer formed by pericyte-like cells that have recently been characterized as true pericytes[6,7]. Whereas the endothelium serves as the first line of defence against the development of atherosclerotic lesion, the pericyte-containing subendothelial layer can be regarded as the second defence line essential for normal functioning and protection of the arterial wall. Apart from pericytes, this layer contains other cell types, including smooth muscle cells, macrophages, lymphocytes, mast cells, dendritic cells, and other cell types. Pericyte-containing subendothelial layer is a characteristic component of both arterial and venous intima[6]. Its role in the development of human pathology remained unknown until recently. However, the accumulating evidence demonstrated its importance in many severe vascular disorders, such as saphenous vein graft disease, thrombosis and atherosclerosis. Macrovascular pericytes are capable of rapid proliferation and participate in immune reactions. Moreover, these cells have been identified as a source of coagulation-inducing tissue factor[7]. In this review we will summarize the current knowledge on the structure and function of the sub-endothelial leaflet of human macrovascular intima and its role in the pathogenesis of atherosclerosis.

STRUCTURE OF NORMAL AND ATHEROSCLEROTIC ARTERIAL INTIMA

Aortic intima is the part of the blood vessel wall located between the internal elastic lamina and the lumen with endothelial lining, and consists of two distinct layers (Figure 1)[8,9]. Muscular-elastic layer represents the external part of the intima, and is separated from the internal intimal layer by the limiting membrane. This layer is formed by longitudinally oriented elongated cells and elastic fibres. The internal intimal layer, also known as proteoglycan-rich or connective tissue layer[10,11], contains randomly-oriented connective tissue fibres and morphologically heterogeneous cell population[12]. The intimal layers differ from each other by the composition of glycosaminoglycans and fibres. Muscular-elastic layer is rich in elastin fibres, and proteoglycan-rich layer - in collagen and reticulin[13]. Moreover, collagen composition and structure are different between the two layers: longitudinally oriented collagens Ⅰ and Ⅲ are common in the muscular-elastic layer, while collagens Ⅳ and Ⅴ are detected primarily in the proteoglycan layer, where they form the endothelial basal membrane.

The development of atherosclerotic lesion has been carefully studied by our group on human aorta samples from healthy subjects and atherosclerotic patients[8-13]. Atherosclerotic process is tightly associated with thickening of the arterial intima. Careful analysis of the intima thickness along the arteries affected by atherosclerosis in comparison to normal tissues revealed that muscular-elastic layer remained unaltered in the fatty streak area and became only slightly thicker in the atherosclerotic plaque area[8-13]. By contrast, the proteoglycan layer was 2-fold thicker in the fatty streak and 4-fold - in

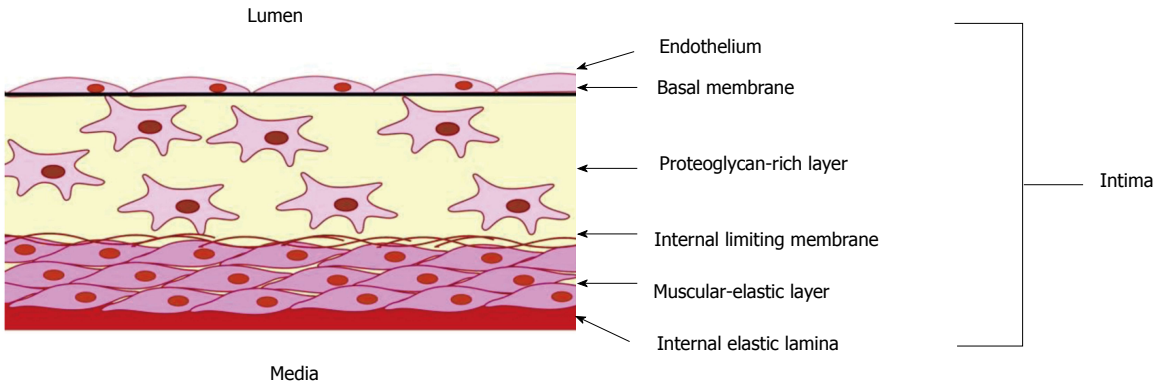

Figure 1 Schema showing the organization of the intima of the arterial wall. The proteoglycan-rich layer which contains a heterogeneous population of cells, including macrovascular pericytes, is located just below the endothelial monolayer. Intimal pericytes form a network of cells interconnected through gap junctions. The muscular-elastic layer, formed by elongated contractile smooth muscular cells, lies below the proteoglycan-rich layer.

the atherosclerotic lesion areas, and was the major contributor of the arterial stenosis. This thickened proteoglycan layer had increased collagen content. Moreover, longitudinal orientation of collagen fibres was altered, and lipid droplets were present between the interstitial collagen fibres[8-13]. Atherosclerotic plaques were characterized by the accumulation of all collagen types, especially in the fibrous cap area. Collagens Ⅳ and Ⅴ formed a thick layer in the endothelial basal membrane area and surrounded the subendothelial cells. At the same time, no prominent alterations of collagen structure and composition were present in the muscular-elastic layer of the intima[8-13].

Changes of lipid content accompany the development of atherosclerotic plaques in the aortic intima. In the normal tissue, extracellular lipid droplets visualised by Oil Red O staining were located along the elastic membrane. In the fatty streaks, both extra- and intracellular droplets were present, mostly in the proximity of the lumen. In atherosclerotic plaques, lipid deposition could be observed in the proteoglycan layer, and total lipid content was 8-fold higher than in the unaffected tissue[6]. Lipid content of muscular-elastic layer was increased to a lesser extent, being 4.4-fold higher than control. Cellular composition of the proteoglycan-rich layer of atherosclerotic intima was also altered in comparison with the healthy tissue[6]. Total cell count assessed by alcohol-alkaline dissociation of the fixed tissue, was 1.5 and 2-fold higher in the fatty streak and atherosclerotic plaque respectively[6].

Taken together, these observations clearly indicate that the subendothelial proteoglycan-rich layer of the arterial intima undergoes the most prominent alterations in course of the atherosclerotic plaque development, including thickening, lipid deposition and the accumulation of collagen fibres with disturbed orientation[6,8-13].

CELLULAR COMPOSITION OF MACROVASCULAR INTIMA

Human macrovascular intima is made of a heterogeneous cell population. Immediately below the endothelial lining and in close contact with it, there is a three-dimensional net formed by pericyte-like cells. Early studies have identified pericytes as mostly microvascular cells that play an important role in angiogenesis and vessel branching and are essential for maintaining the normal structure of the capillary wall and the endothelial barrier function, including the maintenance the blood-brain barrier[14,15]. Pericytes were also demonstrated to contribute to embryonic development of the aorta[16]. It has become evident, however, that pericyte-like cells are also present in the walls of large blood vessels[17]. Apart from vasa vasorum microvessels[18], pericyte-like stellate cells were found in the intima of large arteries[6,7,19-21].

Accurate identification of pericytes, as well as their characterisation in *in vitro* studies, remains challenging, since these cells have flexible phenotype. The expression of numerous pericyte marker proteins is highly dynamic and depends on the surrounding milieu. Moreover, many marker proteins are shared between pericytes and vascular smooth muscle cells (VSMCs)[14]. One of such markers is the α-smooth muscle actin (αSMA), which is normally expressed in VSMCs, but is also common in pericytes. However, its expression in the latter cell type can vary depending on the surrounding milieu[22]. For instance, pericytes from non-contractile capillaries can be αSMA-negative[23]. The expression of αSMA in pericytes can also be regulated by cell maturity[23] or stimulation by endothelin-1[24]. These considerations have to be taken into account while analyzing the cell population of macrovesicular intima. In the intima of large human arteries, the majority of resident cells were found to be αSMA-positive, especially in the muscular-elastic layer, where this population reached two thirds of the total amount of cells[25]. In the proteoglycan layer, the percentage of αSMA-positive cells was much lower. These cells were different from typical VSMCs, were less densely packed and had a characteristic branched morphology, with long processes forming intracellular contacts. Moreover, some αSMA-positive intimal cells expressed marker proteins that were unusual for muscular cells,

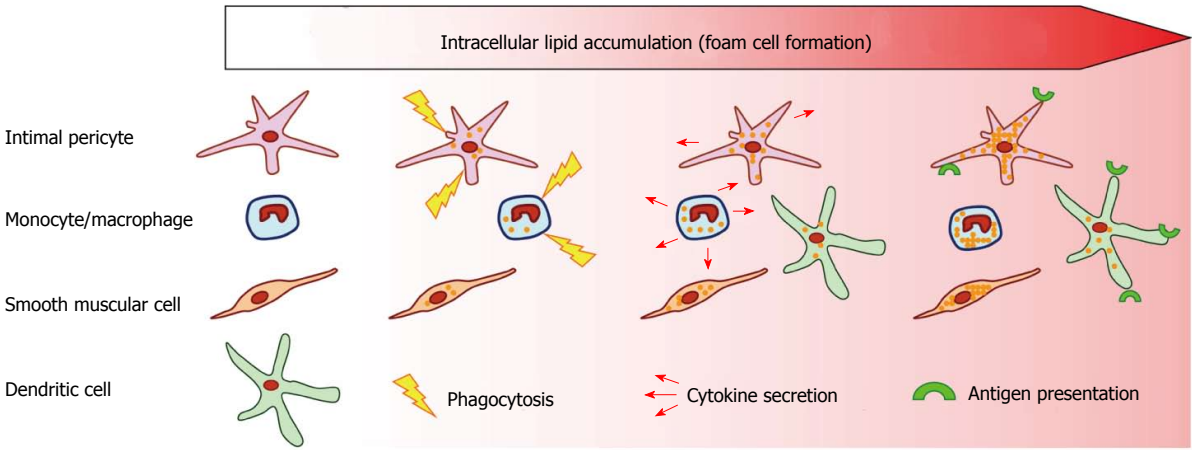

Figure 2 Scheme showing the roles of arterial wall cells in atherogenesis. Several types of arterial wall cells participate in lipid accumulation and foam cell formation. Macrophages and intimal pericytes accumulate lipids through phagocytosis and participate in the local inflammatory process secreting pro-inflammatory cytokines. Dendritic cells, together with macrophages and intimal pericytes express antigen-presenting complexes, further promoting the inflammatory process.

such as CD68, which is considered a macrophage-specific antigen[26]. Interestingly, the proportion of αSMA+CD68+ cells increased in atherosclerotic lesions, as well as in primary cell culture exposed to atherogenic modified low-density lipoprotein (LDL). Apparently, the acquisition of the "macrophage"-specific marker reflects the engagement of cells into phagocytic activity[27,28]. The large percentage of αSMA-negative cells in the arterial intima can partly be explained by the loss of contractile apparatus, since these cells acquire other functions than maintaining the vascular tone, such as metabolic homeostasis and nutrition or participation in the immune response in the blood vessel wall[29].

Therefore, accurate identification of pericytes in the intimal layer should not be based on αSMA expression exclusively, and has to include the analysis of other pericyte markers expression and morphological data. Commonly used pericyte markers include platelet-derived growth factor receptor β, CD146, aminopeptidase A and N (CD13), endoglin, neuron-glial 2, non-muscle myosin, desmin, vimentin and nestin[14,30]. However, most of these markers are shared with VSMCs and/or dependent on pericyte maturity or activation state, and therefore should be used in combination to avoid false-positive results. It has been demonstrated that some antigens expressed in resident intimal cells are not present in VSMCs. Antigen 3G5 is an O-sialoganglioside specific for microvascular pericytes[31]. It was found in some intimal resident cells, but not in the tunica media[26,32]. In humans, 3G5-positive pericytes form the net-like subendothelial tissue layer in normal human arterial intima and account for approximately one third of intimal cells (Figure 2)[26]. Another pericyte antigen detected in the macrovascular intima is 2A7, also known as melanoma chondroitin sulphate proteoglycan[26,33]. The expression of this antigen is typical for activated pericytes in the active angiogenesis phase. The expression of these pericyte marker antigens alters in atherogenesis. As demonstrated on primary cultures of subendothelial cells exposed to atherogenic modified LDL, intracellular lipid deposition results in the reduction of 3G5-positive cell fraction, whereas 2A7-expressing fraction increases[33].

Studies of the primary cell culture obtained from human macrovascular intima helped revealing the mechanisms of pericyte acquisition of characteristic stellate shape. Pericyte arborisation could be induced by increasing the intracellular cAMP concentration[33]. Interestingly, cells originating from the proteoglycan layer were more susceptible of arborisation, with up to 100% of them being capable of acquiring the stellate shape, whereas in population originating from the muscular-elastic layer it could be induced in only 50% of cells. The arborisation was associated with re-distribution of connexion 43 (Cx43), which is responsible for gap junction formation. Stellate cells formed large Cx43-positive sites located at the ends of cellular processes, where intracellular contacts were formed. *In vivo*, pericytes form stable contacts with the endothelial cells, which could also be reproduced in co-culture of the two cell types[7].

Apart from pericytes, other cell types populating the arterial intima have been described. These include cells of hematogenous lineage - macrophages[34-36], lymphocytes[37,38], mast cells[39] and dendritic cells. Cells of hematogenous lineage are located exclusively in the subendothelial proteoglycan layer of intima and are enriched in atherosclerotic plaques, where they can account for up to 20% of total cell population.

ROLE OF PERICYTE-LIKE CELLS (INTIMAL PERICYTES) IN THE PATHOGENESIS OF ATHEROSCLEROSIS

According to current consensus, pericytes are pluripotent cells that can serve as progenitors for other cell types of

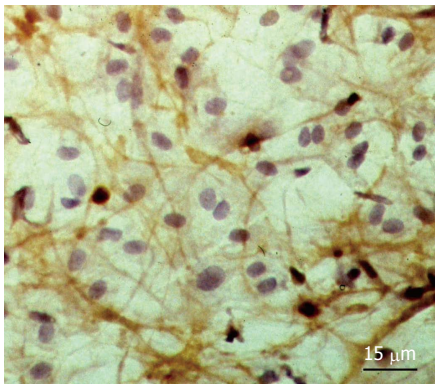

Figure 3 Cellular network formed by 3G5+ cells located under the luminal endothelium in undiseased intima. This cellular network was identified by means of the application of peroxidase-anti-peroxidase immunohistochemical analysis (brown colour of reaction product) in en face preparation of a tissue specimen of the human aorta. Counterstain with haematoxylin.

mesenchymal origin, including smooth muscle cells[40], fibroblasts, osteoblasts[41,42], chondrocytes[40] and adipocytes[43]. Pericytes are actively involved in various conditions associated with impaired microcirculation, such as diabetes, inflammation, wound healing and tumor growth. Converging evidence indicates pericyte implication in the pathogenesis of atherosclerosis. In presence of proinflammatory microenvironment and atherogenic modified LDL typical for early stages of atherosclerosis, intimal pericytes can accumulate lipids and become activated. The development of atherosclerotic plaque is associated with the increase of total cell count and the percentage of pericytes indicative of their involvement into the pathological process[21]. In fatty streaks, these cells actively accumulate lipids, which leads to the increase of cell size, acquisition of irregular shape, loss of Cx43-mediated cell contacts[44] and disturbance of the net-like subendothelial tissue[45]. Pericytes may not only proliferate and store lipids contributing to the plaque growth[46,47], but also promote thrombogenesis being a source of tissue factor[17]. Figure 3 depicts the impact of different arterial cells, including intimal pericytes, in the atherosclerotic process.

Microvascular pericytes are important for atherosclerosis progression, as they participate in neovascularization of the atherosclerotic plaques[48]. The recruitment of pericytes to growing neovessels could potentially be mediated by T-cadherin signalling. T-cadherin is an unusual member of the cadherin family, which is up-regulated in atherosclerosis[49]. It might play a role during LDL-induced pericyte activation through ERK1/2-nuclear factor κB signalling pathway[50]. It has been demonstrated that pericytes could also be recruited to neovessels in atherosclerotic plaques through hepatocyte growth factor signalling triggering c-Met-PI3K/Akt pathway in pericytes[51].

Participation in vascular wall remodelling and calcification is another possible contribution of pericytes to the pathological process in atherosclerosis. Activation of Wnt/β-catenin signalling stimulates chondrogenic differentiation of pericytes[52], which can be enhanced by transforming growth factor-β3[53]. The latter is abundantly produced by macrophages, foam cells and VSMCs in the atherosclerotic plaque[54]. Intimal pericytes were shown to express vascular calcification-associated factor. Moreover, pro-inflammatory environment in the plaque may promote osteogenic differentiation of the resident vascular cells. These observations indicate the potential involvement of pericytes in ectopic vascular calcification associated with atherosclerosis[55,56].

Taken together, the presented observations strongly support the hypothesis that macrovascular pericytes play an important role in all stages of the atherosclerotic lesion development, which makes them an attractive potential target for therapy development[7,57]. Interestingly, pericytes may also take part in the innate immunity reactions, which will be discussed in the next section.

PERICYTE-LIKE CELLS IN INNATE IMMUNITY

The development of atherosclerotic lesion is tightly associated with local inflammatory process. At the initial stages of atherosclerosis, formation of focal intimal thickening is accompanied by the increase of intimal cell count[58-60]. Such increase can be explained by the enhanced proliferation of intimal cells, recruitment of circulating hematologous cells or a combination of these processes. Cell proliferation has been demonstrated to be important for atherosclerotic process[61], although the differences in cell composition depending on different types of large arteries remained unknown. Detailed study of cell count and proliferation was performed on 29 post-mortem specimens of human carotid and coronary arteries with different stages of atherosclerotic plaque development: diffuse intimal thickening (grossly normal tissue), initial lesions, fatty streaks, lipofibrous plaques and fibrous plaques[62]. Proliferating cells in S phase were identified by proliferating cell nuclear antigen (PCNA) staining. The authors report the increased total cell count in atherosclerotic lesions and more frequent macrophages and lymphocytes in comparison with normal tissue. Number of proliferating cells was also increased in atherosclerotic plaques as compared to normal intima. Maximal total cell count and maximal amount of proliferating cells were detected in lipofibrous plaques in both types of arteries. Interestingly, the proliferative index (determined as the percentage of PCNA-positive cells in the total subpopulation) hematogenous cells in atherosclerotic lesions was lower than in the unaffected intima. It is therefore likely that the increase of hematogenous cells in atherosclerotic intima occurs due to immune cell recruitment from the bloodstream and not from the local proliferation[63-65]. By contrast, proliferative index of resident cells was higher in atherosclerotic lesions than in unaffected tissue, reaching its maximum in lipofibrous plaques[62].

It is well documented that modified atherogenic LDL

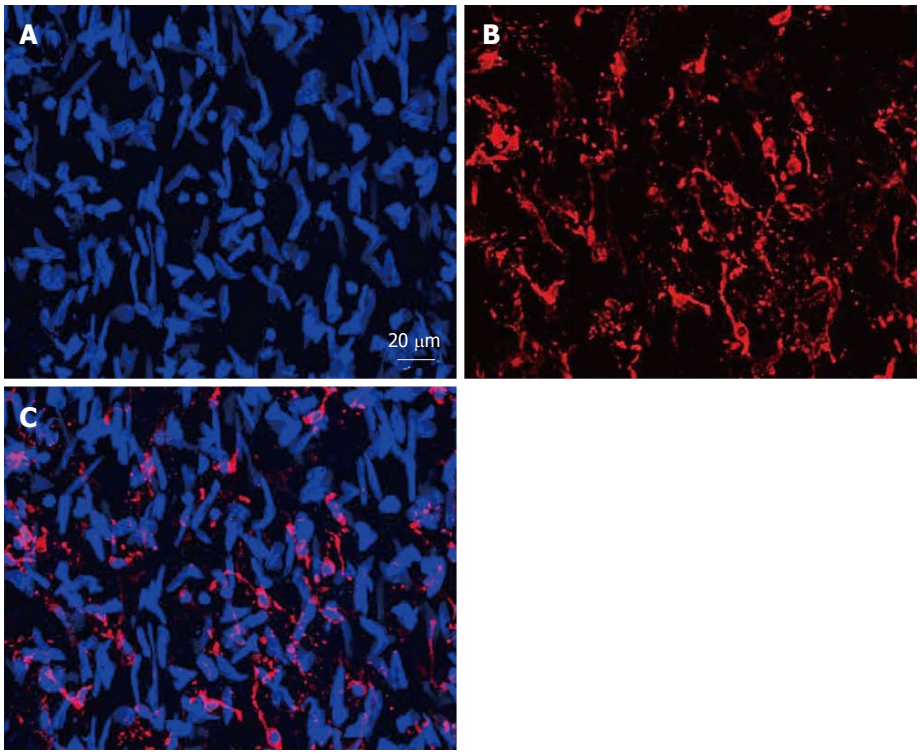

Figure 4 Immunofluorescent images representing the merge of 45 optic "confocal" sections of the intima obtained with interval of 1 μm between consecutive sections (A and B). A: Nuclei were visualized by staining with ethidium bromide; B: Distribution and networks formed by HLA-DR+ cells, detected with the use of anti-HLA-DR antibody conjugated with Alexa 633; C: A merge of the images shown in (A) and (B). Human aorta specimen. Reproduced from Bobryshev *et al*[74], with permission from Elsevier. HLA: Human leukocyte antigen.

not only causes lipid deposition in the arterial intima, but also initiates pro-inflammatory conditions, stimulating both adaptive and innate immunity[66,67]. During the atherosclerotic plaque formation, inflammatory cells are migrating into the lesion zone, where they release proinflammatory cytokines and chemokines, inducing proliferation of the resident intimal cells[65,68]. This model may explain the observed divergence of inflammatory and resident cells proliferative index dynamics in atherosclerotic lesions. Study of immune-inflammatory processes in diffuse intimal thickening demonstrated the link between lipid deposition in the arterial wall and the immune-inflammatory cell content[69]. Lipid deposition in the proteoglycan-rich layer of intima positively correlated with the expression of major histocompatibility complex class Ⅱ (MHC Ⅱ) molecule HLA-DR[70] and the amount of immune-inflammatory cells in that area. These findings demonstrate that lipid accumulation at the early stages of atherosclerotic lesion development is accompanied by local immune activation. HLA-DR is a marker of antigen presenting cells (APCs)[70,71] that include macrophages, B cells and dendritic cells. The latter were described as professional APCs, as they play the most prominent role in antigen presentation and initiation of the immune response. Apart from these cell types of hematogenous origin, some non-hematogenous cells can serve as APCs. For instance, epithelial cells of the thymus are involved in antigen presentation[71]. Human endothelial cells are capable of T cell activation and basally express both MHCI and MHC Ⅱ, although the expression is less prominent in larger arteries[72]. Moreover, fibroblasts and endothelial cells can become activated to express MHC Ⅱ under certain conditions both *in vitro* and *in vivo*[70,73].

Immunofluorescent analysis of HLA-DR expression in the aortic intima revealed a large population of interconnected HLA-DR-positive cells that formed a net-like tissue (Figure 4)[74]. In some segments of the intima up to 15% of total cell population was expressing HLA-DR[74]. Morphologically, these cells could be identified as pericytes, with their typical net-forming intercellular contacts.

These results indicate that antigen presentation in the arterial wall can be performed by a variety of intimal cell types, including macrovascular pericytes. Importantly, microscopic study has revealed some HLA-DR-positive cells that also contained apo-B in the perinuclear space, possibly representing the early events of lipid accumulation in the intimal cells[74]. It is therefore possible that pericytes play a double role in atherogenesis, participating both in lipid accumulation and in local immune reaction.

Immunohistochemistry demonstrated the expression of tumor necrosis factor (TNF)-α and CCL18 cytokines in both normal and atherosclerotic human aorta. These two cytokines were expressed by distinct populations of cells, with CCL18 mostly located in the subendothelial layer, and TNF-α - in deeper layers of the unaffected intima. The expression pattern was altered in atherosclerotic plaques, with both TNF-α and CCL18 upregulated compared to grossly normal arterial intima. Apart from macrophages, other cytokine-producing cells types were detected, including stellate pericyte-like cells.

The immune functions of pericytes remain an attractive topic for future investigation[75]. Microvascular placental pericytes were demonstrated to interact with $CD4^+$ T cells in co-culture. Pericytes stimulated the expression of CD25 and CD69 in resting allogenic $CD4^+$

T cells, indicative of MHC recognition. This, however, did not lead to the induction of cytokine production and proliferation of T cells[76]. The possibility that macrovascular pericytes have immune-modulating properties remains to be explored. The three-dimensional network of subendothelial cells participating in immune reactions may play important protective functions in the blood vessel wall. As demonstrated on the biopsy material from arteries, unaffected by atherosclerosis or with different stages of atherosclerotic lesion development, changes in this network occur early in the pathological process.

OTHER CELL TYPES PARTICIPATING IN IMMUNE REACTIONS IN THE SUBENDOTHELIAL INTIMA

Cells of hematogenous origin actively participate in immune reactions in the blood vessel wall. The development of atherosclerotic lesion is accompanied by infiltration and population of the lesion site by lymphocytes and macrophages. In human atherosclerotic lesions, the population of T cells consists mostly of the effector memory T cells. Substantial part of them are $CD4^+$ T helper cells[77]. $CD8^+$ cytotoxic T lymphocytes are also present in atherosclerotic lesions. T cells are especially numerous in so called vulnerable plaques that are susceptible to rupture and thrombosis initiation[78]. B cells have also been demonstrated to participate in atherogenesis[79,80]. However, these cells are mostly found in the adventitia of the affected vessels, and not in the atherosclerotic plaques[77,81].

Pro-inflammatory stimuli in blood vessels affected by atherosclerosis attract circulating monocytes that rapidly migrate to the atherosclerotic lesion site and differentiate where, predominantly to macrophages. This polarization is driven by stimulation of specific receptors, including C-C chemokine receptor type 2 and CX3C chemokine receptor 1[82,83]. Both of these chemokines are implicated in the atherosclerotic plaque progression[84]. Macrophages play a prominent role in the inflammatory process associated with the initiation and progression of atherosclerotic lesions. Macrophages are involved in the uptake of atherogenic modified LDL and form typical foam cells. Toll-like receptor (TLR) signalling in macrophages plays important role in lipid accumulation through regulation of scavenger receptor expression and suppression of cholesterol efflux[85,86]. Macrophages also produce a number of inflammatory cytokines and contribute to vascular remodelling.

In atherosclerotic lesions, two distinct macrophage subpopulations can be found: M1 (classical) and M2 (alternative). Pro-inflammatory M1 phenotype can be induced in response to bacterial infection and pro-inflammatory cytokines, such as interferon (IFN)-γ and TNF-α[87]. They produce a spectrum of cytokines and chemokines stimulating the inflammatory response, as well as nitric oxide and reactive oxygen species. M2 macrophages have anti-inflammatory properties, producing interleukin (IL)-10. In addition, M2 subpopulation of macrophages is heterogeneous: M2a macrophages are induced in response to IL-4 and IL-13 and participate in tissue remodelling, M2b cells are involved in immunoregulation, and M2c, induced by IL-10 and transforming growth factor-β, are involved in clearance of apoptotic cells[88,89]. All three subtypes of M2 macrophages can be found in human atherosclerotic lesions. Human-specific M4 macrophages can be induced by platelet-derived chemokine CXCL4 and are characterized by resistance to excessive lipid uptake. This makes them susceptible to rapid transformation into foam cells and indicates their potential role in atherosclerotic lesion development[90]. Specific populations of macrophages can be found in hemorrhagic atherosclerotic plaques. In humans, they represent M(Hb), HA-mac and Mhem subsets. HA-mac and M(Hb) macrophages are involved in hemoglobine clearance[91]. All three subpopulations possess anti-inflammatory properties and can play a protective role in atherosclerosis.

Dendritic cells are also frequent in the subendothelial layer of intima, just below the liminal endothelium, where they contribute up to 10% of total cell population[74,92,93]. In the subendothelial space, dendritic cells form cellular networks by means of their long interconnected processes[74,92,93]. Dendritic cells play an important role in the immune response, producing a spectrum of cytokines and surface co-stimulatory molecules. They can be differentiated from monocytes at the periphery through stimulation with granulocyte-macrophage colony-stimulating factor (GM-CSF) and TLR4 ligands[94]. These monocyte-derived dendritic cells are involved in antigen presentation and cross-presentation[95]. It has been demonstrated that monocyte-derived DCs from patients with atherosclerosis had increased sensitivity to GM-CSF and IL-4 as compared to healthy subjects[96]. Pro-inflammatory microenvironment of the atherosclerotic plaque accounts for preferential differentiation of monocytes and dendritic cell precursors towards pro-inflammatory dendritic cells that play an important role in the inflammatory process and stimulate differentiation of the naïve T cells to Th1 and Th17 phenotypes[97]. Dendritic cells also produce pro-inflammatory IFN-α and a number of chemokines that induce the migration of inflammatory cells to the lesion site[98]. In summary, pro-inflammatory dendritic cells play a prominent role in the development of atherosclerotic plaque. Populations of atheroprotective tolerogenic and anti-inflammatory dendritic cells could also be found in atherosclerotic plaques. In Apo-E-deficient mice, tolerogenic dendritic cells generated in response to immunogenic bacterial peptides were demonstrated to decrease inflammation and contribute to the plaque decrease through induction of IL-10-producing Tregs[99]. It is possible that employing the

pathways of tolerogenic dendritic cell induction can be beneficial for treatment of atherosclerosis.

CONCLUSION

The subendothelial layer of human arterial intima contains a cellular network made of pluripotent pericytes that form multiple intracellular contacts through gap junctions. Together with the professional immune cells, such as macrophages and dendritic cells, pericytes may execute functions, typical for innate immune cell types: participate in LDL trapping by phagocytosis, produce pro- and anti-inflammatory cytokines and other factors and present antigens (Figure 2). Whereas the aortic endothelium plays a role as the first line of defence in atherosclerosis development, the subendothelial pericytes can be regarded as the second defence line and should be considered for the development therapeutic approaches for atherosclerosis treatment.

Abstract

The objective of this study is to develop a cost-effectiveness model comparing drug eluting stents (DES) *vs* bare metal stent (BMS) in patients suffering of stable coronary artery disease. Using a 2-years time horizon, two simulation models have been developed: BMS first line strategy and DES first line strategy. Direct medical costs were estimated considering ambulatory and hospital costs. The effectiveness endpoint was defined as treatment success, which is the absence of major adverse cardiac events. Probabilistic sensitivity analyses were carried out using 10000 Monte-Carlo simulations. DES appeared slightly more efficacious over 2 years (60% of success) when compared to BMS (58% of success). Total costs over 2 years were estimated at 9303 € for the DES and at 8926 € for bare metal stent. Hence, corresponding mean cost-effectiveness ratios showed slightly lower costs ($P < 0.05$) per success for the BMS strategy (15520 €/success), as compared to the DES strategy (15588 €/success). Incremental cost-effectiveness ratio is 18850 € for one additional percent of success. The sequential strategy including BMS as the first option appears to be slightly less efficacious but more cost-effective compared to the strategy including DES as first option. Future modelling approaches should confirm these results as further comparative data in

stable coronary artery disease and long-term evidence become available.

Key words: Cost-effectiveness; Percutaneous coronary; Coronary artery disease; Drug eluting stent

Core tip: The objective of this study is to develop a robust cost-effectiveness model comparing drug eluting stents (DES) *vs* bare metal stent (BMS) in patients suffering of stable coronary artery disease. DES appeared slightly more efficacious over 2 years (60% of success) when compared to BMS (58% of success). Mean cost-effectiveness ratios showed slightly lower costs per success for the BMS strategy (15520 €/success), as compared to the DES strategy (15588 €/success). The sequential strategy including BMS as the first option appears to be less efficacious but more cost-effective compared to the strategy including DES as first option.

INTRODUCTION

Coronary heart disease is an important disorder in Western industrialized societies, with regard to both the epidemiologic and economic burden of illness[1]. Stable angina (SA) is a clinical syndrome subset of the acute coronary artery disease (CAD), which is a major cause of emergency medical care in developed countries. The prognosis of SA is highly variable and depends on the initial treatment strategy which could be invasive (surgical procedure) or conservative (medical management). Angiographic and angioscopic studies suggest that CAD often results from the disruption of an atherosclerotic plaque and a subsequent cascade of pathological processes that decrease coronary blood flow. A modern therapeutic strategy consists of coronary interventions and the implantation of drug-eluting vascular stents. The idea that devices could be placed inside the arteries to maintain the blood flow came to a reality in 1986 when the first stents were successfully implanted in coronary arteries[2,3]. The technology evolved rapidly even if the incidence of in-stent restenosis was between 20% and 30%[4]. Then different generations of Drug Eluting Stents (DES) from heparin coated Palmaz-Schatz stents[5] to chemotherapeutic releasing agent or copolymer coating have been proposed to lower the incidence of restenosis. Because of their high efficacy and good safety profile, DES is reported to be used in 45% to 80% of all percutaneous coronary interventions[6,7]. However, clinical evidence of medical devices is not really supported by robust randomized control clinical trials such as for pharmaceutical agents. Furthermore, cost-effectiveness of such strategies is rarely fully documented and based on numerous assumptions, making difficult the full evaluation of such strategies. Recent studies have continued to show improved procedural and clinical outcomes with DES both in the setting of acute coronary syndromes and stable coronary artery disease[8]. A recent meta-analysis published by Palmerini *et al*[9] analyzed twenty-two trials involving a total of 12453 patients and established that at one year DES were associated with lower rates of cardiac death or myocardial infarction and stent thrombosis than bare metal stents (BMS). Peterson *et al*[10] studied the medical costs and outcomes of coronary stenting *vs* simple balloon angioplasty and estimated that the mean in-hospital cost for stent patients was $3268 higher than for those receiving coronary angioplasty ($14802 *vs* $11534, $P < 0.001$). However, stent patients were less likely to be re-hospitalized (22% *vs* 34%, $P = 0.002$) or to undergo repeat revascularization (9% *vs* 26%, $P = 0.001$) than coronary angioplasty patients within six months of the procedure. A South Korean cost-minimisation model established that DES resulted in higher costs than Bare metal stent by 985 Euros per patient[11]. However, it is possible that some selection bias influenced the results of such studies based on descriptive clinical data sources. A United States study published by Amin *et al*[12] specifically focused on DES indications in current practices and concluded that the use of DES in the United Sates would vary widely among physicians, with only a modest correlation to patients' risk of restenosis. Thus less DES used among patients with low risk of restenosis would have the potential for significant cost savings for the United States health care system while minimally increasing restenosis events. As large controlled clinical trials are very difficult to implement in this indication, a modelling approach would allow to generate robust comparative results and assess the value for money[13]. The objective of this study is to develop a cost-effectiveness model comparing DES *vs* BMS in patients suffering of stable coronary artery disease according to the French health system.

LITERATURE STUDY

Given the scarcity of head-to-head clinical trials, there is a need to use decision analytic models to assess and compare expected costs and effectiveness of percutaneous coronary interventions (PCI) strategies, using published evidence and cost estimates. Hence, evaluating the cost-effectiveness of a therapeutic sequence may identify the most clinically suitable population for a new strategy, and the most effective

Table 1 Charge table (i€)

Resource utilization	Mini	Mean	Max	Tariff
GP visit				22
Specialist visit (cardiologist)				23
Lab tests without markers of myocardial damage				21
Lab tests with markers of myocardial damage				39
ECG at rest				14
Stress test ECG				77
Stress test echocardiography				165
Myocardial scintigraphy				409
Coronary angiography				1954
Standard combination therapy (1 yr): aspirin + statin + ACE inhibitors	364		743	
GTN (1 yr)	39.4		73.2	
β-Blocker (1 yr)	52.9		210.9	
Calcium Inhibitors (1 yr)	87.5		311	
Hospitalization stay for PCI with BMS (1.6 stent)	4074		4573	
Hospitalization stay for PCI with DES (1.6 stent)	5284		5704	
Hospitalization stay for CABG surgery		14065		
Hospitalization stay for a clinical failure		2096		

DES: Drug eluting stents; BMS: Bare metal stent; PCI: Percutaneous coronary interventions; CABG: Coronary artery bypass graft; ACE: Angiotensin-converting-enzyme; ECG: Electrocardiogram.

and cost-effective treatment sequence. A model is a mathematic formula linking different variables to generate results relevant to a given environment based on local medical practices. A cost-effectiveness model is classically composed of a framework structure populated with costing and effectiveness data. Best modelling practices suggest that data populating a model should be based on relevant costs and existing published clinical data at the time of model development[14]. The model assumptions should also be validated by expert clinicians according to their current medical practice in a given country. Specific to stable coronary artery disease management, results generated by such modelling approach provide unique information on the expected effectiveness, overall costs and cost-effectiveness of different PCI strategies to assist medical decision-making as well as resource allocation decisions.

Resource utilization

French direct medical costs were derived from a standard costing approach performed with a panel of three expert clinicians highly experienced in CAD management. Direct medical costs were estimated per 12 mo considering ambulatory costs (GP visits, cardiologist visit, laboratory tests, imaging, drugs) and hospital costs (percutaneous intervention, coronary artery bypass graft, coronary angiography alone, hospitalization due to complications), while initial diagnostic costs were not considered. Unit costs of interventions were derived from Diagnosis Related Groups list and from the national payer perspective for ambulatory costs. Item costs were collected from minimum and maximum costs. Costs are reported in Euros (2012), and the charge table is reported in Table 1.

Resource utilizations were assessed from existing clinical guidelines. In the absence of guidelines, expert opinions were used from the clinician co-authors (YJ, OD and ND). Guidelines used were: "diagnosis and management of patients with stable ischemic heart disease" (American Heart Association 2012), "acts and services of long-term disease coronary heart disease" (Haute Autorité de Santé 2012) and "guidelines on the management of stable angina pectoris" (European Society of Cardiology 2006)[15-17]. Treatment costs include a combination of drugs prescribed to every patient (low-dose aspirin, statin and angiotensin-converting enzyme inhibitor) and specific costs of the selected treatment. When the options are "PCI with BMS" or "PCI with DES", specific costs are associated with hospitalisation costs required for the angioplasty, the number and type of the implanted stents, and the costs of clopidogrel prescription to prevent intrastent thrombosis. Costs for the hospitalisation are determined using the French official hospital information system according to the specific diagnosis-related groups (DRGs) named "PCI without myocardial infarction". DRG costs include treatments and all examinations (invasive or non-invasive cardiac investigations, biological analyses, *etc.*). Total costs of stents are calculated according to the average number of stent implanted per patient: 1.6 per patien[7]. The therapeutic option "drugs" includes the costs of basic drugs (see above) plus either β-blockers, calcium antagonists or long acting nitrates.

Costs of follow up after a clinical success include costs of ambulatory medicals visits, lab and medical imaging. The number of medical visits during follow-up has been estimated to 3 per year for GPs and 1 for specialist (cardiologist). Medical imaging includes one echocardiography and one myocardial scintigraphy. Lab tests (2 per year) include fasting lipid profile, including total cholesterol, low density lipoprotein (LDL), high density lipoprotein (HDL), and triglycerides, fasting glucose, full blood count including haemoglobin and white cell count, and serum creatininemia. Cost of follow up after a clinical failure are similar to costs after a clinical success plus one specific hospitalisation for management of the clinical failure. As no specific DRG exists for clinical failure, the following DRGs were considered: "myocardial infarction", "angina", "chest pain", "coronary atherosclerosis" and "arrhythmias and cardiac conduction disturbances". When a coronary angiography is not followed by an intervention, but by a drug prescription, the costs of the DRG "intravascular diagnostic procedure" have been used (mean costs of 5 related DRG).

Effectiveness

One relevant effectiveness endpoint aligned with stable coronary artery disease treatment goals has been used

Table 2 Effectiveness data of drug eluting stents model

	Minimum	Maximum	Ref.
Probability of success of a CABG surgery following a coronary angiography after a failure of a DES	90%	-	Sheiban *et al*[18]
Probability of success of pharmaceutical treatment after a failure of a DES	85%	90%	Sheiban *et al*[18]
Probability of success after a first DES	82.2%	97.5%	Simsek *et al*[19] Bakhai *et al*[20] Meredith *et al*[21] Morice *et al*[22] Toutouzas *et al*[23] Weisz *et al*[24] Serruys *et al*[25] Yan *et al*[26]
Probability of success after 1 yr of surveillance following a first DES	86.3%	98.7%	Simsek *et al*[19] Meredith *et al*[21] Park *et al*[27]

DES: Drug eluting stents; PCI: Percutaneous coronary interventions; CABG: Coronary artery bypass graft; CBA: Coronary balloon angioplasty.

and expressed as treatment "success rate". The success endpoint was defined as the absence of a MACE (major adverse cardiac events), that is to mean the absence of death or non fatal myocardial infarction or the need of a subsequent revascularization. Effectiveness estimates of PCI were derived directly from published clinical trials at the time of model development.

Assuming comparable patient populations, probabilities of patients in success at each simulated 12-mo time point have been estimated from an extensive literature review. If different values are presented in different publications, expert opinions were used to validate the use of a range between the minimum value and the maximum value observed in the literature. When no relevant values have been reported in the literature, a range of potential values is estimated based on the clinical experience of the expert panel. Then 10000 Monte-Carlo simulations were carried out to screen every possible value according to a uniform distribution shape. Effectiveness values are presented in Table 2 for the DES strategy and Table 3 for the BMS strategy.

Model structure

Using a 2-year time horizon, two PCI simulation models have been developed: BMS first line strategy (Figure 1A) and DES first line strategy (Figure 1B). The first step of the BMS model is the coronary angiography, followed by bare metal stent. After one year, patient could be in clinical situation of success or failure. In case of success, the surveillance without new treatment will occur during the second year. In case of failure at the end of the first year, a new coronary angiography will lead to either a PCI (either bare metal stent or DES), a Coronary Artery Bypass surgery (CABG), or a pharmaceutical treatment. The first step of the DES model is the coronary angiography, followed by DES. In case of success, a simple surveillance is proposed as in the first model. In case of failure, a new coronary angiography will lead to either a PCI (new DES or balloon alone without any stent), a CABG, or a pharmaceutical treatment.

The models were specifically programmed in D-script language (Vanguard Studio 5.2). To manage uncertainty, and as per best practice in economic modeling, 10000 Monte-Carlo simulations generated mean values and standard deviations of the sub-model outputs: costs, effectiveness, and average cost-effectiveness over 2 years. Monte Carlo simulations consist of a class of computational algorithms that rely on repeated random sampling to compute their results. This approach, also called "probabilistic sensitivity analysis", allows screening all possible values of a given parameter according to a defined distribution shape and to recalculate the results. For the purpose of this study, uniform distributions have been programmed between minimum-maximum ranges of values. Therefore, the models were able to construct distributions of results which are presented with their standard deviations (SD). Statistical tests (two groups mean tests with known variances deducted from cost-effectiveness SD) were performed to calculate potential significant differences between cost-effectiveness ratios of treatment strategies.

COST-EFFECTIVENESS

Using stable coronary artery disease management medical costs, cost of interventions and pharmaceutical therapies and published effectiveness data, the models

Table 3 Effectiveness data of bare metal stent model

	Minimum	Maximum	Ref.
Probability of success after a first bare metal stent	70.9%	86.4%	Simsek *et al*[19] Daemen *et al*[33] Bakhai *et al*[20] Morice *et al*[22] Weisz *et al*[24]
Probability of success after 1 yr of surveillance following a first bare metal stent	85%	96%	Simsek *et al*[19]
Probability of undergoing a second PCI following a coronary angiography after a failure of a bare metal stent	80%	-	Malenka *et al*[28]
Probability of undergoing a surgery following a coronary angiography after a failure of a bare metal stent	10%	15%	Malenka *et al*[28]
Probability of undergoing a DES after a failure of a bare metal stent	50%	-	Konstance *et al*[34]
Probability of success of a DES after a failure of a bare metal stent	78%	89%	Steinberg *et al*[29]
Probability of success of a second bare metal stent after a failure of a first bare metal stent	58%	67.3%	Singh *et al*[35]
Probability of success of a CABG surgery following a coronary angiography after a failure of a bare metal stent	90%	-	Malenka *et al*[28] Konstance *et al*[34]
Probability of success of pharmaceutical treatment after a failure of a bare metal stent	85%	90%	Sheiban *et al*[18]

DES: Drug eluting stents; PCI: Percutaneous coronary interventions; CABG: Coronary artery bypass graft.

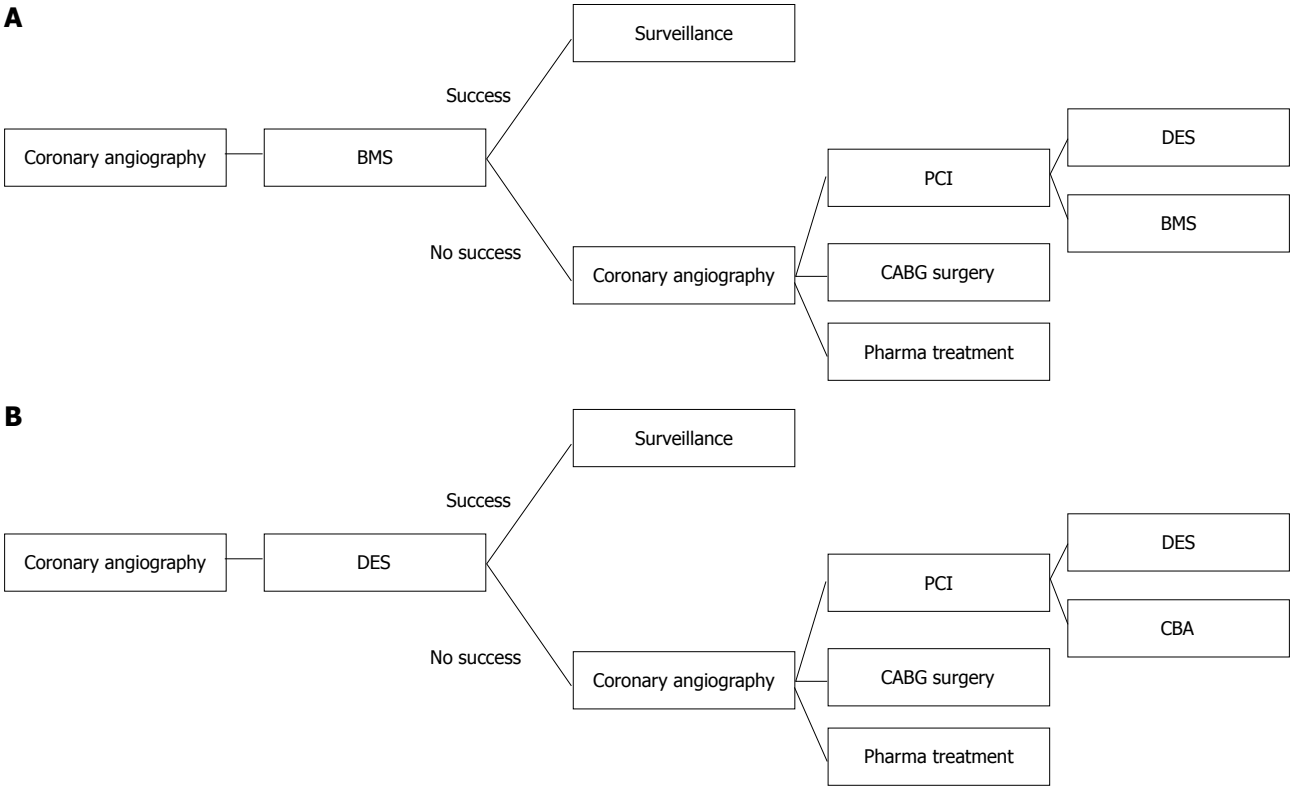

Figure 1 General architecture of the bare metal stent (A) and drug eluting stents (B) sequential model. DES: Drug eluting stents; BMS: Bare metal stent; PCI: Percutaneous coronary interventions; CABG: Coronary artery bypass graft; CBA: Coronary balloon angioplasty.

generated the overall treatment costs over 2 years, the probability of success, and the cost-effectiveness expressed in cost per success.

Strategy DES appeared slightly more efficacious (Figures 2 and 3) over 2 years (60% of success, SD 0.03) when compared to the strategy BMS (58% of success, SD 0.02). Total costs over 2 years were estimated at 9303 € (SD 3415) for the strategy DES and at 8926 € (SD 3778) for the strategy bare metal stent. Hence, corresponding mean cost-effectiveness ratios showed slightly lower costs per success for the bare metal stent strategy (15520 €/success, SD 6634), as compared to the strategy DES (15588 €/success, SD 5787). Incremental Cost-Effectiveness Ratio is 18850 € for one additional percent of success.

DISCUSSION

The results of this cost-effectiveness model based on published clinical evidence suggest that in patients in stable coronary artery disease, the sequential strategy including bare metal stent as the first PCI option

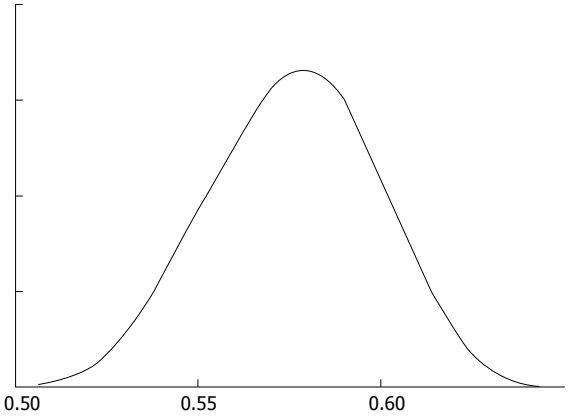

Figure 2 Cost distribution shape of the bare metal stent strategy (X axis: % success rate; Y axis: Occurrence probability).

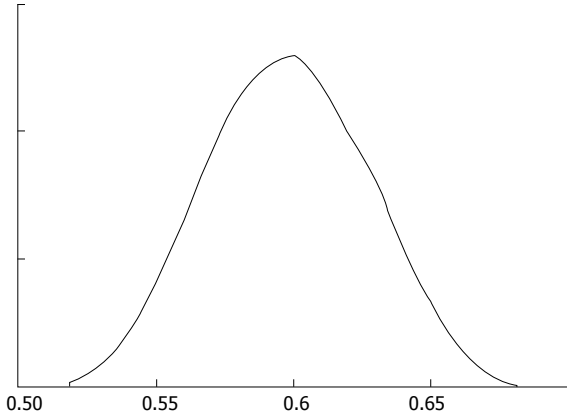

Figure 3 Cost distribution shape of the drug eluting stents strategy (X axis: % success rate; Y axis: Occurrence probability).

appears to be slightly less efficacious but more cost-effective compared to the strategy including DES as the first option. Two factors contribute to the better cost-effectiveness of the bare metal stent strategy. First, the results are driven by the efficacy reported in clinical trials. Secondly, the slightly higher success rates of the DES strategy do not offset the difference in costs between the two strategies. One of the most important issues in the creation of valid medico-economic models is the use of clinical effectiveness endpoints that are clinically meaningful and consistent across different settings. Selecting objective and consistent clinical outcomes allow defining clinical effectiveness of a given treatment more accurately and to compare across different treatment strategies for a specific patient population. Given that the goal of percutaneous coronary interventions is to reach a therapeutic success, this clinical endpoint appeared to be the most relevant effectiveness criteria for the purpose of conducting this cost-effectiveness analysis. Using a dichotomous approach of achieving success or no-success also appeared more clinically meaningful. Such cut-off points also avoid the need of using continuous scales with cardinal metrics (same origin and regular degrees) to compute effectiveness endpoints. Not only the proposed dichotomous approach success/no success is clinically meaningful, but it also requires fewer assumptions than using other outcomes,

The model assumes a 12-mo treatment period prior to allowing a potential switch to the next potential intervention in case of treatment failure. This assumption is based on the fact that most clinical trials report effectiveness data at 12 mo time points. These assumptions could be further discussed but they appeared to be consistent with medical practices in France, as validated with the expert panel. Furthermore, the time horizon of the model is limited to 2 years in order to reflect the data available at the time of model development. Hence, no long term effectiveness assumptions were made, as is it often the case in published "lifetime" cost-effectiveness models in stable coronary artery disease. Wisløff *et al*[36] carried out a cost-effectiveness model comparing DES *vs* BMS and concluded that DES was more cost-effective over a life time horizon using life years saved as an effectiveness endpoint. However, this model is based on life-time horizon projections speculating well beyond clinical trials evidence and diluting costs over years.

Co-morbidity such as diabetes is a risk factor of re-stenose after stent implantation, particularly for BMS as confirmed by the meta-analysis of Bangalore *et al*[37] carried out on 42 controlled randomized clinical studies. However, no specific calculations have been carried out for patients suffering of co-morbidities such as diabetes. Data inputs come from studies where proportion of diabetes patients were similar than European population, as described in the Euro Heart Survey[38].

This approach does not capture potential Quality of Life (QOL) improvement, as we would recommend that such evidence be considered separately, to its full merit. Furthermore, it is not the purpose of one clinical indicator to capture all the dimensions of life, so QOL dimensions should be collected separately using appropriate validated instruments. Many published "cost-utility" models (often presented under the label of "cost-effectiveness" models) consider the use of Quality Adjusted Life Years (QALY) as "effectiveness" criteria in order to take into account both the Quality of Life and the survival perspectives[39]. Not only the QALY approach is not specifically recommended in France (and several other countries such as USA and Germany) for methodological issues, but such approach reveals to be inconsistent in Stable coronary artery disease[40]. This is because the results are directly dependent on how the utility scores have been derived, explaining the possibility of data manipulation and why these studies often lead to divergent results[41,42]. The advantage of cost-effectiveness models using clinical effectiveness outcomes (such as Success probabilities) from published clinical trials is that the effectiveness criteria are not further transformed into

utilities. Hence, classic cost-effectiveness assessments (cost/clinical outcome achieved or per medical event avoided) generate more transparent and consistent results. Also, this cost-effectiveness analysis does not use a societal perspective but the perspective of the public payer in France. In such case, the results do not take into account the reported favourable impact of PCI on indirect costs. As indirect costs related to CAD are substantial and are estimated to be 2-3 times as high as direct costs, the results of this economic evaluation are likely to be understated. Finally, a frequent concern about cost-effectiveness models is that most publications seem to support the product of the study sponsor, suggesting a potential publication bias such as for publications of clinical trials. As they are used to inform and optimize resource allocation decisions, cost-effectiveness models are country specific and should always define the assumptions and conditions underlying the results where a therapeutic strategy is found to be cost-effective[14], which should also be in line with medical practices. Any model assuming very hypothetical clinical practices or theoretical outcomes should be considered with caution, as for any scientific studies.

CONCLUSION

This sequential cost-effectiveness model proposes a new approach to assess complex strategies based on clinical evidence based data and avoids any extrapolation over time, which could be subject to criticism. The model outcome expressed in costs per clinical success appears to be a clinically meaningful endpoint, allowing to compare various strategies. The sequential strategy including BMS as the first option appears to be slightly less efficacious but more cost-effective compared to the strategy including DES as first option in the frame of the French health system. Future modelling approaches should confirm these results as further comparative data in stable coronary artery disease and long-term evidence become available, but also to assess the value of innovative strategies such as biodegradable coronary stents.

Abstract

Obesity used to be among the more neglected public health problems, but has unfolded as a growing medical and socioeconomic burden of epidemic proportions. Morbid obesity is linked to traditional cardiovascular risk factors like, hypertension, hyperlipidemia and diabetes, and suspected to incur increased morbidity and mortality in the Western and even third world populations. This patient cohort is also at greater risk to develop coronary artery disease. Recent population-based registries revealed that 43% and 24% of all cases of coronary revascularization were carried out in overweight and obese patients, respectively. However, despite evidence of a positive correlation between obesity and increased cardiovascular morbidity, some authors have described a better clinical outcome in overweight and obese patients, a phenomenon they coined "obesity paradoxon". Thus, there is an ongoing debate in light of conflicting data and the possibility of confounding bias causing misconception and challenging the "obesity paradox". In this review article we present the current evidence and throughly discuss the validity of the "obesity paradoxon" in a variety of clinical settings.

Key words: Coronary stent; Obesity paradox; Mortality; Body mass index

Core tip: Obesity is one of the leading health problems within the last years and is associated with several cardiovascular risk factors resulting in increased prevalence of coronary artery disease as well as atherosclerotic disease in head vessels and peripheral artery system. Despite these positive correlations there are reports describing a protective effect in patients undergoing coronary revascularization. This review will enlight the potential causes and bias regarding this "obesity paradoxon" in several clinical setting and will present the latest data.

INTRODUCTION

Epidemiologic data on obesity, traditionally defined

as a body mass index (BMI) > 30 kg/m^2, range in the Western population with a prevalence of up to 36.5%[1]. Prevalence in United States is up to 70% that is much higher than 40 years ago (25%)[2]. Obesity and associated disorders like arterial hypertension, dyslipidemia, diabetes mellitus and sleep apnoea syndrome are linked to increased morbidity and mortality[3,4]. Common recommendation is weight loss to modify cardiovascular risk as an attempt for primary and secondary prevention of cardiovascular disease in overweight and obese patients[5-7]. Obesity is associated with increased atherosclerotic diseases, especially coronary artery disease by reduced insulin sensitivity, enhanced free fatty acid turnover, increased basal sympathetic tone, a hypercoagulable state, and finally by promotion of systemic inflammation[8,9]. Population-based data revealed that 43% and 24% of all coronary revascularization were carried out in overweight and obese patients, respectively[10]. Clinical outcome speculations should indicate that these patient cohorts would be associated with worse outcomes as compared to normal weight patients. Nevertheless, despite proven evidence of a causative association between morbid obesity and increased cardiovascular morbidity, previous studies have described the phenomenon of "obesity paradoxon", reporting a protective effect of obesity with regards to postoperative morbidity and mortality in patients receiving a surgical of interventional revascularization[11]. The observation of better clinical outcome is not only restricted to coronary revascularization but also in other clinical settings like acute myocardial infarction and heart failure[12,13]. With this review article we would like to give an overview and summary on the evidence of an "obesity paradoxon" in coronary artery disease.

STABLE CORONARY ARTERY DISEASE

Correlation of BMI with clinical endpoints in the setting of interventional coronary revascularization was first reported in 1996 from a single-center experience in patients (n = 3571) receiving balloon angioplasty[14]. In-hospital outcomes revealed higher rates of mortality (2.8% *vs* 0.9% *vs* 3.7%; P < 0.001) in normal weight and obese patients as compared to overweight patients. Similar differences were seen in need for blood transfusion (11.9% *vs* 7.4% *vs* 8.4%; P = 0.003) and rise in creatinine > 1 mg/dL (3.6% *vs* 1.8% *vs* 1.8%; P = 0.018); whereas rates for myocardial infarction were not different (3.5% *vs* 3.4% *vs* 4.7%; P = ns). A total of 3634 patients from the multicenter BARI registry undergoing elective revascularization [2108 by interventional procedure (PCI) and 1526 by surgery (CABG)] between 1988 and 1991 were evaluated for BMI at study entry[15]. Body mass index (BMI) was associated with increased risk of a major in-hospital event just in the PCI arm. However, at five year follow-up there was a correlation between mortality and BMI only in the CABG arm. While these results from the BARI trial suggested an inverse correlation of BMI with in-hospital outcome after PCI and no such difference with long-term follow-up, Gruberg *et al*[11] revealed an inverse correlation during 12-mo follow-up in 9633 patients that had been evaluated between 1994 and 1999 for mortality (10.6% *vs* 5.7% *vs* 4.9%; P < 0.0001); conversely rates of myocardial infarction (7.4% *vs* 7.0% *vs* 6.7%; P = 0.66) and target vessel revascularization (20.2% *vs* 22.0% *vs* 22.4%; P = 0.16) were not different.

Postprocedural clinical events like arterial hypotension, pulmonary congestion, impairment of renal function, as well as bleeding events, access site complications and mortality rates were more frequently seen in underweight patients than in overweight or obese ones. Different from previous all-comers trials, the Scottish Coronary Revascularisation Register included only patients (n = 4880) receiving elective PCI between 1997 and 2006 without a history of previous known coronary artery disease. During five years of follow up BMI between 27 and 30 kg/m^2 was correlated with lower all-cause mortality as compared to other weight groups. Introduction of a blanking time (< 30 d) to exclude periprocedural events and an adjustment to different baseline data did not impact on outcomes of their study[16]. These results could be confirmed in the APPROACH registry in 31021 patients treated medically (n = 7801), by PCI (n = 7017) or by CABG (n = 15601)[17]. In the first group, mortality rates were lower in overweight and obese patients as compared to normal ones. Similar findings were found in both the CABG and PCI group. Interestingly, the use of bare-metal stents (BMS), or any metaanalysis of these single trials revealed an inverse relationship between BMI and clinical outcome after stenting[18]. In contrast to the above-mentioned results from the balloon angioplasty and BMS era, some other studies from that time do not support the "obesity paradoxon" in patients with both, BMS or DES. Poston *et al*[19] revealed in 1631 patients that normal weight patients were older than the non-normal weight ones at the time of hospital admission[18]. During one year follow-up mortality and risk for repeat procedures was not different between groups. In the TAXUS trials, 1307 patients were stratified according to BMI and use of stent type (BMS *vs* DES)[20]; restenosis rates with use of BMS were higher in obese and overweight patients as compared to normal weight ones (29.2% *vs* 30.5% *vs* 9.3%, respectively; P = 0.01). Although rates for major cardiac events were also significant different in favour of normal weight patients, clinical event rates were not different in patients receiving DES. These findings were underlined by the results of the German DES.DE registry[21]. At 98 sites in Germany 5806 patients receiving DES in an all-comers design were included and followed over 12 mo. Similar to previous trials baseline comorbidity index was higher in obese patients as compared to overweight and normal weight patient are in-hospital events were similar in all three

groups. One-year follow-up revealed no differences in rates of death (3.3% *vs* 2.4% *vs* 2.4%; $P = 0.17$), myocardial infarction (2.8% *vs* 2.3% *vs* 2.3%; $P = 0.45$), target vessel revascularization (10.9% *vs* 11.7% *vs* 11.6%; $P = 0.56$) and major bleeding (2.5% *vs* 2.1% *vs* 2.8%; $P = 0.53$) between normal weight, overweight and obese patients, respectively (Table 1).

ACUTE CORONARY SYNDROME

In contrast to stable coronary artery disease an acute myocardial infarction is characterized by a proinflammatory state with different forms of hemodynamic, rhythmogenic and hemostatic disturbances. The phenomenon of an "obesity paradoxon" has also been evaluated in this patient population; yet, data on a potential link between BMI and clinical events in patients with acute myocardial infarction are scarce and inhomogenous in the literature. Data from the PREMIER and TRIUMPH registries including 6359 patients with acute coronary syndrome were taken to look for any relationship between BMI with survival rate[22]. Similar to patients with stable coronary artery disease there was an inverse relationship between BMI and rate of mortality (9.2% *vs* 6.1% *vs* 4.7%; $P < 0.001$) without any interactions of demographic data like age and sex. Similar findings were revealed in the KAMIR registry involving 3824 patients with ST-elevated myocardial infarction[23]. Baseline characteristics were characterized by the fact that normal weight patients were older, had more impairment of left ventricular ejection fraction, and a higher comorbidity index. Nevertheless, normal weight in this scenario was associated with higher mortality. In contrast of these trials several other trials showed no inverse relationship between BMI and clinical outcome[24,25]. Our group analyzed 890 patients suffering from ST-elevated myocardial infarction including patients with cardiogenic shock and followed them up to 12 mo; clinical events were not significantly different between all three weight groups, again challenging an obesity paradox. These findings were also seen in patients suffering from cardiogenic shock[26] (Table 2).

RATIONALE FOR THE "OBESITY PARADOX"

Self-reported obesity increased by 37% from 13.6% to 18.6% among men aged 35-49 since 1970. Simultaneously, epidemiology of other cardiovascular risk factors like arterial hypertension and diabetes increased[27,28]. However, mortality attributed to coronary events declined during the last 40 years mainly due to decreased cholesterol levels and damaging smoking habits with greatest reduction seen in overweight and obese patients, and to some degree as a result of more frequent revascularization[29-31]. Nevertheless, overweight and obesity, as part of the metabolic syndrome, are still linked to other cardiovascular risk factors, endothelial dysfunction, and inflammation and are often associated with an increased risk of suffering from atherosclerosis.

The key question to answer is how to explain better survival rates from coronary events despite increasing rates of obesity in light of above mentioned correlation. There is an ongoing debate whether the phenomenon of "obesity paradoxon" is real in the space of coronary artery disease[10-26].

Close examination of the current literature revealed that some published and most often retrospective data just claimed a U-shaped nonsignificant trend towards lower survival among underweight patients, compared with normal or mildly overweight patients; this however might predominantly result from a technical bias, that cannot be completely corrected by statistical means.

Detailed analyses reveal that up to 2% of patients who were underweight were likely to suffer from comorbid conditions, including malignancies, heart failure, malnutrition, multiorgan dysfunction, and happened to be significantly older than the normal and obese patients[10,11,15]. There is clear evidence that elderly and frail patients have worse clinical outcomes after any coronary event regardless of reperfusion or reperfusion strategy[32,33]. It is important to recognise that increasing age with its concomitant comobidity index results in weight change[34,35]. Chronic diseases might lead to gradual weight-loss, which is not taken

into consideration in presented trials. Along these lines, another important confounding observation was the fact that obese patients tended to be diagnosed and treated at an earlier stage than lean patients[36]. Furthermore, the "obesity paradoxon" is clearly challenged by a recent survey on > 130000 patients, revealing that adherence to guidelines was better with higher BMI with regards to standard medication such as aspirin, b-blockers, acetylcholinesterase inhibitor and angiotensin Ⅱ receptor blockers, as well as lipid lowering drugs and also an increased likelihood of receiving invasive diagnostic and treatment[15,18,21]. Furthermore overweight and obese patients present in a much more stable status with lack of hemodynamic compromise, lower Killip class, and less impairment of ventricular function. Novel theories to explain the "obesity paradoxon" after PCI have included the suggestion that obese patients have "larger vessels" and outcome after PCI is worse in patients with smaller vessel[37,38]. Antithrombotic medications usually given as standard dosage and not weight adjusted, may be too high in normal weight and underweight patients according to their BMI, resulting in more bleeding events which are associated with higher mortality rate[39]. Similarly, sheath-to-artery size ratio is different in BMI groups resulting in different rates of vascular complications[15]. All these differences in periprocedural events can contribute to improved survival among overweight patients[11,40]. The fact that BMI alone was the only measure of obesity is containly a limiting factor. There is no information in several trials regarding the distribution of obesity that might be very important, as there is a worse outcome in patients with central obesity[41]. Moreover additional information regarding waist circumference, waist-to-hip ratio and weight changes are missing in several trials describing the "obesity paradoxon"[42-45]. Additionally, all trials supporting the "obesity paradoxon" suffer from the inherent limitation of an observational retrospective registry. Potentially confounding variables such as physical inactivity, unintended weight loss and even socioeconomic factors were not analyzed, and may be the source to further bias, not to mention the short follow-up of these registries. Eventually any potential relation between obesity and in-hospital and short-term survival may be lost the longer patients are followed. Therefore with extended follow-up a cumulative detrimental effect of obesity may manifest over time as increased late mortality[46,47].

It is sensible to ask what is left to support the so-called "obesity paradoxon", or is it just a paradoxical concept? Protagonists claim that adipose tissue is being recognized as an endocrine organ[48] that produces soluble tissue necrosis factor receptor with its protective effect[49]. Morbidly obese patients (BMI > 40 kg/m^2) certainly have higher adjusted rates of post-PCI mortality that might be due to higher levels of prothrombotic factors as well as elevated levels of plasminogen activator inhibitor- Ⅰ[50]. On aggregate, while early studies may have suggested an inverse relationship between being underweight with outcomes in heart failure, which led to the assumption of a "obesity paradoxon", the analysis of the published evidence denies any such "obesity paradoxon" in the context of coronary artery disease and modern coronary interventions. In fact there is no plausible concept to turn away from the classic relationship between risk factors, confounding variables and prognostic outcomes. The limitations of such association studies are not only the lack of a pathophysiologic underpinnings, but moreover the mere association with descriptive notions and the unknown impact of confounding variables. With respect to the neutralizing results from the German DES.DE Registry[21], the perception of obesity as a protective condition of outcomes after PCI is shattered and the provocative construct of an "obesity paradoxon" evaporates, as such hypothesis was never really substantiated in the clinical setting of coronary artery disease and PCI. Finally, as it turns out, associative studies with little to no statistical evidence lended support to invent a "obesity paradox" which was never supported by biological evidence and seems now shattered by new interpertation of recent clinical data. Any concept will eventually survive only if supported by plausible physiology. In the context of coronary artery disease and PCI there is hardly any plausible explanation and certainly no clinical data to justify an "obesity paradoxon".

Abstract

Atherosclerosis manifests itself clinically at advanced stages when plaques undergo hemorrhage and/or rupture with superimposed thrombosis, thus abruptly stopping blood supply. Identification of markers of plaque destabilization at a pre-clinical stage is, therefore, a major goal of cardiovascular research. Promising results along this line were provided by studies investigating the lipoprotein-associated phospholipase A2 (Lp-PLA2), a member of phospholipase A2 proteins family that plays a key role in the metabolism of pro-inflammatory phospholipids, as oxidized low-density lipoproteins, and in the generation of pro-atherogenic metabolites, including lysophosphatidylcholine and oxidized free fatty acids. We herein review the experimental and clinical studies supporting use of Lp-PLA2 activity for predicting cardiovascular events. To his end we considered not only Lp-PLA2 activity and mass, but also *Lp-PLA2* gene variations and their association with incident coronary artery disease, stroke, and cardiovascular mortality. Based on these evidences the major scientific societies have included in their guidelines the measurement of Lp-PLA2 activity among the biomarkers that are useful in risk stratification of adult asymptomatic patients at intermediate cardiovascular risk. The results of two recently published major clinical trials with the Lp-PLA2 inhibitor darapladib, which seem to challenge the pathogenic role of Lp-PLA2, will also be discussed.

Key words: Lipoprotein-associated phospholipase A2; Atherosclerosis; Coronary artery disease; Myocardial infarction; Prognosis

Core tip: Lipoprotein-associated phospholipase A2 (Lp-PLA2) is a promising new marker of atherosclerotic plaque destabilization, which plays a key role in the metabolism of pro-inflammatory phospholipids and in the generation of pro-atherogenic metabolites. This review focuses on the experimental and clinical studies supporting use of Lp-PLA2 for predicting cardiovascular events considering not only Lp-PLA2 activity and mass, but also *Lp-PLA2* gene variations. Based on current evidences the major scientific

societies have included Lp-PLA2 activity measurement in their guidelines among the biomarkers that are useful in risk stratification of adult asymptomatic patients at intermediate cardiovascular risk.

INTRODUCTION

Exposure of endothelial cells to damaging stimuli, as smoking, arterial hypertension, diabetes mellitus, dyslipidemia can induce qualitative changes that are collectively defined as "endothelial activation", and are currently postulated regarded as one of the earliest events in atherogenesis[1]. An "activated" endothelium expresses adhesion molecules and chemotactic substances, increases its permeability to macromolecules with ensuing variation of the sub-endothelial extracellular matrix composition. As a result, low-density lipoproteins (LDLs), particularly those that are smaller and denser and therefore more pro-atherogenic, penetrate the vessel wall and remain trapped in the sub-intimal space, where they undergo oxidative changes. Oxidized LDLs induce recruitment of monocytes by vascular cells and promote their differentiation into macrophages[2]. The latter internalize oxidized LDLs and become foam cells[3], the distinctive feature of the atherosclerotic lesions.

Atherosclerosis manifests itself clinically either when the arterial vessel stenosis prevents the increase of blood flow and oxygen supply during augmented demand (*e.g.*, exercise or digestion) causing the onset of pain (angina pectoris, abdominis or claudication intermittens, depending on the segments involved), or when an unstable plaque undergoes hemorrhage and/or rupture with superimposed thrombosis.

Several studies showed that athero-thrombosis, which is responsible for acute ischemic events, does not correlate strictly with the degree of atherosclerotic plaque narrowing[4,5], but rather with the plaque features, and, more specifically, with the extent of inflammation, thinning of the fibrous cap, and expression of inflammatory cytokines and metalloproteinases that degrade the fibrous cap[6,7]. This explains why the atherosclerotic disease might manifest clinically with acute catastrophic events even in patients with apparently mild lesions.

Identification of circulating markers that can be useful to improve the prediction of cardiovascular events is akin the current frontiers of Cardiology. C-reactive protein and cholesterol levels, despite being among the most studied biomarkers[8,9], bear a rather small predictive value: for example, in the Framingham Heart Study most of the patients who developed ischemic heart disease during twenty-six years follow-up had "normal" total cholesterol levels comparable to those not developing any cardiovascular disease[10].

In the Get with the Guidelines study database[11], which included 231896 patients admitted to 541 United States hospitals with a diagnosis of acute coronary syndrome, 136905 (59%) subjects had the lipid levels determined at admission and 21.1% of them were treated with cholesterol-lowering drugs. The average lipid profile was: LDL cholesterol 104.9 mg/dL (2.17 mmol/L), high-density lipoprotein (HDL) cholesterol 39.7 mg/dL (1.03 mmol/L), and triglycerides 161 mg/dL (1.82 mmol/L). According to this study about half of the patients admitted to the hospital with an acute coronary syndrome had LDL cholesterol levels in the normal range (Figure 1)[11]. These data provide compelling evidence for the urgent need to perform clinical and laboratory research to identify new biomarkers of imminent plaque destabilization. Along this line, encouraging results were provided by studies investigating the lipoprotein-associated phospholipase A2 (Lp-PLA2), a member of phospholipase A2 proteins family that plays a crucial role in the metabolism of pro-inflammatory phospholipids, such as oxidized LDLs, and in the generation of pro-atherogenic metabolites, such as lysophosphatidylcholine and oxidized free fatty acids (Figure 2).

ROLE OF LP-PLA2 IN ATHEROSCLEROSIS

Lp-PLA2 is a calcium-independent lipase mainly produced by monocytes and macrophages[12], which catalyze the hydrolysis of the sn-2 acyl chain of the phospholipid substrate[13] on the surface of LDLs[14], releasing lysophosphatidylcholine and oxidized fatty acids. The latter are well-established triggers of the inflammatory cascade[14-16], *via* stimulation of endothelial cells expression of adhesion molecules and cytokines, induction of chemotaxis of monocytes and leucocytes, and promotion of their entry in the sub-intimal space of the arterial walls.

The accumulation of lysophosphatidylcholine and oxidized fatty acids in the sub-intimal space contributes to the development of the plaque lipid "core". Moreover, these substrates once taken up by macrophages promote their conversion into foam cells[17]. In addition, lysophosphatidylcholine induces the production of reactive oxygen species, such as superoxide, by activating the endothelial nicotinamide adenine dinucleotide phosphate oxidase and by inducing the endothelial nitric oxide synthase (eNOS) "uncoupling"[18,19]. Through the latter mechanism the enzyme becomes a superoxide and peroxynitrite producer, thus contributing to atherogenesis and plaque destabilization, as corroborated by the increased cardiovascular mortality found in coronary artery disease patients carrying an *eNOS* gene polymorphism that implies enhanced eNOS

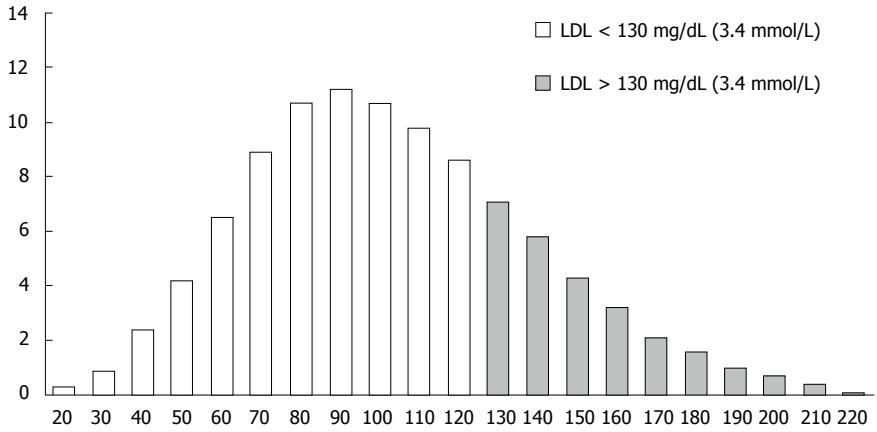

Figure 1 Low-density lipoprotein cholesterol levels on admission in patients with acute coronary syndrome[74]. LDL: Low-density lipoprotein.

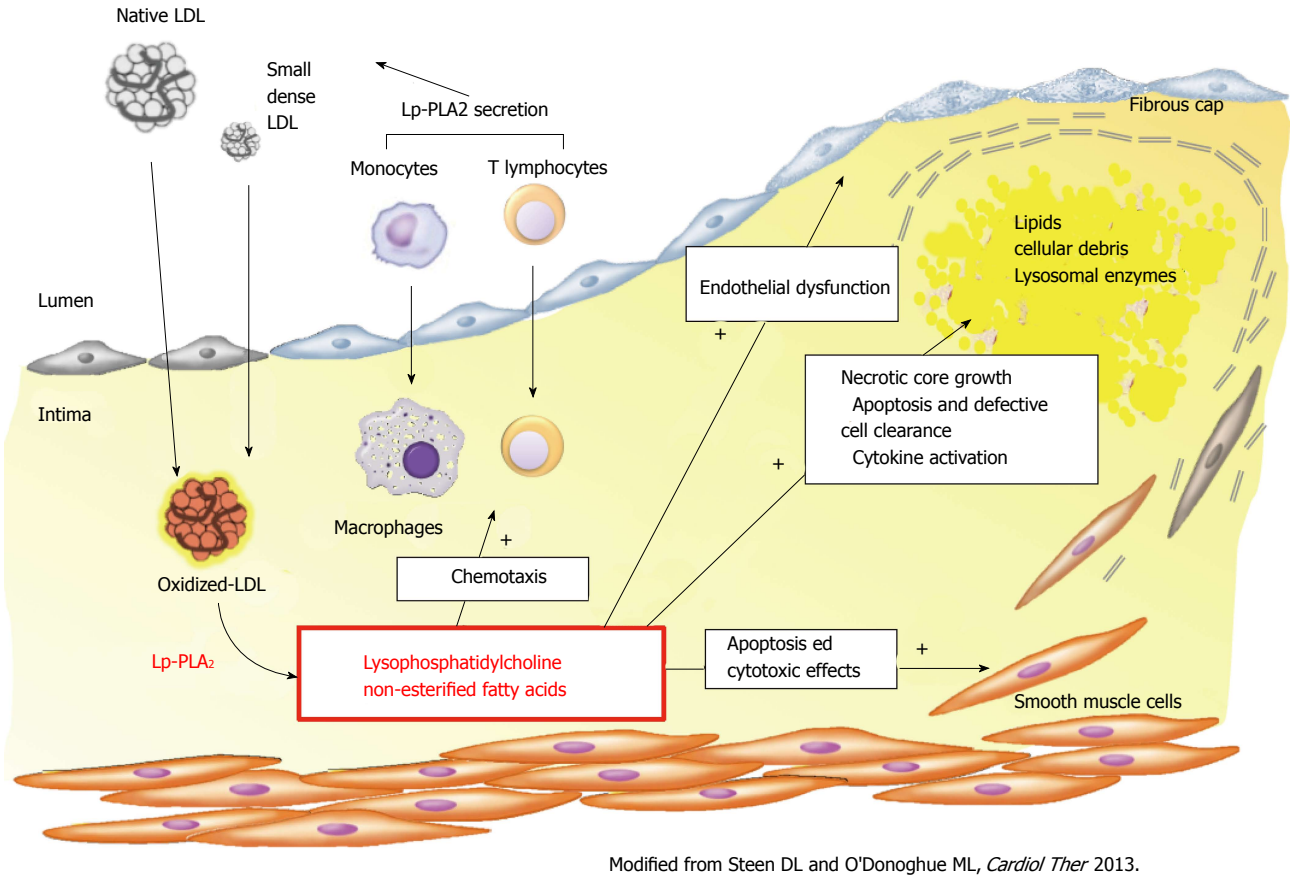

Modified from Steen DL and O'Donoghue ML, *Cardiol Ther* 2013.

Figure 2 Pathogenic role of lipoprotein-associated phospholipase A2 in atherosclerosis development. LDL: Low-density lipoprotein; Lp-PLA2: Lipoprotein-associated phospholipase A2.

expression and reactive oxygen species generation[20].

In summary, experimental evidences indicate that due to its pro-inflammatory and pro-oxidative effects Lp-PLA2 plays a key role in the pathogenesis of atherosclerosis.

LP-PLA2 SECRETION AND CIRCULATION IN THE BLOOD-STREAM

Hematopoietic (monocytes, macrophages, lymphocytes, mastocytes, and platelets) and hepatic cells (Kupffer's cells) produce Lp-PLA2; however, its synthesis and release in the circulation occur with monocytes maturation into macrophages[21] alongside activation by inflammatory mediators[22].

In the bloodstream Lp-PLA$_2$ circulates by two-thirds bound to the LDLs and by one third to HDLs[23,24]. It is, however, worth highlighting that with normal LDL-levels the total plasma Lp-PLA2 activity associated with HDL accounts for only 4.9% of the total enzyme activity[25].

Plasma ultracentrifugation leads to partial separation

of Lp-PLA2 from the lipoproteins, thus indicating that there is a dissociable and a non-dissociable form of the enzyme[26]. The transition between them might be one of the mechanisms regulating the activity of Lp-PLA2 *in vivo*. The association with HDL and LDL is controlled by post-translational chemical modifications: Glycosylation of specific residues decreases the association of Lp-PLA2 and lipoproteins, even though these changes do not seem to influence the enzyme secretion by the cells[27].

As regards the relationship of Lp-PLA2 with apolipoproteins, B100 plays a key role in the association of Lp-PLA2 with LDLs, especially its carboxyl terminus, which interacts with the Lp-PLA2 residues Tyr-205, Trp-115, and Leu-116 and, to lesser extent, with the Met-117[28]. In spite of the fact that Lp-PLA2 preferentially associates with the most dense and electronegative LDLs fractions, even among the latters only 1% of the particles contain Lp-PLA2[29-31]. As mentioned, only one third of Lp-PLA$_2$ circulates in plasma with HDLs. Multiple amino-acid residues, as well as the carbohydrate content of the enzyme, appear to play a crucial role for its association with HDL apolipoprotein A-I[27,32].

Finally, when plasma lipoprotein(a) concentrations are $\geqslant$ 30 mg/dL detectable amounts of Lp-PLA2 are associated with this lipoprotein. A major role for its attachment is played by apolipoprotein B-100[33].

PLASMA LP-PLA2 DETERMINATION

Originally specific tests were developed to determine the Lp-PLA2 plasma concentration (mass) and enzymatic activity. The plasma mass assays were thereafter abandoned due to lack of significant advantages and lower accuracy in patients' risk stratification than enzymatic activity assays. The assessment of Lp-PLA2 activity exploits enzymatic substrates, such as 2 Tio-PAF, whose degradation releases free thiol groups, which are detectable by spectrophotometric reading.

GENETIC DETERMINANTS OF LP-PLA2 ACTIVITY

The prognostic relevance of Lp-PLA2 measurement raised the question whether the enzyme levels and activity are genetically determined ("nature") or influenced by environmental factors ("nurture"). According to one study and a recent meta-analysis Caucasians carry higher Lp-PLA2 activity levels than Hispanics and African-Americans, suggesting that Lp-PLA2 is genetically influenced[34,35]. Moreover, Lp-PLA2 activity was reported to be 10% lower in females compared to males, possibly due to higher estrogen levels in the former, which down-regulate Lp-PLA2 activity and decrease LDL-cholesterol[34,35]. A conclusive demonstration of hereditability was provided by twins' studies. In fact, genetically identical monozygotic twins showed differences in their plasma levels of Lp-PLA2 much smaller than dizygotic twins, who share only half of their genes, thus showing that about 62% of the variance of Lp-PLA2 activity levels is under genetic control[36].

The *Lp-PLA2* gene (*PLA2G7*) is located in chromosome 6p21.2 to 12 and entails 12 exons. Its cDNA was cloned in 1995[37] and comprises an open reading frame codifying a precursor of 441 amino acids that is cleaved into a 45.4 kDa mature protein[38]. The *PLA2G7* gene is characterized by non-synonymous polymorphisms that could cause reduction or loss of the enzymatic activity.

The first evidence of the functional relevance of these mutations dates back to the identification of five Japanese families with absent circulating Lp-PLA2, an autosomal recessive trait[39] linked to a Val279Phe polymorphism on the exon 9[40]. This variant causes the absence of Lp-PLA2 enzymatic activity because of an amino acid change in proximity of Ser-273 and Asp-296 that is responsible of folding and, thus, functioning of the mature protein.

The Val279Phe polymorphism was associated to atherosclerosis[41,42], stroke[43], and dilated cardiomyopathy[44]. However, these early evidences, which have been produced when Lp-PLA2 was believed to be anti-atherogenic, were not confirmed by subsequent studies that, in fact, showed just opposite results[45]. Thus, it remains unclear whether the lack of Lp-PLA2 activity is pro- or anti-atherogenic and if carriers of this genetic variant, who are exclusively Asian, could have inherited compensatory mechanisms that change unpredictably the final clinical phenotype.

Other polymorphisms were thereafter identified in Caucasians[46,47]: Arg92His (exon 4), Ile198Thr (exon 7), Ala379Val (exon 11). In particular, the Ile198Thr variation is located near the Tyr205 residue, a binding site for LDLs, in a position that might decrease the affinity for the substrate, thus explaining the observed reduction of enzymatic activity[46]. Another polymorphism, the Ala379Val, is located near the residue belonging to the catalytic triad of lipase (Hys-351), suggesting that it could influence the enzymatic activity[48].

Ala379Val and Arg92His variants have been associated with coronary artery disease (CAD)[49], but only the former correlated with the severity of atherosclerosis in a Taiwanese population[50] and to acute myocardial infarction in two case-control studies[49,50]. In other studies this association was neither confirmed[51] nor denied[52,53]. Two recent meta-analyses[54,55], which included more than 10000 patients of European ancestry, failed to demonstrate any association between the *PLA2G7* gene polymorphisms and CAD risk. These studies, as well as the meta-analyses that included them, were biased and affected by confounding factors, in that: (1) only a minority of studies used a prospective cohort study design, which is more reliable compared to case-control studies; and (2) the adjustment for potential confounders by multivariate analysis was not consistently performed. Therefore, likely their results

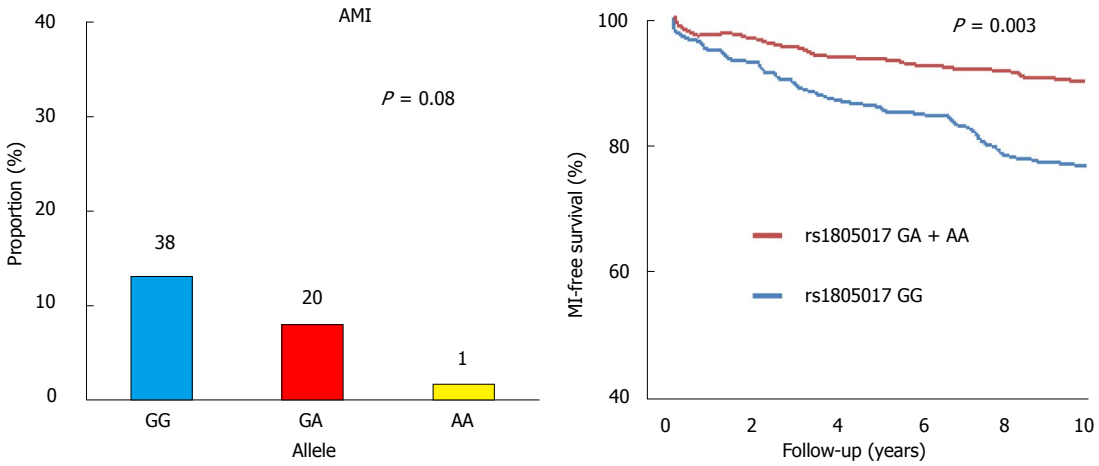

Figure 3 Increased number of acute myocardial infarction depending on the variant gene Arg92His. A: The patients with variant gene GG (Arg92) have a greater number of infarcts compared to the other two variants; B: The Kaplan-Meyer curve shows a lower survival free from acute myocardial infarction in patients with variant GG (Arg92). AMI: Acute myocardial infarction.

could not be considered conclusive even despite the large number of patients analyzed.

A recently published prospective cohort study performed with an appropriate prospective cohort design and an utmost care to the role of potential confounders, showed that Arg92His is associated to both high levels of Lp-PLA2 activity, and a 1.75-fold increase of relative risk of acute myocardial infarction (Figure 3)[56]. Hence, it would appear that genetic predisposition to high Lp-PLA2 activity translates into increased susceptibility to acute coronary events.

LP-PLA2 ACTIVITY AND CARDIOVASCULAR DISEASE

The first study showing an association between elevated Lp-PLA2 plasma levels and cardiovascular events was the West of Scotland Coronary Prevention Study (WOSCOPS)[57]. Other studies thereafter confirmed Lp-PLA2 to be a predictor of cardiovascular events in different cohorts[58-66], but the large Women Health Study[67], which enrolled a healthy female population, found just an opposite association. In apparently healthy populations, three trials demonstrated the Lp-PLA2 prognostic role. In the ARIC study, which enrolled a large cohort of healthy subjects of both genders, those with low LDL cholesterol (< 130 mg/dL) and high Lp-PLA2 levels had an increased relative risk of ischemic heart disease [HR 2.08, 95% confidence interval (CI): 1.20-3.62] compared to those with low levels of Lp-PLA2[68]. The JUPITER trial also showed that patients with high Lp-PLA2 activity (fourth quartile) had a more than two-fold increased relative risk (HR 2.15, 95%CI: 1.13-4.08) of developing cardiovascular events than those with low activity (first quartile)[69]. Finally, the Bruneck study also reported that the population in the third tertile of Lp-PLA2 activity had a higher relative risk of incident cardiovascular events (HR 2.2, 95%CI: 1.1-4.8) compared to those in the first tertile[70].

Lp-PLA2 activity might predict the occurrence of events also in patients at high cardiovascular risk: in the MDCS study, which enrolled healthy subjects, those with metabolic syndrome and high Lp-PLA2 activity had a 1.97 (95%CI: 1.34-2.90) relative risk of cardiovascular events[71]. The combined analysis of two studies, HPFS and NHS, including patients with diabetes mellitus, showed that those with a high Lp-PLA2 activity had a 1.75 (95%CI: 1.05-2.92) relative risk of cardiovascular mortality and AMI[72].

The ability of Lp-PLA2 to predict cardiovascular events was also confirmed in subjects with cardiovascular disease. The VA-HIT study, which included patients with ischemic heart disease, the increase of Lp-PLA2 activity levels was associated with a higher relative risk of cardiovascular events (HR 1.17, 95%CI: 1.04-1.32) and death (HR 1.23, 95%CI: 1.01-1.50)[73]. Similar results were obtained in the LIPID trial that entailed subjects with history of acute coronary syndrome in whom Lp-PLA2 activity was associated to a higher risk of cardiovascular mortality (HR 1.32, 95%CI: 1.00-1.75)[74]. Another study that included 1051 patients affected by CAD showed that Lp-PLA2 activity predicted the risk of cardiovascular events (HR 2.40, 95%CI: 1.35-4.29)[63]. Finally, in a large cohort of subjects with CAD of the GENICA Study, we demonstrated that a high Lp-PLA2 activity level predicted both cardiovascular mortality (HR 1.01, 95%CI: 1.00-1.02) and acute myocardial infarction (HR 1.01, 95%CI: 1.00-1.02) (Figure 4)[75].

Circulating Lp-PLA2 activity levels could be an index of systemic inflammation as suggested by the finding of a direct link between Lp-PLA2 enzymatic activity and activation of lympho-monocytic cells[76]. These data were confirmed by studies on CAD patients (Rotterdam Study and Ludwigshafen Risk and Cardiovascular Health Study) that demonstrated an association

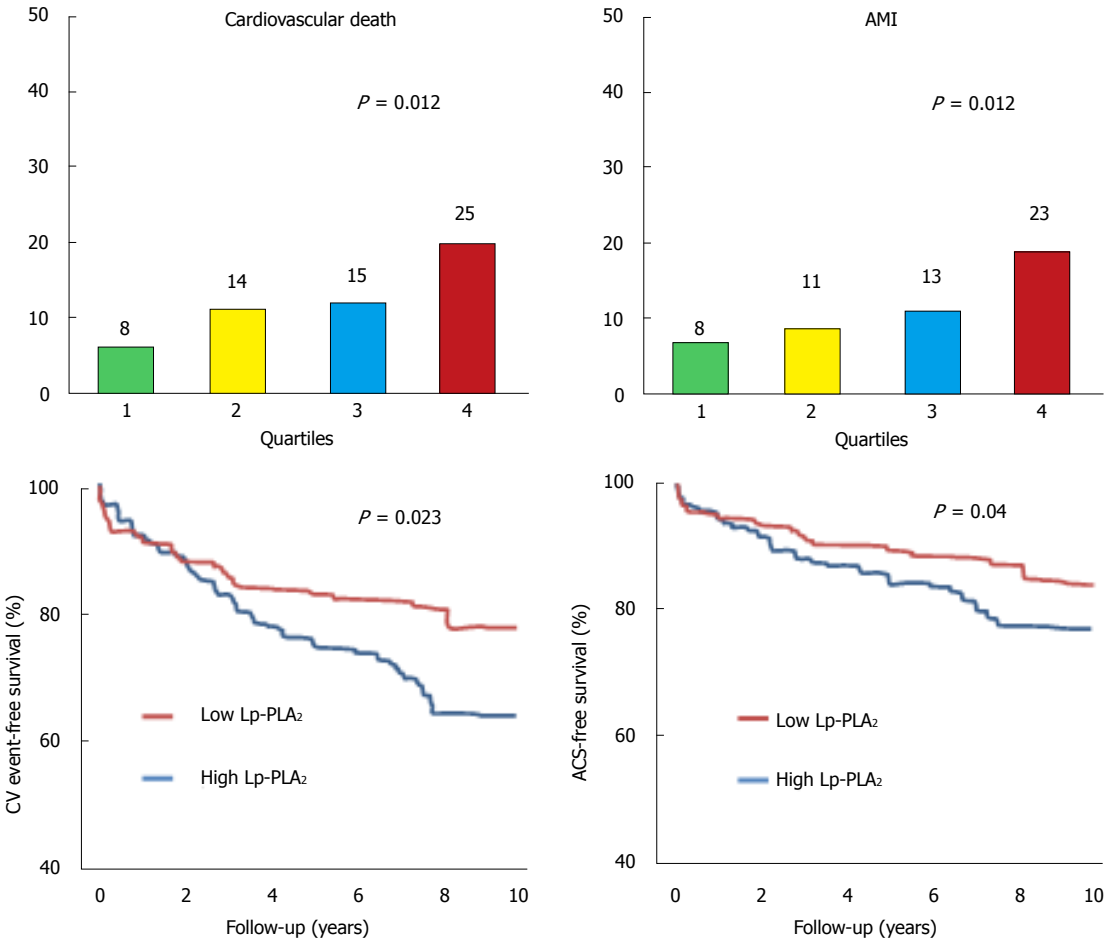

Figure 4 The Kaplan-Meyer curves underline a greater survival free from cardiovascular events (death, acute myocardial infarction) in patients with lower lipoprotein-associated phospholipase A2 activity. ACS: Acute coronary syndrome; CV: Cardiovascular.

between Lp-PLA2 enzymatic activity and CAD risk[77,78].

A meta-analysis that included all prospective studies conducted on Lp-PLA2 including a total of 79036 patients showed a relationship between Lp-PLA2 activity and mass and incidence of CAD, stroke, and cardiovascular mortality[79].

LP-PLA2 AND GUIDELINES

Based on these evidences, the guidelines of four major international societies, including the European Society of Cardiology, the American College of Cardiology, the American Heart Association, and the American Society of Endocrinology, included the Lp-PLA2 activity measurement among the biomarkers that are useful for risk stratification of asymptomatic adult patients. The use of this marker is particularly advantageous in patients at moderate cardiovascular risk (> 2 risk factors) and in those at high-risk in whom an increase of Lp-PLA2 activity levels should guide the lipid-lowering treatment to reach a target LDL-cholesterol lower than, respectively, 130 mg/dL (< 3.3 mmol/L) or 100 mg/dL (< 2.5 mmol/L) in primary prevention[80] (Figure 5).

THERAPEUTIC STRATEGY TO REDUCE LP-PLA2 LEVELS

As the majority of plasma Lp-PLA2 is linked to LDLs, a therapeutic strategy aimed at decreasing LDL cholesterol levels could be expected to reduce Lp-PLA2 activity. Accordingly, several cholesterol-lowering treatments, such as statins[66,74,81,82], fibrates[81,83], ezetimibe[81], and omega-3 fatty acids[84], were found to reduce plasma Lp-PLA2 activity. However, it remained unclear whether the reduction of Lp-PLA2 activity with a lipid-lowering treatment translates into a lower mortality and cardiovascular event rate, and if these benefits could be explained by the reduction of plasma lipids, of Lp-PLA2 activity levels, or of both. This hypothesis has been tested in the LIPID (Long-term Intervention with Pravastatin in Ischemic Disease) study, a double blind multicenter trial that randomized to placebo or pravastatin 9014 patients with CAD[74]. The levels of many biomarkers, such as cholesterol fractions and Lp-PLA2 activity were determined at "baseline" and after one year of treatment. The study showed that after one-year follow-up, the statins group

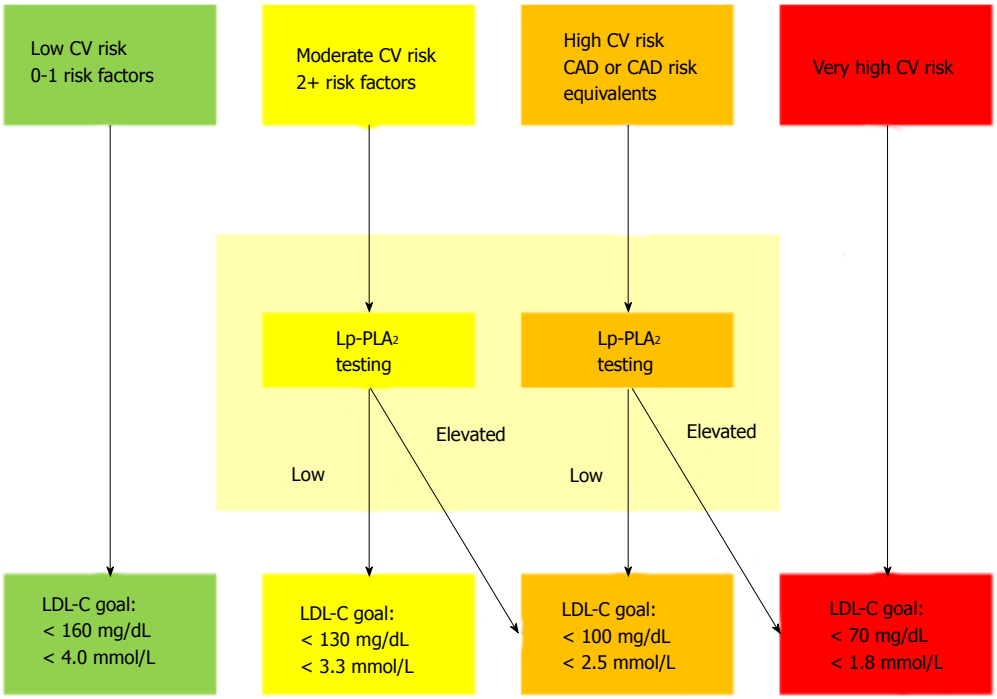

Figure 5 Relevance of measuring of lipoprotein-associated phospholipase A2 activity for risk stratification in adult patients with moderate cardiovascular risk (> 2 risk factors) or higher[80]. Lp-PLA2: Lipoprotein-associated phospholipase A2; LDL: Low-density lipoprotein; CAD: Coronary artery disease; CV: Cardiovascular.

had a reduction Lp-PLA2 activity (50 nmol/min per milliliter, $P < 0.001$) compared to both baseline values and to the placebo group. Similarly to previous studies, the "baseline" values of Lp-PLA2 activity predicted the risk of cardiovascular events, including CAD mortality and acute myocardial infarction, and total mortality; after adjustment at multivariate analysis, the baseline values of Lp-PLA2 activity predicted only CAD mortality. The key finding was that after one year of treatment low Lp-PLA2 levels predicted less major CAD events (HR 0.65, 95%CI: 0.50-0.86, $P = 0.002$), less major cardiovascular events (cardiovascular death, less non fatal acute myocardial infarction or stroke, HR 0.70, 95%CI: 0.55-0.89, $P = 0.003$), and less cumulative cardiovascular events (major cardiovascular events, unstable angina, revascularization, HR 0.70, 95%CI: 0.59-0.83; $P < 0.001$), comparing the first with the fourth quartile of Lp-PLA2 levels. These prognostic value persisted unaltered after adjustment for twenty-three risk factors at enrolling, which led the authors to conclude that the reduction of Lp-PLA2 during treatment with statin was as predictive, or even more predictive, than the decrease of LDL cholesterol[74]: about 59% of the beneficial effects of pravastatin were explained by a decrease of Lp-PLA2 values. This study could not, however, verify whether the reduction of circulating Lp-PLA2 was associated with a decrease of the enzyme activity into the atherosclerotic plaque, a data that, if confirmed, could explain the observed decrease of events.

RANDOMIZED CONTROLLED CLINICAL TRIALS TESTING THE EFFICACY OF LP-PLA2 INHIBITORS

This piece of information was, however, obtained, in diabetic and dyslipidemic pigs: darapladib, a Lp-PLA2 inhibitor, reduced the lysophosphatidylcholine levels in coronary artery plaques and decreased macrophage infiltration and necrotic "core" in the plaques[85]. Moreover, in the IBIS-2 study in humans, darapladib decreased the Lp-PLA2 activity and the necrotic "core" in coronary plaques[85]. Two randomized trials were conducted to test whether pharmacological inhibition of Lp-PLA2 with darapladib reduces cardiovascular events in stable and unstable CAD and were recently published, the STABILITY[86] and the SOLID-TIMI 52[87].

The STABILITY trial randomized 15828 patients with stable CAD to receive darapladib or placebo for a median period of 3.7 years with a composite primary end-point of cardiovascular death, myocardial infarction, or stroke[86]. The trial fell short of proving its primary end-point and could not demonstrate any beneficial effect of darapladib on each individual component of the primary end-point, or on the overall mortality. However, it demonstrated a beneficial effect of Lp-PLA2 inhibition in that darapladib reduced the rate of major coronary events and total coronary events.

The SOLID-TIMI 52 trial enrolled 13026 patients with an acute coronary syndrome in the last 30 d

before randomization to darapladib or placebo for a median period of 2.5 years with a composite primary end-point of cardiovascular death, myocardial infarction or urgent coronary artery revascularization[87]. The results did not demonstrate any beneficial effect of darapladib on any of the either primary or secondary endpoints.

These disappointing results might seem to challenge the pathogenic role of Lp-PLA2 in atherosclerosis and plaque destabilization. However, considering the wealth of data demonstrating that Lp-PLA2 predicts cardiovascular events, one could argue that the plasma activity of Lp-PLA2 is only a prognostic marker and does not play a causative role. Another possibility is that the trials, due to the high rate of drug discontinuation (20% in the STABILITY trial and 17% in the SOLID TIMI 52), ultimately lacked the statistical power to challenge the hypothesis that darapladib is efficacious in reducing cardiovascular events. If this was the case the possibility that another, possibly better tolerated, antagonist could improve outcomes needs to be tested. Furthermore, the selection criteria did not include a threshold Lp-PLA$_2$ level, whereas it is well known that the risk of cardiovascular events is dependent on the Lp-PLA2 levels. Moreover, the drug adherence assessment used, *e.g.*, pill count, is well known to underestimate the true therapeutic compliance[88]. The absence of any report of the Lp-PLA2 levels reached after darapladib administration, testing the therapy efficacy and the patients' compliance, is a missing crucial piece of information in these trials.

At present, from the available data it is possible to speculate that darapladib is not an efficacious therapy. Considering the extensive proof of the Lp-PLA2 prognostic value and the crucial information missing in the completed trials, it is possible to hypothesize that Lp-PLA2 is a marker of disease and does not have a pathogenic role, or that another more efficacious way to inhibit Lp-PLA2 activity by means of new drugs should be investigated.

CONCLUSION

In summary, compelling evidence indicate that high Lp-PLA2 activity levels predict an increased risk of cardiovascular events in the general population, as well as in patients with metabolic syndrome, diabetes, and coronary heart disease[63,68-75]. Many cholesterol-lowering medications besides decreasing LDL-cholesterol lower circulating Lp-PLA2 levels. Moreover, the Lp-PLA2 levels achieved with pravastatin treatment is a marker of cardiovascular risk and coronary events, even better than the LDL cholesterol level[74]. The available evidences support the usefulness of the measurement of plasma Lp-PLA2 activity in the clinical practice to stratify the cardiovascular risk, especially in patients at intermediate or high risk. In these subjects Lp-PLA2 activity levels should prompt the physician to pursue two aims: (1) a more aggressive LDL-cholesterol treatment; and (2) the normalization of Lp-PLA2 levels (Figure 5). For this reason, the scientific societies guidelines introduced the measurement of Lp-PLA2 as a marker of risk in these categories of patients.

The role of Lp-PLA2 as a therapeutic target has been disproven by two large randomized clinical trials thus far. However, due to their intrinsic limitations, it remains unclear if these results depended on the Lp-PLA2 being only a marker of cardiovascular events devoid of a pathogenic role, or on the lack of efficacy of the drug tested in these trials. Further studies are needed to resolve this dilemma.

Abstract

In remote ischemic conditioning (RIC), several cycles of ischemia and reperfusion render distant organ and tissues more resistant to the ischemia-reperfusion injury. The intermittent ischemia can be applied before the ischemic insult in the target site (remote ischemic preconditioning), during the ischemic insult (remote ischemic perconditioning) or at the onset of reperfusion (remote ischemic postconditioning). The mechanisms of RIC have not been completely defined yet; however, these mechanisms must be represented by the release of humoral mediators and/or the activation of a neural reflex. RIC has been discovered in the heart, and has been arising great enthusiasm in the cardiovascular field. Its efficacy has been evaluated in many clinical trials, which provided controversial results. Our incomplete comprehension of the mechanisms underlying the RIC could be impairing the design of clinical trials and the interpretation of their results. In the present review we summarize current knowledge about RIC pathophysiology and the data about its cardioprotective efficacy.

Key words: Remote ischemic conditioning; Ischemic heart disease; Percutaneous coronary intervention; Cardiac surgery; Atherosclerosis

Core tip: Remote ischemic conditioning (RIC) is a safe, non-invasive, and inexpensive technique that has the potential to protect the heart against the ischemia-reperfusion injury. Its cardioprotective efficacy is currently being evaluated, and diverging results are emerging. It is thus worth resuming current understanding of RIC pathophysiology and clinical efficacy.

INTRODUCTION

The myocardium can tolerate brief periods (up to 15 min) of severe and even total ischemia. Such ischemic episodes occur in the settings of angina, coronary vasospasm, and balloon angioplasty, and are not associated with concomitant myocyte cell death. With increasing duration and severity of ischemia, greater myocardial damage, and the predisposition to further damage during reperfusion develop. The combined deleterious effects of coronary occlusion and revascularization configure the "ischemia-reperfusion (IR) injury"[1].

The counterintuitive idea to apply several brief episodes of IR cycles to protect the myocardium against IR injury was firstly advanced in 1986, when Murry *et al*[2] reported that the infarcted area following a 40-min coronary occlusion was reduced if preceded by four 5-min IR cycles. This phenomenon was called "ischemic preconditioning". Its clinical application is hindered by the unpredictable timing of acute myocardial infarction (AMI), and by the necessity to intervene on coronary vessels[3]. However, several IR cycles were found to confer cardioprotection even when applied at the onset of coronary revascularization (ischemic postconditioning)[4,5], both in animals and in human patients undergoing primary percutaneous coronary intervention (PCI).

In 1993, it was demonstrated in anesthetized dogs that 4 episodes of 5-min ischemia and reperfusion in the left circumflex coronary territory, followed by a 1-h occlusion of the left anterior descending coronary artery, significantly reduced the infarct size[6]. The "remote ischemic conditioning (RIC)" paradigm has been progressively extended[7]. At present, RIC is defined as the phenomenon by which brief episodes of ischemia and reperfusion in one vascular bed, tissue, or organ render distant sites resistant to the ischemia-reperfusion injury[7,8]. The IR cycles are effective when applied before myocardial ischemia (remote ischemic preconditioning), during coronary occlusion (remote ischemic perconditioning), and during cardiac revascularization (remote ischemic post-conditioning)[7-12].

The mechanisms conferring protection at distance have not been completely defined[7], yet their characterization would be relevant to achieve a full comprehension of the phenomenon, and to exploit its full potential in clinical practice. In fact, understanding whether humoral mediators, neural mechanisms, or their combination mediate remote ischemic conditioning would be crucial to determine the optimal number of IR cycles, the better site and timing of their application, to select the patients according to age, comorbidities, and medical treatment, and to optimize the overall therapeutic management of the patient.

In the first part of the present review, we analyze current knowledge of the mechanisms underlying RIC, comparing humoral and reflex-mediated mechanisms. In the second half of this work, we attempt a critical analysis of the available literature concerning the cardioprotective potential of RIC in different settings.

THE "HUMORAL HYPOTHESIS" OF RIC, AND POTENTIAL CIRCULATING MEDIATORS

The "humoral hypothesis" has been formulated in the setting of remote ischemic preconditioning (RIPC). It postulates that the IR cycles in a distant site cause the local accumulation of mediators which are then released into the bloodstream and finally reach the heart[7] (Figure 1).

Several data from animal models support this hypothesis. In particular, it has been demonstrated that the effluent from preconditioned hearts could transfer the protection to naïve recipients[13-15]; this protection seems to be mediated by small hydrophobic proteins whose molecular weight ranges between 3.5 and 15-30 kDa[16].

Since these humoral mediators must be effective in remote sites after dilution into the bloodstream, their release from the peripheral tissue has to be massive[16]. The identification of humoral mediators should therefore be relatively easy to perform in animals or humans undergoing a RIPC protocol[16]. Indeed, proteomic approaches have been attempted in both animals and humans, still they have yielded controversial results[17-19].

Among the proteins potentially involved, there are kallistatin, apolipoprotein A-I, and stromal-derived factor 1α (SDF-1α)[16].

Kallistatin is a serine protease which reduces inflammation, apoptosis, and oxidative stress in endothelial cells[20]. It has been recently characterized as a protective factor against renal ischemia-reperfusion injury in mice[21], and has been found to be increased in the plasma of healthy humans undergoing a RIPC protocol[16]. However, its role as a humoral mediator of RIPC has not been properly evaluated yet.

Apolipoprotein A-I has anti-inflammatory properties, which could prove useful in the protection against ischemia-reperfusion injury[18]. In humans, its circulating levels have been found to be either increased[18] or decreased[17,22] after a RIPC protocol; therefore, its exact role is still debated.

Finally, SDF-1α has been proposed to be an important, and possibly the main, mediator of RIPC[23]. In a study on rats, a 50% plasma increment was detected in rats subjected to a RIPC protocol compared to control animals (890 ± 70 pg/mL *vs* 590 ± 50 pg/mL; n = 8, $P < 0.01$)[23]. Nevertheless, the administration of a selective inhibitor of SDF-1α did not completely abrogate the reduction in infarct size following RIPC[24], suggesting the existence of other mechanisms of cardioprotection[24].

Several potential other mediators have been identified: among them, there are microRNAs (miRNAs),

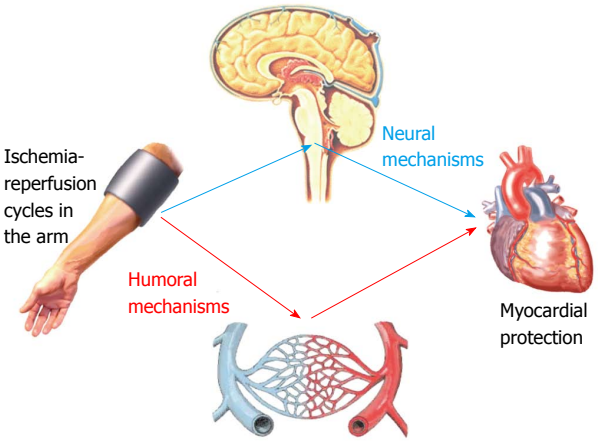

Figure 1 Mechanisms of remote ischemic conditioning. The cardioprotective effects of several ischemia/reperfusion cycles applied in a distant site (most commonly the upper limb) have been ascribed to the activation of humoral and/or neural pathways. The pathogenesis of remote ischemic conditioning is incompletely known, however it is possi-ble that both humoral and neural mechanisms underlie this response.

bradykinin, adenosine, and nitric oxide (NO).

miRNAs have been involved in both muscle ischemia[25] and protection against myocardial IR injury[26]. The circulating levels of miR-144 have been found to increase by 1.6 folds in healthy human subjects undergoing a RIPC protocol, even though the exact mechanism of its action is still unknown[27].

Bradykinin is released by damaged tissues and can activate afferent fibers (see below), possibly contributing to a cardioprotective effect known as "remote preconditioning of trauma"[28]. A release of bradykinin from ischemic tissues into the bloodstream has been reported[29]; the involvement of bradykinin in the RIPC response has been postulated, but the data from an animal study were inconclusive[30].

Finally, both adenosine and NO have been extensively studied in the setting of ischemic preconditioning[31], and have been considered potential mediators of RIPC as well[7,32], although their extremely short half-life makes unlikely that they could exert a significant cardioprotective effect.

To summarize, it is quite established the existence of humoral mechanisms underlying RIPC, but the nature of the mediator(s) is currently unclear. Potential humoral mediators should be assessed with respect to their potential mechanism of action, the increase in their circulating levels following a conditioning protocol, and their half-life; in fact, all these parameters should be compatible with a cardioprotective role. Further studies are required to define the existence and the role of humoral mechanisms underlying RIPC, as well as the other forms of remote ischemic conditioning.

NEURALLY-MEDIATED CARDIOPROTECTION

Neural control of the heart

The autonomic nervous system consists of an afferent pathway, integrating centers located into the central nervous system, and two efferent limbs, the sympathetic and the parasympathetic nervous systems[33]. In the heart, sensory innervation is provided by afferent neurons located into the nodose and dorsal root ganglia, and projecting to brainstem areas controlling the activity of both sympathetic and parasympathetic nuclei[33]. Sympathetic efferent fibers innervate the sinoatrial and atrioventricular nodes, the atria, and the ventricles[33]. Parasympathetic efferent fibers are traditionally believed to control exclusively the nodal tissue and the atria[33]. Nevertheless, the presence of cholinergic innervations have been detected in both ventricles, and it has been demonstrated that vagal activation decreases the force of ventricular contraction irrespective of its effect on heart rate, in both animals and humans[33].

The "neural hypothesis" of RIPC, and potential role of the sympathetic system

The "neural hypothesis" of remote ischemic preconditioning (RIPC) postulates that ischemia-reperfusion (IR) cycles in peripheral sites might activate a neural reflex resulting in myocardial protection against a subsequent myocardial insult[34] (Figure 1).

In animals, cycles of occlusion and reopening of the renal artery, mesenteric artery, or femoral artery resulted in significant cardioprotection; in all these cases, the resection of the afferent fibers projecting to the ischemized territories abolished the cardioprotective effect[35-37]. In rats, IR cycles in the mesenteric artery conferred a cardioprotection similar in entity to that provided by ischemic preconditioning (*i.e.*, IR cycles of the coronary vessel before sustained occlusion); the systemic administration of hexametonium, a blocker of both sympathetic and parasympathetic ganglia, abolished this effect[38].

Conflicting results have been provided by Kingma *et al*[39], who reported that, in dogs anesthetized with isoflurane, a RIPC protocol conferred robust myocardial protection against a subsequent ischemic injury even during autonomic blockade or surgical denervation of the heart. It should be noted that in this study the animals were anesthetized with isoflurane[39], which is *per se* a powerful preconditioning agent (see below).

The activation of neural afferents during RIPC has been ascribed to local accumulation of mediators such as calcitonin-gene related peptide (CGRP), adenosine, and bradykinin[40]. Interestingly, the accumulation of adenosine[41,42], bradykinin[43], and other mediators[44,45] in the exercising muscle has been implied as a determinant of the metaboreflex[46], which is a neural mechanism coupling sympathetic tone to exercise requirements[47,48]. It could then be speculated that the IR cycles of a conditioning protocol cause metaboreflex activation. The subsequent increase in sympathetic outflow could confer myocardial protection through the activation of β1 and/or β2 adrenergic receptors; this phenomenon has been discovered in animal hearts perfused with β-agonists, and has been named

"β-adrenergic preconditioning"[49-51].

Evidences of vagal activation following RIPC

As discussed above, a theoretical framework could be provided for sympathetic outflow as the final mediator of RIPC. Nevertheless, a growing body of evidences points to RIPC as a vagal reflex.

The possibility to precondition the heart by the infusion of acetylcholine (ACh) was demonstrated in 1993 by Yao *et al*[52] The preconditioning potential of ACh has been confirmed by several other studies[53-55]. It has been demonstrated that cardioprotection by RIPC is suppressed by spinal cord section, bilateral vagotomy or the systemic administration of the muscarinic receptor antagonist atropine, while vagal stimulation closely recapitulates the effects of RIPC[56,57].

Using a viral transfer gene approach in rats, Mastitskaya *et al*[58] confirmed that an intact parasympathetic outflow is crucial for myocardial protection by RIPC. The neurons in the dorsal motor nucleus of the vagus nerve were selectively silenced, thus abolishing the cardioprotective effect of a RIPC protocol[58]. The selective activation of the same neurons closely recapitulated the cardioprotective effect of RIPC; this response was suppressed by atropine[58]. Again in rats, Basalay *et al*[59] reported that IR cycles in the limb conferred cardioprotection when applied 25 min prior to myocardial ischemia. The authors then found that the cardioprotective effect was abolished by the denervation of the peripheral ischemic organ or bilateral vagotomy[59].

Autonomic function in RIPC: What happens in humans?

To our knowledge, only two studies have evaluated the consequences of a RIPC protocol on the autonomic function in humans. In 2005, Loukogeorgakis *et al*[60] evaluated the possibility to protect against endothelial ischemia-reperfusion injury by RIPC. A cuff inflation to 200 mmHg for 20 min in the non-dominant arm was used as the ischemic insult; the subsequent endothelial damage was denoted by reduced flow-mediated dilation (FMD)[60]. When arm ischemia was preceded by a RIPC protocol in the dominant arm, the ischemic insult in the other arm caused no significant reduction in FMD compared to baseline, suggesting endothelial protection by RIPC[60]. Such response was abolished by the autonomic ganglion blocker trimetaphan[60]. These results suggested an autonomic activation underlying the endothelial protection by RIPC; however, being trimetaphan an aspecific autonomic blocker, it was not possible to ascertain if either the sympathetic or the parasympathetic system accounted for the protection by RIPC[60].

Parasympathetic activation was detected as the underlying mechanism by Enko *et al*[61] in 2011. After 3 cycles of 5 min ischemia and 5 min reperfusion in the left arm, a significant dilation of the right brachial artery was observed; in the power spectral analysis of heart rate, the high frequency domain displayed a simultaneous increase, denoting increased parasympathetic outflow[61].

Remote ischemic perconditioning and postconditioning: does vagal activation play a role?

The first demonstration of remote ischemic perconditioning was provided in 2007: in pigs, four 5-min cycles of lower limb ischemia during a 40-min left anterior descending coronary artery occlusion caused a significant reduction in infarct size, improved indexes of systolic and diastolic function, and less arrhythmic events during the reperfusion phase[11]. With respect to remote ischemic postconditioning, a cardioprotective effect of IR cycles at the beginning of reperfusion was demonstrated for the first time in 2005[12], and subsequently corroborated by other animal studies[62,63].

To our knowledge, only Basalay *et al*[59] assessed the pathophysiology of remote ischemic perconditioning and postconditioning. These authors reported that deafferenting the site of IR cycles or cutting both vagus nerves abolished the preconditioning and perconditioning responses in rats, but did not alter the postconditioning effect[59]. These results suggest that remote ischemic perconditioning relies on neural mechanisms, while remote ischemic postconditioning is mediated by humoral mediators[59].

Further studies are required to assess this hypothesis. However, it should be noted that neural mechanisms are more qualified than humoral mechanisms to protect the ischemic myocardium in the setting of remote ischemic perconditioning, at least when the coronary flow is completely blocked. In the same setting, an activation of the parasympathetic system would probably be more effective than a sympathetic response.

Excessive concentrations of catecholamines have been detected in the ischemic area during an acute myocardial infarction[64]. Increased cardiac sympathetic outflow is due to pain, anxiety, and a fall of cardiac output or arterial blood pressure; a further release of catecholamines is promoted by the ischemic damage of nerve endings[64]. As a result, extracellular norepinephrine reaches up to 100-1000 times its normal plasma concentrations within 30 min of coronary occlusion[64]. Far from being protective, local concentrations of this magnitude are capable of producing myocardial necrosis even in nonischemic myocardium, and might promote malignant arrhythmias[64]. This mechanism accounts for the positive effects of early administration of β-blockers during acute myocardial infarction[65,66], and probably excludes increased sympathetic outflow as the final mediator of cardioprotection by remote ischemic perconditioning.

PROTECTING THE HEART IN THE SETTING OF PCI

Stable coronary artery disease (SCAD) is associated with impaired quality of life, reduced physical endurance,

recurrent hospitalizations and outpatient visits[67]. Revascularization by either elective PCI or CABG can relieve symptoms, reduce the use of anti-ischemic drugs, improve exercise capacity and quality of life, compared to medical therapy alone[67]. The efficacy of elective PCI in addition to medical therapy in patients with SCAD has been demonstrated in a large number of randomized controlled trials, meta-analyses, and large-scale registries[67].

Albeit elective PCI is becoming increasingly safe, balloon inflation during PCI often causes transient ischemia[68]. Myocardial injury with necrosis may derive from recognizable peri-procedural events such as coronary dissection, occlusion of a major coronary artery or a side-branch, disruption of collateral flow, slow flow or no-reflow, distal embolization, and microvascular plugging; alternatively, the ischemic insult can have no detectable cause[68]. Myocardial ischemia is attested by a rise and fall of cardiac biomarkers after the procedure, with values rising five or more folds over the 99th percentile being indicative of peri-procedural myocardial infarction (PMI)[68].

Four recent meta-analyses have demonstrated that RIPC is effective in reducing PMIs in patients undergoing elective PCI[69-72]. For example, in the meta-analysis by Zografos *et al*[71], PMI occurred in 40.3% of patients in the RIPC group and in 51.3% of patients in the control group (odds ratio 0.57).

Several trials have assessed the long-term outcomes after elective PCI. An improvement in prognosis was not found by Prasad *et al*[73] over 1 year follow-up. By contrast, in the Cardiac Remote Ischemic Preconditioning in Coronary Stenting study, a significant reduction of major adverse cardiac and cerebral events (MACCE; a composite of all-cause mortality, myocardial infarction, readmission for heart failure, and ischemic stroke or transient ischemic attack) was found at 6 mo[74]. A recent follow-up study evaluating the same cohort demonstrated that the MACCE rate at 6 years remained lower in the RIPC group[75].

The significant heterogeneity of the study protocols could be hindering a careful assessment of RIPC efficacy in the setting of elective PCI. For example, the studies assessed in the meta-analysis by Zografos *et al*[71] differed with regard to the RIPC procedure (number of IR cycles, duration of the IR periods, site of application of the IR cycles), the percentage of patients with multivessel disease, and the positivity or the negativity of cardiac troponin I (cTnI) before PCI[71]. By contrast, in all the studies evaluated in this meta-analysis the IR cycles were performed immediately before elective PCI[74-80], so that a different time span between the IR cycles and the angioplasty procedure cannot be regarded as a potential confounding factor.

On the whole, a protective role for RIPC in the setting of elective PCI is emerging, even though its efficacy seems to be lower than in primary PCI. Nevertheless, only one long-term follow-up study has been published so far[75]; the prognostic role of RIPC should therefore receive extensive evaluation, as well as the optimal RIPC protocol to achieve effective cardioprotection.

Remote ischemic perconditioning refers to the application of ischemia-reperfusion cycles in a distant site shortly before revascularization. The first evidences of a protective role of remote ischemic perconditioning in human patients was provided in 2010 by Bøtker *et al*[81], who assessed 333 patients with suspected first ST-elevation myocardial infarction. The primary endpoint was myocardial salvage index (MSI), quantified as the proportion of the area at risk preserved by the treatment, 30 d after primary PCI. MSI was significant higher in the conditioning group than in controls; the protective effect of remote ischemic perconditioning seemed to be strongest in patients with more severe infarctions, *i.e*., presenting with occluded vessels or infarcts in the left anterior descending artery[81].

The long-term outcome of remote ischemic perconditioning was assessed in the same study population[82]. A significant reduction of MACCE and all cause mortality was observed in the conditioning group over a median follow-up of 3.8 years. There was also a trend toward reduced myocardial reinfarction, readmission for heart failure, and ischemic stroke or transient ischemic attack[82].

In 2013, remote ischemic postconditioning was assessed on 232 patients undergoing elective PCI[83]. In the conditioning group, the patients underwent three 5-min cycles of cuff inflation in the nondominant arm just after the end of the angioplasty. No significant difference was found between the conditioning group and the control group in terms of peak troponin I levels, PMI rate, recurrence of myocardial ischemia[83]. In another study, the incidence of PMIs was similar between all groups, and no difference was remarked with respect to the creatine kinase (CK) levels or the incidence of acute kidney failure[84]. In other studies, significant reductions in the incidence of acute kidney failure were observed; the prevention of acute kidney failure is currently regarded as the most promising perspective for the application of remote ischemic postconditioning during PCI[85,86].

For the details of the studies cited in the present paragraph, see Table 1.

REMOTE ISCHEMIC PRECONDITIONING BEFORE ELECTIVE CARDIAC SURGERY

Elective coronary artery bypass surgery (CABG) stands as an alternative to elective PCI for the management of SCAD[87]. The safety and efficacy of both techniques are similar, as well as the incidence of PMIs[87].

In 2007, a randomized controlled study enrolled 57 adult patients undergoing elective CABG surgery[88]. In the RIPC group, three IR cycles were performed

after the induction of anesthesia, resulting in a 43% reduction in the 72 h area under the curve (AUC) of cTnT compared with the control group[88]. Other randomized trials confirmed a cardioprotective role of RIPC, in terms of reduced cTnT[89], cTnI[90], and CK isoenzyme MB[91] levels. By contrast, several studies failed to detect significant differences among the RIPC group and the control group[92-95]; the use of volatile anesthetics with preconditioning potential (isoflurane, enflurane, sevoflurane) possibly accounts for discrepant results[96-98].

In a meta-analysis, D'Ascenzo *et al*[99] reported a significant reduction in cTnI and cTnT levels in the RIPC group after elective CABG surgery. Such difference persisted after excluding the trials with potentially confounding factors (among them, the use of isoflurane)[99]. It has been suggested that the cardioprotective effect of RIPC could be masked by the administration of volatile anesthetics and blunted by the perioperative administration of β-blockers[99,100]. Indeed, previous studies on animals or isolated human atrial trabeculae had demonstrated that β-blockers could attenuate ischemic preconditioning-induced cardioprotection[100,101], perhaps since even the activation of β-adrenergic receptor is protective against ischemia-reperfusion injury (β-adrenergic preconditioning; see paragraph The "neural hypothesis" of RIPC, and potential role of the sympathetic system).

Two studies evaluating the long-term efficacy of RIPC provided diverging results. Lucchinetti *et al*[94] did not find any difference at 6 mo in terms of deaths or revascularizations, whereas Thielmann *et al*[102] found significantly lower mortality rates in the RIPC group than in controls over a mean 1.54 year follow-up.

With respect to the settings of elective valve replacement surgery and congenital cardiac surgery, a recent metanalysis detected a significant cardioprotective role for RIPC[103]. Nevertheless, the small number of studies, and the high heterogeneity among them[103] might undermine the reliability of these conclusions. Another recent meta-analysis considered cumulatively CABG, valve replacement surgery, and congenital cardiac surgery, and detected a significant reduction in the post-operative cTnI levels among the patients undergoing RIPC[104]. No subgroup analysis was performed, and the heterogeneity among studies assessing non-CABG surgery was marked[104]. A third meta-analysis took into consideration the studies evaluating RIPC efficacy in adult patients undergoing "major elective or emergency cardiac or vascular surgery"[105]. In such a broad and mixed setting, no significant efficacy of RIPC was detected with regard to several outcomes: perioperative death, myocardial infarction, new-onset cardiac arrhythmias requiring treatment, cerebrovascular accidents, renal failure requiring renal replacement therapy, mesenteric

ischemia, length of hospital stay and intensive care unit stay[105].

The few studies evaluating the effects of RIPC in the sole setting of valve replacement yielded conflicting results. For example, Wu *et al*[106] did not find a significant effect of a standard RIPC protocol on cTnI release after mitral valve replacement surgery, whereas Xie *et al*[107] reported a significant reduction of the 72 h cTnI-AUC in patients undergoing mitral valve, aortic valve or tricuspid valve surgery.

On the whole, RIPC seems to exert a protective role against PMIs caused by elective CABG surgery, while its long term effects are still uncertain. Furthermore, no definite statement can be made about the RIPC efficacy in other forms of elective cardiac surgery, namely valve replacement surgery and congenital cardiac surgery (Table 2). Finally, volatile anesthetics and β-blockers are emerging as potential confounding factors, although the mechanisms are still unclear.

CONCLUSION

Remote ischemic conditioning (RIC) has been proposed as a "non-invasive, simple, safe, and cheap"[108] strategy to protect the heart against ischemic insults. A great research effort has been performed in order to verify the existence of a myocardial protection by RIC, and to evaluate the extent of such protection. Nevertheless, clinical studies have provided conflicting results. A deeper comprehension of the mechanisms underlying RIC is advisable in order to correctly assess the cardioprotective potential of RIC, and to guide future clinical research.

Abstract

After the successful introduction of highly active antiretroviral agents the survival of patients infected with the human immunodeficiency virus (HIV) in developed countries has increased substantially. This has allowed the surfacing of several chronic diseases among which cardiovascular disease (CVD) is prominent. The pathogenesis of CVD in HIV is complex and involves a combination of traditional and HIV related factors. An accurate assessment of risk of CVD in these patients is still elusive and as a consequence the most appropriate preventive and therapeutic interventions remain controversial.

Key words: Human immunodeficiency virus infection; Atherosclerosis; Cardiovascular risk; Antiretroviral therapy; Dyslipidemia; Hypertension; Smoking; Cardiovascular death

Core tip: Infection with the human immunodeficiency virus (HIV) was initially universally lethal but with the introduction of highly active antiretroviral therapies (HAART) the life span of HIV infected patients has drastically increased. Along with the lengthening of life span chronic diseases such as non-acquired immuno-deficiency syndrome related cancers and cardiovascular diseases surfaced. Currently cardiovascular disease is the primary cause of death among HIV infected patients in industrialized countries and its pathogenesis is very complex. A combination of direct virion injury, chronic low-grade inflammation, adverse cardiometabolic effects of HAART and high burden of traditional risk factors

contribute to this new epidemic.

Shahbaz S, Manicardi M, Guaraldi G, Raggi P. Cardiovascular disease in human immunodeficiency virus infected patients: A true or perceived risk? *World J Cardiol* 2015; 7(10): 633-644 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i10/633.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i10.633

INTRODUCTION

In the era of highly active antiretroviral therapy (HAART), the prognosis for human immunodeficiency positive (HIV+) patients in developed countries has dramatically improved[1,2]. As a consequence HIV infected patients live longer[3] and the medical care for this population is becoming more focused on the management of non-acquired immunodeficiency syndrome (AIDS) related morbidities, including cardiovascular diseases (CVDs)[4].

Although CVD is a leading cause of mortality and morbidity in HIV+ patients[5,6], there remains some controversy as to whether the disease is accelerated (promoted by traditional and non-traditional risk factors for atherosclerosis) or accentuated (greater prevalence of traditional cardiovascular risk factors) in these patients[7,8]. The prevention and treatment may vary considerably according to which mechanism is the prevailing one. In this review, we address the epidemiology of CVD in HIV+ patients, we discuss the impact of traditional and HIV-related risk factors; we review risk assessment for CVD in HIV and provide a brief overview of future therapeutic approaches to prevention of CVD in patients infected with HIV.

BURDEN OF CVD IN HIV

Epidemiology of CVD in HIV (Table 1)

A large body of evidence supports the notion that the burden of both clinical and sub-clinical CVD is increased in HIV infected patients. Investigators in the Veterans Aging Cohort Study Virtual Cohort (VACS-VC) analyzed data collected in 82459 veterans followed for an average of 5.9 years. The 27350 veterans infected with HIV had a significantly higher risk of myocardial infarction (AMI) compared with uninfected veterans (HR, 1.48; 95%CI: 1.27-1.72)[6]. The highest AMI risk was recorded among patients with HIV-RNA levels of at least 500 copies/mL and CD4 cell (CD4+) count less than 200 cell/mL; the risk remained elevated among patients who achieved HIV-RNA levels less than 500 copies/mL over time, suggesting that HAART may have contributed to some of the AMI risk[6]. The increased risk of CVD was noted both in HIV infected men and women[9]. When the VACS-VC participants were categorized according to the presence or absence of standard risk factors (diabetes mellitus, current smoking, total cholesterol, blood pressure, statins and antihypertensive medications use), HIV-infected veterans without major CVD risk factors had a 2-fold greater risk of AMI compared with uninfected veterans and the risk increased rapidly with each additional risk factor added[10]. In a cohort of 3851 HIV-infected patients examined at two Boston health care facilities the rate of AMI was significantly higher than in 1044589 controls after adjustment for age, sex, race, hypertension, and dyslipidemia (RR, 1.75; 95%CI: 1.51-2.02; $P < 0.0001$). Importantly, race appeared to have a different influence on the rate of AMI, with risk being higher in African-Americans and in Hispanics compared to Caucasians[11]. Although the prevalence of hypertension, diabetes mellitus and dyslipidemia was higher in HIV patients, this study further suggested that traditional risk factors cannot fully account for the increased risk of CVD in HIV[11]. Other studies performed outside of the US confirmed an increased risk of CVD in infected individuals[12,13].

The evidence of an increased risk of CVD in HIV extends to studies of subclinical atherosclerosis. Hsue *et al*[14] measured carotid artery intima-media thickness (IMT), an independent predictor of AMI and stroke[15,16], in 148 HIV+ patients and 63 age and sex matched controls. They reported that the mean carotid IMT of HIV+ patients was significantly greater and progressed faster in HIV+ patients than in controls. Of note, HIV infection was a predictor of carotid IMT independent of all other risk factors such as age, sex, smoking, HTN, lipid abnormalities and diabetes mellitus; a nadir CD4 count < 200 cells/mL was associated with IMT progression. However, Currier *et al*[17] failed to show any association between HIV infection and rate of carotid IMT progression.

Coronary computed tomography with and without intravascular iodinated contrast provides information about coronary artery calcium and non-calcified plaques both measures of subclinical atherosclerosis. Post *et al*[18] showed that HIV-infected men had a greater prevalence of coronary artery plaques compared to uninfected men and more extensive non-calcified plaques. On the contrary, the extent of coronary calcification was similar in the two groups.

In contrast with the above reported increased prevalence of CVD, Klein *et al*[19] recently reported a decline in incidence of AMI and CVD in HIV-patients. They reviewed data collected among the members of Kaiser Permanente Southern California and Northern California health plans between 1996 and 2011 (24768 HIV-infected patients and 257600 controls). The unadjusted relative risk of AMI for HIV+ patients decreased from 2.0 in 1996-1999 to 1.2 in 2010-2011, and the adjusted RR declined from 1.8 in 1996-1999 to 1.0 in 2010-2011 (Table 2). The decreased incidence of AMI in HIV+ patients may be due to the use of more lipid-friendly HAART medications, earlier initiation of HAART, resulting in lower incidence of severe immunodeficiency, and better control of CVD risk factors. The latter notion was supported by the finding that the

Table 1 Epidemiological studies evaluating the impact of human immunodeficiency virus on cardiovascular disease

Ref.	Size	Follow-up	Findings
Freiberg *et al*[6]	82459 27350 HIV+ 55109 HIV-	5.9 yr	Increased risk of MI among HIV+ patients VACS-VS study[6] (HR: 1.48; 95%CI: 1.27-1.72)
Womack *et al*[9] VACS-VS study	2187 women 32% HIV+	6 yr	Increased risk of CVD in HIV+ women compared to uninfected women (HR: 2.8; 95%CI: 1.7-4.6)
Paisible *et al*[10] VACS-VS study	81322 33% HIV+	5.9 yr	HIV+ veterans without major CVD risk factors had a 2-fold increased risk of MI compared with HIV- veterans without CVD risk factors (HR: 2.0; 95%CI: 1.0- 3.9)
Triant *et al*[11]	3851 HIV+ 1044589 HIV-	8 yr	Increased risk of MI among HIV+ patients (RR: 1.75; $P < 0.0001$)
Silverberg *et al*[12]	22081 HIV+ 23069 HIV-	13 yr	Higher risk of MI among HIV+ patients with a low recent or nadir CD4 cells (< 200) compared with HIV- subjects (RR, 1.76; 95%CI: 1.31-2.37 for low recent CD4 RR, 1.74; 95%CI: 1.47-2.06 for low nadir CD4)
Lang *et al*[13] FHDH-ANRS CO4	74958 HIV+	6 yr	The risk of MI was higher in both HIV+ men and women compared with the general population Standardized mortality ratio: 1.4 (95%CI: 1.3-1.6) for HIV+ men and 2.7 (95%CI: 1.8 -3.9) for HIV+ women compared with the general population
Hsue *et al*[14]	148 HIV+ 63 HIV-	1 yr	Higher baseline carotid IMT of HIV+ patients ($P = 0.0001$) and faster progression ($P = 0.002$)
Currier *et al*[17]	133 subjects in 45 triads[1]	144 wk	HIV infection and PI use did not contribute to the rate of carotid IMT progression. The median paired difference in IMT change between the PI and non-PI subjects was not statistically significant ($P = 0.19$). When the HIV+ groups were combined and compared with the HIV-negative group, the difference in progression was also not significant ($P = 0.71$)
Post *et al*[18]	618HIV+ 383HIV- men cross-sectional study		HIV-infected men had a greater prevalence of CAC [PR: 1.21 (95%CI: 1.08); $P = 0.001$] and any plaque [PR: 1.14 (CI: 1.05- 1.24); $P = 0.001$], including non-calcified [PR: 1.28 (CI: 1.13-1.45); $P < 0.001$) and mixed [PR: 1.35 (CI: 1.10-1.65); $P = 0.004$) plaque, than uninfected men
Klein *et al*[19] VACS-VS study	95687 31% HIV+	15 yr	Decline in adjusted MI rate ratio for HIV status over time, reaching 1 (95%CI: 7-1.4) in 2010-2011

[1]Each triad consisted of one subject from each of the following categories: (1) HIV+ with continuous PI therapy; (2) HIV+ without prior PI use; (3) HIV- subject. HIV: Human immunodeficiency virus; IMT: Intima-media thickness; MI: Myocardial infarction; PR: Prevalence ratio; CVD: Cardiovascular disease.

Table 2 Crude and adjusted rate ratios (95%CI) of myocardial infarction comparing human immunodeficiency virus infected and uninfected patients during a 13-year time span in the California Kaiser Permanente health system

Year	1996-2011	1996-1999	2000-2003	2004-2007	2008-2009	2010-2011
Crude	1.6 (1.5, 1.8)	2.0 (1.5, 2.8)	2.0(1.6, 2.5)	1.5 (1.2, 1.9)	1.5 (1.1-2.0)	1.2 (0.9-1.6)
Adjusted	1.4 (1.2, 1.6)	1.8 (1.3, 2.6)	1.7(1.4, 2.1)	1.3 (1.0, 1.6)	1.3 (0.9, 1.7)	1.0 (0.7, 1.4)

Modified from Klein *et al*[19].

Framingham risk scores were lower in HIV+ patients in more recent years compared to the late 90's[19].

In summary, a considerable body of literature shows a greater incidence of clinical CVD and a greater prevalence of subclinical atherosclerosis in HIV infected patients compared to the general population, supporting the notion that HIV is an independent risk factor for CVD. Whether the recently reported trend reversal is due to a greater awareness and more effective implementation of preventive measures in HIV+ patients remains to be demonstrated in different geographical areas and health delivery settings.

Etiopathogenesis of atherosclerosis in HIV

Infection related factors: The increased CVD risk in HIV may be dependent on a direct role of the HIV virus and on the immunological dysregulations caused by chronic HIV infection (Figures 1 and 2); data from observational studies provide evidence that both of these elements are involved[6,10,11].

The importance of continuous suppression of viral replication was investigated in the strategies for management of antiretroviral therapy (SMART) study[20]. The investigators compared the risk of all-cause death and cardiovascular, renal or hepatic complications in 2720 HIV+ patients receiving intermittent antiretroviral therapy and 2752 HIV+ patients receiving continuous antiretroviral therapy[20]. After a mean follow-up of 16 mo, the risk of death from any cause and for major cardiovascular, renal and hepatic diseases was significantly higher in patients who received intermittent compared to those who received continuous antiretroviral therapy (HR for all-cause death: 2.6; 95%CI: 1.9-3.7; $P < 0.001$, HR for major CVD, renal and hepatic disease: 1.7; 95%CI: 1.1-2.5; $P = 0.009$). The authors suggested that the increased CV risk may be

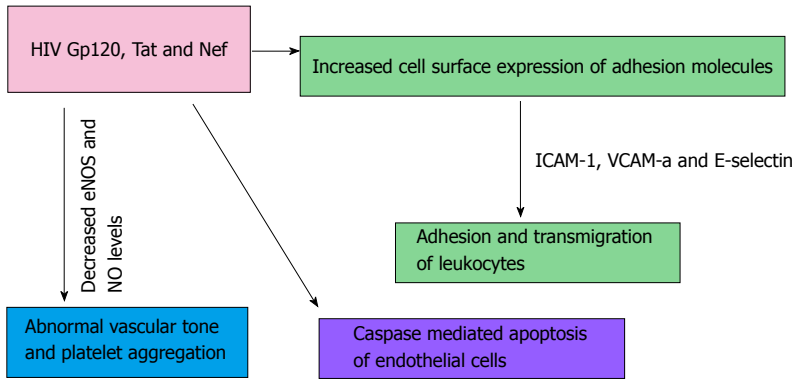

Figure 1 Putative mechanisms by which the human immunodeficiency virus virion increases the risk of atherosclerosis. The virus induces expression of adhesion molecules for leukocytes, reduce the secretion of nitric oxide with reduced vasodilation and induce endothelial cells apoptosis. ICAM: Intercellular adhesion molecule; VCAM: Vascular cell adhesion molecule; eNOS: Endothelial nitric oxide synthase; NO: Nitric oxide; HIV: Human immunodeficiency virus.

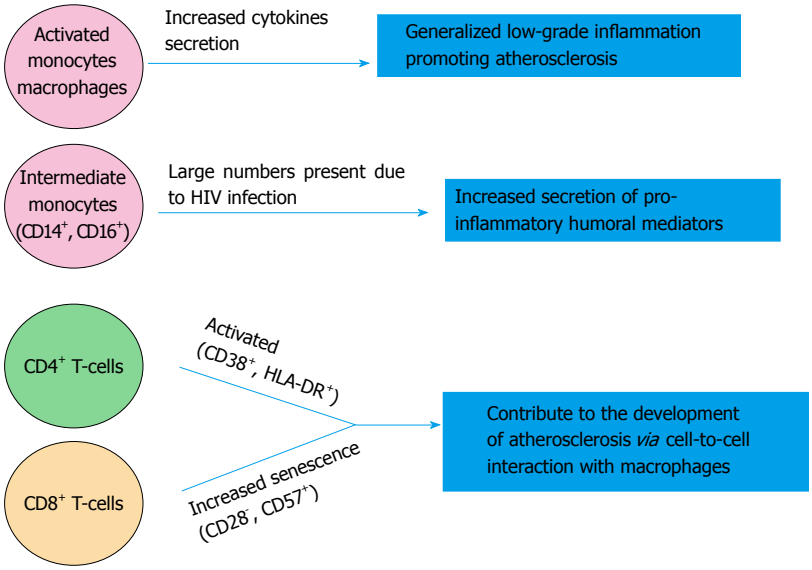

Figure 2 The human immunodeficiency virus promotes a state of low-grade chronic inflammation that increases the risk of atherosclerosis through the activation of lymphocytes, monocytes and macrophages. HIV: Human immunodeficiency virus; HLA: Human leukocyte antigen.

the consequence of alternating low and high CD4 cell numbers and viral loads experienced by the patients while receiving intermittent antiretroviral therapy, hence the importance of early and vigorous control of HIV replication and immune dysfunction[20].

In a cohort study of 22081 HIV+ and 230069 HIV- adult patients Silverberg *et al*[12] showed that the risk of AMI was 44% higher in HIV+ subjects compared with HIV- controls after adjustment for traditional risk factors. HIV+ patients with a nadir CD4 cell count < 200/mcl had a greater risk of AMI compared to controls[12]. However, the AMI rate of HIV+ subjects with a recent or nadir CD4 cell count ⩾ 500 /mcl and that of HIV- subjects was the same. In a case-control study of 289 HIV+ patients and 884 HIV-infected controls[21], a viral RNA level > 50 copies/mL, a low CD4 nadir and a high current CD8 count (> 1150/mm^3) were significantly associated with an increased risk of AMI. The ratio of nadir CD4/current CD8 count was the best predictor of an event[21].

In summary it would appear that a tight control of the HIV reproduction and maintenance of a good CD4 count may be protective against the risk of CV events. However, there exists conflicting evidence as to the actual association between CD4 cell count and the risk of AMI[22,23], as well as the HIV RNA levels and CV risk. Some investigators reported a direct association[21,22], while others were not able to identify one[24-26]; therefore this aspect of the CV pathogenicity of HIV needs to be clarified further.

The HIV can penetrate into endothelial cells utilizing CD4 receptors, galactosyl-ceramide receptors or chemokine receptors pathway[27-29], and different components of the HIV may have a role in the pathogenesis of CVD. Gp120 is a glycoprotein exposed on the surface of the HIV envelope and can also be found in the circulation from viral turn over[30,31]. It mediates HIV-1 entry into human cells by interacting with the HIV receptor for CD4 and co-receptors CXCR4 or CCR5[32]. Jiang *et al*[33] showed that Gp120 and tumor necrosis-alpha (TNF-α) synergistically decrease endothelial nitric oxide synthase (eNOS) and nitric oxide (NO) levels in both porcine and human coronary artery endothelial cells. NO is an important factor in the regulation of vascular tone and inhibition of platelet adhesion and aggregation[34]. HIV infection is a chronic inflammatory state, characterized by elevated serum levels of factors such as TNF-α and TNF-β, interferon gamma (IFN-γ) and monocyte chemo-attractant protein-1 (MCP-1)[32,35,36] and Gp120 can magnify the pro-atherosclerotic effects of these mediators. Gp120 can also induce apoptosis by interacting with CXCR4,

a chemokine receptor[37,38], which is also expressed on vascular endothelium[39,40].

The trans-activator of transcription (Tat) protein is a regulatory protein that enhances the efficiency of viral transcription[41]. In a study on the role of Tat on the expression of adhesion molecules in human endothelial cells, Tat was shown to induce the expression of intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin[42]. In the early phases of atherosclerosis, leukocytes adhere on the surface of endothelial cells and subsequently transmigrate between vascular endothelial cells into the intima layer of the vessel wall. While E-selectin is involved in the initial rolling of leukocytes on the endothelial cells[40], ICAM-1 and VCAM-1 induce firm adhesion and transmigration of leukocytes across the vascular endothelium[43]. High levels of soluble ICAM-1, VCAM-1 and E-selectin are associated with and increased risk of AMI in healthy men and women[44-46]. The levels of ICAM-1, VCAM-1 and E-selectin are elevated in HIV+ patients and there is a correlation between ICAM-1 concentration and the progression of HIV disease as well as the reduction of CD4 count[47,48]. Similarly to Gp120, Tat can also decrease endothelium dependent vasorelaxation and eNOS secretion in porcine coronary arteries[49].

Negative factor (Nef) protein is an HIV regulatory protein with an important role in cell apoptosis and enhancement of viral infectivity[50]. Nef blocks the ATP-binding cassette transporter A1 (ABCA1) pathway, leading to impaired cholesterol efflux from HIV infected macrophages to HDL particles[51]. As a result, HIV-infected macrophages accumulate lipids turning into foam cells, a step that may contribute to atherosclerosis formation[51]. Like Gp120 and Tat protein, Nef decreases endothelium-dependent vasorelaxation in porcine pulmonary arteries and reduces eNOS expression in both porcine pulmonary artery and human pulmonary artery endothelial cells[52]. In the same model Nef increased the levels of reactive oxygen species (ROS)[52], with an attendant decrease in NO bioavailability[53]. In endothelial cells, Nef can induce monocyte chemoattractant protein-1 (MCP-1) expression and apoptosis through NF-κB signaling and ROS-dependent mechanisms, respectively[54].

In addition to the humoral effects described above, cellular immune activation may play a role in the increased incidence of CVD in infected patients[35]. Monocytes are readily infected by HIV[55]; they adhere to the endothelial surface and eventually penetrate in the subendothelial space and intima. Monocytes, especially intermediate monocytes expressing $CD14^{++}$ and $CD16^{+}$, are prone to a greater pro-inflammatory activity once infected with HIV[56]. Furthermore, Hearps *et al*[57] showed that infected monocytes and macrophages of HIV+ patients have a reduced phagocytic activity and demonstrate telomere shortening a marker of premature ageing. High levels of monocyte activation markers, such as soluble CD163, CD14 and MCP-1 have been associated with subclinical coronary artery atherosclerosis, after adjustment for traditional CVD risk factors, in a large cohort of HIV-infected men[58]. T-lymphocytes are also activated in HIV infection[59]. In the Women Interagency HIV study, Kaplan *et al*[59] showed that HIV infection was associated with significantly elevated levels of activated [$CD38^{+}$ human leukocyte antigen (HLA)-DR^{+}] peripheral $CD4^{+}$ and $CD8^{+}$ cells and $CD8^{+}$ senescent cells ($CD28^{-}CD57^{+}$). The trend was reduced but not totally reversed after effective viral suppression with HAART. After adjustment for multiple confounders, $CD4^{+}$ and $CD8^{+}$ cell activation and $CD8^{+}$ senescent cells were associated with subclinical carotid artery lesions detected by 2D ultrasound[59].

Traditional risk factors in HIV: Traditional risk factors are more prevalent in HIV infected patients and likely represent a major driver for CVD in HIV.

(1) Cigarette smoking: The prevalence of cigarette smoking in HIV infected patients has been reported to be higher than in the general population. Analyzing data from 4217 infected (who participated in the Medical Monitoring Project) and 27731 non infected adults (who participated in the National Health Interview Survey in 2009), Mdodo *et al*[60] reported that 42.4% of HIV patients (95%CI: 39.7%-45.1%) were current cigarette smokers, while 20.3% (CI: 18.6%-22.1%) were former smokers, and 37.3% (CI: 34.9%-39.6%) had never smoked. Compared with the US adult population, in which an estimated 20.6% of adults smoked cigarettes in 2009, adults with HIV were nearly twice as likely to smoke [adjusted prevalence difference, 17.0% (CI: 14.0%-20.1%)], but were less likely to quit smoking (quit ratio, 32.4% *vs* 51.7%). A higher prevalence of smoking was also described in the SMART trial[61] and in the D:A:D study[62], where the rates of smoking were 40.5% and 51.5% respectively in HIV infected patients. Social and psychological factors such as ethnicity, lower educational level, poverty, illicit drug use, depression are likely contributing to the tobacco epidemic in HIV[60]. The noxious effects of smoking may be enhanced in HIV patients. Recently Helleberg *et al*[63] reported a greater number of life-years lost due to smoking in HIV infected patients compared to smoking controls [12.3 years (95%CI: 11.5-13.0) *vs* 3.6 years (95%CI: 3.1-4.0), respectively].

(2) Diabetes mellitus: Using data from the Multicenter AIDS Cohort Study (MACS), Brown *et al*[64] reported that the incidence of diabetes mellitus in HIV-infected men with HAART exposure was four fold higher than that of HIV-seronegative men. Subsequently De Wit *et al*[65] reported an incidence rate of 5.72 per 1000 patient follow-up year (95%CI: 5.31-6.13). The incidence of diabetes increased with cumulative exposure to HAART, and the association remained significant after adjustment for confounding factors. Besides the possible influence of HAART, some investigators reported a higher incidence

of insulin resistance and diabetes mellitus in patients co-infected with hepatitis C virus (HCV). The impact of the directly active agents used in the therapy of HCV to reduce the incidence of diabetes mellitus is currently unknown[66,67].

(3) Dyslipidemia: The dyslipidemia that develops during HAART is characterized by an increase in total and LDL cholesterol, and triglycerides levels. The effect varies according to the different HAART classes and within each class with different drugs. While this drug-induced toxicity was very common with the older antiretroviral drugs, it has become much less problematic with second generation nucleoside reverse transcriptase inhibitors (NRTI), (namely Rilpivirine) and with integrase inhibitors (Dolutegravir, Elvitegravir and Raltegravir). The HIV is a metabolically active virus capable to alter reverse cholesterol transport *via* modification of the HDL particles functionality and/or impairment of cellular cholesterol efflux. As discussed above, *in vitro* experiments have demonstrated that the HIV-related Nef protein can impair cellular cholesterol efflux through down-regulation of ABCA1[68,69]. ABCA1 plays a crucial role in stimulating cholesterol export from macrophages. Recently Lo *et al*[68] showed that, in the acute phase of HIV infection, HAART can restore the HDL-mediated cholesterol efflux capacity primarily through the suppression of viremia, providing additional evidence that prompt HAART initiation can potentially reduce atherosclerotic risk.

(4) Systemic hypertension: Among HIV infected patients the prevalence and incidence of systemic hypertension ranges from 20%-40% in high-income countries[70-72] to 11%-28% in low and middle income countries[73,74]. These trends may reflect the distribution of risk in the general populations of the same regions of the world. As a result, it is currently unclear whether hypertension is more prevalent in HIV infected patients than the general population.

Several studies failed to show a correlation between blood pressure levels and CD4 cell count and between viral load and hypertension. There are sparse and conflicting data on the role of antiretroviral therapy in the pathogenesis of hypertension[75,76], and the association remains inconclusive.

Impact of antiretroviral therapy on CVD: The first cases of myocardial infarction in HIV-infected patients receiving protease inhibitor were described in the late 1990s; since then several epidemiological studies have examined the association between HIV infection, HAART and the risk of CVD. In 2003 the investigators of the D:A:D study (Data Collection on Adverse Events of Anti-HIV Drugs) reported for the first time an increased incidence of myocardial infarction with longer exposure to combination antiretroviral therapy [adjusted risk rate per year of exposure, 1.26 (95%CI: 1.12-1.41); $P < 0.001$]. Patients with no exposure to therapy had a lower incidence of myocardial infarction than any of the treated groups[24]. Several years later the same investigators showed that cumulative exposure to some of the protease inhibitors (Indinavir, Lopinavir-Ritonavir) was associated with an increased risk of myocardial infarction (relative rate per year, 1.12 and 1.13, respectively) after adjustment for the impact of these drugs on lipid metabolism[77]. This was the first report that suggested that HAART might be responsible for an increased incidence of cardiovascular events independent of their lipid effects. The case of Abacavir remains paradigmatic in this setting. Several observational cohorts and a few randomized clinical trials reported an association between current, but not cumulative exposure of Abacavir and myocardial infarction. Abacavir, as a guanosine analogue, inhibits soluble guanylyl cyclase leading to enhanced platelet adhesion and, ultimately, to increased risk of myocardial infarction[78].

Numerous other studies implicated Abacavir and protease inhibitors in the development of cardiovascular events, however none of the reports provided conclusive evidence. The adverse effects of these drugs may be particularly harmful in patients with pre-existing high cardiovascular risk, and they should therefore be avoided in those patients.

In spite of early observations reporting an increased risk of CVD in patients receiving HAART, particularly protease inhibitors, more recent evidence suggests a safer cardio-metabolic profile of some categories of HAART[20,79]. Current strategies to decrease the risk of CVD in HIV infected patients include early initiation of HAART regimens known to be associated with the fewest metabolic adverse effects and careful management of traditional CV risk factors during HAART treatment.

SCREENING ALGORITHMS FOR CARDIOVASCULAR RISK STRATIFICATION IN HIV

Cardiovascular risk assessment in HIV infected patients has traditionally been based on recommendations drafted for the general population. In 2010 Friis-Møller *et al*[80] reported on the performance of a new model (derived from the D.A.D. cohort) that included exposure to HAART along with traditional risk factors. Although the new model estimated outcomes more accurately than the Framingham Risk Score (FRS) in the HIV population, it has not been widely adopted.

A new risk prediction algorithm for the general population [atherosclerotic cardiovascular disease (ASCVD)] was introduced in 2013 by the American College of Cardiology/American Heart Association[81]. In preliminary analyses it appeared that the ASCVD might overestimate CVD risk in the general population[82]. However the situation is probably the opposite in HIV disease. In a cohort of 2270 HIV infected patients, Regan *et al*[83] recently reported that the ASCVD algorithm classified a larger proportion of HIV patients as high-

risk compared to the FRS (25% *vs* 10%). However, comparing the 5-year observed-*vs*-predicted event rates, both models underestimated the actual CVD risk in HIV. Similarly, Thompson-Paul *et al*[84] compared ASCVD[81], FRS[85], the European algorithm known as SCORE[86] and the DAD score[80] to predict events in 2392 ambulatory HIV+ patients. After a median follow-up of 6.5 years they recorded 204 events; all models underestimated the actual risk of events. The FRS, ASCVD, and DAD equations showed moderate discrimination (C-statistic range, 0.68 to 0.72), while SCORE showed poor discrimination (C-statistic = 0.59).

Imaging of subclinical atherosclerosis has been suggested as a method to improve risk prediction and implementation of preventive therapies in the general population with variable success. Zanni *et al*[87] described a disproportion in HIV infected individuals between presence of subclinical atherosclerosis and statins recommendation. One third of 108 HIV infected patients without known CVD who underwent computed tomography angiography hosted coronary artery plaques with features of high vulnerability. Although a larger number of patients would require statins according to the new ASCVD algorithm compared to the FRS recommendations (26% *vs* 10%), the majority (74%) of HIV infected patients with subclinical coronary atherosclerosis did not have an indication to receive treatment even with the new algorithm.

Coronary artery calcium (CAC) has been proven to be incremental to risk factors for the prediction of events in the general population[88,89], but to date it has not been shown to be as useful in HIV infected patients. In a metanalysis Hulten *et al*[90] described a similar prevalence of CAC between HIV-positive and uninfected patients (OR: 0.95, P = 0.851). In the MACS[91], among 615 HIV infected men and 332 controls, the adjusted odds ratio for CAC was 1.35 (95%CI: 0.7-2.61). No outcome study has yet been published demonstrating the utility of CAC as an incremental prognostic factor in HIV.

Inflammation plays a central role in the patho-physiology of atherosclerosis and 18-fluorede-oxyglucose positron emission tomography can identify activated macrophages infiltrating the arterial wall. Subramanian *et al*[92] compared 27 HIV positive patients receiving HAART without prior CVD, with two non-HIV control groups: one group was matched for age, sex and FRS (non-HIV, FRS-matched controls), while the second one was sex-matched but had known atherosclerotic CVD (non-HIV, atherosclerotic controls). Inflammation in the aortic wall (measured as target to background signal ratio, TBR) was similar between HIV infected patients and non-HIV atherosclerotic controls (2.23; 95%CI: 2.07-2.40 *vs* 2.13; 95%CI: 2.03-2.23; P = 0.29), but was higher than in the non-HIV FRS-matched controls (2.23; 95%CI: 2.07-2.40 *vs* 1.89; 95%CI: 1.80-1.97; P = 0.001).

In HIV infected patients the aortic TBR was associated with the serum concentration of soluble CD163, a novel marker of activated macrophages (P = 0.04)[93], but not with C-reactive protein (P = 0.65) or D-dimer (P = 0.08) levels.

More recently, Tawakol *et al*[94] performed 18-FDG-PET imaging in 41 HIV+ patients on stable HAART regimen without prior CVD, but with coronary plaques on coronary CT angiography. A higher tracer uptake was correlated with the presence of low-attenuation plaques (P = 0.02) and positive remodeling (P = 0.04), both features of plaque instability.

Despite these encouraging results, no algorithm to date has incorporated imaging information in risk models for HIV patients. Therefore risk assessment remains reliant on the use of traditional risk factors despite their demonstrated limitations, although there is hope that imaging may add useful information in the future (Figure 3).

MANAGEMENT OF HIV INFECTED PATIENTS TO PREVENT CVD

In view of the information discussed so far it appears true that the CV risk of HIV infected patients is greater than that of the general population; a combination of higher prevalence of traditional risk factors and HIV specific factors likely predispose patients to such increased risk. Four questions emerge regarding risk reduction management in HIV patients: (1) should HIV infected patients be treated more aggressively than the general population for traditional risk factors? (2) As a corollary of the former, should a lower risk threshold be used to initiate treatment? (3) What HAART should be chosen to minimize CV risk in HIV? and (4) Finally, should therapy for HIV infected patients be guided by imaging and/or non-imaging biomarkers?

To date no study has addressed the impact of more aggressive therapy of traditional risk factors in HIV patients to reduce the attendant CV risk. While it would appear that there is a trend toward a relative reduction of CV morbidity and mortality in the past 10-15 years[95], it is unclear whether this is due to greater physicians' awareness and increased preventive efforts in HIV patients or other as yet unknown factors. The current recommendations for risk assessment and risk reduction in HIV patients mimic those of the general population. However, as discussed above, in spite of a slightly better performance of newer versus older risk assessment algorithms, the majority of patients at risk are not identified as high-risk and are therefore not receiving potentially life saving therapies. The newest algorithm (ASCVD) lowered the threshold for identification of high-risk patients to 7.5% from 20% as recommended in the ATP-Ⅲ guidelines[96], but it continues to under perform in HIV patients. In fact, despite the greater proportion of patients at risk identified by the ASCVD, as many as 40% of the patients suffering an acute cardiovascular event would not have met the requirement for prescription

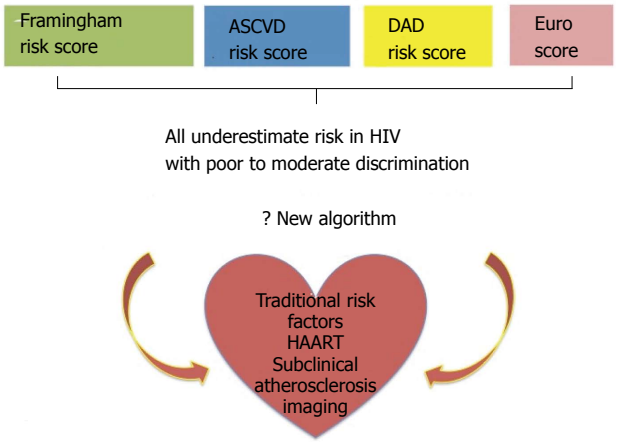

Figure 3 All algorithms currently used to estimate risk of cardiovascular disease in the general population underestimate the actual risk of human immunodeficiency virus positive patients. Although unproven, it is likely that a combination of traditional risk factors, risk linked with some anti-retroviral agents and data on subclinical atherosclerosis collected *via* imaging, may improve risk prediction in the future. ASCVD: Atherosclerotic cardiovascular disease; HAART: Highly active antiretroviral therapies; HIV: Human immunodeficiency virus.

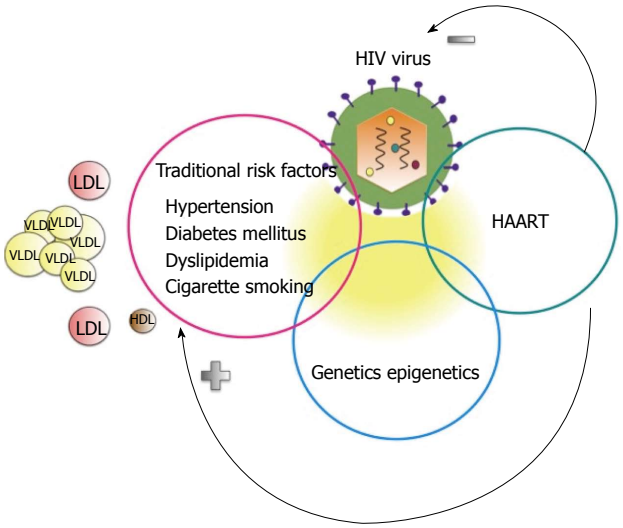

Figure 4 The pathophysiology of human immunodeficiency virus associated atherosclerosis is very complex; a high prevalence of traditional risk factors, direct effects of the human immunodeficiency virus virion and side effects of some the antiretroviral agents, along with yet unknown genetic and epigenetic factors predispose these patients to a high incidence of cardiovascular disease. The impact of anti-retroviral therapy is particularly difficult to estimate since suppression of viral replication may have an anti-atherosclerotic activity (curved arrow with negative sign) while side effect of some antiretroviral drugs may promote atherosclerosis (curved arrow with positive sign). HAART: Highly active antiretroviral therapies; LDL: Low-density lipoprotein; VLDL: Very low-density lipoprotein; HIV: Human immunodeficiency virus.

of statins prior to the event according to two recent studies[83,97]. Hence, a mere lowering of the threshold for initiation of preventive therapies may be insufficient to effectively lower risk of events in HIV patients. In view of the difficulties highlighted above, a new study was launched[98] that aims to show that early statin treatment in asymptomatic HIV infected patients will delay the development of inflamed atherosclerotic plaques and reduce cardiovascular events (death, myocardial infarction, angina, stroke and revascularizations).

The choice of HAART and timing of therapy initiation likely carry a significant weight in risk reduction, as some of these drugs appear to have both direct and indirect cardiovascular toxicity while others may lower CV risk. Since the initial observation from the SMART study[20] reporting a reduced incidence of CV events in patients reaching a stable viral suppression, newer antiretroviral agents have been introduced with improved cardiometabolic toxicity. However, there are currently no long-term studies to demonstrate the safety and effectiveness of new anti-retroviral agents such as integrase inhibitors, although the safety profile of drugs such as atanazavir (a protease inhibitor) and tenofovir (member of the NRTI family) has been established. To address the paucity of prospective follow-up data, the D.A.D. registry has been tasked with the collection of safety data on drugs with a minimum of 30000 person-year follow-up[99].

Surrogate markers of atherosclerosis and serological biomarkers may provide some insight into the effectiveness of a novel therapeutic agent. In a preliminary communication, Stein *et al*[79] reported the effect of various antiretroviral combinations on the progression of the intima-medial thickness (IMT) of the carotid artery bulb in 234 HIV+ patients followed for a maximum of 144 mo from randomization. Atanazavir (protease inhibitor) was associated with less IMT progression than darunavir (integrase inhibitor), but the progression was similar for atanazavir and raltegravir (first generation integrase inhibitor) despite the better lipid profile of patients receiving raltegravir. Hence, it would appear that only part of the pro-atherogenic effect of HAART may be dependent upon lipid metabolism alterations. Additionally, in a recent publication the authors reported that various HAART regimen did not differ as far as expression of markers of inflammation and immune activation, confirming the notion that the anti- or pro-atherogenic effects of HAART cannot be gauged by their effect on serological biomarkers at the current state of research[100]. The lack of effect on biomarkers and a not markedly different effect on measures of atherosclerosis suggests that despite a reduction of viral load with HAART, there are residual immunological perturbations and reservoirs of viral replication that may induce atherosclerosis progression. Timing of HAART initiation has recently received renewed interest with the publication of the INSIGHT-START trial results[101]. In this trial 4685 HIV infected patients were randomized to receive HAART (mainly based on tenofovir, emtricitabine and efavirenz) with a $CD4^+$ cell count > 500/cc (median $CD4^+$ at initiation 651/cc) or only once the $CD4^+$ cell count dropped below 350/cc. The primary end point was a composite of death from all causes, and any serious AIDS related and non-AIDS related events (mostly cardiovascular). After a mean follow-up of 3 years the patient group

that received early HAART demonstrated a significantly reduced event rate (HR: 0.43; CI: 0.30-0.62, $P < 0.001$) compared to the delayed treatment group. These results fuelled an intense debate as to the pros- and cons of early HAART initiation, an approach that needs to be carefully considered in view of the potential side effects of some HAART discussed above.

CONCLUSION

The etio-pathogenesis of CVD in HIV is very complex, with contributions from the retrovirus and the attendant immunologic perturbations, HAART, highly prevalent traditional risk factors and genetics (Figure 4). Therefore a multifaceted approach will be necessary to effectively prevent its development and progression. Since atherosclerosis in HIV patients is characterized by immune activation in association with highly inflamed, non-calcified, potentially vulnerable plaques, these may become the targets of choice in future clinical trials to test the effectiveness of therapy.

Abstract

Acute coronary syndromes remain a leading single cause of death worldwide. Therapeutic strategies to treat cardiomyocyte threatening ischemia/reperfusion injury are urgently needed. Remote ischemic preconditioning (rIPC) applied by brief ischemic episodes to heart-distant organs has been tested in several clinical studies, and the major body of evidence points to beneficial effects of rIPC for patients. The underlying signaling, however, remains incompletely understood. This relates particularly to the mechanism by which the protective signal is transferred from the remote site to the target organ. Many pathways have been forwarded but none can explain the protective effects completely. In light of recent experimental studies, we here outline the current knowledge relating to the generation of the protective signal in the remote organ, the signal transfer to the target organ and the transduction of the transferred signal into cardioprotection. The majority of studies favors a humoral factor that activates cardiomyocyte downstream signaling - receptor-dependent and independently. Cellular targets include deleterious calcium (Ca^{2+}) signaling, reactive oxygen species, mitochondrial function and structure, and cellular apoptosis and necrosis. Following an outline of the existing evidence, we will furthermore characterize the existing knowledge and discuss future perspectives with particular emphasis on the interaction between the recently discovered hypoxic nitrite-nitric oxide signaling in rIPC. This refers to the protective role of nitrite, which can be activated endogenously using rIPC and which then contributes to cardioprotection by rIPC.

Key words: Remote ischemic preconditioning; Ischemia/reperfusion injury; Nitrite; S-nitrosation; Mitochondria

Core tip: Therapeutic strategies to treat ischemia/reperfusion injury are urgently needed. Remote ischemic preconditioning (rIPC) appears to exert beneficial effects for patients. The underlying signaling remains incompletely understood. Following an outline of the existing evidence, we will characterize the existing knowledge and discuss future perspectives with particular emphasis on the interaction between the recently discovered hypoxic nitrite-

nitric oxide signaling in rIPC.

INTRODUCTION

Current guidelines of both European and United States cardiac societies emphasize one primary goal for patients with acute myocardial infarctions - the timely and successful reperfusion[1]. This concept among many additional pharmaceutical treatments has significantly reduced mortality and morbidity in patients suffering from acute coronary syndromes. Experimental evidence, however, has largely implicated that rapid restoration of coronary perfusion, in turn, may paradoxically harm cardiomyocytes[2,3]. This phenomenon has been named ischemia/reperfusion (I/R) injury. The underlying signaling is complex and yet incompletely understood. Current concepts for the modulation of myocardial I/R injury have particularly emphasized three major contributors to the final I/R injury: reactive oxygen species (ROS), Ca^{2+}, and mitochondria. Particularly the latter are now not only regarded as targets during I/R but also as mediators of cellular injury and death. For a detailed description of the signaling in myocardial I/R injury the reader is kindly referred to the recently published excellent review sources[2-7]. Experimental and initial clinical studies implicate that all three signaling components of I/R injury may serve as potential targets in attempt to reduce I/R injury. Although early reperfusion therapy has led to a marked decrease in mortality following acute myocardial infarction, application of such cardioprotective strategy might further reduce the burden of cardiovascular disease.

Ischemic conditioning regimens are among the most effective cardioprotective approaches. These techniques are capable of reducing the final infarct size by up to approximately 30%-60%[8-10]. Brief episodes of sublethal I/R applied to the index organ [ischemic preconditioning (IPC)] - or a remote organ (rIPC) - before, during or after a main ischemic event initiate a powerful cellular signaling cascade rendering the cardiomyocyte capable of protecting itself. The majority of relevant clinical phase Ⅱ trials have produced favorable results for ischemic conditioning techniques. However, a definitive implementation into the clinical routine is still warranted. The underlying signaling in the scope of rIPC remains incompletely understood. Here we first outline the events leading to myocardial I/R injury, followed by an introduction to ischemic conditioning. Finally, we will put a major focus on the recently discovered nitrite-nitrogen oxides (NO) signaling, which targets mitochondria during I/R and protects the heart from lethal injury.

MYOCARDIAL I/R INJURY

Reperfusion therapy either by invasive coronary intervention, bypass surgery or pharmacological lysis causes a rapid increase in cellular oxygen levels[2]. One key pathological consequence of this is an insufficient mitochondrial respiration in consequence of an incomplete electron transport over mitochondrial membranes. This can cause an excess formation of ROS[11]. While ROS at physiological concentrations contribute to the general cellular homeostasis, higher levels may initiate a deleterious signaling. This contributes to an increase in cell death by necrosis or apoptosis[12].

The reperfusion phase is not only characterized by increased ROS levels, but also by a reduction in the bioavailability of NO. NO is a gaseous signaling molecule that regulates a wide variety of cardiomyocyte functions including scavenging of radicals, cardiac immune response, improvement of blood flow and left ventricular function[13-17]. By consequence, these functions are impaired during reperfusion. In addition, interactions between the ROS system and NO signaling may further contribute to the final myocardial I/R injury. This relates to the increase formation of peroxynitrite (an oxidant) in the reperfusion period[18], which in turn may contribute to nitrosative stress-related cell injury to membranes[19,20]. The exact role of peroxynitrite and whether peroxynitrite signaling can be effectively modulated in patients remains to be determined.

The second major contributor to cardiomyocyte dysfunction in I/R is a deteriorated Ca^{2+} signaling[21-24]. Elevated intracellular Ca^{2+} levels can not only trigger arrhythmias, and cardiomyocyte hypercontracture[25], they may also activate Ca^{2+}-dependent signaling pathways. This pertains especially to Ca^{2+}-dependent proteases named calpains, which then cleave cellular elements involved, *e.g.*, in apoptosis, mitochondrial respiration or mitochondrial turnover[26-28]. Hypercontracture and necrosis are not limited to one cell but can also be distributed from cell to cell either by direct contracture or by cell-to-cell progression through intercellular gap junctions[29]. Off note, high calcium levels may also directly target and disrupt cell membranes[20]. While both ROS and intracellular Ca^{2+} elevation mark the initial events of myocardial I/R injury, the central target of reperfusion-associated impaired signaling is the mitochondrion.

MITOCHONDRIA IN I/R INJURY

Mitochondrial injury in I/R comprises at least three relevant entities: (1) Destruction of mitochondrial membrane integrity by permeabilization; (2) deficits in mitochondrial structural dynamism, the recently termed mitochondrial fusion and fission and, finally; and (3) the deterioration of mitochondrial respiration[30].

The exact events leading to mitochondrion-driven cell death by mechanisms of necrosis, apoptosis, or autophagy are incompletely understood. Dysregulated Ca^{2+} signals and ROS concentrations, as found in early reperfusion, provide excellent circumstances to deteriorate mitochondrial integrity[31].

Apoptosis causes cell shrinkage, cellular fragmentation, and finally phagocytosis. The general characteristics of necrosis include cellular swelling and rupture, and a marked depletion of energy resources. Newer studies argue that apoptosis as well as necrosis are regulated by a complex signaling machinery with overlapping processes[32]. The critical step for apoptosis is the permeabilization of the mitochondrial outer membrane pore (MOMP). This occurs by activation of pro-apoptotic BH3 proteins, *e.g.*, Bax[31]. Subsequently, a release of apoptogenic factors is initiated, *e.g.*, cytochrome c or apoptosis-inducing factor (AIF)[33,34] By contrast, the key characteristic of necrotic cell death is the permeabilization of the inner mitochondrial membrane causing the formation of a yet incompletely identified mitochondrial permeability transition pore (mPTP).

Mitochondrial morphology and structural dynamism is regulated by fission and fusion[35]. Interestingly, Bax - previously introduced as major contributor to cell death - is also involved in mitochondrial fusion and fission. As a consequence, Bax supplementation deteriorates mitochondrial structural dynamism in conjunction with a much-increased I/R injury. Taken together both regulation of mitochondria-driven cell death as well as mitochondrial structure is complex but many overlapping yet incompletely defined processes exists that contribute to cardiomyocyte damage in I/R injury.

In case the initial phase of reperfusion is survived the preservation and restoration of mitochondrial function becomes a major goal. Mitochondria comprise one third of the cell mass of cardiomyocytes. Recent evidence suggests that at least three subpupulations exist: Subsarcolemal (SSM), interfibrillary (IFM) and perinuclear (PNM) mitochondria. Their relative contribution to the function of cardiac cells remains to be completely elucidated[30,32]. Mitochondria generate a vast amount of adenosine triphosphate per day[36] and the electron transfer through the complexes of the mitochondrial respiratory chain is under control of a delicate regulatory machinery. I/R may cause a major functional disturbance with a subsequent incomplete respiration and a burst in the generation of ROS[37]. Many cardioprotective strategies have attempted to reduce these excessive ROS levels. Newer approaches, *e.g.*, rIPC, have focused on regulatory posttranslational modifications of respiratory chain elements and particularly complex I, which we will outline in the following.

THE CONCEPT OF RIPC

rIPC is among the most effective techniques in rendering the myocardium capable of protecting itself against I/R injury[38]. rIPC-associated protection is initiated *via* short non-deleterious phases of I/R prior to an index ischemia. The maneuver is applied to an organ or tissue at distance to the one undergoing the main ischemic event[38,39]. Clinical evidence from recent phase Ⅱ trials favors a potential translation into clinical routine[40-42]. The underlying rIPC-related signal mechanism remains under intense debate. Generally, the signal transduction machinery initiated by the rIPC stimulus involves a trigger, the transfer of the trigger to the target organ and a distinct cardiomyocyte signaling leaving the cardiomyocyte protected from I/R[13]. As triggering pathways both humoral/blood borne factors[43-45] and neuronal transmission[46] have been proposed. However, the cardioprotection can be transferred when transfusing blood from rIPC animals to unconditioned littermates[43,45,47]. This argues in favor of important contribution of a humoral factor. This does not preclude a role for the nervous system to be involved in the modulation of the rIPC response[48]. However, an intact nervous system is particularly important for the remote and not the target organ[48]. Off note, the signaling is at least to certain degrees species-specific with some of the pathways that are active in murine studies being irrelevant in large animal models and humans[48,49].

TRANSFER OF PROTECTION *VIA* HUMORAL FACTORS

It is now generally accepted that rIPC initiates a complex interplay between several mediators not only at the remote site, but also in the circulation as well as in the target cell. Over the past two decades many components have been forwarded, and it is presently unlikely that one single mediator is responsible for the complete protection associated with rIPC. Among the factors which have been evaluated in experimental studies are adenosine, bradykinin, opioids, interleukins, stromal cell-derived factor, hypoxia-inducible factor 1α and members of the so-called RISK pathway. These studies have in part revealed conflicting results especially when comparing experimental results with those from trials in patients[6].

We and other groups have recently investigated a potential involvement of hypoxic NO signaling in the course of rIPC. Using a mouse model of warm liver I/R, it was demonstrated that ablation of endothelial NO synthase (eNOS) abrogates the protective effects seen with rIPC on microscopic liver damage[50]. eNOS generates NO which can then modulate cardiovascular functions either at the place of synthesis or at a distance when transported as nitrite or nitroso species (nitrosated proteins)[51]. Changes in shear stress, *e.g.*, due to an increase in blood flow as seen in hyperemia after short phases of ischemia, are the strongest physiological stimulus of eNOS activity, which is mirrored in higher circulating NO metabolites[13]. This led to the hypothesis that nitrite-NO signaling is involved in the pathways

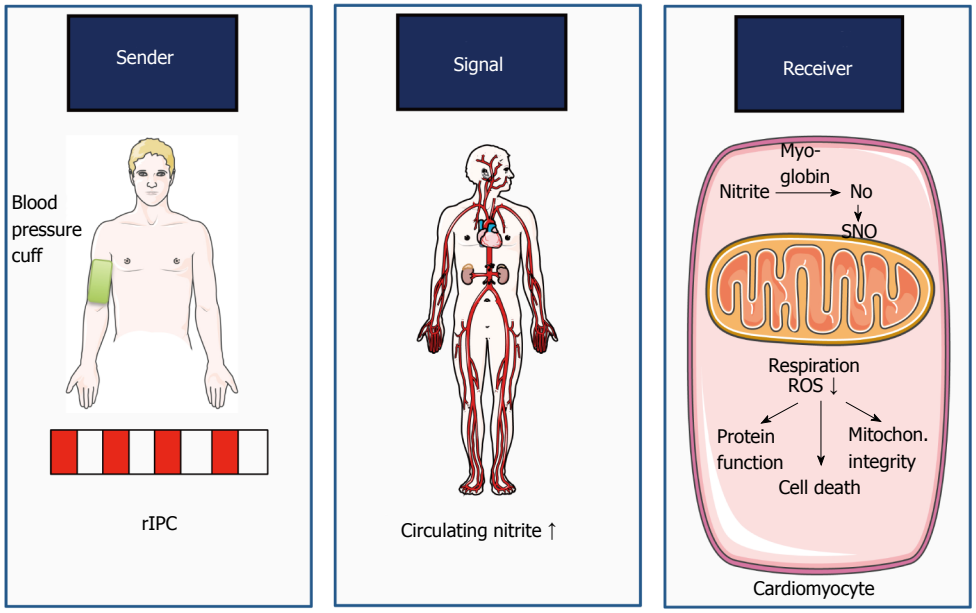

Figure 1 Nitrite/nitrogen oxides related signaling in remote ischemic preconditioning - proposed mechanism. The nitrite/NO signaling involves three components. The sender of the signal is shown in the left panel. In this case the upper extremity receiving rIPC *via* repetitive in-/deflations of a blood pressure cuff. During this maneuver, the classical L-arginine-NOS-nitrogen oxides (NO) pathway is activated. This includes the activation of eNOS, which generates NO from l-arginine while using several cofactors. Off note, the eNOS system is under tight control of several systems, *e.g.*, the calcium-calmodulin pathway. The middle panel represents the signal transmitted from the sender (remote organ) to the receiver (cardiomyocytes), as nitrite is transmitted from the site of generation *via* the circulation to the heart. In the receiving target organ, this signal is translated into cardioprotection *via* myoglobin-dependent nitrite reduction and S-nitrosation of mitochondrial complex I with a protective regulation of mitochondrial functions and reduced reactive oxygen species (ROS). The generation of NO in the last panel activates the alternative pathway for NO generation, which reduces nitrite to NO *via* hemeglobins, *e.g.*, myoglobin in the heart or hemoglobin in the circulation. The reduction of ROS in turn may help reduce cellular stress as indicated. This relates to an improvement of protein function, cell death and mitochondrial integrity[8]. rIPC: Remote ischemic preconditioning; NOS: NO synthase.

leading to cardioprotection from the rIPC stimulus.

THE ROLE OF NITRITE/NO SIGNALING IN REMOTE ISCHEMIC PRECONDITIONING

NO is a signaling molecule with a wide variety of functions in the cardiovascular system. Generally, NO protects the heart from I/R injury except for excessive levels during inflammation. However, in the course of I/R the canonical NO generation pathway *via* the classical L-arginine-NOS-NO signaling pathway becomes impaired due to a lack of molecular oxygen[52]. Nitrite, formerly regarded a mere NO oxidation product, may serve as an alternative source under these conditions[14,53]. The majority of the bodily nitrite provision derives from the oxidation of NO, which is enzymatically formed by one of at least three NO synthase (NOS) isoforms[54]. The remainder of nitrite in the circulation and tissues has been related to nutritional sources[55]. The half-life of nitrite is quite long in contrast to NO - approximately 35-60 min depending on the models and compartments used to evaluate nitrite distribution[56]. We have previously shown that the endogenous levels of nitrite can be modified by intravenous infusion of nitrite and certain diets[14,57,58]. An adequate nitrite production along with sufficient endogenous levels has implications for numerous cardiovascular functions. We have shown that trained athletes with higher nitrite levels performed superior in exercise tests as compared to those with lower concentrations[59].

In hypoxia or ischemia, nitrite may be reduced to bioactive NO, thus providing an alternative pathway to the enzymatic formation of NO, which is inactive under these circumstances. Nitrite activation may occur through reaction with hemoglobins such as myoglobin[60]. With decreasing oxygen gradients, cardiac myoglobin changes its function from an oxygen storage and NO scavenger to an NO producer by reducing nitrite to bioactive NO[13,15,37,60,61]. This can significantly reduce myocardial I/R injury[37].

The downstream mechanism following a formation of NO from nitrite largely involves mitochondria. In an experimental approach using exogenous nitrite during myocardial I/R injury we identified an S-nitrosation modification of mitochondrial complex Ⅰ. This, in turn, regulates myocardial energetics *via* the modulation of mitochondrial respiration and formation of mitochondria derived ROS. S-nitrosation of complex Ⅰ is furthermore associated with an adaption of myocardial functions to a reduced O_2 supply. This mechanism has been recognized as hibernation. Finally, nitrite reduction to NO and the downstream signaling cascade contributes to a decrease in myocardial necrosis and apoptosis[16,37,60,62].

In our recent study using rIPC as protective regimen we revealed that this maneuver also involves a protective nitrite/NO signaling with similarities to the

one described above for exogenous nitrite[13]. Figure 1 summarizes the general concept. This involves a sender, the transfer of the signal to the target organ, and a receiver - the cardiomyocyte. We propose the sender to be the endothelium of the extremity treated with rIPC. Repetitive phases of in- and deflations of the blood-pressure cuff cause high blood flow and a subsequently increased shear stress. This results in shear-stress dependent eNOS activation and NO formation, which converts to nitrite - the stable oxidation product.

This circulating nitrite is transmitted as signal of cardioprotection to the heart. The stability of nitrite and its half time argues in favor of nitrite[56]. In transfer experiments, the effects were preserved when infusing conditioned human plasma to isolated mouse hearts. Nitrite scavenging in conditioned human plasma abolished the transmission of cardioprotection to the conditioning-naïve Langendorff hearts.

The receiver of protection is the cardiomyocyte. In the myocardium, cardiomyocyte myoglobin reduces nitrite to NO during I/R with subsequent S-nitrosation modifications of mitochondrial complex I finally leading to cardioprotection. Presently, it is not known whether other signaling molecules regulating for instance apoptosis, necrosis and mitochondrial structure, *e.g.*, the BH3 proteins, are also affected by S-nitrosation modifications by rIPC.

Our recent findings were further evidenced by studies by a group who demonstrated that ischemic conditioning applied locally leads to a wide variety of proteins being S-nitrosated[63,64]. However, this appears to be a selective process in which SSM mitochondria are favored. This furthermore required connexin-43[64] to be active. It is tempting to speculate that particularly the subgroup of SSM are largely responsible for cardioprotection during I/R injury. Taken together, current evidence from experimental studies currently implicates a substantial contribution of nitrite/NO to cardioprotection by ischemic conditioning. This involves a specific modulation of mitochondria a targeted S-nitrosation and a reduction in the formation of ROS as well a distinct signaling *via* connexins.

CONCLUSION

In summary, rIPC has been demonstrated to protect the myocardium from I/R injury. Several clinical trials have demonstrated beneficial results for patients. Arguably, the underlying signaling is delicate involving many signaling processes. This pertains to humoral factors, blood cells, neurohumoral mediators and presumably a complex interplay. The data from ours and several other groups implicate a role for hypoxic NO signaling in the course of rIPC[13,50,64,65]. This requires particularly an S-nitrosation modification of mitochondrial elements. Naturally, many previously forwarded mechanisms will work along-side the proposed one based on NO[6]. Further studies will be required to elucidate the complex interplay involved in signal generation, signal transfer and final cardioprotection in the target organ. It will be of particular interest to evaluate the decisive signal transduction pathway in patients treated with rIPC. This is naturally a limitation of the current studies in the field of nitrite-NO signaling in rIPC[13,50,64,66-68], which involve healthy mice without significant co-morbidities and relevant medications.

Abstract

Endothelial dysfunction with impaired bioavailability of nitric oxide (NO) is the hallmark in the development of cardiovascular disease. Endothelial dysfunction leads to atherosclerosis, characterized by chronic inflammation of the arterial wall and stepwise narrowing of the vessel lumen. Atherosclerosis causes deprivation of adequate tissue blood flow with compromised oxygen supply. To overcome this undersupply, remodeling of the vascular network is necessary to reconstitute and sustain tissue viability. This physiological response is often not sufficient and therapeutic angiogenesis remains an unmet medical need in critical limb ischemia or coronary artery disease. Feasible approaches to promote blood vessel formation are sparse. Administration of pro-angiogenic factors, gene therapy, or targeting of microRNAs has not yet entered the daily practice. Nitric oxide is an important mediator of angiogenesis that becomes limited under ischemic conditions and the maintenance of NO availability might constitute an attractive therapeutic target. Until recently it was unknown how the organism provides NO under ischemia. In recent years it could be demonstrated that NO can be formed independently of its enzymatic synthesis in the endothelium by reduction of inorganic nitrite under hypoxic conditions. Circulating nitrite derives from oxidation of NO or reduction of inorganic nitrate by commensal bacteria in the oral cavity. Intriguingly, nitrate is a common constituent of our everyday diet and particularly high concentrations are found in leafy green vegetables such as spinach, lettuce, or beetroot. Evidence suggests that dietary nitrate supplementation increases the regenerative capacity of ischemic tissue and that this effect may offer an attractive nutrition-based strategy to improve ischemia-induced revascularization. We here summarize and discuss the regenerative capacity of dietary nitrate on the vascular system.

Key words: Dietary; Nitrate; Vasculature; Regeneration; Hind limb

Core tip: Nitrate is a common constituent of our everyday diet and particularly high concentrations are found in leafy green vegetables such as spinach, lettuce,

or beetroot. Evidence suggests that dietary nitrate supplementation increases the regenerative capacity of ischemic tissue and that this effect may offer an attractive nutrition-based strategy to improve ischemia-induced revascularization. We here summarize and discuss the regenerative capacity of dietary nitrate on the vascular system.

BREAKDOWN OF NITRIC OXIDE AVAILABILITY IS THE HALLMARK OF CARDIOVASCULAR DISEASE

Nitric oxide (NO) is biosynthesized endogenously from the amino acid L-Arginine (L-Arg) and oxygen by various NO synthases (NOS) which are termed either according to their distribution within the body or allowing for the order where they first purified and cloned. NOS produce NO by catalyzing a five-electron oxidation of guanidino nitrogen of L-Arg that requires binding of five cofactors. These cofactors are: flavin adenine dinucleotide, flavin mononucleotide, heme iron, tetrahydrobiopterin, and calcium-calmodulin[1]. If any of these co-factors becomes limited, NO production from NOS is restricted and NOS produce superoxide (O_2^-) instead. This mechanism has been termed "NOS uncoupling"[2]. Consequently, a physiological oxygen concentration as well as sufficient substrate supply is necessary for a proper NOS function. NO is involved in a wide variety of regulatory mechanisms of the cardiovascular system, including vascular tone (as a major mediator of endothelium dependent vasodilatation), vascular structure (inhibition of smooth muscle cell proliferation), and cell-cell interactions in blood vessels (inhibition of platelet adhesion and aggregation and inhibition of monocyte adhesion). Risk factors like hypercholesterolemia, hypertension, diabetes mellitus or cigarette smoking lead to the inability of the endothelium to produce NO[3-5]. A decrease of endothelial NO formation due to insufficient oxygen and cofactor supply or inactivation by reactive oxygen species is the hallmark of endothelial dysfunction. Importantly, this is the key element and a facilitative factor in the development of atherosclerosis. Lack of NO in turn promotes aggregation and invasion of inflammatory cells in the vessel wall and aggravates sclerosis of arteries. Thus, a vicious cycle takes place that results in progressive deprivation of blood supply with hypoxia of tissues and organs. Growth of new vessels result as an adaptive mechanism in response to tissue hypoxia or ischemic injury, called angiogenesis. The physiological repair response, however, is often not sufficient and therapeutic angiogenesis remains an unmet medical need.

ROLE OF NO IN ANGIOGENESIS

Angiogenesis is strongly stimulated in response to tissue hypoxia or ischemic injury and requires several key processes, including dissolution of matrix, endothelial cell proliferation and migration, and organization into tubes followed by lumen formation. One of the most potent angiogenic growth factors is represented by the vascular endothelial growth factor (VEGF) that induces proliferation, migration, survival and permeability of endothelial cells[6,7]. VEGF upregulates the expression of endothelial NO synthase (eNOS) and stimulates the release of endothelium-derived NO what is believed to play a critical role in the angiogenic action of this factor[8]. In line with these findings, it could be demonstrated that eNOS gene delivery promotes angiogenesis in animal models of ischemia[9]. On the contrary, the angiogenic response following hind limb ischemia in mice is impaired in eNOS- deficient mice and this cannot be reversed by VEGF substitution[10]. From these findings, NO appears to be a downstream mediator of VEGF-induced endothelial cell proliferation and migration and is suggested to even regulate VEGF expression[11]. However, it should be noted that a major limitation of these investigations is the use of NO donors. The drawback of this approach is that the influence of the released NO might be masked by the NO-independent actions of donating compounds or their derivatives. Likewise, animal models using eNOS overexpression to determine whether the effect of NO on VEGF synthesis could be achieved in ischemic limb neglect that eNOS is dysfunctional in ischemic tissues[12].

NO GENERATION WITHOUT NOS: THE NITRATE-NITRITE-NO PATHWAY

Since the classical NO-pathway is not functional during ischemia, NOS independent mechanisms must exist to maintain NO homeostasis under hypoxic conditions. The reduction of nitrite, the oxidation product of NO, by several "nitrite-reductases" under hypoxia was identified to be such an alternative pathway (Figure 1 and Table 1)[13-17]. These nitrite reductases operate along the physiological and pathological oxygen gradient and allow a graded nitrite reduction to NO according to the circulating and metabolic need. The reduction of nitrite to NO reflects a major mechanism by which the NO homeostasis is maintained independent of NOS. New insights evidence that nitrate and nitrite metabolism occurs in blood and tissues to recycle NO and other bioactive nitrogen oxides[18,19]. Commensal bacteria in the crypts of the tongue own a nitrate reductase enzyme that is utilized for energy metabolism in the absence of oxygen[20,21]. It was known that nitrate is

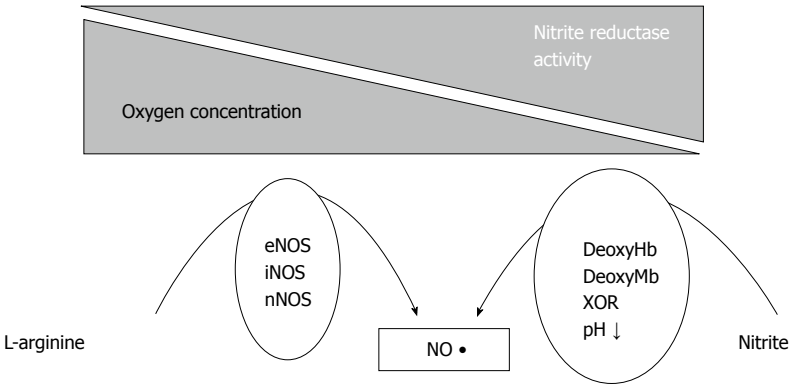

Figure 1 Non-enzymatic nitric oxide formation. One-electron reduction of nitrite (NO_2^-) to NO by ferrous heme proteins like hemoglobin in the blood or myoglobin in the heart can occur under conditions of low oxygen (O_2); the nitrite-reductase activity of these proteins contributes to NOS independent NO formation. eNOS: Endothelial NO synthase; iNOS: Inducible NO synthase; nNOS: Neuronal NO synthase.

Table 1 Nitric oxide generation pathways

Nitrate-nitrite-NO pathway	
NO synthases	
	Endothelial NO synthase
	Neuronal NO synthase
	Inducible NO synthase
Nitrate reductases	
	Xanthin oxidoreductase
	Mitochondrial respiratory chain enzymes
	Cytrochrome P-450
	Acidic reduction
	Myoglobin
	Neuroglobin
	Hemoglobin

NO: Nitric oxide.

taken up by the salivary glands and concentrated in the saliva. However, the reason for this active process could not be explained until the finding that nitrate serves as substrate for the nitrate reductase enzyme of bacteria in the mouth. These bacteria reduce both plasma extracted nitrate as well as dietary nitrate to form nitrite resulting in salivary nitrite levels that are 1000-fold higher than those found in human plasma[22]. When nitrite-rich saliva meets the acidic gastric juice after swallowing, nitrite is protonated to form nitrous acid (HNO_2), which then decomposes to NO. This acidic disproportionation takes part in the human defense against pathogens entering *via* the alimentary tract. Furthermore it could provide protection against ulcers from drugs or stress[23-25]. Beside the intragastric formation of NO it has been demonstrated that ingested nitrite reaches the systemic circulation, thus making it systemically available[22]. Nitrite in turn can be reduced *in vivo via* numerous pathways to form bioactive NO. These include the reduction *via* deoxygenated myoglobin within the heart muscle, deoxygenated hemoglobin, intracellular xanthin oxidoreductase, enzymes of the mitochondrial respiratory chain, cytochrome P-450 and even *via* the NOS[13,15,17,26-29]. Thus, several mechanisms exist by which NO is generated in the body, including the NOS enzymes or the non-enzymatically acidic reduction of nitrite. Nitrite mediates hypoxic vasodilation, enhances blood flow and matches oxygen supply to increased metabolic demands under hypoxic conditions[30]. Moreover, application of exogenous nitrite bears the potential to reduce myocardial damage after myocardial ischemia and reperfusion injury[26,31]. In addition, dietary approaches using nitrate to elevate circulating nitrite levels are emerging as a potential treatment regimen for high blood pressure[32]. Considering the upcoming evidence that nitrite and nitrate mediate cytoprotective effects in human physiology and especially under pathophysiological conditions, it is not unlikely that dietary nitrate and nitrite may positively affect human health and disease. Recognizing that NO is the most important molecule in regulating blood pressure and maintaining vascular homeostasis, food sources rich in NO compounds may provide beneficial effects primarily to the heart and vessels. Although there are clear reports on certain foods and diets that have shown a benefit in terms of preventing cancer and cardiovascular disease, the specific nature of the active constituents responsible for the cardioprotective effects of certain foods is still unknown. Viable candidates are fibers, minerals or antioxidants. High intake of fruits and vegetables is indeed associated with reduced risk for coronary artery disease and apoplectic stroke and the strongest protection against coronary heart disease was seen with high intake of green leafy vegetables[33]. Dietary intakes of nitrate-rich vegetables lowers blood pressure in subjects with borderline hypertension to the same extend as mono-therapy with a standard antihypertensive drug[34,35]. Likewise, blood pressure lowering effects could be demonstrated for dietary nitrate and ingestion of beetroot juice respectively[32,36]. We could recently demonstrate that dietary supplementation with inorganic nitrate improves prognostic relevant outcome measures that have been shown to predict cardiovascular events, namely endothelial dysfunction, vascular stiffness and systolic blood pressure in the elderly with moderately increased cardiovascular risk[37]. Improvements in blood pressure following the nitrate rich diet were associated with reductions of pro-inflammatory cytokines, which points to the potential anti-inflammatory actions of the nitrate-nitrite-NO pathway[38,39]. The hypothesis that dietary nitrate might provide cardiovascular benefit is further encouraged by animal models of myocardial infarction,

where dietary supplementation of these anions provided beneficial effects on I/R injury[40]. Interestingly, a diet rich in vegetables, such as the Mediterranean and the traditional Japanese diets, contains more nitrate than the recommended acceptable daily intake by the World Health Organization[41]. Even a portion of spinach consumed in one serving of salad can exceed the acceptable daily intake for nitrate[22]. Taken together, the current evidence supports the conclusion of the European Food Safety Authority that benefits of vegetable and fruit consumption outweigh any perceived risk of developing cancer from the consumption of nitrate and nitrite in these foods. The outlined above data from observational epidemiologic and human clinical studies support the hypothesis that nitrates and nitrites of plant origin play essential physiologic roles in supporting cardiovascular health.

REGENERATIVE CAPACITY OF DIETARY NITRATE ON VASCULATURE

Increased oxygen radicals (ROS) and subsequent reduced NO bioavailability impair vascular growth and remodeling, which highlights important targets for therapeutic angiogenesis in ischaemic myocardial infarction, peripheral vascular disease, as well as stroke. Significant advances have been made with respect to quantitative analytical methods to detect specific ROS and NO species. This must be employed in future studies to enhance the understanding of the relationship between ROS levels and stimulation of vascular remodeling in conjunction with NO bioavailability. Moreover, studies indicate impaired eNOS function in diabetes and atherosclerosis as a result of increased vascular generation of ROS and reduced NO bioavailability[42,43]. Despite endeavors to promote blood vessel formation by administration of pro-angiogenic factors, gene therapy or targeting of microRNAs, clinically applicable strategies have not been developed yet or are still in a preclinical phase[44-47]. In this context, dietary nitrate becomes an attractive candidate in the field. A nitrate rich diet can be achieved *via* consumption of leefy green vegetables, as spinach or lettuce, or by consumption of beet-root. However, for comparative reasons, most studies have used nitrate in the pure chemical form of sodium nitrate or potassium nitrate. Mechanistically, nitrate and nitrite can be viewed as stable storage pools for NO-like bioactivity. To further determine the mechanisms of a healthy diet through dietary nitrate on the vasculature we investigated the age-related changes that occur at a molecular level and determined the age-related vascular transcriptome altered by dietary nitrate[48,49]. Intriguingly, a chronic nitrate supplementation was shown to act as a modifier of gene expression, highlighting the plethora of putative mechanisms, which dietary nitrate influences[49]. Our results highlight the potential of a dietary approach counteracting the compromised cardiovascular system. Further investigations in ischemic tissues applying the hind limb model in mice highlighted the potential of dietary nitrate in angiogenesis[50]. A cytoprotective role of nitrite in the setting of myocardial, liver, kidney, and brain ischemia-reperfusion (I/R) injury has previously been demonstrated and continuous pharmacological intervention with nitrite injections increases vascular density in hind limb models[51-55]. We could show that dietary nitrate supplementation strongly augments perfusion recovery in chronic hind limb ischemia *in vivo via* a significant increase in capillary density. This improvement was associated with an increase in circulating nitrite concentrations, an elevated mobilization of $CD34^+/Flk\text{-}1^+$ cells and migration of bone marrow-derived $CD31^+/CD45^-$ cells into ischemic tissue[50]. The mobilization of circulating angiogenic cells following dietary nitrate supplementation was recently supported by a phase I clinical study[56]. A further effect of the dietary nitrate supplementation to drinking water was an attenuated apoptosis in myoblasts in chronic hind limb ischemia. Intriguingly, disruption of the nitrate-NO pathway by chronic eradication of the oral bacteria completely abolished beneficial effects of dietary nitrate supplementation and likewise effectively suppressed circulating nitrite levels, which were observed after intake of nitrate-rich food or dietary nitrate supplementation in drinking water. In line with these findings, the results of this study further point to a distinct contribution of dietary nitrate supplementation on tissue viability. Dietary nitrate ameliorated the remarkable capacity of adult skeletal muscles to regenerate myofibers after damage. This rapid repair process is mainly carried out by satellite cells (SCs) with contribution of NO[57,58]. Quiescent SCs become active and proliferate upon injury and display the regenerative capacity of the muscle. Committed daughter cells, the myoblasts, continue to proliferate followed by definite differentiation as initialized by a coordinated cellular signaling[59]. The precise pathways that are influenced by the nitrate-nitrite-NO pathway are under intensive investigations and not fully understood yet.

In summary dietary nitrate supplementation increases the regenerative capacity of ischemic tissue and may offer an attractive nutrition-based strategy to improve ischemia-induced revascularization.

Abstract

While cardioplegia has been used on millions of patients during the last decades, the debate over the best technique is still going on. Cardioplegia is not only meant to provide a non-contracting heart and a field without blood, thus avoiding the risk of gas emboli, but also used for myocardial protection. Its electromechanical effect is easily confirmed through direct vision of the heart and continuous electrocardiogram monitoring, but there is no consensus on the best way to assess the quality of myocardial protection. The optimal approach is thus far from clear and the considerable amount of literature on the subject fails to provide a definite answer. Cardioplegia composition (crystalloid *vs* blood, with or without various substrate enhancement), temperature and site(s) of injection have been extensively researched. While less frequently studied, re-dosing interval is also an important factor. A common and intuitive idea is that shorter re-dosing intervals lead to improved myocardial protection. A vast majority of surgeons use re-dosing intervals of 20-30 min, or even less, during coronary artery bypass graft and multidose cardioplegia has been the "gold standard" for decades. However, one-shot cardioplegia is becoming more commonly used and is likely to be a valuable alternative. Some surgeons prefer the comfort of single-shot cardioplegia while others feel more confident with shorter re-dosing intervals. There is no guarantee that a single strategy can be safely applied to all patients, irrespective of their age, comorbidities or cardiopathy. The goal of this review is to discuss the rationale for short re-dosing intervals.

Key words: Myocardial protection; Del Nido cardioplegia; Continuous cardioplegia; Intermittent cardioplegia; Single-shot cardioplegia; Multidose cardioplegia; Crystalloid cardioplegia; Blood cardioplegia; Custodiol®; Histidine-ketoglutarate-tryptophan

Core tip: During myocardial ischemia, cardioplegia is the preferred method of myocardial protection. However, decades after its implementation, there is still no consensus on the optimal re-dosing interval. Shorter re-dosing (15-30 min) has been preferred to longer intervals (45-60 min), but the choice of one approach over another relies more on the surgeon's preference than on clear advantages. As the interest for one-shot

cardioplegia has been increasing recently, we intend to discuss the rationale, if any, for short cardioplegia re-dosing interval.

Durandy YD. Is there a rationale for short cardioplegia re-dosing intervals? *World J Cardiol* 2015; 7(10): 658-664 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i10/658.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i10.658

INTRODUCTION

The successful curative treatment of certain congenital or acquired heart diseases requires a method allowing direct vision of the open heart. For decades, cardioplegia has been the preferred and best method to provide a non-contracting heart and a field without blood. However, despite its use on millions of patients, the debate over the ideal cardioplegic technique is still going on. Strictly speaking, cardioplegia means paralysis of the heart: the visual appearance of standstill heart and continuous monitoring of the electrocardiogram allow for an easy control. But cardioplegia is also the major component of myocardial protection. There is no consensus on the best tools for myocardial protection assessment. First, there is no way to routinely perform real-time myocardial protection evaluation. Second, myocardial protection is clinically assessed post-operatively *via* a number of indirect factors such as troponin I/T or creatine kinase MB levels, ischemic electric signs on EKG or myocardial infarction, stroke, atrial fibrillation, myocardial function on echo, low cardiac output state, inotropic support, intra-aortic balloon pump, extracorporeal membrane oxygenation, as well as time to extubation and length of stay in intensive care unit[1-6]. These indirect factors are affected by several causes including surgery, anesthesia, intensive care, and, in the case of complex cardiopathies, resultant physiology following surgical palliation or cure. It is impossible to determine the role played by each cause. Myocardial protection is a concept without clear and specific clinical signs.

Experimental works on cardioplegia aiming to assess myocardial protection use time-consuming, invasive and often expensive approaches such as continuous monitoring of intra-myocardial pH, myocardial lactate production, or myocardial biopsy for ATP dosage, which are unrealistic in routine clinical practice[7-9]. However, there is a huge amount of publications on cardioplegia trying to find the best technique for cardiac arrest and myocardial protection. The composition of the cardioplegic solution (blood *vs* crystalloid, with various substrate enhancement), the injection site(s) (antegrade, retrograde or both), the temperature (cold, tepid or warm) and the re-dosing intervals were the main factors explored. The large number of combinations of these factors makes studies difficult to compare. Furthermore, the type of cardiac repair interferes with re-dosing intervals. During coronary artery surgery, re-dosing is usually done after each distal anastomosis, *i.e.*, every 10 ± 5 min, but 60-min re-dosing intervals have also been described[10]. During valvular or complex procedures, re-dosing intervals are variable from one surgeon to another[2,11-22].

Shorter re-dosing intervals could be a more critical factor than total aortic cross-clamp time in terms of myocardial protection, which would imply that shorter intervals lead to improved protection[23]. This intuitive observation was supported by experimental and clinical works[24-26]. Unexpectedly though, other works suggested that single-shot cardioplegia was better or at least equivalent to multidose cardioplegia[27-30].

We have learned from heart transplantation that myocardial ischemia may be tolerated for several hours[31]. The upper limit for donor heart ischemic time, which was 4 h in the early days of heart transplant surgery, was progressively increased to 6-8 h[32]. Successful heart transplantation with a donor heart ischemic time of 13 h was published, but in this clinical case, the follow-up was limited to three months[33]. Cold blood cardioplegia[34], histidine-tryptophan-ketoglutarate (HTK) solution or Custodiol®, a solution developed for organ preservation in transplantation[35,36], and Del Nido cardioplegia were all proposed for single-shot cardioplegia[37,38].

The debate over the best re-dosing interval is not new but while multidose cardioplegia has been the "gold standard" for decades, one-shot cardioplegia is becoming more commonly used and is likely to be a valuable alternative. This is particularly true for minimally invasive vascular surgery[39,40]. However, the use of single-shot cardioplegia relies more on the surgeons' preference than on true advantages in terms of immediate outcomes[41].

The goal of this work is to discuss the rationale for short re-dosing intervals.

FROM CONTINUOUS BLOOD CARDIOPLEGIA TO SINGLE-SHOT CARDIOPLEGIA *VIA* INTERMITTENT CARDIOPLEGIA

From a theoretical point of view, a continuous injection of normothermic oxygenated blood containing the arresting agent is the best way to perform cardiac arrest and optimal myocardial protection. Gott *et al*[42] proposed this technique of aerobic arrest in 1957, but it was long to establish itself. In 1989, a clinical case was published on retrograde continuous blood cardioplegic warm infusion *via* the coronary sinus during mitral surgery. After a cross-clamp time of 393 min, the patient was easily weaned from bypass without intra-aortic balloon pump or inotropic support. It is noteworthy that the cardiac output was higher

immediately after bypass than before surgery[43]. The same team used the same technique of aerobic arrest in 308 consecutive procedures with warm surgery. Twenty-two of these patients needing an aortic cross-clamp time greater or equal to 3 h had excellent results[44]. The technic never became really popular for several reasons. First, it is technically more demanding and blind insertion of the cannula into the coronary sinus may be uneasy. Second, drawbacks were described, such as hyperkalemia, coronary sinus damage, catheter misplacement, migration or dislodgment in the right atrium[45-47]. Third, a major concern was the distribution of cardioplegia to the right hypertrophic ventricle or when the right coronary vein is next to the coronary sinus[48,49]. Last, for coronary artery bypass graft, a micro blower delivering compressed air is often needed for completion of distal anastomosis[50].

To overcome constraints related to retrograde continuous cardioplegia, intermittent, antegrade warm blood cardioplegia was proposed as an alternative. From November 5, 1990 to December 31, 1992, a study was conducted at three adult cardiac surgical centers of the University of Toronto on 720 patients operated on for aortocoronary. Warm blood cardioplegia was interrupted during 5-15 min for enhancing visualization during distal anastomosis. The longest ischemic time, equivalent to the longest time off cardioplegia (LTOC, in minutes per patient) and the total duration of ischemic time as a proportion of the aortic cross-clamp time were collected. The quality of myocardial protection was assessed on post-operative mortality at 30 d (or in-hospital deaths for patients with a length of stay > 30 d), myocardial infarction by enzyme criteria and low-output syndrome. The authors postulated that short periods of normothermic ischemia should be well tolerated if followed by adequate cardioplegic reinfusion. Their study aimed to evaluate the relation between intermittency of cardioplegia and cardiac events.

The results suggested that the longest ischemic time was more important than the cumulative ischemic time and that prolonged LTOC > 13 min was a risk factor for adverse outcomes[23]. For a vast majority of surgeons, thirteen minutes is a reasonable time for distal anastomosis construction. In summary, intermittent, antegrade warm blood cardioplegia is a valuable alternative to antegrade cold blood cardioplegia when the time off cardioplegia remains under 13 min. In a clinical scenario, this time off cardioplegia is more realistic than the maximal cardioplegia halted time of 5 min proposed by Menasché *et al*[51] in 1992. In 1995, a simpler technique was described, allowing a re-dosing interval of 15 min. Two groups of 250 patients undergoing elective coronary artery bypass grafting were compared using either intermittent warm blood cardioplegia or intermittent cold blood cardioplegia. For the surgeon, the two types of cardioplegia were similarly demanding. After an initial injection in the aortic root, re-dosing was done after each distal anastomosis or after 15 min. This maximal ischemic time was chosen to be long enough for a difficult distal anastomosis. The outcome was superior in the warm group, with significantly less cardiac-related deaths and a dramatic decrease in morbidity. There was lactate washout in both groups 1 min after aortic cross-clamping, but lactate production was still present 20 min after reperfusion in the cold group, while there was evidence of normal lactate extraction in the warm group, suggesting a rapid restoration of a normal metabolism. In summary, in this study, intermittent warm cardioplegia was superior to intermittent cold blood cardioplegia, with lower morbidity, mortality and decreased length of stay in ICU and hospital[52]. The re-dosing interval was later increased to 20-30 min without complication[53,54]. Other authors confirmed the good tolerance of 30-min warm ischemia time in 1996 and 2000[55,56]. In 2009, a comparison between intermittent warm blood cardioplegia and single-shot warm blood cardioplegia was published. The study was done from January 2001 to December 2006 and included 4014 patients: 1708 had single-shot cardioplegia and 2306 had intermittent warm blood cardioplegia with a 20-min re-dosing interval. There was statistical insignificance for mortality, intra or postoperative intra-aortic balloon pump, postoperative inotropics or postoperative arrhythmia. Single-shot had a favorable effect on post-operative myocardial infarction and an unfavorable effect on intraoperative inotropics and postoperative dialysis. Authors found that the first shot of warm cardioplegia may safely exceed 20 min and, in case of short cross-clamping (35 to 40 min), cover the whole cross-clamping time without increased risk[57]. However, there is probably an individual threshold for tolerance due to pre-, intra- and post-operative factors.

Interestingly, the same evolution in re-dosing interval was described in pediatric cardiac surgery. We introduced this technique in 2002 with a cardioplegia protocol identical to the one described in adults in 1995: warm oxygenated blood was diverted from the arterial line *via* a roller pump and St Thomas' solution was added downstream the pump with an electrical syringe. The blood to arresting agent ratio was 60:1, therefore the hydric balance of cardioplegia was negligible and it was named microplegia[58]. The re-dosing interval was 15 min and a nomogram was developed for volume and duration of the first injection and re-injection[59].

Another group implemented the same approach of intermittent warm blood microplegia, except for the re-dosing interval (10 min). They also suggested, on a group of arterial switch, that intermittent warm blood microplegia was a valid alternative to intermittent cold blood cardioplegia[60].

Following our initial experience on 1400 pediatric patients, we demonstrated that the technique was safe for long aortic cross-clamp time on 38 patients with a cross-clamp time > 90 min[61]. Using the same protocol for cardioplegia with a 15-min re-dosing interval, a group from Brussels used cardiac biopsies to demonstrate a significant increase in myocardial ATP

stores during the first cardioplegic ischemic time and a return to initial values after coronary reperfusion. This reproducible method was considered safe, with low morbidity and mortality and a similar quality of cardiac repair[62].

The technique was gradually implemented in several European units and more than 10000 cases with re-dosing intervals varying from 10 to 25 min were published in 2010[63]. As in adult surgery, intervals gradually increased between 2001 and 2013, from 10 to 35-40 min, without any adverse effect[64,65]. However, the major issue remains: how long is too long? It is likely that re-dosing intervals cannot be indefinitely increased without inducing adverse cardiac events.

The merits of single-dose *vs* multidose cardioplegia in the infant heart were described in animal experiments several decades ago[27-30], but there was a certain lack of enthusiasm for its clinical use. However, in 1988, a clinical study was published, comparing two groups of arterial switch operated on with single-dose or multidose cold blood cardioplegia with a 15-min re-dosing interval. The incidence of mortality and ST-T changes was significantly higher in the multidose group. The conclusion was that single-dose is as good as, or better than, multidose cardioplegia[34]. In 1989, another group confirmed the efficiency of single-shot cold crystalloid cardioplegia in arterial switch procedure[66].

There is increasing interest in HTK or Custodiol® single-dose cardioplegia. In 1998, Sakata suggested that single high-volume HTK provided a more adequate myocardial protection for mitral surgery than multidose cold blood cardioplegia[67]. In 2001, the benefit of single-dose HTK cardioplegia over multidose cold crystalloid cardioplegia was also suggested in a clinical work comparing two groups of 15 patients. The incidence of arrhythmia and inotropic support decreased significantly in the HTK group and so did the ICU length of stay[68]. The feasibility and safety of single-shot HTK cardioplegia was suggested in adult and pediatric surgery[35,36,69,70]. A new modified HTK solution named Custodiol-N, likely to enhance the organ protective potential of the previous solution, was tested on animals during a 60-min hypothermic cardiac arrest[71,72].

Del Nido cardioplegia has been used for two decades at the Boston Children's Hospital, generally in a single-dose fashion[73]. Its use was expanded to adult surgery, triggering a growing interest in this solution[74]. Recent works in adults and pediatrics suggest that it is a safe and valuable alternative to conventional multidose cardioplegia[37].

WHERE ARE WE? WHERE DO WE GO FROM HERE?

A review of the literature published prior to 1975 concluded that a 20-min ischemic period at 32℃ could be tolerated by the heart without the need for inotropic support, while the anoxic safe period was extended to 30 min when temperature was lowered to 16℃-20℃[75]. Forty years later, despite ample evidence that the ischemia time can be safely increased, even during warm surgery, a vast majority of surgeons use re-dosing intervals of 20-30 min, or even less, during coronary artery bypass graft. Some surgeons prefer the comfort of single-shot cardioplegia while others feel more confident with shorter intervals. How can we explain the myocardial tolerance to anoxia? Is it due to the composition of the arresting solution, the temperature of cardioplegia, or both?

We have seen that for cold and warm blood cardioplegia, short-term outcomes are equivalent with identical re-dosing intervals, just as they are identical for cold blood and cold crystalloid cardioplegia. The temperature is likely to have little effect, if any, but studies focused on aortic cross-clamp times < 90 min. We have also seen that different cardioplegic solutions can be safely used for hypothermic single-shot cardioplegia[34-38]. The composition did not seem to be critical, or, at least, different solutions can be used for single-shot cardioplegia and comparisons between these solutions are missing.

It is probably a fool's errand to look for a universal gold standard. The best cardioplegia with optimal re-dosing interval is likely to vary with different patients having different pathologies, and different aortic cross-clamp time. Dr J Vaage's stated: "If you had a clamp time of < 60 min, you could actually use whatever cardioplegia or myocardial protection you wanted, you could always get to the shore, so to say"[57]. It is probably true, but we are still looking for the optimal cardioplegia, for simple and complex cardiopathies. The goal is not just to get to the shore, but also to use the best, simplest, fastest and cheapest way to deliver optimal results to our patients. Furthermore, we intend to prevent cardiac events not just during the initial outcome - the one that allows getting to the shore - but also during mid- and long-term outcomes[76]. Myocardial fibrosis could be a late side effect of cardioplegia[77]. This is more challenging and less extensively studied.

CONCLUSION

This review does not solve the issue on the rationale for short-term re-dosing interval. However, facts are facts, and many works suggest or demonstrate that short-term re-dosing intervals are not critical for every patient. There is probably no rationale to use the same re-dosing interval for all patients needing aortic cross-clamping for surgical cardiac repair. Despite the lack of consensus on cardioplegia composition, temperature, way of administration and re-dosing interval, the outcomes of adult and pediatric cardiac surgery are continuously improving.

Abstract

Myocardial infarction is the most common cause of congestive heart failure. Novel strategies such as directly reprogramming cardiac fibroblasts into cardiomyocytes are an exciting area of investigation for repair of injured myocardial tissue. The ultimate goal is to rebuild functional myocardium by transplanting exogenous stem cells or by activating native stem cells to induce endogenous repair. Cell-based myocardial restoration, however, has not penetrated broad clinical practice yet. Platelet-rich plasma, an autologous fractionation of whole blood containing high concentrations of growth factors, has been shown to safely and effectively enhance healing and angiogenesis primarily by reparative cell signaling. In this review, we collected all recent advances in novel therapies as well as experimental evidence demonstrating the role of platelet-rich plasma in ischemic heart disease, focusing on aspects that might be important for future successful clinical application.

Key words: Platelet-rich plasma; Ischemic heart disease; Myocardial infarction; Myocardial regeneration; Cardiac repair

Core tip: Tissue regeneration requires precise coordination among endothelial, epithelial and mesenchymal morphogenesis. Growth factor-induced angiogenesis plays a key role in recovery from ischemic disease and organ regeneration. Recent studies show that stem-cells and PRP together have opened new horizons in the myocardial infarction treatment.

INTRODUCTION

Coronary infarction is the most frequent cause of death globally[1]. The loss of cells during ischemia and resultant fibrosis are the main reasons for cardiac failure[2].

As cardiac muscle has very little potential to create new cells, methods of heart regeneration have been studied further as repair modalities for failing myocardium after acute coronary infarction or chronic ischemia[3].

In this article, we investigate current advances and demonstrate approaches such as the upcoming challenges of platelet-rich plasma (PRP) application as well as opportunities to develop its role.

We have gathered all experimental and clinical studies in which PRP was used as a therapy post-MI, and have focused on aspects that might be important for future successful clinical application. The PubMed database was searched for articles using the terms "platelet-rich plasma" and keywords "ischemic heart disease", or "myocardial infarction", or "coronary disease".

NOVEL REGENERATIVE THERAPIES

The majority of patients survive a myocardial infarction (MI). Their outcome, however, is negatively influenced by several events, such as loss of viable cardiomyocytes due to a post-MI inflammatory response, eventually resulting in heart failure and/or death. Regenerating the human heart is a challenge that has engaged researchers around the globe almost a century. Although the human cardiac muscle has not been regenerated yet, decades of experimental progress have guided us onto a promising path[4].

Stem cell approach has become a promising tool for cardiac regeneration[5]. The main target is to repair functional myocardial tissue by implanting exogenous or by activating native stem cells.

Cardiac stem progenitor cells (CS/PCs) are one kind of adult stem cell with the ability to differentiate into heart lineages. Induced pluripotent stem cells (iPSCs) may differentiate into the needed cells in order to repair injured myocardium. These two types of stem cells play a key role in cardiac regeneration. Two main delivery modes of stem cells (percutaneous intramyocardial or intracoronary) are used today for patients with recent acute MI or ischemic cardiomyopathy[6]. Other delivery routes, such as intravenous *via* coronary sinus or peripheral veins and surgical have also been used with less success[6].

While further studies intent to increase the efficacy of current approaches, experimental protocols using new methods such as exploiting paracrine effect and tissue engineering could enhance repair of injured human heart.

Various chemical methods, including both microRNA and anti-microRNA approaches, proteins and modified peptides demonstrate serious potential[7].

Takahashi *et al*[8] investigated pluripotent stem cells (iPSCs) revealing in a new horizon of cellular reprogramming in organ regeneration. It has been shown that iPSCs can be differentiated efficiently into multiple cell types that may be used in the future for regenerative strategies[9].

Finally, transmyocardial laser revascularization (TMR) is a controversial therapeutic technique that relieves angina but can't create a significant effect on heart function[10]. It improves the clinical status without confronting the underlying atherosclerotic disease. Therefore, TMR offers palliation and not cure[10].

ROLE OF PRP

What is PRP

Autologous PRP is an increased amount of platelets in a small portion of plasma[11]. This is why the term PRP is preferred to plasma-rich growth factors (PRGFs), platelet concentrate or platelet-rich gel. PRP is a source of autologous growth factors, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), epithelial growth factor and transforming growth factor beta 1 (TGF-β1), that is secreted by platelets in order to trigger the healing cascade[11,12]. Structurally similar to the natural fibrin clot, it can be used as scaffold for cells infiltration and assembly of vascular networks.

One of the most crucial questions regarding methodology, refers to the ideal mechanisms of intramyocardial delivery of PRP. Surgical (epicardial) application is performed into ischemic areas with a thin needle, allowing for multiple injections within and especially around the infarct area. The other less invasive interventional delivery route is the transendocardial catheter injection.

PRP and neovascularization

Neovascularization plays a significant role post-ischemia regeneration and organ repair.

It has been reported that the mixture of angiogenic factors in an certain percentage is crucial for the creation of functional blood vessels[13,14]. Angiogenesis-induced vessels, not only deliver nutrients and oxygen but also provide instructive regulatory signals to surrounding tissue affecting organ regeneration[15,16].

Neovascularization involves multiple complex events such as the maturation and enlargement of size of the preexisting small vessels through vascular remodeling

(arteriogenesis), sprouting of pre-existing resident endothelial cells (angiogenesis) and the recruitment of bone marrow derived endothelial progenitor cells (vasculogenesis)[17].

Angiogenesis involves both microvascular and macrovascular mechanisms. At the microvascular level, neovascularization is the genesis of capillaries, which, however, regress after pause of basic fibroblast growth factor (bFGF) triggering if pericytes are not gathered efficiently. Therefore, the stabilization of newly formed capillary networks by pericytes, known to be recruited by PDGF-BB, is crucial for therapeutic angiogenesis[18]. The enhancement of blood vessel maturation is one of the main modalities implemented to treat such patients.

According to the above-mentioned issues, a limited portion of plasma enriched in platelets, is an attracting attention as a safe and cost-effective source of various growth factors[19]. PRP, by containing these various cytokines, plays an important role in repairing damaged tissue[20]. As we have already discussed, little is known about the mechanism of PRP-related regeneration of damaged tissue. Successful reperfusion of ischemic tissue depends not only on stimulation of angiogenesis but also on arteriogenic activity. Different growth factors in PRP have different roles in angiogenesis and restoration of blood flow following ischemia[21]. It has also been shown that PRP effectively restores blood flow by significant increase of the number of capillaries (angiogenesis) as well as mature vessels (arteriogenesis) in the murine hind limb ischemia, which was confirmed by double staining with endothelial marker and pericytes marker respectively[22].

The VEGF, TGF-β and PDGF-BB, have a significant effect as pro-angiogenic stimulators. Evidence shows that PDGF-BB has a potential as arteriogenic factor, promoting differentiation of endothelial cells[17,23]. VEGF is known to trigger post-ischemia neovascularization[24], and TGF-β enhances cell mitosis[25]. Other reports, however, demonstrated that many growth factors, such as TGF-β and PDGF-BB, inhibit the angiogenic ability of bFGF[26]. These studies evaluated the angiogenic impact using combined solutions of growth factors. Within growth factors, PDGF-BB is the one that allows blood vessels to grow functionally[27,28]. According to this fact, multiple releases of prostaglandin F2 alpha metabolite and bFGF will improve the maturation of blood vessels. It is also demonstrated that the mixed release of VEGF and PDGF promoted the maturation of newly created blood vessels against VEGF release alone[29].

VEGF is the principle stimulatory factor of angiogenesis after ischemia[30]. However, VEGF enhances the creation of unstable capillaries[31]. It promotes mural cell accumulation, presumably through the release of PDGF-BB. It also causes endothelial cell proliferation and migration, resulting in capillary sprouting or angiogenesis. Lastly, it recruits hematopoietic stem cells to ischemic site from bone marrow *via* circulation.

Basic FGF and PDGF are chemoattractants to smooth muscle cells. Those are also causes of growth of smooth muscle cell as well as enlargement of vessel (formation of mature vessels or arteriogenesis). These stem cells produce a capillary plexus and eventually form mature vessels. All of these together cause formation of new vessels for vascular supply in ischemic limbs. So, combined administration of different growth factors may lead to potentially therapeutic angiogenesis[31,32]. PDGFR-beta are needed for vascular stabilization by gathering of mesenchymal progenitors. Absence of PDGF leads to fragile neovasculature[33], indicating that PDGF-BB has potent arteriogenic effect after ischemia.

Insulin-like growth factor-1 (IGF-1) triggers angiogenesis and myogenesis, the pro-angiogenic impact, however, seems to be less efficient than that of other angiogenic factors[34]. Finally stromal cell-derived factor 1 (SDF-1) has direct or indirect (*via* certain secondary cytokines) effects on endogenous angiogenesis[35]. There is also cross talk between VEGF and bFGF; bFGF and PDGF-BB to induce post-ischemia angiogenesis[36]. Finally, inhibition of Ang1-Tie2 signaling suppresses angiogenic ability of the PRP *in vivo* and PRP-induced angiogenesis *in vitro*.

Experimental evidence

Inspite of a large amount of evidence on PRP's usefulness, limited work has been conducted using PRP in myocardium.

Gallo *et al*[37] evaluated histological and morphological impact of the injection of PRP in ischemic sheep myocardium. Noteworthy was the formation of new blood vessels in hematoxylin-eosin-stained sections and factor Ⅷ in PRGF-treated myocardia. According to this report, implantation of platelet growth factors in previously infarcted sheep hearts promoted neovascularization.

Hargrave *et al*[38] utilized the technique of nanosecond pulsed electric fields (nsPEF) in order to determine the efficiency of a protocol involving the *in vivo* treatment of the ischemic and reperfused myocardial cells in culture with PRP in rabbits. The left ventricle had faster contraction/relaxation rate and the size of the infarct was diminished in PRP-treated hearts compared to saline-treated. Mitochondrial depolarization and reactive oxygen species (ROS) production were reduced in PRP-treated cells. These facts show that PRP contributes in cardiac protection by stabilizing the mitochondria and reducing ROS generation of the ischemic-reperfused heart.

Mishra *et al*[39] used permanent ligation, in order to find out whether PRP, enhances cardiac function in an ischemia-reperfusion model as measured by left ventricular ejection fraction (LVEF).

Compared with phosphate-buffered saline (PBS) controls, PRP-treated animals had a higher LVEF after ischemia, while PRP-treated animals who underwent ischemia-reperfusion had higher LVEF after ischemia. Histology revealed increased granulation in the control group *vs* the PRP group. In the same time, magnetic resonance imaging (MRI) revealed a positive impact

Table 1 Summary of the effects of platelet-rich plasma in ischemic heart disease

Ref.	Type of study	Animal model	Delivery method	Effect
Gallo *et al*[37]	Experimental	Sheep	Implantation	Increased formation of new vessels
Hargrave *et al*[38]	Experimental	Rabbit	Intramyocardial injection	Reduced reactive oxygen species generation Stabilized the mitochondria of the ischemic/reperfused heart
Mishra *et al*[39]	Experimental	Murine (Mouse)	Intramyocardial injection	Higher left ventricular ejection fraction after ischemia
Vu *et al*[40]	Experimental	Porcine	Intramyocardial injection	Attenuated adverse cardiac remodeling
Yu *et al*[41]	Experimental	Murine (Rat)	Intramyocardial injection	Decreased infarct size Increased ventricular wall thickness Improved cardiac function and reperfusion
Li *et al*[42]	Experimental	Murine (Rat)	Intramyocardial injection	Limitation of ventricular expansion, Attenuated myocardial hypertrophy in the noninfarct region Facilitated angiogenesis and arteriogenesis in the infarct.
Sun *et al*[43]	Experimental	Murine (Rat)	Intramyocardial injection	Improved LV performance
Wehberg *et al*[10]	Clinical	-	Intramyocardial injection	More efficacious at relieving angina Improved myocardial function

of PRP on left ventricular function in both ligation and ischemia/reperfusion murine model.

Vu *et al*[40] attempted a translational, large-scale restorative but minimally invasive approach in a porcine model, aiming at both structurally stabilizing the LV wall and improving function following ischemic injury.

In this study, a combination of PRP, anti-oxidant and anti-inflammatory factors with intramyocardial injection of hydrogel had the potential to structurally and functionally enhance the injured heart muscle while attenuating adverse cardiac remodeling after acute myocardial infarction.

Yu *et al*[41] conducted a study in order to investigate the impact of direct myocardial injection of PRP on cardiac function, ventricular remodeling and myocardial perfusion in rats. EF was significantly higher and myocardial perfusion significantly improved in the PRP group. Histological examination also confirmed that PRP treatment can decrease infarct size, increase ventricular wall thickness and improve cardiac function.

Li *et al*[42] demonstrated that a platelet-mediated paracrine effect may accelerate the healing process after myocardial infarction in rats. According to this experimental protocol, implantation of thrombin-activated PRP into the ischemic myocardium lead in enhancement of ventricular remodeling and accelerated repair, as shown through the limitation of ventricular expansion, facilitation of neovascularization, arteriogenesis in the infarct and attenuation of myocardial hypertrophy in the noninfarct part.

Sun *et al*[43] reported that adipose-derived mesenchymal stem cells (ADMSC) in a platelet-rich fibrin (PRF) scaffold were superior to direct ADMSC injection in enhancing LV function and diminishing LV remodeling in a post-MI animal model.

PRP and TMR

TMR induces a reconfiguration of the microcirculation, with blood shunted from epicardial to endocardial areas. Current literatures propose a synergistic effect among TMR and exogenously delivered growth factors.

Wehberg *et al*[10] assessed the impact of PRP intramyocardial injection combined with TMR. Angina relief was similar in both groups (TMR-alone and TMR + PRP); the TMR + PRP group, however, had a decreased average angina score and more were angina free compared to the TMR-alone group. EF improved significantly in the TMR + PRP group compared to the TMR-alone group. This study suggested that intramyocardial injection of PRP and TMR may be more effective at treating angina and enhancing heart function than TMR alone.

All above-mentioned studies are summarized in Table 1.

CONCLUSION

While stem-cell therapies and cellular reprogramming hold promise, the use of PRP emerges as an additional modality for repairing cardiac muscle.

Development of tissues is based on accurate coordination among epithelial, mesenchymal and endothelial morphogenesis. Furthermore, growth factor-induced angiogenesis is significant in organ regeneration after ischemia. Recent tissue engineering researches suggest that cells and PRP-derived growth factors together into biomaterials have opened new horizons in the myocardial infarction treatment.

PRP should be investigated for its potential regenerative properties and its use as a therapeutic modality for ischemic myocardium.

Abstract

AIM: To study the genesis of neointima formation in pulmonary hypertension (PH), we investigated the role of caveolin-1 and related proteins.

METHODS: Male Sprague Dawley rats were given monocrotaline (M, 40 mg/kg) or subjected to hypobaric hypoxia (H) to induce PH. Another group was given M and subjected to H to accelerate the disease process (M + H). Right ventricular systolic pressure, right ventricular hypertrophy, lung histology for medial hypertrophy and the presence of neointimal lesions were examined at 2 and 4 wk. The expression of caveolin-1 and its regulatory protein peroxisome proliferator-activated receptor (PPAR) γ, caveolin-2, proliferative and anti-apoptotic factors (PY-STAT3, p-Erk, Bcl-xL), endothelial nitric oxide synthase (eNOS) and heat shock protein (HSP) 90 in the lungs were analyzed, and the results from M + H group were compared with the controls, M and H groups. Double immunofluorescence technique was used to identify the localization of caveolin-1 in

pulmonary arteries in rat lungs and in human PH lung tissue.

RESULTS: In the M + H group, PH was more severe compared with M or H group. In the 4 wk M+H group, several arteries with reduced caveolin-1 expression in endothelial layer coupled with an increased expression in smooth muscle cells (SMC), exhibited neointimal lesions. Neointima was present only in the arteries exhibiting enhanced caveolin-1 expression in SMC. Lung tissue obtained from patients with PH also revealed neointimal lesions only in the arteries exhibiting endothelial caveolin-1 loss accompanied by an increased caveolin-1 expression in SMC. Reduction in eNOS and HSP90 expression was present in the M groups (2 and 4 wk), but not in the M + H groups. In both M groups and in the M + H group at 2 wk, endothelial caveolin-1 loss was accompanied by an increase in PPARγ expression. In the M + H group at 4 wk, increase in caveolin-1 expression was accompanied by a reduction in the PPARγ expression. In the H group, there was neither a loss of endothelial caveolin-1, eNOS or HSP90, nor an increase in SMC caveolin-1 expression; or any alteration in PPARγ expression. Proliferative pathways were activated in all experimental groups.

CONCLUSION: Enhanced caveolin-1 expression in SMC follows extensive endothelial caveolin-1 loss with subsequent neointima formation. Increased caveolin-1 expression in SMC, thus, may be a prelude to neointima formation.

Key words: Endothelial cells; Neointima; Pulmonary hypertension; Smooth muscle cells

Core tip: Neointima in pulmonary hypertension (PH) is associated with poor prognosis. Caveolin-1, a cell membrane protein has a critical role in PH. We investigated the association of caveolin-1 and neointima formation in monocrotaline (MCT) + hypoxia-treated rats, and in human PH lung sections. The progressive caveolin-1 reduction in endothelial cells is followed by an increased caveolin-1 expression in smooth muscle cells (SMC). In human PH as well as in the MCT + hypoxia model, neointima was observed only in the arteries exhibiting an increased caveolin-1 expression in SMC. Thus, the increased caveolin-1 expression in SMC may in part, facilitate neointima formation.

Enhanced caveolin-1 expression in smooth muscle cells: Possible prelude to neointima formation. *World J Cardiol* 2015; 7(10): 671-684 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i10/671.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i10.671

INTRODUCTION

Pulmonary hypertension (PH) is a rare, but a progressive disease with a high morbidity and mortality rate. Although considerable progress has been made in the field; the pathogenesis of PH, however, is not yet fully understood, which makes the design of preventive and curative treatment a daunting challenge. The advances in therapeutic modalities have improved the life expectancy as well as the quality of life; the pulmonary vascular remodeling, however, remains progressive[1]. A number of diverse diseases can develop PH, and several PH-associated gene mutations are known to significantly increase the risk of familial PH[2,3]. Irrespective of the underlying disease, severe PH is typically characterized by endothelial dysfunction, impaired vasodilatation, increased vasoconstriction, cell proliferation, medial wall thickening, PH and right ventricular hypertrophy (RVH)[4]. The development of neointima and plexiform lesions in pulmonary arteries associate with poor outcomes although whether or not they are causative of disease or result from an abnormal hemodynamic milieu remains unclear in the human PH[5].

In the monocrotaline (MCT) model, endothelial caveolin-1 loss and the activation of proliferative and anti-apoptotic pathways are observed before PH becomes evident. Concurrent loss of several endothelial cell (EC) membrane proteins including PECAM-1, soluble guanylate cyclase and Tie2 is suggestive of an extensive EC membrane damage. At 2 wk post-MCT, PH and RVH are observed, accompanied by a further disruption of EC as indicated by the loss of cytosolic proteins such as heat shock protein (HSP) 90, Akt and IκB-α[6-8]. Importantly, preventive measures restore endothelial caveolin-1 resulting in the inhibition of proliferative pathways and attenuation of PH[9,10]. Caveolin-1 is a major scaffolding protein of caveolae (50-100 nm), a subset of lipid rafts in the plasma membrane of a number of different cell types including EC and smooth muscle cells (SMC). It plays a pivotal role in maintaining vascular homeostasis. It directly interacts with transducing molecules within caveolae and stabilizes them in an inactive form. It regulates cell proliferation, apoptosis, cell differentiation, cell cycle, and also eNOS function[11-13].

The presence of pulmonary arterial hypertension (PAH) in patients with *CAV-1* mutation associated with reduced endothelial caveolin-1 expression, further supports a critical role of caveolin-1 in the lung vasculature[14,15]. Importantly, the loss of endothelial caveolin-1 and vWF accompanied by an increased caveolin-1 expression in SMC has recently been reported in children and adults with PAH associated with drug toxicity, congenital heart disease and idiopathic PAH (IPAH)[16-18]. Furthermore, pulmonary arterial SMC from the patients with IPAH revealed increased capacitative Ca^{2+} entry and DNA synthesis; both could be attenuated by silencing caveolin-1[18]. Thus, caveolin-1 switches from being an anti-proliferative to a pro-proliferative factor. Interestingly, the dual role of caveolin-1 is a known phenomenon in cancer[19].

Studies with rat models of PH using "VEGF receptor blocker (Sugen) + hypoxia"[20], MCT + pneumonectomy[21] and MCT + hypoxia[22] have shown severe PH with neointima and plexiform lesions, closely mimicking human PH. In these models, underlying EC damage is an important initial phase. We hypothesized that the extensive EC damage and/or loss might be a prerequisite for the increased caveolin-1 expression in SMC and subsequent development of neointima. To test this hypothesis, we treated rats with MCT and exposed them to hypobaric hypoxia (MCT + hypoxia) to accelerate the disease process. Hemodynamic data, lung histopathology, the expression of caveolin-1, and proliferative and anti-apoptotic factors, endothelial nitric oxide synthase (eNOS) and HSP90 proteins were examined. We evaluated the expression of caveolin-2 because it co-localizes with caveolin-1[23], and the expression of peroxisome proliferator-activated receptor (PPAR) γ, because it regulates caveolin-1 expression[24,25], and its loss is implicated in the pathogenesis of PH[26,27]. In addition, we examined caveolin-1 expression in the lung tissue from patients with IPAH and heritable PAH (HPAH).

MATERIALS AND METHODS

Male Sprague-Dawley rats (150-175 g, Charles River Wilmington, MA) were maintained at 22℃ on a 12 h light and dark cycle in the Animal Facility. They were allowed to acclimatize for 5 d, with free access to laboratory chow and water. The Protocols were approved by the Institutional Animal Care and Use Committee at New York Medical College (IACUC # 4-1-0113), and conform to the guiding principles for the use and care of laboratory animals of the American Physiological Society, and the National Institutes of Health. Rats were divided into 4 groups: Gr1, Control rats maintained in room air; Gr2, rats received MCT (40 mg/kg, sc), and kept in room air; Gr3, rats subjected to hypobaric hypoxia (atmospheric pressure 380 mmHg); and Gr4, rats received MCT 40 mg/kg and were subjected to hypobaric hypoxia starting on day 1. The hypoxia chamber was opened twice per week for 15 min to weigh the rats, replenish food and water, and to provide clean bedding similar to the other rats in room air. At the end of 2 and 4 wk, these rats were studied.

Human lung tissue was obtained from PAH patients at the time of post-mortem autopsy or lung transplantation; control tissue was obtained from healthy subjects who died due to traumatic injuries. Vanderbilt Pulmonary Hypertension Research Cohort study participants were recruited *via* the Vanderbilt Pulmonary Hypertension Center. The Vanderbilt University Medical Center Institutional Review Board approved all study protocols (IRB #9401). All participants, or their surrogate custodians as appropriate, gave informed written consent to participate in genetic and clinical studies. PAH was defined either by autopsy results showing plexogenic pulmonary arteriopathy in the absence of other causes such as congenital heart disease, or by clinical and cardiac catheterization criteria. These criteria included a mean pulmonary artery pressure ⩾ 25 mmHg with a pulmonary capillary wedge or left atrial pressure ⩽ 15 mmHg, and exclusion of other causes of PH in accordance with accepted international standards of diagnostic criteria[2]. HPAH was considered the type of PAH if a subject met one or both of the following criteria: (1) family history of two or more subjects with confirmed PAH according to international standards of diagnostic criteria; or (2) detection of a mutation in a PAH-specific gene, such as *BMPR2*. The majority of lung tissue specimens available for this study from PAH patients were from subjects deceased prior to the discovery of the *BMPR2* gene and other genes that could be considered PAH-specific genes which are mutated in association with HPAH. Included in this study were 7 patients: 3 with IPAH and 4 with HPAH. The age ranged from 29 to 55 years except for one patient who was 6 years old diagnosed with HPAH.

Chemicals and antibodies

All chemicals including MCT were purchased from Sigma Aldrich, St Louis, MO. Antibodies: caveolin-1α (sc894), PPARγ (sc7273), HSP90 (sc13119) purchased from Santa Cruz laboratories, Santa Cruz, CA. PY-STAT3 (Tyr705, 9145), Bcl-xL (2764), p-Erk (Thr202/Tyr204, 4370), and Erk (4695) from Cell Signaling, Beverley, MA, β actin (A5441) and α-actin (C6198) from Sigma, caveolin-2 (610684), eNOS (610297) and STAT3 (610190) from BD Transduction, Palo Alto, CA.

Measurement of right ventricular systolic pressure

Rats anesthetized with pentobarbital (60 mg/kg, *ip*), were ventilated through a tracheostomy (roughly equivalent to 70-80 breaths/min)[6]. A thoracotomy was performed; and right ventricular systolic pressure (RVSP) measured with a small needle attached to a tubing (PE50). After perfusing the lungs with normal saline, heart and lungs were removed. Right lung was frozen and stored at -80℃. The heart and the left lung were kept in 10% buffered formaldehyde.

Estimation of right ventricular hypertrophy

The ratio of the right ventricle (RV) and the left ventricle including septum (LV) was used to assess right ventricular hypertrophy (RVH)[6,7]. In addition, the ratio of RV (mg)/final body weight (FBW, g) and the ratio of LV (mg)/FBW (g) were calculated.

Estimation of protein expression

Proteins (50-100 μg) from lung supernatants were used to examine the expression of proteins of interest[6,7]. The antibodies used were caveolin-1 (1:5000), Caveolin-2 (1:500), PPARγ (1:100), PY-STAT3 (1:200), Bcl-xl (1:200), p-Erk (1:2000), eNOS (1:400), or HSP90 (1: 3000). Loading protein was evaluated using β actin (1:10000), STAT3 (1: 2000) or Erk

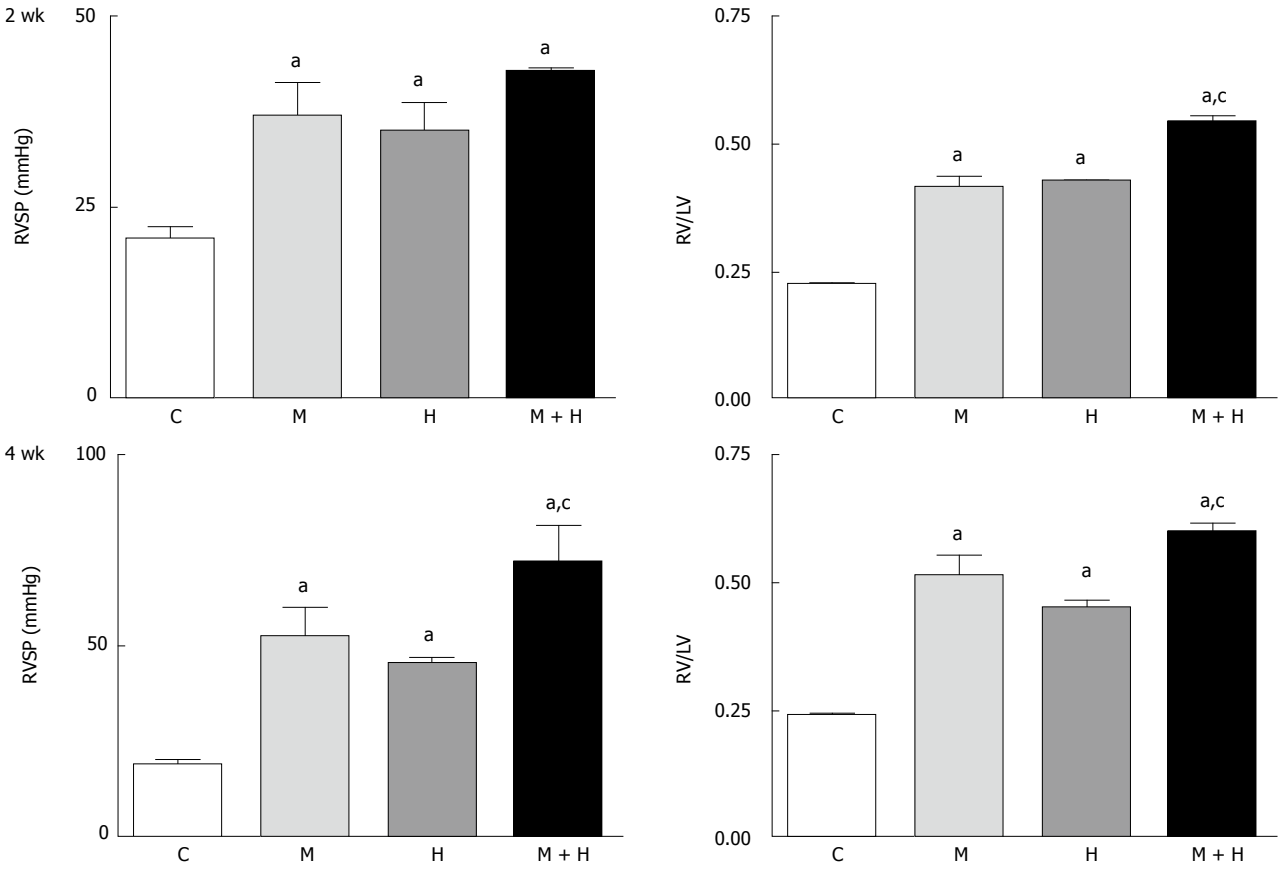

Figure 1 This figure depicts right ventricular systolic pressure and right ventricular hypertrophy in controls, monocrotaline, hypoxia and monocrotaline + hypoxia at 2 (*n* = 5-8) and 4 wk (*n* = 6-10). $^{a}P < 0.05$ *vs* C, $^{c}P < 0.05$ *vs* M and H. RVSP: Right ventricular systolic pressure; C: Controls; M: Monocrotaline; H: Hypoxia; M + H: Monocrotaline + hypoxia.

(1:2000) as appropriate. Protein bands visualized by chemiluminescence are expressed as % normal.

Lung histopathology and double immunofluorescence

Five to 6 μm lung sections were cut from the paraffin blocks, which were processed form the lung tissue preserved in 10% formaldehyde. Hematoxylin/eosin and elastic van Gieson stains were used for histopathological evaluation. Double immunofluorescence study (on all sections) was carried out at New York Medical College Facility, using caveolin-1 and α-actin antibodies as described previously[6,7]. Immunofluorescence was evaluated using a laser scanning confocal microscope.

Statistical analysis

The data are expressed as means ± SEM. Differences among multiple means were determined by one way Anova analysis using SPSS program. Specific differences were determined using Scheffe's test with < 0.05 as significant.

RESULTS

Weight gain

At 2 wk (*n* = 5-8), the weight gain in the MCT and hypoxia groups was lower compared with the controls (controls, 63 ± 3 g; MCT, 38 ± 3 g^{a}; hypoxia, 39 ± 2 g^{a}). In the MCT + hypoxia group, there was a further reduction in the weight gain (6 ± 7 g^{a,c}). There was no mortality in any of the groups. $^{a}P < 0.05$ *vs* controls, $^{c}P < 0.05$ *vs* MCT and hypoxia groups.

At 4 wk (*n* = 7-11), the mortality in the MCT and the MCT + hypoxia groups were 22% and 30% respectively, but none in the hypoxia alone group. Weight gain in the hypoxia group was comparable to the controls (97 ± 7 g *vs* hypoxia 94 ± 4 g, *P* = NS). The weight gain in the MCT group was significantly reduced (68 ± 7 g^{a}) and a further reduction was noted in the MCT + hypoxia group (45 ± 5 g^{a,c}). $^{a}P < 0.05$ *vs* controls, $^{c}P < 0.05$ *vs* MCT.

Hemodynamic data

At 2 wk, RVSP and RV/LV ratio were significantly higher in the MCT, hypoxia and MCT + hypoxia groups compared with the controls (Figure 1, top panel); with a further increase at 4 wk (Figure 1, bottom panel). The ratios of RV (mg)/FBW (g) confirmed increased RVH in the MCT + hypoxia groups at 2 and 4 wk compared with the MCT and hypoxia alone groups. RV (mg)/FBW (g) ratio: 2 wk; C, 0.5 ± 0.01, MCT, 1.02 ± 0.57^{a}, Hypoxia, 1.19 ± 0.057^{a}, MCT + Hypoxia, 1.54 ± 0.04^{a,c}, 4 wk; C, 0.55 ± 0.019, MCT, 1.15 ± 0.56^{a},

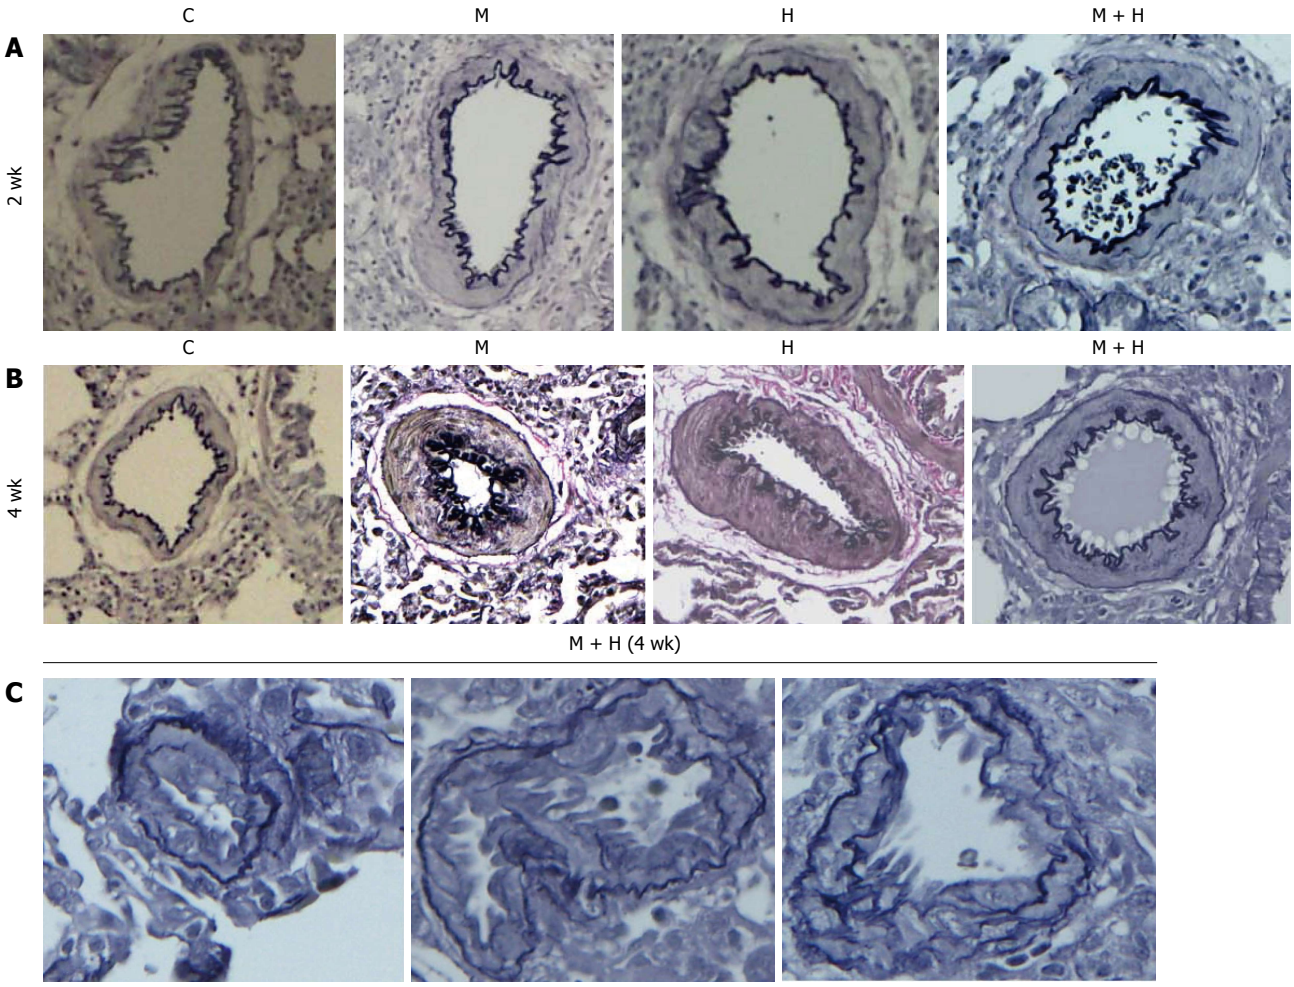

Figure 2 Pulmonary arteries (experimental groups). A and B: Pulmonary arteries (size 200-317 μm) from the controls and different experimental groups (elastic van Gieson stain): At 2 and 4 wk, arteries from MCT (M), hypoxia (H) and MCT + hypoxia (M + H) exhibit increased medial wall thickening compared with the control (C). Magnification = × 100; C: Arteries (size 100-155 μm) from 4 wk M + H group showing the presence of neointima. Fragmentation of internal elastic lamina can be seen in these arteries. Magnification = × 400.

hypoxia, 1.05 ± 0.08[a], MCT + hypoxia, 1.59 ± 0.01[a,c]. [a]$P < 0.05$ *vs* C, [c]$P < 0.05$ *vs* MCT or hypoxia group. The LV (mg)/FBW (g) ratio, however, was not different in any of the experimental groups compared with the controls (data not shown).

Histopathology

Experimental groups: Increased pulmonary arterial medial wall thickening is present in all the experimental groups at 2 and 4 wk (Figure 2A and B). Panel C shows neointima in small arteries at 4 wk in the MCT + hypoxia group.

Humans: Pulmonary arteries from IPAH and HPAH patients show varying degrees of medial wall thickening, neointima and luminal narrowing (Figure 3).

Caveolin-1 and caveolin-2 expression

The expression of both caveolin-1 and caveolin-2 was significantly reduced in the MCT and MCT + hypoxia groups at 2 wk. In the hypoxia alone group, caveolin-1 expression was not reduced; however, the caveolin-2 expression was slightly but significantly reduced compared with the controls (Figure 4).

At 4 wk, caveolin-1 and caveolin-2 were significantly reduced in the MCT group. In the hypoxia group, the expression of caveolin-1 was comparable to the controls; however, the expression of caveolin-2 was reduced, but not as low as seen in the MCT group. Importantly, in the MCT + hypoxia group, caveolin-1 expression was significantly increased compared with the MCT group (81% ± 3.9% *vs* 17% ± 3.6%, $P < 0.05$), although still low compared to the controls (81% ± 3.9% *vs* 100% ± 0%, $P < 0.05$). However, despite an increased caveolin-1 expression in this group, caveolin-2 showed a further reduction (Figure 4).

Localization of caveolin-1

Experimental groups: At 2 wk post-MCT, only 23% ± 0.87% of arteries exhibited the presence of endothelial caveolin-1. Consistent with previous observations[7]; in the current study, the endothelial caveolin-1 loss at 2 wk was not associated with an increased caveolin-1 expression in SMC. The MCT + hypoxia group showed a further reduction in the endothelial caveolin-1 expression (11% ± 1%). A few

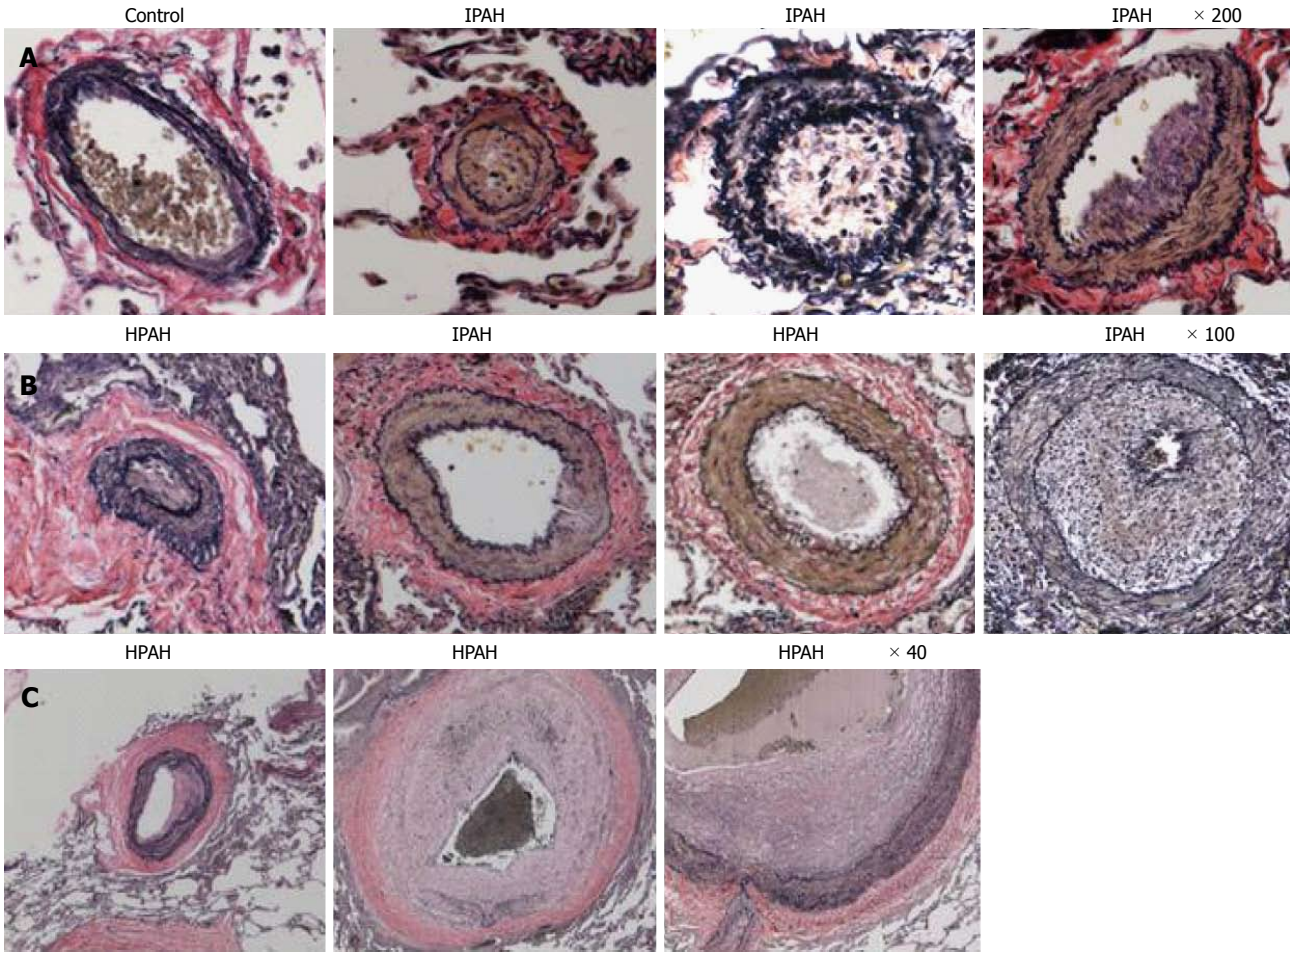

Figure 3 Pulmonary arteries (Human). A and B: Pulmonary arteries (size 134-323 μm) from a control, IPAH and HPAH patients. Control artery is thin walled. The arteries from patients exhibit varying degrees of muscular thickening, neointima and significant narrowing of the lumen; C: Larger arteries exhibiting vascular remodeling, extensive neointima formation and narrowing of the lumen.

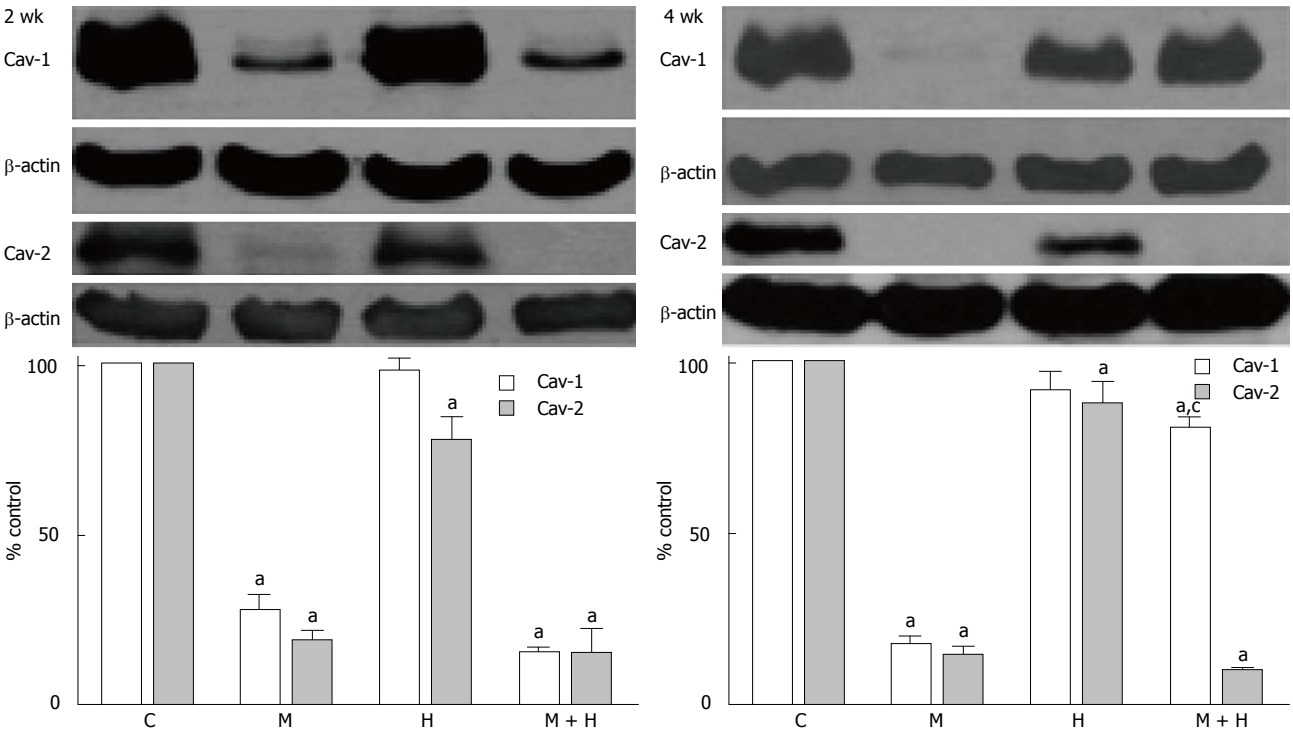

Figure 4 Western blots and bar graphs showing the expression of caveolin-1, caveolin-2 and β actin in controls, monocrotaline, hypoxia and monocrotaline + hypoxia at 2 (*n* = 3-6) and 4 wk (*n* = 5-8). [a]*P* < 0.05 *vs* C, [c]*P* < 0.05 *vs* M. C: Controls; M: Monocrotaline; H: Hypoxia; M + H: Monocrotaline + hypoxia.

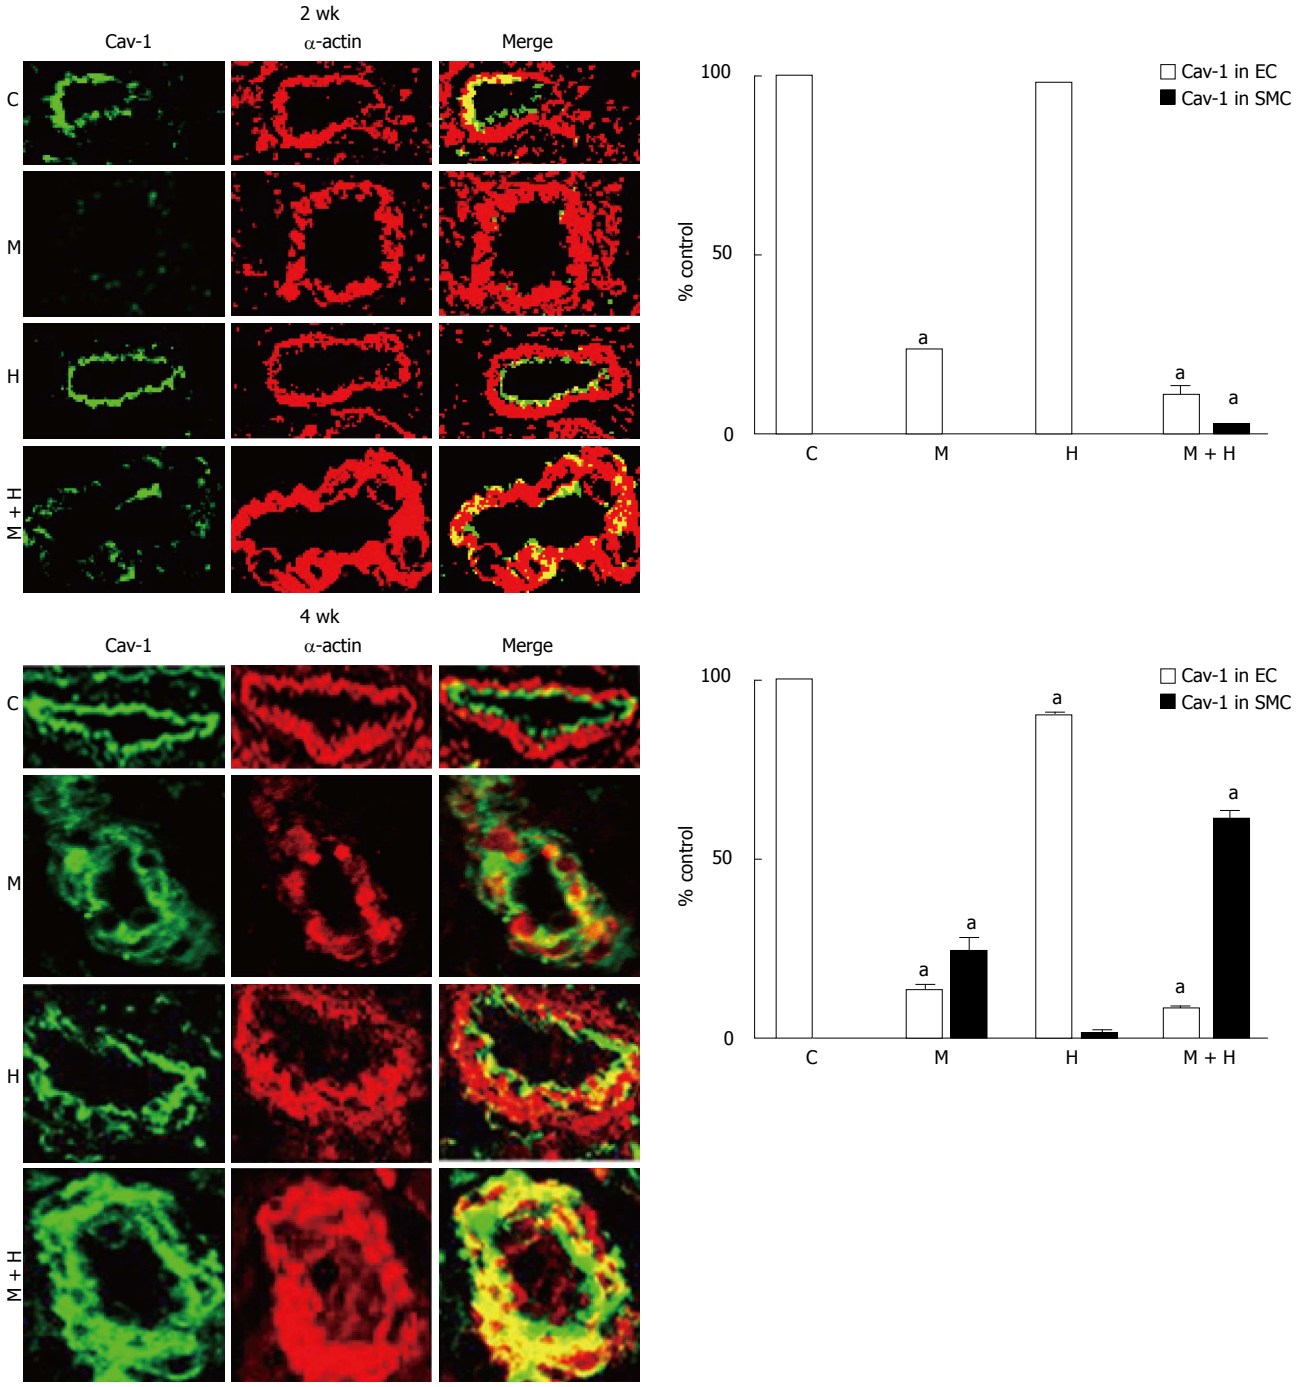

Figure 5 Immunofluorescence study depicting the expression of caveolin-1 (green) and smooth muscle α actin (red) in pulmonary arteries from controls, monocrotaline, hypoxia and monocrotaline + Hypoxia groups at 2 and 4 wk. The accompanying bar graphs (n = 4-5) shows the % arteries exhibiting the presence of caveolin-1 in endothelium (EC) and in smooth muscle layer (SMC). [a]$P < 0.05$ *vs* C. C: Controls; M: Monocrotaline; H: Hypoxia; M + H: Monocrotaline + hypoxia.

arteries displaying endothelial caveolin-1 loss exhibited increased expression of caveolin-1 in SMC (2.9% ± 0.25%). Expression of endothelial caveolin-1 in the hypoxia group, however, was not different compared with the controls (Figure 5, top panel).

At 4 wk, in the MCT and MCT+ hypoxia groups, endothelial caveolin-1 was expressed in 13% ± 1.4% and 8% ± 0.79% of arteries respectively. In the MCT group, increased caveolin-1 expression in SMC was observed in 24% ± 3.5% of arteries. Importantly, in the MCT + hypoxia group, 61% ± 2% of arteries displayed increased caveolin-1 in SMC, consistent with the observed increase in total caveolin-1 expression in the lungs. However, the neointimal layer revealed scant expression of caveolin-1. Interestingly, in the hypoxia group, there were a few arteries with endothelial caveolin-1 loss (90% ± 0.89% *vs* C, 100% ± 0%, $P < 0.05$); and a smaller number of arteries (1.2%

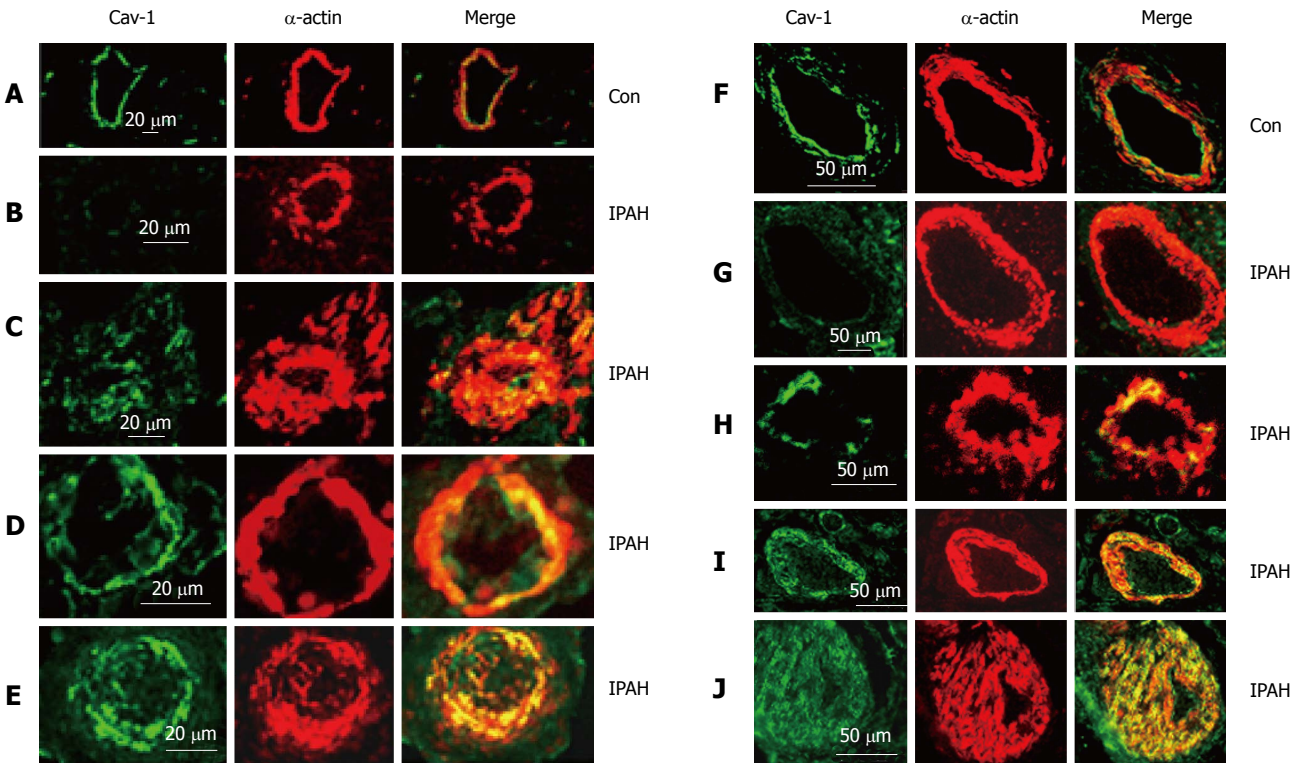

Figure 6 Immunofluorescence study showing the expression of caveolin-1 (green) and smooth muscle α-actin (red) in pulmonary arteries from the controls (A and F), and from the patients with idiopathic pulmonary arterial hypertension (B-E) and with heritable pulmonary arterial hypertension (G-J). In controls, endothelial caveolin-1 is well preserved and there is no enhanced expression of caveolin-1 in smooth muscle layer. Two arteries each from patients, IPAH (B and C), HPAH (G and F) show loss of endothelial caveolin-1 in B and G, and the appearance of increased expression of caveolin-1 in SMC in C and H. The next panels D, E, I and J from 4 different patients show loss of endothelial caveolin-1 and enhanced expression of caveolin-1 in SMC. PAH: Pulmonary arterial hypertension; IPAH: Idiopathic PAH; HPAH: Heritable PAH; SMC: Smooth muscle cells.

± 0.58%) with endothelial caveolin-1 loss, exhibited an increased caveolin-1 expression in SMC (Figure 5, bottom panel).

Human lungs: The control pulmonary arteries showed well preserved caveolin-1 in the endothelial layer. Arteries from IPAH and HPAH patients showed varying degrees of alterations in caveolin-1 expression not unlike what was noted in the 4 wk MCT + hypoxia group, such as endothelial caveolin-1 loss, increased caveolin-1 expression in SMC and the presence of neointima (Figure 6).

Caveolin-1 and PPARγ expression

At 2 wk, caveolin-1 loss in the MCT and MCT + hypoxia groups was accompanied by an increase in the expression of PPARγ ($P < 0.05$ *vs* controls, Figure 7). Since our previous studies had shown caveolin-1 loss at 48 h after MCT injection, we investigated the expression of PPARγ and caveolin-1 at 48 h ($n = 4$) and 1 wk ($n = 4$). At 48 h post-MCT, caveolin-1 expression was reduced to 56% ± 1.4% ($P < 0.05$ *vs* controls) associated with a PPARγ expression of 118% ± 9% (P = ns *vs* control). At 1 wk post-MCT, a further reduction in caveolin-1 (38% ± 1%) was associated with an increase in the expression of PPARγ (203% ± 22%, $P < 0.05$ *vs* control). No alterations were observed in the expression of PPARγ in the 2 wk hypoxia group (Figure 7).

At 4 wk, in the MCT group, a reciprocal increase in PPARγ expression accompanied the caveolin-1 loss. Importantly, in the MCT + hypoxia group, the increased total caveolin-1 expression in the lungs correlated with a reduction in the expression of PPARγ. In the hypoxia group, the expression of caveolin-1 was slightly decreased (90% ± 0.89%), and the PPARγ expression, however, was not altered (Figure 7).

Proliferative and anti-apoptotic pathways

As shown in Figure 8, both at 2 and 4 wk, the activation of p-Erk and PY-STAT3, and increased Bcl-xL expression were present in all experimental groups.

eNOS and HSP90 expression

Although eNOS expression in the 2 wk-post MCT group was not significantly reduced compared with the controls, the expression of HSP90, however, was reduced ($P < 0.05$ *vs* controls). Expression of eNOS was increased in the hypoxia group, but the HSP90 expression was unaltered. In the MCT + hypoxia group, an increased eNOS expression, and a normal HSP90 expression were observed (Figure 9).

At 4 wk, in the MCT group, eNOS and HSP90 levels were reduced. In the hypoxia and MCT + hypoxia

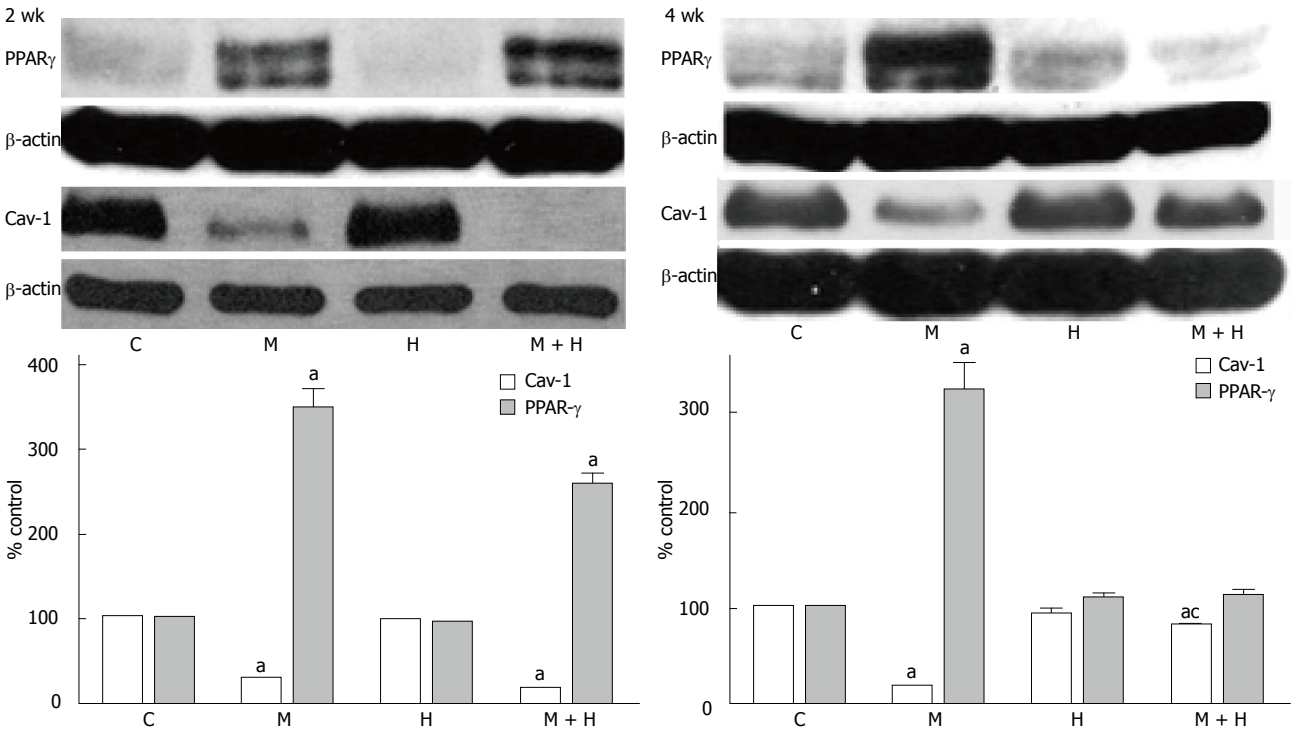

Figure 7 Representative western blots and bar graphs depicting the expression of caveolin-1 and peroxisome proliferator-activated receptor γ in controls, monocrotaline, hypoxia and monocrotaline + hypoxia groups at 2 (*n* = 5-8) and 4 wk (*n* = 5-8). $^{a}P < 0.05$ *vs* C, $^{c}P < 0.05$ *vs* M. C: Controls; M: Monocrotaline; H: Hypoxia; M + H: Monocrotaline + hypoxia; PPAR: Peroxisome proliferator-activated receptor.

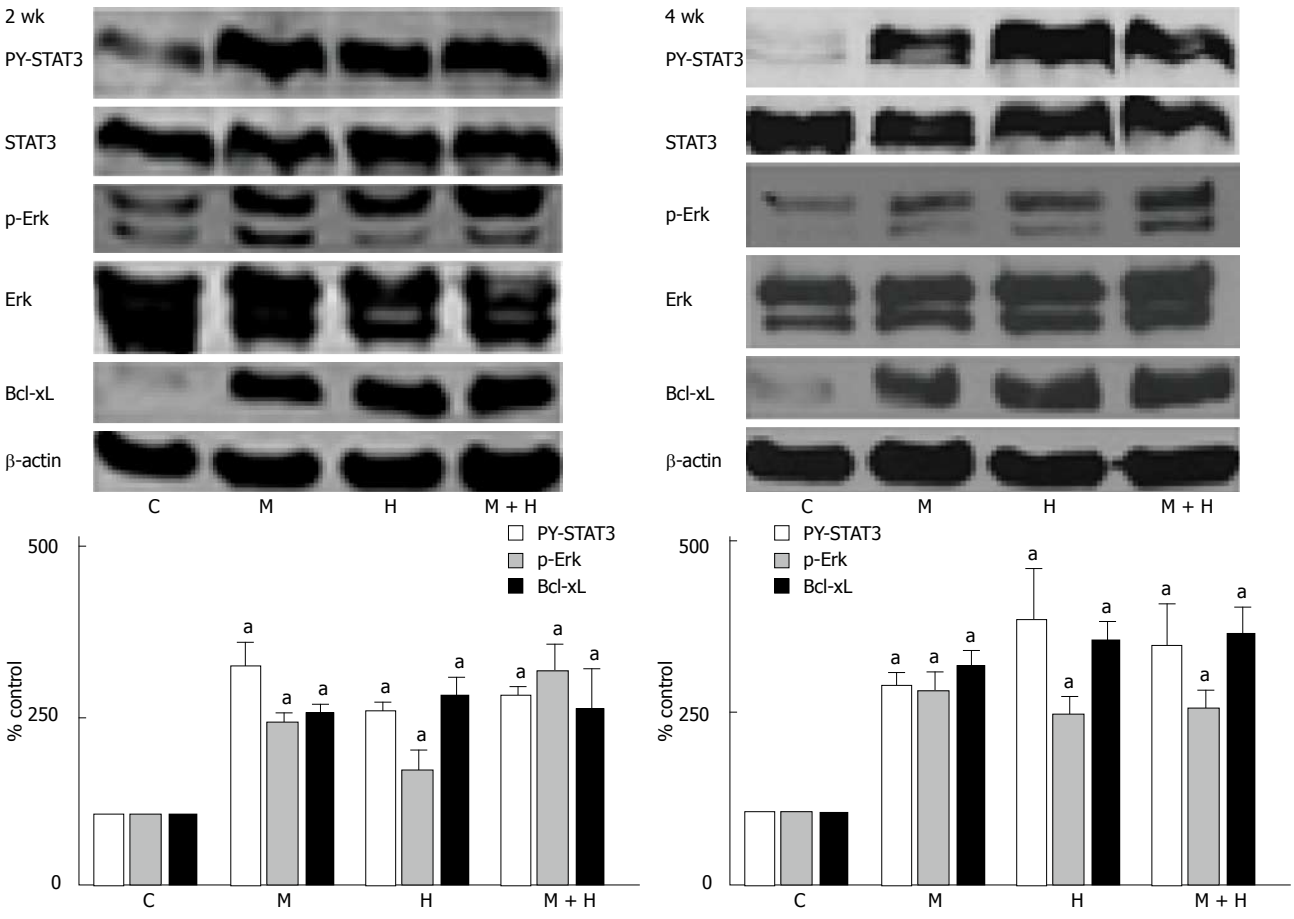

Figure 8 Representative western blots and bar graphs depicting the expression of PY-STAT3, p-Erk and Bcl-xL in controls, monocrotaline, hypoxia and monocrotaline + hypoxia at 2 (*n* = 4-7) and 4 wk (*n* = 5-8). STAT3, Erk and β-actin were used to assess the protein loading. $^{a}P < 0.05$ *vs* C. C: Controls; M: Monocrotaline; H: Hypoxia; M + H: Monocrotaline + hypoxia.

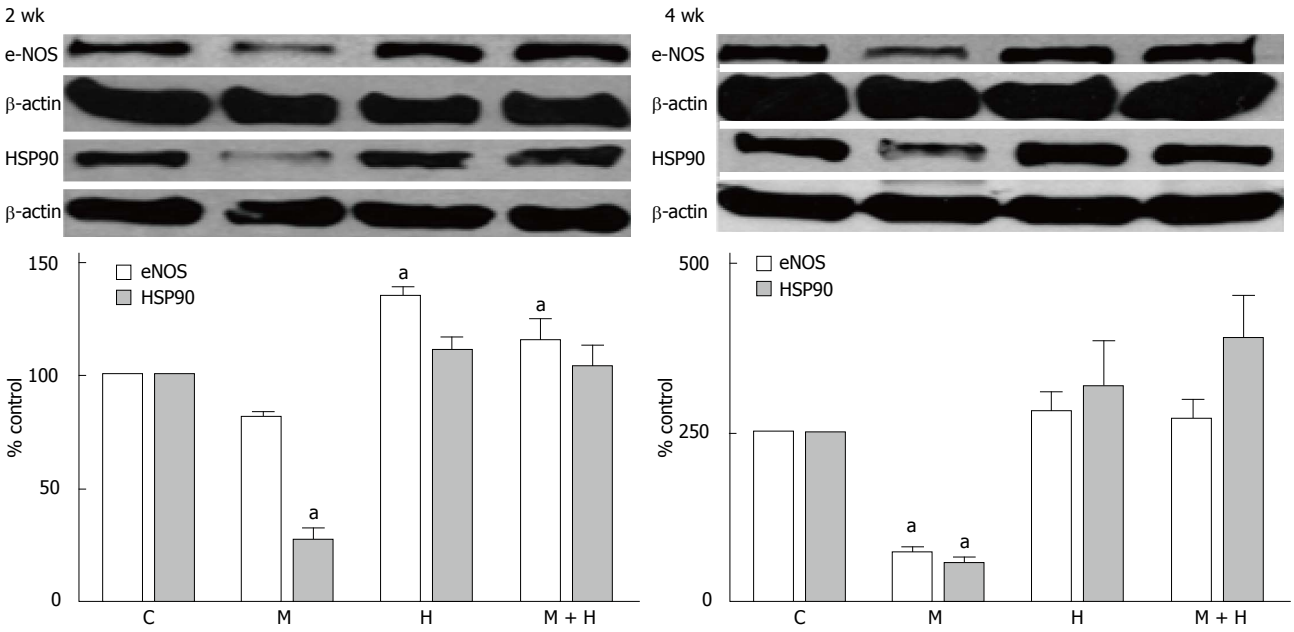

Figure 9 Representative western blots and bar graphs depicting the expression of endothelial nitric oxide synthase, HSP90 and β-actin in controls, monocrotaline, hypoxia and monocrotaline + hypoxia at 2 (*n* = 3-6) and 4 wk (*n* = 4-7). [a]*P* < 0.05 *vs* C. C: Controls; M: Monocrotaline; H: Hypoxia; M + H: Monocrotaline + hypoxia.

groups, eNOS and HSP90 levels were not altered (Figure 9).

DISCUSSION

The significant aspect of our study is the progressive disruption and loss of endothelial caveolin-1, activated proliferative pathways leading to PH in the MCT model. By 4 wk, a further reduction in endothelial caveolin-1 is accompanied by an increased caveolin-1 expression in SMC, observed in 24% of the arteries. The total caveolin-1 expression, however, remained significantly low. Exposure of MCT-treated rats to hypoxia accelerated the disease process. An increased number of arteries exhibited augmented caveolin-1 expression in SMC associated with an increase in total caveolin-1 expression. Importantly, some of the arteries exhibiting an increased caveolin-1 expression in SMC displayed neointima with scant caveolin-1. Furthermore, lung sections from patients with IPAH as well as HPAH showed similar changes, *i.e.*, endothelial caveolin-1 loss, increased caveolin-1 in SMC. Neointimal lesions were seen only in arteries with increased caveolin-1 expression in SMC.

Neointima and plexiform lesions have been described in rodent PH models such as Sugen + hypoxia and pneumonectomy + MCT[20,21,28]. In the Sugen + hypoxia model, the initial EC apoptosis is followed by cellular proliferation and angiogenesis deregulation resulting in plexiform lesions with significantly reduced caveolin-1 expression[29,30]. The reduced expression of caveolin-1 in plexiform lesion is supported by the electron microscopic examination showing a lack of caveolae[31]; the total caveolin-1 protein levels in the lungs, however, are not decreased[32]. *In-vitro* studies have shown that in response to cyclic stretch, caveolin-1 in SMC shifts to non-caveolar sites, mediates Erk activation and participates in cell proliferation. Interestingly, SMC not expressing caveolin-1 fail to proliferate when subjected to cyclic stretch[33,34]. It is likely, that the extensive damage and/or loss of EC, leads to the exposure of SMC to direct shear stress and pressure, resulting in the caveolin-1 shift from caveolae to non-caveolar sites, thus altering caveolin-1 function.

In the hypoxia group, at 2 wk, there was no endothelial caveolin-1 loss, indicating that there was no physical disruption of EC. During hypoxia, caveolin-1 forms a tight complex with eNOS[19,35], leading to the dysfunction of both factors. Removal of hypoxia[36,37] or eNOS/caveolin-1 complex disruption attenuates PH[38]. At 4 wk, the total caveolin-1 expression in the lungs was not altered, but immunofluorescence studies revealed a small loss in endothelial caveolin-1 accompanied by 1.2% of arteries exhibiting increased caveolin-1 expression in SMC. It is noteworthy that in infants with respiratory distress syndrome or bronchopulmonary dysplasia, PH in the absence of EC disruption, does not lead to endothelial caveolin-1 loss or increased caveolin-1 expression in SMC. However, accompanying inflammation results in endothelial cell membrane disruption and endothelial caveolin-1 loss with subsequent increased caveolin-1 expression in SMC[16]. These studies suggest that the endothelial disruption and the endothelial caveolin-1 loss may be necessary for the increased caveolin-1 expression in SMC.

Caveolin-2 loss concomitant with caveolin-1 loss has been shown in the experimental models of PH,

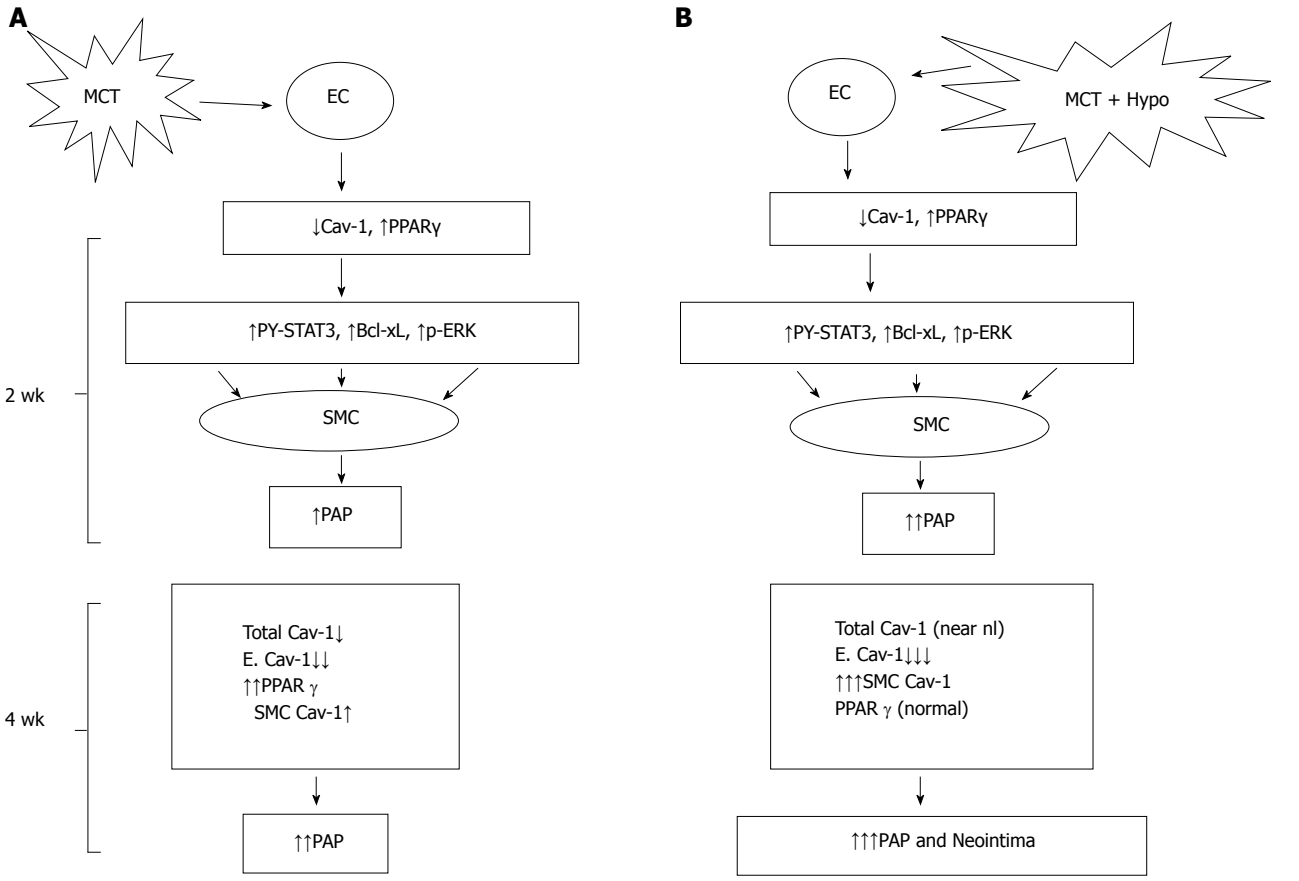

Figure 10 Monocrotaline injury to endothelial cells resulting in the loss of caveolin-1 and the activation of the proliferative pathways (PY-STAT3, Bcl-xL, p-ERK) leading to PH at 2 wk; and a reciprocal relationship between caveolin-1 and peroxisome proliferator-activated receptorγ expression (A) and MCT + hypoxia (MCT + Hypo) accelerates the disease process (B). At 4 wk, there is a further loss of endothelial caveolin-1 (E. Cav-1) and enhanced expression of cav-1 in smooth muscle cells (SMC), however, the total cav-1 levels remain low (17% vs C, 100%). These alterations are accompanied by a further increase in pulmonary artery pressure. Panel B shows MCT + hypoxia (MCT + Hypo) accelerates the disease process. At 2 wk, extensive endothelial caveolin-1 is accompanied by the activation of proliferative pathways and PH (higher pulmonary artery pressure compared with MCT alone group). At 4 wk, a further loss of E. Cav-1 is accompanied by significantly increased expression of caveolin-1 in SMC compared with MCT alone group. At this stage total caveolin-1 level is closer to normal (81% vs C, 100%), and neointimal lesions can be seen. MCT: Monocrotaline; EC: Endothelial cells; PPAR: Peroxisome proliferator-activated receptor.

and the rescue of caveolin-1 restores caveolin-2 expression[10,39]. Caveolin-2 is expressed in a number of cell types including EC and SMC, and it colocalizes with caveolin-1 and necessitates caveolin-1 for its transport to caveolae[23]. However, caveolin-2 is not necessary for caveolar localization of caveolin-1; but the co-expression of caveolin-1 and 2 results in a more efficient formation of caveolae[40,41]. In the present study, MCT-treated rats exhibited a significant loss of caveolin-2 concomitant with the loss of caveolin-1. In the MCT + hypoxia group at 4 wk, despite an increase in the total caveolin-1 expression, a significant loss of caveolin-2 was present, which supports the view that the major part of caveolin-1 in SMC may not be localized in caveolae. In the hypoxia group, despite the presence of caveolin-1, some loss of caveolin-2 was observed, suggesting that a part of caveolin-1 may not be available for caveolin-2 localization.

All experimental groups (MCT, hypoxia and MCT + hypoxia) at 2 and 4 wk revealed the activation of PY-STAT3, pERK1/2 and Bcl-xL. Caveolin-1 is a well known inhibitor of pro-proliferative and anti-apoptotic factors[11,42]; and the rescue of caveolin-1 as a preventive measure in the MCT model, inhibits the activation of proliferative pathways and attenuates PH[9,10]. Interestingly, in the presence of caveolin-1 in hypoxia groups and MCT + hypoxia group at 4 wk, proliferative pathways were activated; which strongly suggest that caveolin-1 is dysfunctional in these groups.

In the 4 wk MCT group, the expression of eNOS and HSP90 was significantly reduced, but was normal in the MCT + hypoxia groups. In addition, caveolin-1 expression in native EC and in neointimal cells was sparse in the latter group. Strong eNOS expression and low caveolin-1 expression have been reported in the plexiform lesions[39,43], besides, oxidant stress is a critical feature in patients with IPAH[44]. The major cause of PH in caveolin-1 knockout mice is thought to be eNOS uncoupling and subsequent oxidative and nitrosative stress; and PH is attenuated by caveolin-1 re-expression, eNOS inhibition or treatment with superoxide dismutase mimetic[45,46]. Furthermore, EC from patients with IPAH show caveolin-1 degradation induced by sustained eNOS and Src signaling[47]. It

is important to note, that caveolin-1 regulates eNOS-derived NO and superoxide, and NOX activity. Caveolin-1 sequestrates uncoupled eNOS, inhibits superoxide formation and prevents eNOS oxidase activity[48,49]. These observations support a pivotal role for caveolin-1 in preventing oxidative and nitrosative stress.

Protein and mRNA expression of PPARγ is described to be low in IPAH, Sugen + hypoxia[26] and the shunt[27] models of PH, but not in chronic obstructive pulmonary disease patients[26]. PPARγ, a ligand-activated transcription factor belongs to the nuclear hormone superfamily. In several cell systems, PPARγ has been shown to upregulate caveolin-1 expression[24,25,50]. In the present study, PPARγ levels revealed an inverse relationship with caveolin-1 in the MCT groups; initial low endothelial and total ceveolin-1 levels were associated with increased PPARγ levels. At 4 wk in the MCT + hypoxia group, an increase in total caveolin-1 was associated with a decrease in PPARγ levels. The increased expression of PPARγ may be a compensatory mechanism to upregulate the caveolin-1 expression during the initial phase of PH associated with significantly reduced caveolin-1 levels. In the hypoxia group, however, the PPARγ levels were not altered. A thiazolidinedione (TZD) compound (PPARγ activator) has been reported to attenuate hypoxia-induced PH[51]. Some of the TZD compounds are reported to have cholesterol disruptive function independent of PPARγ[52]. Interestingly, cholesterol lowering statins in the hypoxia model of PH has been shown to disrupt the tight complex of eNOS and caveolin-1 resulting in the restoration of eNOS function and the attenuation of PH[38]. Recent studies have shown that increased PPARγ expression portends poor prognosis in some forms of cancer[53,54]. In view of these observations, increasing PPARγ levels as a therapeutic measure in PH is of some concern. It is possible that PPARγ activation may be beneficial in some forms of PH or at some stage during the disease; or a selective increase in PPARγ expression in EC may be useful. In any case, further studies are necessary to ascertain the roles of PPARγ and caveolin-1, and their interrelationship in PH.

In conclusion, addition of hypoxia to MCT-treated rats results in an acceleration of the disease process. Extensive endothelial damage, progressive endothelial caveolin-1 loss, and increased caveolin-1 expression in SMC accompanied by an augmented total caveolin-1 protein expression in lungs is followed by neointima formation. In addition, caveolin-1 and PPARγ revealed an inverse relationship (Figure 10). Importantly, lung sections from IPAH and HPAH patients showed similar alterations in caveolin-1 expression, *i.e.*, endothelial caveolin-1 loss and increased caveolin-1 expression in SMC. Both in humans and the MCT + hypoxia group, neointimal lesions were observed only in the arteries exhibiting increased caveolin-1 expression in SMC. Since increased caveolin-1 expression in SMC has been shown to be actively pro-proliferative, this alteration in caveolin-1 expression may be a prelude to neointima formation. In the hypoxia group, in the absence of endothelial disruption or the endothelial caveolin-1 loss, there was neither an increased expression of caveolin-1 in SMC nor neointima. These results suggest that the endothelial cell integrity may be an important factor that determines the course of the disease.

ACKNOWLEDGEMENTS

We thank the patients for their valuable contributions, and acknowledge Lisa Wheeler (Vanderbilt University, Nashville) who coordinated the study enrollment and sample acquisition for human studies.

COMMENTS

Background

Neointima formation in pulmonary hypertension (PH) portends poor prognosis. Despite major advances in the field, the mechanism/s of pathogenesis is not yet clear, which makes the therapeutic measures a challenge.

Research frontiers

Caveolin-1, a membrane protein plays a significant role in pulmonary vascular homeostasis and in the pathogenesis of PH.

Innovation and breakthroughs

An important aspect of the study is that caveolin-1 plays a dual role in the pathogenesis of PH, *i.e.*, as an anti-proliferative and a pro-proliferative factor. This change in function of caveolin-1 is similar to what has been reported in cancer. Loss of endothelial caveolin-1 leads to the activation of proliferative pathways, vascular remodeling and PH. As the disease progresses, the resulting extensive endothelial caveolin-1 loss associated with endothelial cell damage is followed by an enhanced expression of caveolin-1 in smooth muscle cells (SMC). The authors have shown that by subjecting monocrotaline-treated rats to hypoxia accelerates the disease process; by 4 wk, a large number of arteries exhibit enhanced expression of caveolin-1 in SMC. This caveolin-1 becomes pro-proliferative and facilitates cell proliferation, cell migration and neointima formation. In the experimental models and humans, neointima is observed only in the arteries exhibiting extensive endothelial damage and enhanced expression of caveolin-1 in SMC.

Application

The results would lead to further research in the role of caveolin-1 in SMC in PH, and in assessing the effects of modulation of caveolin-1 expression.

Peer-review

The present investigation is well written and interesting.

Abstract

AIM: To compare the performance of the re-expressed Modification of Diet in Renal Disease equation *vs* the new Chronic Kidney Disease Epidemiology Collaboration equation in patients with non-valvular atrial fibrillation.

METHODS: We studied 911 consecutive patients with non-valvular atrial fibrillation on vitamin-K antagonist. The performance of the re-expressed Modification of Diet in Renal Disease equation *vs* the new Chronic Kidney Disease Epidemiology Collaboration equation in patients with non-valvular atrial fibrillation with respect to either a composite endpoint of major bleeding, thromboembolic events and all-cause mortality or each individual component of the composite endpoint was assessed using continuous and categorical $\geqslant$ 60, 59-30, and < 30 mL/min per 1.73 m^2 estimated glomerular filtration rate.

RESULTS: During 10 ± 3 mo, the composite endpoint occurred in 98 (10.8%) patients: 30 patients developed major bleeding, 18 had thromboembolic events, and 60 died. The new equation provided lower prevalence of renal dysfunction < 60 mL/min per 1.73 m^2 (32.9%),

compared with the re-expressed equation (34.1%). Estimated glomerular filtration rate from both equations was independent predictor of composite endpoint (HR = 0.98 and 0.97 for the re-expressed and the new equation, respectively; $P < 0.0001$) and all-cause mortality (HR = 0.98 for both equations, $P < 0.01$). Strong association with thromboembolic events was observed only when estimated glomerular filtration rate was < 30 mL/min per 1.73 m^2: HR is 5.1 for the re-expressed equation, and HR = 5.0 for the new equation. No significant association with major bleeding was observed for both equations.

CONCLUSION: The new equation reduced the prevalence of renal dysfunction. Both equations performed similarly in predicting major adverse outcomes.

Key words: Atrial fibrillation; Anticoagulants; Follow-up studies; Kidney; Prognosis

Core tip: In atrial fibrillation, renal dysfunction entails more adverse events. Limited data exist on the performance and prognostic value of the re-expressed Modification of Diet in Renal Disease equation *vs* the new Chronic Kidney Disease Epidemiology Collaboration equation in atrial fibrillation. We compared the performance of both equations at predicting major outcomes in patients with non-valvular atrial fibrillation. The study encouraged the use of the new equation as it decreased the prevalence of patients with renal dysfunction, in a real world cohort of patients with non-valvular atrial fibrillation and at the same time showed similar prognostic impact like the re-expressed equation.

Renal function assessment in atrial fibrillation: Usefulness of chronic kidney disease epidemiology collaboration *vs* re-expressed 4 variable modification of diet in renal disease. *World J Cardiol* 2015; 7(10): 685-694 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i10/685.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i10.685

INTRODUCTION

Renal dysfunction is a common comorbidity observed in patients with atrial fibrillation (AF). Patients with AF and renal dysfunction are more likely to develop thromboembolic (TE) events compared to those with AF and normal renal function[1,2]. The presence and severity of renal dysfunction is also a recognized predictor in the bleeding risk scores used commonly to estimate the hemorrhagic risk in anticoagulated patients with AF[3,4].

Therefore, accurate assessment of renal function is of paramount importance as it will help inform the decision making process aiming for optimizing the management of patients with AF. Current recommendations advocate the estimation of renal function by means of estimated glomerular filtration rate (eGFR) using the validating prediction equations instead of serum creatinine[5].

Until recently, the two most commonly used creatinine based equations estimating GFR were the 4 variable Modification of Diet in Renal Disease (MDRD-4) Study[6] and the Cockcroft-Gault (C-G) equation[7]. The MDRD-4 equation was re-expressed to be used in the current era of standardized serum creatinine assay, whereas the C-G equation was not updated, and its use is not recommended currently[8]. More recently, a new equation, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation[9], has been proposed as an alternative equation to replace the widely used re-expressed MDRD-4 formula in routine clinical use, on the basis that it estimates measures of GFR more accurate than the re-expressed MDRD-4 equation.

Several studies have demonstrated the higher accuracy of the new CKD-EPI at estimating the true renal function, thus enabling it to provide better clinical risk prediction in different disease contexts[10-12]. However, it is currently unknown if the better estimates from the new CKD-EPI would be translated into better risk prediction in the particular context of patients with AF, since very few patients in the derivation cohort of the new CKD-EPI formula had AF[9].

In this study, we aimed to comparatively evaluate the re- expressed MDRD-4 and the new CKD-EPI formulas at predicting the occurrence of major adverse outcomes in a real world cohort of patients with non-valvular AF (NVAF) who are recently on vitamin K antagonists (VKA).

MATERIALS AND METHODS

Patient's sample

Retrospectively, we identified all consecutive patients of ⩾ 18 years of age with a confirmed diagnosis of AF on VKAs attending outpatient cardiology consultations of a tertiary hospital between January 2011 and February 2013. Only patients who fulfilled the following criteria were included in this study: Patients with permanent or paroxysmal AF recently started on VKAs (*i.e.,* not more than 8 mo passed since the beginning of their VKAs therapy), and who have regular visits for INR measurements. Patients with prosthetic valve (n = 452), rheumatic heart disease (n = 43), active cancer (n = 41), dementia (n = 26), and/or interrupted vitamin K antagonist > 3 d (n = 73) were excluded. Thus, the final analyzed cohort consisted of 911 patients. A detailed medical history was recorded for each patient, and the basal clinical characteristics at study entry together with information on follow up were carefully

gathered by cardiologists.

The vast majority of patients were on acenocoumarol (93%; and the remaining patients were on warfarin).

The study was approved by the Clinical Research Ethics Committee of our hospital.

Calculation of eGFR

For each patient, Serum creatinine was measured by the modified kinetic Jaffe method in a single clinical laboratory in our institution. All creatinine measurements were performed with an isotope dilution mass spectroscopy (IDMS)-traceable enzymatic assay that has previously been shown to provide very reliable eGFR results compared with the measured GFR[13]; these measurements were analyzed automatically using the ADVIA 2400 Chemistry System (Siemens Diagnostics, Tarrytown, NY, United States).

We calculated the eGFR using the IDMS-traceable version of the MDRD-4 equation[8]: 175 × [standardized serum creatinine (mg/dL)]$^{-1.154}$ × age$^{-0.203}$ × (0.742 if female) × (1.212 if black).

The new CKD-EPI equation was also used[9]: 141 × (minimum of standardized serum creatinine (mg/dL)/κ or 1)$^{\alpha}$ × [maximum of standardized serum creatinine (mg/dL)/κ or 1]$^{-1.209}$ × 0.993^{age} × (1.018 if female) × (1.159 if black). Where κ is 0.7 for females and 0.9 for males and α is -0.329 for females and -0.411 for males.

We categorized the eGFR obtained from each formula into three categories: ⩾ 60 mL/min per 1.73 m^2 (normal or mild renal dysfunction), 30-59 mL/min per 1.73 m^2 (moderate renal dysfunction) and < 30 mL/min per 1.73 m^2 (severe renal dysfunction). No patients were on renal replacement therapy.

Endpoints and definitions

Patients were followed up to 1-year after the enrolment. The primary endpoint of the present study was a composite endpoint of major bleeding, TE complications, or death; whichever comes first. The secondary endpoint was each individual component of the composite endpoint.

Data on major bleeding, and TE complications were gathered from the cardiology clinic visits and records, and through hospital files as well as through primary care centers reports.

We used the 2005 International Society on Thrombosis and Haemostasis (ISTH) criteria to define major bleeding[14]. Thus, a major bleeding event was adjudicated if one of the following criteria was met: fatal bleeding and/or symptomatic bleeding in a critical area or organ (*e.g.,* such as intracranial, intraspinal, intraocular, retroperitoneal, atraumatic intraarticular, pericardial, or intramuscular with compartment syndrome); and/or bleeding causing drop of hemoglobin of ⩾ 2 g/dL, or leading to transfusion of ⩾ 2 units of whole blood or packed red blood cells.

A TE complication was defined as the occurrence of ischemic stroke, transient ischemic attack, or peripheral embolism (including fatal TE events). Diagnosis of stroke or transient ischemic attack required an acute neurological deficit lasting for more or less than 24 h, respectively, which could not be explained by other causes and with at least 1 image test (computed tomography or magnetic resonance) compatible with the diagnosis, as well as confirmation from a neurologist. A diagnosis of peripheral embolism was defined as non-central nervous system embolism leading to an abrupt vascular insufficiency associated with clinical or radiographic evidence of arterial occlusion in absence of another mechanism such as atherosclerosis, instrumentation, or trauma.

Statistical analysis

Qualitative data were expressed as frequencies and percentages while quantitative data were summarized as mean and standard deviation. Comparison between qualitative data was performed using the χ^2 test or the Fisher exact test, as appropriate. The *t*-Student test was used to compare quantitative data.

The relationship between the primary endpoint and eGFR according to both formulas was evaluated using separate Cox proportional hazard regression models. The candidate variables to construct the multivariate Cox models were those variables presented $P < 0.10$ in the univariate Cox analysis, or those co-variables of recognized prognostic value in the medical literature. Once the initial Cox models had been established, they were simplified by stepdown elimination. Thus, the final Cox models to determine the adjusted effect of eGFR on the composite endpoint, included: age, sex, previous stroke, basal hemoglobin, chronic obstructive pulmonary disease, diabetes mellitus, congestive heart failure or left ventricular ejection fraction ⩽ 40%, history of malignant disease and coronary artery disease.

The association between eGFR formulas and the individual endpoints of either major bleeding or TE events was determined using competing-risks regression based on Fine and Gray's proportional subhazards models. The Fine and Gray models were adjusted for HAS-BLED score[4] in the case of testing the relationship between eGFR formulas and major bleeding, and for CHA_2DS_2-VASc score[15] in the case of testing the relationship between eGFR formulas and TE events. For all-cause mortality, we used a Cox regression model. Once the initial Cox model for predicting all-cause mortality had been established, it was simplified by stepdown elimination; and finally included the following covariables: age, sex, diabetes mellitus, and history of malignant disease, previous stroke, basal hemoglobin, and congestive heart failure or ejection fraction ⩽ 40%.

The discriminatory capacity of each formula at predicting either the primary or secondary endpoint was determined by calculating the c- statistic. We used

Table 1 Baseline characteristics *n* (%)

CHA2DS2-VASc: Congestive heart failure, hypertension, age ⩾ 75, diabetes mellitus, stroke, vascular disease, female sex category; COPD: Chronic obstructive pulmonary disease; HAS-BLED: Uncontrolled Hypertension: systolic > 160 mmHg, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile international normalized ratio, elderly > 65 years, drugs/alcohol concomitantly; TIA: Transient ischemic attack; PINRR: Percentage of INRs in therapeutic range.

the Delong test to compare the c-statistic values from each formula.

The calibration of the model was assessed with the Grønnesby and Borgan goodness-of-fit test. This test determines how closely the predicted event rate approximates the observed event rate over a range of scores. A significant value of *P* indicates a lack of fit.

The estimated coefficients were expressed as the hazard ratio (HR) with the respective 95%CI. A 2-sided $P < 0.05$ was considered statistically significant for all analyses.

Finally, we also assessed the incremental prognostic value of using one equation over another; using the concept of net reclassification improvement (NRI) as described by Pencina *et al*[16], to determine whether the reclassification of patients by one of the formulas regarding to each other, would result in a more accurate risk estimation.

All the analyses were performed with STATA 13, and by using the MedCalc statistical software version 12.2.1.

The study was reviewed by our expert Biostatistic Emad Abu-Assi, MD, PhD.

RESULTS

Mean age was of 73 ± 11 years, male patients constitute 66.4% of the studied population. Baseline characteristics are summarized in Table 1.

Assessment of renal function according to the formula used

The mean eGFR was higher when computed by the new CKD-EPI than with the re-expressed MDRD-4 (69.8 ± 23, 67.2 ± 19 mL/min per 1.73 m^2), respectively ($P < 0.0001$ for comparison).

There was lower prevalence of eGFR < 60 mL/min per 1.73 m^2 with the new CKD-EPI than with the re-expressed MDRD-4 (32.9% *vs* 34.1%).

Events throughout the follow-up

During a follow up of 10 ± 3 mo, the composite endpoint occurred in 98 (10.8%) patients: 30 (3.3%) patients developed major bleeding, 18 (2%) had TE events, and 60 (6.6%) patients died.

Relation with the composite endpoint

The rate of the composite endpoint increased monotonically from the higher to the lower eGFR categories for both formulas (Figure 1).

Significant association was observed between the eGFR using both formulas as continuous variables and the composite endpoint. The adjusted hazard ratios of eGFR by each formula on the composite endpoint were: 0.98 (95%CI: 0.967-0.988) and 0.97 (95%CI: 0.963-0.987) for the re-expressed MDRD-4 and the new CKD-EPI, respectively (Table 2).

Similarly, the eGFR as a categorical variable was a strong independent predictor of the occurrence of the composite endpoint regardless of the formula used (Table 3).

The discriminative capacity of both formulas at predicting the composite endpoint, were quite similar, regardless of the eGFR was used as continuous (0.683 *vs* 0.695 for the re-expressed MDRD-4 and the new CKD-EPI, respectively; $P = 0.748$) or categorical variable (0.632 *vs* 0.639 for the re-expressed MDRD-4 and the new CKD-EPI, respectively; $P = 0.45$) (Table 4).

Relation with major bleeding

There was a step increase in the major bleeding rate, as the eGFR declines, independently of the formula used to calculate the eGFR (Figure 1).

After adjusting for HAS-BLED bleeding risk score, the re-expressed MDRD-4 eGFR as well as the new CKD-EPI eGFR, as continuous variables, showed a tendency to predict major bleeding: HR for both formulas = 0.98 (95%CI: 0.965-1.000; $P = 0.07$) (Table 2).

No significant association was observed between

eGFR: Estimated glomerular filtration rate; CKD-EPI: Chronic Kidney Disease Epidemiology Collaboration; MDRD-4: 4-variable Modification of Diet in Renal Disease Study equation.

using the continuous new CKD-EPI eGFR: c-statistic = 0.677 (*P* = 0.85).

When eGFR was considered as a categorical variable, the discriminative capacity of each formula at predicting major bleeding was of 0.550 and of 0.571 for the re-expressed MDRD-4 and the new CKD-EPI, respectively (*P* = 0.79) (Table 4).

Relation with thromboembolic event

As shown in Figure 1, the distribution of the TE event rate in the different eGFR categories, demonstrated a consistent gradient of risk, regardless of the formula used.

After adjusting for the CHA_2DS_2-VASc risk score, no significant association was observed between eGFR as a continuous variable and TE events: HR = 0.98 (95%CI: 0.965-1.000) and 0.98 (95%CI: 0.965-1.001), for the re-expressed MDRD-4 and the new CKD-EPI, respectively (Table 2).

When eGFR was considered as a categorical variable, only significant association existed between eGFR < 30 mL/min per 1.73 m^2 and the TE complications, after

controlling for CHA_2DS_2-VASc score: HR = 5.1 (95%CI: 1.04-25.4) for the re-expressed MDRD-4, and HR = 5.0 (95%CI: 1.0-24.9) for the new CKD-EPI (Table 3).

The discriminative power of GFR estimates determined by both formulas was also modest. For continuous eGFR, the c-statistic values were of 0.616 and 0.644 for the re-expressed MDRD-4 and the new CKD-EPI, respectively, (P = 0.27), and for categorical eGFR, the c-statistic values were 0.617 and 0.622 when using the re-expressed MDRD-4 and the new CKD-EPI, respectively, (P = 0.76) (Table 4).

Relation with all-cause mortality

The rate of all-cause mortality increased progressively from the higher to the lower eGFR values for both formulas (Figure 1).

Continuous eGFR calculated by either the reexpressed MDRD-4 or the new CKD-EPI was an independent predictor of all-cause mortality; adjusted HR = 0.98; (P < 0.01) (Table 2).

A strong association was also found between categorical eGFR and all-cause mortality after adjusting for several confounders (Table 3).

Good discrimination was obtained from continuous eGFR: c-statistic = 0.715 for the re-expressed MDRD-4 and 0.722 for the new CKD-EPI (P = 0.52).

The discriminative power of eGFR as a categorical variable in terms of c-statistic was: 0.679 and 0.678 when using the re-expressed MDRD-4 and the new CKD-EPI, respectively, (P = 0.91) (Table 4).

Estimated GFR from both formulas demonstrated good calibration for the major cardiovascular events with P value > 0.1 (Table 4).

The NRI analysis did not significantly favor the new CKD-EPI over the re-expressed MDRD-4 whether for predicting the composite endpoint, major bleeding and all-cause mortality (NRI = 2.13%, 4.35%, and 0.9%, with P = 0.27, 0.19, and 0.7, respectively).

However, at predicting the TE event, the NRI favored the new CKD-EPI formula with NRI of 1% (95%CI: -0.08 to +2.0, P = 0.07) indicating a strong tendency to reclassify better the patients according to their risk of developing TE event, compared with the re-expressed MDRD-4.

DISCUSSION

In this real world cohort of patients with NVAF on VKAs, the new CKD-EPI formula classified lower percentage of patients as having eGFR < 60 mL/min per 1.73 m^2 than the re-expressed MDRD-4 equation did. This means that the use of the new CKD-EPI formula results in lower prevalence of renal dysfunction. We also found that renal dysfunction assessed either by the re-expressed MDRD-4 or the new CKD-EPI was strongly associated with the composite endpoint of major bleeding, TE event and all-cause mortality, and with all-cause mortality, as well.

Patients with NVAF are often elderly with multiple comorbidities which require pharmacotherapy of growing complexity, and this makes the reliable estimation of renal function to be undeniably a critical issue. Moreover, the availability of the new oral anticoagulants have renewed the great interest toward the accurate evaluation of renal function in patients with NVAF[17,18].

Up to our knowledge, this is the first study comparing the prognostic performance of the re-expressed MDRD-4 and the new CKD-EPI formulas used for estimating GFR in a real world population of patients with NVAF on VKAs who have a full range of eGFR.

In this cohort, the new CKD-EPI formula classified lower percentage of patients as having eGFR < 60 mL/min per 1.73 m^2 (32.9% with new CKD-EPI *vs* 34.1% with re-expressed MDRD-4). This reasonable ability of the new CKD-EPI formula to reduce the rate of patients with renal dysfunction could be highly appreciated by the clinicians in daily clinical practice which usually needs close attention to the status of renal function to reach the optimal management, and more safe use of renally excreted medications and nephrotoxic contrast agents, in patients with NVAF. Our finding is consistent with that found in the derivation cohort of the new CKD-EPI[9] and to the findings obtained from multiple studies in different clinical settings[12,19-21].

In our analysis, renal dysfunction determined by GFR estimates using both formulas was a significant predictor of the composite endpoint and all-cause mortality. Similar findings have been shown in previous study used the MDRD-4[22], but until now, no study has compared the prognostic usefulness of these formulas in a real world patients with NVAF. In this study, we did not find any significant difference in the prognostic impact between the new CKD-EPI and the re-expressed MDRD-4 at predicting major adverse cardiovascular outcomes.

In our analysis, we found that both formulas with the eGFR as a continuous variable and after controlling for HAS-BLED risk score[4], showed a tendency to predict major bleeding. Previous association between renal dysfunction and major bleeding were found in AF studies[22,23]. However, the prior tendency was lost when the eGFR using both formulas was tested as categorical variables; this may be explained by the small number of events (30 events, 3.3%) that could limit the detection of significant relationship from the data.

TE prevention remains the primary cornerstone in the management of patients with NVAF. In dealing with this great aim, there are conflicting data about the ability of renal dysfunction to predict this major catastrophe. Several studies demonstrated significant association between reduced eGFR and TE event[22-24], conversely, in other studies, decreased eGFR did not show significant relationship with TE event[25,26]. These differences could be explained by the differences in the formula used to estimate GFR, sample size, patients

characteristics (*i.e.,* from a real world or clinical trial population), and/or the disparities in duration of follow up between the studies. Therefore, there is a strong need for further evaluation of that uncertainty in a real world population. Regarding this important issue, in our real world cohort of patients with NVAF, and after adjusting for the CHA_2DS_2-VASc risk score[15] there was a significant association between eGFR as categorical variable and TE event only when the eGFR was < 30 mL/min per 1.73 m^2 (*i.e.,* severe renal dysfunction category) with similar prognostic impact of both the re-expressed MDRD-4 and the new CKD-EPI. Furthermore, the NRI analysis showed a tendency of the new CKD-EPI to reclassify better the patients according to their risk of developing TE event, compared with the re-expressed MDRD-4.

It should be kept in mind that the eGFR formulas were designed to most accurately estimate renal function and not to predict major adverse outcomes. Indeed, the relative performance of the two different GFR estimating equations in our study can be explained by their respective compositions (*i.e.,* the difference of mathematical modeling and how specific variables are coded and weighted by each equation). Also, the relative variance in performance between both formulas can be explained by the differences in their respective derivation populations. The MDRD-4 formula was originally developed in patients with established renal dysfunction[6]; for this, the re-expressed MDRD-4 formula may be less applicable to patients from the real world with full range of GFR. In contrast, the new CKD-EPI equation could be more precise in our community-based cohort of patients with NVAF, as the new CKD-EPI was developed in population with and without renal dysfunction[9].

Although, many laboratories are preparing their installation to use the new CKD-EPI equation instead of the re-expressed MDRD-4 formula according to the current guideline[27] and a consensus document[28], however, old habits die hard. Our assessment of the prognostic performance of both formulas in the particular clinical context of AF might be of great importance as it could help convince the clinicians and mitigate the doubts and obstacles regarding the adoption of the new CKD-EPI.

Really, patients with NVAF and renal dysfunction continue to represent a complex management problem in relation to decision making for thromboprophylaxis. With respect to the overall concept, the data obtained from our analysis, state that the new CKD-EPI formula reduced the prevalence of patients with renal dysfunction (*i.e.,* eGFR < 60 mL/min per 1.73 m^2), and at the same time continued to have prognostic impact similar to that of the re-expressed MDRD-4 equation at predicting the major adverse events. Taken together, our notable results from a real world cohort encourage the use of the new CKD-EPI equation to assess renal function in patients with NVAF and reinforce the current recommendation[9,27,28] for the use of the new CKD-EPI formula in all clinical situations.

It is clear that our study presents an analysis of a modest sized cohort of patients with NVAF on VKAs from the real world, and the prevalence of patients with eGFR < 60 ml/min/1.73 m^2 was just reduced by 1.2% when using the new CKD-EPI formula. However, our cohort might give a good reflection of the general population with millions of patients having NVAF, in whom the percentage of 1.2% would be highly significant.

Limitations

The main limitation of our study is its retrospective design, but it has interesting strong points as it reflects real world practice by enrolment of consecutive patients with NVAF who have full range of eGFR and were attending our outpatient cardiology clinics with the advantage of careful follow up and data collection by cardiologists.

The sample size might be another limitation of our study that could limit the likelihood of detecting small effects or significant relationships from the data. Important to mention here that we did not have the direct measured GFR, so we cannot determine the extent to which the two formulas reflect the GFR as determined by the gold standard method. However, eGFR is the practical way to estimate renal function which has been used in several patient populations. The fact that we have only one serum creatinine measure for every patient could limit the verification of the acute *vs* chronic nature of the renal dysfunction in some patients, but this limitation was present in several related studies[23-25]. The lack of cystatin C data might be considered a limitation of our study. However, it should be taken into account that all the creatinine measurements in our study cohort were performed with the IDMS-traceable enzymatic assay method, which has been shown to provide very reliable eGFR results[13] and is considered the standard method to assess renal function[29].

Finally, all of the enrolled patients in our cohort have Caucasian race, so the applicability of our findings in other populations with different races should be addressed in other studies.

The new CKD-EPI reduced the prevalence of patients with renal dysfunction, in a real world cohort of patients with NVAF on VKAs. Renal dysfunction reflected by GFR estimates from the re-expressed MDRD-4 or the new CKD-EPI was an independent predictor of the composite endpoint and all-cause mortality. Both formulas had similar prognostic impacts regarding the prediction of composite endpoint, major bleeding, TE events and all-cause mortality. Our analysis indicates that the more widespread adoption of the new CKD-EPI instead of the re-expressed MDRD-4 may improve the management of patients with NVAF.

COMMENTS

Background

Renal dysfunction is a frequent comorbidity seen in patients with atrial fibrillation. Moreover, renal dysfunction is a strong predictor of thromboembolic event and also of bleeding event (when the patients are anticoagulated). This reflects the need for more accurate estimate of renal function to guarantee the optimal management of patients with atrial fibrillation. The standard way to assess renal function is the glomerular filtration rate. Among the available equations to estimate the glomerular filtration rate are: the re-expressed Modification of Diet in Renal Disease equation which is still the commonly used equation by many laboratories all over the world and the new Chronic Kidney Disease Epidemiology Collaboration equation which has been recently proposed to be used instead of previous equation in daily practice as the new equation has an assumed ability to reduce the prevalence of patients with renal dysfunction and better reclassification of patients. There is limited information about the performance of both equations in patients with atrial fibrillation.

Research frontiers

The authors think that the new Chronic Kidney Disease Epidemiology Collaboration equation to estimate glomerular filtration rate must have a wide diffusion as an alternative to the re-expressed Modification of Diet in Renal Disease equation. In this paper the authors provide support to the hypothesis, reporting the superiority of the new Chronic Kidney Disease Epidemiology Collaboration equation over the re-expressed Modification of Diet in Renal Disease equation in the clinical context of patients with atrial fibrillation on anticoagulation.

Innovations and breakthroughs

The results derived from our analysis, state that the new Chronic Kidney Disease Epidemiology Collaboration equation reduced the prevalence of patients with renal dysfunction (*i.e.,* estimated glomerular filtration rate < 60 ml/min per 1.73 m^2), and at the same time continued to have the prognostic impact similar to the re-expressed Modification of Diet in Renal Disease equation at predicting the major adverse events. Although there are still some concerns about the performance of the new equation in subgroups of elderly and obese patients, the study from a real world cohort encourages the cardiologists to use of the new Chronic Kidney Disease Epidemiology Collaboration equation to assess renal function in patients with atrial fibrillation and increase the confidence to use it in all clinical situations.

Applications

The millions of patients with atrial fibrillation will get benefit and better management if there is wide spread adoption of the new Chronic Kidney Disease Epidemiology Collaboration equation instead of the re-expressed Modification of Diet in Renal Disease equation, giving the ability of the new equation to correctly reclassify patients in comparison with the re-expressed equation.

Terminology

The Chronic Kidney Disease Epidemiology Collaboration equation (CKD-EPI) was published in May 2009 as a reliable tool to estimate glomerular filtration rate. It was developed in an effort to create an equation more accurate than the re-expressed Modification of Diet in Renal Disease equation. Researchers pooled data from multiple studies to develop and validate this new equation. They used 10 studies that included 8254 participants, randomly using 2/3 of the data sets for development and the other 1/3 for internal validation. Sixteen additional studies, which included 3896 participants, were used for external validation. The CKD-EPI equation performed better than the Modification of Diet in Renal Disease equation, as the prevalence of chronic kidney disease was 11.5% *vs* 13.1% according to the National Health and Nutrition Examination Survey data in the United States of America.

Peer-review

First of all I would like to congratulate the authors with their achievement. In this retrospective study including relatively limited sample size of Caucasian subjects, the findings encourage the use and application of the new CKD-EPI equation for assessment not only of renal function in patients with non-valvular atrial fibrillation but also in all clinical situations. For the first time, Abumuaileq RRY *et al* evaluated the re- expressed MDRD-4 and the new CKD-EPI formulas at predicting the occurrence of major adverse outcomes in a real world cohort of patients with non-valvular atrial fibrillation on anticoagulation. The study was well conducted and clinically relevant.

Abstract

To describe preliminary experience of percutaneous pulmonary valve implantation, in a single pulmonary branch position. Two procedures in 2 patients from a single center are described, where implantation of percutaneous valves within a single pulmonary artery branch was technically successful. The procedural indication was pulmonary valve regurgitation and/or residual stenosis. The 2 patients were symptomatic. An Edwards Sapien™ valve (Patient 1), and a Medtronic Melody™ valve (Patient 2) were implanted. Both pts were discharged with an excellent valve function. In this report it is underlined that this modality is technically feasible and may be considered an option in patients with congenital heart defect under special circumstances.

Key words: Congenital heart disease; Tetralogy of fallot; Pulmonary atresia; Percutaneous pulmonary valve; Grown-ups with congenital heart diseases

Core tip: Today MelodyVR valve (Medtronic, Minneapolis, MN) and the SAPIENTM transcatheter heart valve valve (Edwards Lifesciences LLC, Irvine, CA) are available to use in patients with a conduit connecting the right ventricle to the main pulmonary arteries (PA). However, given the anatomic variability of the right ventricular outflow tract and the concomitant occurrence of branch PA disease frequently encountered in this patient population, alternative approaches to valve replacement needs to be explored. In order to solve this problem we use a different approach implementing percutaneous pulmonary valve implantation, in a single pulmonary branch position.

Percutaneous pulmonary valve implantation in a single artery branch: A preliminary experience. *World J Cardiol* 2015; 7(10): 695-699 Available from: URL: http://www.wjgnet.com/1949-8462/full/v7/i10/695.htm DOI: http://dx.doi.org/10.4330/wjc.v7.i10.695

INTRODUCTION

The first successful percutaneous pulmonary valve implantation (PPVI) was described by Bonhoeffer *et al*[1], Currently two balloon expandable transcatheter valves are available for PPVI: the MelodyVR valve (Medtronic, Minneapolis, MN) and the SAPIENTM transcatheter heart valve (Edwards Lifesciences LLC, Irvine, CA).

Both valves are indicated in patients with a conduit connecting the right ventricle to the main pulmonary arteries (PA). However, given the anatomic variability of the right ventricular outflow tract (RVOT) and the concomitant occurrence of branch PA disease frequently encountered in this patient population, alternative approaches to valve replacement have been explored[2-4]. We report our preliminary experience of PPVI in a single pulmonary branch.

CASE REPORT

Two patients (Table 1) underwent PPVI in a single branch between 2013 and 2014.

Patient 1 had a complete repair of tetralogy of Fallot in 2001, followed by a re-operation in August 2003 for residual ventricular septal defect (VSD) + right ventricular outflow tract obstruction (RVOTO). During the second intervention a trans-annular patch + VSD closure + Tricuspid Valve plasty and patch enlargement of a hypoplastic left pulmonary artery (LPA) were performed. In 2006, the patient underwent a cardiac catheterization that showed absence of the LPA, confirmed in 2013 with a cardiac magnetic resonance (CMR) patient 2 had a left modified Blalock-Taussig Shunt, and then at age 1 year, underwent a complete correction of her PA-VSD + MAPCAs unifocalization and FreeStyle 14 mm RV-PA conduit implantation. The conduit was changed when she was 5-year-old using a 23 mm FreeStyle conduit associated with PA bifurcation plasty.

A CMR showed a dilated RV (EDVI = 157 mL/m^2) with severe pulmonary valve regurgitation (PVR) (RF = 43%), moderate RVOTO (peak gradient 40 mmHg), preserved RV systolic function, and absence of the right pulmonary artery (RPA) branch.

Informed consent was obtained for both two patients. Femoral venous and arterial accesses were obtained under general anesthesia. A complete left and right heart catheterization was done in both pts.

The RV angiography in patient 1 showed a dilated RVOT with a diameter of 32 mm (Figure 1A-C), too large for classical PPVI. At the origin of the RPA, there was the evidence of a waist (Figure 1D) with a diameter of 24 mm; a prestenting of the PA branch was made with a 43 mm ANDRA XXL stent mounted on 25 mm × 50 mm Crystal Balt balloon (Figure 1E).

The RV angiography in patient 2 showed a dilated, calcified, and moderate stenotic conduit (Figure 2A and B). A prestenting of the conduit was made using 2 premounted covered CP stents (45 mm length, 8 zigs and dilated with a BiB balloon 22 mm × 55 mm) (Figure 2C-E). The final stented conduit had a proximal angle which was considered not perfectly suitable (Figure 2F) for a traditional implant of the percutaneous valve. The valve was implanted at the origin of the LPA were the landing zone was better.

After a standard valve preparation including a thorough washing protocol and crimping protocol, a 26 mm Edwards Sapien valve in patient 1, and a 22 mm MelodyVR valve in patient 2 were deployed.

There were no immediate procedure-related complications. The trans-thoracic echo (TTE) performed the day after showed excellent valve function with no regurgitation and no stenosis. Therefore the patient 2 complained, 48 h later, about an abrupt onset of chest pain, shortness of breath, and hypoxia. She immediately underwent a computed tomography angiograpy (CTA) and the final diagnosis was micro pulmonary embolismi with evidence of filling defects in the distal pulmonary branches in the latero-basal segment of the lower lobe + in the inferior segment of the lingula.

She was immediately transferred to the ICU and she was started on Eparine.

The patient recovered immediately, the saturation became normal and she was discharged at home 10 d after.

At the last follow-up (range 6-12 mo) both pts were asymptomatic, with neither pulmonary valve regurgitation nor residual stenosis.

Patient 1 repeated the CMR 1 year after and the EDVI was 123 mL/m^2.

DISCUSSION

Robb *et al*[5], reported an animal study, with a Melody valve implantation in the pulmonary artery branches. The Authors demonstrated that RVOT dilation and distortion consistent with transanular patch repair of ToF could be reliably mimicked with an animal model. Secondly, it was shown that PPVI into the right and left branch PAs resulted in a significant reduction in pulmonary regurgitation, with preserved biventricular function demonstrated by MRI and catheterization.

Qureshi *et al*[6], reported a case of a transcatheter placement of the Melody valve in the proximal left pulmonary artery of a patient with acquired right pulmonary artery occlusion.

In our patients the valve was inserted in the only pulmonary artery branch available either because the RVOT was judged to be too large to allow a PPVI in a regular position, or the previous implanted conduit had a better angle (after prestenting) in the distal part, in the area in which there was a conjunction with the left pulmonary artery.

The complication experienced by Patient 2 could have occurred to the fact that some microemboli originate in the lower part of the conduit just under the pulmonary valve. Since this zone in which there is a

Table 1 Patients' characteristics

Patient	DoB	Weight (kg)	Diagnosis	Surgery	L/R PAB	PVR (yes/no)	RVOTO (yes/no)	Previous Caths (year)	CMR/ CT scan	Valve	Prestening	Compli-cations	Follow-up
1st (male)	June-2000	43	ToF	TAP	RPAB	Yes	No	2006	CMR	Sapien 26	Yes	No	12-mo

PA-VSD-MAPCAs: Pulmonary arteries-ventricular septal defect-major aortopulmonary collateral arteries; TAP: Trans-annular patch; RVOTO: Right ventricular outflow tract obstruction; CMR: Cardiac magnetic resonance; PVR: Pulmonary valve regurgitation.

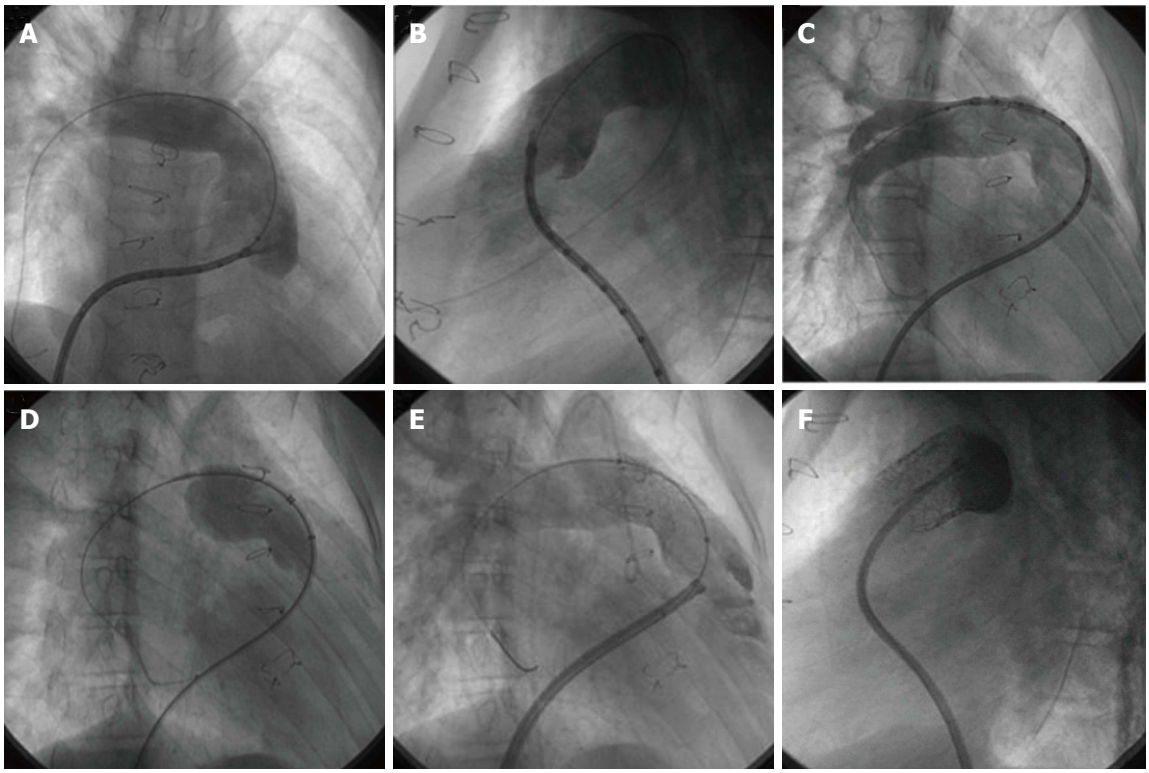

Figure 1 Angiograms in anterior-posterior, LL, right anterior oblique projections of the percutaneous pulmonary valve implantation using a Melody valve. A-C: Injections in the RV and origin of the RPA showing a dilated RVOT and stenosis at the origin of the RPA; D: Evidence at the balloon sizing of a waist at the origin of the RPA; E: Pre-stenting of the PA branch with a 43 mm ANDRA XXL; F: Good final result after Valve implantation with no evidence of PVR. PPVI: Percutaneous pulmonary valve implantation; RVOT: Right ventricular outflow tract; PA: Pulmonary arteries; RPA: Right pulmonary artery; AP: Anterior-posterior.

flow is not contractile, it could have favored a slowing down of the flow, creating a favorable condition for the formation of microemboli. It is difficult to support the idea that these emboli were related to the large sheaths used, because the episode was 48 h later. The pt was anticoagulated with a Heparine bolus of 100 IU/kg and the ACT was > 200 during all the procedure-time: She was just on antiplatelet therapy (ASA: 100 mg as in our protocol), after the procedure. Anticoagulation prophylaxis *vs* standard platelet antiaggregation should be take into consideration for these specific pts.

This brief report shows that PPVI can be performed in Pts with a congenital heart defect, and with a single pulmonary artery branch.

The use of a percutaneous valve in a branch pulmonary artery is not to be proposed for all the pts with a large or with a complex RVOT anatomy; what can be underlined with this report is that this modality is technically feasible and it may be considered as an option in high-risk patients under special circumstances.

COMMENTS

Case characteristics

Patient 1: Dyspnea and low stress tolerance; and Patient 2: Chest pain, shortness of breath, and hypoxia.

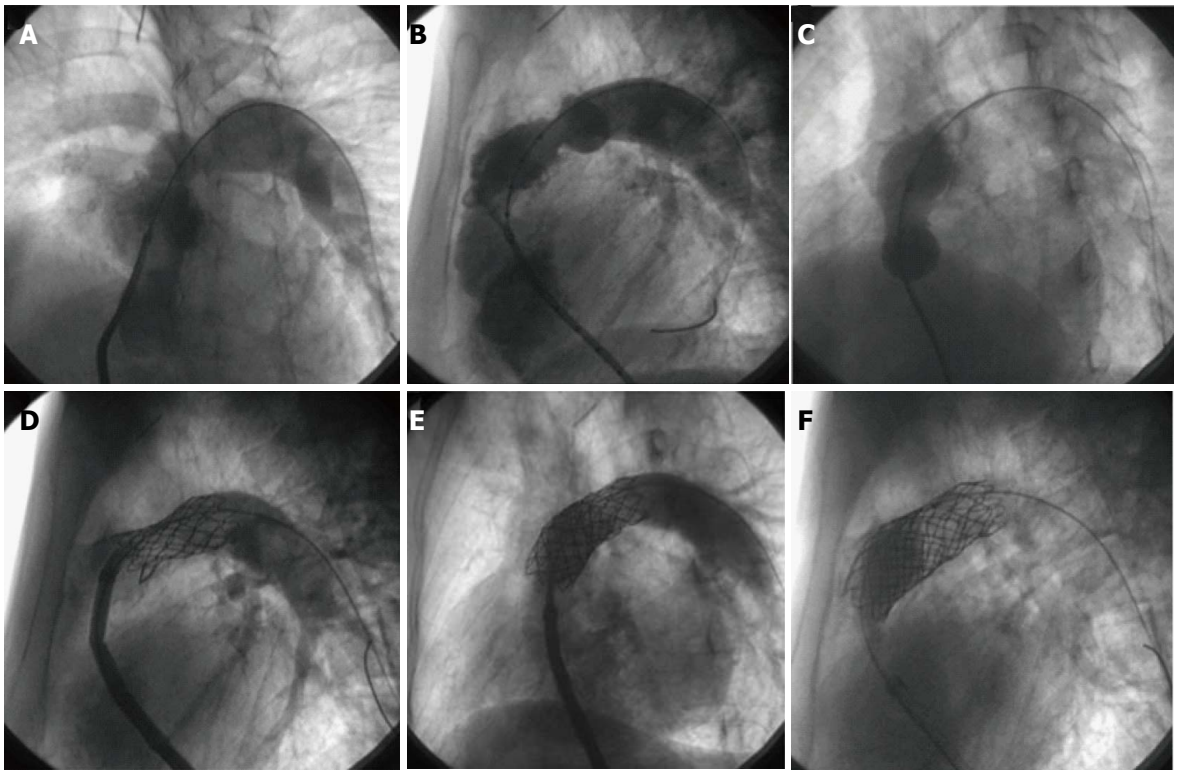

Figure 2 Angiograms in anterior-posterior, LL, projections of the percutaneous pulmonary valve implantation using a Sapien valve. A, B: Injections in the RV showing a dilated and calcified conduit with some degree of stenosis at the PA edge; C: A compliant AGA 34 mm ASD sizing balloon was inserted into the Freestyle conduit showing the stenotic area; D: Prestenting of the conduit using a premounted covered CP stent 45 mm; E: Second covered CP stent was implantation; F: After a re-dilation by utilizing an ATLAS 22 × 40 balloon dilatated at 14 Atm a final stented conduit was obtained with a proximal angle nor suitable for a PPVI in a regular position. PPVI: Percutaneous pulmonary valve implantation; RV: Right ventricular; PA: Pulmonary arteries.

Clinical diagnosis

Patient 1: Hypoplasia of left pulmonary branch; and Patient 2: Occlusion of right pulmonary branch.

Laboratory diagnosis

Patient 1: WBC: 7650/mm^3 (N: 66%; L: 18%; M: 10%). Hb: 13.3 g/dL, Hct: 38.4%; PLT 216000/mm^3; PCR: 2.8 mg/dL; PCT: 0.05 ng/mL; Patient 2: Hb: 10.2 g/dL, Hct: 31.1%; RBC: 3.78 × 10^6 U/L; INR: 2.12.

Imaging diagnosis

Patient 1: Cardiac magnetic resonance (MR), chest X-ray, echocardiography; Patient 2: Cardiac TC multi-slide, cardiac MR, chest X-ray, echocardiography.

Pathological diagnosis

Patient 1: The right ventricular angiography showed a dilated right ventricular outflow tract with a diameter of 32 mm and at the origin of right pulmonary artery there was an evidence of a waist with a diameter of 24 mm; Patient 2: A cardiac RM show a dilated right ventricle (EDVI = 157 mL/m^2) with severe pulmonary valve regurgitation (PVR) (RF = 43%), moderate right ventricular outflow tract obstruction (RVOTO) (peak gradient: 40 mmHg), preserved RVC systolic function.

Treatment

Patient 1: 26 mm Edward Sapien Valve implantation in left pulmonary branch; Patient 2: 22 mm MelodyVR valve implantation.

Related reports

Patient 1: ToF s/p complete surgical repair and following surgical treatment of residual Ventricular septal defect + RVOTO with trans annular patch (TAP) + VSD closure + Tricuspid valve plasty and patch enlargement of hypoplastic left pulmonary artery (LPA). In 2006 a cardiac catheterization showed the absence of LPA, confirmed in 2013 with a cardiac MR that show hypoplasia of left pulmonary branch; Patient 2: pulmonary atresia + VSD and MAPCAs s/p a left modified Blalock-Taussing shunt (MBTS) and following complete correction with unifocalization and 14 mm RV-PA conduit implantation that five years later was change with a 23 mm FreeStyle conduit + PA bifurcation plasty.

Term explanation

PPVI is the Percutaneous Pulmonary Valve Implantation that can be done in case of congenital heart disease in a GUCH population (Grown Ups with Congenital Heart Diseases) with RVOTO and/or PVR.

Experiences and lessons

Valve implantation in pulmonary branches could be a useful approach in high-risk patients under special circumstances.

Peer-review

This article provided the innovative approach to a particular kind of diseases in critical patients and gave the good results at the last follow up.

Abstract

Intra-hisian atrioventricular (AV) block is not a common phenomenon, but it is important for the development of advanced or complete AV block. We observed a 77-year-old female patient with the 2:1 AV block due to an intra-hisian block. In this case we tried to detect the block site, but an alternating pattern of the AH conduction was noted on the His-electrogram in the electrophysiological study (EPS). The cause of the confusing finding might have been the instability of the catheter to record a His potential. We could detect a splitting of the His-electrogram with an intra-hisian block after minimal manipulation of the catheter. The authors' observations suggest that catheter stability is important for a precise recording in the EPS and radiofrequency catheter ablation procedure.

electrophysiological study (EPS); 2:1 atrioventricular (AV) block is usually a disease of various levels such as supra-, intra- and infra-hisian[1,2]. We report a case with some confusion caused by the instability of the catheter used for the His-electrogram recording during 2:1 AV block due to an intra-hisian block.

CASE REPORT

A 77-year-old female complained of dizziness. Her past history had hypertension, and had been taking dihydrophyridine calcium channel blockers for 10 years. The chest radiograph showed cardiomegaly. The echo-cardiography revealed a normal function and wall motion. A resting electrocardiogram (ECG) revealed 2:1 AV block and right bundle branch block. After an intravenous injection of atropine and an exercise treadmill test, the ECG exhibited persistent 2:1 AV block.

The patient underwent an EPS to determine the position of the conduction block. EPS catheters located in right ventricle, His bundle and right atrium. Firstly, we found an infra-hisian block with a normal A-H interval (70 ms) and long H-V interval (70 ms) on the intracardiac ECG (Figure 1A), and then a supra-hisian block with longer A-H interval (100 ms) and shorter H-V interval (40 ms) (Figure 1B). After a while, another intracardiac ECG revealed a splitting of the His potential (H-H') in the A-V conduction and only the proximal activation of the His potential during A-V block, which meant an intra-His bundle block (Figure 1C).

The patient was performed the implantation of permanent pacemaker as a result of the intra-His bundle block. The patient has no other symptoms until now.

DISCUSSION

In our case, we tried to detect the block site but an alternating pattern of the AH conduction was noted in the His-electrogram during the EPS. The cause of

this confusing finding might have been due to the instability of the catheter to record a His potential. However, the His potential was distinct in the first recoding of the His bundle (Figure 1A). In addition, the His potential spontaneously moved and the AH interval prolonged during the AV conduction, which concluded that the catheter was not stable.

A consistent intracardiac electrogram reflects a stable catheter position. Among the several catheters used during the EPS, the catheter used for the His-electrogram recoding is the most unstable in a beating heart. Catheter stability is important for obtaining a precise recording during the EPS and radiofrequency catheter ablation procedure. Instability of catheters can contribute to a misdiagnosis and procedural complications especially with AV nodal reentrant tachycardia. Recently, a remote magnetic navigation system is able to provide better catheter stability during the radiofrequency catheter ablation procedure[3]. However, that system cannot be used during diagnostic procedures such as in our study because of the high cost. Fortunately, we could detect the splitting of the His-electrogram with an intra-hisian block after a minimal manipulation of the catheter.

Intra-hisian AV block during 2:1 AV block is not a common phenomenon, but it tends to develop into advanced or complete AV block[4]. We should try to obtain a precise His electrogram and find the exact block site when conducting an EPS for 2nd degree high grade AV block.

COMMENTS

Case characteristics

A 77-year-old female complained of dizziness.

Clinical diagnosis

Intra-hisian atrioventricular (AV) block detected a splitting of the His-electrogram after a correction of the catheter instability during the electrophysiological study (EPS).

Differential diagnosis

Second-degree Mobitz 1 block with 2:1 AV is easily misdiagnosed as general two to one conductive rate regardless of block site.

Laboratory diagnosis

The laboratory test results were unremarkable.

Imaging diagnosis

The intracardiac electrocardiogram revealed splitting of the His potential of the AV conduction during the EPS.

Treatment

A permanent pacemaker was implanted as a result of intra-hisian AV block.

Related reports

To best of our knowledge, intra-hisian AV block is an uncommon phenomenon.

Term explanation

Intra-hisian AV block in His-electrogram exhibited a splitting of the His potential during the AV conduction and only the proximal activation potential of the His bundle during the AV block, which meant an intra-His bundle block.

Experiences and lessons

The authors should try to achieve a precise recording of the His electrogram and find the exact block site when conducting an EPS for 2nd degree high grade AV block.

Peer-review

It is an interesting case report.

Abstract

Bacterial endocarditis following atrial septal defect closure using Amplatzer device in a child is extremely rare. We report a 10-year-old girl who developed late bacterial endocarditis, 6 years after placement of an Amplatzer atrial septal occluder device. Successful explantation of the device and repair of the resultant septal defect was carried out using a homograft patch. The rare occurrence of this entity prompted us to highlight the importance of a closed long-term follow up, review the management and explore preventive strategies for similar patients who have multiple co-morbidities and a cardiac device. A high index of suspicion is warranted particularly in pediatric patients.

Key words: Endocarditis; Atrial; Septal; Device

Core tip: Bacterial endocarditis following atrial septal defect closure using Amplatzer device in a child is extremely rare.

We report a 10-year-old girl who developed late bacterial endocarditis, 6 years after placement of an Amplatzer atrial septal occluder device. This case report demonstrates the need for long-term follow up of patients with intracardiac device especially those with multiple co-morbidities or who have vulnerability to infection due to poor general condition or extreme of age such as our's. A high index of suspicion for device complication is required if there is a sepsis or embolic phenomenon found. Incomplete endothelization of the prosthetic devices may be linked to the endocarditis and needs to be explored.

INTRODUCTION

Bacterial endocarditis of intracardiac devices including Amplatzer atrial septal occluder in pediatric population is extremely rare. In view of the limited experience, this is an opportunity to highlight such cases in order to review management and explore preventive strategies for a successful outcome in future. We, therefore, presenting herewith a child with multiple co-morbidities who developed late bacterial endocarditis of an Amplatzer device following closure of secundum atrial septal defect and underwent successful management.

CASE REPORT

A 10-year-old girl was referred to us with a high-grade intermittent fever of 2 wk duration being treated for septic shock and altered sensorium. She also had a pyopericardium which was drained. She required ventilatory and minimal inotropic support. She had generalised anasarca, bilateral mild pleural effusions and generalised muscle spasticity. Additionally, there was cellulitis on the chest wall requiring surgical debridement. Blood and wound cultures were positive for Streptococcus Pyogenes, sputum for *Pseudomonas* and urine for *Escherichia coli*. She was managed with appropriate antibiotics. Other medications included diuretics, anti-convulsive therapy and ACE-inhibitors. She was known to have global developmental delays associated with cerebral atrophy and epilepsy with clonic seizures. In the past, at the age of 4 years, she underwent device closure of atrial septal defect in a hospital abroad. However, the details of the procedure were not available.

Routine blood tests revealed elevated markers of infection in addition to evidence of hepato-renal dysfunction. Computerized tomography of the chest revealed minor effusions in the pleural cavities and an Amplatzer device in the atrium.

A two dimensional echocardiogram confirmed moderately depressed biventricular function, thickened pericardium and a prosthetic device in the inter-atrial septum with attached mobile vegetation (Figure 1). Other cardiac structures were normal.

It was suspected that the atrial septal occluder device was infected and possibly was a source of multiple systemic embolization and persistent bacteraemia. Therefore, we proceeded for surgical removal of the device.

Surgery was performed through the median sternotomy under systemic heparinization, standard cardiopulmonary bypass using aortic and bicaval cannulation, aortic cross-clamping and cardioplegic arrest at moderate systemic hypothermia *via* right atrial approach. The pericardium was thickened and adherent all around featuring constrictive pericarditis. The Amplatzer device's surface was partially covered with the soft tissue (endothelized) with patchy bare areas. However, there was no active vegetation found (Figure 2). Other cardiac structures including valves were grossly normal. After explantation of the device, a resultant atrial septal defect was repaired using a patch obtained from the pulmonary homograft.

The patient had a slow but steady recovery. The post-operative echocardiography showed improved cardiac function without residual defects. There was a constant decline in the levels of inflammatory markers. She recovered fully except that generalized spasticity is still persistent. The histopathological examination of the tissue attached to the device showed evidence of severe acute and chronic inflammation in the connective tissue (Figure 3). However, a stain for fungal organism and culture of the tissue within the device was negative. Further studies to investigate the tissue infection within the soft tissue such as biofilm study or electron microscopy was not available.

DISCUSSION

Transcatheter occlusion technique using Amplatzer device has become a preferred approach for atrial septal defects in selected patients. The common complications associated with occluding devices are mal-positioning or migration of device, thromboembolism, arrhythmias or endocarditis[1-5]. Bacterial endocarditis of an Amplatzer septal occluder device in the pediatric population is very rare. However, few reports have described early and late endocarditis associated with such device in adult population[2-4].

Early device infection could be due to inoculation of organisms during implantation. However, hematogenous infection is the primary source of late endocarditis. In our patient, the source of infection could have been cellulitis or respiratory infection. In addition, there was purulent pericarditis. This combination suggests a hematogenous spread of infection leading to prosthesis endocarditis. In the only published report in a 4-year-old

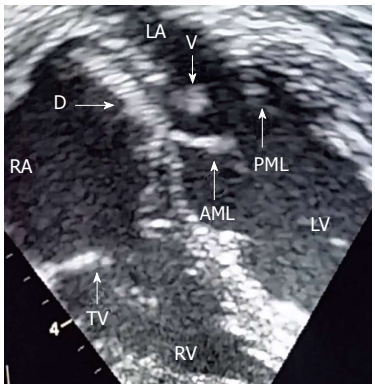

Figure 1 Two dimensional echocardiography image showing a large mobile vegetation (V) attached to the lower surface of an Amplatzer device (D) near the mitral valve. AML: Anterior mitral leaflet; PML: Posterior mitral leaflet; LV: Left ventricle; RV: Right ventricle; LA: Left atrium; TV: Tricuspid valve; RA: Right atrium.

Figure 2 Explanted Amplatzer device showing embedded soft tissue and bare metal surface.

child, authors have proposed incomplete endothelization of the device as a mechanism of late endocarditis[3]. Upon closer look of the explanted device, we also have noticed gross evidence of incomplete endothelization in the form of exposed metallic surface of the device in places without soft tissue coverage.

There are no established guidelines for the management of late endocarditis involving intra cardiac devices. We suggest that intensive management involving prolonged antibiotic therapy, monitoring of inflammatory markers and frequent blood cultures may be the first step. However, surgery is warranted if there is evidence of septal perforation, dehiscence, fistula formation, vegetation or embolization[6,7]. The relative indication may include persistent positive blood cultures in spite of maximal medical therapy[6,7].The homograft patch may be preferred choice for repair of resultant septal defect after explantation of the device in this situation presumably due to resistant nature of the homograft tissue against infection and better antibiotic penetration as compared to synthetic materials. Bovine pericardium may be an alternative.

In the clinical and experimental studies, it has been

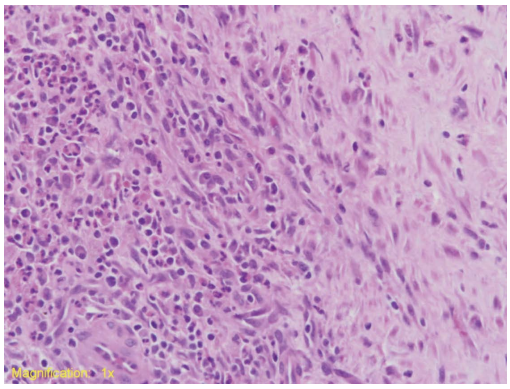

Figure 3 Microphotograph of the tissue within the explanted device showing connective tissue with dense, mixed, acute and chronic inflammatory infiltrates.

demonstrated that it takes 3-6 mo for complete neo-endothelization of the device[3]. Therefore, appropriate length of bacterial endocarditis prophylaxis for patients with atrial septal device closure was arbitrarily determined and usually extends from 6 mo to 1 year after implantation[2-4]. We hope that in future, additional investigations, imaging techniques or biochemical markers will allow identification of patients with incomplete endothelization who warrant long-term endocarditis prophylaxis.

This case report demonstrates the need for long-term follow up of patients with intracardiac device especially those with multiple co-morbidities or who have vulnerability to infection due to poor general condition or extreme of age. A high index of suspicion for device complication is required, if there is a sepsis or embolic phenomenon found. An intensive medical or surgical management and a prolonged follow up is warranted for a successful outcome.

COMMENTS

Case characteristics

A 10-year-old girl presented with late bacterial endocarditis of a cardiac Amplatzer device in addition to multiple co-morbidities and pancarditis.

Clinical diagnosis

Late bacterial endocarditis of cardiac prosthesis with cellulitis and pancarditis.

Differential diagnosis

Primary endocarditis of cardiac device, septicemia, pericarditis.

Laboratory diagnosis

Leucocytosis and mildly elevated hepato-renal function markers.

Imaging diagnosis

CT scan of the chest and an echocardiograhy showed evidence of a cardiac prosthesis (Amplatzer atrial septal occluder device) with a large vegetation.

Pathological diagnosis

The histopathology of the soft tissue attached to the explanted cardiac device showed the presence of acute and chronic inflammatory infiltrates. In addition, gross examination of the explanted Amplatzer device confirmed the presence of

bare metal exposed to the surface and the blood within the device.

Treatment
The patient was treated with intravenous antibiotics according to the culture and sensitivity reports of the blood, urine and pericardial fluids. Additionally, explantation of the atrial septal occluder device was done on cardiopulmonary bypass on urgent basis in order to remove the source of persistent bacteraemia and to avid thromboembolism.

Related reports
The biofilm and electron microscopic studies were not available which may have a precise-diagnostic value to prove the presence of specific infection within the device.

Term explanation
Cardiopulmonary bypass is a term used to commonly indicate open heart surgery using a cardiopulmonary bypass machine with an oxygenator.

Experience and lessons
This case report not only represents a very rare occurrence of the late endocarditis of the cardiac device in association with pancarditis and multiple co-morbidities in a child but also provides authors an opportunity to focus their attention on the mechanism and prevention of this pathology for a better outcome in future. They have substantiated the hypothesis of the role of exposed bare metal surface and deficient soft tissue coverage (incomplete endothelization) as a cause of prosthetic endocarditis. This fact not only guides us to explore the preventive measures while designing cardiac devices in future but also to be aware of a possibility of endocarditis in similar patients with multiple comorbidities and low resistance especially in pediatric population in order to have a cautious long-term follow-up and antibiotic prophylaxis.

Peer-review
The case report is very interesting and well described.

Abstract

Congestive heart failure (CHF) secondary to chronic coronary artery disease is a major cause of morbidity and mortality world-wide. Its prevalence is increasing despite advances in medical and device therapies. Cell based therapies generating new cardiomyocytes and vessels have emerged as a promising treatment to reverse functional deterioration and prevent the progression to CHF. Functional efficacy of progenitor cells isolated from the bone marrow and the heart have been evaluated in preclinical large animal models. Furthermore, several clinical trials using autologous and allogeneic stem cells and progenitor cells have demonstrated their safety in humans yet their clinical relevance is inconclusive. This review will discuss the clinical therapeutic applications of three specific adult stem cells that have shown particularly promising regenerative effects in preclinical studies, bone marrow derived mesenchymal stem cell, heart derived cardiosphere-derived cell and cardiac stem cell. We will also discuss future therapeutic approaches.

Key words: Congestive heart failure; Adult stem cells; Mesenchymal stem cell; Cardiosphere-derived cell; Cardiac stem cell

Core tip: Cell-based therapy emerged as a new approach to restore damaged heart function. Although cell therapy in experimental animal models is promising, beneficial effects in clinical trials are variable. This review summarizes recent preclinical and clinical applications on three specific adult stem cells (bone marrow derived mesenchymal stem cell, heart derived cardiosphere-derived cells and cardiac stem cell) and discuss about future approaches.

recent advances in medical and device therapies that delay the progression of disease[1]. Currently available medical interventions attenuate neurohormonal activation (*e.g.*, renin-angiotensin-aldosterone system, sympathetic nervous system, and arginine vasopressin), reducing myocyte apoptotic cell death, reducing interstitial connective tissue proliferation and attenuating the progression of myocyte cellular hypertrophy. However, none of the current therapies are effective in reversing myocyte loss and cellular abnormalities associated with myocyte contractile performance which are impaired in the failing heart. Recent investigations have demonstrated that there is an endogenous cardiac repair system that arises from resident cardiac stem cells regulating cardiac engraftment by maintaining a low level of myocyte proliferation, regeneration and cell death[2]. Nevertheless, the regenerative capacity of this endogenous stem cell pool is limited.

Expansion of adult stem cells *ex vivo* can stimulate the heart to induce endogenous or exogenous cell based repair. Cell-based therapy has emerged as a promising therapy to regenerate the failing heart through its potential to repair dead myocardium and improve left ventricle (LV) function[3-5]. Although clinical trials have demonstrated the safety and feasibility of using bone marrow-derived stem cells [Bone marrow mononuclear cells (MNCs) or mesenchymal stem cells (MSCs)] or heart-derived stem cells [cardiac stem cells (CSCs) or cardiosphere-derived cells (CDCs)] in humans with MI who do not have severe heart failure, the long term clinical efficacy of this approach is variable with a small improvement in LV function[6-8]. Although the biological action of adult stem cells *in vivo* is still controversial, for now, the beneficial effects of adult stem cells are considered to be associated with the secretion of paracrine factors rather than direct differentiation of *de novo* cardiac cells[9]. Accordingly, stem cells secrete multiple growth factors and cytokines which reduce scar volume and myocyte apoptosis, increase myocyte proliferation and activate endogenous CSCs to produce new myocytes. Therefore, current research using adult stem cells has focused on optimizing cell based therapy that effectively improves LV function and decreases disease progression. This would have a major impact on the survival and quality of life in patients with ischemic heart disease as well as reduce healthcare expenditures related to recurrent hospitalizations from advanced disease. In this review we will discuss three types of adult stem cells, MSCs, CDCs and CSCs, which are involved in the early phase of clinical trials (Table 1) and address current problems and future directions (Table 2).

MSCS IN ISCHEMIC CARDIOMYOPATHY

MSCs arise from a small proportion of bone marrow mononuclear cells (0.001%-0.01% of nucleated cells in the bone marrow). Although it has been reported that MSCs can be differentiated into cardiomyocytes and vascular-like structures[10-14], actual *in vivo* differentiation is infrequent. Moreover, current approaches using direct myocardial injection or intracoronary infusion of cells in the infarcted region result in a low myocardial retention of stem cells[15]. Thus, most of the beneficial effects derived from MSCs are considered to be related to a paracrine mechanism. MSCs produce a wide variety of cytokines, chemokines and growth factors, and many are involved in restoring cardiac function or regenerating myocardial tissue. Factors such as basic fibroblast

Table 2 Alternative strategies of stem cell therapy

Enhancement of cell survival, mobilization and paracrine secretion
Pharmacology (Statins, *etc.*)
Genetic modification (Akt and Ang1, VEGF and SDF-1, HO-1, bFGF/IGF-1/BMP2)
Preconditioning (Hypoxia, TLR3 stimulation)
Combination of different cell types or delivery approaches
MSCs and CSCs
Stop-flow (infarct area) and global intracoronary infusion (viable area)
Others
Cell infusion immediate after revascularization (allogeneic MSCs, CDCs, *etc.*)
Repeated cell infusion
Stimulation of exosome release
Direct exosome (or microRNAs) injection
Cell therapy in hypertrophied myocardium or dysfunction due to congenital heart disease

MSCs: Mesenchymal stem cells; CSCs: Cardiac stem cells; CDCs: Cardiosphere-derived cells; VEGF: Vascular endothelial growth factor; SDF: Stromal cell-derived factor; bFGF: Basic fibroblast growth factor; IGF: Insulin-like growth factor; BMP2: Bone morphogenetic protein 2; HO-1: Heme-oxygenase 1; Ang1: Angiopoietin 1.

growth factor (bFGF), hepatocyte growth factor (HGF), insulin-like growth factor-1 (IGF-1), vascular endothelial growth factor (VEGF), transforming growth factor (TGF)-β, and stromal cell-derived factor (SDF)-1 inhibit LV remodeling[16] and apoptosis, stimulate proliferation of endogenous myocytes and angiogenesis, activate endogenous CSCs[4] and mobilize bone marrow progenitor cells to the heart[17]. Importantly, MSC are immunoprivileged because they do not express MHC class II molecules therefore they escape immune-rejection, release immunomodulatory factors and inhibit T-cell proliferation. Allogeneic cells can be expanded *ex vivo* and stored to use in patients[18,19]. This would allow for "off-the-shelf" treatment of patients with severe LV dysfunction, without the need to wait for cell processing and expansion[19].

A large number of preclinical investigations have been performed using MSCs, and demonstrate a significant beneficial effect on cardiac structure and function[13,20-23]. In a large animal model, Quevedo *et al*[18] demonstrated that administration of allogeneic MSCs to a swine model of chronically infarcted myocardium resulted in improvements in regional contractility and myocardial blood flow, as well as engraftment, differentiation and enhanced survival. Williams *et al*[24] assessed serial cardiac MRI in animals with post-MI LV remodeling and showed progressive scar size reductions, improvements in ejection fraction (EF) and reverse LV chamber remodeling in animals receiving allogeneic MSCs as compared to controls[24]. Mesenchymal precursor cells (MPCs) are subpopulation of MSCs expressing the STRO-3 cell surface marker. MPCs are highly proliferative and secrete abundant paracrine factors. Houtgraaf *et al*[25] demonstrated that slow infusion of allogeneic MPCs (12.5 to 37.5 million cells) to an bovine model with acute MI improved regional and global function and reduced scar volume and LV remodeling. Interestingly, MPC infusion in the infarct-related coronary artery caused myocyte cell size reduction in the infarcted and remote regions. Based on these data a clinical trial is currently ongoing (NCT01781390, phase Ⅱ) that investigates the safety of MPCs in patients with *de novo* anterior MI.

We have demonstrated that slow infusion of allogeneic MSCs into the three major coronary arteries in swine with hibernating myocardium increased regional cardiac function in both the ischemic left anterior descending (LAD) artery and remote regions (wall thickening: LAD: 24% to 43%, Remote: 60% to 85%, $P < 0.05$)[17]. Intracoronary MSCs (icMSCs) significantly increased cKit+/CD133 positive cells (or bone marrow-derived progenitor cells) in the bone marrow and circulation corresponding to the increase in myocardial localization of cardiac progenitor cells (cKit+/GATA4 or Nkx2.5+). icMSCs also induced myocytes to enter the cell cycle and increased the production of small cardiac myocytes indicating the presence of cardiac regeneration. Although some laboratories have identified rare myocytes arising from MSCs in swine[18], our own studies using multiple reporter genes could not identify cardiac myocytes differentiating from labeled MSCs[26]. Thus, cardiac regeneration after icMSCs is related to a bone marrow-derived progenitor cell mediated endogenous cardiac repair mechanism.

Chen *et al*[10] administered 48-60 billion bone marrow derived MSCs by intracoronary injection into 34 patients and reported a 13% increase in EF compared to placebo groups at 3-6 mo follow-up. The Percutaneous Stem Cell Injection Delivery Effects on neo-myogenesis (POSEIDON) trial, by Hare's group, tested the ability of autologous and allogeneic MSCs (20, 100 and 200 million cells) in patients with ischemic cardiomyopathy to promote cardiac recovery following transendocardial stem cell injection[27,28]. Using multidetector computed tomography and biplane left ventriculography, this study reported a 32% reduction in scar size in allogeneic MSCs group *vs* a 35% reduction in autologous MSCs groups without improvement of LV EF. Subgroup analysis demonstrated that 20 million MSCs improvement in LV EF and LVEDV. Furthermore, autologous MSCs showed improvement in the 6 min walk test and allogeneic MSCs reduced LVEDV. Additionally, allogeneic MSCs did not stimulate a donor specific alloimmuno reaction. Thus, this study clearly demonstrates the importance of cell injection site and the safety of using allogeneic MSCs in patients. The Prospective Randomized Study of Mesenchymal Stem Cell Therapy in Patients Undergoing Cardiac Surgery (PROMETHEUS) trial investigated injection of autologous MSCs (20-200 million cells) into akinetic or hypokinetic areas in hearts that were unsuitable for surgical revascularization during coronary artery bypass graft surgery (CABG)[29]. Cardiac MRI analysis demonstrated that MSC injection increased EF by 9.4% as well as increased scar reduction by 48%

and contractile improvement in dysfunctional areas where surgical reperfusion was not performed[29]. Although this study lacked a placebo control group and had a limited patient number (6 patients), it demonstrates the potential benefits of injection of MSCs directly into non-revascularized myocardium. The Cardiopoietic stem Cell therapy in heart failure (C-CURE) trial tested the ability of a "cardiogenic cocktail" to enhance the therapeutic benefits of autologous MSCs[30]. Bartunek *et al*[30] pretreated MSCs with growth factors to enhance their cardioprotective functions. Twenty-one patients with class 2 or 3 heart failure received over 700 million cardiogenic cocktail treated MSCs by electromechanically guided endomyocardial injections. No adverse events or systemic toxicity was observed. Moreover, in LV EF, end-systolic volume and the 6-min walking test were significantly improved. Subsequently, the Safety and Efficacy of Autologous Cardiopoietic Cells for Treatment of Ischemic Heart Failure (CHART-1) trial is currently ongoing. This study is investigating the efficacy and safety of Bone Marrow-derived Mesenchymal Cardiopoietic Cells for the Treatment of Chronic Advanced Ischemic Heart Failure. The safety and efficacy of MSCs and modified MSCs in patients have been confirmed. In the future, randomized controlled trials involving a large population of patients are anticipated.

CDCS IN ISCHEMIC CARDIOMYOPATHY

Smith *et al*[31] expanded in culture tissue from percutaneous myocardial biopsies to form cardiospheres as the basis for cardiac stem cell expansion. They selected floating cardiospheres (out-growing cells) for culture and expanded them in a monolayer to isolate what is termed CDCs. Cardiospheres and CDCs express antigens specific for stem cells (cKit, CD90, CD105 and the absence of CD34 and CD45) as well as proteins vital for cardiac contractile (Nkx2.5, GATA4) and electrical function (Cx43)[32]. This defines cardiospheres and CDCs as a population of cardiac progenitor cells. Cardiospheres are heterogeneous groups of cells that contain not only adult CSCs, which are capable of long-term self-renewal and cardiomyocyte differentiation, but also vascular cells and differentiated progenitor cells[33]. Preclinical investigations were exclusively reported from Marban's group, they demonstrated that administration of CDCs in an experimental acute MI model reduced LV remodeling, improved contractility and reduced the infarct size without improvement in cardiac function[5]. Specifically they show that injection of 10 million of autologous CDCs to a swine model of infarcted myocardium resulted in a significant reduction in infarction size (approximately 5%) compared to a 2.4% reduction in placebo with no change in global function[5]. Malliaras *et al*[34] showed that injection of 12.5 million of allogeneic CDCs significant reduced scar size (3.6%) and preserved EF in a swine model of MI compared to no reduction in scar size (0.4%) and deterioration of EF (approximately 9.9%) in placebo. Lee *et al*[33] compared the effects of CDCs and their precursor cells, cardiospheres, in a swine MI model. They found that the effects on infarct reduction and preservation of EF were similar in both CDCs and cardiospheres whereas there was improved hemodynamics and regional function and preservation of LV chamber remodeling (all quantified by serial cardiac MRI) in animals receiving cardiospheres.

We previously demonstrated that slow infusion of CDCs into the three major coronary arteries (total dose 30 million CDCs) in swine with hibernating myocardium improved regional function in ischemic LAD (wall thickening: 23% to 51%, $P < 0.05$) as well as in the normal right coronary artery (RCA) regions (68% to 107%, $P < 0.05$) and global function (EF: 54% to 71%, $P < 0.05$)[35]. Quantitative histochemical analysis demonstrated that CDCs increased myocyte nuclear density and significantly reduced myocyte cellular hypertrophy in hibernating LAD and normal RCA regions indicating viable myocardium is a main therapeutic target.

The cardiosphere-derived autologous stem cells to reverse ventricular dysfunction (CADUCEUS) involved 25 patients who were given 12.5-25 million autologous CDCs[36] after successful percutaneous coronary intervention. The CDCs were expanded for approximately 36 d in culture from right ventricular endomyocardial biopsies taken 2-4 wk after acute MI. After expansion CDCs were injected into the previously stented coronary artery between 6-12 wk after heart attack. Despite the lack of improvement in left ventricular EF or patient reported outcomes, the scar reduction was 28% and 46% at 6 and 12 mo respectively and regional wall thickening was significantly improved in treated patients by 7.7%[37]. Serious adverse events were also reported to be three times higher in the treated group, however due to the relatively small number of patients enrolled, this trial cannot ascertain to the safety of CDCs. The autologous human cardiac-derived stem cell to treat ischemic cardiomyopathy (ALCADIA) trial investigated CDCs expanded from cardiac (endomyocardial) tissue isolated during CABG. This trial combined the use of stem cells, bioengineered scaffolds and biologics to create a hybrid therapy. CDCs were cultured for 1 mo before intracoronary injection followed by placement of a gelatin sheet containing bFGF over the injection site. Six months after therapy, cardiac MRI indicated a 12.1% increase in EF, a 3.3% reduction in infarct size and a significant improvement in wall motion as well as maximum aerobic exercise capacity. Since this study enrolled only 6 subjects, study is anticipated to enroll larger patients.

The transcoronary Infusion of Cardiac Progenitor Cells in Patients with Single Ventricle Physiology trial involved in 14 patients who had hypoplastic left heart syndrome. Tissue was isolated from the right atrium of patients receiving stage 2 (Glenn) or stage 3 (Fontan) surgeries[38]. Cardiospheres were expanded from this right atrium tissue for 2-3 wk in culture. CDCs (2-3

million autologous cells, n = 7) were injected into the 3 major coronary arteries 1 mo after surgery[38]. At 18 mo post injection, cardiac echo and MRI indicated an increase in right ventricular EF from 46.9% to 54.0% (P = 0.0004) compared to no change in EF (46.7% to 48.7%, P-ns) in control. This was a small study (only 7 patients received CDCs) but indicates that viable and dysfunctional myocardium can be treated with autologous CDCs. Although CDCs are beneficial in patients with heart disease, CDCs have many characteristics that overlap with MSCs[39]. Therefore, it is necessary to identify the similarities and differences in biological responses of both MSCs and CDCs prior to further proceeding with clinical applications.

CSCS IN ISCHEMIC CARDIOMYOPATHY

Several investigators have demonstrated the presence of small clusters of Sca-1+, cKit+ or a side population cells (multipotent stem cells identified by the ability to efflux Hoechst dye) in the cardiac atria and apex[40-42]. These cells were named CSCs and are most abundant during postnatal cardiac development after birth. Progeny of CSCs acquire a cardiomyocyte phenotype therefore resident CSCs are optimal candidates for cardiac regeneration studies. CSCs are self-renewing, can replace senescent and apoptotic CSCs *via* mobilization of BM-derived stem cells, and participate in maintaining the CSC pool in the heart[43-45]. In adulthood, the cells are quiescent and reside within the heart. Following ischemic injury, activation by paracrine signals induces CSCs to divide. Nevertheless, their proliferative potential is limited and the extent of the myocardial injury (*e.g.*, necrosis and fibrosis following MI) is frequently too large to be compensated by new cardiomyocytes formed from dividing resident CSCs[40]. In the normal organism the heart retains a pool of CSCs that regulate cardiac homeostasis by maintaining a low level of myocyte proliferation, regeneration and cell death[2]. It is well known that CSCs are a rare population in the myocardium making their isolation and cultivation difficult and time-consuming. Since these cells are located in the heart and are primed for cardiac repair, protocols to enhance their endogenous activity or expand these cells *in vitro* before re-implanting them in the heart are currently being tested. A limited number of animal studies indicate that the administration of CSCs can slow left ventricular remodeling and cardiac improve function after ischemic injury[40,46,47]. Welt *et al*[48] demonstrated that intramyocardial injection of autologous CSCs in a canine infarct model with permanent LAD occlusion resulted in the preservation of global function (31% to 33%) and reduced LV remodeling compared to functional deterioration (35% to 26%, P < 0.05) and LV remodeling in vehicle animals[48]. Bolli *et al*[49] demonstrated that administration of autologous CSCs to a swine model of chronically infarcted myocardium resulted in improvements in regional and global contractility (45.4% to 51.7%, P < 0.05) as well as engraftment and differentiation of injected CSCs[49].

The stem cell infusion in patients with ischemic cardiomyopathy (SCIPIO) trial isolated autologous CSCs during CABG[50]. SCIPIO involved 23 patients who had experienced MI in the past and exhibited an EF of under 40%. One million of cKit positive and lineage negative CSCs were isolated with magnetic beads from cultures of right atrial appendage tissue and administered *via* intracoronary infusion 1 mo after CABG. Twelve months after the treatment, infarct size was decreased by 30.2%, regional wall thickening was increased by 18% and left ventricular EF was increased by 8.2%. The benefits of treatment continued to increase and left ventricular EF was increased by 12% after 2 years[51]. Although studies have shown the beneficial effects of CSCs on the infarcted myocardium, their biological actions in the heart are still controversial[52]. Further studies are necessary to clarify the significance of CSCs in clinical applications.

FUTURE DIRECTIONS

Based on current achievements in experimental large animal studies and clinical trials of cell-based therapies, it is evident that cell therapies still require significant progress to be registered in the daily practice of modern medical therapies. The following strategies are solutions to overcome current limitation of cell-based therapies.

PRECONDITIONED MSCS

Since the safety and efficacy of MSCs has been demonstrated by clinical work, there has been an increasing interest on enhancing the benefits of MSC therapy. For example, combining MSC and pharmacotherapy[53], genetically modifying MSCs[54-56] and pre-conditioning MSCs[57] are approaches that are being explored to augment MSC-mediated cardiac repair. MSCs transfected to overexpress Akt or cell survival protein promoted myocardial protective function[16,55]. Furthermore, MSCs engineered to express combinations of gene products such as Akt and angiopoietin-1 (Ang1) have also shown functional benefits in experimental animal models[58]. MSCs overexpressing VEGF and SDF-1 improved cardiac function by activating Akt pathway[54]. MSCs transfected to express heme-oxygenase 1 (HO-1), an enzyme that improves MSC tolerance to hypoxia, infused into a cardiac ischemia-reperfusion model improve EF and lower end systolic volume compared to controls[59]. MSCs pretreated with growth factors, bFGF, IGF-1 and bone morphogenetic protein 2 (BMP2), improved myocardial repair in a rat model of MI[60]. Those preconditioned MSCs improved engraftment and survival of transplanted cells. Although data are promising, the safety of these cells must be carefully evaluated before use in humans.

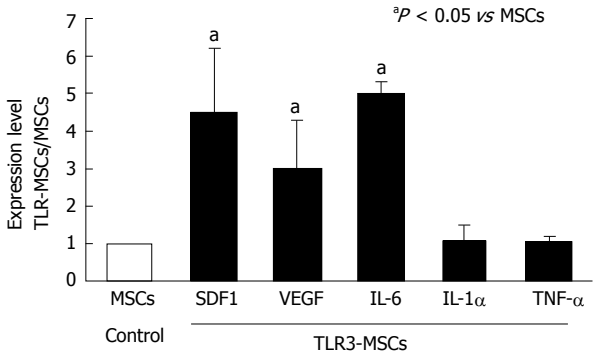

Figure 1 Toll-like receptor 3-mesenchymal stem cells enhance to secrete paracrine factors. RNA mimetic polyinosinic-polycytidylic acid [poly(I:C)] stimulated TLR3 system on MSCs. TLR3-MSCs secreted a variety of paracrine factors. RT-PCR detected significant upregulation of SDF1, VEGF and IL6 while inflammation related cytokines (IL-1α, TNFα) were downregulated. Injection of TLR3-MSCs in cardiomyopathy model improved cardiac function more than standard MSCs in association with increasing myocyte proliferation, reducing fibrosis and myocyte apoptosis. TLR3: Toll-like receptor 3; MSCs: Mesenchymal stem cells; SDF1: Stromal cell-derived factor-1; VEGF: Vascular endothelial growth factor; IL: Interleukin; TNF: Tumor necrosis factor.

PRECONDITIONED MSCS WITHOUT GENETIC MODIFICATION

As mentioned above, the currently used approaches to enhance stem cells are mostly through genetic modification. Thus, modified cells are not considered as a clinically relevant approach because genetically engineered stem cells may have increased unwanted long-term side-effects. We demonstrated that stimulation of toll-like receptor 3 (TLR3) produced many trophic factors without induction of inflammatory-related cytokines[26]. Poly (I:C) is structurally similar to double-stranded RNA and is known to interact with TLR3, which is expressed on the membrane of B-cells, macrophages, dendritic cells, MSCs and CDCs. Poly (I:C) directly reacts with the TLR3 receptor on the surface of MSCs/CDCs. Thus, after washing and collecting MSCs/CDCs after stimulation, poly (I:C) does not reside within the cells and does not affect the heart environment after injection of cells. Interaction of Poly (I:C) with TLR3 on MSCs causes secretion of the growth factors VEGF and the cytokine IL-6 without up-regulation of the inflammatory cytokines IL-1 and TNFα (Figure 1). Injection of TLR3 activated MSCs (TLR3-MSCs) in a non-ischemic cardiomyopathy model improved cardiac function more than standard MSCs in association with increasing myocyte proliferation, reducing fibrosis and myocyte apoptosis[61]. Activation of TLR3 on CDCs (TLR3-CDCs) stimulated the secretion of HGF, IGF1 and IL-6 without up-regulation of inflammatory cytokines. TLR3-MSCs or TLR3-CDCs are safe and feasible to use in the human heart. Further investigation is necessary to confirm the safety and feasibility to use in the heart.

MSCS AND CSCS

Combining MSC and CSC in post-MI treatment may further enhance the therapeutic effects of each cell type. Recent work by Williams *et al*[62] demonstrated that the combined use of 1 million human CSCs with 200 million human MSCs provided greater recovery, almost to baseline, in a swine model of anterior wall MI[62]. While all stem cell treated animals demonstrated improved LV EF compared to placebo controls, notably, animals receiving dual cell therapy had a 2-fold greater reduction in scar size (21.1% for CSC/MSC *vs* 10.4% for CSC alone or 9.9% for MSC alone) and had improved rates of pressure change during diastole. Overall left ventricular chamber dynamics were improved in both the dual therapy and CSC or MSC alone treated groups. Interestingly, CSC alone treated animals demonstrated better isovolumic relaxation as compared to controls, while MSC alone treated animals exhibited improved diastolic compliance, indicating that the enhanced effect of dual therapy on both systolic and diastolic function may be due to a synergistic effect between CSC and MSC targeted mechanisms.

REGIONAL INFUSION WITH STOP-FLOW *VS* GLOBAL INFUSION WITH SLOW INFUSION

Clinically applied techniques for cell delivery include endomyocardial injection using an injection needle or infusion of cells into a coronary artery supplying the infarcted region using a stop coronary flow technique. Although both approaches elicit significant improvements in cardiac function, they increase the risk of endomyocardial hemorrhage and MIs caused by stem cells plugs in the capillaries which could potentially limit the beneficial effects of cell-therapy. We previously demonstrated that slow infusion of MSCs into the three major coronary arteries without stop flow technique (global infusion) did not cause microembolization and stimulated prominent cardiac regeneration in ischemic as well as normally perfused RCA regions in swine with hibernating myocardium[17]. Likewise, intracoronary injection of autologous CDCs[35] without a stop-flow technique in swine with hibernating myocardium stimulated myocyte proliferation and regeneration in an ischemic LAD region as well as the normally perfused RCA regions. Subsequently, we applied the global infusion approach in an acute MI model, CDC infusion significantly improved cardiac function despite no changes in the size of infarction area. These results indicates that scar reduction and functional improvement are independent phenomenon[63]. Accordingly, the approach of stem cell injection in the entire heart is safe and feasible to improve LV dysfunction and our results indicate that normally perfused and viable myocardium could be the target for regenerative therapy. Alternatively, combining stop-flow infusion in the infarcted area with slow flow infusion into the viable myocardium may be a method to enhance therapeutic efficacy.

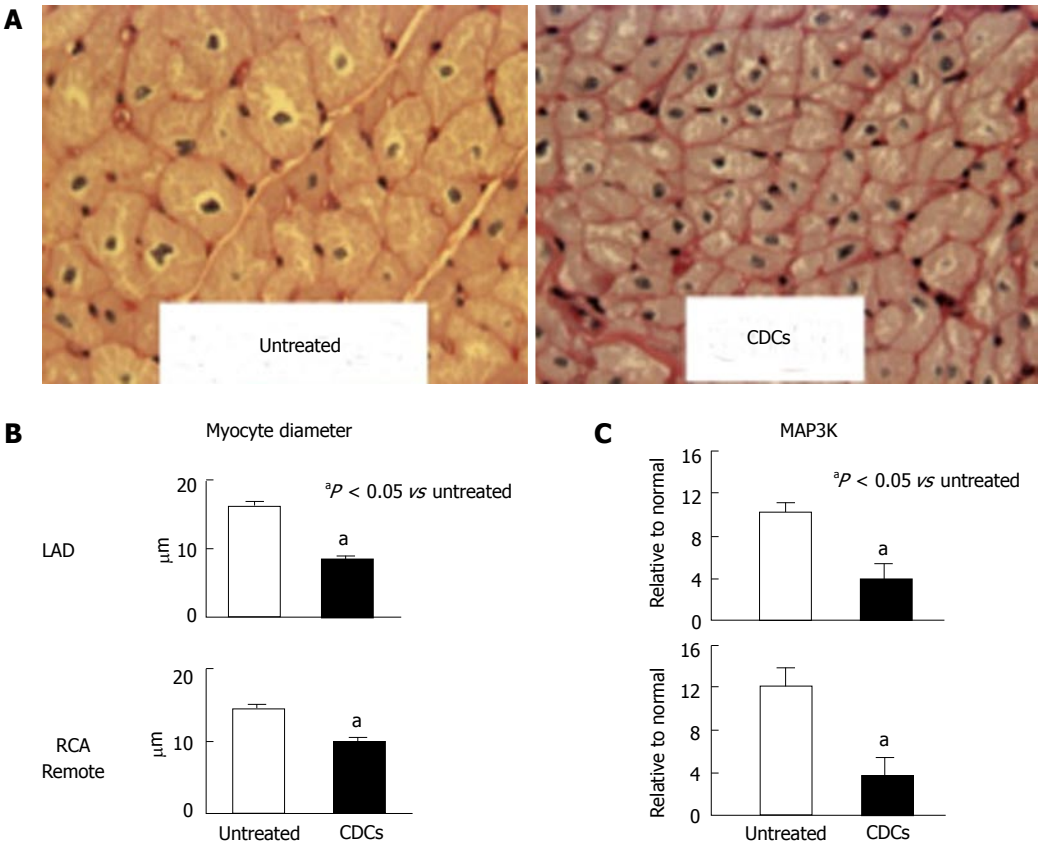

Figure 2 The effect of cardiosphere-derived cells on myocyte cell size and MAP kinase in the dysfunctional left anterior descending *vs* remote regions. A: Images (PAS staining) demonstrate that hypertrophied myocytes in untreated hibernating LAD became smaller after CDCs. Myofibrils were condensed indicating the production of healthy myocytes; B: Myocyte diameter was significantly reduced in hibernating LAD and remote regions; C: Corresponding to the morphological change, protein level of MAP3K was downregulated in LAD and remote regions. Data indicates CDCs induced myocyte regeneration and hypertrophy regression. CDCs: Cardiosphere-derived cells; LAD: Left anterior descending; RCA: Right coronary artery.

ALLOGENEIC CDCS INFUSION IMMEDIATE AFTER REPERFUSION

Allogeneic CDCs can escape direct recognition of helper T cells due to the lack of expression of MHC class Ⅱ antigen (SLA class Ⅱ on pig)[34,64] and therefore are immunoprivileged. Based on these observations, a recent clinical trial was initiated using allogeneic human CDC treatment in patients with chronic myocardial infarction (ALLSTAR trial). These allogeneic cells can be expanded *ex vivo* and stored for use at a future time[18]. This "off-the-shelf" treatment for patients with AMI immediately after revascularization is unique in that *ex vivo* expanded cells are available immediately for treatment and the patient does not need to wait for cell processing and expansion[19]. Recently, administration of CDCs immediately after reperfusion demonstrated the protective effects in swine with acute myocardial infarction[65]. Thirty minutes after ischemia-reperfusion, CDCs were injected into the infarct-related coronary artery and reduced the size of the infarct area and myocyte apoptosis in the border region. Although data were collected 48 h post CDCs injection, we recently demonstrated that functional improvement and myocyte regeneration were maintained up to 1-mo follow-up. These data indicate that the cardioprotective effects at early times were maintained. Previously bone marrow cell and endothelial progenitor cells injection in patients were performed within 7 d after AMI and demonstrated superiority to cell injection within 24 h[66,67]. Since stem cell homing factors (mobilization, migration and adhesion) are maximized between day 3 and day 7[68], these therapies are effective for stem cell homing. However, the inflammation caused by MI is already developed and the potential cardioprotective effects (*i.e.*, *via* anti-apoptotic effects or modulation of the inflammatory response) are limited when cells are delivered. Since CDCs secrete multiple cytokines (SDF-1, Akt)[69], growth factors (HGF, IGF-1, VEGF)[69,70] and exosomes[71,72], CDCs early after reperfusion might reduce the inflammatory response and protect the heart from functional deterioration due to reperfusion injury.

REPEATED INJECTION OF STEM CELLS

Since single injection of CDCs improved regional function and reduced scar volume[36,37], repeated injection of stem cells has been considered a more effective approach to regenerate myocardial tissue[73,74]. However, the initial infusion of cells activates and enhances the immune response[34,64] and the subsequent injected cells are quickly eliminated and ineffective. This quick

reaction is mainly associated with acquired/adaptive rather than innate immunity. Repeated infusion of autologous/allogeneic CDCs may overcome the limited functional recovery from a single injection[73,74]. However, the extent of immune activation caused by repeated injections is unclear and optimal immunosuppressive therapy is still undetermined. Development of efficacious CDC platforms administered with optimal immune suppression would circumvent barriers related to multiple injections of stem cells and allow the widespread application of "off-the-shelf" cell therapy to treat the large number of patients in need[64,75,76].

EXOSOME ACTIVATION AND MICRORNAS

The beneficial effects of adult stem cells are mainly associated with the secretion of paracrine factors rather than direct differentiation of *de novo* cardiac cells[9]. They secrete multiple growth factors and cytokines which reduce scar volume and myocyte apoptosis, increase myocyte proliferation and activate endogenous CSCs to produce new myocytes. Recently, it was reported that CDCs secrete exosomes and they play important roles for cardiac regeneration[71]. Exosomes transfer microRNAs from cell to cell and they inhibit inflammation and apoptosis and increase angiogenesis and myocyte proliferation. Therefore, a new method of treatment may focus on how to effectively stimulate secretion of exosomes from stem cells or may be directly injecting exosomes in the infarcted myocardium.

ANTI-HYPERTROPHIC EFFECT

Besides their regeneration potential, adult stem cells have other beneficial effects such as anti-apoptosis, anti-inflammation, extracellular matrix reduction, contractile alternation and anti-hypertrophy. Pathological cardiac hypertrophy in post MI remodeling is a major cause of mortality and morbidity including the risk of sudden cardiac death and heart failure in patients[77-81]. It is associated with increased interstitial fibrosis, cell death and cardiac dysfunction. LV assist devices used in heart failure patients as a bridge to heart transplantation not only improved peripheral circulation but also reversed the geometric remodeling of the heart and restored the function of the heart[82-85].

We demonstrated that global infusion of CDCs into hearts with chronically ischemic myocardium's improved myocardial function in the ischemic and remote regions[86]. CDCs significantly increased newly formed small myocytes. Interestingly, CDCs also reduced the cell size of pre-existing myocytes and hypertrophic signaling (mitogen activated kinases) in the ischemic and remote regions. Data indicate that CDCs have the potential to reverse cardiac hypertrophy (Figure 2). Future studies are necessary to determine whether hypertrophy regression is primary or secondary to myocardial regeneration and functional improvement.

CONCLUSION

Promising data derived from experimental models indicate the potential success of using cell based therapy in clinical applications. To overcome the current limitations in the field, development of new methods to enhance cardiac repair is necessary. In light of their proven safety profiles, MSC, CDC and CSC are prime candidates for cell based therapies. Recently, it was reported that a combination of CSCs and MSCs may be more effective than either one alone, and this approach is under investigation. Similarly, pre-conditioning MSC and CDCs are also promising approaches, and further investigation is anticipated. Optimizing the dose and method of delivery, as well as the timing for delivery are important variables that should be studied. It is anticipated that cell based therapies will become a mainstream treatment for heart diseases due to their potential ability to improve functional outcomes and decrease mortality.

Abstract

The endothelium exerts multiple actions involving regulation of vascular permeability and tone, coagulation and fibrinolysis, inflammatory and immunological reactions and cell growth. Alterations of one or more such actions may cause vascular endothelial dysfunction. Different risk factors such as hypercholesterolemia, homocystinemia, hyperglycemia, hypertension, smoking, inflammation, and aging contribute to the development of endothelial dysfunction. Mechanisms underlying endothelial dysfunction are multiple, including impaired endothelium-derived vasodilators, enhanced endothelium-derived vasoconstrictors, over production of reactive oxygen species and reactive nitrogen species, activation of inflammatory and immune reactions, and imbalance of coagulation and fibrinolysis. Endothelial dysfunction occurs in many cardiovascular diseases, which involves different mechanisms, depending on specific risk factors affecting the disease. Among these mechanisms, a reduction in nitric oxide (NO) bioavailability plays a central role in the development of endothelial dysfunction because NO exerts diverse physiological actions, including vasodilation, anti-inflammation, antiplatelet, antiproliferation and antimigration. Experimental and clinical studies have demonstrated that a variety of currently used or investigational drugs, such as angiotensin-converting enzyme inhibitors, angiotensin AT1 receptors blockers, angiotensin-(1-7), antioxidants, beta-blockers, calcium channel blockers, endothelial NO synthase enhancers, phosphodiesterase 5 inhibitors, sphingosine-1-phosphate and statins, exert endothelial protective effects. Due to the difference in mechanisms of action, these drugs need to be used according to specific mechanisms underlying endothelial dysfunction of the disease.

Key words: Endothelial dysfunction; Endothelium-dependent vasodilation; Endothelial nitric oxide synthase; Inflammation; Nitric oxide; Pharmacological treatment; Reactive nitrogen species; Reactive oxygen species; Risk factors

Core tip: The endothelium is involved in the regulation of vascular tone and permeability, coagulation and fibrinolysis, inflammatory and immunological reactions

and cell growth. Cardiovascular risk factors cause vascular endothelial dysfunction through impairing endothelium-derived vasodilators, enhancing endothelium-derived vasoconstrictors, producing reactive oxygen species and reactive nitrogen species, activating inflammatory and immune reactions and promoting thrombosis. Among these mechanisms, a reduction in nitric oxide bioavailability plays a central role in the development and progression of endothelial dysfunction. A variety of currently used or investigational drugs exert endothelial protective effects according to specific mechanisms underlying endothelial dysfunction of the disease.

INTRODUCTION

The endothelium is formed by a monolayer of endothelial cells. It constitutes a physical barrier between blood and tissues and regulates the exchange of molecules between blood and tissues. In addition, endothelial cells metabolize, synthesize and release a variety of substances, including vasoactive substances regulating vascular tone, blood pressure and local blood flow, the substances participating in coagulation, fibrinolysis and inflammatory and immunological reactions, reactive oxygen species (ROS) and reactive nitrogen species (RNS) involved in oxidation and nitrosylation of proteins and lipids, and growth factors promoting cell growth (Table 1). Any perturbation affecting the capacity and equilibrium of the endothelium as a physical barrier and to metabolize, synthesize and release these substances will cause endothelial dysfunction, which contributes to the development and progression of cardiovascular diseases. After summarizing the role of a number of endothelium-derived vasoactive substances and risk factors of endothelial dysfunction, this review focus on several categories of pharmacological substances that may be used for improving endothelial function.

Table 1 Some of endothelium-derived substances

Vasoactive substances
Endothelium-derived vasodilators
Adrenomedullin
Endothelium-derived hyperpolarizing factors
Kinins
Nitric oxide
Prostacyclin
Endothelium-derived vasoconstrictors
Angiotensin II
Endothelin-1
Vasoconstrictor prostanoids
Coagulation and fibrinolysis
Coagulation
Factor V
Heparan sulfate
Protein C
Protein S
Thrombomodulin
Tissue factor
von Willebrand factor
Fibrinolysis
Plasminogen activator inhibitor
Tissue plasminogen activator
Urokinase
Growth factors
Basic fibroblast growth factor
Insulin-like growth factor
Platelet-derived growth factor
Transforming growth factor
Inflammatory and immunological mediators
Cytokines
Interleukins
Monocyte chemoattractant protein 1
Transforming growth factor
Tumor necrosis factor-α
Adhesion molecules
Intercellular adhesion molecules
Platelet-endothelial cell adhesion molecules
Selectins
Vascular cell adhesion molecules
Reactive oxygen species and reactive nitrogen species
Reactive oxygen species
Hydrogen peroxide (H_2O_2)
Hydroperoxyl (HO_2)
Superoxide (O_2^-)
Reactive nitrogen species
Nitrite (NO_2^-)
Nitrogen dioxide (NO_2)
Peroxynitrite ($ONOO^-$)
Nitryl chloride (NO_2Cl)

ENDOTHELIUM-DERIVED VASOACTIVE SUBSTANCES

The endothelium releases a variety of vasoactive substances, including different vasodilators such as nitric oxide (NO), prostacyclin, kinins, and endothelium-derived hyperpolarizing factors (EDHF), vasoconstrictors such as endothelin-1 and PGH_2, and ROS. Among endothelium-derived vasodilators, NO occupies a central position because changes in the release of endothelial NO play a crucial role in the perturbation of vascular homeostasis and in the development of endothelial dysfunction associated with various cardiovascular disorders.

NO

NO is synthesized from the amino acid L-arginine by a family of enzymes, the NO synthase (NOS), through the L-arginine-NO pathway. Three isoforms of NOS have been identified. Neuronal NOS (nNOS), initially found in the nervous system, is also constitutively expressed in skeletal and cardiac muscles, vessels and many other tissues. Endothelial NOS (eNOS) is constitutively expressed mainly in endothelial cells, whereas the expression of inducible NOS (iNOS) can

be stimulated by diverse factors such as cytokines and endotoxin in different circumstances. The endothelium-derived NO release is primarily ensured by eNOS and complemented by nNOS expressed in vascular endothelial cells. Therefore, eNOS is primordial in the regulation of NO production by endothelial cells. The activity of eNOS depends on several factors, including eNOS mRNA and protein expression, the abundance of asymmetric dimethylarginine (ADMA, an endogenous eNOS inhibitor that competes with L-arginine for binding to eNOS)[1,2], the quantity and quality of cofactors such as tetrahydrobiopterin (BH4) and NADPH that are necessary for eNOS catalyzing NO production from L-arginine[3,4], its interaction with caveolin and heat shock protein 90 (hsp90)[5,6], and its translational modifications such as phosphorylation at different sites by multiple kinases or phosphatases [for example, phosphorylation at ser-1179 by phosphotidylinositol-3-kinase (PI3K)/protein kinase B (Akt) activates eNOS to initiate NO synthesis][7,8] and S-nitrosylation at cysteine residues[9]. In addition, excessive superoxide (O_2^-) and hydrogen peroxide (H_2O_2) production due to increased NAD(P)H oxidase[10,11] and eNOS uncoupling induced by changes in oxidized low density lipoprotein (OxLDL), caveolin-1, BH4, a switch from S-nitrosylation to S-glutathionylation and oxidation of the zinc-thiolate complex by peroxynitrite ($ONOO^-$) also affects effective eNOS activity[12-15].

NO released by eNOS participates in the regulation of vascular tone. NO activates soluble guanylate cyclase by binding to its ferrous heme, leading to the conversion of guanosine triphosphate (GTP) into cyclic guanosine monophosphate (cGMP) that causes vascular smooth muscle relaxation. Moreover, NO exerts antiinflammatory, antiplatelet, antiproliferative and antimigration actions that contribute to the maintenance of an adequate environment for the endothelium. Lacking eNOS gene in mice induces insulin resistance, hyperlipidemia and hypertension[16]. NO released by nNOS also participates in the regulation of vascular tone, especially for the regulation of vascular tone in skeletal muscles. Altered nNOS activity and protein levels contribute to muscular damage due to sustained vasoconstriction in patients with Duchenne muscular dystrophy[17,18] and endothelial dysfunction in dogs with Duchenne muscular dystrophy[19].

Prostacyclin

Prostacyclin (also called PGI2) is generated from arachidonic acid by cyclooxygenase (COX) in endothelial cells. Activation of IP receptors by PGI2 activates adenylate cyclase to synthesize cyclic adenosine monophosphate (cAMP) from adenosine triphosphate, causing vascular smooth muscle relaxation. However, PGI2 synthesis can be inactivated by increased cytokines[20] and under certain conditions, PGI2 exerts vasoconstrictor action and contributes to endothelial dysfunction[21].

EDHF

The term "EDHF" describes a set of substances causing vascular myocyte hyperpolarization and spreading endothelial hyperpolarization to vascular myocytes, resulting in vascular myocyte relaxation, which is not affected by blocking NO or prostacyclin production[22]. Interestingly, in eNOS/COX-1 double-knockout mice, EDHF-mediated vasodilation plays a compensatory role for the absence of endothelial NO[23]. EDHF hyperpolarize myocyte membranes by opening calcium-activated potassium channels named as BKca, IKca, and SKca according to their conductance (big, intermediate, and small conductance), leading to K^+ efflux[24-26]. EDHF-mediated vasodilation also involves epoxyeicosatrienoic acids (EETs), gap junction, reactive oxygen species and hydrogen peroxide, depending on the vascular beds and vessel types[24,25,27]. Cytochrome P450 epoxygenase catalyzes the production of EETs from arachidonic acid in different vessels and EETs participate in, at least partly, the hyperpolarization and relaxation of myocytes in these vessels[28,29]. It is worth noting that EDHF-mediated vasodilation is a complex phenomenon, which involves multiple signaling pathways that may be not exclusive in response to different stimuli[24-26]. Altered EDHF signalings may account for endothelial dysfunction in some cardiovascular disorders as suggested by studies in animals. For example, a defect in connexins that compose gap junctions is partly responsible for impaired vasodilator responses in hypertensive rats[30] and in diabetic rats[31]. However, the role of EDHF in endothelial dysfunction in human cardiovascular diseases remains elusive. This may be related to the difficulty that the function of EDHF can only be deciphered after impairment of NO and prostacyclin-mediated responses.

Kinins

Kinins such as bradykinin can be generated in vessel walls, especially in endothelial cells that contain the components such as kinin precursors and kinin-generating enzymes, necessary for the production of kinins[32]. The biological effects of kinins are mediated by stimulation of constitutively expressed B2 receptors and inducible B1 receptors. In endothelial cells, activation of B2 receptors by bradykinin releases NO, prostacyclin, EDHF and tissue plasminogen activator, which exert diverse physiological and pathological actions on cardiovascular system, including regulation of coronary vascular tone and local blood flow of organs, coagulation, fibrinolysis, and water-electrolyte while[33,34]. Stimulation of B1 receptors by its agonists also induce NO-mediated vasodilation[35]. Due to very short half-life in the blood, bradykinin essentially plays an autocrine/paracrine role. Experimental studies have demonstrated a protective role of bradykinin B2 receptors on cardiovascular function. It is, at least in part, due to opposing effects of bradykinin B2 receptor activation on angiotensin Ⅱ AT1 receptor activation because of multiple cross-talks between the kallikrein-kinin system and the renin-

angiotensin system[36]. This explains the contribution of kinins to the cardiovascular protective effects of angiotensin-converting (ACE) inhibitors and angiotensin AT1 receptor blockers. Deletion of both B1 and B2 receptors in diabetic mice exacerbates nephropathy as indicated by increased oxidative stress, mitochondrial DNA deletions and renal expression of fibrogenic genes, suggesting a protective role of the kallikrein-kinin system on diabetic nephropathy[37]. However, these mice exhibit neither accelerated cardiac dysfunction nor ROS production, challenging the protective role of kinins in this setting[38]. Otherwise, kinins can increase endothelial permeability[39] and are involved in inflammatory responses by activating phospholipase A2 to release arachidonic acid that is used for the production of vasoconstrictor prostanoids, which may be harmful for endothelial function.

Adrenomedullin

Adrenomedullin (AM), a vasodilator peptide initially identified from human pheochromocytoma, can be secreted by vascular cells, especially by endothelial cells[40-42]. AM exerts its action in the cardiovascular system through receptor complexes composed of the calcitonin receptor-like receptor and receptor activity-modifying proteins. In vessels, the receptors for AM are expressed in both endothelial and smooth muscle cells[43,44]. AM-induces endothelium-dependent and -independent vasodilation, depending upon species and vascular beds[42]. AM-induced endothelium-dependent vasodilation is mediated by PI3K/Art/NO/cGMP pathway, the activation of cGMP-stimulated protein kinase G and/or the production of a vasodilator prostanoid (likely prostacyclin)[42,45,46], whereas AM-induced endothelium-independent vasodilation involves the opening of K^+ channels (calcium-activated K^+ channels or ATP sensitive K^+ channels, probably depending upon vascular beds) and the activation of cAMP-dependent protein kinase A[42,47]. In addition to vasodilator effect, AM was shown to inhibit angiotensin II-induced ROS generation by NAPDH[48], and AM -deficient mice developed insulin resistance due to increased ROS[49]. AM protects bone marrow-derived mononuclear cell and endothelial progenitor cells from apoptosis and exerts a vascular protective role[50,51]. AM also exerts an protective effect on endothelial barrier function and reduces endothelial permeability in response to inflammation and endotoxin[52-56]. Otherwise, AM posses angiogenesis property and participates in vascular remodeling [50,57,58]. Plasma AM levels were shown to be higher in many pathological situations such as arteriosclerosis, sepsis, essential or pulmonary hypertension and heart failure[52,59-63], whereas intracoronary AM levels were lower in patients with stable coronary disease[64] and in infants with brain damage after surgery under cardiopulmonary bypass[65]. Increased AM levels were interpreted as a compensatory mechanism to protect cardiac and vascular function[61,66]. Expression of receptors for AM was shown to be increased in rats with heart failure though its signification remains elusive[67,68]. Despite its protective role in the cardiovascular system, AM was shown to be involved in the growth of different tumors such as prostate, colorectal and bladder tumors, and AM and its receptors are potential targets for the treatment of these tumors[69-71].

Angiotensin Ⅱ

Endothelial cells express ACE and angiotensin AT1 and AT2 receptors. Once released, angiotensin Ⅱ immediately binds to these receptors and those expressed on smooth muscle cells. Although angiotensin Ⅱ causes both vasoconstriction *via* AT1 receptors and vasorelaxation by stimulating AT2 receptors, angiotensin Ⅱ-induced vasoconstriction is predominant in many circumstances. Moreover, angiotensin Ⅱ exerts multiple actions affecting endothelial function. Angiotensin Ⅱ upregulates endothelial receptors for OxLDL, stimulates OxLDL uptake, and enhances OxLDL-mediated ROS generation and endothelial cell apoptosis[72]. Angiotensin II increases receptors for vascular endothelial growth factors and matrix metalloproteinases (MMPs), which may account for increases in endothelial permeability and vascular remodeling[73-75]. Angiotensin Ⅱ increases the expression of plasminogen activator inhibitor type 1 (a natural inhibitor of tissue-type plasminogen activator and urokinase-type plasminogen activator) in endothelial cells[76], thereby favoring thrombosis. Angiotensin II favors inflammation by inducing COX-2 expression[74] and increasing cytokine tumor necrosis factor-alpha (TNF-α)[75]. Although angiotensin Ⅱ can upregulate eNOS and inducible NO synthase (iNOS) expression, it reduces eNOS-derived NO by promoting eNOS uncoupling through monocyte-dependent S-glutathionylation[77]. In addition, the activation of AT2 receptors also contributes to the angiotensin Ⅱ-induced vascular remodeling[78]. These actions of angiotensin Ⅱ may contribute to endothelial dysfunction as the renin-angiotensin system is activated, as is the case in atherosclerosis[79] and heart failure.

Endothelin-1

Although endothelin-1 can upregulate eNOS expression by enhancing eNOS mRNA stability *via* protein tyrosine kinases and protein kinase C-dependent pathways[80,81], endothelin-1 *via* type A endothelin receptors induces expression of adhesion molecules and neutrophil adhesion to endothelial cells, and promotes cytokine and ROS generation[82-84]. Elevated endothelin-1 blood levels can be seen in atherosclerosis[85], pulmonary hypertension[86] and heart failure[87,88], which may account for the development of endothelial dysfunction under these circumstances. Although the activation of Type B endothelin receptors generally induces vasodilation, these receptors appear to mediate endothelin-1-induced ROS production and contribute to endothelial dysfunction in obese rats[82].

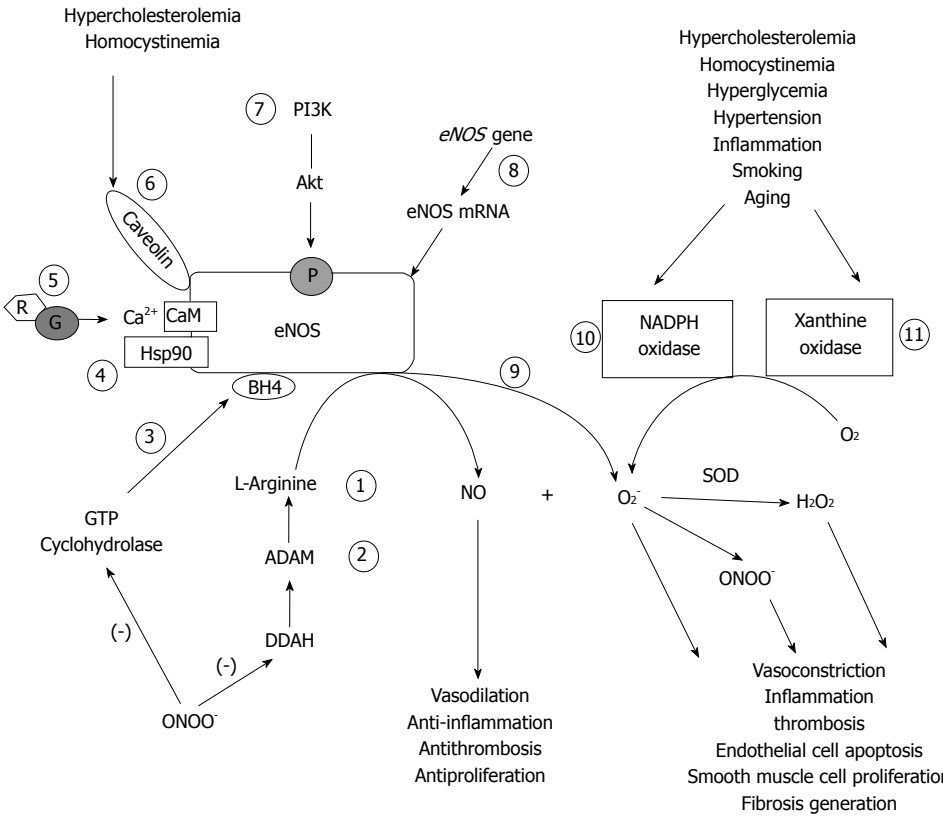

Figure 1 Mechanisms underlying the reduction in nitric oxide bioavailability involve both reduced nitric oxide production and increased nitric oxide scavenging. A reduction in NO production can be resulted from: (1) decreased L-arginine availability due to L-arginine deficiency and/or changes in L-arginine transporter; (2) accumulation of asymmetric dimethylarginine (ADMA), an endogenous inhibitor of endothelial NO synthase (eNOS); (3) deficiency or modification of cofactor tetrahydrobiopterin (BH4); (4) altered interactions between eNOS and caveolin due to increased caveolin-1; (5) changes in receptor-coupled G proteins; (6) altered eNOS-heat shock protein 90 (Hsp90) interaction due to changes in Hsp90 abundance; (7) changes in calcium-independent phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt)-mediated eNOS activation by tyrosine or serine phosphorylation; and (8) decreased eNOS expression due to reduced *eNOS* gene transcription and/or decreased eNOS mRNA stability. Increased NO scavenging by reactive oxygen species (ROS) and reactive nitrogen species (RNS) can be due to: (9) eNOS uncoupling related to changes in BH4, cavelin-1 and oxidized low density lipoproteins; (10) increased NADPH (reduced form of nicotinamide adenine dinucleotide phosphate) expression and activity; and (11) increased xanthine oxidase expression and activity. CaM: Calmodulin; DDAH: Dimethylarginine dimethylaminohydrolase; SOD: Superoxide dismutase; NO: Nitric oxide.

Vasoconstrictor prostanoids

Endothelial cells can produce vasoconstrictor prostaglandin H2 (PGH2), thromboxane A2 (TXA2) and PGF2α. The production of these prostanoids is enhanced in hypertension, hypercholesterolemia, diabetes and vitamin E deficiency[89], which in turn upregulates NAPDH oxidase and type 4 and type 5 phosphodiesterases (PDE4 and PDE5)[90,91], resulting in increases in ROS production, cAMP and cGMP degradation, and vasoconstriction. TXA2 is also a potent activator of platelets, while activated platelets in turn release a large amount of TXA2 to promote thrombosis. Furthermore, TXA2 interacts with EDHF by inhibiting potassium channels, EETs and gap junction-mediated signaling pathways[27], which could account for the development of endothelial dysfunction.

RISK FACTORS CAUSING ENDOTHELIAL DYSFUNCTION

Clinically, endothelial dysfunction is characterized by impaired endothelium-dependent vasorelaxation in response to endothelium-dependent agonists such as acetylcholine and bradykinin, or to maneuvers that increase shear stress such as flow-mediated dilatation. Although mechanisms leading to endothelial dysfunction are multiple, a reduction in NO bioavailability is largely observed in many cardiovascular disorders. As shown in Figure 1, reduced NO bioavailability can be the consequence of decreased L-arginine availability[92], increased ADMA[1,2], altered interaction with hsp90[93] and phosphorylation of eNOS[94], as well as increased NO scavenging by excessive ROS generated by NADPH and xanthine oxidases[10,11,95] and eNOS uncoupling. It is worth noting that changes in caveolin-1[96], BH4[97], S-glutathionylation of eNOS[15,98] and OxLDL[12] are all involved in eNOS uncoupling. Importantly, a reduction in eNOS protein expression also leads to impaired eNOS activity and NO production, which can be observed in different cardiovascular diseases such as atherosclerosis, acute myocardial infarction and heart failure in animals and in humans[99-103]. However, mechanisms underlying endothelial dysfunction in different cardiovascular

disorders may be different, depending on risk factors contributing to the development of specific disease.

Hypercholesterolemia/atherosclerosis

Atherosclerosis is a chronic arterial disease involving the formation of multiple atheromatous plaques within arteries by accumulation of lipids due to the inability to remove LDL from macrophages. In this process, endothelial dysfunction related to hypercholesterolemia plays a pivotal role in the development of atherosclerosis. Hypercholesterolemia induces endothelial cell activation, leukocyte recruitment and adherence, platelet activation and adhesion within the vasculature, reflecting an inflammatory response and high thrombotic state that may cause endothelial dysfunction. Hypercholesterolemia increases superoxide and hydrogen peroxide production by increasing NAD(P)H oxidases[79], xanthine oxidase[95], and myeloperoxidase[104]. Increased superoxide reacts with NO, resulting in the formation of RNS and reduced eNOS-derived NO bioavailability. ROS induce oxidation of lipids, proteins and DNA, which cause cell damage, necrosis and cell apoptosis. Increased RNS induce nitrosylation reactions that modify the structure and function of proteins. Hypercholesterolemia increases caveolin-1 levels[105], also contributing to impaired eNOS activity. In addition, hypercholesterolemia disturbs reactions between oxygen radicals or enzymatic oxidation and lipoproteins, particularly LDL phospholipids and results in the production of oxidized phospholipids. These phospholipids contain arachidonic acid and bind to their membrane receptors, resulting in their accumulation within the cellular membrane, immune and inflammatory responses and ROS generation, which in turn induces eNOS uncoupling that impairs endothelium-dependent vasodilation induced by endogenous vasodilator such as kinins but enhances the role of endogenous vasoconstrictors such as angiotensin Ⅱ and endothelin-1, and promote endothelial dysfunction[106,107]. Therefore, endogenous vasoactive substances such as NO, prostanoids, ROS, RNS, AM, angiotensin Ⅱ, endothelin-1 and other substances interact and reduced NO bioavailability due to eNOS uncoupling is a key event contributing to the development of endothelial dysfunction and ultimately atherosclerosis.

Hyperhomocysteinemia

Homocysteine is a non-protein α-amino acid synthesized from methionine. Hyperhomocysteinemia is observed in patients with coronary disease and is correlated with endothelial dysfunction[108]. Homocysteine causes endothelial dysfunction through NO inhibition, vasoconstrictor prostanoid production, EDHF inhibition[109,110], angiotensin AT1 receptor activation, and ROS generation[111]. Homocysteine reduces eNOS activity by increasing asymmetric dimethylarginine production[112] and eNOS uncoupling *via* decreasing intracellular do novel synthesis of BH4[97], leading to decreased NO bioavailability and increased ROS generation. Furthermore, homocysteine downregulates eNOS expression in human endothelial cells[113], and induces endothelial loss, vascular deendothelialization and increases platelet adherence and consumption in baboons[114]. Homocysteine also increases ROS generation by phosphorylating NAPDH oxidase[115], and/or by increasing ACE activity *via* ACE homocysteinylation to generate angiotensin Ⅱ that activates NAPDH oxidase[116].

Hyperglycemia/diabetes mellitus

Endothelial dysfunction is associated with both insulin-dependent and independent diabetes mellitus. In this setting, hyperglycemia increases ROS generation through activating protein kinase C-mediated NAD(P)H oxidases[117] and peroxynitrite-mediated eNOS uncoupling[118], which also leads to reduced NO bioavailability. In addition, hyperglycemia increases iNOS expression and iNOS-derived NO and peroxynitrite production, leading to increased ROS and RNS levels and pancreatic islet endothelial cell apoptosis[119]. Moreover, hyperglycemia promotes platelet aggregation by increasing expression and circulating levels of endothelial adhesion molecules through protein kinase C-NFκB signaling pathway[120-122], and increases endothelial apoptosis[123]. All of these effects of hyperglycemia contribute to endothelial dysfunction observed in diabetes mellitus. Otherwise, increased release of vasoconstrictors such as prostanoids and endothelin-1 through protein kinase C-mediated pathway in response to hyperinsulinemia and hyperglycemia appears to precede changes in vascular complication or NO production[124,125]. Changes in EDHF also contribute to endothelial dysfunction, especially in type 2 diabetes as suggested in rat models in which an impaired EDHF-mediated vasorelaxation was observed before marked alteration in NO-mediated responses[126-129]. Therefore, altered NO bioavailability in type 2 diabetes appears to be a relatively late event worsening endothelial dysfunction.

Hypertension

An impaired endothelium-dependent vasorelaxation has been observed in patients with essential hypertension[130] and in several animal models of hypertension. This is related to a lower production of endothelium-derived vasodilators and/or over production of vasoconstrictors. An increased endothelin-1 production also plays a role in endothelial function, especially in pulmonary hypertension as lung is an important metabolic organ of circulating peptides such as adrenomodullin and endothelin-1. In this regard, pulmonary endothelin-1 extraction affects the incremental resistance of pulmonary vascular bed in response to increased cardiac work[131] and plasma endothelin-1 levels are closely related to clinical worsening of patients with pulmonary hypertension[132]. An impaired NO and EDHF-mediated vasorelaxation linked to an increased ADMA that inhibit eNOS and downregulates SKca in

endothelial cells has been reported in hypertensive patients and in spontaneous hypertensive rats[133]. Interestingly, alterations in EDHF appears to occur before alterations in NO pathways in different rat models of hypertension[134]. An reduced vasodilator response to AM has been observed in hypertensive patients[45]. However, an increased eNOS expression is generally observed in animal models of hypertension associated with angiotensin Ⅱ. In this case, angiotensin Ⅱ-induced oxidative stress and increases in the production of vasoconstrictor prostanoids and cytokines may account for the development of endothelial dysfunction. Furthermore, a reduced NO bioavailability has been reported in some models of hypertension. This appears to be linked to reduced substrate availability due to L-arginine deficiency and changed L-arginine transport[92] and to eNOS uncoupling due to oxidation of BH4 and/or S-glutathionylation, leading to increased ROS production[4,15]. Thus, although altered NO bioavailability may not be an initial event to induce endothelial dysfunction, it participates in its progression in hypertensive subjects.

Smoking

Endothelial dysfunction is one of the primary damages induced by cigarette smoke. Circulating cigarette toxins such as free radicals and reactive glycation products can react with endothelial cells and cause vascular impairment[135]. Cigarette smoking induces inflammatory state as indicated by elevation of white blood cells, adhesion molecules and cytokines, and increases ROS production and lipid peroxidation[136-141]. These mechanisms may contribute to impaired endothelium-dependent vasodilation observed in active smokers, even at young healthy adult, and in passive smokers[142,143]. However, despite a reduced NO bioavailability, eNOS expression has been shown to be increased in different endothelial cells or decreased in platelets in response to cigarette smoke[144,145]. Cigarette smoke extracts inhibits eNOS activity of pulmonary arterial endothelial cells through modifying eNOS phosphorylation pattern, which cannot be protected by antioxidants such as vitamin E and C[146,147]. In this setting, decreased NO bioavailability is probably the consequence of decreased eNOS activity due to modified eNOS phosphorylation and uncoupling as well as NO scavenging by increased ROS.

Inflammation

Endothelial cells produce inflammatory and immune mediators (Table 1) and undergo morphological modifications in response to inflammatory stimuli. The inflammatory and immune mediators increase endothelial permeability and promote adhesion of leukocyte to endothelial cells and interactions between chemokine receptors on leukocyte and proteoglycans on endothelial cells, leading to leukocyte transendothelial migration to inflammation sites. Inflammation induced endothelial dysfunction is often associated with impaired NO bioavailability. For example, typhoid vaccination induced an inflammatory response as indicated by increased cytokines and oxidative stress as well as a decreased endothelium-dependent vasodilation that was partially restored by antioxidant vitamin C[148]. In patients with viral myocarditis, acetylcholine induced a coronary vasoconstriction rather vasodilation[149]. Similar responses were also observed in mice with virus-induced myocarditis, which was attributed to reduced eNOS activity and expression[150]. In some autoimmune diseases, anti-endothelial antibodies cause abnormal immune activation that activates endothelial cells to release adhesion molecules and cytokines, leading to inflammation, increased permeability of the endothelium, thrombosis and cell apoptosis[151-153], which are, at least in part, responsible for endothelial dysfunction in this setting. Patients with rheumatoid arthritis have increased levels of cytokines and ADMA and impaired flow-mediated dilation[154]. Similarly, increased arterial stiffness is closely correlated with ADMA blood levels in systemic lupus erythematosus patients[155]. The increase in ADMA levels may account for reduced NO bioavailability in these autoimmune diseases.

In some cases, an over production of NO occurs in response to inflammation. Septic shock associated with a severe infection and sepsis is characterized by a profound hypotension, widespread endothelial injury and activation, multiple organ failure and death. In this setting, toxic microbe products, including endotoxins (bacterial membrane lipopolysaccharides, LPS) of gram-negative bacteria and analogous molecules in the walls of gram-positive bacteria and fungi, dramatically activate mononuclear cells to release cytokines[156] that upregulate bradykinin B1 receptors[157,158], inducible NO synthase[159] and COX-2[160], which increase NO and prostaglandin E2. In this regard, blocking or deleting bradykinin B1 receptors might yield benefits for the treatment of septic shock. However, experimental studies showed conflicting results regarding the role of kinins in septic shock in animals. Mice with overexpression of B1 receptors exhibited an increased susceptibility to develop septic shock and mice lacking B1 receptors or both B1 and B2 receptors had an enhanced resistance to LPS-induced sepsis[161-163], whereas mice lacking B1 receptors had an higher mortality in response to LPS[164] and additional B1 receptor blockade suppressed the beneficial effect of B2 receptor blockade[165]. Similarly, B2 receptor blockade showed no effect or amelioration in porcine sepsis[165,166]. Results regarding the role of NO, particularly iNOS in septic shock are also elusive. Experiments in rats and in human blood cells showed that iNOS expression is correlated with cell apoptosis in septic shock[167,168]. Selective iNOS inhibition improved hemodynamics and mortality in nondiabetic rats with LPS-induced sepsis but not in diabetic rats[169], whereas depletion of iNOS resulted in increased dysfunctional mitochondria, IL-

1β production and caspase-1 activation in response to LPS in myeloid cells from both mice and humans and increased NLRP3 inflammasome-mediated cytokine production and mortality in mice with LPS-induced sepsis, which was prevented by NLRP3 deficiency[170]. Although treatment with methylene blue that has the ability to scavenge NO and to inhibit NO synthase showed a transient and reproducible beneficial effect on systemic vascular resistance, arterial pressure and organ function in patients with septic shock, but its effect on mortality remains unknown[171,172].

Aging

Aging is accompanied by complex structural and functional modifications of the vasculature, leading to dysfunction of both the endothelium and smooth muscle cells. Changes in aged smooth muscle cells are characterized by changed migration, proliferative and apoptotic behavior, increased response to vasoconstrictors and decreased expression of Ca^{2+}-activated K^+ channels in coronary arteries[173,174]. Aged endothelial cells are associated with decreased NO synthesis and sensitivity to agonist and mechanic stimuli that promote eNOS expression but increased sensitivity to be apoptotic[175,176]. Loss of PI3K/Akt-dependent eNOS phosphorylation seems to be a main mechanism explaining the reduction in NO production in old rats[94]. In addition, aging of endothelial cells is associated with increased production of vasoconstrictor prostanoids, endothelin-1 and ROS[176-178]. ROS are mainly produced by mitochondrial respiratory chain and NADPH oxidases, although eNOS uncoupling my also contribute to increased ROS during aging[179].

METHODS FOR MEASURING ENDOTHELIAL DYSFUNCTION

In animals, endothelial dysfunction can be measured by examining vasodilator responses to endothelium-dependent substances such as acetylcholine, bradykinin and serotonin in comparison with responses to endothelium-independent molecules such as NO donor in the absence and presence of NOS inhibitor and COX inhibitor *in vivo*[180,181] and in isolated vessels[19,182].

The methods used in clinical practice to measure endothelial dysfunction are detailed elsewhere[183]. This includes invasive methods by using quantitative angiography and intracoronary Doppler wire within coronary circulation and non-invasive methods, including venous occlusion plethysmography to measure forearm blood flow, flow-mediated dilatation in brachial artery, and peripheral arterial tonometry measuring pulsatile volume changes in the distal digit[183].

In addition, some circulating biomarkers such as endothelin-1, E-selectin, von Willebrand factor, thrombomodulin, intercellular adhesion molecules and vascular cell adhesion molecules can also be analyzed to detect endothelial dysfunction, although none of them are specific[183].

CARDIOVASCULAR DRUGS IMPROVING ENDOTHELIAL FUNCTION

Experimental and clinical studies have shown that numerous currently used or investigational drugs can improve endothelial function, although they have different structure and mechanisms of actions.

ACE inhibitors and AT1 blockers

Since the success of ACE inhibitors in the treatment of heart failure and discovery of their multiple actions, ACE inhibitors and AT1 blockers are widely used to the treatment of hypertension, arthrosclerosis, diabetes and some autoimmune diseases. It is well established that ACE inhibitors can improve endothelial function in animals with heart failure[184] and in patients with coronary artery disease[185,186]. This effect is related to both reduction in angiotensin Ⅱ and increase in bradykinin accumulation. In addition, ACE inhibitors upregulate eNOS expression in animals[102,187]. The effect of ACE inhibitors on eNOS expression is mediated by bradykinin B2 receptors, which can be blocked by B2 receptors blockers[102,187]. ACE inhibitors and AT1 blockers also inhibit ROS production and COX-2-derived vasoconstrictors, which contribute to endothelial protective effects of these drugs[188]. It appears that the combination of both ACE inhibitor and AT1 blocker does not produce more beneficial effects on endothelial dysfunction than monotherapy in a murine model of atheroclerosis[189], whereas the combination of a stain with an ACE inhibitor or an AT1 blocker produces additive effects on systemic inflammation biomarkers[190]. Also, the combination of ramilapril with felodipine, an calcium channel blocker does not induce more effect on endothelium-dependent vasodilation than each drug alone but increases endothelium-independent vasodilation in spontaneous hypertensive rats[191].

Antioxidant agents

Several substances having very different molecular structure and proprieties, such as vitamin C and E, N-acetylcysteine and genistein exert antioxidant effects through different mechanisms.

Vitamin C can improve endothelium-dependent response in circumstances such as chronic smoking, diabetes mellitus, hypercholesterolemia and hypertension[136,192-195]. Vitamin C protects the endothelium by scavenging superoxide, which in turn prevents NO scavenging, lipid peroxidation, platelet and neutrophil activation, and adhesion molecule upregulation[136,196]. Vitamin C scavenges peroxidase-generated reactive nitrogen species and inhibits myeloperoxidase/H_2O_2/nitrite-mediated LDL oxidation[197]. Vitamin E also exerts endothelial-protective effects in smoking and hypercholesterolemia[194,198] but its effects in diabetes remains controversial[199,200]. Vitamin E acts as a lipid

soluble antioxidant, scavenging hydroperoxyl radicals in lipid milieu[201].

N-acetylcysteine is a non-essential amino acid, essentially used in the treatment of cough. However, experimental studies have demonstrated that N-acetylcysteine is a potent antioxidant. It acts on the production of glutathione, which protects the cardiovascular system from harmful effects of TNF-α that induces glutathione depletion and ROS production *via* NADPH oxidase and ceramide[202-206]. For example, N-acetylcysteine improves coronary and peripheral vascular endothelium-dependent responses in patients with or without atherosclerosis[203]. The effect of N-acetylcysteine on endothelial dysfunction is associated with inhibition of NADPH oxidase expression, leukocyte adhesion and inflammatory cytokine secretion[204]. In addition, N-acetylcysteine inhibits von Willebrand factor dependent platelet aggregation and collagen binding in human plasma and in mice[207], attenuates MMPs expression in microvascular endothelial cells and in rats[202,208], and inhibits caveolin-1 upregulation and improves endothelial barrier function in mice[209], which may also contribute to the endothelial protective effect of N-acetylcysteine. N-acetylcysteine interacts with endogenous and exogeneous vasodilators. For example, in patients with systemic sclerosis, N-acetylcysteine induces vasodilation in association with a reduction in plasma AM concentrations[210] and potentiates hypotensive effects of ACE inhibitors in hypertensive patients[211].

Genistein is a soya-derived phytoestrogen and exerts an antioxidant effect. Genistein attenuates endothelial dysfunction in hypertensive rats and hyperhomocysteinemic rats. This endothelial protective effect appears to be due to increases in eNOS activity and expression and decreases in cytokine and ROS generation[212-215]. Genistein also improves endothelium-dependent vasodilator response in healthy postmenopausal women, increases plasma nitrite/nitrate concentration but decreases plasma endothelin-1 levels[216]. In this regard, genistein may be useful for the treatment of endothelial dysfunction associated with atherosclerosis and hypertension.

Beta blockers

Some beta blockers, particularly the β1-selective beta blockers exert endothelial protective effects. Nebivolol, a β1-antagonist with β2,3-agonist property, improves endothelium-dependent vasodilator responses in patients with essential hypertension[217,218] and in smokers[219]. Nebivolol also improves endothelial function, which is associated with reduced vascular remodeling and expression of endothelin-1 and cytokines in rats with pulmonary hypertension and in endothelial cells taken from these rats[220]. The effect of Nebivolol on endothelial function appears to be mediated by increasing NO release and reducing prothrombotic blood levels of fibrinogen, homocysteine and plasminogen activator inhibitor-1, especially in smokers[218,219]. Carvedilol, a non-selective β1- and β2 antagonist with α-antagonist property, also improves endothelium-dependent responses in patients with essential hypertension but this seems to be related to its antioxidant capacity[218]. The combination of carvedilol with an ACE inhibitor produces more beneficial effect on endothelial function than each drug alone in hypertensive patients with obesity[221]. Thus, this type of beta blockers and its combination are suitable for the treatment of endothelial dysfunction associated with hypertension, atherosclerosis, and probably diabetes.

Dihydropyridine calcium channel blockers

Nicardipine and nifedipine protects against ROS-induced endothelial cell death and lose of glutathione in cultured cells[222]. Benidipine exerts an endothelial protective effect against OxLDL induced ROX generation in human endothelial cells[223]. Israpidine improves endothelial function in cholesterol-fed rabbit[224]. Thus, the endothelial protective effect of dihydropyridine calcium channel blockers is mainly mediated by their antioxidant actions related to reduction in lipid peroxidation and associated ROS generation[222,225]. In addition, some dihydropyridines such as, amlodipine, azelnidipine and nifedipine were shown to exert an antiinflammatory action as indicated by decreased C-reactive protein and interleukin-6 levels as well as leucocyte activation[226,227]. Amlodipine or in combination with an renin inhibitor improves endothelial dysfunction in hypertensive patients, which seems to be linked to its NO-releasing action and anti-inflammatory effect[181,228-230]. In addition, the combination of amlodipine with a statin induces more favorable vascular effects than each drug alone in rats with hypertension or diabetes[231,232]. Thus, in addition to hypertension, dihydropyridines may also be useful for the treatment of endothelial dysfunction in diabetes.

Phosphodiesterase-5 inhibitors

Phosphodiesterase-5 (PDE5) is a cytosolic enzyme localized in vascular smooth muscle, heart, skeletal muscle, platelet, placenta, brain, kidney, liver, pancreas, gastrointestinal tissues and lung[233]. In vasculature, the primary action of PDE5 is to degrade cGMP and thereby induces vasoconstriction. PDE5 inhibitors are a class of drugs used to improve erectile dysfunction. These drugs block PDE5-induced cGMP degradation, leading to tissue cGMP accumulation and vasodilation[234]. PDE5 inhibitors upregulate eNOS expression and thereby increase NO release[235,236], which may contribute to long-term vasodilator effects of PDE5 inhibitors. PDE5 inhibitors also exert other initially unexpected effects. For example, in mouse hind limb ischemia model, treatment with sildenafil not only improves blood flow recovery but also increases capillary density and endothelial progenitor cell mobilization[237]. In patients with vasculogenic erectile dysfunction, daily treatment with vardenafi reduces both arterial stiffness and plasma AM level[238]. These effects may also account

for the effects of chronic PDE5 inhibition. In addition to erectile dysfunction, PDE5 inhibitors can improve endothelial dysfunction in other circumstances. For example, PDE5 inhibition improves coronary and peripheral vascular endothelial function, and inhibits platelet activation in patients with coronary artery disease[239] or with congestive heart failure[240-242], and improves endothelium-dependent vasorelaxation in rats with experimental diabetes mellitus[243]. PDE5 inhibitors also improves erectile function in patients with systemic sclerosis and reduces plasma endothelin-1 concentration[244]. Similarly, PDE5 inhibitors improve Raynaud's phenomenon characterized by reduced blood flow to fingers and toes in response to cold and stress, probably through decreasing plasma endothelin-1 and improving microcirculation[245]. However, the mechanism underlying endothelin-1-reducing effect of PDE5 inhibitors remains to be determined.

Statins

Statins, inhibitors of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase are a class of drugs utilized to reduce hypercholesterolemia, especially LDL cholesterol. In 1994, pravastatin was shown to improve endothelium-dependent response of coronary and peripheral arteries in patients with hypercholesterolemia[246], which was confirmed later by other studies[247]. The beneficial effect of statins on endothelial function involves multiple mechanisms. Statins improving endothelial dysfunction is partly due to their lowering LDL cholesterol effect, while native LDL and OxLDL reduce eNOS expression[248,249] and increase levels of caveolin-1[250]. Statins also exert direct antioxidant effects on LDL to reduce electronegative form of LDL[251,252]. Statins increase NO bioavailability by activating eNOS *via* the PI3K/Akt signaling pathway[253], agonist-stimulated eNOS-hsp90 interaction[250], and BH4-mediated eNOS coupling. This latter was demonstrated in patients with atherosclerosis[254] and in rat model of insulin resistance of diabetes[231]. These studies showed that atorvastatin increased vascular BH_4 content and NO bioavailability and reduced O_2^- production *via* upregulating GTP-cyclohydrolase Ⅰ gene expression and activity. These effects occurred rapidly in patients with atherosclerosis and could be reversed by mevalonate, indicating a direct effect of vascular HMG-CoA reductase inhibition[254]. In addition, statins upregulate eNOS expression through enhancing eNOS mRNA stability. Indeed, statins increase eNOS mRNA polyadenylation through Rho-mediated changes in the actin cytoskeleton[255,256]. However, a study showed that statins can increase eNOS gene transcription by upregulating Kruppel-like factor 2 through inhibition of Rho pathway[257]. The effect of statins on eNOS expression may account for the long-term effect of stains on endothelial function. Statins also exerts antiinflammatory effects[258]. For example, atorvastatin treatment reduces proinflammatory cytokines (TNF-α, IL-1 and IL-6), intercellular adhesion molecules and C-reactive protein blood levels in hypercholesterolemic patients[259], while rapid withdrawal of statin treatment increases proinflammatory and prothrombotic biomarkers[260]. Statins were also shown vascular benefice in other inflammatory diseases such as rheumatoid arthritis[261]. Otherwise, statins increase circulating endothelial progenitor cells, likely through the PI3K/Akt pathway[262], which could contribute to long-term effects of statins on endothelial function.

Anther type of LDL-lowering drugs, the proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors, may be expected to improve endothelial function. In humans, PCSK9 mutation is closely correlated with LDL cholesterol levels and inhibition of PSCK9 with a monoclonal antibody reduces LDL cholesterol levels[263] and enhances the LDL cholesterol-lowering effect of atorvastatin[264]. Studies in cells and animals have shown that PCSK9 is associated with inflammation and endothelial cell apoptosis. In mice, systolic inflammation and OxLDL upregulate PCSK9, whereas PCSK9 interacts with macrophage, leading to NF-κB activation[265,266]. Knockdown of PCSK9 with PCSK9 siRNA or induction of gain of function mutant D374Y-PCSK9 reduces expression of stress-response genes and specific inflammation pathways, inflammation pathway activation and OxLDL-induced endothelial apoptosis[266-268]. Nonetheless, the effects of PCSK9 inhibition on human endothelial function are not yet explored.

Angiotensin-(1-7)

Angiotensin-(1-7) is a metabolite of angiotensin I under the action of various enzymes, including neutral endopeptidase, prolylendopeptidase, aminopeptidase A and neprilysin[36]. It can also be generated from angiotensin Ⅱ by prolylcarboxypeptidase[269] and carboxypeptidase (ACE2)[270]. In endothelial cells, angiotensin-(1-7) activates eNOS *via* the Mas/PI3K/Akt pathway and inhibits angiotensin Ⅱ-induced NAD(P)H oxidase activation[271,272]. Chronic treatment with angiotensin-(1-7) improves renal endothelial dysfunction associated with apolipoprotein E-deficiency[273] and diet-induced obesity in mice[274], which is likely mediated by increasing NO release[275] and eNOS expression[276,277]. Otherwise, angiotensin-(1-7) restores vascular ACE2-angiotensin-(1-7)-Mas receptor axis function that impairs ROS production by angiotensin AT1 receptor-activated NAD(P)H oxidases in hypertensive or diabetic rats[278,279]. Angiotensin-(1-7) restores NO/cGMP production and migration, decreases NADPH oxidase activity, and enhances survival and proliferation of endothelial progenitor cells isolated from the blood of diabetic patients in a Mas/PI3K/Akt-dependent manner[280]. Interestingly, overexpression of angiotensin-(1-7) gene restores the vasoreparative function of endothelial progenitor cells in mice[280]. Despite these encouraging results in cells and in animals, the information regarding the effects of angiotensin-(1-7) on human endothelial function

remains lacking.

Bradykinin

As discussed above, endogenous bradykinin exerts multiple actions that affect endothelial function. It is worth noting that bradykinin as an investigational drug protects against ROS- and toxin-induced microvascular endothelial cell death[281], and chronic treatment with bradykinin not only preserves eNOS expression in dogs with pacing-induced heart failure[101], but also upregulates eNOS and nNOS expression in vessels and in the heart of dogs with dystrophin-deficiency cardiomyopathy[19,282]. However, due to the very short half-life and implication of bradykinin in the inflammation[283] and cancers[284,285], the clinical use of bradykinin remains a challenge.

eNOS transcription enhancer

Interestingly, specific targeting eNOS transcription with a chemical compound, AVE3085, increases eNOS expression but reduces oxidative stress and platelet activation, which is associated with improved endothelium-dependent relaxation and cardiac function in animals with different experimental diseases[286-289]. This compound also prevents the inhibitory effect of ADMA on endothelium-dependent vasodilation in human internal thoracic artery rings and in pig coronary artery rings[290,291]. Thus, this compound showed a potential for the treatment of endothelial dysfunction although its effects in human clinical situations remains to be demonstrated.

I_f inhibitor, ivabradine

I_f current is an inward current carried by Na^+ and K^+, activated by hyperpolarization and conducted by hyperpolarization-activated cyclic nucleotide-gated channels (f-channels)[292]. I_f current participates in the spontaneous depolarization during Phase 4 of the action potential and plays a crucial role in the pacemaker activity of pacemaker cells located in the sinus node and atrioventricular node. Inhibition of this current by ivabradine slows down heart rate and exerts cardioprotective effects[293-296], which may involves pleiotropic actions of ivabradine[297]. Among them, beneficial effects of ivabradine on the endothelium-dependent vasodilation and on the expression of eNOS expression in both animals and humans have been reported[298-300]. Nevertheless, the effects of ivabradine on human endothelial dysfunction are controversial. Several studies did not observe significant improvement in flow-mediated vasodilation by ivabradine in patients with microvascular angina pectoris[301] or stable coronary heart disease[302] and in patients with type Ⅱ diabetes[303]. In addition, in patients with stable of coronary disease without heart failure, the additional ivabradine plus standard treatment did not improve outcome but was associated with increased frequency of atrial fibrillation, questioning the utility of this drug in the treatment of stable coronary disease[304].

Sphingosine-1-phosphate

Sphingosine-1-phosphate (S1P), a signaling sphingolipid formed by sphingosine kinase in the blood and in tissues, regulates different biological responses such as angiogenesis, vascular permeability and trafficking of T- and B-cells. S1P enhances endothelial barrier function[305,306], stimulates endothelial NO release through Akt-mediated phosphorylation of eNOS[307], and reconstitutes high density lipoproteins[308]. S1P also has antiinflammatory properties and exerts protective effect against endotoxin-induced lung injury[309,310]. Moreover, S1P exhibits a potent effect on the differentiation of adipose-derived stem cells into endothelial-like cells and upregulation of eNOS in these cells[311]. All of these properties of S1P may contribute to its endothelial protective effects. Interestingly, an orally active of S1P analogue, FTY720 also shows similar effects[312]. Thus, S1P and analogues may be used to improve endothelial function, especially in atherosclerosis and acute lung injury where presents an impairment of endothelial barrier function[313].

CONCLUSION

Endothelial dysfunction is a common mechanism involved in many cardiovascular diseases, although in some diseases such as atherosclerosis, endothelial dysfunction plays a critical role in the development of diseases, whereas in others such as essential hypertension and type Ⅱ diabetes, endothelial dysfunction generally occurs as a complication but thereafter contributes to the development and progression of organ damages. Clearly, multiple mechanisms such as inflammation, increased ROS and RNS, cellular apoptosis, increased vasoconstrictor production, decreased vasodilator production and vascular remodeling are involved in endothelial dysfunction and a specific pathology may involve more or less them as described above. However, a decreased NO bioavailability appears to play a central role because in many pathologies such as atherosclerosis, diabetes, essential and pulmonary hypertension and heart failure except for septic shock where there is a overproduction of NO, a reduction in NO bioavailability occurs sooner or later in response to different risk factors. This may explain the beneficial effects of some drugs in the treatment of a variety of cardiovascular disorders. It appears that a drug with endothelium-protective property may yield more therapeutic benefits than that without such feature. For this reason, the evaluation of endothelium-improving action may be helpful for the development of a novel cardiovascular drug. Moreover, due to the differences in risk factors contributing to the different cardiovascular diseases and the differences in mechanisms of action, treatment of endothelial dysfunction with drugs needs to be carried out according to specific mechanisms

underlying endothelial dysfunction of the disease.

Abstract

Arterial stiffness has been recognized as a marker of cardiovascular disease and associated with long-term worse clinical outcomes in several populations. Age, hypertension, smoking, and dyslipidemia, known as traditional vascular risk factors, as well as diabetes, obesity, and systemic inflammation lead to both atherosclerosis and arterial stiffness. Targeting multiple modifiable risk factors has become the main therapeutic strategy to improve arterial stiffness in patients at high cardiovascular risk. Additionally to life style modifications, long-term ω-3 fatty acids (fish oil) supplementation in diet may improve arterial stiffness in the population with hypertension or metabolic syndrome. Pharmacological treatment such as renin-angiotensin-aldosterone system antagonists, metformin, and 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors were useful in individuals with hypertension and diabetes. In obese population with obstructive sleep apnea, weight reduction, aerobic exercise, and continuous positive airway pressure treatment may also improve arterial stiffness. In the populations with chronic inflammatory disease such as rheumatoid arthritis, a use of antibodies against tumor necrosis factor-alpha could work effectively. Other therapeutic options such as renal sympathetic nerve denervation for patients with resistant hypertension are investigated in many ongoing clinical trials. Therefore our comprehensive review provides knowledge in detail regarding many aspects of pathogenesis, measurement, and management of arterial stiffness in several populations, which would be helpful for physicians to make clinical decision.

INTRODUCTION

Arteries provide not only blood flow conduits from the heart to peripheral organs, but also play a major role in hemodynamic cushioning, buffering the forward propagating flow from the heart, and the backward resistance by the peripheral arterioles, which maximize cardiovascular efficiency. Arterial stiffness characterized by higher intravascular distending pressure has been recognized as a marker of cardiovascular disease (CVD) and associated with long-term prognosis in several populations[1-4]. A recent meta-analysis including 17 longitudinal studies demonstrated that aortic stiffness was an independent predictor of incident CVD and all-cause mortality in the general population[4]. Therefore, evidence-based approaches for improving arterial stiffness are of clinical importance to reduce the hazards of subsequent CVD. This review article will discuss the latest knowledge of the pathological backgrounds, the measurements, and the effects of pharmacological and non-pharmacological interventions for arterial stiffness.

The pathophysiology of arterial stiffness

As a major component of the circulatory system, the arterial system can be functionally and structurally divided into two sub-systems: (1) the large elastic, conducting arteries (*e.g.*, the aorta, the carotid arteries, and the iliac arteries), which store blood ejected from the heart during systole, and expel blood to the peripheral tissues during diastole, thereby ensuring a steady blood flow irrespective of cardiac cycles or concurrent blood pressure; (2) resistance muscular arteries, especially those of the lower limb (*e.g.*, femoral, popliteal, and posterior tibial arteries), which are capable of altering vascular smooth muscle tone, allowing them to modulate the velocity of pressure wave that is conducted to the resistance muscular arteries from the central aorta[5]. The sites of aortic flow reflection are not simply anatomically determined, but also subjected to systemically structural and functional control. For example, the site of reflection is more central in the case of hypertension, atheromatous arteries or increased sympathetic activity[6].

The pressure waveform recorded at any site of aorta is the summation of the forward-traveling waveform generated by cardiac pumping force and the backward traveling wave, the "echo" wave reflected at peripheral sites. The summation result determines the cardiac afterload during systolic phase and the augmented backward coronary perfusion pressure during diastolic phase. When the arteries are compliant and elastic, the reflected wave merges with the incident propagating wave during diastole, thus augmenting the diastolic blood pressure and enhancing coronary perfusion[7]. On the contrary, when arteries are stiffer, pulse wave velocity increases, and both the incident and the reflected wave travel faster; therefore, the reflected wave merges with the incident wave at systole and increase systolic pressure and cardiac afterload, while, concomitantly, losing the augmented diastolic perfusion pressure[7] (Figure 1). The added part on systolic pressure and cardiac afterload was named aortic augmentation index [AIx, (second/first systolic peak) $\times$ 100%][8]. In the long term, increasing pulsatility causes stretching of load-bearing elastic lamellae and mechanical stress on the wall leading to vascular structural changes and stiffening. Hence, the harm of arterial stiffness is two-sided, negatively affecting the heart and blood vessels[9] (Figure 2).

Factors affecting arterial stiffness

Age is a main determinant of stiffness in large elastic arteries[7,10]. The stiffness of these arteries increases significantly after the age of 55 years. Aging causes the degeneration and remodeling of elastic components of arterial wall. At the cellular-molecular level, an age-related decrease in intra-cellular magnesium concentration is associated with increases in stiffness[10].

Most traditional cardiovascular risk factors and CVD have an adverse effect on arterial stiffness, *via* endothelial dysfunction and adverse vascular remodeling. Hypertension, diabetes, dyslipidemia, and insulin resistance, which contribute to atherosclerosis, have been involved in the process of arterial stiffening. In essential hypertension, the elastic properties of large arteries are impaired, although it is not clear whether the disease itself alters the intrinsic elastic properties or this is the ultimate final effect of increase in distending pressure[11,12]. Distending pressure as estimated by 24-h pulse pressure was another major factor additionally to older age contributing to the occurrence of arterial stiffness[13]. In patients with diabetes or metabolic syndrome, arterial stiffening is consistently observed across all age groups, even in childhood[14]. Insulin resistance is dose-dependent and positively correlated with arterial stiffness[15-17]. Chronic hyperglycemia and hyper-insulinemia may increase local activity of renin-angiotensin-aldosterone system (RAAS) and expression of angiotensin type I receptor in vascular tissue and thus promote the development of arterial wall hypertrophy

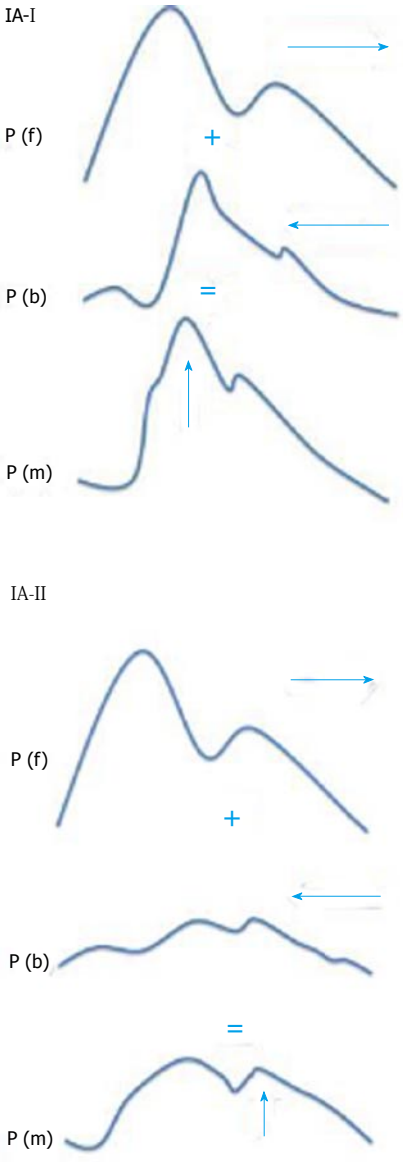

Figure 1 The central aortic pressure waveform is the summation of forward travelling wave, P (f) and the reflected backward-travelling wave, P (b). On the top graph IA-I, is an illustration of a stiff aorta or peripheral vasoconstriction, both P (f) and P (b) travel fast and the magnitude of the reflected wave is increased, thus augmenting the systolic pressure of summated central aortic pressure waveform, P (m). In graph IA-II, is another illustration of a distensible aorta or with vasodilatation. Length and thickness of horizontal arrows correspond to the waveform velocity and the magnitude of the reflected wave, respectively. Vertical arrows indicate point of merging of P (f) and P (b).

and fibrosis[18,19].

In addition hyperinsulinemia has proliferative effects, *via* unbalanced activities on growth-promoting mitogen activated kinase pathways and PI3-kinase-dependent signaling[20]. In pre-diabetic stage, impaired glucose tolerance enhances nonenzymatic glycation of proteins with covalent cross-linking of collagen and alters the mechanical properties of interstitial tissue of arterial wall[21,22].

Chronic kidney disease (CKD) is a well-known risk factor of arterial stiffness[23]. Several mechanisms have been proposed to explain the effect of CKD. For instance, upregulation of matrix metalloproteinases enhances collagen and elastin turnover through enzymatic cross-link degradation[24], causing weakening of the extracellular matrix[25]. Accumulation of advanced glycation end-products makes collagen stiffer as well[26]. In addition, CKD may cause endothelial dysfunction, which attributes to high oxidative stress, increased endothelin-1 concentrations and impairment of endothelial nitric oxide synthase and arterial relaxation[27]. Chronic inflammation and RAAS activation are also involved in the process of arterial stiffening in CKD[28,29]. CKD alters bone metabolism to promote vascular calcification by increasing osteoclast activity, fibroblast growth factor 23, osteoprotegerin which inhibit bone morphogenic proteins, and reducing pyrophosphate, Matrix G1a protein, and fetuin A levels[30].

Arterial elastic properties are impaired in young people with a family history of hypertension, diabetes or myocardial infarction[31]. It has been recognized that genetic factors may contribute to arterial stiffening as well. The latest advances in genome-wide association study have identified that some genetic variants and specific polymorphisms may affect arterial stiffness. The Framingham Heart Study showed that four regions of suggestive linkage were found in chromosomes 2, 7, 13, and 15 (LOD scores 2.0) for higher risk of arterial stiffness[32]. Potential candidate genes in these regions included the insulin-like growth factor-1 receptor, myocyte-specific enhancer factor 2A, chondroitin synthase (CHSY1), proprotein convertases (PACE4 and FURIN), b-adducin (ADD2), neurokinin-1 receptor (TACR1), a-2B adrenergic receptor (ADRA2B), and interleukin-6 (IL-6). Other candidate gene polymorphism, such as the renin-angiotensin-aldosterone genes, the Matrix and metalloproteinase genes, the endothelial cell-related genes, and the inflammatory genes, are all in undergoing investigations[33].

Lifestyle characteristics are important determinants of arterial stiffness. Cigarette smoking, including passive smoking and current smoking has an adverse impact on the arterial stiffness[34-36]. Elevated arterial stiffness has been found among patients with chronic obstructive pulmonary disease and inflammation, which are highly related to the adverse effect of smoking. Obesity, weight gain, lack of physical activity and high dietary intake of sodium chloride, which is associated with blood pressure elevation, can aggravate arterial stiffness[37-40]. Intake of caffeine, a neurotoxin has also been acknowledged of an unfavorable effect on arterial compliance[40]. Other risk factors such as chronic cytomegalovirus infection, has been known as a novel potential contributor to arterial stiffening[41]. Table 1 lists the main demographic, clinical and lifestyle characteristics that may influence arterial stiffness.

Measurement of arterial stiffness

A stiffer vessel will conduct the pulse wave faster than a

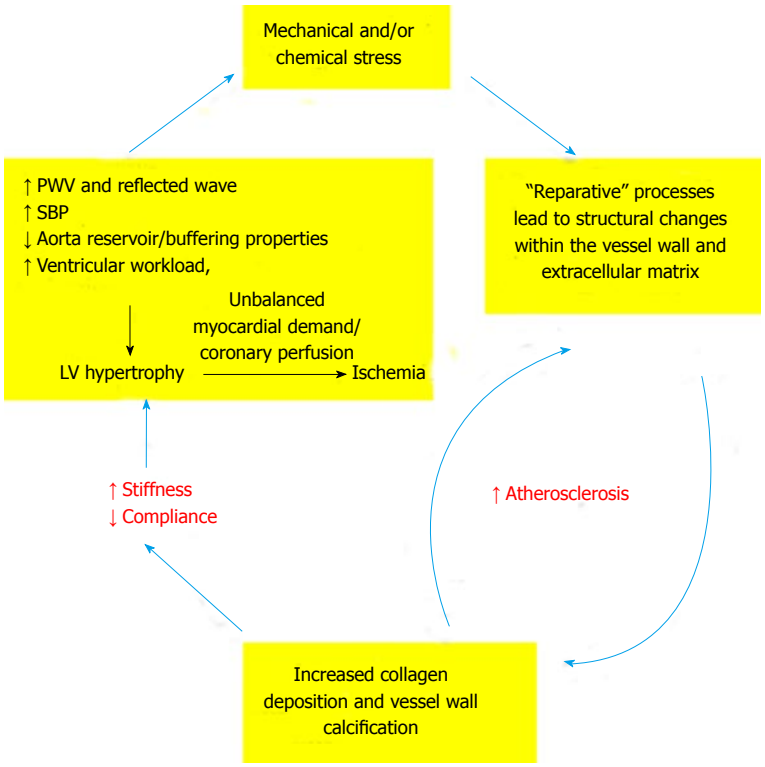

Figure 2 Aortic elastic properties may be altered by several processes, resulting in increased stiffness, decreased compliance, and encompassing the diseased ventricular-arterial coupling. Mechanical and chemical stress factors include hypertension, inflammation, advanced glycation end products, *etc.* LV: Ventricular; PWV: Pulse wave velocity; SBP: Systolic blood pressure.

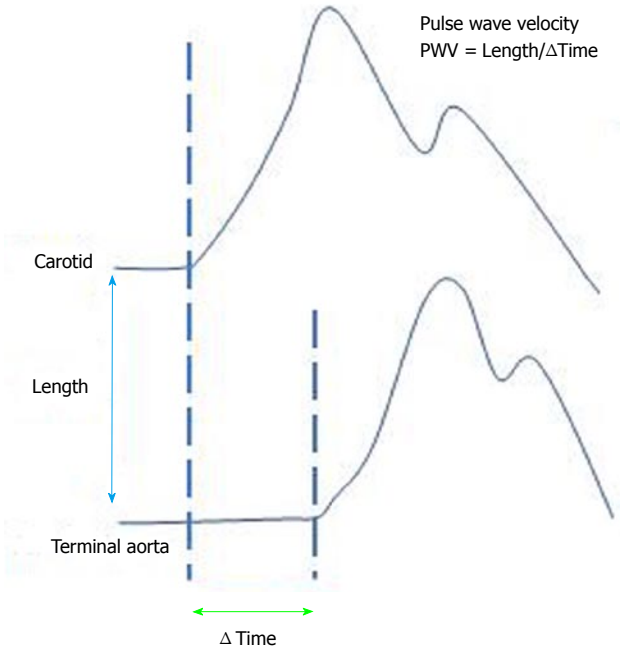

Figure 3 For practical purpose, femoral artery is counted as the terminal aorta. The measured distance is length. If ΔTime represents the time delay between the feet of the 2 waves, pulse wave velocity.

more distensible and compliant vessel. Arterial stiffness can be noninvasively evaluated by measuring pulse-wave velocity (PWV). The PWV is calculated by the distance (L) between the 2 vascular sites divided by the wave foot-to-foot time (ΔT) it takes for that forward wave to reach the end measuring point (Figure 3) Currently, PWV is the most validated measurement to noninvasively quantify arterial stiffness. It is considered the gold standard index to measure arterial stiffness, given its simplicity, reproducibility, accuracy, and strong prediction of adverse CVD events[42-44]. An increase in aortic PWV by 1 m/s corresponds to an age-, sex-, and risk factor-adjusted risk increase of 14%, 15% and 15% in total CVD events, CVD mortality, and all-cause mortality, respectively[5]. Nowadays, two kinds

of PWV were frequently used to evaluate arterial stiffness. Carotid-femoral PWV (cfPWV) measured by Doppler ultrasound is the most widely used measure of aortic stiffness and is regarded as the gold standard measure for evaluating arterial stiffness. Alternatively, brachial-ankle PWV (baPWV) measured by the Omron oscillometric/plethysmographic system has recently received attention because of its consistent association with CVD risk factors and its ease of use for large-scale population studies[42-44]. Based on the formula assumptions, cfPWV reflects the stiffness of descending aorta, while baPWV reflects the stiffness of both descending aorta and leg arteries. In a study conducted among healthy men aged 40-49, cfPWV strongly correlated with central PWV, and baPWV correlated with both central and peripheral PWVs[45]. The two indexes were highly correlated and the predictive values of these two PWVs were comparable[46]. Both cfPWV and baPWV have been reported to be independent predictors of subclinical coronary artery calcification, incident vascular events, incident heart failure, and all-cause mortality in the general population[47,48]. The main disadvantage of cfPWV is inevitably affected by blood pressure, which is an important confounder for CVD. In addition, cfPWV is often overestimated for the inaccurate measurement in the distance between the carotid and the femoral to measure the pulse wave[49]. Other methods for the PWV measurements include single-point, carotid–radial or femoral–tibial arterial segments. The predictive values of these more peripheral PWV measurements to incident vascular events remain unknown[50]. Aortic characteristic impedance standing for the minimal impedance for higher frequencies of pressure-and-flow harmonics and being proportional to PWV is an indirect technique, but this is rarely used alone now[51]. AIx, arterial wave reflection magnitude [(reflected/forward wave amplitude) × 100%], and pulse pressure amplification [(radial/aortic pulse pressure) × 100%], the analysis of pulse waveforms parameters of central arteries, have been associated with the development of end organ damage as well[52].

The stiffness parameter β is another measure of arterial stiffness. The equation for stiffness parameter β is ln(Ps/Pd) × D/ΔD, where Ps is the systolic blood pressure, Pd is the diastolic blood pressure, D is the diameter of the artery, and ΔD is the change in arterial diameter between Ps and Pd[53]. The stiffness parameter β is less affected by blood pressure; however it is limited by assessing a local segment of the artery, and becoming dependent on blood pressure for those with hypotension or moderate and severe hypertension[53]. Therefore, the cardio-ankle vascular index, CAVI, was developed to incorporate the stiffness parameter β[54]. The equation for CAVI is a $[(2\rho/\Delta P) \times \ln(Ps/Pd) \times PWV^2] + b$, where ρ is the blood viscosity, ΔP is Ps - Pd, PWV is the pulse wave velocity from the aortic origin to the ankle region *via* the femoral artery, and a and b are constants for converting a CAVI value to a value obtained by Hasegawa's method[55]. Theoretically, the CAVI is essentially intrinsic to the stiffness parameter β and thus less dependent of blood pressure than PWV. Table 2 summarizes the merits and disadvantages of different measurements of arterial stiffness.

Therapeutic modification of arterial stiffness

Lifestyle modification: Obesity is related to insulin resistance, hypertension, obstructive sleep apnea (OSA), and eventually arterial stiffness. A meta-analysis involving 20 studies (including 3 randomized controlled trials) revealed that modest weight loss (mean 8% of initial body weight) could improve PWV values by 32% in the collected 1259 participants[56]. In addition, weight reduction was found in association with decreased CAVI values in a cohort of 47 obese individuals in Japan[57]. Effects of exercise on arterial stiffness were extensively investigated. Physical activity was associated with 35% reduction in cardiovascular mortality and 33% reduction in all-cause mortality[58]. Almost 60% of the benefits are contributed by the reduction of body weight, blood pressure and serum lipids[59], and the other 40% may be explained by the improvement of vascular hemodynamics including endothelial function, arterial compliance and remodeling[60]. Whether mode and dose of exercise affecting arterial stiffness had been recently reviewed in a meta-analysis[61]. In total, forty-two studies and 1627 participants were included in the study, which concluded aerobic exercise, but not resistant exercise or combined aerobic and resistant exercise, improved PWV weighted mean difference (WMD): -0.63 m/s, 95%CI: -0.90 to -0.35, and AIx (WMD: -2.63%; 95%CI: -5.25 to -0.02). The benefits for improving arterial stiffness were greater in the peripheral index, baPWV (WMD: -1.01 m/s; 95%CI: -1.57 to -0.44) than in central index, cfPWV (WMD: -0.39 m/s; 95%CI: -0.52 to -0.27). There was dose-dependent relationship between exercise intensity (frequency of exercise sessions and absolute exercise intensity) and the improvement of AIx. Nevertheless, the exercise session duration was not significantly associated with the reduction of AIx[61]. In individuals with stiffer arteries (PWV ⩾ 8 m/s), aerobic exercise had a larger effect in reducing PWW. In addition, the benefits of aerobic exercise were documented in subpopulations with normal health, overweight/obese, pre-hypertension, hypertension, or CKD.

Smoking cessation has been proven to decrease aortic stiffness. In one 60 wk follow-up observational study, smoking cessation group had better arterial stiffness indices (central blood pressure, -7.1 ± 1.4 mmHg *vs* 1.2 ± 2.7 mmHg, $P < 0.01$; baPWV, -204 ± 64 cm/s *vs* -43 ± 72 cm/s, $P < 0.01$; reduced radial AIx, -6.4 ± 2.8% *vs* -1.0 ± 3.9%, $P < 0.01$)[62]. Another observational study also showed that smoking cessation was associated with improved arterial stiffness as evaluated by CAVI values[63]. Moreover, avoidance of second-hand smoke, such as workplace smoking bans,

Table 2 A summary of the advantages and disadvantages of different measurements for evaluating arterial stiffness

	Advantage	Disadvantage
cfPWV[42-44]	Reflects the stiffness of the descending aorta The gold standard measure for arterial stiffness	Largely affected by the change of BP Overestimated for the inaccurate measurement in the distance between the carotid and the femoral arteries
baPWV[116]	Reflects the stiffness of both the descending aorta and the leg artery High association with CV risk factors Ease of use for large-scale population studies	Largely affected by the change of BP Underestimates arterial stiffness in hypertensive patients with a history of cardiovascular events
hfPWV[117]	Strongly correlated with cfPWV moderately correlated with baPWV	Require a high level of proficiency in order to obtain accurate results
faPWV[117]	Moderately correlated with baPWV	The predictive value to incident vascular events remains unknown
pAIx[110]	Assessed non-invasively and peripherally, *e.g.*, carotid, and radial arteries Correlated well with the central AIx	Largely affected by the change of BP Not a valid surrogate of arterial compliance in the elderly and diabetic populations
The stiffness parameter β[53,54]	Independent of the change of BP	Assessing only a local segment of the artery Loss of the independence of BP for those with moderate to severe hypertension or hypotension
CAVI[118]	Independent of the change of BP A novel atherosclerotic index that incorporates PWV and BP measurements The coefficients of variation are small (< 4%), and does not require significant training	CAVI, as a cardiovascular risk marker has not to be investigated definitively in large prospective clinical trials

Ba: Brachial-ankle arteries; CAVI: Cardio-ankle vascular index; BP: Blood pressure; cf: Carotid-femoral arteries; fa: Femoral-ankle arteries; hf: Heart-femoral arteries; pAIx: Peripheral augmentation index; PWV: Pulse-wave velocity.

has been reported to improve PWV after introducing smoke-free workplaces[64].

Dietary and nutrient interventions: Several dietary modifications had been reported with beneficial effects on arterial stiffness. Among them, omega (ω)-3 fatty acids (fish oil) supplementation was mostly studied. In most of clinical trials, ω-3 fatty acids supplementation improved arterial stiffness, especially in the population with overweight, metabolic syndrome, diabetes or hypertension[65]. Aside from a study with acute ω-3 fatty acids administration in healthy participants, almost all ω-3 trials were long-term prescribed varying from 1.5 to 25 mo. In this acute fish-oil supplementation study, there were no immediate reductions in parameters of arterial stiffness[66]. The lowest daily dosage of long-chain polyunsaturated fatty acids (PUFAs) that documented an effect on arterial stiffness was 540 mg eicosapentaenoic acid (EPA) along with 360 mg docosahexaenoic acid (DHA) in overweight patients with hypertension[67]. Sjoberg *et al*[68] introduced 2, 4, and 6 g of fish oil supplementation per day into the diets of overweight or obese adults for 12 wk. Only the highest dose group (6 g of fish oil per day) revealed significant improvement in arterial distensibility, as measured by PWV. Among healthy subjects, Chong *et al*[69] reported a significant improvement in PWV and AIx immediately after a long chain ω-3 PUFA-rich meal containing 4.7 g of DHA and EPA. In a randomized controlled trial in Japan, highly purified EPA administration (1.8 g/d for 3 mo) significantly reduced both PWV and CAVI values in individuals with metabolic syndrome[70]. However, other two studies using smaller amount (1.7 g of EPA/ DHA per day for 12 wk and 1.8 g of EPA/ DHA per day for 12 mo) did not improve arterial stiffness among slightly overweight but relatively healthy subjects[71,72]. Accordingly, the benefits from ω-3 supplementation could be more evident using a comparable dose over a greater duration within an older age, more diseased populations.

Soy isoflavones was another nutrient, which has been studied frequently. Among five soy isoflavone interventional studies, four interventional studies showed an improvement in PWV or systemic arterial compliance in subjects taking soy isoflavone relative to their placebos[73-76], whereas one study reported no effect[77]. Notably, the majority of the soy interventions were conducted in postmenopausal women. In other studies with positive results, one study reported that consumption of alcoholic red wine might decrease AIx acutely relative to that after consumption of dealcoholized red wine[78], and a study showed that consumption of black tea flavonoids could reduce the digital volume pulse-stiffness index but not PWV[79]. Other dietary and nutritional interventions, nonetheless, reported no definite effect on arterial stiffness, such as garlic[80], conjugated linoleic acid[81], vitamins or folic acid[82-86] on PWV.

Among the minerals, salt plays a detrimental role. Consistent evidence suggest that 10-140 mmol sodium chloride supplementation per day would increase arterial stiffness in individuals with hypertension[87,88]. In a randomized clinical trial, salt reduction was associated with decreased pulse pressure across all ethnic groups including white, black and Asians, whereas PWV decreased only in blacks in response to salt reduction[87].

In addition, Gates *et al*[89] revealed that large elastic artery compliance was much improved in the older adults with systolic hypertension following only one-week of dietary sodium restriction.

Pharmacological therapy: Since blood pressure is the strongest modifiable factor directly leading to arterial stiffness, a number of clinical trials have been conducted to investigate the effect of antihypertensive medications on the change of arterial stiffness. Notably almost all classes of anti-hypertensive medications except diuretics and non-vasodilating beta-blockers such as atenolol could decrease arterial stiffness effectively[90,91]. Among all classes of anti-hypertensive medications, RAAS system antagonists have shown the best clinical results, probably due to their anti-fibrotic properties[91]. With regard to other modifiable risk factors, 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) could decrease arterial stiffness by lowering low-density lipoprotein cholesterol concentrations, the effect of anti-inflammation, and stabilizing the atheroma plaques[92,93]. In patients with diabetes, glycemic control with oral anti-diabetic agents with metformin and glitazone were reported to improve arterial stiffness[94,95]. Using high dose of RAAS antagonists was extremely effective in attenuating the severity of arterial stiffness in diabetic patients with hypertension[96]. Notably, pharmacological modifications to these traditional vascular risk factors have been confirmed to improve arterial stiffness evaluated by PWV or CAVI[97]. In patients with chronic inflammatory disease such as rheumatoid arthritis, several anti-inflammatory agents have been tested, but until now, only antibodies against tumor necrosis factor-alpha have been shown to improve arterial stiffness, independently of adequate blood pressure control[98,99]. In menopausal women, although the effect of sex hormone replacement therapy on arterial stiffness is uncertain, one study showed that using raloxifene, a potent selective estrogen receptor modulator may lead to positive result[100]. The phosphate binder, sevelamer was found to improve arterial stiffening in patients with end-stage renal disease[101]. Alagebrium, an advanced glycation end-products crosslink breaker, has shown to improve arterial stiffness in animal studies despite the effect was missing in a small group of older individuals[102,103]. However, further clinical trials were not conducted because of financial problems of the developing company. Currently, some ongoing trials are conducted to evaluate the effect of antidiabetic pharmacological therapy including metformin and alogliptin, the dipeptidyl peptidase 4, on the improvement of arterial stiffness in obese children and adolescents, and in adult individuals with type 2 diabetes, respectively[104,105].

Device and interventional therapy: It is well known that OSA is related to obesity and correlated with several CVD risk factors, such as hypertension and metabolic syndrome, which contributes to adverse clinical outcomes. A meta-analysis involving 15 articles, investigated the effect of continuous positive airway pressure (CPAP) on arterial stiffness in 615 patients with OSA. A significant improvement of all indices of arterial stiffness was observed after CPAP treatment (SMD = -0.74; 95%CI: -1.08 to -0.41). Neither the proportion of compliance nor the duration of CPAP use altered the outcomes after CPAP treatment[106].

Enhanced external counterpulsation (EECP), using pneumonic cuffs over the legs to inflate and deflate according to the cardiac cycle, is a non-invasive modality for treatment of symptomatic patients with coronary artery disease not amenable to revascularization procedures. In a randomized clinical trials conducted in 42 patients with coronary artery disease, central arterial stiffness and AIx were reduced following 17- and 35-sessions respectively, as well as peripheral arterial stiffness was reduced following 35 sessions in the EECP treatment group as compared with the placebo[107].

Since autonomic nervous system is involved in the pathogenesis of hypertension, its modification such as renal sympathetic denervation, and baroreflex activation therapy could attenuate arterial stiffness by improving arterial stiffness indices and central hemodynamics in patients with resistant hypertension[108,109]. However, these studies were conducted in patients with resistant hypertension, and the result may not be simply extrapolated to all the patients with arterial stiffness.

CONCLUSION

Arterial stiffness has been recognized as a marker of CVD and associated with long-term prognosis in several populations. Older age, hypertension, cigarette smoking, and dyslipidemia, known as traditional vascular risk factors, as well as diabetes, obesity, and systemic inflammation contribute to arterial stiffness. Targeting multiple modifiable risk factors has become the main therapeutic strategy to improve arterial stiffness in patients at high cardiovascular risk. Additionally to life style modifications, long-term ω-3 fatty acids intake in diet may improve arterial stiffness in the population with hypertension or metabolic syndrome. Pharmacological treatment such as RAAS antagonists, metformin, and HMG-CoA reductase inhibitors were useful in individuals with hypertension or diabetes. In obese people with OSA, weight reduction, aerobic exercise, and CPAP treatment may improve arterial stiffness as well. In specific populations such as with chronic inflammatory disease, a use of antibodies against tumor necrosis factor-alpha could work effectively. Other therapeutic options such as renal sympathetic nerve denervation for patients with resistant hypertension remains under investigated clinically. Therefore this comprehensive review provides knowledge in detail regarding the aspect of pathogenesis, measurement, and management of arterial stiffness in several populations, which

would be helpful for physicians to make clinical decision.

Abstract

Endocardial access to the left atrium is commonly achieved to treat patients with atrial fibrillation, using different device delivery systems for cardiac ablation. But the large variation in human anatomy presses the limits of existing medical devices. In this unique study, we directly visualized the device-tissue interface in fresh reanimated human hearts using Visible Heart® methodologies. Our goal was to better understand any opportunities to improve therapeutic approaches. The visual images obtained in this study (also featured in this article) allow a more intimate grasp of the key steps required in various ablation procedures, as well as some limitations of current device designs. These images show the potential risks of conducting transseptal punctures and the difficulties of placing catheter tips in certain scenarios (*e.g.*, when creating circumferential lesions); they also demonstrate potential problems that could occur while attempting to place catheter tips on such anatomies like the mitral isthmus. In our analysis of these images, we focus on where enhancements are needed to refine device functionality.

Key words: Atrial fibrillation; Cryogenic catheter ablation; Radiofrequency ablation; Transseptal puncture

Core tip: Visible Heart® methodologies are utilized to directly visualize a functional human heart anatomy and key steps in the cardiac ablation procedure to emphasize limitations of current device delivery systems. Specifically, these images illustrate potential risks of transseptal punctures as well as the challenges faced by clinicians when placing catheter tips in certain scenarios, considering the wide variation in human anatomy. The focus is on where enhancements are

needed to refine device functionality and improve therapeutic approaches.

INTRODUCTION

For many years, ablation (either radiofrequency or cryogenic) has been used to treat patients with atrial fibrillation (AF)[1-3]. But variations in cardiac anatomy have consistently influenced therapeutic success[4-8]. Different medical device designs have been developed for creating effective lesions in such varied anatomic structures[9-12]. However, in order to apply therapies for left atrium (LA) targets, navigation is first required into the right atrium (RA) and then across the septum.

Ablating the anatomic locations within the left heart was initially made feasible by a modified Cox's maze procedure[13-16]. In such a procedure, each step requires an intimate understanding of the endocardial anatomy[17]. Importantly, the inappropriate placement of devices in any ablation procedure can result in significant unintended consequences, including the creation of ineffective lesions (no transmurality), the need for subsequent ablation procedures, and/or cardiac tamponade during transseptal punctures[18-20]. In an effort to reduce the incidence of such unintended consequences, ablation is commonly performed with the assistance of imaging tools such as fluoroscopy or echocardiography. Imaging tools not only help eliminate unintended consequences such as perforation, but also help ensure occlusion of pulmonary veins (PVs). In addition, the use of fluoroscopy, angiography, and noncontact mapping has improved the quality of the images[21]. However, no imaging method allows one to directly visualize the device-tissue interface or to take into consideration the impact of accuracy on heart rhythm[21,22].

In this unique study, we used Visible Heart® methods to directly visualize the device-tissue interface in fresh human hearts reanimated in a clear Krebs-Henseleit buffer (Sigma-Aldrich Corporation, St. Louis, MO, United States), as previously described[22,23]. Our goal was to better understand any opportunities to improve therapeutic approaches during the key steps of various ablations procedures. The visual images obtained in our study (and featured in this article) allow a more intimate grasp of the steps required as well as any limitations of current device designs.

In particular, the images reveal the interaction of ablation technology with human tissue, providing a sense of the spatial relationship between the device and anatomic structures. In our analysis of these images, we focused on where enhancements are needed to refine device functionality. For purposes of analysis, we separated the key steps of ablation procedures into 3 distinct image sets, based on the device used and the anatomy: (1) navigating the RA; (2) conducting transseptal punctures from the RA to the LA; and (3) creating lesions and reaching the key anatomic locations in the LA with different types of ablation devices. Delineating the limitations of current devices and pinpointing the major anatomic challenges should prove to be of great importance for both practicing physicians and medical device designers[23].

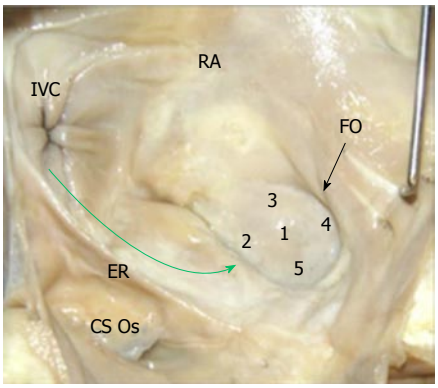

Figure 1 Fossa ovalis and transseptal punctures. All of the 5 locations shown on the fossa ovalis (black arrow) are transseptal puncture possibilities, and the path of device delivery to the fossa ovalis is shown (green arrow). CS Os: Coronary sinus ostium; ER: Eustachian ridge; FO: Fossa ovalis; IVC: Inferior vena cava; RA: Right atrium.

NAVIGATING THE RA

Success in navigating the RA has been limited, given the challenging anatomies of key RA structures combined with the limitations of current device designs. Endocardial cardiac ablations of the atria commonly originate *via* access from the inferior vena cava (IVC). An introducer, at the groin, is inserted into the femoral vein and then advanced into the RA. The IVC serves as a low-pressure return path of deoxygenated blood to the RA. Thus, the IVC is a suitable starting point for endocardial procedures because it eliminates risks associated with device introduction. Key ablation procedure structures in the RA include the fossa ovalis (FO), coronary sinus (CS), and right atrial appendage (RAA).

FOSSA OVALIS

The FO serves as the access point for ablation of the LA. As devices enter the RA, the Eustachian valve of the IVC forms a bridge between the IVC and the Eustachian ridge (ER) (Figure 1).

The FO is also a structure that causes devices to bind or become lodged, and device tips can catch on the compliant membrane of the valve[24-26]. Because the

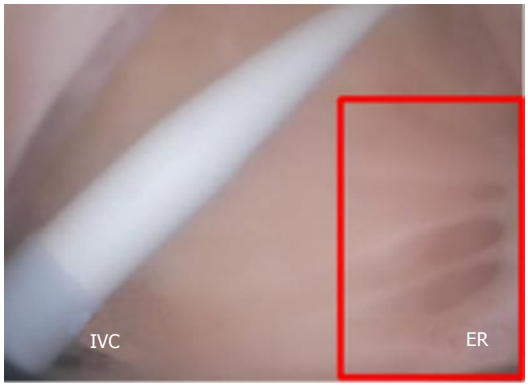

Figure 3 Catheter dilator and sheath in the right atrium. Pectinated muscles border the Eustachian ridge (ER, red rectangle). IVC: Inferior vena cava.

FO and the IVC are located on the superior aspect of the ER, the ER can serve as a guide to facilitate device delivery to the FO, allowing the device to glide along the valve and onto the ER (Figure 2B and C).

The ER is a prominent rise between the FO and the CS ostium (Os)[27-29]. The superior and posterior margins of the FO are enfolded to produce the prominent muscular protrusion on the endocardial surface. The FO lies next to the aorta, in some cases making transseptal punctures difficult[30]. Bordered by septal tissue and the ER, the FO is typically slightly recessed (Figure 2B and C). These structures can either facilitate or inhibit the operation of a medical device, either directing it in the intended direction or preventing it from being placed in the desired location.

Current catheter delivery systems often face challenges in reaching the FO and conducting transseptal punctures. Pectinated muscles adjoin the ER, which itself is pronounced and moves with each contraction. The pectinated muscles adjacent to the FO are composed of undulations that are capable of restraining the tip of a dilator or catheter (Figure 3). Dilator tip dimensions are sized to only allow a transseptal needle to pass. This small tip size also increases the chance of binding in these muscles if the tip is placed incorrectly.

During transseptal punctures, the FO is manipulated extensively. Both its size and thickness contribute to changes in the amount of compliance when force is applied (Figure 4). A large amount of compliance in the FO, coupled with a lack of compliance in the much thicker septal wall, can result in concentration of the transseptal force on the FO.

Dilator tips enable practitioners to confirm anatomic location by tenting the FO. Once tenting is achieved, a transseptal needle can be advanced through the FO (Figure 5A and B). The large amount of tenting that is usually required and the compliance of the membrane draw into question how much force the FO is able to tolerate before the procedure fails. Though necessary to perform transseptal punctures, FO tenting-combined with excess extension of the transseptal needle tip into the LA - can result in cardiac tamponade.

The very close proximity of the FO to both the right superior pulmonary vein and the right inferior pulmonary vein makes it challenging to reorient device tips after transseptal punctures (Figure 6).

Devices whose total deflection is limited, or whose deflection is located more proximally in the shaft, result in tip changes that make it nearly impossible to orient the device in a way that facilitates catheter introduction into the right PVs. Consequently, the FO needs to be manipulated more. Additionally, an incorrect puncture site location can increase the difficulty of introducing a catheter into the right PVs.

Once a transseptal puncture is complete, the tissue is stretched over the outside diameter of the dilator and onto the outside diameter of the sheath (Figure 5B). This transfer of force, the overall diameter of the sheath, and manipulation of the device in the LA can all contribute to the possibility of tearing the FO. As the sheath is deflected and the device is introduced into the LA, the resulting forces on the sheath push and pull the FO. If these forces become excessive, the FO can tear (Figure 7).

This step in the procedure prompts additional consideration of the use of the transseptal needle in the

Figure 4 Fossa ovalis manipulation during transseptal punctures. Figure 6 Fossa ovalis anatomy and device delivery for transseptal punctures. A: Path of device delivery to the pulmonary vein originating from the fossa ovalis (green arrows); B: Left atrial sheath placement after a transseptal puncture, with a guidewire introduced into the right superior pulmonary vein (RSPV). FO: Fossa ovalis; RIPV: Right inferior pulmonary vein.

LA. The transseptal needle extends beyond the tip of the dilator. The amount of extension is dictated by the interference fit of the diameter on the needle shaft to the internal diameter reducer in the dilator tip. Given the large amount of needle extension and the relative thickness of the FO, future device designs must improve the needle tip to reduce the risk of cardiac tamponade, while still preserving the ability to achieve successful punctures. Clearly, anatomic variations can have an impact on the ability to conduct transseptal punctures as well as possible complications.

Such variability in anatomic structures - combined with current device limitations in sheath size and in needle, length, and deflection capabilities - will require continued advancements in order to decrease the risk to patients. Device developers must continue to collaborate with electrophysiologists. A partnership between engineers and health care providers is critical

for improving patient outcomes.

CORONARY SINUS

Arrhythmia ablation procedures commonly involve the CS[6,31]. Its ostium is located on the opposing side of the ER. In addition, the thebesian valve is located at the CS ostium (Figure 8). Inferior to the CS ostium, anatomic structures can be of various shapes and sizes[32].

Clearly, anatomic factors can increase the complexity of device delivery. The CS ostium resides in a deep pocket that is bordered by the ER, making catheter tip placement challenging. The location of the CS ostium relative to the IVC, along with the size of the ostium, can also present challenges.

To enter the CS, devices must have a high degree of deflection; furthermore, the region of deflection must have a small radius. With devices whose deflection is located more proximally in a stiff shaft and whose diameter is 8-Fr or larger, it will be more difficult to orient the tip so that it aligns with the CS ostium (Figure 9). Further design work is needed to develop devices that can deflect in a small radius, allowing the catheter tip to be oriented in such a way that it can align with the CS ostium.

RIGHT ATRIAL APPENDAGE

Right atrial ablation is required in instances of AF in which the cycle length recorded in the RAA is shorter than is the cycle length recorded in the left atrial appendage (LAA). The RAA location near the ostium of the IVC prompts the need to deflect devices (Figure 10A). The appendage can be a large structure; it is composed of very thin tissue as well as pectinated muscle and a sagittal band (Figure 10B and C).

Given the thin tissue of these anatomic structures, devices need to have very smooth tips that do not focus force into a point. With devices that have a rigid shaft, the risk of perforating the RAA is greater, because of the higher transfer of force. In contrast, with devices that have a compliant tip at the distal end, the tip can bend, thereby lessening the chance of perforating the RAA.

ABLATING LEFT ATRIAL STRUCTURES: PV, MI, AND LAA ROOFLINE

The LA has a venous component, along with a vestibule and an appendage. The additional 4 venous orifices serve as corners to the atrium. The vestibule surrounds the mitral ostium. The LAA is typically a small extension that originates adjacent to the mitral valve annulus and the left PVs.

In the atrial areas, the anterior wall behind the aorta is commonly thin and can be torn during transseptal punctures[33]. The thicker parts of the LA are on the superior wall[34]. The ostium of the right PVs are adjacent to the plane of the atrial septum. The tissue that makes this transition is smooth. The target of PV isolation is a muscular sleeve that extends into each vein and ends inside the sleeve; the role of the sleeve has been reviewed in other studies[35,36]. The organization of electrical activity from the PV is well known[37,38].

The smooth wall of the LA facilitates a uniform drag of the catheter tip against the tissue. The size of the LA is conducive to catheter tip placement against the tissue surface[27]. But the formation of a small gap is possible; complex cardiac navigation systems do provide some guidance as to gap location, yet it might not be sufficient.

LA ablation can occur in a number of different locations and can be prompted by continuous electrical activity, with a minimum duration of 100 ms[39] and either fractionated or fragmented electrical activity[40].

LEFT ATRIAL PULMONARY VEINS

Pulmonary vein isolation is currently considered as a key step in treating patients with all forms of AF. Of note, the muscle sleeves in the ostial opening of all 4 PVs emit ectopic beats. Electrical isolation of each vein is now the standard of care for treating AF, using either cryogenic or radiofrequency ablation[28-30]. In electrical isolation procedures, both ablation and diagnostic devices are used around and inside the PVs including guidewires, balloons, diagnostic catheters, and focal ablation catheters.

The ostia of the right PVs are adjacent to the FO. The ostial opening of the PV is a smooth surface. The close proximity of the PV ostia to the FO, and the sharp angle between them, make it difficult to orient a catheter through the puncture site and into the PV (Figure 11).

The ostia can comprise ridges and are adjacent to each other on opposing sides of the atrium. The shape and orientation of the PV can vary; other anatomic

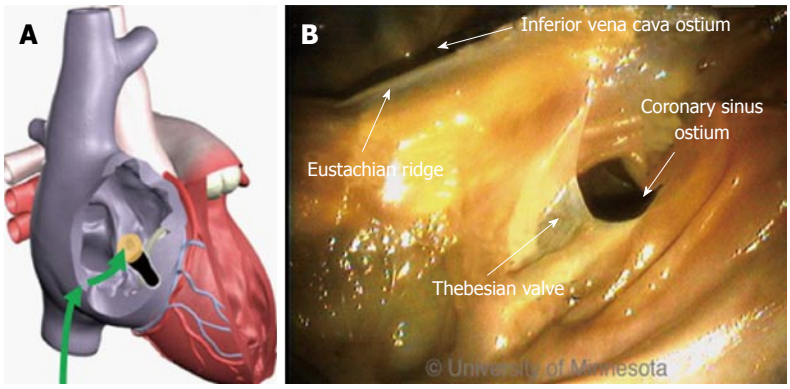

Figure 8 Coronary sinus and ablation procedures. A: Device approach originating from the inferior vena cava into the coronary sinus ostium (green arrows); B: Regional anatomy in the area of the coronary sinus is bordered by the thebesian valve, including the inferior vena cava catheter introduction point.

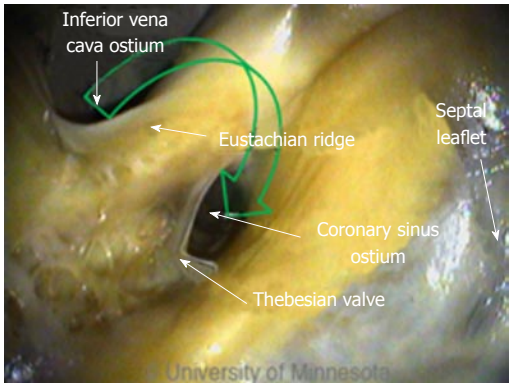

Figure 9 Deflection of devices in the coronary sinus. Green arrow depicts the device approach originating from the inferior vena cava; devices in this region require a high degree of deflection.

structures can be atypical. Variations can include differences in ostial size and the existence of a common shared ostium. All of these factors can affect the effectiveness of the devices used to electrically isolate the tissue.

The PVs interface with guidewires, sheaths, balloons, and focal ablation catheters. The location of the transseptal puncture can have a dramatic effect on the ability to place the catheter tip in the ostium of the PV, especially because the distance from the FO to the ostium is short. In addition, the orientation of the opening of the PV is directed in a way that can result in the need to twist the guidewire to allow it to migrate inside the PV (Figure 12A). This anatomic orientation of the FO and the PV illustrates the importance of a sheath that has a small radius of deflection at the tip in order to facilitate guidewire insertion.

Catheter placement into the PV is also affected by the contour of the catheter tip. The angle of the catheter's approach might require anatomic guidance to properly position the tip (Figure 12B). This device-tissue interface shows the importance of a smooth, contoured tip.

The complete insertion of the ablation catheter is affected by its size and by the size of the atrium. The proximity of the FO to the PV can limit the ability to have both the sheath and the catheter in the chamber (Figure 12C). Limiting the distance of the therapeutic region of the catheter would provide greater latitude for use of the entire system in the atrium. Operation of these devices on the right side of the atrium is one of the more challenging steps of the procedure.

Performing the same steps on the left side of the atrium requires different device performance. The orientation of the FO to the left PV ostia (as compared with the right side of the atrium) is more conducive to device delivery. Guidewire introduction is typically facilitated by the nearly linear orientation of the FO to the PV ostium (Figure 13A), which allows the guidewire to be placed and lodged in the PV (Figure 13B).

The alignment of the FO and left PVs allows for easy catheter introduction into the LA and sufficient room to operate the device, thereby reducing the stress on the FO and lessening the demands on the sheath (Figure 13C). For balloon-based devices, which require more area to operate than do focal ablation catheters, the alignment of the FO and left PVs is of particular importance.

Once the catheter is delivered into the PVs, therapy delivery remains challenging. For example, balloon-based therapeutic devices are larger, with only a limited amount of deflection ability, so they require more room to operate. Given the orientation of the transseptal puncture to the ostium of the PV, the balloon is able to fully occlude the vein. However, uniform cooling may not be achieved, because the balloon's orientation is limited by the FO's orientation to the PV's muscular sleeve (Figure 14).

These anatomic challenges accentuate the importance of having an acute distal deflection segment on the ablation device, in order to improve catheter tip orientation to, and alignment with, the PV ostium. Such challenges also jeopardize the ability of the sheath to maintain its placement in the LA. Decreasing the length of the distance between the distal tip of the sheath and the proximal end of the balloon would allow more sheath to be retained in the LA. The sheath must have a very distal deflection control with an acute radius of deflection. The smooth wall of the atrium facilitates placement of the ablation catheter.

If additional lesions are necessary beyond PV isolation, they can be created in the LA in the form of a linear lesion along the roofline or a mitral isthmus (MI)

lesion, or *via* ablation of the LAA.

LEFT ATRIAL APPENDAGE

Many times, the LAA is a site for the deposition of thrombus. A stroke is a possibility if the thrombus is able to dislodge and travel to a part of the vasculature that supplies blood to the brain. The LAA is oriented on the opposing side of the LA from the FO, making device delivery less challenging (Figure 15A).

For achieving and retaining device placement, the

opening of the LAA can be challenging. The ability to place a focal ablation device at the ostial opening is complicated by the presence of prominent ridges in the ostial area of the LAA. Focal devices for performing point-by-point ablation around the opening are difficult to operate. Alternatively, devices that encircle the LAA, or that occlude it, preclude the need to create point-by-point lesions and remove the complexity of attempting to place a catheter tip on a ridge structure.

Devices that deploy into the LAA and then place the therapeutic region at the opening are able to encircle the opening (Figure 16). Focal ablation devices need the ability to apply sufficient force on the tissue for lesion generation, without slipping into the pectinated muscles of the LAA interior.

Dynamically shaped ablation devices that could occlude the LAA would have an advantage, as they might be able to maintain position and sufficient force for lesion generation.

MITRAL ISTHMUS AND ROOFLINE ABLATION

The MI is a region of tissue that borders the annulus of the mitral valve and the LAA, and then rises over the ridge toward the left PV (Figure 17A). This is a common area to create a contiguous lesion in which it helps to terminate conduction patterns in patients with AF in whom PV isolation is not sufficient[27,31,32].

The creation of the MI or roofline linear lesion is affected by even a minor amount of anatomic movement of the MI with each contraction, making catheter tip placement on the ridge difficult. Any anatomic movement changes the force on the catheter tip and can contribute, at times, to a temporary loss of sufficient contact for lesion creation. The ability to maintain tissue contact is a byproduct of the amount of force on the catheter tip. For MI linear lesion creation, given the orientation of the FO in relation to the mitral valve annulus (MVA), the catheter tip must be able to reach to the MVA, and the deflection must be able to place force on the catheter tip (Figure 17B). The presence of a ridge is an additional complicating factor; the shape of the ridge can be pointed, making it difficult for the catheter to be placed on it.

To ensure necessary contact when creating a linear lesion, a focal catheter may be used against a

supporting structure, such as another catheter (Figure 18A) or the wall of the atrium (Figure 18B).

A focal ablation catheter has the advantage of adaptability. This device design could be extended to include repositioning of electrodes, softening of the tip, and better deflection capabilities - all of which could widen application across an array of atrial anatomies, resulting in an improvement in energy delivery.

CONCLUSION

Understanding how ablation devices interface with tissue and anatomic structures can make a crucial difference in their therapeutic application. Anatomic structures vary from person to person. Within each person, the endocardial surface changes shape with each heartbeat and can prompt catheter migration, making it difficult to know exactly where the device was placed and what is happening at the device-tissue interface. By using Visible Heart® methods to directly visualize the device-tissue interface in fresh reanimated human hearts, we assembled and analyzed an array of illuminating images, providing a critical aid to clinicians and medical device designers alike. For examples of

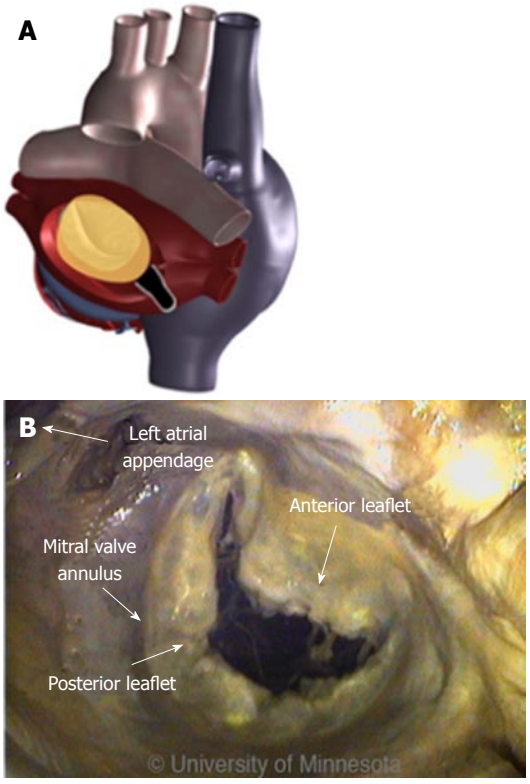

Figure 17 Mitral isthmus and roofline ablation. A: Diagram shows the mitral valve in the left atrium; B: Various structures, including the mitral valve annulus, which serve as the starting point for creating a linear lesion in the mitral isthmus.

functional anatomies of the human heart, refer to the free-access website, "The Atlas of Human Cardiac Anatomy" (www.vhlab.umn.edu/atlas).

The tools that have traditionally been used to treat patients with AF have numerous limitations, all of which lengthen ablation procedure time and increase the likelihood of disease recurrence. Future research in this field needs to focus on reducing the risks of transseptal procedures, increasing catheter mobility, enhancing the anatomic precision of catheter tip placement, and improving imaging capabilities. Studies must investigate

Abstract

Coarctation of the aorta is a relatively common form of congenital heart disease, with an estimated incidence of approximately 3 cases per 10000 births. Coarctation is a heterogeneous lesion which may present across all age ranges, with varying clinical symptoms, in isolation, or in association with other cardiac defects. The first surgical repair of aortic coarctation was described in 1944, and since that time, several other surgical techniques have been developed and modified. Additionally, transcatheter balloon angioplasty and endovascular stent placement offer less invasive approaches for the treatment of coarctation of the aorta for some patients. While overall morbidity and mortality rates are low for patients undergoing intervention for coarctation, both surgical and transcatheter interventions are not free from adverse outcomes. Therefore, patients must be followed closely over their lifetime for complications such as recoarctation, aortic aneurysm, persistent hypertension, and changes in any associated cardiac defects. Considerable effort has been expended investigating the utility and outcomes of various treatment approaches for aortic coarctation, which are heavily influenced by a patient's anatomy, size, age, and clinical course. Here we review indications for intervention, describe and compare surgical and transcatheter techniques for management of coarctation, and explore the associated outcomes in both children and adults.

Key words: Coarctation of the aorta; Cardiac surgery; Cardiac catheterization; Balloon angioplasty; Stents

Core tip: This review explores both surgical and transcatheter approaches for the treatment of coarctation of the aorta and examines outcomes of these techniques in children and adults.

INTRODUCTION

Coarctation of the aorta was first described by Morgagni in 1760[1], and in its simplest form refers to congenital narrowing of the proximal thoracic aorta. While aortic coarctation most commonly occurs as a discrete stenosis in the juxtaductal position, it may also be associated with long segment narrowing, hypoplasia of the transverse aortic arch, or stenosis of the abdominal aorta[2-4]. Coarctation of the aorta accounts for 5%-7% of all congenital heart disease[5], with an incidence of approximately 3 cases per 10000 births[6]. Coarctation may be seen in isolation or with additional cardiac lesions, such as bicuspid aortic valve, ventricular septal defect, patent ductus arteriosus, transposition of the great arteries, atrioventricular canal defects, or left-sided obstructive heart defects, including hypoplastic left heart syndrome[7-11]. Crafoord was the first to perform a successful surgical repair of aortic coarctation in 1944[12]. Since then, various surgical and transcatheter approaches have been developed, allowing patients to have significantly improved outcomes. Here, we briefly review the presentation and diagnosis of aortic coarctation and then focus on surgical and transcatheter approaches with their most recent associated outcomes.

DIAGNOSIS

Clinical presentation

Coarctation can present at any age. Neonates with ductal dependent or "critical coarctation" often present with heart failure, acidosis, and shock following closure of the ductus arteriosus. Without prompt medical resuscitation and surgical intervention, death may occur rapidly[13,14]. Prenatal diagnosis can prevent these sequelae by allowing for intervention before ductal closure. However, prenatal diagnosis of coarctation is challenging due to the presence of the ductus arteriosus and limited blood flow across the aortic isthmus in utero[13]. In the United States, fewer than 1 in 4 patients with isolated coarctation requiring neonatal intervention are diagnosed prenatally[15,16]. Moreover, approximately 30% of neonates with coarctation remain undiagnosed upon discharge after delivery[17]. For these reasons, many physicians advocate for newborn pulse oximetry screening programs, which increase the likelihood of detecting lesions like coarctation before ductal closure[18,19]. Additionally, coarctation must be suspected in infants with other left-sided obstructive heart lesions and may be diagnosed in infants with chromosomal defects, especially those with Turner syndrome and Jacobsen syndrome[20].

Patients with less severe coarctation may not be diagnosed until later in childhood when a murmur is heard or hypertension noted. In these patients, collateral vessels develop from the internal thoracic and subclavian arteries, thyrocervical trunks, and vertebral and anterior spinal arteries to supply blood to the descending aorta[21,22]. For those who enter adulthood undiagnosed, hypertension is the most common presenting symptom[23]. Others may complain of frequent headaches or claudication of the lower extremities with exertion. In these patients, the most telling exam findings suggestive of coarctation are diminished and/or delayed lower extremity pulses and a systolic pressure gradient between the upper and lower extremities[13,23]. However, for patients with extensive collateral blood flow, femoral pulses and lower extremity blood pressures may only be minimally diminished[24].

Evaluation

Chest X-ray is often nonspecific in young patients. In older patients, an anterior-posterior film may show indentation of the aorta at the site of coarctation with pre- and post-stenotic dilation of the aorta, creating the classic "3 sign". Notching of the posterior fourth to eighth ribs due to dilated intercostal arteries may also be seen in older patients[24,25]. Electrocardiogram is typically normal in infants, but in older children and adults, left ventricular hypertrophy is common due to ventricular pressure overload[24].

Transthoracic echocardiography can assess the presence and severity of aortic coarctation and any associated cardiac defects and is the diagnostic gold standard in neonates and infants (Figure 1). Although transthoracic echocardiogram remains the initial test of choice for coarctation, in larger children and adults[24], echocardiographic windows may be suboptimal. When this is the case, a computed tomography scan or magnetic resonance imaging (MRI) provides excellent anatomic detail at the site of coarctation, and these modalities are commonly used to create three-dimensional images for interventional planning (Figure 2). MRI has the additional benefit of defining and quantifying collateral vessel flow. Although cardiac catheterization was frequently used for diagnosis of coarctation in the past, it is now typically reserved for therapeutic intervention or in those cases where hemodynamic data is additive to the diagnostic evaluation[24,25].

TREATMENT

Without intervention, the outcome for patients with coarctation of the aorta is poor. In his classic 1970 natural history study, Campbell examined autopsy and clinical records of 465 patients with coarctation who survived beyond one year of age. The mean age of death was 34 years, with 75% mortality at 43 years of age. Causes of death included congestive heart failure (26%), aortic rupture (21%), bacterial endocarditis (18%), and intracranial hemorrhage (12%)[26]. Fortunately, several treatment options are now available, including surgical and transcatheter interventions. Guidelines regarding indications for

Table 1 Notable studies and guideline statements in the treatment and outcome of coarctation in adults and children

Ref.	*n*	Follow-up	Outcome
Cowley *et al*[60]	36	Mean 14 yr	Randomized trial comparing BA and surgery for native coarctation in children. Aortic aneurysm developed in 35% of BA patients and none of the surgical patients
Carr[81]	846	Mean 36 mo for catheter-based group and 7.8 yr for surgical group	Meta-analysis comparing catheter *vs* surgical intervention for adults with coarctation. Higher risk of restenosis and need for reintervention found in catheter-based group
Forbes *et al*[68]	578	Median 12 mo	Retrospective multicenter analysis at intermediate follow-up after stent placement for coarctation. Exceeding a balloon:coarct ratio of 3.5 and prestent BA increased risk of aortic wall injury
Warnes *et al*[24]	-	-	ACC/AHA guidelines for management of coarctation in adults
Holzer *et al*[67]	302	3-60 mo	Prospective analysis of acute, intermediate, and long-term follow-up after stent placement for coarctation using CCISC registry. At long-term follow-up, recoarctation in 20% of patients, 4% required unplanned reintervention, and 1% had aortic wall injury
Feltes *et al*[27]	-	-	AHA guidelines for transcatheter intervention in children with coarctation
Forbes *et al*[69]	350	Mean 1.7 yr	Multicenter observational study comparing surgery, BA, and stent placement for native coarctation in children using CCISC registry. Significantly lower acute complication rates in stent group but higher planned reintervention rates. Hemodynamic and arch imaging outcomes superior in stent and surgical patients compared to BA group
Harris *et al*[55]	130	3-60 mo	Prospective, multicenter analysis of short and intermediate outcomes for BA in native and recurrent coarctation in children. Trend toward increased acute aortic wall injury and restenosis in native coarctation patients
Sohrabi *et al*[75]	120	Mean 31.1 mo	Randomized clinical trial comparing covered and bare CP stents for native coarctation in adolescents and adults. Trend of increased rates of restenosis and lower rates of pseudoaneurysm in bare stent group
Meadows *et al*[70]	105	2 yr	Prospective, multicenter, single-arm study assessing safety and efficacy of CP stent in children and adults with coarctation. Two year follow-up of 86% showed 23 fractured stents with no significant clinical effects, 6 aortic aneurysms, 19 repeat catheter interventions, and no surgical interventions

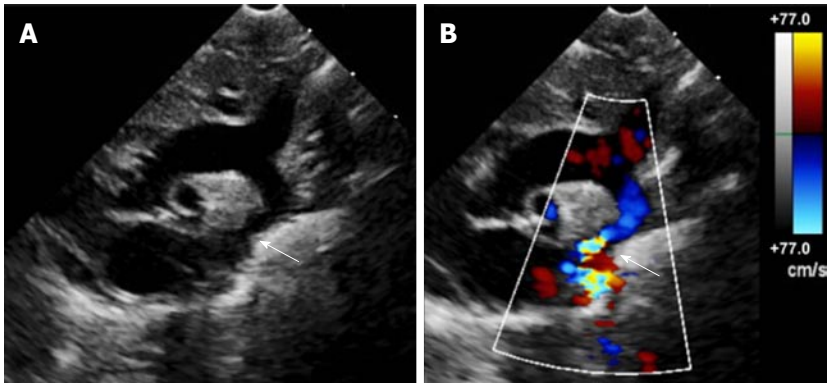

Figure 1 Echocardiogram of coarctation. A: Two-dimensional transthoracic echocardiogram image obtained from the suprasternal notch in an 11-day-old infant demonstrating discrete coarctation (arrow); B: Color Doppler of the same image with aliasing of flow at the site of coarctation (arrow).

intervention exist for both children and adults with coarctation (Tables 1 and 2), which include a peak-to-peak gradient ⩾ 20 mmHg or lesser gradients when there is significant anatomic evidence of narrowing on imaging with extensive collateral flow[24,27]. Other factors that may be considered include the presence of systemic hypertension, additional cardiac defects and/or single ventricle physiology, left ventricular hypertrophy, or elevated left ventricular end diastolic pressure[24,27-29].

Surgical repair

The first surgical technique described for coarctation of the aorta was resection with end-to-end anastomosis by Crafoord in 1944[30] (Figure 3A). Early studies showed recoarctation rates in over half of patients with this technique, and the use of a circumferential suture line was thought to be a major contributor[31,32].

Vosschulte described prosthetic patch aortoplasty as an alternative technique for coarctation repair in 1961. In this approach, the ductal tissue is ligated and divided, a longitudinal incision across the coarctation is made, and a prosthetic patch is sutured in place to enlarge the stenotic region (Figure 3B). This technique can be applied to longer segments of coarctation, avoids a circumferential suture line, and minimizes aortic mobilization and ligation of intercostal arteries[33]. While recoarctation rates of 5%-12%[34] were lower compared to the resection and end-to-end anastomosis technique, aortic aneurysm was a long-term concern, with rates between 18%-51% of patients[35-38]. Using

Table 2 Executive summary on the diagnosis and treatment of coarctation in children and adults

Diagnosis
Accounts for 5%-7% of congenital heart disease diagnoses
Neonates often present with heart failure, acidosis, and shock with critical coarctation
Less severe coarctation often detected during evaluation for hypertension or murmur in the older child or adult
Diminished or delayed lower extremity pulses and a systolic pressure gradient between the upper and lower extremities are the most useful exam findings
Transthoracic echocardiogram is initial test of choice; CT and MRI useful if echocardiogram inconclusive and for surgical planning
Treatment
Surgical repair
Extended end-to-end anastomosis typically preferred surgical method, as it avoids prosthetic material, allows resection of the coarctation, and has a wider incision that is less prone to restenosis
Surgical repair typically preferred over transcatheter approaches in the infant and young child with native coarctation, patients requiring repair of associated cardiac defects, or in those with complex coarctation anatomy
Balloon angioplasty
Often the preferred intervention for recurrent coarctation
Concern for recoarctation and aneurysm formation in native coarctation
Endovascular stent
Provides structural support and decreased rates of aortic wall injury and aneurysm compared to balloon angioplasty
Covered stents may protect against shear stress and subsequent restenosis, though care must be taken to avoid overlying vital branch vessels
Use of stents in small children controversial due to need for large sheath size and limitations in accommodating for somatic growth
Patient follow-up
Lifelong follow-up with at least annual cardiology visits and repeat imaging every 5 yr to assess coarctation site
High suspicion and aggressive treatment of baseline and exercise-induced hypertension
Future perspectives
Further long-term data analysis needed to determine optimal intervention based on patient anatomy, size, and age

CT: Computed tomography; MRI: Magnetic resonance imaging.

more distensible polytetralfluroethylene patch material instead of Dacron was initially promising[34] but still showed a 7% risk for aortic aneurysm and a 25% risk of recoarctation[39].

Subclavian flap aortoplasty was a modified approach reported by Waldhausen and Nahrwold in 1966. Here, the left subclavian artery is ligated and divided, and a longitudinal incision down the proximal left subclavian artery is extended beyond the area of coarctation. The proximal left subclavian stump is then folded down to enlarge the area of coarctation (Figure 3C). This technique avoids a circumferential suture line and the use of prosthetic material, which may allow for improved growth, and it can be used for repair of long segment coarctation[40,41]. Although still occasionally used by surgeons, one of the main reservations of this approach has been the need to sacrifice the left subclavian artery. This can create a subclavian steal phenomenon, with retrograde flow down the vertebral artery, and it has been associated with decreased length and muscle bulk of the left upper extremity, as well as claudication with exercise[42,43].

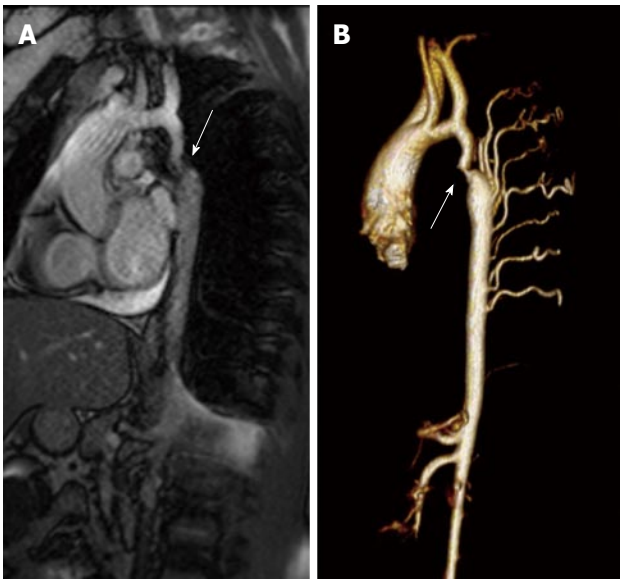

Figure 2 Magnetic resonance imaging of coarctation. A: Magnetic resonance image (steady-state free precession) in a sagittal projection demonstrating transverse arch hypoplasia and long segment coarctation of the aorta distal to the left subclavian artery (arrow) in a 12-year-old male; B: Three-dimensional reconstruction of a gated contrasted angiogram for the same patient, which demonstrates transverse arch hypoplasia, coarctation at the aorta at the distal transverse aortic arch and isthmus (arrow), and dilated intercostal arteries (collaterals).

Coarctation resection and replacement with an interposition graft was described by Gross[44] in 1951. After aortic cross clamp, the stenotic tissue is excised, and either a homograft or Dacron tube graft is sutured into the aorta. This approach is rarely used in the current era, as it is not ideal for pediatric patients due to growth limitations. However, occasionally it is an appropriate technique for adult patients with coarctation, especially those with aneurysm, long segment coarctation, or recoarctation after primary repair[45].

In 1977, Amato *et al*[46] described a modification to Crafoord's resection and end-to-end anastomosis technique, where a broader, longitudinal incision and anastomosis are created across the proximal aorta (Figure 3D). The extended end-to-end anastomosis still avoids the use of prosthetic material and allows resection of the coarctation and residual ductal tissue, but the wider incision is less prone to restenosis and enables enlargement of the transverse aorta, which is particularly helpful in neonates[46,47]. In the present era, extended end-to-end anastomosis is typically the preferred technique for surgical repair, especially in small children, due to low mortality rates and low rates of restenosis, ranging between 4%-11%[47-50].

Balloon angioplasty: Native coarctation

Surgical therapy was the only treatment option for coarctation until 1982, when the use of balloon angioplasty was described by Lock *et al*[51]. Several studies since then have shown balloon angioplasty to be a relatively effective acute intervention for native

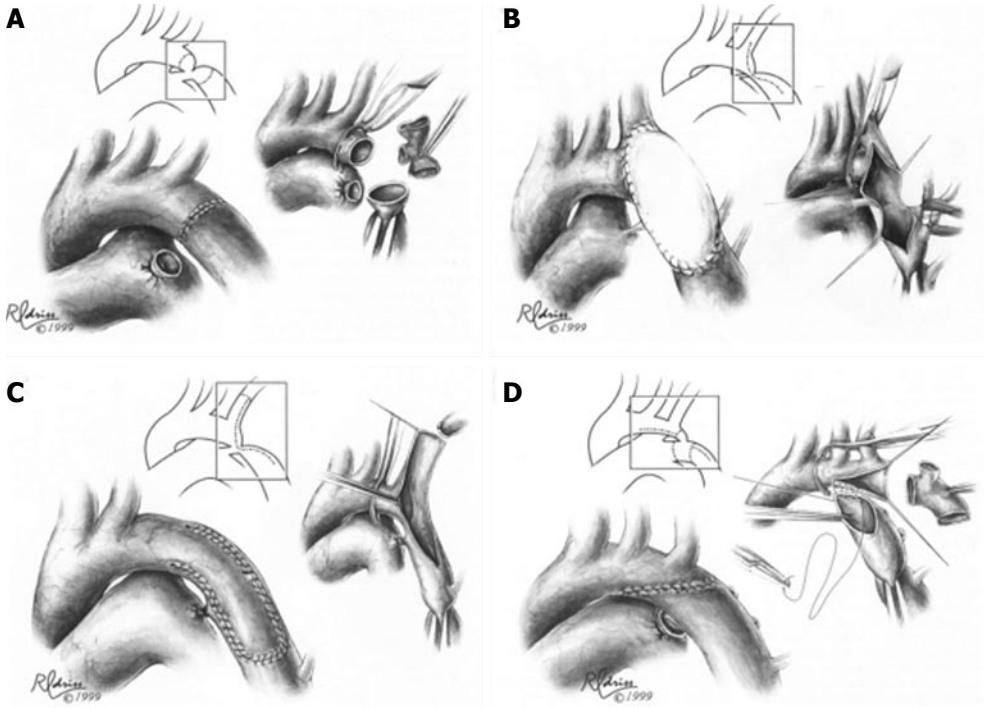

Figure 3 Surgical techniques in coarctation repair. A: Resection and simple end-to-end anastomosis. The coarctation is resected, and an end-to-end, circumferential anastomosis is created; B: Patch aortoplasty. An incision is extended across the coarctation, and a patch is sutured in place to enlarge the stenotic region; C: Subclavian flap aortoplasty. The left subclavian artery is ligated and divided. A longitudinal incision is extended from the proximal left subclavian artery beyond the area of coarctation, and the proximal left subclavian stump is folded down to enlarge the area of coarctation; D: Resection with extended end-to-end anastomosis. The coarctation is resected using a broad, longitudinal incision, and an oblique anastomosis is constructed between the undersurface of the transverse arch and the descending thoracic aorta. Figures adapted and reprinted with permission from the *Journal of Cardiac Surgery*[30].

coarctation, with rates of recoarctation ranging from 8%-32%[52-54]. In a report from the prospective, multicenter Congenital Cardiovascular Interventional Study Consortium (CCISC), 34 patients undergoing balloon angioplasty for native coarctation had adequate intermediate follow-up data at 18 to 60 mo post-intervention. In these patients, the rate of recoarctation was 15%[55]. A second concern with native coarctation angioplasty is aneurysm formation. Histologic and intravascular ultrasound studies have demonstrated the mechanism of angioplasty involves tearing of the intima and media[56-59]. Although some of these tears may heal, disruption of vascular integrity is believed to contribute to a relatively high incidence of aneurysm formation. This was demonstrated in a single center randomized trial comparing balloon angioplasty *vs* surgical repair of coarctation in older children (ages 3 years to 10 years). In this study with mean follow-up of 14 years after intervention, 35% of the balloon angioplasty patients developed aneurysm, compared to none of the surgical patients[60]. Similarly, the 2014 CCISC observational study showed 24% of patients with native coarctation developed aortic aneurysm at intermediate follow-up after balloon angioplasty[55].

Balloon angioplasty: Recurrent coarctation

In contrast to native coarctation, balloon angioplasty is often the preferred intervention for recurrent coarctation in children[27]. Acute success rates for this procedure range from 80%-93%[61]. Reported rates of aortic wall injury are low (1%-2%), and the longer term risk of aneurysm is believed to be ameliorated by scar tissue at the site of the recoarctation, which limits the degree of vascular disruption. However recoarctation rates remain a concern, with a broad range between 6%-53% described[62,63].

Likely the most fragile patient population to develop recurrent coarctation is children with hypoplastic left heart syndrome or other single right ventricle lesions. These patients are at risk for significant morbidity and mortality with recoarctation due to exacerbation of atrioventricular valve regurgitation and ventricular dysfunction[64]. The Pediatric Heart Network Single Ventricle Reconstruction trial was a large, multicenter, prospective study examining the outcome of infants with single right ventricle lesions after randomization to either right ventricle-pulmonary artery shunt or a modified Blalock-Taussig shunt at the time of Norwood procedure[65]. The incidence and timing of intervention for recoarctation in the first 12 mo after randomization was assessed, and 97 of 549 patients (18%) underwent intervention for recoarctation, which was most commonly performed at the time of pre-stage II cardiac catheterization by balloon angioplasty. Balloon angioplasty achieved adequate short term results, but 39% of patients required reintervention for recoarctation, compared to 5% of the patients who underwent surgical reintervention. Reassuringly,

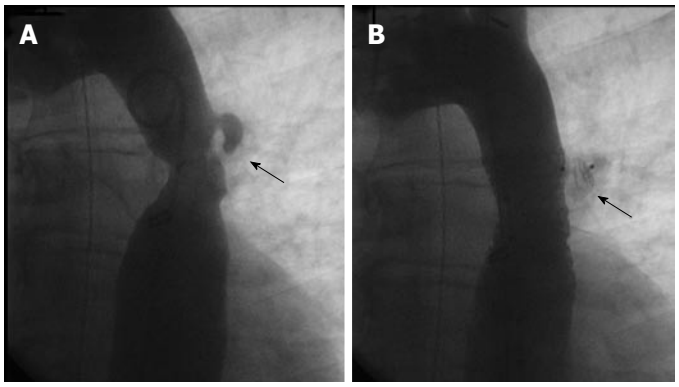

Figure 4 Endovascular stent placement for coarctation. A: Angiogram (LAO 30°, caudal 30°) demonstrating a discrete coarctation and intercostal aneurysm (arrow) in a 45-year-old male; B: Angiogram in the same projection after endovascular bare metal stent placement showing no significant residual stenosis. The intercostal aneurysm was successfully occluded with an Amplatzer Vascular Plug II (arrow).

with catheter or surgical intervention, the presence of recoarctation did not affect survival rates in this tenuous patient population[64].

Endovascular stent placement

In 1991, the use of endovascular stents for the treatment of coarctation was first reported[66], adding another dimension to the utility of transcatheter treatment for coarctation. Endovascular stents are inserted using balloon catheters but do not require overdilation of the vessel wall. Stents also offer structural support, thereby decreasing the rates of aortic wall injury and restenosis observed with balloon angioplasty alone[5] (Figure 4). Several studies have assessed the utility of endovascular stent placement in the treatment of coarctation[67]. Retrospective analysis of acute procedural data from 17 institutions from 1989 to 2005 showed successful stent placement without a significant residual gradient or serious complication in 553 of 565 (97.9%) patients. The overall complication rate was 14.3%, with aortic wall complications (aneurysm, intimal tear, or dissection) contributing 3.9%[68]. In a subsequent study, acute and long-term data regarding endovascular stent placement for coarctation were obtained from the CCISC. Here, the acute results of stent placement were successful without a significant blood pressure gradient or need for reintervention in 249/260 (96%) of cases. During follow-up spanning between 3 to 60 mo, recoarctation was seen in 20% of the 164 patients with follow-up imaging, and 4% of patients required unplanned repeat interventions. Aortic wall complications consisting of dissection or aneurysm were seen in 1% of the 302 total cases[67].

In a multicenter observational study comparing the outcomes of surgical, balloon angioplasty alone, and endovascular stent placement for coarctation using the CCISC registry, patients undergoing stent placement had significantly lower complication rates compared to balloon angioplasty or surgical patients. There was no significant difference among treatment groups for unplanned reintervention rates (4%-7%) at a mean of 1.7 years of follow-up, but those who underwent stent placement were more likely to undergo planned reintervention. Aortic wall injury was more likely to occur in patients who underwent balloon angioplasty alone, at a rate of 9.8% compared to none in the endovascular stent group[69]. In an attempt to more rigorously assess the effectiveness and safety of endovascular stent placement *vs* surgical repair, a Cochrane review was attempted in 2012, but it was determined that there was insufficient data available to identify the best treatment modality[5].

The Coarctation of the Aorta Stent Trial (COAST) has been an influential prospective study examining the effectiveness and safety of endovascular stent placement in children and adults with coarctation. Currently, no endovascular stent has been granted FDA approval for use in the aorta, and initially biliary stents were used off-label for treatment of coarctation. NuMED (Hopkinton, NY) created the Cheatham Platinum (CP) stent for specific use in the aorta, and in 2007, the COAST trial was designed as a prospective, multicenter, single-arm clinical study to assess the safety and efficacy of this stent for the treatment of coarctation[6].

Results for up to two years from CP stent placement are currently available from the COAST trial. CP stent implantation was attempted in 105 patients ranging from 8 to 52 years of age. All but one implantation was successfully completed, with no significant adverse events acutely. No patient had a significant gradient between the ascending and descending aorta after stent placement, and 99% had a gradient < 20 mmHg at one month. There was 89% follow-up at one year after stent placement and 86% follow-up at two years. At two years, 90% of patients maintained a blood pressure gradient < 20 mmHg between the upper and lower extremities. To date, 23 fractured stents have been identified, though none have led to decreased stent integrity, stent migration, aortic wall injury, or hemodynamic obstruction. Aortic aneurysm was diagnosed in 6 patients, one of which resolved without intervention. No patient has required surgical reintervention, and a total of 19 patients have undergone repeat transcatheter intervention, either due to aortic wall injury or dilation of the initial stent[70].

Thus far, the CP stent is felt to be a safe and effective treatment option for coarctation in older children and adults with native or recurrent coarctation. Stent fracture is common but thus far has been clinically insignificant. Reintervention is also common, either due

to planned dilation of smaller stents or aortic wall injury. Follow-up for the COAST trial is planned for up to 60 mo after stent placement and will provide further insight regarding these issues[6].

The use of endovascular stents in small children remains controversial due to the challenges in accommodating for significant somatic growth and the requirement for relatively larger sheath sizes. The ideal stent would be deployed through a small sheath but retain the ability to be dilated to an adult vessel diameter. This technology does not yet exist and still would require multiple interventions for stent dilation throughout a patient's lifetime. Additionally, neonates often have transverse arch hypoplasia, which does not easily lend itself to endovascular stent placement. Some small, single center studies have had positive short-term results with endovascular stent placement in young children, but further follow-up and investigation is needed[71,72].

Covered endovascular stents represent the latest transcatheter innovation and were first used for the treatment of coarctation in 1999. The fabric within the stent provides additional structural support, creates a protective barrier at the site of stent placement, and can help decrease shear stress. All of these factors theoretically reduce the risk of acute vascular trauma as well as longer term aneurysm formation. When aortic aneurysm or stent fracture occurs with bare stent placement, covered stents are often used as a rescue therapy. Covered stents may also be the initial transcatheter intervention of choice, especially in the setting of complex anatomy of the coarctation or in older patients with more friable and calcified aortic wall tissue. However, covered stents require larger sheath sizes, which limits their use in small children. Additionally, care must be taken to avoid stent occlusion of significant aortic branches, including paraspinal branches off of the descending aorta, which can be difficult to identify[73].

Initial smaller studies examining the use of covered stent placement in aortic coarctation were promising, with no reported aneurysms[73,74]. More recently, a randomized clinical trial was performed comparing bare CP stent *vs* covered CP stent placement in 120 patients. Both groups had no acute procedural complications, and at an average follow-up of 31.1 mo, the bare CP stent group had a statistically nonsignificant increase in the rate of recoarctation (6.7% *vs* 0%) and a nonsignificant lower incidence of pseudoaneurysm (0% *vs* 3.3%), compared to the covered CP stent cohort. The two cases of pseudoaneurysm in the covered stent group occurred at the proximal end of the stent, and both were successfully treated with a second covered stent with no further complications[75]. Further investigation into the safety and efficacy of covered stents is on-going with the COAST Ⅱ trial. This trial was initiated in 2010, hoping to provide information that will support FDA premarket approval of the covered CP stent in preventing aortic wall injury in high risk patients with coarctation as well as treatment of existing aortic wall injury related to complications from previous interventions for coarctation. Results are expected in the near future, but at this time, covered CP stents are not available for the treatment of coarctation in the United States outside of use in the COAST Ⅱ trial[70].

MANAGEMENT ALGORITHM

With many different options, deciding on the optimal treatment strategy for coarctation can be complicated, and there is no comprehensive evidence-based standard of care or algorithm. Guidelines from the American College of Cardiology and the American Heart Association provide some insight, but the level of evidence supporting these recommendations is suboptimal (Level B or C for all recommendations)[24,27]. In general, management is dictated by the age at presentation, complexity of the coarctation, and whether or not the coarctation represents a native *vs* recurrent obstruction. For the infant or young child presenting with native coarctation, most centers prefer surgical repair due to the long-term risk of aneurysm after balloon angioplasty, the need for redilation with stent placement, and the limitations imposed by small arteries unable to accommodate larger sheath sizes[60]. However, balloon angioplasty can be considered as a palliative strategy to stabilize neonates presenting in extremis and considered too sick for immediate surgical intervention[27]. Surgical repair may also be more appropriate in patients with complex coarctation anatomy, including those with transverse arch obstruction, tortuous segments of recoarctation, distortion of adjacent arterial branches, or when repair of associated cardiac defects is required[24].

In the older child, adolescent, or adult presenting with a simple, juxtaductal, native coarctation, stent placement is considered a reasonable approach, offering a less invasive alternative to surgical intervention and good long-term outcomes[24,27,76]. Only stents expandable to an adult size should be used, in an effort to avoid later surgical intervention[27].

For recurrent coarctation in the younger child, it is reasonable to consider initial balloon angioplasty, as aneurysm is less of a long-term concern than with native coarctation[27]. Balloon angioplasty is variably successful, and surgical reintervention may be required when there is incomplete relief of obstruction[55]. Stent placement can also be considered for recoarctation in older children and adolescents when the stent can be dilated to near adult size, thus avoiding the need for multiple redilations[27].

PATIENT FOLLOW-UP

Patients with repaired or unrepaired coarctation must be followed by a cardiologist throughout their lifetime. For those who have undergone repair, this follow-up should be at least annually, with specific attention paid to baseline or exercise-induced hypertension[24].

Hypertension is endemic in patients with aortic coarctation, even if no residual coarctation exists, and it must be appropriately treated[77,78]. The etiology of such high rates of baseline and exercise-induced hypertension remains unclear but may be due to any combination of underlying arteriopathy, decreased aortic wall compliance, abnormal streaming of blood flow, or renal abnormalities[77].

Additionally, imaging of the repaired coarctation should be performed at least every 5 years, or sooner based on original anatomy and symptoms, to assess the coarctation repair site for complications like aortic aneurysm or recurrent stenosis[24]. For repaired patients with a normal upper to lower extremity blood pressure gradient, normotension at rest and with exercise, and no evidence of aneurysm or associated heart defects, exercise is encouraged, and only activities with a large static component should be avoided[79]. Finally, per the 2007 American Heart Association guidelines, endocarditis prophylaxis is not routinely recommended beyond the first six months after surgical or transcatheter intervention, barring a previous history of infectious endocarditis[80].

CONCLUSION

In the seventy years since the first description of surgical intervention for aortic coarctation by Crafoord, tremendous progress has been made in the treatment and outcomes for these patients. Modifications of various surgical techniques have led to low mortality and morbidity rates, even in the smallest patients. Transcatheter balloon angioplasty and subsequently endovascular stent placement have expanded treatment options and provided less invasive approaches for repair in some patients. Still, both surgical and transcatheter approaches retain risks for adverse events and subsequent patient morbidity. As examined in this review, much effort has been spent investigating the intervention which yields the best patient outcomes, but further long-term data assessment is needed. The aortic coarctation patient population is a fascinating and heterogeneous one, and considering an individual patient's clinical presentation, anatomy, size, and age will most certainly continue to heavily influence treatment approach.
